Abstract

Background: Little is known about how individuals engage over time with smartphone app interventions and whether this engagement predicts health outcomes.

Objective: In the context of a randomized trial comparing 2 smartphone apps for smoking cessation, this study aimed to determine distinct groups of smartphone app log-in trajectories over a 6-month period, their association with smoking cessation outcomes at 12 months, and baseline user characteristics that predict data-driven trajectory group membership.

Methods: Functional clustering of 182 consecutive days of smoothed log-in data from both arms of a large (N=2415) randomized trial of 2 smartphone apps for smoking cessation (iCanQuit and QuitGuide) was used to identify distinct trajectory groups. Logistic regression was used to determine the association of group membership with the primary outcome of 30-day point prevalence of smoking abstinence at 12 months. Finally, the baseline characteristics associated with group membership were examined using logistic and multinomial logistic regression. The analyses were conducted separately for each app.

Results: For iCanQuit, participants were clustered into 3 groups: “1-week users” (610/1069, 57.06%), “4-week users” (303/1069, 28.34%), and “26-week users” (156/1069, 14.59%). For smoking cessation rates at the 12-month follow-up, compared with 1-week users, 4-week users had 50% higher odds of cessation (30% vs 23%; odds ratio [OR] 1.50, 95% CI 1.05-2.14; *P*=.03), whereas 26-week users had 397% higher odds (56% vs 23%; OR 4.97, 95% CI 3.31-7.52; *P*<.001). For QuitGuide, participants were clustered into 2 groups: “1-week users” (695/1064, 65.32%) and “3-week users” (369/1064, 34.68%). The difference in the odds of being abstinent at 12 months for 3-week users versus 1-week users was minimal (23% vs 21%; OR 1.16, 95% CI 0.84-1.62; *P*=.37). Different baseline characteristics predicted the trajectory group membership for each app.

Conclusions: Patterns of 1-, 3-, and 4-week smartphone app use for smoking cessation may be common in how people engage in digital health interventions. There were significantly higher odds of quitting smoking among 4-week users and especially among 26-week users of the iCanQuit app. To improve study outcomes, strategies for detecting users who disengage early from these interventions (1-week users) and proactively offering them a more intensive intervention could be fruitful.

Introduction

Background

User engagement in digital behavior change interventions has predicted improved treatment outcomes across a wide variety of domains, including mental health, physical activity, dietary change, weight loss, alcohol use, and smoking cessation [1-9]. A central challenge in creating effective digital health behavior change interventions is that a large proportion of users disengage early from these interventions, thereby contributing to low treatment success rates [2,10,11]. Given the importance of user engagement, designing strategies to increase engagement has been a priority of digital behavioral health interventions [2,7,8,12,13].

Within the domain of cigarette smoking, smartphone apps for smoking cessation have become a ubiquitous intervention approach for which user engagement can be readily measured. Nearly 500 English language smartphone apps for smoking cessation have been downloaded more than 33 million times since 2012 (R Nelson, SensorTower.com, personal communication, April 15, 2020). Higher user engagement in smartphone interventions for smoking cessation is predictive of cessation outcomes [11,14-16]. Although this positive association may partly be driven by self-selection bias (or reverse causation), as users have not been randomized to different levels of engagement, a certain level of exposure to the intervention's active ingredients is logically necessary for successful behavior change [2]. This logic has led to a body of work focusing on identifying design strategies that promote user engagement. For example, tailoring content to individuals' characteristics or unique situations, interactivity (eg, through conversational agents) [17], and credibility have been found across a range of studies using mixed methods to be important for engagement with smoking cessation interventions.

Although smartphone intervention engagement is usually measured by the number of log-ins, little is known about how users engage with smartphone interventions *over time* and whether those temporal patterns predict higher odds of smoking cessation. In the educational literature, a well-documented finding is that learning new material becomes more effective when it occurs over a longer period [18]. This process, called spaced practice, increases the variability in learning and remembering new information [19]. The purpose of this study was to determine, in the domain of smartphone apps for smoking cessation, whether user engagement over time leads to improved cessation outcomes.

Smartphone apps for smoking cessation are commonly available for participants to use at will, resulting in high variations in use trajectories over time. For example, some users may follow a trajectory of logging in several times within the first few days of starting an intervention and then never return. Others may follow a trajectory in which they log in consistently and then gradually taper off. Other users may follow a trajectory in which they consistently log in over the course of several months. Conceivably, some groups of individuals might follow unique use trajectories over time that are associated with differential health outcomes. For example, people who log in consistently over the course of many months might have higher cessation rates, because they have consistently benefited from the information and skills presented in the app.

There is a dearth of studies analyzing use trajectories for digital smoking cessation interventions. We are aware of 3 publications for SMS text messaging interventions [20-22], 4 publications for website interventions [5,23-25], and none for smartphone interventions. Regarding SMS text messaging interventions, a study identified 5 distinct use trajectories of an SMS text messaging–based smoking cessation program over the 6 weeks after quit date, namely high engagement, increasing engagement, rapid decrease, delayed decrease, and low engagement [20]. The study found that the high engagement and increasing engagement groups were more likely than the other groups to quit smoking over the course of 6 weeks. Within the context of smoking cessation websites, our group conducted a functional clustering analysis of log-in data from both arms of a large (N=2637) randomized trial of 2 website interventions for smoking cessation (WebQuit and Smokefree), with a primary outcome of 30-day point prevalence smoking abstinence at 12 months [24]. Compared with 1-week WebQuit users, 5- and 52-week users had 57% higher odds (odds ratio [OR] 1.57, 95% CI 1.13-2.17; *P*=.007) and 124% higher odds (OR 2.24, 95% CI 1.45-3.43; *P*<.001), respectively, of being abstinent at 12 months. The 5-week use of either website predicted higher odds of quitting smoking, with the highest odds for 52-week WebQuit users. These results suggest that experimental testing strategies to increase digital intervention engagement for 4 more weeks (ie, from 1 week to 5 weeks) would be valuable. Studying distinct groups of use trajectories can help identify which use patterns are beneficial and thereby make recommendations for future program use. These results will help inform the design of more engaging digital interventions for smoking cessation, with the ultimate goal of a higher likelihood of cessation.

If we can identify smartphone intervention use trajectories that predict cessation, understanding the sociodemographic characteristics of individuals who tend to follow more or less successful trajectories is important. Knowing the characteristics of individuals who are likely to have certain engagement patterns might allow researchers and intervention designers to tailor smartphone interventions according to users' unique baseline characteristics. There is an emerging literature of randomized trial designs that algorithmically use baseline characteristics predictive of treatment outcomes in the design of tailored interventions [26,27]. Although studies have found that being female, being older, and having a higher education are generally consistent predictors of greater digital intervention use [28-31], very little is known about the user characteristics that are associated with different patterns of use over time [32,33]. For example, a study found that being female and having higher baseline motivation were associated with more consistent log-in trajectories [34]. For the WebQuit website intervention, we found that smoking for at least the past 10 years and screening negative for anxiety predicted a 90% higher odds (OR 1.90, 95% CI 1.14-3.14) and a 56% higher odds (OR 1.56, 95% CI 1.06-2.33), respectively, of being a 52-week user (compared with being a 1-week user) [24]. Regarding smoking cessation smartphone apps, we are aware of no literature on baseline predictors of their use patterns over time.

We recently developed and tested iCanQuit, a smartphone app for smoking cessation based on acceptance and commitment therapy (ACT), a behavioral approach that teaches skills for allowing cravings to smoke to pass without smoking, which is conceptually distinct from the US Clinical Practice Guidelines (USCPG)–based approaches that teach avoidance of urges [35]. In a large 2-arm randomized trial, iCanQuit was compared with QuitGuide, a USCPG-based smartphone app. At the 12-month follow-up, iCanQuit was 1.5 times more efficacious than QuitGuide for smoking cessation among 2415 adults who smoked (36% racial or ethnic minority groups) from all 50 US states [35]. The iCanQuit study was the first full-scale randomized controlled trial with long-term follow-up to show that a smartphone app was efficacious for smoking cessation.

Objectives

Using data from the iCanQuit parent randomized trial, this study identified the following: (1) distinct groups of smartphone app log-in trajectories, (2) their association with the 12-month smoking cessation outcome, and (3) baseline sociodemographic user characteristics that are associated with different use trajectory groups. Log-in trajectories (ie, log-ins over time) are a generalizable metric that can be useful for other digital intervention researchers—agnostic of the intervention-specific content contained in any one app. The overall goal of this study is to inform the design of future smartphone health interventions that could be more efficacious by identifying trajectory groups in need of further intervention. To accomplish these aims, in this study we analyzed 182 consecutive days of log-in data from both arms of the large (N=2415), 2-arm randomized trial of iCanQuit versus QuitGuide smartphone app interventions for smoking cessation (NCT02724462).

Methods

Design

A total of 2415 individuals were enrolled in the 2-arm iCanQuit randomized controlled trial for smoking cessation, with full protocol details previously described [12]. In brief, a racially and ethnically diverse sample of 2415 adult daily smokers from all 50 US states was randomized 1:1 to receive access to an ACT-based smartphone app (iCanQuit) or a USCPG-based smartphone app (QuitGuide) for smoking cessation. Data for this analysis were from the 2133 individuals who logged into their assigned app at least once and had a complete 182 days of engagement data available.

Eligibility Criteria

Eligibility criteria included individuals who (1) were aged ≥18 years; (2) smoked 5 or more cigarettes per day for the past year; (3) wanted to quit smoking within the next 30 days; (4) if concurrently using any other tobacco products, wanted to quit all tobacco products within 30 days; (5) were interested in learning skills to quit smoking and willing to be randomized to either treatment condition; (6) had daily access to their own smartphone; (7) knew how to download smartphone apps; (8) were willing and able to read in English; (9) had never used QuitGuide and not currently using another smoking cessation treatment; (10) had never participated in our prior studies; (11) had no household members already enrolled; (12) were willing to complete outcome surveys, and (13) could provide contact information for themselves and 2 relatives.

Recruitment, Enrollment, and Follow-up

Adults were recruited nationally via Facebook advertisements, a survey sampling company, search engine results, and friend or family referrals. Participants completed an encrypted web-based screening survey and were notified of their eligibility via email. They then clicked on their secured emailed link to the study website where they provided consent and completed the baseline survey. At each enrollment step, the study was presented as a comparison of 2 smartphone apps for smoking cessation.

Participants were randomized (1:1) to iCanQuit or QuitGuide using randomly permuted blocks of sizes of 2, 4, and 6, stratified by smoking frequency (≤20 vs ≥21 cigarettes per day), education (≤high school vs ≥some college), race or ethnicity (minority race or ethnicity vs non-Hispanic White), and depression screening (Center for Epidemiologic Studies Depression score ≤15 vs ≥16) [31]. Random assignments were concealed from participants throughout the trial. The random allocation sequence was generated by a database manager and implemented automatically by the study website. Neither research staff nor study participants had access to the upcoming randomized study arm assignments. In both arms, participants could access their interventions from the moment of randomization and beyond (ie, after the end of the 12-month follow-up period). All participants provided their consent on the web and were compensated with up to US $105 for completing study data collection. The data retention rate was 88% (1886/2133) and differed slightly between arms (90% in QuitGuide vs 87% in iCanQuit; P=.01).

Interventions

iCanQuit

Participants randomized to the iCanQuit arm received access to download the iCanQuit smartphone app (version 1.2.1). iCanQuit intervenes on the ACT-focused processes of acceptance of internal cues to smoke and enacting one’s values that guide smoking cessation [12]. The acceptance component of the app teaches skills to accept physical sensations, emotions, and thoughts that trigger smoking by distancing oneself from thoughts about smoking (“cognitive defusion”), mindfulness skills, and flexible perspective taking. The values component of the app teaches skills for determining the core life domains that motivate quitting smoking (eg, family, health, and spirituality) and taking repeated small actions within these domains (eg, playing with grandchildren) to develop a smoke-free life. The program is self-paced, and the content is sequentially unlocked across 8 levels. Each of the first 4 levels is made accessible immediately after the prior level is completed, whereas each of the last 4 levels is only unlocked upon recording 7 consecutive days without smoking. If a participant lapses, the program encourages (but does not require) them to set a new quit date and return to the first 4 levels for preparation. The program also includes on-demand tools to help in coping with smoking urges, tracking the daily number of cigarettes smoked, and urges passed without smoking. Content was presented in a sequenced format with short paragraphs of text and some audio or visual content for experiencing ACT concepts.

QuitGuide

Participants randomized to the QuitGuide arm received access to download the QuitGuide smartphone app (version 1.2.2). QuitGuide content is delivered in four main sections: (1) "Thinking about quitting," which focuses on motivations to quit by using reason and logic such as identifying reasons to quit and providing information on the health consequences of smoking and quitting; (2) "Preparing to Quit," which helps users develop a quit plan, identify smoking behaviors, triggers, and reasons for being smoke free, and social support for quitting; (3) "Quitting," which teaches skills for avoiding cravings to smoke; and (4) "Staying Quit," which presents tips, motivations, and actions to stay smoke free and skills for coping with slips. No smoking cessation medications or coaching was provided in either intervention arm [12]. Content was presented in a sequenced format with short paragraphs of text.

Study Measures

Baseline Characteristics and Covariates

Data collected at baseline included age, gender, race, ethnicity, education, employment, income, marital status, and sexual orientation. Study participants completed validated positive screening tools to assess mental health, including depression [31], panic [32], and posttraumatic stress disorder [33]. Alcohol consumption and heavy drinking were assessed using the Quick Drinking Screen [34]. Smoking behavior variables included nicotine dependence (measured using the Fagerström Test for Nicotine Dependence) [35], number of cigarettes smoked per day, years of smoking, use of e-cigarettes, quit attempts, and relationships with other smokers. Acceptance of internal cues to smoke was measured via the Avoidance and Inflexibility Scale (adapted from the study by Gifford et al [36]), using means of the three 9-item subscales that assess one's willingness to experience physical sensations, emotions, and thoughts that cue smoking. The items are rated on a 5-point scale from 1="not at all" to 5="very willing" and averaged, with higher scores indicating greater acceptance. A sample physical sensation item was "How willing are you to notice these bodily sensations without smoking?" and items from the emotions and thoughts subscales were similar, substituting "feelings" or "thoughts" for "bodily sensations." Valued living was measured using the 10-item Valuing Questionnaire [37], designed to assess the extent of personal values enactment. Each item is rated on a 7-point scale ranging from 0="not at all true" to 6="completely true." Scores were averaged, and 2 distinct factors were derived: progress and obstruction, with higher scores indicating either greater progress or greater obstruction toward valued living, respectively. A sample progress item was "I worked toward my goals even if I didn't feel motivated to" and a sample obstruction item was "I was basically on auto-pilot most of the time."

Engagement: Baseline to Day 182 Log-ins

Engagement with the assigned app was measured objectively using Google Analytics. The measure of engagement was the number of days each application was opened, which was consistent with other digital interventions' measures of engagement [7,24,25]. For each participant, time- and date-stamped log file records of each page opening were recorded. For this analysis, we used a binary measure indicating whether each participant logged in at least once each day (ie, had at least one log-in recorded in the log file data). Using this method, each participant had a 0/1 code for each day for 182 days from the date of randomization. Owing to a technical error in the Google Analytics system, only the first 182 days of engagement data were available for the study sample.

Smoking Cessation Outcome: 12 Months

The parent trial's primary smoking cessation outcome was specified a priori as self-reported complete case 30-day point prevalence abstinence (PPA) at the 12-month follow-up. As reported in the parent trial, for the primary outcome of 30-day PPA at the 12-month follow-up, iCanQuit participants had 1.49 times higher odds of quitting smoking as compared with QuitGuide participants (293/1040, 28.17% abstinent vs 225/1067, 21.08% abstinent; OR 1.49, 95% CI 1.22-1.83; P<.001). Note that when missing data were coded as smokers, 12-month 30-day PPA results were very similar (293/1214, 24.13% abstinent for iCanQuit vs 225/1201, 18.73% abstinent for QuitGuide; OR 1.40, 95% CI 1.14-1.71; P<.001).

Statistical Analyses

The analyses were conducted separately for each app. As mentioned in the engagement measurement, log-in data were summarized as a binary time series indicating log-in occurrence on each day of the first 6 months (ie, 182 days) of using the application, from the date of randomization of each participant. Next, log-in time series were presmoothed as the average number of days logged in over a window of 7 previous days [24,36]. This type of dense trajectories data is known as functional data. We applied functional clustering based on functional principal component (FPC) analysis. Specifically, we conducted an FPC analysis [37] by smoothed covariance to summarize each participant's log-in trajectory using a set of low-dimensional FPC scores. We chose to retain the first 3 and 4 FPC scores for clustering in the iCanQuit and QuitGuide arms, respectively, based on a minimum threshold of 90% for the percentage of variance explained. Trajectories were clustered using the Clustering for Large Applications algorithm [38] into k=2 and 3 groups in each arm, which met a minimum prediction strength [39] threshold of 0.6. The Clustering for Large Applications procedure does not rely on parametric assumptions on the shapes of trajectories and is capable of handling densely recorded longitudinal data and complex missing data patterns. We then examined the cluster solutions in each arm for a minimum group size ≥5% of the sample and reasonable separation of the mean log-in trajectories among groups to determine the optimal number of groups for each.

After determining distinct trajectory groups, smoking cessation rates were compared among the groups using logistic regression, with the lowest use group as the reference group. Baseline characteristics with significant univariate associations with cessation were considered as covariates, to control for characteristics that may confound the association between trajectory group and cessation [40]. Thus, the aim of the analysis, as guided by the study's scientific questions, was to understand the unique prediction of the 12-month cessation outcome by trajectory group membership. A shared set of covariates (ie, all baseline characteristics) was considered for each treatment arm. We conducted stepwise logistic regression using Akaike Information Criterion to determine the subset of covariates to be included in the final adjusted model [41]. Finally, baseline characteristics were compared among the groups. Those with significant univariate association with trajectory group membership were considered in stepwise selection, using Akaike Information Criterion, of an adjusted multinomial logistic regression model (iCanQuit arm) or logistic regression model (QuitGuide arm) to determine the best baseline predictors of group membership. All statistical tests were 2-sided, with α=.05, and analyses were conducted in R (version 4.0.3; R Foundation for Statistical Computing [42]), using the R packages "refund" [43] for FPC analysis, "fpc" [44] for prediction strength, and "nnet" [41] for multinomial logistic regression.

Ethics Approval

All study activities were approved by the institutional review board at the Fred Hutchinson Cancer Research Center (approval number IR-8317).

Description of Sample

Multimedia Appendix 1 shows the baseline demographics and participant characteristics in both the iCanQuit and QuitGuide arms. The mean (SD) age at enrollment was 37.8 (10.8) years. Furthermore, 70.28% (1499/2133) of the participants were female and 35.72% (762/2133) of the participants reported racial and ethnic minority backgrounds. There were 40.46% (863/2133) of the participants with a high school or less education. Regarding smoking, 74.54% (1590/2133) of the participants smoked more than half a pack (at least 11 cigarettes) per day. Less than half (785/2030, 38.67%) of the participants had made a quit attempt in the last year, and 82.47% (1759/2133) of the sample had been smoking for >10 years, with an average Fagerström Test for Nicotine Dependence score of 5.86 (moderate nicotine dependence; SD 2.04). There were no statistically significant differences between the 2 arms for any baseline variable (all *P*>.05).

Description of Distinct Groups of Trajectories

The functional clustering analysis of 26 weeks of log-ins revealed 3 distinct groups of trajectories for iCanQuit versus 2 distinct groups for QuitGuide. Log-in patterns are shown in Figure 1 (for iCanQuit) and Figure 2 (for QuitGuide). For iCanQuit (Figure 1), the first trajectory group (610/1069, 57.06%) logged in a mean of 2.0 days in the first week and then had <1 mean log-in day in weeks 2 and beyond. They were termed "1-week users." The second trajectory group (303/1069, 28.34%) logged in a mean of 4.6 days in week 1, a mean of 3.1 days in week 2, a mean of 2.0 days in week 3, a mean of 1.2 days in week 4, and then had <1 mean log-in day in weeks 5 and beyond. They were termed "4-week users." The third trajectory group (156/1069, 14.59%) logged in a mean of 5.0 to 5.4 days per week in weeks 1 through 5, a mean of 3.1 to 4.7 days per week in weeks 6 through 10, tapering to a mean of twice every week starting week 17, and continuing in this pattern until week 26. They were termed "26-week users."

For QuitGuide (Figure 2), the first trajectory group (695/1064, 65.32%) logged in a mean of 1.4 days in the first week and then had <1 mean log-in day in weeks 2 and beyond. As with iCanQuit, they were termed "1-week users." The second trajectory group (369/1064, 34.68%) logged in a mean of 2.8 times in week 1, a mean of 1.7 times in week 2, a mean of 1.1 times in week 3, and then had few log-ins after that. They were termed "3-week users."

Figure 1. Mean weekly log-ins for each trajectory group from the iCanQuit arm. Error bars represent IQRs.

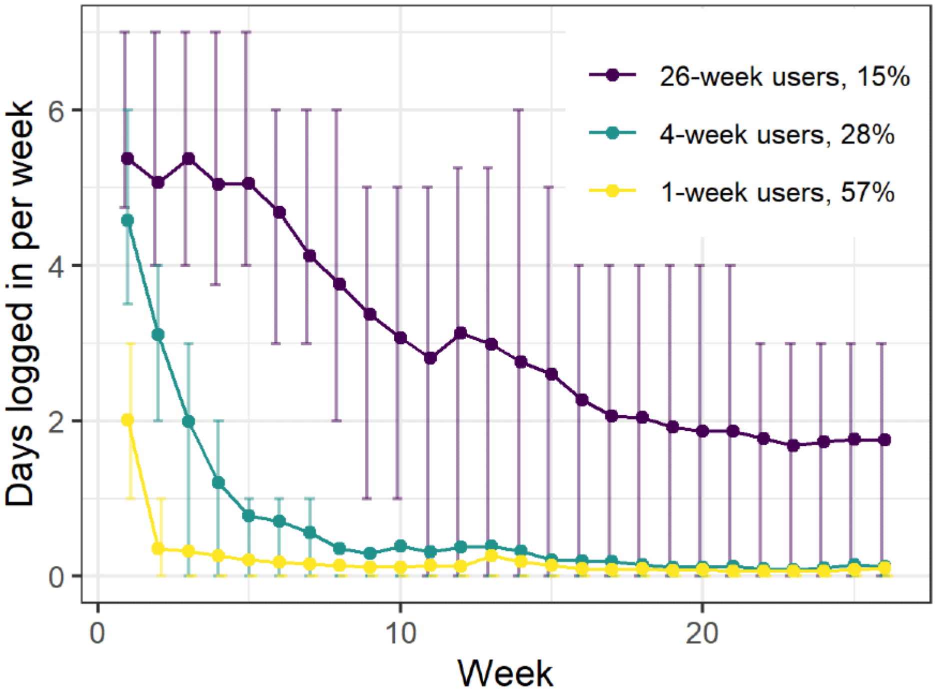

Figure 2. Mean weakly log-ins for each trajectory group from the QuitGuide arm. Error bars indicate IQRs.

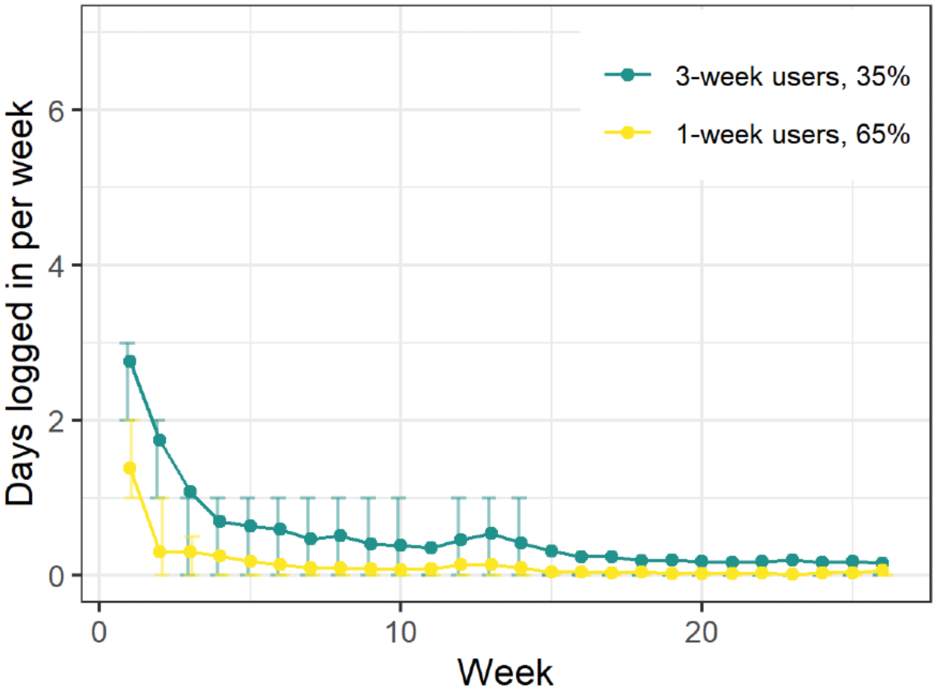

Trajectory Membership Prediction of Smoking Cessation Outcome

Table 1 shows each intervention arm's trajectory group membership as a predictor of 30-day PPA at the 12-month follow-up, after controlling for all baseline covariates included in the statistical model. For iCanQuit, abstinence rates for the 3 trajectory groups were 23% for 1-week users, 30% for 4-week users, and 56% for 26-week users. Compared with the 1-week users, the 4-week users had 50% higher odds (OR 1.50, 95% CI 1.05-2.14; *P*=.03), whereas 26-week users had 397% higher odds (OR 4.97, 95% CI 3.31-7.52; *P*<.001), respectively, of being abstinent at 12 months. Descriptively, for QuitGuide, abstinence rates for the 2 trajectory groups were 21% for 1-week users and 23% for 3-week users. There was no significant difference in the odds of being abstinent at 12 months for 3-week versus 1-week users (OR 1.16, 95% CI 0.84-1.62; *P*=.37). The above models adjusted for the baseline covariates selected, as outlined in the statistical methods, and are shown in Table 1.

Table 1. Logistic regression models predicting 12-month smoking cessation outcome by log-in trajectory group, adjusted for Akaike Information Criterion model–selected covariates[a].

Treatment arm and covariate	Odds ratio (95% CI)	*P* value
iCanQuit		
4-week users	1.50 (1.05-2.14)	.03
26-week users	4.97 (3.31-7.52)	<.001
Gender (male)	1.87 (1.33-2.62)	<.001
High school or lower education	1.42 (1.03-1.95)	.03
Depression screen positive	0.69 (0.50-0.97)	.03
Panic disorder screen positive	0.74 (0.50-1.09)	.14
Used e-cigarettes at least once in past month	0.66 (0.45-0.96)	.03
Confidence in being smoke free	1.01 (1.01-1.02)	<.001
Drinks per day on a typical drinking day	0.95 (0.91-1.00)	.048
QuitGuide		
3-week users	1.16 (0.84-1.62)	.37
Used e-cigarettes at least once in past month	1.44 (0.99-2.08)	.05
Confidence in being smoke free	1.01 (1.00-1.02)	.005
Close friends who smoke	0.89 (0.81-0.97)	.01
Heavy drinker[b]	0.64 (0.37-1.07)	.10
Valuing questionnaire—progress	1.03 (1.01-1.06)	.01

[a] The reference group is 1-week users for both arms.

[b] Heavy drinkers are defined as women who had 4 or more drinks and men who had 5 or more drinks on a typical drinking day.

Baseline Characteristics Predicting Trajectory Membership

Because the trajectory groups were different across the 2 arms, Table 2 presents the results for baseline characteristics predicting membership in the groups for the 2 arms separately. For iCanQuit, the baseline characteristics significantly associated with more engaged group membership, as compared with 1-week user group membership, were age in years (OR 1.05, 95% CI 1.03-1.06 for 26-week users), smoking up to one-half pack per day (OR 1.90, 95% CI 1.25-2.87 for 26-week users), smoking first cigarette >5 minutes after waking (OR 1.42, 95% CI 1.05-1.92 for 4-week users), and higher mean acceptance of internal physical sensations (OR 1.82, 95% CI 1.41-2.35 for each 1-point increase for 4-week users).

For QuitGuide, the baseline characteristics significantly associated with 3-week user group membership, as compared with 1-week user group membership, were female gender (OR 1.46, 95% CI 1.10-1.95), minority race (people of color) or ethnicity (Hispanic; OR 1.40, 95% CI 1.08-1.83), and smoked for 10 or more years (OR 1.56, 95% CI 1.04-2.35).

Table 2. Multinomial logistic regression (iCanQuit arm) and logistic regression (QuitGuide arm) results predicting log-in trajectory group membership from Akaike Information Criterion model–selected baseline characteristics[a].

Arm, trajectory group, and characteristic	Odds ratio (95% CI)
iCanQuit	
4-week users	
Age (years)	1.01 (0.99-1.02)
Smokes ≤10 cigarettes per day	1.25 (0.89-1.76)
First cigarette >5 minutes after waking	1.42 (1.05-1.92)
Number of quit attempts in previous year	1.03 (0.99-1.08)
Each point increase in acceptance of physical sensations	1.82 (1.41-2.35)
26-week users	
Age (years)	1.05 (1.03-1.06)
Smokes ≤10 cigarettes per day	1.90 (1.25-2.87)
First cigarette >5 minutes after waking	1.42 (0.96-2.08)
Number of quit attempts in previous year	0.92 (0.83-1.02)
Each point increase in acceptance of physical sensations	1.23 (0.88-1.71)
QuitGuide: 3-week users	
Gender (female)	1.46 (1.10-1.95)
Minority race or ethnicity	1.40 (1.08-1.83)
Anxiety screen positive	0.75 (0.55-1.02)
Smoked for ≥10 years	1.56 (1.04-2.35)

[a]The reference group is 1-week users for both treatment arms.

Discussion

Principal Findings

This study contributes to the nascent literature on longitudinal use trajectories of digital health interventions and their prediction of health outcomes [20-25]. The study found (1) 1-, 4-, and 26-week trajectories for iCanQuit versus 1- and 3-week trajectories for the QuitGuide smoking cessation apps; (2) that these trajectory groups differentially predicted smoking outcomes at 12 months for iCanQuit but not for QuitGuide; and (3) that certain user characteristics were associated with membership in certain trajectory groups. Notably, compared with the 1-week iCanQuit users, the 4-week users had 50% higher odds, whereas 26-week users had 397% higher odds, respectively, of being abstinent at 12 months. The results are discussed in the following sections.

Use Trajectories and Health Outcomes

At least half of the participants in both arms were 1-week users. Similarly, our 2018 study examining log-in trajectories of 2 smoking cessation websites found that half of the participants were 1-week users, and similar to this study, that study showed that these participants were the least likely to have quit smoking at the 12-month follow-up [24]. Thus, there are now 4 separate digital interventions (2 in this study and 2 in the 2018 study [24]) showing large proportions of users (645/1309, 49.27% to 610/1069, 57.06%) who are 1-week users, suggesting overall that 1-week use may be a common engagement pattern of digital health interventions. Thus, it is imperative to identify early who would likely become a 1-week user. For example, the baseline characteristics results of this study suggest that a younger age, smoking at least one-half pack per day, smoking the first cigarette within 5 minutes of waking (a marker of nicotine dependence), and scoring lower on acceptance of internal physical sensations that trigger smoking (a marker of avoidance of cigarette cravings) predicted membership in the iCanQuit 1-week trajectory group. Measuring these factors at baseline might allow for the early identification of individuals who would be more likely to disengage from iCanQuit in the first week. Another approach that might be worth testing in future research is investigating use patterns within the first week (eg, number of log-ins per day and time spent on the app per day) to predict whether a participant would become a 1-week user. Once identified, more intensive intervention strategies could be used with this group, which might range from push notification communications or proactive intervention. Beyond this study, it would be worthwhile to determine whether 1-week use is a common pattern across multiple digital platforms (eg, websites and smartphone apps) and health domains (eg, tobacco, exercise, and diet) and to what extent this use pattern affects health outcomes.

The second trajectory group for each arm was the 4-week users for iCanQuit (303/1069, 28.34%) and 3-week users for QuitGuide (369/1064, 34.68%). Although the length of each group was similar (3-4 weeks) and the proportion of each group was somewhat smaller in iCanQuit, only the iCanQuit 4-week users had significantly higher quit rates than their 1-week comparators (ie, 50% higher odds of quitting). Two potential reasons why iCanQuit's, but not QuitGuide's, second trajectory group had higher quit rates are most likely due to the content and structure of the iCanQuit app. Regarding content, we have published multiple studies showing that the effect of iCanQuit (but not QuitGuide) on smoking cessation was mediated by ACT-based processes of acceptance of internal cues to smoke (ie, sensations, thoughts, and emotions) [35,45-48]. The differences in content, with iCanQuit focused on ACT versus QuitGuide focused on standard USCPG content [49], suggest that 4 weeks of engaging with ACT content that targets acceptance of internal cues is effective at improving quit rates. Regarding structure, the iCanQuit app presented content in a sequenced interactive format (eg, content is unlocked in a sequential manner) with short paragraphs of text and some audio or visual for experiencing ACT concepts, whereas the QuitGuide app presented content in a sequenced format with short paragraphs of text [35]. Thus, the extent to which intervention engagement predicts behavior change might depend on the content and structure of the intervention, which is a valuable topic for future research. For iCanQuit, these results suggest that strategies to increase engagement 3 more weeks (ie, from 1 to 4) could be an effective approach to improving quit rates. Example strategies worth testing include (1) proactive check-ins (via SMS text messages or phone calls) from staff about progress with the iCanQuit app, (2) rewarding each day's use of iCanQuit, and (3) a "four-week challenge," which shows other users' daily log-in progress toward the goal of 4 weeks of use.

Only iCanQuit had a third trajectory group, namely 26-week users (156/1069, 14.59% of the iCanQuit arm sample). The 26-week users' group had nearly 400% higher odds of quitting smoking (as compared with 1-week users). The 12-month 56% quit rates observed in this group are the highest we have ever observed in a digital smoking cessation intervention and suggest that iCanQuit could be a highly effective and scalable intervention for this group of users. Our 2018 paper found a similar group of long-term users on the WebQuit website (159/1240, 12.82% of WebQuit arm sample) who had high 12-month quit rates (34.2% [24]) but not as high as those found here for iCanQuit. The iCanQuit ACT-based content and structure may have encouraged long-term, spaced skills practice [6]. Taken together, the findings for both the iCanQuit and WebQuit third trajectory groups suggest that consistent use of each program over time is prognostic of a better health outcome, which is contrary to the notion that consistent log-ins may be a marker of ongoing challenges and struggles to change a health behavior. Instead, consistent log-ins over time may be a marker of a participant's commitment to changing a health behavior. Digital intervention designs could focus on methods to encourage commitment and prevent lapses over time, which may include strategies similar to those suggested above, in addition to just-in-time adaptive interventions that aim to provide the right type of lapse-prevention support to smokers at the right time [50].

Personal Characteristics and Use Trajectories

The impact of personal characteristics on use trajectories appears to vary according to the intervention. For example, among iCanQuit participants, smoking the first cigarette >5 minutes after waking and higher levels of acceptance of physical cues to smoke predicted being a 4-week user, whereas older age and smoking ≤10 cigarettes per day predicted being a 26-week user. The findings generally suggest that less dependence and greater acceptance of cravings predict long-term engagement with iCanQuit. The results on increasing age predicting iCanQuit's 26-week use trajectory membership are consistent with past research showing that older age is a predictor of higher digital health intervention use [28-31], including our 2018 WebQuit trajectories paper [24]. In contrast to the view that as people age, their willingness to use technology decreases [51], this study suggests that increasing age may actually indicate which one is more likely to remain long-term users of iCanQuit, and in turn, have very high quit rates. In contrast, although there were baseline factors that predicted QuitGuide's use trajectory membership, neither of the 2 trajectories predicted smoking cessation, so the value of these baseline prediction results is unclear. Nonetheless, we recommend that future research explore a variety of baseline subgroup differences (eg, sex, race, and age) in digital intervention trajectories to better understand who is most or least likely to engage over time. Overall, these analyses suggest a need for further research on which baseline factors might predict different use trajectories and therefore inform the development of tailored interventions that facilitate long-term, consistent engagement based on an individual's specific baseline characteristics.

Limitations

This study has several key limitations. First, only 2 smartphone apps were tested, and both were focused on smoking cessation; thus, future research should examine the extent to which the results generalize to other behaviors and to other types of digital interventions. Cessation outcome data were self-reported for the reasons stated in the Methods section. Remote biochemical validation of smoking cessation would have introduced biases including low response rates, prohibitive cost, challenges with confirming the identity of the person providing the sample, and inability to confirm abstinence beyond 24 hours [52-59]. Owing to a technical error, log-ins were recorded for the first 6 months of the trial. Finally, as users self-select to different app use patterns (rather than being randomized), the associations observed in this study may not be causal, and care should be taken in their interpretation.

Conclusions

Patterns of 1-, 3-, and 4-week use of smartphone apps may be common for how people engage in digital health interventions. In addition, 4-week users, and especially 26-week users of iCanQuit, have higher odds of quitting smoking. Strategies to detect potential 1-week iCanQuit users and proactively offer them more intensive intervention could be fruitful.

Abstract

Background: Investigating ways to improve well-being in everyday situations as a means of fostering mental health has gained substantial interest in recent years. For many people, the daily commute by car is a particularly straining situation of the day, and thus researchers have already designed various in-vehicle well-being interventions for a better commuting experience. Current research has validated such interventions but is limited to isolating effects in controlled experiments that are generally not representative of real-world driving conditions.

Objective: The aim of the study is to identify cause–effect relationships between driving behavior and well-being in a real-world setting. This knowledge should contribute to a better understanding of when to trigger interventions.

Methods: We conducted a field study in which we provided a demographically diverse sample of 10 commuters with a car for daily driving over a period of 4 months. Before and after each trip, the drivers had to fill out a questionnaire about their state of well-being, which was operationalized as arousal and valence. We equipped the cars with sensors that recorded driving behavior, such as sudden braking. We also captured trip-dependent factors, such as the length of the drive, and predetermined factors, such as the weather. We conducted a causal analysis based on a causal directed acyclic graph (DAG) to examine cause–effect relationships from the observational data and to isolate the causal chains between the examined variables. We did so by applying the backdoor criterion to the data-based graphical model. The hereby compiled adjustment set was used in a multiple regression to estimate the causal effects between the variables.

Results: The causal analysis showed that a higher level of arousal before driving influences driving behavior. Higher arousal reduced the frequency of sudden events (P=.04) as well as the average speed (P=.001), while fostering active steering (P<.001). In turn, more frequent braking (P<.001) increased arousal after the drive, while a longer trip (P<.001) with a higher average speed (P<.001) reduced arousal. The prevalence of sunshine (P<.001) increased arousal and of occupants (P<.001) increased valence (P<.001) before and after driving.

Conclusions: The examination of cause–effect relationships unveiled significant interactions between well-being and driving. A low level of predriving arousal impairs driving behavior, which manifests itself in more frequent sudden events and less anticipatory driving. Driving has a stronger effect on arousal than on valence. In particular, monotonous driving situations at high speeds with low cognitive demand increase the risk of the driver becoming tired (low arousal), thus impairing driving behavior. By combining the identified causal chains, states of vulnerability can be inferred that may form the basis for timely delivered interventions to improve well-being while driving.

KEYWORDS

well-being; daily driving; causal inference; commute; field study; directed acyclic graph; just-in-time interventions; mental well-being; stress; mental health

Introduction

With rising numbers of mental disorders worldwide, maintaining well-being has become an important public health issue [1], with a special focus on untreated cases [2]. In recent years, there has been an increased interest in investigating ways to improve well-being in everyday situations in order to prevent mental disorders [3,4]. Especially interventions aimed at improving well-being in moments when a person is susceptible to a deteriorating mental state, a so-called *state of vulnerability*, have shown great promise [5,6]. In this regard, the just-in-time adaptive intervention (JITAI) framework has recently gained major attraction as it guides researchers in their way to develop effective interventions that are delivered at the right time and in the right situation. To implement such a JITAI effectively, a profound understanding of the contextual factors leading to a state of vulnerability is necessary [7].

A suitable everyday situation in which an intervention may promise beneficial effects on well-being is daily driving [8]. Daily car commuters spend a considerable amount of time on the street every day, often associated with events causing frustrations and loss of time, such as caused by traffic jams, congestion, and unpredictability [9,10]. Kahneman et al [11] found the daily commute to be one of the least pleasant activities of the day. Accordingly, states of deteriorating well-being are likely to occur in daily driving. Simultaneously, the car is a suitable place for JITAIs as there are multiple sensors to detect the current driving conditions (eg, lane or traffic object detection [12,13]) and driver states (eg, arousal states [14] or emotions [15,16]) as well as to deliver interventions using advanced multimedia systems.

Recent work investigated when drivers are interruptible by [17,18] or even responsive to interventions [19] while driving. Moreover, researchers designed and validated the effect of well-being interventions that can be conducted while driving, for example, breathing exercises [20] and music or mindfulness experiences [21]. According to the JITAI framework, interventions are most effective when triggered in a state of reduced well-being [7]. To identify such states of vulnerability and thereby improve road safety [22], the factors influencing well-being while driving must be determined. Since well-being likely influences driving behavior and vice versa, a thorough understanding of the causal relationships is crucial for evaluating the driver's mental state. Therefore, this study examines the interactions between driving behavior and well-being during daily driving.

Because drivers are exposed to a variety of contextual factors, it is difficult to establish robust causal relationships based on existing statistical analysis [23]. Previous studies on driving and well-being have been primarily limited to isolating specific relationships in simulation experiments [24-28]. However, this controlled environment limits the results as stimuli are artificially induced, and thus effects do not generalize well to the wide range of situations encountered in everyday road traffic [29-31]. To thoroughly understand the relationship between driving and well-being, it seems necessary to study real-world data using novel methods for causal analysis.

The aim of this analysis is to unveil a robust causal architecture, that is, the underlying network of causes and effects [32], between driving behavior and well-being. We applied novel causal inference algorithms to derive these relationships from complex observational data collected in a real-world driving study, in which we investigated drivers' well-being over a period of 4 months. The derived causal architecture forms a basis for inferring states of vulnerability that can be targeted by digital interventions.

Methods

Field Study Setting and Variables

The data were gathered in a field study in which we handed over to 10 participants between the ages of 26 and 55 years a car each for daily driving. For maximizing external validity, we selected a broad spectrum of typical daily commuters with different demographics, life and family situations, and driving habits (purposive sampling). Detailed information about the participants is documented in Multimedia Appendix 1. Participants completed most of their driving in their residence area, which for all of them was the region around Stuttgart (Germany). The field study lasted for a period of 4 months, from July to November 2019.

To measure a wide variety of factors that could impact the well-being of the driver, we retrofitted the study cars for data collection. The participants self-assessed their current emotional state before and after driving based on questionnaires by a smartphone mounted next to the multimedia system. Moreover, we installed in every car a data collection system that recorded various variables from the vehicle in high frequency (eg, the steering wheel speed, brake pedal and gas pedal positions, or the Global Positioning System [GPS] location) to measure the driving behavior as well as the vehicle state. Our final data set comprised 13 variables that were classified into 4 categories: emotions, driving behavior, trip-dependent factors, and predetermined factors. We chose these 4 categories based on related work examining driving behavior and well-being [19,21]. A detailed list of the included variables can be found in Multimedia Appendix 2. This set of variables provides a comprehensive exploratory basis for understanding how driving behavior and well-being relate to each other. We explain these categories in the following paragraphs.

The *emotions* of the driver were assessed according to the circumplex model of affect, which is composed of the 2 dimensions *arousal* and *valence* [33,34]. The arousal dimension describes the drivers' feeling of being awake, and the valence dimension indicates the corresponding level of happiness. Before and after each drive, the driver indicated their state of arousal and valence on a scale from 0 (very low) to 100 (very high) using the *Affective Slider* [35], which is depicted in Multimedia Appendix 3.

We measured the *driving behavior* using the sensors that each car was equipped with. To quantify the driving behavior, we analyzed the steering and braking behavior of the driver. The *steeringbehavior* was quantified as the proportion of the trip in which the driver was turning the steering wheel. Analogously, the *brakingbehavior* reflected the ratio of the seconds in which the brake pedal was engaged to the total duration of the trip. To account for the risk that a driver takes, we included the frequency of sudden accelerations, sudden braking, or sudden steering as the variable *sudden events*. An event was classified as sudden when the acceleration or steering angle exceeded a prespecified threshold. To identify these events, we used the same approach as in prior work [19] based on the peak detection algorithm from the Python package SciPy [36].

Since the field study was conducted in an uncontrolled setting, we needed to account for contextual and environmental factors that drivers experience. We distinguished between *trip-dependent factors*, which are related to the drive itself, and *predetermined factors*, which are explicitly known to drivers before starting. The *trip-dependent factors* comprise information about the *length* of the trip in seconds and the average *speed* in kilometers per hour. In addition, the *flow* of the trip quantifies the ratio of the actual speed to the potential maximum speed throughout the trip. By combining these 3 factors, we aimed at representing the built environment in which the trip takes place [37]. For example, urban driving will likely result in short trips at low speeds with low flow.

The included *predeterminedfactors* in the causal model were the weather, quantified by the minutes of *sunlight* in the hour that the drive started and whether the trip was or was not performed on the *weekend*. Furthermore, we recorded whether another *occupant* was present and whether the trip was a *commute* between home and work, as derived from the GPS location at the beginning and end of each trip. To reduce skewness and to establish a common scale across all continuous variables, we standardized the data to a mean of 0 and an SD of 1.

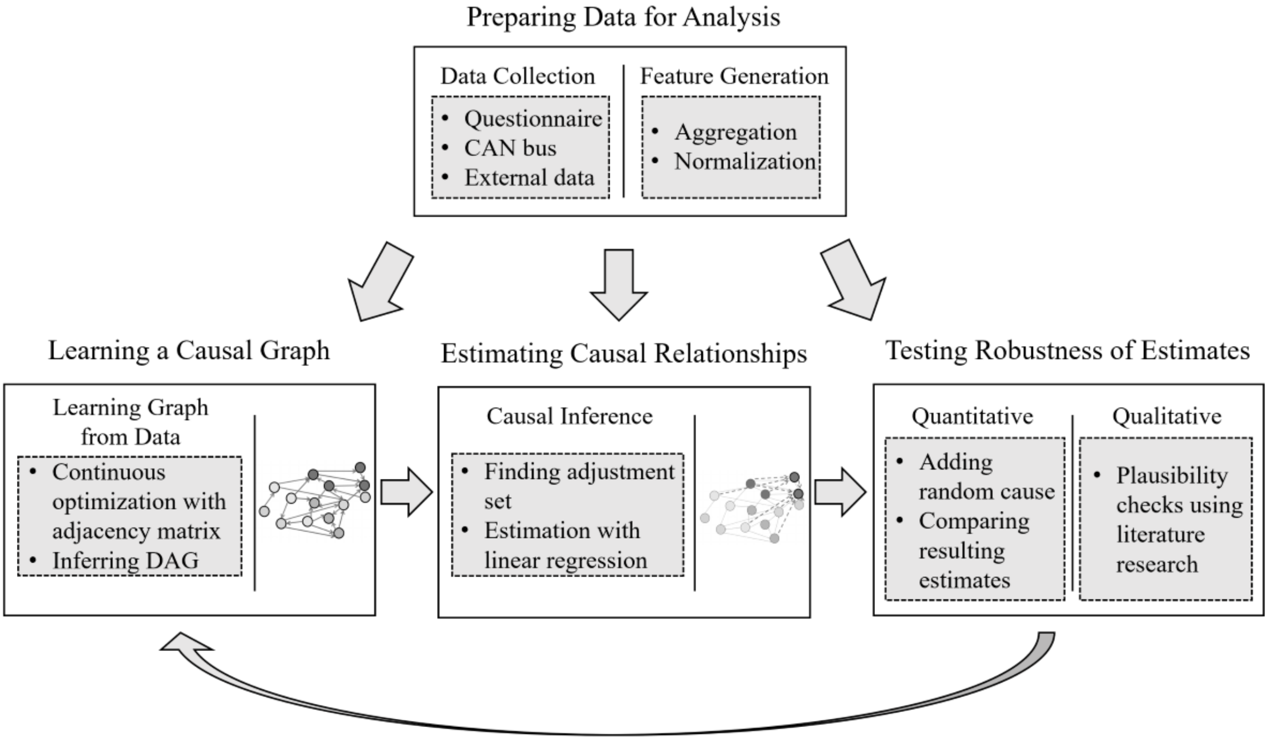
Ethical Considerations

This field study was reviewed by the Institutional Review Board of the University of Bern, Switzerland (approval #2019.04-00003).

Establishing a Causal Relationship

We conducted a field study to examine well-being in real-world driving situations, while maximizing the generalizability of our results. However, this purely observational study design comes at the cost of controllability. Therefore, the interactions between factors of well-being and driving behavior cannot be directly estimated as in a controlled experiment. Instead, we propose a framework for causal inference based on a causal directed acyclic graph (DAG), which visually represents the causal architecture formed by all recorded variables [38-68]. Our workflow for causal inference was designed as a 3-step process, as illustrated in Figure 1. Detailed theoretical information about the workflow and the causal methodology can be found in Multimedia Appendix 4.

Figure 1. Our workflow for causal analysis. CAN: controller area network (car sensor data); DAG: directed acyclic graph.



The causal DAG was constructed using the *DAG with NOTEARS* algorithm [69] on the data of the field study. This algorithm performs continuous optimization on a matrix representation of the graph rather than using constraint-based or local methods for inferring a graphical model. Thereby, a single graph maximizing the score function of the algorithm is found. We used the resulting graph to determine paths, which depict relationships between variables. To isolate the effect of one variable on another, the paths carrying spurious associations must be eliminated, while preserving the paths that transmit the causal effect. We isolated the relevant paths by applying the *backdoor criterion* [47], which identifies the set of variables that need to be controlled. This so-called *adjustment set* was subsequently used in a multiple regression to identify the causal effect between the variables of interest.

For determining the robustness of the resulting estimates, the effect was recalculated in a DAG with an added random confounder [65]. More specifically, a difference between the original and the new estimate close to 0 indicates that an effect is robust to unobserved confounders. Moreover, this test indicates the robustness of the estimate against a potential violation of the linear regression assumptions. Additionally, trivially impossible effects, such as an effect from arousal after to before driving, were a priori excluded from the causal DAG. A full list of excluded effects can be found in Multimedia Appendix 5.

Results

Descriptive Results

The 10 participants completed on average 163.8 trips (SD 89.28) during the 4 months of the study. The mean duration of a trip was 29 minutes (SD 20), and an average participant drove 19.5 km (SD 28.15). Our data set appears to cover typical daily driving, as the drivers followed a large variety of routes both in urban and in rural areas. Of the 1638 trips, 1343 (82%) took place during the week. In addition, 393 (24%) of the trips were labeled as a commute, and 1245 (76%) were drives to frequently visited destinations. On all these trips, the participants completed the affective slider. The affective slider results before driving were on average 73.66 (SD 18.24) for arousal and 69.76 (SD 16.74) for valence and after driving were on average 71.53 (SD 19.58) for arousal and 69.26 (SD 16.91) for valence.

Causal Analysis

To understand which factors impact well-being, we conducted a causal analysis based on the causal DAG learned from data, which can be found in Multimedia Appendix 6. The causal effect sizes, hereinafter abbreviated as *CE*, describe the impact of a 1-SD change in the source variable on the target variable. As all variables were standardized and to facilitate comparisons, the resulting effect size is also given in SDs. The statistically significant (α=.05) causal effects grouped by origin and target nodes are listed in Table 1. The robustness test reports the difference between the causal estimate from the analysis and the causal estimate when adding a random confounder to the model. A value close to 0 indicates robust causal estimates.

Table 1. Results of our causal analysis.

Source	Target	CE[a]	95% CI	*P* value	Robustness test
Emotions on driving behavior					
Before arousal	Steering	0.13	0.09- 0.16	<.001	−0.00003
Before arousal	Sudden events	−0.06	–0.11 to 0.02	.04	0.00031
Before arousal	Speed	−0.11	–0.13 to –0.07	.001	−0.00104
Driving behavior on emotions					
Braking	After arousal	0.10	0.06-0.14	<.001	−0.00089
Speed	After arousal	−0.17	–0.20 to –0.12	<.001	0.00001
Predetermined factors on emotions					
Sun	Before arousal	0.12	0.08-0.18	<.001	−0.00048
Sun	After arousal	0.14	0.11-0.18	<.001	0.00016
Occupants	Before valence	0.38	0.26-0.49	<.001	−0.00008
Occupants	After valence	0.37	0.24-0.51	<.001	0.00021
Trip-dependent factors on emotions					
Length	After arousal	−0.13	–0.45 to –0.06	.001	−0.00073
Emotions on emotions					
Before arousal	Before valence	0.18	0.14-0.22	.002	−0.00084
Before arousal	After arousal	0.74	0.70-0.76	<.001	0.00000
Before arousal	After valence	0.19	0.15-0.24	.01	0.00009
Before valence	After valence	0.77	0.74-0.80	<.001	−0.00161
After valence	After arousal	0.13	0.08-0.18	<.001	0.00013

[a] CE: causal effect size.

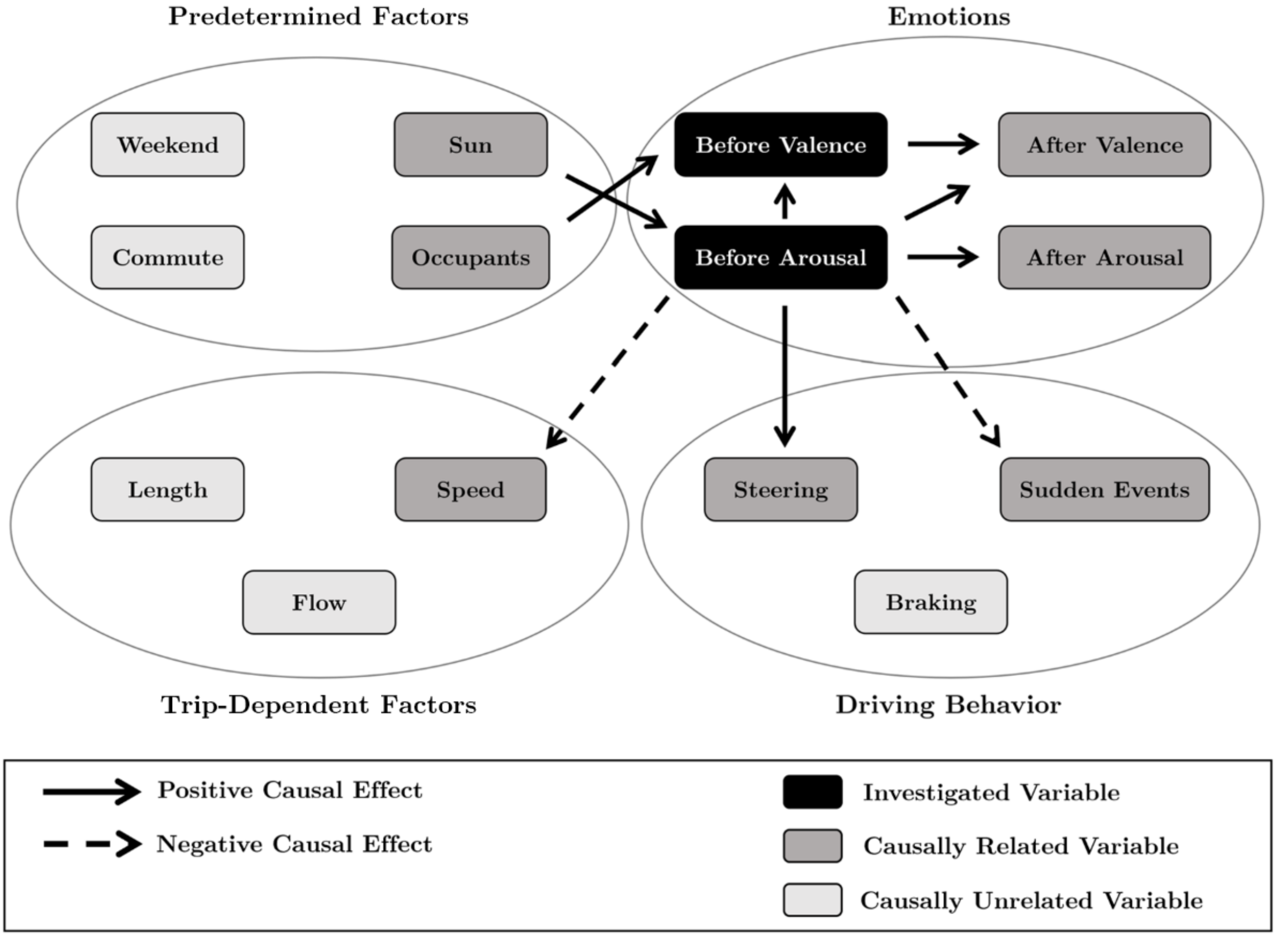
For developing a better understanding of the interaction between driving and well-being, we investigated the effects in both directions (ie, well-being on driving and driving on well-being). In the following paragraphs, we report on the significant results (α=.05). All effects that we discuss are highly robust with respect to omitted variables and to violations of the linear regression assumptions as the change in the causal estimate is smaller than 0.001 after adding a random confounder.

Effects Related to Well-being Before Driving

Figure 2 shows all causal effects related to well-being before driving. The analysis showed that before-driving emotions cause changes in the driving behavior as well as in trip-dependent factors. Regarding behavioral variables, a higher level of *before-driving arousal* significantly increased the frequency of *steering* (CE=0.13, *P*<.001) and decreased the occurrence of *sudden events* (CE=−0.06, *P*=.04). More specifically, these effects mean that an increase of 1 SD of arousal prevented 8 sudden events per hour. Moreover, higher *before-driving arousal* decreased the *speed* of trips (CE=−0.11, *P*=.001), which amounted to 2 km/hour per 1 SD of arousal. Moreover, a significant interaction between emotions existed. *Before-driving arousal* positively influenced the level of *before-driving valence* (CE=0.18, *P*=.002). *Before-driving valence* had no statistically significant effects on driving behavior or on trip-dependent factors.

Before-driving emotions were also influenced by predetermined factors. The presence of *occupants* caused an increase in *before-driving valence* (CE=0.38, *P*<.001), and more *sunlight* caused higher levels of *before-driving arousal* (CE=0.12, *P*<.001). The variable *weekend* had no causal impact on the *before-driving valence* or the *arousal* of the participants.

Figure 2. Causal effects regarding well-being before driving.



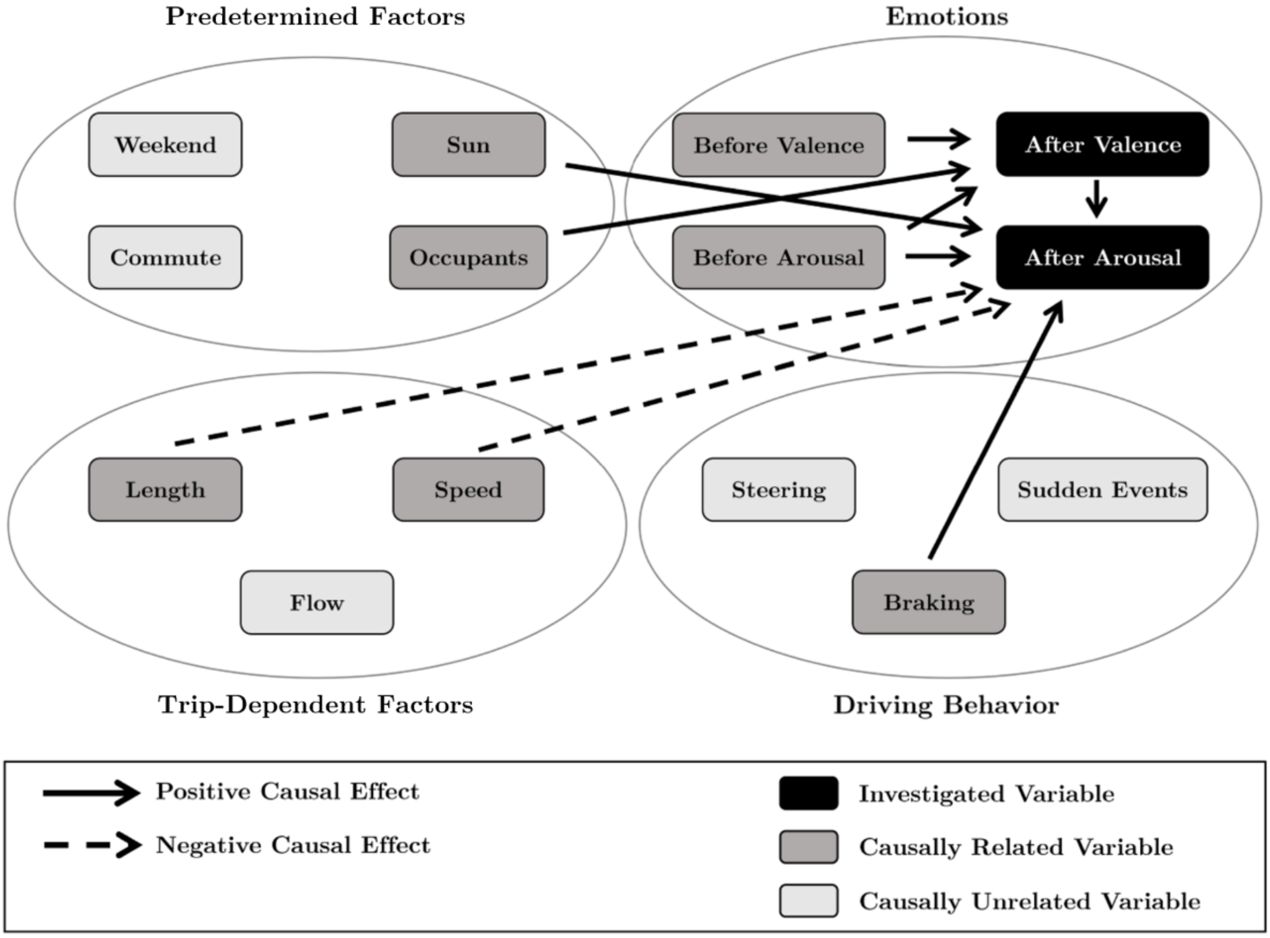
Effects Related to Well-being After Driving

Figure 3 shows the causal effects related to well-being after driving. The emotions after driving a car are influenced by the driving behavior as well as by trip-dependent and predetermined factors. Variables related to actual driving showed that both higher average *speeds* (CE=−0.17, *P*<.001) as well as longer *trips* (CE=−0.13, *P*=.001) caused lower levels of *arousal*. Moreover, driving behavior had an influence, with more frequent *braking* increasing the *after-driving arousal* (CE=0.1, *P*<.001).

Analogously to the effects of predetermined factors before the trip, *sunlight* increased *after-driving arousal* (CE=0.14, *P*<.001) and the presence of *occupants* increased *after-driving valence* (CE=0.37, *P*<.001). Thus, the effect of *sunlight* on *arousal* was stronger after than before driving, whereas the effect from *occupants* on *valence* was smaller after driving.

The emotions before starting the trip strongly influenced the emotions after having completed the trip. This relationship was especially evident when examining the causal effects from *before-driving* to *after-driving arousal* (CE=0.74, *P*<.001) and *valence* (CE=0.77, *P*<.001). Further, a significant interaction existed between *emotions*, with the *before-driving arousal* influencing the level of *after-driving valence* (CE=0.19, *P*=.005). In addition, higher *after-driving arousal* states causally increased *after-driving valence* (CE=0.13, *P*<.001).

Figure 3. Causal effects regarding well-being after driving.



Discussion

Principal Findings

The results of our field study indicate that well-being significantly influences driving behavior and vice versa. Moreover, we found effects from predetermined and trip-dependent factors on valence. In the following paragraphs, we highlight our findings and contextualize them with potential explanations.

We found a significant impact of arousal on several driving behavior variables. With higher levels of arousal, drivers had fewer sudden maneuvers, steered more, and drove at lower speeds. We explain these effects with improved alertness due to high arousal [70]. More alert drivers react faster and in a more controlled manner to unexpected events. Therefore, they can proactively avoid sudden driving maneuvers, which reduces the risk of accidents [24]. Moreover, this anticipatory driving behavior with higher arousal leads to more steering and is potentially a sign of active control of the vehicle. Due to alertness and anticipatory driving, drivers may also proactively adapt the speed of the vehicle earlier to changing driving situations, which results in lower speeds.

For the inverse relationship, we found significant effects showing that driving-related factors impact the arousal of drivers. First, the higher the average speed was, the lower the after-driving arousal state was. Second, we found that the length of the trip negatively influences arousal. Since this deterioration of arousal is counteracted by frequent braking, we assume that monotonous driving situations (ie, long trips at high speeds with no need to brake frequently) cause a decrease in arousal. Cognitive tasks, such as braking, seemed to interrupt the perceived monotony and, thus, reduced the negative effect on arousal throughout the trip.

In contrast, we could not identify any statistically significant effect between valence and driving. The missing impact of low flow or sudden events on valence may be explained by the high driving experience of the participants, who may have grown accustomed to these conditions (eg, daily experience of traffic jams on commutes). However, the lack of effects may also be explained by a possible transient impact of adverse events, such as a traffic jam or consecutive red lights. After having reached the destination, these occurrences may have been forgotten and other thoughts may determine the disclosed end-of-trip valence. Further studies should evaluate the immediate impact of adverse conditions on valence.

Besides the actual driving, we identified predetermined factors that influenced well-being. First, more sunlight (ie, better weather) increased before- and after-driving arousal. Sunlight is known to impact daily mood in general and to reduce tiredness [71]. Second, the presence of occupants increased before- and after-driving valence. The explanation of this effect may be that social interaction is associated with a better sense of well-being [72]. In contrast, occupants had no influence on the arousal of drivers. Although occupants may reduce the monotony of a drive, the social interactions may also lead to social fatigue [73] and thus limit a potential arousal improvement.

Furthermore, we found significant interactions between the dimensions of well-being. The levels of arousal and valence before driving were highly correlated with the respective levels after driving. Most likely, carry-over effects occur, for example, awake drivers are still more awake at the end of the trip than drivers who already started while feeling tired. Moreover, both well-being dimensions are positively associated with each other. Building upon our prior reasoning, we propose 2 potential explanations. First, alert drivers experience fewer adverse events and therefore feel more positive by the end of the trip. Second, higher valence can make drivers more resistant to boredom, which reduces the feeling of monotony.

Comparison With Prior Work

This study aimed at investigating the complex causal architecture of well-being in daily driving using a real-world, uncontrolled field study. In contrast, previous studies have mainly focused on isolating specific effects in controlled experiments (eg, simulator studies). In the following paragraphs, we compare the significant effects between daily driving and well-being of our exploratory study to prior driving studies. These studies serve hereby as a plausibility check of our findings.

Our explanation of the positive impact of increased arousal on driving behavior is in line with the prior literature. Corfitsen [74] found in a survey combined with a reaction time test that low arousal states (ie, fatigue) are a major cause of longer reaction times while driving at night. Moreover, McGehee et al [24] showed in an experimental study on a test track that these longer reaction times are a major risk factor for accidents. However, our findings concerning valence differ from the previous literature. Prior simulator studies have revealed a significant negative effect of extreme valence states (very happy and very unhappy) on driving behavior [25]. The lack of effects of valence in our study could be explained by the setting of the field study. Whereas in the simulator study [25], strong valence-changing stimuli were induced, our study aimed to collect data on everyday driving situations with less strong valence changes.

Furthermore, we find confirmation that monotonous driving reduces the arousal of drivers. Thiffault and Bergeron [26] observed in a simulator study that continuous driving without any external stimulus induces fatigue and tiredness, which increases with time. Moreover, our conclusion that arousal levels are reduced by driving at high speeds due to the monotonous setting is supported by a simulator study by Ting et al [27]. Their study showed that highway driving leads to fatigue, which negatively affects driving performance and increases the risk of accidents, as priorly discussed [24,71]. We can further confirm that cognitive tasks, such as frequent braking, improve after-driving arousal. The results of a simulator experiment by Dunn and Williamson [28] showed that cognitive demand mitigates monotony.

Implications for Intervention Research and Practice

Our findings can be used to allow for more effective JITAIs by providing an estimate for when drivers are likely at risk of feeling tired or unhappy, that is, when they are in a state of vulnerability. By improving the well-being of the driver, such interventions have the potential to increase road safety and reduce the frequency of accidents.

Interventions for increasing well-being while driving can be conceptualized in 2 ways. First, the causes for states of vulnerability can be directly targeted according to our causal architecture. For instance, the findings indicate that a long drive with little braking and steering generates a monotonous driving situation, which sets the driver at risk of a state of low arousal. Second, interventions can react to detected states of vulnerability. For instance, if an increased number of sudden events, less steering, or increased speeds are recognized, it is an indication that the arousal of the driver has decreased. Thus, an intervention could be triggered that acts as a mental stimulus to increase arousal and thereby prevent drowsy driving. Past research developed and evaluated such interventions, for example, using highly personalized music playlists [21] or gamified driving challenges [75]. Our findings could pave the way for the ideation of new interventions. For instance, valence can be raised with an intervention that leads to social interaction, for example, by recommending calling someone during a break. As another example, a driver’s arousal deterioration due to high-speed driving could be addressed by reminding drivers about the speed limit.

Strengths and Limitations

We identified relationships between well-being and driving from a 4-month longitudinal field study on real roads with a sample representative of a wide range of commuters. To derive robust relationships, we applied causal inference methods in our analysis. This overall approach has multiple benefits. First, we observed in our study setup the true emotions participants experienced while they were driving. Contrary to laboratory experiments, which often induce or inspect single isolated effects, our results reflect realistic driving situations and therefore generalize better to the real world. Second, our findings can serve as a basis for delivering interventions to react to well-being changes impacting driving behavior. Finally, all identified effects are explainable by the prior literature and robust to violations of assumptions. Therefore, our study serves as a practical example that inferring causal architectures from observational field studies is feasible and may provide insights that go beyond the capabilities of controlled experiments.

The exploratory design of the study comes with some limitations. The analysis was conducted on the aggregated data set of trips during a longitudinal field study of naturalistic driving on public roads. Hence, it does not regard variation between drivers on a personal level. However, by combining experiences from 10 drivers, we could examine interactions that are present across multiple individuals. Further research could include a psychological analysis on the personal level and could combine valence and arousal to construct more complex emotions. Regarding the causal methodology, the *DAG with NOTEARS* algorithm does not definitely guarantee a precise causal DAG and is especially sensitive with respect to the scale of the variables [63]. We mitigated this issue by standardizing all continuous variables and by introducing a random confounder for testing the robustness of the estimates. Further research should establish a framework for assessing the robustness of the causal DAG itself.

Conclusion

In this paper, we unveiled the complex causal architecture of well-being in daily driving in a real-world field study. Daily driving is a complex setting in which many contextual and personal factors interact. In a real-world field study, this complexity can be replicated more adequately than in a controlled experiment. However, in observational studies, an elaborate causal methodology is necessary for identifying causal effects. Our study identified that arousal is more susceptible to changes while driving than valence. Especially monotonous driving situations, such as long drives on a highway without the need to decelerate or steer frequently, set the driver at risk of becoming more tired. This tiredness impairs driving behavior and can be seen as a state of vulnerability that can be utilized as a trigger for interventions. The knowledge about robust causal effects between well-being and driving behavior can therefore be applied as a basis for deciding when to initiate an intervention to improve the well-being of the driver.

Abstract

Background: Patients use social media as an alternative information source, where they share information and provide social support. Although large amounts of health-related data are posted on Twitter and other social networking platforms each day, research using social media data to understand chronic conditions and patients' lifestyles is limited.

Objective: In this study, we contributed to closing this gap by providing a framework for identifying patients with inflammatory bowel disease (IBD) on Twitter and learning from their personal experiences. We enabled the analysis of patients' tweets by building a classifier of Twitter users that distinguishes patients from other entities. This study aimed to uncover the potential of using Twitter data to promote the well-being of patients with IBD by relying on the wisdom of the crowd to identify healthy lifestyles. We sought to leverage posts describing patients' daily activities and their influence on their well-being to characterize lifestyle-related treatments.

Methods: In the first stage of the study, a machine learning method combining social network analysis and natural language processing was used to automatically classify users as patients or not. We considered 3 types of features: the user's behavior on Twitter, the content of the user's tweets, and the social structure of the user's network. We compared the performances of several classification algorithms within 2 classification approaches. One classified each tweet and deduced the user's class from their tweet-level classification. The other aggregated tweet-level features to user-level features and classified the users themselves. Different classification algorithms were examined and compared using 4 measures: precision, recall, F1 score, and the area under the receiver operating characteristic curve. In the second stage, a classifier from the first stage was used to collect patients' tweets describing the different lifestyles patients adopt to deal with their disease. Using IBM Watson Service for entity sentiment analysis, we calculated the average sentiment of 420 lifestyle-related words that patients with IBD use when describing their daily routine.

Results: Both classification approaches showed promising results. Although the precision rates were slightly higher for the tweet-level approach, the recall and area under the receiver operating characteristic curve of the user-level approach were significantly better. Sentiment analysis of tweets written by patients with IBD identified frequently mentioned lifestyles and their influence on patients' well-being. The findings reinforced what is known about suitable nutrition for IBD as several foods known to cause inflammation were pointed out in negative sentiment, whereas relaxing activities and anti-inflammatory foods surfaced in a positive context.

Conclusions: This study suggests a pipeline for identifying patients with IBD on Twitter and collecting their tweets to analyze the experimental knowledge they share. These methods can be adapted to other diseases and enhance medical research on chronic conditions.

Introduction

Background

Social networking sites and web-based communities have served as alternative information sources for patients in recent years. Patients everywhere use social media to share health and treatment information, learn from each other's experiences, and provide social support. Mining these informative conversations may shed some light on patients' ways of life and support research on chronic conditions.

In recent years, text mining and social network analysis have been used to detect mentions of health on Twitter [1,2] or to track the spread of the COVID-19 pandemic and symptoms [3-5]. Regarding chronic conditions, previous research has focused on analyzing patients' tweets and uncovering their Twitter community [6-10]. Although a relatively large amount of research has been dedicated to diabetes or cancer, research on inflammatory bowel disease (IBD) is only just starting to consolidate.

IBD is a chronic inflammatory condition of the digestive system characterized by flares and remission states. The 2 primary diseases identified with IBD, Crohn disease and ulcerative colitis, are usually diagnosed in young patients (in the age range of 15-30 years). The incidence of IBD is rapidly increasing, and it has evolved into a global disease [11-14].

There are no medications or surgical procedures that can cure IBD. Treatment options can only help with symptoms, and they affect each patient differently. They involve prescription drugs and lifestyle-related solutions such as diets and therapies. Symptoms include abdominal pain, diarrhea, and fatigue, and severe cases may result in hospitalization or surgical interventions [15,16]. As chronic bowel diseases, both Crohn disease and ulcerative colitis require day-to-day care for drug consumption and special nutrition.

Patients describe IBD as an embarrassing disease that causes the immediate disruption of daily activities. They experience difficulties in adjusting to the changes it entails and consider themselves different from their peers. As IBD is characterized by frequent bowel movements, people do not hasten to share their disease with others [15,17-19]. According to patients with IBD, part of the embarrassment can be attributed to a lack of public awareness. Outsiders cannot see that a person's stomach hurts or that their bowels are scarred. The disease is invisible, and others might doubt that it exists [20,21].

The embarrassment caused by IBD and the need to confide in people with similar experiences help explain the creation of IBD-related communities on Twitter. By overcoming space and distance, Twitter users form a community that disregards physical boundaries or immobility. A sense of common ground can help break down barriers and enable conversation, increasing a person's willingness to share [22,23]. It may be easier to consult with other patients who can relate and better understand the situation based on personal experience. One can identify more closely with user stories similar to one's own and embrace their advice more easily [24]. When people disclose health information on Twitter, they expose themselves to a large variety of opinions and reduce the uncertainty about their disease [25].

Owing to the nature of IBD and its influence on the digestive system, patients with IBD are forced to deal with their disease daily, adhere to strict dietary regimens, and maintain a calm routine. Changes in nutrition or physical activity, which are currently tested by trial and error, result in a long and excruciating process for the patients. We can learn from their personal experiences and provide an additional foundation for existing medical knowledge of the disease by collecting and analyzing patients' social media data. Complementary recommendations based on the wisdom of the crowd can ease patients' lives and shorten the process of finding the right lifestyle for them.

Objective and Contribution

This study aimed to uncover the potential of using Twitter data to promote the well-being of patients with IBD by collecting and analyzing the personal experiences they share about their disease. We suggested a framework for identifying patients with IBD on Twitter and examining the content they share regarding their disease. We started by building a user classifier that distinguishes patients from other entities who talk about IBD on Twitter and then used the classifier to collect patients' tweets and explore the lifestyle-related treatments they undergo to cope with their disease.

This study focused on creating a pipeline for using Twitter data for identifying patients with IBD and exploring the information they share. Although each part of this study can be extended by trying other classification methods or enriching the analysis of the patients' tweets, this study shows the potential of using Twitter data to enhance medical knowledge of IBD. We showed that patients can be identified on Twitter based on their communication even using classic, simple classification algorithms. We compared the performances of 2 different approaches for user classification—a single instance (SI) learning approach and a multiple instance (MI) learning approach—and showed the benefits of using the latter. The preliminary analysis in the second part of this study showed that it is possible to derive health-related insights from self-reported tweets by patients.

Using the suggested framework to identify more patients and collect more of their data could uncover their sentiments toward the treatments they try or explore other aspects of the disease, such as its influence on patients' quality of life. The framework is also feasibly extended to other chronic conditions. It can be used to compare discussion patterns of patients with IBD with those of the general population or of patients with other chronic conditions.

Related Work

Twitter and Health

The study of social media in the context of health and well-being continues to position Twitter as a new medium for disseminating health-related information. Health-related tweets range from a simple toothache to more severe and chronic diseases such as diabetes, asthma, or cancer [9,10,26,27]. Patients with amyotrophic lateral sclerosis use Twitter as a means of communication, and local health departments in the United States use Twitter to educate and disseminate information related to diabetes [28,29]. Even a sensitive disease such as HIV is discussed on Twitter [30-32]. Communication patterns regarding who tweets about what and why vary by disease [26].

Twitter is a powerful tool for disseminating health information and an accessible platform for patients needing immediate social support or relief. It provides a collaborative environment for health-related conversations where patients with chronic illnesses share their health status daily. They use Twitter to exchange knowledge about lifestyle implications or better understand a medical procedure. Through Twitter, they can easily and conveniently reach a large audience and various opinions [33].

In total, 2 previous studies have presented models for detecting personal health mentions on Twitter and shown promising, scalable results [1,2]. However, their goal differs from ours as they considered all tweets that discussed a specific person's health condition as positive. In our study, we sought to identify patients with a specific disease. We not only classified tweets written by patients but also classified the users themselves.

Communication Patterns on Twitter

Different types of users communicate differently on Twitter. They connect differently with others, have different tweeting habits, and differ in style and linguistic content. Studying the conversational connections between Twitter users and text mining their tweets can help classify users based on their characteristics and identify different types of users [34-38].

Private individuals reflect mainly on their personal experiences or sentiments and tend to engage with others. They are both frequently mentioned and frequently mentioning other users. By contrast, organizations often point to external information sources via URLs and are not that active at connecting with others. They are frequently mentioned in tweets, perhaps as sources of information, but are much less inclined to mention other users [39,40].

By analyzing a user's screen name (ie, the username of their Twitter account) or their biography (ie, their Twitter user description), one can determine whether the user is an ordinary individual or an organization and reveal latent user properties [41,42].

Our study relies on those previous findings and constructs classification features that help differentiate patients with IBD from other users who tweet about the disease. We adapted and extended previous methods to cope with the different task of identifying patients with IBD on Twitter.

Twitter and IBD

Exploring the entities that engage in IBD-related discussions on Twitter reveals that patients with IBD are the most common type of users who talk about IBD on Twitter [43,44]. Patients with IBD use Twitter for sharing personal experiences and seeking social support. They exchange thoughts about symptoms and medications and recommend treatments to one another [45,46]. By sharing their life experiences with the disease on Twitter, patients fight disease invisibility and raise public awareness of IBD [47].

Perez et al [48] explored the IBD community on Twitter and identified the types of users who talk about the disease and the key topics they discuss. They categorized users based on their Twitter profiles by analyzing their screen names and biographies. In our study, we investigated a large set of classification features and suggested a model to detect patients with IBD on Twitter based on the way they communicate and the content they share.

Patients with IBD tend to be more emotional and negative than patients with other chronic conditions [49]. They usually express a negative sentiment when they talk about the disease and its symptoms but positively address the diets and drugs that help manage them [48]. Patients who engage in tweets offering social support are more likely to post positive tweets [50].

Unlike previous research related to patients' sentiments on Twitter [48-50], we focused our research on entity sentiment rather than the sentiment of the entire tweet. By analyzing patients' sentiments toward specific keywords related to nutrition and fitness, we uncovered the sentiments of certain lifestyles that influence the disease.

Methods

Overview

This study was conducted in 2 main stages. In the Patient Identification section, we built a user classifier that distinguishes patients from other entities who talk about IBD on Twitter. We considered three types of classification features: (1) features extracted from the user's activity on Twitter, (2) the content of the user's tweets, and (3) the social structure of the user's network. We compared the performances of several classification algorithms within 2 classification approaches: one that starts by classifying tweets separately and then deduces the user's class from their tweet-level classification and one that starts by aggregating tweet-level features to user-level features and then classifies the users themselves.

In the Analyzing Patients' Tweets section covering the second stage of the study, we derived insights regarding IBD from the personal experiences that patients share on Twitter. We collected lifestyle-related tweets by querying the Twitter application programming interface (API) for special keywords related to nutrition or fitness. We then filtered their authors using a classifier from the first stage of the study to obtain a collection of tweets where patients with IBD describe the different diets and physical activities they adopt to deal with their disease. We identified frequently mentioned lifestyles and used IBM Watson Service for entity sentiment analysis to assess their effectiveness.

Figures 1 and 2 describe the general flow of the 2 main stages of the study. Figure 1 describes how we used Twitter data to classify users and identify patients with IBD. Figure 2 demonstrates how we used the classification to analyze patients' tweets.

Figure 1. The general workflow of the first stage of the study: building a classifier of Twitter users for identifying patients with inflammatory bowel disease (IBD).

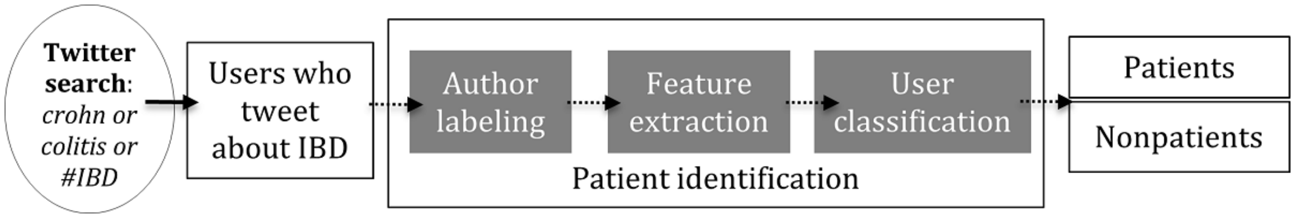

Figure 2. The general workflow of the second stage of the study: using the classification from the first stage for analyzing patients' tweets. IBD: inflammatory bowel disease.

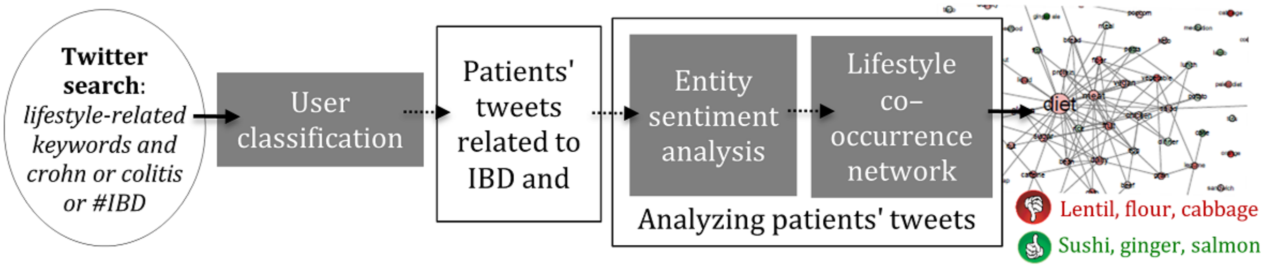

Patient Identification

Data Collection and Preparation

We used the Twitter Search API to collect 10 days of IBD-related tweets (from February 11, 2018, at noon to February 21, 2018, at noon). We used the OR operator to search for at least one of 3 keywords: *crohn*, *colitis*, and *#IBD*. The abbreviation IBD was searched as a hashtag to avoid news-related tweets by the Investor's Business Daily Editorials account, which is usually marked with *IBD*. We limited the search to tweets written in English and collected 2045 tweets.

The 722 authors of the collected tweets were then manually classified as patients (1) or not (0). In total, 3 different annotators, the authors of this paper (MS, YP, and GR), did the labeling process and labeled the users based on their tweets. Each user received a tag of 1 if they had at least one tweet revealing their illness and a tag of 0 otherwise (ie, if none of their tweets suggested that they were patients with IBD).

Regarding 655 users (n=181, 27.6% patients and n=474, 72.4% other users), the annotators were in complete agreement, and their labels were set. To settle the dispute regarding the other 9.3% (67/722) of the users, the annotators challenged their tweet-based decisions by considering the users' screen names and biographies and reviewing their timelines if necessary. Considering the new data, of the 67 remaining users, 45 (67%) were classified as patients after explicitly mentioning their illness in their biographies or timelines. A total of 12% (8/67) talked about others who were sick, and the annotators unanimously agreed that they were not patients with IBD themselves. Regarding the remaining 21% (14/67) users, the annotators did not reach a consensus and, therefore, the users were omitted from the data set. The labeling process ended with a collection of 708 tagged users: 226 (31.9%) patients and 482 (68.1%) nonpatients.

To train the tweet-level classifiers, we had to annotate the tweets manually as well. We addressed the tweets collected in the original search query (in February 2018) and excluded retweets (RTs) from the collection. As the purpose was to identify patients, we were not interested in reshared content and only considered the user's tendency to RT as a behavioral classification feature. After excluding RTs and the 14 users for whom we did not reach an annotation consensus, we were left with 1687 tweets. To consider the users' biographies as we did when annotating users, we added each biography as another *tweet* by its author. A total of 83.5% (591/708) of the users had nonempty biographies, and the process resulted in a collection of 2278 *tweets*.

During the annotation process, we wanted to determine whether a certain tweet revealed that the user was a patient with IBD. Tweets that unambiguously implied that their authors were patients with IBD received a tag of 1, and all others received a tag of 0. As we had already annotated the users, all 1638 tweets written by nonpatient users automatically received a tag of 0. The 3 annotators (MS, YP, and GR) then manually classified all the tweets written by patients. A total of 346 tweets were unanimously classified as 1, and 288 tweets were unanimously classified as 0. The annotators did not reach a consensus on 6 tweets (written by 6 different users), and they were excluded from the collection. All 6 users had at least one more tweet and, therefore, none of them were excluded entirely from our data set. Finally, we reached a collection of 2272 tweets, of which 346 (15.23%) explicitly revealed their authors' illness.

To enrich our data, we collected another week of tweets (from June 10, 2018, at noon to June 17, 2018, at noon) for each tagged user, this time without additional filtering. In the months that had passed, 6.6% (47/708) of the users had been either suspended by Twitter or changed their accounts to private, and their data were no longer available for collection. The additional week was collected for the other 93.4% (661/708) of the users, and the process resulted in a data set of 82,884 tweets overall written by 194 patients and 467 nonpatients. We excluded the same 47 users from the tweet data set as well, and the final data set contained 2204 tweets, with 325 (14.75%) positive tweets.

MI Learning Approach

Traditional classification problems are supervised learning problems in which one receives a collection of individually labeled instances and tries to predict the class label for new instances. MI learning, by contrast, is a supervised learning approach in which each learning example is a *bag of instances* associated with 1 label, and the task is to predict the labels for unseen bags [51].

Previous research related to identifying health mentions on Twitter has relied on traditional supervised learning to determine whether a *tweet* discusses a health condition [1,2]. However, we wished to determine whether *patients* can be identified on Twitter and not examine the tweets separately. Our unique task and the unbalanced structure of our data were compatible with an MI learning approach—we had 661 users and a different number of tweets posted by each of them. Positive tags (patients) were determined collectively by finding at least one piece of evidence that the user had IBD; negative tags (nonpatients) meant that all the user's evidence suggested otherwise or, rather, was not sufficient for a positive tag.

We used the metadata-based MI approach and extracted a vector of metadata for each bag (user) that was not related to any specific instance (tweet) [52]. The Classification Features section explains how we applied feature engineering techniques to generate features that characterize the users themselves and not just their tweets.

To assess the effectiveness of using this collective approach, we compared the results of 5 standard classification algorithms in both user- and tweet-level classification, as explained in detail in the Classification Models section.

Classification Features

Overview

Rao et al [38] and Pennacchiotti and Popescu [36,37] showed that Twitter users' demographics and political views could be distinguished by considering 3 types of user classification features: behavioral features (features extracted from the user's activity on Twitter), linguistic features (features extracted from the content of the user's tweets), and social structure features (features describing the user's social network). We followed their work and adapted these types to our different domains of distinguishing patients with IBD from others who talk about the disease. We also integrated MI learning into our classification setting, which was not part of their research. We constructed a set of classification features for each feature type, as explained in detail in the following sections and summarized in Table 1.

Table 1. Summary of classification features and their types.

User classification feature, feature level, and features	Type
Behavioral features	
Tweet-level features	
Tweet counter	Integer
Retweet counter	Integer
Retweet to tweet ratio	Float (0 to 1)
IBD[a] flag	Binary
User-level IBD ratio	Float (0 to 1)
Crohn flag	Binary
User-level Crohn ratio	Float (0 to 1)

Log in-degree	Float
Log out-degree	Float

User classification feature, feature level, and features	Type
Closeness	Float (0 to 1)

[a] IBD: inflammatory bowel disease.

[b] LDA: latent Dirichlet allocation.

Behavioral Features

Features of this type were designed to capture users' activity on Twitter: How often do they tweet? Do they write new content or mainly RT others? Furthermore, how often do they refer to IBD? We counted the number of tweets and RTs in our data set and calculated the RT ratio for each user. We counted the number of times they used one of our keywords in their tweets to account for the frequency with which they addressed IBD. Aggregated features for user-level classification were also copied to all the users' tweets to enrich the tweet-level classification.

Linguistic Features

The second class of features is derived from the users' linguistic style on Twitter: Do they write in first-person voice? Do they tend to use emoticons or add a reference to an external source via URL? We used 2 types of linguistic features. On the basis of previous research [36-38] and our data's nature, we extracted several features from the text that we believed would help the classification.

Acknowledging that individuals and organizations communicate differently on Twitter [35,39], we searched for specific characteristics that could distinguish private persons from businesses and help identify patients. We checked specific characteristics for each tweet in our data: Was there use of emojis, interjections, or profanities? Was it written in the first person? Did it point to an external source via URL? Did it contain Twitter special characters indicating mentions (@) or hashtags (#)? We used a Python (Python Software Foundation) library called *TextBlob* to add sentiment-related features such as the text's polarity and subjectivity. The length of the tweets and the number of words they contained were also considered. The Python library *emoji* was used to detect emojis within the text. A part-of-speech identifier from the library *nltk* was used to indicate the use of first person and identify interjections. On the basis of the Python library *profanity*, we established a list of swear words that we searched for in the text. We had to adjust the list to the special domain of IBD as words related to metabolism were not necessarily swear words.

We started with tweet-level features, which were later grouped by user to represent personal writing style. To reflect the way a user expresses themselves on Twitter, we excluded RTs from the aggregation. The number of tweets in which the URL was used, for example, was counted on the original tweets only. As the users' biographies were considered as tweets in the tweet-level classifiers, we added the linguistic features that were extracted from the biographies as bio-features in the user-level classifiers.

In natural language processing, there are several methods to obtain a vector representation of text. One of the more well-known and well-researched techniques is the Bayesian probabilistic model of text documents called latent Dirichlet allocation (LDA). LDA is a topic modeling technique used for discovering the abstract *topics* that occur in a collection of documents [53].

We used LDA to represent text in both tweet- and user-level classification features. In tweet-level features, each tweet was considered a document, and the representations were obtained per tweet. For user-level features, all tweets by the same author were consolidated into 1 document to obtain representations per user. All the features used unigram and bigram representations of the text after data cleaning. The text cleaning process included converting to lower case, removing punctuation and stop words, and normalizing links and other special signs to standard representations.

Social Structure Features

The last type of feature we addressed represented the users' social connections on Twitter. We used the Twitter API to collect each user's followers and followees. For each user, we kept the number of followers they had (out-degree in the sense of influence) and the number of followees they had (in-degree) and scaled the results using a logarithmic scale. We also computed the closeness centrality measure for each user. Aggregated features for user-level classification were also copied to all the users' tweets to enrich the tweet-level classification.

Classification Models

Aiming to distinguish between patients with IBD and other users who tweet about IBD, we compared the performances of several classification algorithms within 2 classification approaches: the SI learning approach, which starts by classifying tweets separately and then deduces the user's class from their tweet-level classification, and the metadata-based MI learning approach, which starts by aggregating tweet-level features to user-level features and then classifies the users themselves.

The metadata-based MI approach starts by transforming the data from MI to SI, and then a standard SI algorithm can be applied to the transformed problem [54,55]. To achieve the users' characterization for the MI approach, we applied arithmetic sum and average to the tweet-level features and obtained aggregated features per user (refer to the Classification Features section for more details). Note that this process may cause some information loss [56].

For both approaches, we tested 5 standard and well-known algorithms for binary classification tasks such as ours: AdaBoost, gradient boosting classifier, linear support vector machine, logistic regression, and random forest. All the algorithms were applied from the scikit-learn (sklearn) package in Python [57].

Experiment

We split our data set by users into training and test sets (approximately 80%-20%). The training set had 155 patients and 377 nonpatients, and the test set had 39 patients and 90 nonpatients; thus, the sets maintained the ratio between the groups.

In the tweet-level classification, the split into training and test sets was performed based on the split of the users—tweets by users belonging to the training set were ascribed to the tweet training set, whereas tweets by users belonging to the test set were ascribed to the tweet test set. As a result, the tweet training set contained 263 positive tweets and 1586 negative tweets, whereas the test set contained 62 positive tweets and 293 negative tweets.

We started with a hyperparameter optimization for all algorithms using a 5-fold cross-validation over the training data in both approaches. The values tested for each algorithm and parameter can be found in Multimedia Appendix 1.

In total, 4 common metrics were used to evaluate the models: precision, recall, F_1 score, and the area under the receiver operating characteristic curve (ROC AUC). All 4 metrics were calculated over the positive class that was of interest to us. In our setting, precision depicts the probability that a positive prediction is indeed a patient, recall depicts the classifier's ability to retrieve patients, and the F_1 score combines the 2. ROC AUC considers the recall of both classes and measures the ability of the model to retrieve patients without collecting a lot of unwanted other users.

To select the best algorithm variant, we used a 10-fold cross-validation technique for a reliable evaluation of the prediction power. In this process, we randomly divided the training set into 10 equal-sized parts; then, we iteratively performed the training on 9 parts and evaluated the model on the part that was left out. We repeated this iteration 10 times, leaving out a different part each time. In addition, we repeated the 10-fold cross-validation process 10 times with different seed initializations to vary the random split. The performance metrics were computed each time, and the results presented in the Results section show the average across these 100 iterations.

In the user-level classification, we obtained all 4 metrics during the classification process using the sklearn package in Python. However, in the tweet-level classification, another aggregation stage was needed before obtaining the metrics directly from the sklearn package—the process returned the predictions for each tweet (whether it was written by a patient), and we had to infer the users' predictions by aggregating the predictions given to their tweets. As in the manual annotation process, if all the user's tweets received a prediction of 0, the user was considered a nonpatient and received a negative prediction. Alternatively, if the user had at least one positive prediction, they were considered a patient and received a positive prediction. We then used the sklearn package to compute the user-level metrics based on the users' predictions that we obtained and their true labels.

Finally, we trained the models from each approach (MI and SI) on the entire training set and evaluated their predictions on the test set. We used built-in sklearn methods for feature importance to investigate the contribution of each feature to both logistic regression and random forest algorithms. The absolute value of the coefficient represents the feature importance for logistic regression.

Analyzing Patients' Tweets

A Corpus of Lifestyle-Related Tweets

The next aim of this study was to obtain a collection of tweets in which patients describe the lifestyle-related treatments they have tried and their symptoms. By filtering and merging different web-based databases [58,59], we established a list of 420 words that are types of food or physical activities (ie, lifestyle-related words; the full list can be found in Multimedia Appendix 2). The Twitter Premium API was used to search for all tweets that mentioned IBD (containing at least one of the 3 keywords described in the Data Collection and Preparation section: *crohn*, *colitis*, and *#IBD*) and at least one of the 420 lifestyle-related words. To build the search query, we used the OR operator within the IBD keywords and the lifestyle-related words and then connected the 2 groups using the AND operator.

We searched for relevant tweets from January 1, 2019, to September 30, 2019. We excluded RTs and duplicated tweets from the search and limited the search to tweets written in English. The search resulted in 20,136 unique tweets containing new content written by 8519 different users.

We used the classifier from the first part of the study on the new data we gathered to classify the tweets as patients' tweets and user tweets. We needed to recreate the classification features for the new set of 8519 users. As we did in the first stage, we collected another week of tweets for all the users from October 1, 2019, to October 7, 2019, without keyword filtering and including RTs. A total of 39.52% (3367/8519) of the users were private, suspended, or otherwise unavailable. The process resulted in a data set of 5152 users who authored 402,843 tweets overall.

We constructed all the classification features described in the Classification Features section on the new data except for the closeness centrality. Obtaining this feature was costly and time-consuming as it was the only feature that required collecting all followers and followees for each user and building their Twitter network. As it was not one of the 10 most helpful classification features, we decided to omit it.

We then used the MI random forest model we trained in the first stage (refer to the Classification Models section for more details) to classify the users and identify patients. A total of 45.79% (2359/5152) of the users were classified as patients, and they authored 4160 of the original tweets containing our keywords. We performed a simple text cleaning of those tweets by removing all screen names (identified by the @ character) and URLs and continued our analysis with the 4160 clean tweets.

Sentiment Analysis of Lifestyle-Related Words

The Natural Language Understanding (NLU) module by IBM Cloud [60] was used to apply category classification and keyword extraction to each of our tweets. The category classification feature aims to identify the theme of the text. Given a text, the NLU module provides a list of possible categories and subcategories and their corresponding likelihoods. The keyword extraction feature recognizes words and phrases of high importance within the text and calculates their sentiments. Given a text, the NLU module returns a list of keywords and their corresponding sentiments represented as scores on the closed interval of −1 to 1: −1 for extremely negative sentiment and 1 for extremely positive sentiment. A score of 0 means that the keyword was mentioned in a neutral context. The *TextBlob* library used for sentiment analysis in the Linguistic Features section only enables full-text sentiment analysis and does not support entity-level sentiment analysis. Although it was free and easy to use, it did not suit our new task and, therefore, we chose to replace it with the NLU module.

The goal was to identify the lifestyle-related treatments that patients undergo to manage their disease and determine their sentiments toward them. Hence, we focused our analysis on keywords related to health and nutrition. We grouped all tweets that were categorized by the NLU module as related to *health and fitness* (2080 tweets), *food and drink* (1568 tweets), or *religion and spirituality* (15 tweets). Overall, 3663 tweets were selected for keyword sentiment analysis. We gathered all the keywords that appeared in our predefined list of lifestyle-related words and their corresponding sentiments within each tweet. In total, 3 examples of this process are presented in Table 2. Notice how, in the second example, the first word of the original tweet (marked with the @ symbol) is a screen name and was therefore removed in the cleaning process.

Table 2. Three examples of category classification and keyword sentiment extraction after text cleaning.

Number	Original text	Text after cleaning	Category classification	Keyword sentiment
1	Spinach is an inflammatory food with a lot of sulfur. Ban that too. (I noticed my Crohn's tended to flare around spinach season.)	Spinach is an inflammatory food with a lot of sulfur. Ban that too. (I noticed my Crohn's tended to flare around spinach season.)	Food and drink	Spinach: −0.63
2	@bottomline_ibd great poll. I do have the odd binge, but IBD has changed what I can drink. No more red wine or ale	great poll. I do have the odd binge, but IBD has changed what I can drink. No more red wine or ale	Food and drink	Red wine: −0.83; ale: −0.83
3	I am living proof that yoga can help #uchicagoibd #studiothree #yoga #ibd	I am living proof that yoga can help #uchicagoibd #studiothree #yoga #ibd	Religion and spirituality	Yoga: 0.69

To examine the effectiveness of each lifestyle-related phrase (lifestyle, in short) and to assess its overall sentiment, we aggregated the results by lifestyle and calculated the following statistics: the total number of times the lifestyle appeared in all tweets, the number of times it appeared in a positive (or negative) context, the positive to negative ratio of the number of appearances (odds), and the mean sentiment of the lifestyle.

We used the statistics to build a co-occurrence network that visualized the connections between lifestyles and their mean sentiments. The different lifestyles were the nodes, and an arc connected 2 lifestyles if they appeared in the same tweet. The more times they appeared together, the stronger the connection between the lifestyles was. Therefore, the resulting network was undirected and weighted by the number of times the lifestyles co-occurred. The purpose was to identify helpful lifestyles (frequently mentioned in a positive context) and lifestyles that it is better to avoid (frequently mentioned in a negative context) and examine whether certain lifestyles tend to be implemented together.

The network was obtained using *Gephi* software (GNU General Public License) for network analysis and visualization. Each node was colored on a scale from green to red based on the mean sentiment of the lifestyle it represented, with green being very positive and red being very negative. The sizing of the nodes reflected the number of times the lifestyles were mentioned in the tweet database: the more times they appeared, the larger their nodes were. The thickness of each arc represented the number of times the 2 lifestyles it connected co-occurred: the thicker the arc, the more times the 2 lifestyles appeared together. To avoid obtaining an overdense network, we only considered the nodes of lifestyles mentioned at least five times in our database. We included arcs between lifestyles that co-occurred at least four times. The process resulted in 144 lifestyles presented in the network and sorted in a table by mean sentiment.

Ethical Note

The collection and analysis of Twitter data may entail ethical challenges that should be addressed and handled properly. Twitter data are public and available for research via Twitter APIs. By accepting Twitter's Terms of Service and Privacy Policy, Twitter users acknowledge that their tweets can be viewed instantly worldwide and that their information may be collected by third parties [61]. Nonetheless, social media studies have revealed that users on Twitter feel as if they are engaged in a private conversation with their followees and followers [62,63]. Although they are generally not concerned with their posts being used for research purposes, they expect anonymity in publication and to be asked for their consent before publication.

Obtaining informed consent from all the users who *participate* in research on Twitter data may be unfeasible. Data sets are likely to be large and involve many authors [61-63]. Individually seeking consent from all 722 users in our study would be labor-intensive or impossible as some might be unreachable.

Moreover, providing total anonymity to users while directly quoting their content is not practical; tweets are easily searchable, leaving their authors vulnerable to identification.

To adhere to ethical norms and maintain user privacy, we only published aggregated results that do not reveal the specific users. The 3 examples containing direct quotes from tweets (in Table 2) are presented in this study after obtaining informed consent from their authors.

Results

Patient Identification

Table 3 shows the 10-fold cross-validation and test results for the 2 classification approaches: SI classifying tweets and MI classifying users. The table shows the results of the 4 metrics for all 5 classification algorithms.

Table 3. The 10-fold cross-validation and test results for the single instance (SI) and multiple instance (MI) classifications.

Algorithm and metric	SI tweet-level classification		MI user-level classification

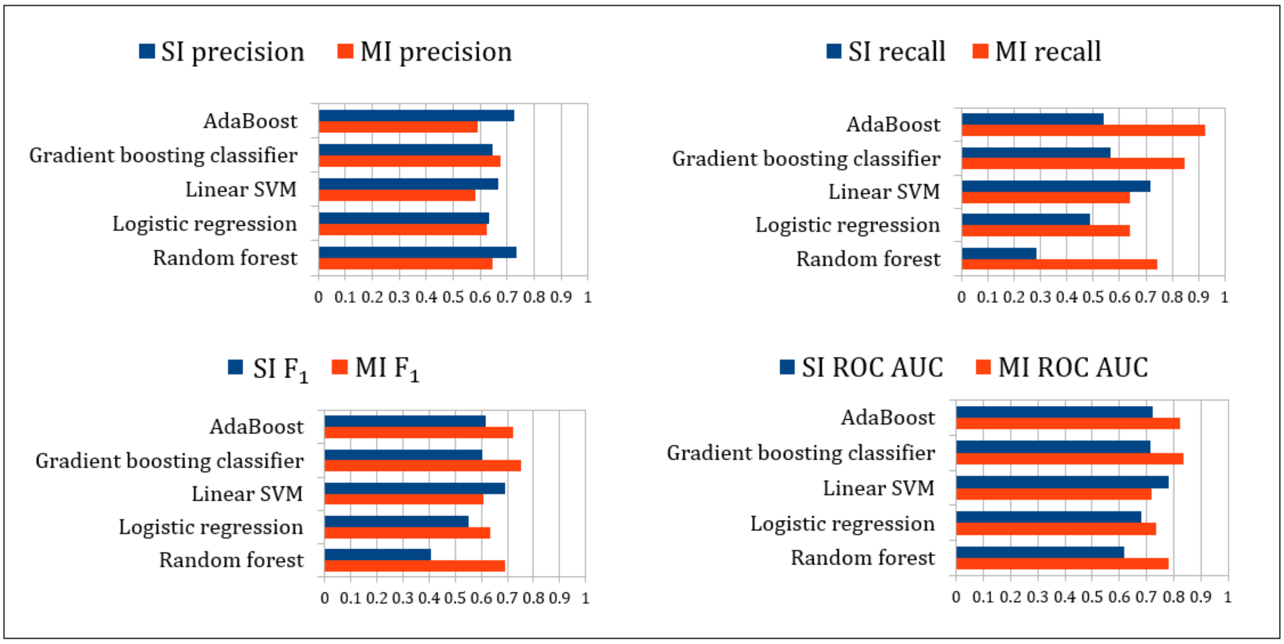
[a] ROC AUC: area under the receiver operating characteristic curve.

[b] SVM: support vector machine.

Both approaches showed satisfactory classification results for the patient classes. Although the precision rates were slightly higher for the SI approach, the recall index of the MI approach was better, and the results for the ROC AUC measure were consistently higher in the MI approach. Figure 3 shows the differences among the 4 measures within the test set results.

Figure 3. Test result comparison between the 2 classification approaches. MI: multiple instance; ROC AUC: area under the receiver operating characteristic curve; SI: single instance; SVM: support vector machine.



Investigating the contribution of each feature to both the logistic regression and random forest algorithms showed the importance of the use of first-person voice. In both classification approaches and algorithms, the most important feature was the use of the first person, which had a significant advantage over the other features. The first-person flag was the best feature of the SI approach, and its average was the best feature of the MI approach. Another dominant feature was the use of profanities as it was one of the most significant features in both approaches and algorithms.

The analysis also highlighted the importance of the LDA features derived from the text. The second-best feature of the SI approach was LDA topic 11 for both the logistic regression and random forest algorithms. This was the only topic that did not contain IBD-related words. The fourth and fifth most important topics of the MI approach were identical for both algorithms—LDA topics 17 and 9, respectively. The LDA topics that were created over the training data for each approach can be found in Multimedia Appendix 3.

Analyzing Patients' Tweets

In the second stage of the study, a network of connections between lifestyles was built and visualized. The obtained network describing the relationships between the different lifestyles can be found in Multimedia Appendix 4.

The most frequent word in our database was *diet*, encapsulating all the nutritional adjustments that patients undergo to manage their disease. Specific diets such as *paleo*, *vegetarian*, or *liquid* diets also surfaced and in a negative context.

It is interesting to note that the negative and positive lifestyles revealed by the analysis were in line with what is known about suitable nutrition for IBD. Among the most negative lifestyles (by mean sentiment), we found *alcohol*, *milk*, *spicy*, *cabbage*, *flour*, *lentil*, and *orange juice*, all known to cause inflammation and irritate the stomach. Among the most positive lifestyles (by mean sentiment), we found activity-related lifestyles such as *fitness* or *yoga* and healing foods such as *salmon*, *ginger*, and *garlic*. The most positive lifestyle turned out to be *sushi*, which usually contains anti-inflammatory ingredients such as *salmon* or *tuna*, *seaweed*, and *rice*. Table 4 presents the 20 most positive and 20 most negative lifestyle-related words sorted by mean sentiment.

Table 4. The 20 most positive and 20 most negative lifestyles sorted by mean sentiment.

Rank	Keyword	Count	Sentiment, mean (SD)	Count of positive	Count of negative	Odds
1	Sushi	9	0.466 (0.814)	7	2	3.500
2	Ginger ale	5	0.407 (0.597)	3	1	3.000
3	Salmon	7	0.344 (0.691)	4	3	1.333
4	Cherry	10	0.33 (0.696)	6	2	3.000
5	Breakfast	29	0.28 (0.75)	19	9	2.111
6	Garlic	8	0.244 (0.671)	4	2	2.000
7	Bagel	5	0.224 (0.633)	3	1	3.000
8	Almond	9	0.193 (0.668)	6	3	2.000
9	Yogurt	14	0.189 (0.688)	7	3	2.333

143	Flour	6	−0.785 (0.211)	0	6	0.000
144	Lentil	6	−0.785 (0.188)	0	6	0.000

Discussion

Principal Findings

This study presents a workflow for identifying patients with IBD on Twitter and exploring their tweets. The aim was to identify patients with IBD based on the way they communicate on Twitter and to learn from the personal experiences they share.

In the first stage of the study, a classifier of Twitter users designed to distinguish patients with IBD from other users was constructed and evaluated. Classification features combining social data and text analysis were extracted from the users' activity on Twitter, their social connections, and the content of their tweets. Various classification algorithms were considered, and 4 evaluation measures were calculated for each of them. The encouraging results shown in the previous section helped convince us that patients with IBD can be identified on Twitter based on such features.

Classification results from both the SI and MI approaches show that patients with IBD differ in the way they communicate on Twitter from other users who tweet about the disease. They talk in the first person more often and use more profanities in their tweets. These gaps, which can be explained by the fact that patients are private individuals whereas nonpatients also include organizations and voluntary associations that communicate in a much more formal manner, helped distinguish patients from other entities in the different classification models we tried in this study.

Our analysis differs from previous research regarding user classification on Twitter [36-38] in 2 aspects. Conceptually, we investigate a different domain and try to identify patients on Twitter. Practically, we compare the results from the user-level classification with a tweet-level classification.

In the second stage of the study, tweets of patients with IBD were collected to investigate the different lifestyles they implemented to deal with their disease and assess these lifestyles' effectiveness. Unlike previous research on patients' sentiments on Twitter [48-50], we focused our research on entity sentiment for specific words rather than the entire tweet's sentiment. We suggested a novel approach by considering entity sentiment analysis to obtain patients' sentiments toward the different nutrition and fitness-based solutions they try. These findings were in line with what is known about IBD as several foods known to cause inflammation were pointed out in a negative sentiment, whereas relaxing activities and anti-inflammatory foods surfaced in a positive context.

This study suggests that there is room for collaboration between physicians and engineers regarding understanding chronic diseases. Owing to the chronic nature of the disease and the fact that it involves bowel movements, patients with IBD are compelled to follow special nutrition and maintain a calm routine. By collecting and analyzing patients' personal experiences on social media, we can monitor patients' lifestyles and support medical knowledge of IBD. We can identify and assess complementary treatments to diets and physical activity and maybe ease patients' processes of finding the right treatments for them. Although such analysis should not strive to replace physicians or draw conclusions of a clinical nature, it may provide complementary recommendations for healthy lifestyles based on the wisdom of the crowd.

Limitations and Future Work

Overview

The focus of this study was on showing the potential of identifying patients with IBD on Twitter and learning from their tweets. This study emphasized the entire process, and we did not perfect each part separately. As this section explains, each part can be improved by trying different methods and enriching the analysis.

Patient Identification

The classifier developed in the first stage of this study uses 1-level, binary classification to separate patients with IBD from other users who tweet about the disease. Some of its features distinguish organizations from individuals in general and do not necessarily detect patients, such as the use of the first person in the tweet. Therefore, our nonpatient class is heterogeneous and somewhat ambiguous, containing both organizations that significantly differ from patients in their communication patterns and healthy individuals who differ from patients in a more refined manner. Even during the manual labeling process, all 14 users excluded from the data set owing to classification disagreements were individuals talking in the first-person voice.

A possible direction for future work would be to try a 2-step classification: separating persons from organizations and continuing by searching for patients among these individuals. It can improve the robustness of some of the features by overcoming the heterogeneity of the nonpatient class in our model. Alternatively, we could try replacing the binary classification with a multinomial one that will capture not only organizations and patients but also individuals who talk about the disease and maybe mention other patients but are not sick themselves.

During the construction of the network-based features, we only collected immediate connections on Twitter (ie, the followers and followees of each patient). The sampling method resulted in basic network features that mainly included degree measures. We encourage future research to consider more interesting network features such as other centrality measures or structures. Such enhancement will require collecting at least one more level of connections (eg, followees of followees) to understand network patterns better.

Finally, the classifier uses standard classification algorithms and did not try current state-of-the-art learning techniques based on neural networks. Text representation using word embeddings, where words are mapped to vectors of real numbers in a predefined vector space [64,65], is also worth examining.

Analyzing Patients' Tweets

The NLU module by IBM Cloud was used in this study for entity sentiment analysis as a proof of concept. We did not evaluate its results or compare them with similar tools available in the market, such as the Natural Language API by Google Cloud. Future research should consider performing similar analyses with different natural language processing tools and comparing their results. Even training designated algorithms on data from lifestyle-related tweets such as those used in this study can benefit the analysis.

Overall, the results for the second part are preliminary, and much more can be done to understand what patients with IBD are talking about on Twitter. For example, by characterizing treatment options and patients' sentiments toward them, one can derive recommendations for a healthy lifestyle based on the wisdom of the crowd. Thoroughly exploring outliers, such as the 4 positive mentions of milk as opposed to the 35 negative ones, can reveal new information regarding the disease that has not yet been covered in the literature.

Conclusions

In the era of personalized medicine and patient-centered care, it is important to derive insights that reflect the patients' perspectives as manifested in social media. Although the time between physician appointments can be lengthy, messages on social media are being posted each day, and patients constantly use them to exchange inputs and recommendations.

This study provides a potential pipeline for identifying patients with chronic illnesses on Twitter and collecting their tweets to analyze the experimental knowledge they share on the web. The method presented in this study was applied to IBD and can also help explore other medical conditions. The classifier for IBD-related entities can be adapted to identify other patients with chronic illnesses. The analysis of patients' tweets can benefit research on other chronic conditions with similar characteristics. With conditions such as celiac disease or diabetes, which involve strict dietary guidelines, one can better understand patients' difficulties with adherence to their new lifestyles. When considering diseases that cause embarrassment, such as HIV, one can learn more about the constant struggle of patients living with the disease.

Therefore, the contribution of this study is 2-fold: it provides an analytical contribution to the fields of text mining and social media and a practical contribution by better understanding chronic conditions and promoting a healthy lifestyle for patients with chronic illnesses.

Abstract

Background: Research has repeatedly shown that exposure to suicide-related news media content is associated with suicide rates, with some content characteristics likely having harmful and others potentially protective effects. Although good evidence exists for a few selected characteristics, systematic and large-scale investigations are lacking. Moreover, the growing importance of social media, particularly among young adults, calls for studies on the effects of the content posted on these platforms.

Objective: This study applies natural language processing and machine learning methods to classify large quantities of social media data according to characteristics identified as potentially harmful or beneficial in media effects research on suicide and prevention.

Methods: We manually labeled 3202 English tweets using a novel annotation scheme that classifies suicide-related tweets into 12 categories. Based on these categories, we trained a benchmark of machine learning models for a multiclass and a binary classification task. As models, we included a majority classifier, an approach based on word frequency (term frequency-inverse document frequency with a linear support vector machine) and 2 state-of-the-art deep learning models (Bidirectional Encoder Representations from Transformers [BERT] and XLNet). The first task classified posts into 6 main content categories, which are particularly relevant for suicide prevention based on previous evidence. These included personal stories of either suicidal ideation and attempts or coping and recovery, calls for action intending to spread either problem awareness or prevention-related information, reporting of suicide cases, and other tweets irrelevant to these 5 categories. The second classification task was binary and separated posts in the 11 categories referring to actual suicide from posts in the off-topic category, which use suicide-related terms in another meaning or context.

Results: In both tasks, the performance of the 2 deep learning models was very similar and better than that of the majority or the word frequency classifier. BERT and XLNet reached accuracy scores above 73% on average across the 6 main categories in the test set and F_1-scores between 0.69 and 0.85 for all but the suicidal ideation and attempts category (F_1=0.55). In the binary classification task, they correctly labeled around 88% of the tweets as about suicide versus off-topic, with BERT achieving F_1-scores of 0.93 and 0.74, respectively. These classification performances were similar to human performance in most cases and were comparable with state-of-the-art models on similar tasks.

Conclusions: The achieved performance scores highlight machine learning as a useful tool for media effects research on suicide. The clear advantage of BERT and XLNet suggests that there is crucial information about meaning in the context of words beyond mere word frequencies in tweets about suicide. By making data labeling more efficient, this work has enabled large-scale investigations on harmful and protective associations of social media content with suicide rates and help-seeking behavior.

suicide prevention; Twitter; social media; machine learning; deep learning

Introduction

Background

Suicide is a major public health problem worldwide, accounting for 1.4% of all deaths, equaling almost 800,000 in 2017, with many more suicide attempts [1]. Research shows that exposure to suicide-related news media content can influence suicidal behavior in vulnerable individuals in both harmful and beneficial ways. Whether suicide cases increase or decrease after exposure to suicide-related news seems to depend on specific elements of media content and language. As a recent meta-analysis of media effects research on suicide shows, most solid evidence exists for increases in suicides after exposure to news about celebrity deaths by suicide [2]. This imitation of suicidal behavior is commonly referred to as the Werther effect [3]. In contrast, exposure to other types of content may have a protective effect, with the strongest evidence existing for stories of hope, recovery, and coping [4-6]. However, broader prevention texts (ie, texts focused on prevention that were not personal stories of recovery) have also been found to be associated with protective effects in some studies [7,8]. The association of positive messaging on suicide prevention with later decreases in suicide rates has been labeled as the Papageno effect [4].

Studies investigating how exposure to media content is associated with suicidal behavior have mainly focused on traditional news outlets, such as print and web-based newspapers, radio, and television broadcasts. Investigations of the associations between social media content and suicides remain extremely scarce [9-13]. Most of the previous research on social media has focused on detecting suicidal ideation in users' posts with the purpose to identify individuals at risk, but very little research has been conducted to analyze media effects. The applied methods for identifying such individuals include machine learning as well as word dictionaries, word frequencies, topic models, and social network analysis (eg, [14-18]; for more information, see reviews by Bernert et al [19], Castillo-Sánchez G [20], Ji et al [21], Wongkoblap et al [22], and Yin et al [23]). A small number of studies have started developing machine learning classifiers for content other than suicidal ideation, despite evidence from research on traditional media that other content types can affect suicidal behavior (eg, [2,4]).

Limitations of Previous Similar Machine Learning Studies

A machine learning study categorized tweets according to expressed emotions [9], whereas 2 further studies [24,25] classified typically occurring content types, including celebrity suicide reports, suicidal intent, awareness campaigns, prevention information, condolences, and flippant remarks. Although these 2 studies include several different prevention-relevant content types, they both use the same and relatively small data set, which is limited to tweets containing celebrity names or suicidal intent. Furthermore, all these machine learning studies have used word frequency statistics as predefined features for model training, which cannot capture differences in the meaning of words across different contexts. This study addresses several gaps in the existing literature on media effects on suicidal behavior. The first is the lack of research on suicide-related social media content other than suicidal ideation. Suicide is a leading cause of deaths among young adults [1] who predominantly receive news on such platforms [13,26]. This highlights the urgency of systematic research on social media effects. In addition, social media posts often feature other content types than traditional news outlets, on which research is required. This includes diary-like posts in which people describe their personal experiences or posts addressed to their social network with the intention to prevent suicides. In this study, we investigated Twitter data and created a detailed annotation scheme for the types of suicide-related tweets that are potentially relevant to prevention efforts.

Second, regarding prevention-related media content, there is currently a discussion in the literature on whether content that highlights prevalence data to increase problem awareness has a protective effect or may even be detrimental [27]. By highlighting the prevalence of suicide and risk factors such as mental health or abuse without mentioning solutions to the issue, attempts to spread awareness may normalize suicidal behavior and trigger harmful effects [28]. In this study, we have addressed the lack of studies differentiating between prevention messages focusing on prevalence and prevention opportunities [27]. Specifically, we distinguish between awareness and prevention-focused calls for action on Twitter.

Third, the samples used in previous studies on suicide-related social media content are limited either in size (eg, [10,11]) or by a set of search terms used to collect tweets (eg, [12,29]). Sample sizes are usually small as all content needs to be annotated manually. Search terms either narrowly focus on events such as the suicide of specific celebrities (eg, [12]) or broadly include all texts containing the word suicide. Therefore, the effects of different content types may cancel each other out [2]. Thus, to systematically investigate the potentially harmful and protective effects, a large-scale and simultaneously fine-grained approach is necessary.

Overview of This Study

We have addressed these challenges by first developing a comprehensive annotation scheme that systematically organizes tweets about suicide into categories most likely to beneficially or harmfully affect suicidal and help-seeking behavior based on available evidence (eg, [2,4,6,30]). Second, we compared different natural language processing and machine learning methods to automatically detect and classify particularly important categories in large quantities of social media data. Extending previous work on different prevention-related social media content types [9,24,25], we included not only word frequency–based models but also 2 deep learning models that can capture content-dependent meanings of words [16]. We trained all models in two tasks: a multiclass classification problem with 6 main content categories and a binary classification problem of tweets about actual suicide versus off-topic tweets, which use the word suicide in another meaning or context.

The 6 main categories assessed include 5 content types that are particularly relevant for suicide prevention based on previous research. As described earlier, the strongest evidence exists for celebrity suicide case reports having harmful effects and for personal stories of hope and coping having protective effects. A second type of personal stories in Twitter posts mentions suicidal ideation and attempts without any hint at coping or recovery. Preliminary evidence suggests that such posts may have a protective effect [11]. Some evidence also suggests protective effects for general prevention messages [7,8]. We have distinguished between general prevention messages calling for action by either spreading prevention-related information or solution-oriented attitudes from those spreading problem awareness only. Finally, we included an irrelevant category to identify tweets outside the other 5 possible categories described.

Objectives

The objective of our study was to enable large-scale studies on the association between tweet content and suicidal and help-seeking behaviors. Specifically, we aimed to provide volume estimates for the different prevention-relevant tweet categories for follow-up studies on the associations of these estimates with the number of suicide cases and helpline calls.

Methods

Data Set for Training Machine Learning Models

Given that this study is part of a project on media messaging for suicide prevention in the United States, all data sets of this study include English tweets of users located in the United States. We retrieved tweet IDs via the data reseller Crimson Hexagon (now known as Brandwatch), previously used for suicide research [9,12], and then downloaded the full text of these tweets via the Twitter application programming interface. Crimson Hexagon provides access to the entire history of Twitter data and includes reliable language and location filters. The location algorithm matches 90% of all posts in a country to a location using a combination of geocoordinates, location information from user profiles, and users' time zones and languages [1].

Using a list of keywords and exclusion terms, we created a pool of unique tweets without duplicates or retweets, based on which we prepared a labeled set of tweets for training the machine learning models. We retrieved tweets posted between January 1, 2013, and May 31, 2020 (see note on dates in Multimedia Appendix 1), which contained at least one of the suicide-related search terms taken from a previous study [11]. The search terms were *suicide*, *suicidal*, *killed himself*, *killed herself*, *kill himself*, *kill herself*, *hung himself*, *hung herself*, *took his life*, *took her life*, *take his life*, *take her life*, *end his own life*, *end her own life*, *ended his own life*, *ended her own life*, *end his life*, *end her life*, *ended his life*, *ended her life*, *ends his life*, and *ends her life*.

The exclusion terms were identified by inspecting word frequency plots for common terms that may indicate that tweets used the term suicide to describe something other than someone ending their life or terms that indicated tweets about suicide bombing. We then verified whether these terms were actual mismatches by reading examples of tweets containing these terms. Thus, tweets with the most common use of the term suicide in contexts that do not refer to actual suicide could be excluded. The final list of exclusion terms was *suicide squad (a movie)*, *suicidechrist*, *SuicideGirl* (a website featuring pin-up photographs of models)*, *SuicideBoy* (male models)*, *suicideleopard (a frequently mentioned Twitter user)*, *suicidexjockey* (a Twitter user)*, *suicidal grind (a music album)*, *Epstein (excessive speculations about whether the death of Jeffrey Epstein was or was not a suicide)*, *political suicide (tweets using suicide as a metaphor for political failure)*, *Trump*, *clinton**,*Hillary*, *Biden*, and *sanders (also mostly about political suicide)*.

To avoid overlearning from multiple identical tweets, we ensured that the labeled data used for machine learning did not include any tweet duplicates. We excluded retweets (tweets categorized as retweets by Crimson Hexagon given the metadata of tweets as well as tweets containing the manual labels RT for retweets or MT for slightly modified tweets). We assembled a labeled data set of 3202 tweets by iteratively selecting tweets from a larger pool of tweets as described in the *Creating the Annotation Scheme and Labeled Data Set* section. We refer to these 3202 tweets as the *total labeled data set.* Although part of this data set was combined using keywords and model predictions (see below), a second subsample of 1000 tweets was selected randomly. We refer to these 1000 tweets as the *randomly selected labeled data set.*

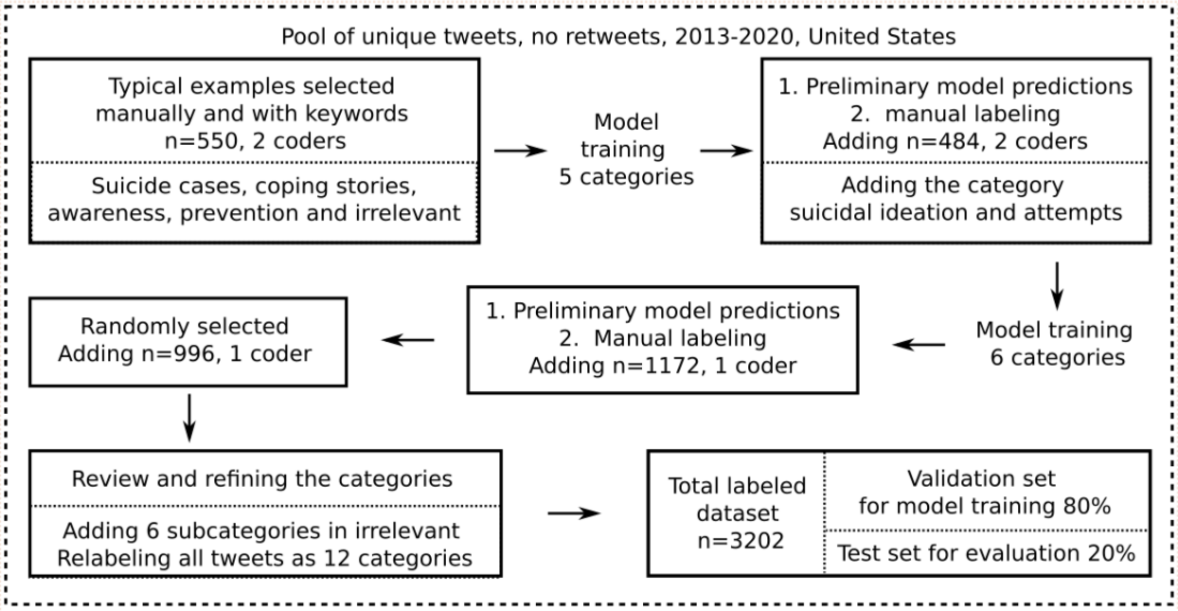
In the course of the study, we combined two other data sets: the first to compare model and human interrater reliability and the second for a face validity check and a follow-up study (Niederkrotenthaler et al, unpublished data, May 2022; see Multimedia Appendix 1 for details). Both are described in detail in the *EvaluatingReliability and Face Validity of Model Predictions for BERT* section.

Creating the Annotation Scheme and Labeled Data Set

Creating the annotation scheme and the labeled data set was an iterative human-in-the-loop process building on preliminary classifiers and annotations. We started with 5 broad categories which appeared most relevant, given previous research on traditional media (see the *Introduction* section). We then added additional categories when tweets did not fit into the existing categories but might nevertheless be associated with suicides. Given that the tweets of interest are relatively rare compared with irrelevant tweets, we used the following stepwise procedure to identify examples, which is also illustrated in Figure 1.

1. We manually selected approximately 100 tweets for each of the 5 main categories (550 tweets in total): *suicide cases*, *coping stories*, *awareness*, *prevention*, and *irrelevant tweets.* To gather the first set of tweets, we searched the data set for typical examples, both randomly and with keywords that might indicate each particular category. We iteratively expanded the list of keywords by inspecting the most frequent terms in the resulting tweets in a systematic way [31]. The full list of keywords is provided in Multimedia Appendix 1; examples are *committed or found dead* for suicide cases, *recover** or *hope* for coping stories, *lifeline or prevention* for prevention, *awareness*, and *please retweet* or *please copy* for awareness.
2. We used a preliminary machine learning model to make predictions based on the first training data set of 550 tweets to identify potential examples for each category. Next, two authors with domain expertise (TN and HM) continued annotating 100 tweets from each of the 5 predicted categories (484 after removing duplicates and missing labels from a coder). The interrater reliability for these 500 tweets was a Cohen κ of 0.75. On the basis of a careful inspection of all disagreements, we refined the definitions for all categories and adjusted the labels of all previously annotated tweets accordingly. Annotating these tweets, we further noticed a novel type of message not described in research on traditional news reporting, namely purely negative descriptions of suicidal experiences without any hint at coping, hope, or recovery. We updated the annotation scheme to include this new category *suicidal ideation and attempts*, resulting in 6 main categories. The total training set of tweets included 1034 tweets.
3. At this stage of the labeling process, we found that two dimensions were generally helpful in differentiating between categories: message type (eg, a personal story, a news story, and a call to action) and the underlying perspective about suicide (ie, if the tweet applies a problem- and suffering- or solution- and coping-centered perspective). For each message type, we noticed that some tweets implicitly or explicitly frame suicide only as a problem or from an exclusively negative or suffering perspective (categories: suicidal ideation and attempts, suicide cases, and awareness), whereas other tweets implied that coping was possible or suggested ways of dealing with the problem (categories: coping stories and prevention).
4. Repeating step 2, we trained our best preliminary model to make new predictions for the 6 categories based on all labeled tweets. Each coder annotated a different set of tweets for each predicted label until we reached a minimum of 200 training examples for the smallest categories (suicidal and coping stories). This resulted in 2206 tweets in total.
5. To mitigate bias from the search terms we used to assemble our initial training set and to estimate the distribution of tweets across categories on Twitter, HM labeled a random sample of 996 tweets (initially 1000, with 4 were not labeled owing to a displaying error in the used spreadsheet). These were then added to the training set, resulting in a total sample of 3202 tweets.
6. After reviewing the entire training set, we finally refined the categories to allow for the following distinctions: for stories about coping and suicidal experiences, we differentiated the perspective from which an experience was described (first or third person), which experience was described (the one of a concerned or a bereaved individual), and whether a tweet was shared by news media or individual users. For reporting of cases, we distinguished tweets about individuals who had actually died by suicide from tweets about someone saving the life of an individual who was about to take his or her life. Finally, we organized the tweet categories according to 2 dimensions further described in the *Annotation Scheme* section.

Figure 1. Creating the labeled data set and annotation scheme. Each box describes how tweets were selected from the large pool of available tweets, how many tweets were added to the training data set in each step (after removing duplicates), and how many coders labeled each tweet. When we used preliminary model predictions to identify potential candidates for each category, we deleted the model labels before manual coding. After rounds with 2 coders, we checked interrater reliability, adapted the annotation scheme until all disagreements were clarified, and relabeled the respective sample.



Annotation Scheme

Overview

The annotation scheme divides tweets into 12 categories, including 10 categories of interest and 2 irrelevant categories. Each category can be described in terms of two dimensions: the message type (eg, a personal story, a news story, and a call to action) and the underlying perspective about suicide (ie, if the tweet applies a problem- or solution-centered perspective). The perspective distinguishes messages that implicitly or explicitly frame suicide only as a problem or from an exclusively negative or suffering perspective from messages that imply that coping is possible or suggest ways of dealing with the problem. The organization of the tweet categories along these 2 dimensions is presented in Table 1. Detailed instructions for annotating tweets are provided in Multimedia Appendix 2. These include prioritization rules for how to deal with ambiguous tweets that may fit into more than one category.

Table 1. Annotation scheme of content categories organized along two dimensions: message type and underlying perspective about suicide.

Message type	Underlying perspective	
	Problem and suffering	Solution and coping
Personal experiences first or third person	Suicidal ideation and attempts[a]	Coping (Papageno)[a]
News about experiences and behavior	News suicidal ideation and attempts	News coping
Experience of bereaved	Bereaved negative	Bereaved coping
Case reports	Suicide cases (Werther)[a]	Lives saved
Calls for action	Awareness[a]	Prevention[a]
Irrelevant[a]		
Suicide other	Murder-suicides, history, fiction, not being suicidal, and opinions	
Off-topic[b]	Bombings, euthanasia, jokes, metaphors, and band or song names	

[a] The 6 main categories classified in machine learning task 1.

[b] Task 2 distinguished the off-topic category from all other categories (see *Classification Tasks*).

Description of Content Categories

For each message type (except for irrelevant messages), there is a category for more problem- or suffering-focused tweets and for more solution- or coping-focused tweets:

1. Personal stories describing the experience of an affected individual either in first- or third-person perspective:
    - Suicidal ideation and attempts: Personal stories about an individual's negative experiences with suicidal thoughts, related suffering (eg, depression), suicidal communication and announcements, or suicide attempts without a sense of coping or hope

- Coping: Personal stories about an individual's experience with suicidal thoughts or a suicide attempt, with a sense of hope, recovery, coping, or mentioning an alternative to suicide. The sentiment does not have to be positive. A neutral tone or talking about difficult experiences with a sense of coping or mentioning recovery is sufficient. Previous research has suggested that such messages may have a Papageno effect.

2. News reports about suicidal experiences and behavior except cases, often about celebrities:
    - News suicidal ideation and attempts: About suicidal experiences without any mention of coping, including reports on suicidal ideation, suicide attempts, announcements of suicide, and someone being put on "suicide watch"
    - News coping: About attempted or successful coping with or recovering from a suicidal crises.
3. Tweets describing the experience of a person who has lost someone to suicide from the first- or third-person perspective:
    - Bereaved negative: Describes the suffering or purely negative experience of a person who has lost someone to suicide, including depression, grief, and loss. These tweets necessarily refer to a suicide case but are labeled as bereaved as long as they focus on the experience of bereaved individuals.
    - Bereaved coping: Describes the experience of a bereaved person with a sense of hope, recovery, or coping. The sentiment does not have to be positive. A neutral tone, or talking about difficult experiences with a sense of coping or mentioning recovery is sufficient.
4. Reports of a particular completed or prevented suicide cases, often news reports:
    - Suicide cases: About an individual suicide or a timely or geographical suicide cluster. Suicide cases have priority over the definition criteria of other categories (except tweets focusing on bereaved individuals, which are always related to a suicide case). Previous research suggests that such messages on individual suicide deaths (especially about celebrities) may have a Werther effect.
    - Lives saved: News report or personal message about someone saving a life. In contrast to prevention tweets, these lives are often being saved coincidentally.
5. Calls for action are general statements calling for actions addressing the problem of suicide and intending to spread problem awareness or prevention-related information:
    - Awareness: Tweets intending to spread awareness for the problem of suicide, often focusing on high suicide rates or associations with bullying, racism, depression, and Veterans without hinting at any solution. These are often the reports of research findings or suicide statistics.
    - Prevention: Tweets spreading information about a solution or an attempt to solve the problem of suicide, including prevention at an individual (eg, do not leave people alone in crisis situations) or public health level (eg, safety nets on bridges). Hinting at a solution or a way of dealing with the problem is sufficient. No specific action needs to be described. These tweets often include a helpline number. Announcements of prevention events and broad recommendations for actions also count—donations and prayers with a focus on a solution for suicide, being there for someone, telling people that they matter, taking a course about suicide prevention, and warning signs to watch out for.
6. Irrelevant, including messages that do not fit into any of the above categories:
    - Suicide other: Anything about actual suicide but not clearly related to any other above category, including murder-suicides, confident statements that something was not a suicide, convincing statements of not being suicidal, historical tweets about suicides that were a minimum of 40 years ago (eg, about the suicide of Hitler), movies, books, novels, and fiction about suicide.
    - Off-topic: Messages that use the term suicide in a context other than suicide. This includes messages on euthanasia, suicide bombing and suicide attacks, messages that are (suspected) jokes, irony, sarcasm, flippant remarks or really unclear in terms of authenticity, and messages that use suicidal or suicide to exaggerate an emotional experience (unclear if serious) or as a metaphor (eg, political, financial, or career suicide, suicide workout, and suicidal immigration policies), and messages about "suicidal animals" (eg, killed by car).

Analysis

Software

Data analysis was performed using R for intercoder reliability, descriptive statistics, and figures (version 3.6.3, R Foundation for Statistical Computing). The main libraries used in R were tidyverse, caret, and DescTools [32-34]. For training deep learning models, we used Python 3.6 (Python Software Foundation). The main packages were the ktrain wrapper [35] for the deep learning library TensorFlow Keras [36] and the scikit-learn library [37] for term frequency-inverse document frequency (TF-IDF) and support vector machines (SVM). For links to code and data, refer to the *Data and Code Availability* section.

Text Preprocessing

We applied standard preprocessing strategies (eg, [38]) and replaced all URLs with a general marker token "*http*," all mentions (tags of Twitter users) with "*@user*," and lowercased all words. The latter allowed using the smaller, more resource-efficient Bidirectional Encoder Representations from Transformers (BERT)–lowercase model (see the *BERT-base* section). We kept emoji, stop words, and punctuation separated into single tokens, given that they can indicate the emotional connotation of a message (eg, expressing excitement or surprise [39] or frequent singular pronouns indicating suicidal ideation [15]). We report the effects of additional standard different preprocessing steps, namely removing digits, punctuation, stop words, and lemmatization, in Multimedia Appendix 1. The basic preprocessing strategy yielded the most consistently high-performance scores on the validation set and was therefore used for all analyses. After preprocessing, the mean length of tweets in our labeled data set was 25 tokens, the 95th and 99th percentile were 57 and 67 tokens, respectively (Figure S1 in Multimedia Appendix 1). On the basis of this, we used 80 tokens as the maximum sequence length for model input.

Classification Tasks

Task 1: 6 Main Categories

We trained our models to classify among categories with at least 200 tweets to allow sufficient training data. From the categories of interest, these were messages about (1) *personal experiences of coping*, (2) *personal experiences of suicidal ideation and attempts*, (3) *suicide cases*, (4) *awareness*, and (5) *prevention*. We assigned all tweets from smaller categories (suicidal and coping news, negative and coping experiences of the bereaved, and lives saved) to the category *suicide other*, which belongs to the larger category of *irrelevant* tweets. In this task, we did not differentiate between irrelevant tweets that were about suicide (suicide other) and off-topic tweets, which used the word suicide in some other way. Instead, we subsumed suicide other and off-topic tweets in the category (6) *irrelevant*.

Task 2: Detecting Content About Actual Suicide

This binary classification distinguishes tweets that are (1) *about actual suicide* in the meaning of someone taking their own life, from tweets that are (2) *off-topic*, that is, use the word suicide in some other context. In our annotation schema, this task therefore separates the off-topic category from all other categories. The resulting label predictions allow to estimate the total volume of tweets about actual suicide, thereby improving the total volume estimates only based on keyword searches.

Machine Learning Models and Model Training

Train-, Validation-, and Test Set

Before training models, we divided the data set of 3202 tweets into training (2049/3202, 63.99%), validation (512/3202, 15.99%), and test sets (641/3202, 20.02%), stratifying per tweet category to have a similar distribution in all sets. The training set was used for fitting the parameters of the classifier using 5-fold cross-validation. The validation set was used to tune the hyperparameters (eg, learning rate) and evaluate the model developed on the training data. After model training, we used the test set only once per model to estimate its ability to generalize to novel texts.

Majority Classifier

We used a naïve classifier that always predicts the majority class as a baseline to compare the other models.

TF-IDF and SVM

TF-IDF represents the text of tweets using weighted word *frequencies (f)*, which reflect how important a *term (t)* is to a *document (d, here a tweet)* in a corpus (all tweets). We slightly adjust the original formula for TF-IDF by adding 1 in the numerator and denominator, to ensure each word occurs at least once and prevent 0 division [40]: $tf\text{-}idf(t,d) = tf(t,d) \times \log([N+1]/[df+1])$.

The resulting value increases proportionally to the number of times a word appears in the document and is offset by the number of documents in the corpus that contain the word. This helps to adjust the weight of uncommon words that are more important for distinguishing different documents from each other than words that occur in every single document. After building the TF-IDF representation, we trained a SVM classifier using all term values as features.

To identify the best TF-IDF representation and SVM classifier, we ran a grid search across the following dimensions. For TF-IDF, we (1) included only unigrams or unigrams+bigrams and (2) reduced the text to its n top features ordered by term frequency, where $n \in \{10{,}000; 25{,}000; 50{,}000\}$. For the SVM, we tested different hyper-parameters, namely (1) regularization parameter $C \in \{0, 1\}$, which determines the strength of the regularization and (2) class weight $cw \in \{\text{balanced, none}\}$, which determines whether the weights of the classes are automatically adjusted inversely proportional to class frequencies. We further tested (3) a linear and a radial basis function kernel and (4) decision function shapes one versus one and one versus rest. Optimal results were achieved including both unigrams and bigrams as text representation, 10,000 top features, and an SVM with C=0.82 in task 1 and C=0.46 in task 2, cw=balanced, a linear kernel, L2 penalty, and a one-versus-one decision function shape.

BERT Base

We used a transfer learning approach based on a pretrained BERT-base-uncased model [41]. BERT is an autoencoding deep contextual language representation model developed by Google AI, which has 12 transformer layers, 12 self-attention heads, and a hidden size of 768. It is designed to pretrain bidirectional representations of word sequences, that is, it learns from both the left-side and right-side context of a word in all of its layers. BERT was pretrained with masked language modeling: a percentage (approximately 15%) of words in the sentence is randomly masked, and the model tries to predict the masked words from the sequence of other words. BERT was further trained to predict the next sentence from the previous sentence in the data.

XLNet Base

A known limitation of BERT is that it neglects the dependence between the different masked words in a sentence. When predicting a word from a sequence that does not include the other masked words, BERT lacks information about the dependence between the masked words and the predicted word. Unlike autoregressive models, BERT further predicts all masked words simultaneously, and thus lacks some information about the order of words. XLNet [42] has a similar architecture as that of BERT but addresses these shortcomings through permutation language modeling, predicting each word from all possible permutations of other words in the sentence. It thereby improves both on previous autoregressive models by using all words in the sentence and on BERT by considering the order dependence of words. In addition, it incorporates some techniques from Transformers-XL [43], which also allows it to learn from the longer context before each word (relative positional encoding and segment recurrence mechanism).

Fine-tuning of BERT and XLNet

We fine-tuned the pretrained BERT-base uncased model and the XLNet-base model to our training data set as in the study by Liu et al [16], added one dense output layer to reduce the dimensions of the model's last layer to the number of labels in the classification task, and trained all the parameters simultaneously. We ran a hyper-parameter search to determine good learning rate (LR) candidates and subsequently tested each LR by running 3 experiments with different seeds ∊ {1,2,3}. We aimed to find the maximal LR associated with a still-falling loss (before the loss diverging) by training for 5 epochs with learning rates ∊ {2e-5, 3e-5, 5e-5}. The reported results for BERT in Task 1 (6 classes) were the result of fine-tuning with a LR=2e-5 for 7 epochs and seed=1. The results for task 2 (about actual suicide) were based on a BERT model trained with a LR=1e-5, 10 epochs, and seed=1. The reported results for XLNet were based on model training with LR=2e-5, 8 epochs, and seed=1 in both tasks.

Metrics for Comparing Machine Learning Models

We used various evaluation metrics to compare different machine learning models. *Accuracy* indicates the percentage of correct predictions (true positive and true negative). It is a global metric calculated for all the classes in a data set. In data sets with large class imbalances, it can be high even if it always predicts only the majority class (eg, the irrelevant category in task 1). In this case, the model may not have learned anything despite its high accuracy. *Precision* indicates the proportion of correct "positive" predictions out of all predictions; for example, how many of all predicted coping tweets were actually labeled as coping tweets by human raters. *Recall* indicates the proportion of all "true" cases (eg, all actual coping tweets) that the model detects. The F_1-score is the harmonic mean between precision and recall ($F_1 = 2 \times [\text{precision} \times \text{recall}]/[\text{precision} + \text{recall}]$). Precision, recall, and F_1-scores were calculated for each category and can be averaged across classes to produce a macroaverage. For category-specific precision and recall, we provide 95% binomial CIs calculated using the Clopper-Pearson method.

To compare models, we report macroaverages of model performance scores for both the validation and test sets, that is, we calculate the mean of the performance measures of each class to have an aggregate measurement robust to class imbalance. Although good scores on the training set indicate that the model has learned patterns existing in the training set, good scores on the test set additionally indicate an ability to generalize to novel data.

For determining the model to make predictions for a follow-up study (Niederkrotenthaler et al, unpublished data, May 2022; see Multimedia Appendix 1 for details), we decided a priori that we would prioritize precision over recall for task 1, which aims to identify specific categories of tweets. The rationale behind this is that our follow-up study focused on identifying specific Twitter signals (ie, the percentage of coping tweets) that are associated with suicide cases and helpline calls. In such a situation, a false negative is less costly than a false positive, that is, missing a tweet is less costly than falsely including a tweet in a certain category. Prioritizing precision ensures that we only count a tweet when it belongs to a category with a high probability. Furthermore, because of the large number of tweets, the proportion assigned to each category should accurately reflect the true proportion, even if not all the tweets are recognized. In contrast, task 2 makes predictions that aim to capture the entire discussion about actual suicides on Twitter. When choosing the best model for task 2, we focused on the F_1-score. Here, we aimed to capture the total volume of tweets about suicide as fully as possible, as well as at accurate predictions at the tweet level. False positives are less critical as a problem in task 2 than in task 1, because we look at total tweet volume and do not try to distinguish between the specific effect of a certain tweet category. This is best captured with the F_1-score, which balances recall and precision. In any case, none of these a priori decisions had consequences for our results, given that BERT and XLNet performed very similarly and much better than the other models.

Evaluating Reliability and Face Validity of Model Predictions for BERT

Comparing Model and Human Interrater Reliability

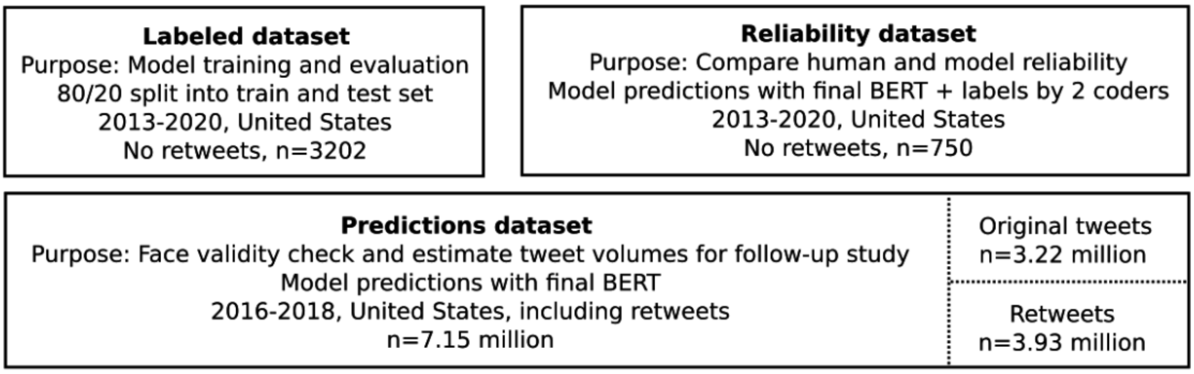
To compare the models' reliability to human interrater reliability on novel data, we made predictions using one of the best models (BERT) for tweets from the full data set that were not part of the labeled data set. We selected 150 tweets per predicted label for each of the 5 relevant main categories. In all, 2 independent human coders manually labeled these tweets until we reached at least 80 tweets per main category. The final set of 750 labeled tweets comprised the reliability data set.

Face Validity Check With the Predictions Data Set

For a face validity check and a follow-up study [30], we estimated the daily volume of tweets per category that Twitter users may have been exposed to between January 1, 2016, and December 31, 2018. For this, we created a data set with the same keywords and exclusion terms as the machine learning data set but including retweets (to account for the full volume) and for a shorter period of 3 years (determined by the follow-up study [30]). This resulted in 7,150,610 tweets in English from users in the United States. We used the machine learning model BERT to predict the category labels for these tweets and calculated the daily percentage of tweets per category. We refer to this data set with model predictions for approximately 7 million tweets as the prediction data set. As a face validity check, we plotted the time series of tweet volumes per category and identified the events associated with the largest frequency peaks. We investigated word frequencies on these days, read the tweets containing the most frequent terms, and Googled these terms plus the date, or the tweet in quotes, to find (news) reports about the event. The follow-up study [30] investigated the associations of these daily tweet volumes with suicide cases and helpline calls in the United States. It has access to suicide case data from the Centers for Disease Control and Prevention and call data from the United States suicide prevention lifeline for the years 2016 to 2018, which was the reason for estimating tweet volumes for this period.

Properties of all data sets used in this study, including the labeled machine learning data set and those for comparing model and human performance and the face validity check are depicted in Figure 2.

Figure 2. Overview of characteristics of data sets. Each box describes the purpose of the data set, further details on how it was used or created, and the sample size. Only the predictions data set includes retweets, as it aims to capture the full volume of tweets posted on a given day. BERT: Bidirectional Encoder Representations from Transformers.



Results

Frequency of Tweets per Category

Table 2 displays the proportion of tweets per main category in our labeled data set and in 2 different samples used to estimate the natural frequency of categories on Twitter. First, we used a subsample of the labeled data set of 1000 randomly selected tweets (ie, selected without keywords or model predictions, 996 after 4 labeling; see *Creating the Annotation Scheme and Labeled Data Set* section) to estimate the frequency of original tweets, without counting retweets. For the second estimate, we used predictions by the best model (BERT) to label tweets in the prediction data set, which included retweets. The 2 estimates were similar for suicidal ideation and attempts and suicide cases.

The percentages per category in Table 2 demonstrate that we managed to include proportionally more rare tweet categories, such as coping and suicidal ideation stories in our training set. Nevertheless, irrelevant tweets, particularly off-topic tweets, still make up a majority of tweets in our data set.

Table 2. Distribution of tweets across categories for manual labels and model predictions.

Category label	Total labeled sample (n=3202)	Subset of labeled tweets, randomly selected (n=1000)	Estimated frequency in predictions data set (including retweets; n=7.15 million), n (%)[a]	
			Task 1	Task 2
Suicidal ideation and attempts, n (%)	284 (8.87)	63 (6.33)	367,135.56 (5.13)	5,471,499 (76.52)
Coping, n (%)	205 (6.4)	26 (2.71)	90,328.99 (1.26)	5,471,499 (76.52)
Awareness, n (%)	314 (9.81)	126 (12.54)	1,577,650 (22.06)	5,471,499 (76.52)
Prevention, n (%)	457 (14.27)	71 (7.13)	1,109,223.6 (15.51)	5,471,499 (76.52)
Suicide cases, n (%)	514 (16.05)	129 (12.95)	1,155,277.92 (16.16)	5,471,499, (76.52)
Irrelevant, n (%)	1428 (44.5)	581 (58.33)	2,850,994 (39.88)	5,471,499 (76.52)
Subcategories of irrelevant, n (%)				
News suicidal	68 (2.12)	20 (2.01)	2,850,994 (39.88)	5,471,499 (76.52)
News coping	27 (0.84)	5 (0.5)	2,850,994 (39.88)	5,471,499 (76.52)
Bereaved negative	34 (1.06)	7 (0.7)	2,850,994 (39.88)	5,471,499 (76.52)
Bereaved coping	34 (1.06)	5 (0.5)	2,850,994 (39.88)	5471499 (76.52)
Live saved	13 (0.41)	2 (0.2)	2,850,994 (39.88)	5,471,499 (76.52)
Suicide other	440 (13.74)	206 (20.68)	2,850,994 (39.88)	5,471,499 (76.52)
Off-topic	812 (25.36)	336 (33.73)	2,850,994 (39.88)	1,679,111 (23.48)

[a] For the predictions data set: Absolute values and percentages were weighted (ie, divided) by the model's recall (proportion of all true cases the model detects). Sample values (n) and percentage for the irrelevant category were calculated by subtracting the sum of all other categories from the total sample size and 100, respectively. If several cells contain the same values, this is because they were subsumed to one higher-level category (*irrelevant* in task 1, *about suicide* in task 2) in the respective classification task.

Model Performance

Task 1: 6 Main Categories

Performance scores averaged across all 6 tweet categories (Table 3) show that all deep learning models performed very similarly and substantially better than the TF-IDF and SVM approaches. However, TF-IDF and SVM were clearly better than a naïve majority classifier. It reached scores from 0.61 to 0.66, which were nearly identical on the validation and test sets. For BERT and XLNet, all scores were at or above 0.70, and only 0.1 to 0.3 lower on the test than the validation set, indicating a good ability to generalize to new tweets. The macroaverage performance scores in all 5 runs for BERT and XLNet were approximately 10% higher than the TF-IDF and SVM macroaverages (Table S2 in Multimedia Appendix 1).

Given that the macroaverage performances were substantially lower for the majority classifier, we focused on the 3 other models for intraclass scores (Table 4 and Figure 3). To choose a model for making predictions, we focused on F_1-scores and precision (see the section on evaluation metrics). F_1-scores were higher for BERT and XLNet than for TF-IDF and SVM for all relevant categories, with clear differences for some categories (suicidal, coping, and awareness) and very small differences for others (suicide cases and prevention). For BERT and XLNet, F_1-scores were almost identical for all categories. BERT yielded higher precision for coping and prevention tweets, 2 crucial categories for a follow-up publication (Niederkrotenthaler et al, unpublished data, May 2022; see Multimedia Appendix 1 for details). Therefore, we chose BERT as the model to make predictions for further analyses. It should be noted here that CIs are quite large because of the limited size of the test set per class and entirely overlap for BERT and XLNet and somewhat overlap for most categories with TF-IDF and SVM. Nonetheless, the performance scores in the 5 runs of BERT and XLNet were higher than those of TF-IDF and SVM in almost all cases for all relevant categories (Table S3 in Multimedia Appendix 1). Only in the case of precision for prevention tweets, TF-IDF and SVM performed similarly well in 3 out of 5 runs.

Overall, BERT correctly classified 73% of the tweets in the test set. F_1-scores lay between 0.70 and 0.85 for the different categories of interest (Table 4 and Figure 3), with the exception of the suicidal ideation and attempt category, with an F_1-score of 0.51. More specifically, recall for suicidal ideation and attempt was relatively low (0.45), indicating difficulties in detecting all such tweets, whereas precision was higher, with 0.58. All performance scores were particularly good (>0.81) for prevention tweets and high for tweets about suicide cases (>0.75). For coping tweets, BERT achieved very high precision (0.76) but lower recall (0.69), which resembles the pattern observed for suicidal tweets. Performance scores for awareness tweets were approximately 70%.

Table 3. Macroaveraged performance metrics and accuracy cross all 6 categories on the validation and test set.

Model	Validation set (n=513)				Test set (n=641)			
	Precision	Recall	F_1	Accuracy	Precision	Recall	F_1	Accuracy
Majority classifier	0.07	0.17	0.10	0.45	0.07	0.17	0.10	0.44
TF-IDF[a] and SVM[b]	0.61	0.63	0.62	0.66	0.61	0.65	0.62	0.66
BERT[c,d]	0.73	0.71	0.71	0.76	0.72	0.69	0.70	0.73
XLNet[d]	0.74	0.73	0.73	0.77	0.71	0.71	0.71	0.74

[a] TF-IDF: term frequency-inverse document frequency.

[b] SVM: support vector machine.

[c] BERT: Bidirectional Encoder Representations from Transformers.

[d] Given that the performance of both deep learning models with fixed seeds and parameters varied slightly from run to run owing to internal segmentation, we ran these models 5 times. We report the average of all 5 runs in this section and include the metrics for each individual run in Table S2, in Multimedia Appendix 1.

Table 4. Intraclass performance metrics on the test set.

Category	TF-IDF[a] and SVM[b]			BERT[c,d]			XLNet[d]		
	Precision (95% CI)	Recall (95% CI)	F_1	Precision (95% CI)	Recall (95% CI)	F_1	Precision (95% CI)	Recall (95% CI)	F_1
Suicidal ideation (n=57)	0.32 (21.93-43.58)	0.44 (30.74-57.64)	0.37	0.58 (43.25-73.66)	0.45 (32.36-59.34)	0.51	0.60 (46.11-74.16)	0.54 (40.66-67.64)	0.55
Coping (n=42)	0.44 (31.55-57.55)	0.64 (48.03-78.45)	0.52	0.76 (59.76-88.56)	0.69 (52.91-82.38)	0.72	0.71 (54.80-83.24)	0.74 (57.96-86.14)	0.73
Awareness (n=63)	0.65 (51.60-76.87)	0.62 (48.80-73.85)	0.63	0.71 (58.05-81.80)	0.70 (56.98-80.77)	0.70	0.69 (56.74-79.76)	0.74 (62.06-84.73)	0.72
Prevention (n=91)	0.83 (74.00-90.36)	0.82 (73.02-89.60)	0.83	0.81 (71.93-88.16)	0.89 (80.72-94.60)	0.85	0.82 (72.27-88.62)	0.87 (78.10-93.00)	0.84
Suicide cases (n=103)	0.70 (60.82-78.77)	0.74 (64.20-81.96)	0.72	0.75 (65.14-82.49)	0.77 (67.34-84.46)	0.76	0.78 (68.31-85.52)	0.75 (65.24-82.80)	0.76
Irrelevant (n=285)	0.74 (67.78-79.18)	0.63 (57.27-68.77)	0.68	0.64 (57.76-69.11)	0.65 (59.06-70.45)	0.64	0.68 (61.96-73.46)	0.64 (57.99-69.44)	0.66

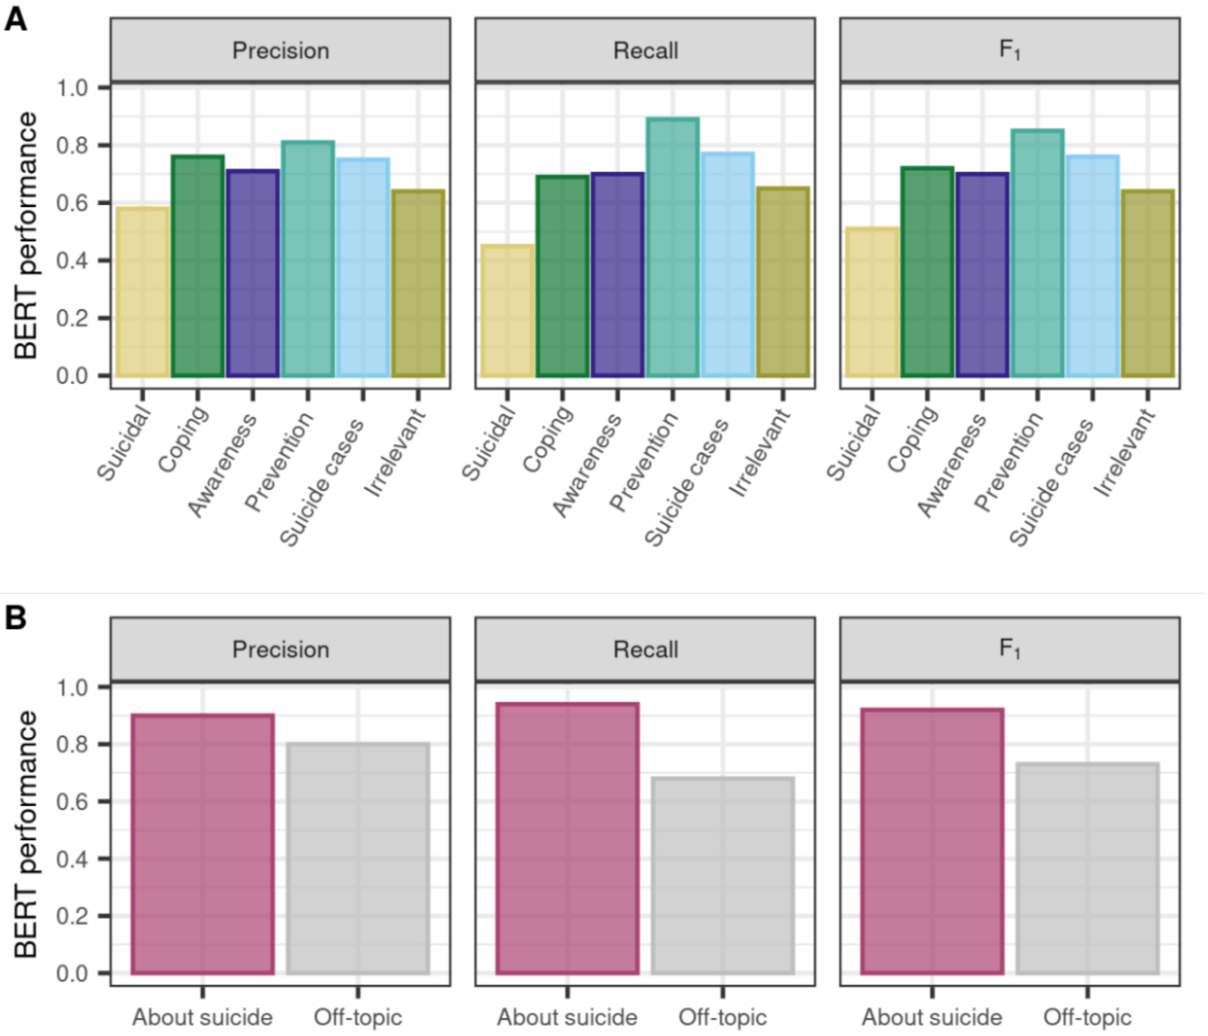
[d] Scores are averages across 5 model runs for BERT and XLNet. Table S3 in Multimedia Appendix 1 shows separate runs.

Figure 3. Performance scores per category for Bidirectional Encoder Representations from Transformers (BERT) for the 6 main categories (A) and for tweets about actual suicide versus off-topic tweets (B).



Task 2: About Actual Suicide

Best performances for separating tweets about actual suicide from off-topic tweets (Table 5) were observed with BERT. However, XLNet performances were very similar, with largely overlapping CIs. With TF-IDF and SVM, recall for about suicide tweets and precision for off-topic tweets were significantly lower than the deep learning scores, whereas precision for about suicide and recall for off-topic was not significantly different. The model with overall highest scores, BERT, correctly labeled 88.5% of tweets as about suicide versus off-topic, with very similar scores on the validation and test sets. F_1-scores for about suicide versus off-topic tweets in the test set were 0.92 and 0.73, respectively (Table 6). All metrics were at least 10% higher for tweets about suicide than for the off-topic tweets. In particular, recall was very high for tweets about suicide (94%), which indicates that volume estimates for tweets related to suicide would be quite complete. The precision for tweets about suicide was 90%, indicating that positive predictions of the model were very reliable.

Table 5. Macroaveraged performance metrics and accuracy for task 2 (about suicide vs off-topic) on the validation and test sets.

Model	Validation set (n=513)				Test set (n=641)			
	Precision	Recall	F_1	Accuracy	Precision	Recall	F_1	Accuracy

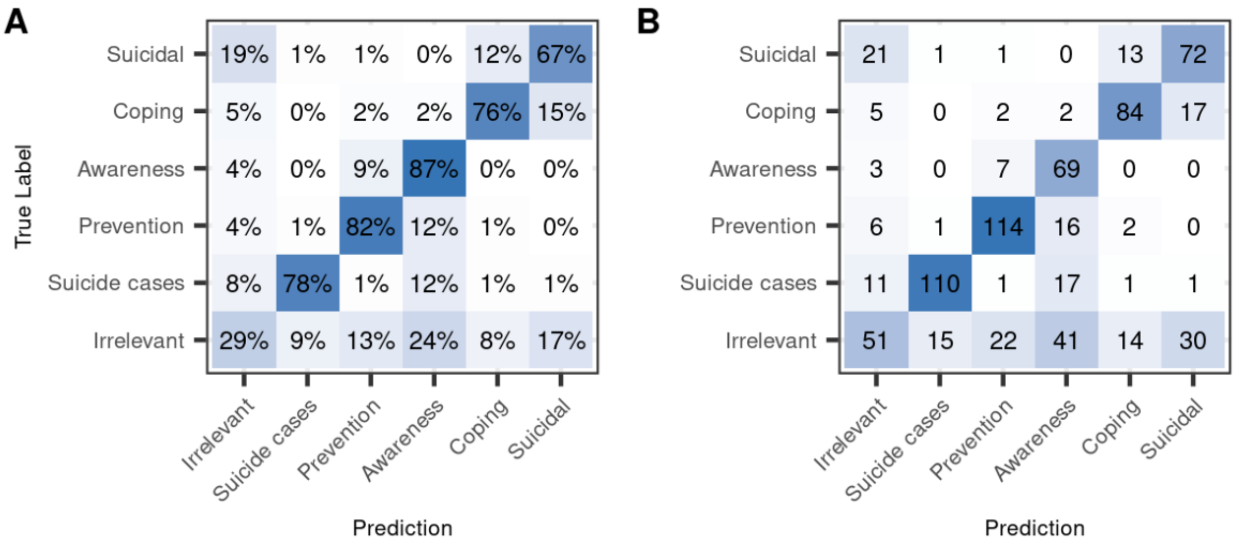
Comparing Model and Human Interrater Reliability

Task 1: 6 Main Categories

The interrater reliability (Cohen κ) for the 6 main categories was 0.70 (95% CI 0.67-0.74) between 2 human coders and 0.60 (95% CI 0.56-0.64) and 0.63 (95% CI 0.59-0.67) between each human coder and the BERT model, respectively. The lower agreement with BERT compared with between humans was mainly driven by the irrelevant class. Excluding it from analysis yielded κ=0.85 (95% CI 0.82-0.89) between human raters and κ=0.81 (95% CI 0.77-0.85) and 0.80 (95% CI 0.76-0.84) between BERT and each human rater. These overlapping CIs indicate a nonsignificant difference and show that BERT achieved near human-level accuracy for the relevant categories.

Precision and recall comparisons between model and human performance per tweet category are shown in Table S6 in Multimedia Appendix 1, and the confusion matrix for coder 1 and BERT is shown in Figure 4. First, we report the metrics for the model versus each coder, with the coder as the ground truth. Second, we report the same metrics for coder 2 compared with coder 1 as the ground truth. Model precision was clearly lower than between-human precision for *suicidal ideation and attempts* and *awareness* messages, more comparable for *coping stories*, and very similar for *prevention* and *suicide case tweets*. Recall is clearly higher between human raters for *suicidal and coping* stories and similar for *suicide cases*. For awareness and prevention tweets, the model actually achieves better recall than human coders. Thus, the model seems quite good at detecting awareness tweets but is not very precise in return.

Figure 4. Confusion matrix of true and predicted labels in the reliability data set. (A) percentages and (B) count of tweets per true and predicted category. The diagonal from bottom left to top right represents correct predictions. True labels are labels by coder 1, and predicted labels are by Bidirectional Encoder Representations from Transformers (BERT).



Task 2: About Actual Suicide

When categorizing tweets as being about actual suicide versus off-topic, human interrater reliability was κ=0.44 (95% CI 0.29-0.58) compared with κ=0.15 (95% CI −0.07 to 0.37) and κ=0.21 (95% CI −0.01 to 0.44) between each coder and BERT. These low κ coefficients were mainly driven by low performances for the irrelevant off-topic category between both human coders (coder 1-coder 2: precision=0.52, recall=0.44, and F_1=0.48), which were even lower when comparing human to model labels (coder 1-BERT: precision=0.26, recall=0.13, and F_1=0.17; coder 2-BERT: precision=0.39, recall=0.16, and F_1=0.23). In contrast, the performance for the suicide category was very high when comparing human labels (precision=0.96, recall=0.97, and F_1=0.96), as well as when comparing human and model labels (coder 1-BERT: precision=0.94, recall=0.98, and F_1=0.96; coder 2-BERT: precision=0.94, recall=0.98, and F_1=0.96). This shows that the 2 coders and the model agreed which tweets were about actual suicide and detected most tweets that the other coder had labeled as about suicide. However, they agreed less when judging whether a tweet was not about actual suicide, hinting at the inherent difficulty of judging whether something is serious, sarcastic, or metaphorical. In any case, for future studies correlating tweets about suicide with behavior in the population, only the about suicide category, which can be reliably detected by humans and the machine learning model, is relevant.

Error Analysis

Figure 4 shows the confusion matrix of the true and predicted labels for BERT for the 6 main categories in the reliability data set. Most misclassifications were predictions of the label irrelevant. Such false negatives are less problematic than misclassifications between relevant categories, as we prioritized precision over recall. Among the relevant categories, there were 5 cases in which coder 1 and the model labeled >9 but a maximum of 15% of tweets differently: (1 and 2) confusions between coping and suicidal tweets in both directions, (3 and 4) confusions between awareness and prevention tweets in both directions, and (5) tweets about suicide cases misclassified as awareness tweets.

For the 13 “true” suicidal labels where coder 1 and the model disagreed (12% of the 108 suicidal tweets), only 2 of the model labels were clear errors, all other tweets were ambiguous. Coder 2 and the model agreed on the coping label for one-third of these tweets (4/13, 31%), indicating the difficulty of clearly separating personal stories about suicidal ideation and coping even for humans. The model’s label more closely matched the category definition than coder 1’s label in at least 5 of the 13 cases (38.4%). Many of the ambiguous tweets described suicidal ideation in the past, implicitly hinting that the suicidal phase was over when the tweet was written. Out of 17 misclassifications of coder 1’s coping tweets (15% of the 110 coping tweets), coder 2 and the model agreed on the suicidal label in 6 cases (35.2%), suggesting that many of these misclassified tweets were ambiguous. Although 12 of these 17 (71%) misclassifications were actual model errors, most of them were understandable, given that coping was described implicitly by means of suicidal ideation in the past or that strong suicidal ideation was expressed along with a way in which the person deals with it.

Misclassifications of awareness as prevention tweets (7/79, 9%) were errors by coder 1 rather than the model in 4 of 7 cases (57%), indicating that model performances are higher for awareness tweets as the scores in Table 3 suggest. In contrast, when the model labeled prevention tweets as awareness, these were mostly clear mistakes (only 3 out of 16, 19%, were ambiguous errors by the coder). Finally, suicide cases mislabeled as awareness were mostly actual errors by the model, but ambiguous in 4 out of 17 cases (24%) and actually correct in 2 out of 17 cases (12%).

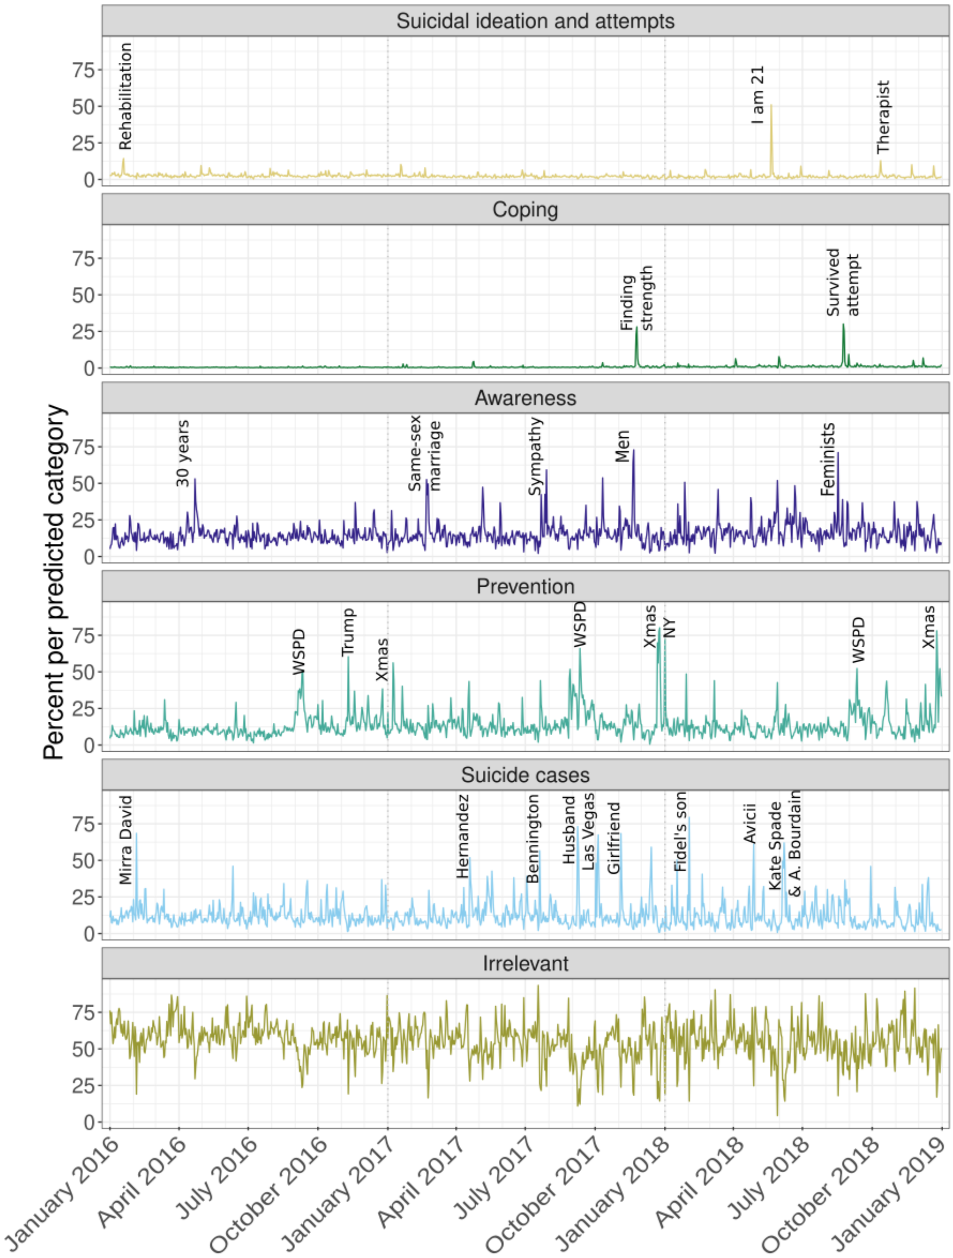
There was further a strong confusion between stories of suicidal ideation and a particular type of irrelevant tweet: tweets manually labeled as not serious or unclear if serious (dimension 3 in Multimedia Appendix 2). Of all tweets predicted to be personal stories of suicidal ideation or attempts, 10.8% (13/120) were not serious or were unclear, compared with only 1%-4% in the other predicted categories. Of all nonserious or unclear tweets, 45% (18/40) were correctly classified as irrelevant, 32% (13/40) were wrongly classified as suicidal compared with 3%-10% wrongly assigned to the other categories. The 13 (32%) nonserious tweets that were misclassified as suicidal included 4 exaggerations, 2 sarcastic remarks, 2 tweets with song lyrics or band names with the terms suicidal ideation or thoughts, 1 metaphoric use, and 2 statements about not being suicidal.

Face Validity Check With Daily Time Series Peaks per Category

Figure 5 illustrates the daily percentage of tweets in each predicted category in the prediction data set. As a face validity check, we identified the events that were mainly associated with each of the largest peaks in the time series of tweets per predicted category. These events are labeled with the following keywords in Figure 5: (1) *Suicidal ideation and attempts*: rehabilitation—4000 retweets of a rather sarcastic tweet from someone getting "punished" in rehabilitation because he said "fucking lit" that another patient was about to commit suicide; I am 21—a personal story retweeted 2200 times, describing someone's successful journey from a difficult childhood, through a long suicidal crisis, to a University degree and a full time job, falsely labeled as suicidal, as it describes not just a suicidal crisis, but also coping; therapist—900 retweets of someone reporting no suicidal thoughts as their therapist asked, although they have them very frequently. (2) C*oping*: finding strength—approximately 6000 retweets of a story of someone finding strength 3 weeks after a suicide attempt; survived attempt—a marine corps Veteran with posttraumatic stress disorder tweets about his survived suicide attempt, approximately 5000 retweets. (3) *Awareness*: sympathy—a tweet saying people who died by suicide need care while still alive, rather than sympathy when they are dead, retweeted 3500 times; men—7000 retweets of a tweet mentioning that suicide is the largest cause of young men; feminists—6000 retweets of a tweet saying that feminists who want equality should also consider that boys are double as likely to die from suicide than girls; 30 years—retweets and discussion of a federal data analysis results that suicide in the United States had risen to the highest levels in nearly 30 years; same-sex marriage—many tweets on research finding that suicide rates drop after legalization of same-sex marriage. (4) *Prevention*: Trump—increased calls to suicide hotline after Trump's election. (5) *Suicide cases* [44]: Aaron Hernandez (American football player); Chester Bennington (singer of Linkin Park); husband—retweets of tweet by a woman remembering her husband's suicide; Las Vegas—many retweets of a reply correcting a tweet by Trump, by stating that the shooter killed himself; girlfriend—many retweets of a tweet about a girlfriend who killed herself; Fidel's son—Fidel Castro Diaz-Balart; NY—new year; WSPD—World Suicide Prevention Day; and Xmas—Christmas.

For coping, prevention, and suicide case tweets, all highly frequent tweets were correctly classified tweets. Both highly shared coping tweets were from individuals who had survived a suicide attempt. Prevention peaks were related to the yearly World Suicide Prevention Day, to increased prevention efforts around Christmas and the New Year, and to increased lifeline calls after Trump's election [45]. All the identified peaks of tweets about suicide cases were related to actual instances of someone taking their own life. For awareness tweets, all but one peak were driven by actual awareness tweets. This single tweet (labeled same-sex marriage in Figure 3) was ambiguous, as it reported a research finding similar to a typical awareness tweet, but the finding was somewhat prevention related. Most awareness peaks were driven by tweets that cite a statistic about suicides. Of the tweets driving the 3 largest peaks in the suicidal category, only 1 was clearly suicidal ideation, another was a somewhat cynical tweet about someone else wanting to commit suicide, and a third was a clear confusion with an actual coping tweet. Thus, this face validity check reflects the high precision of the model for prevention, awareness, and coping tweets, as well as the lower performance for suicidal ideation and attempt tweets.

Figure 5. Daily percent of tweets per predicted category in the predictions data set (n=7.15 million). The daily value subsumes original and retweets per category. Key words for event peaks are explained in the main text.



Discussion

Overview of This Study

Owing to the effort required for manual annotation of texts, previous research on media and suicide prevention was limited by small sample sizes or by data sets put together using keyword search. Keywords either capture only a particular type of text (eg, containing celebrity names) or lump together a variety of different texts that contain broad search terms (eg, "suicide" [2,10-12]) In addition, research on the correlation of social media content with suicide cases in the population remains extremely scarce [9-13]. This study extends media research on suicide prevention by focusing on a broad range of suicide-related content on social media and by developing a reliable and efficient content labeling method based on machine learning, enabling fine-grained analysis of large data sets. We first developed a comprehensive annotation scheme for suicide-related content that includes new content types more typical on social than traditional media, such as personal stories of coping or suicidal ideation, or calls for action addressed at follower networks. On the basis of this systematic labeling scheme, we then tested the ability of different machine learning algorithms to distinguish 5 content types that seem particularly relevant based on previous research [2,4,6,30]. We further applied these methods to separate tweets about actual suicide, that is, in the meaning of someone taking their own life, from tweets that use the word suicide in some other way or context (binary classification). Our results for these 2 classification tasks show that machine learning methods, particularly deep learning models, achieve performances comparable with both human performance and with state-of-the-art methods in similar tasks [24,46].

This study is one of the first to automatically classify social media data other than suicidal ideation into categories relevant for suicide prevention. Only 3 studies, 2 (67%) of which used the same data set, have previously applied machine learning to distinguish specific types of social media posts other than suicidal ideation [9,24,25]. We extend these studies in several ways. Rather than classifying emotions in tweets about specific celebrities [9] or using a relatively small set of 816 tweets put together with a focus on suicidal ideation and celebrity names [24,25], we trained models to categorize any type of tweets containing suicide-related terms in a much larger data set than in previous studies. Furthermore, our larger data set enabled us to use deep learning models that can account for differences in the meaning of words across contexts, rather than only considering word frequencies. Finally, our annotation scheme introduced more fine-grained and particularly prevention-relevant categories. Specifically, it includes personal coping stories, for which some research on traditional media suggests preventive effects [4-6], and distinguishes awareness from prevention-focused tweets [27].

Principal Findings

Regarding the machine learning results, pretrained deep learning models fine-tuned to our data clearly outperformed a naïve majority classifier and a linear SVM classifier based on the word frequency representation TF-IDF. BERT and XLNet achieved F_1-scores of 0.70 and 0.71 in the 6-category classification and 0.83 and 0.81 in the binary about suicide versus off-topic classification in the test set. These scores were only slightly lower or even identical to those in the validation set, indicating good generalization to novel data. The clear advantage of deep learning models over TF-IDF and SVM suggests that there is crucial information about meaning in the context of words beyond what mere word frequencies can capture in tweets about suicide. Performance of the deep learning models was better than the more traditional approaches, but was very similar between BERT and XLNet. Advantages of XLNet over BERT include its ability to learn from long contexts and to consider dependencies between all words in the sentence. It seems that these advantages cannot be fully exploited given the limited number of words in tweets.

The 6 investigated tweet categories separated five important categories, including personal stories about either (1) coping or (2) suicidal ideation and attempts, calls for action that spread (3) problem awareness or (4) prevention-related information and (5) tweets about suicide cases, from other tweets (6) irrelevant to this categorization. The performance scores per category were nearly indistinguishable for BERT and XLNet. The model that performed better depended on the metric and the category and varied between model runs. BERT had slightly higher precision than XLNet for 2 important categories for a follow-up publication Niederkrotenthaler et al, unpublished data, May 2022; see Multimedia Appendix 1 for details) and was therefore chosen as the model to make predictions and test reliability. Although our data set included a much broader set of tweets than previous studies focusing on similar prevention-related tweet categories [24,25], our machine learning performances were comparable or better than in these previous studies, with the exception of the suicidal ideation category.

In general, BERT and XLNet were better at classifying tweets that are also easier to distinguish for humans, including more homogeneous classes such as prevention and suicide cases. These often included similar keywords, such as prevention, hotline, lifeline, or the phrase “committed/commits suicide” (see word clouds in Multimedia Appendix 1). For these categories, BERT performance was very similar to the human interrater performances. BERT and human performance were also comparable for coping stories. The model’s performance was lower only for more subjective classes such as suicidal ideation and attempt stories. Error analysis suggests confusions with sarcastic, joking, exaggerated, or metaphorical uses of the word suicide as one part of the explanation. Such nonserious messages are difficult to distinguish from genuine suicidal ideation for both the model and humans. The gap between human and model performance is the largest for suicidal tweets, suggesting that this distinction is even more difficult for the model. Both humans and the model missed many ambiguous expressions of suicidal ideation (low recall). In contrast, between-human precision is much higher than the model’s precision. This shows that there are many suicidal ideation tweets that humans can clearly identify, whereas model reliability can still be improved for these types of tweets.

The analysis of the most common model errors demonstrates that the mistakes were mostly not trivial. Most confusions of suicidal and coping tweets by the model were tweets in which the feelings of the tweet author were quite ambiguous. This suggests that much higher performance scores are difficult to achieve for these personal stories about suicide. Nonetheless, for tweets about suicidal ideation in the past, which implicitly express that coping occurred, there may be room for improvement through adding more training examples. Furthermore, the error analysis suggests possible improvements for tweets regarding prevention and suicide cases. In contrast, the model actually helped detect errors by the human coder for awareness tweets labeled as prevention.

When distinguishing tweets about actual suicide from off-topic tweets, the model achieved excellent performance scores, particularly for tweets about actual suicide, with no difference between the 2 deep learning models. In other words, tweets labeled as “about suicide” are reliably actual tweets about suicide, and most such tweets are detected by the models. Thus, the use of any of these models for future research is very promising.

Using the final BERT models for both classification tasks, we estimated the percentage of tweets per category out of all suicide-related tweets in the United States from 2016 to 2018. Overall, approximately 6% were personal stories of concerned individuals, with approximately 5% on suicidal ideation or attempts and approximately 1% on coping stories. Estimates for awareness, prevention, and suicide case tweets were approximately 22%, 16%, and 16% of tweets, respectively. We plotted the daily volume per tweet category and investigated tweets during peaks in the time series. Most of these tweets were correctly classified by our models, and peaks often coincided with events matching a particular category (eg, the World Suicide Prevention Day or a celebrity suicide), which highlights the face validity of our model predictions. Finally, approximately three-fourths of all suicide-related tweets actually referred to someone taking their own life, whereas the rest used the term in another meaning or context (eg, euthanasia, suicide bombers, jokes, metaphors, and exaggerations).

Limitations and Future Work

Despite our data set being more comprehensive than any existing data set on the topic, one of the limitations of our study is the size of the training data set, which is crucial for training deep learning models. In particular, this concerns the rarer categories that we have not yet used for machine learning in this study (eg, bereaved experiences and lives saved). The data set could further benefit from adding more examples of coping messages that describe suicidal ideation and behavior in the past, thereby implicitly indicating coping (see category definition in Multimedia Appendix 2). Furthermore, some tweets in the categories suicide other and off-topic might warrant to be investigated separately, given recent findings of the possible protective effects of flippant remarks and humor or negative portrayals of suicide in the form of murder-suicides [11]. Similarly, the suicide case category may warrant being separated into suicide news and condolence messages, which may have protective effects [9], and tweets about suicide cases may warrant filtering out those about celebrities [2]. Higher classification performance for the category suicidal ideation in the study by Burnap et al [24] showed that a focus on this category during data collection could improve our model.

Finally, a number of limitations apply to automated text analyses, such as machine learning. First, there are no traces of images, videos, or content of the URLs shared in the text of tweets, although this additional information can crucially affect the meaning of a tweet. Second, some things are only implicitly expressed or very subjective, and thus difficult to capture with such methods, but also difficult to reliably recognize for humans. For instance, it is difficult to clearly differentiate coping from suffering, even for humans who have some knowledge about how such experiences look like in the real world. It is even more difficult to capture such subjective experiences using word frequencies. Deep learning models such as BERT and XLNet, having been trained on huge amounts of text produced by humans, may be able to capture some of these nuances but require large amounts of training examples. Third, a machine learning model can only recognize example tweets that are sufficiently similar to the examples in the training set and only predict the predefined categories. In contrast, a human coder might recognize new ways of expressing the same meaning or the need to introduce a new category. We partially addressed the latter limitation through an extensive labeling process, ensuring that we captured all typical message categories by including a random set of tweets. Nonetheless, including more and different examples for suicidal ideation and coping stories in future studies would likely improve model performance.

Conclusions and Practical Implications

The field of media and suicide research has only recently begun to evolve to consider social media content as relevant in the assessment of media effects. This study makes 2 major contributions to this field. First, it provides a systematic overview of different content types that are common on social media, which may be useful as a content labeling scheme for future research on the topic. Some of the categories identified have been found to be relevant to suicide prevention, particularly in other media types. For social media content, these associations with indicators of behavior, particularly suicidal behaviors and help-seeking, remain to be tested accordingly. Second, the machine learning methods enable researchers to assess large amounts of social media data and subsequently correlate it with available behavioral data of interest; for example, suicides or help-seeking data. In this way, this work enables systematic large-scale investigations of associations between these behaviors and fine-grained message characteristics of social media posts (eg, Niederkrotenthaler et al, unpublished data, May 2022; see Multimedia Appendix 1 for details). Such large-scale investigations will contribute to accumulating robust evidence on which characteristics are actually harmful and protective. Furthermore, future applications of the developed models might include the screening of social media content to detect other types of content associated with suicide cases that have not been described in previous research. The classification performances of the developed models demonstrate the strong potential of machine learning, particularly deep learning, for media suicide effects research.

Acknowledgments

This study was supported by Project V!brant Emotional Health grant “Suicide Prevention media campaign Oregon” to TN and a grant from the Vienna Science and Technology Fund to DG (grant VRG16-005). The authors would like to thank Konstantin Hebenstreit for assistance with data collection and cleaning.

Data and Code Availability

The data sets generated and analyzed during this study are available on GitHub. The code and data for the statistical analyses and figures (intercoder reliability and frequency of categories) as well as CIs for machine learning are available on the web [47]. The code for training the machine learning models is available on the web [48]. Raw data only include tweet IDs, not tweet text, to protect the identity of the tweet authors. Tweets can be redownloaded via the Twitter API using these IDs.

Conflicts of Interest

None declared.

Abstract

Background: The COVID-19 pandemic caused a critical public health crisis worldwide, and policymakers are using lockdowns to control the virus. However, there has been a noticeable increase in aggressive social behaviors that threaten social stability. Lockdown measures might negatively affect mental health and lead to an increase in aggressive emotions. Discovering the relationship between lockdown and increased aggression is crucial for formulating appropriate policies that address these adverse societal effects. We applied natural language processing (NLP) technology to internet data, so as to investigate the social and emotional impacts of lockdowns.

Objective: This research aimed to understand the relationship between lockdown and increased aggression using NLP technology to analyze the following 3 kinds of aggressive emotions: anger, offensive language, and hate speech, in spatiotemporal ranges of tweets in the United States.

Methods: We conducted a longitudinal internet study of 11,455 Twitter users by analyzing aggressive emotions in 1,281,362 tweets they posted from 2019 to 2020. We selected 3 common aggressive emotions (anger, offensive language, and hate speech) on the internet as the subject of analysis. To detect the emotions in the tweets, we trained a Bidirectional Encoder Representations from Transformers (BERT) model to analyze the percentage of aggressive tweets in every state and every week. Then, we used the difference-in-differences estimation to measure the impact of lockdown status on increasing aggressive tweets. Since most other independent factors that might affect the results, such as seasonal and regional factors, have been ruled out by time and state fixed effects, a significant result in this difference-in-differences analysis can not only indicate a concrete positive correlation but also point to a causal relationship.

Results: In the first 6 months of lockdown in 2020, aggression levels in all users increased compared to the same period in 2019. Notably, users under lockdown demonstrated greater levels of aggression than those not under lockdown. Our difference-in-differences estimation discovered a statistically significant positive correlation between lockdown and increased aggression (anger: P=.002, offensive language: P<.001, hate speech: P=.005). It can be inferred from such results that there exist causal relations.

Conclusions: Understanding the relationship between lockdown and aggression can help policymakers address the personal and societal impacts of lockdown. Applying NLP technology and using big data on social media can provide crucial and timely information for this effort.

Introduction

Background

On March 13, 2020, the United States declared a state of emergency in response to the COVID-19 pandemic. Many states imposed lockdown measures to slow down the spread of the virus. However, lockdown (stay-at-home) policies affect many aspects of human life. The frustration and loneliness people experience under extended periods of confinement may predictably have negative psychological impacts [1-3]. Furthermore, frustration can manifest itself through increased aggressiveness [4]. In a time when people live closely beside intimate family members, emotional problems, such as suicidal thoughts and aggressiveness, may lead to destructive behaviors and have an immediate impact on society [5,6]. Whether scientific investigations corroborate such observations can have significant policy implications for public or private governance. Unsurprisingly, the relationship between lockdown and adverse psychological effects has attracted increasing attention from multiple disciplines of researchers. However, there have been few robust tests of the causal relationship between lockdown and aggressive emotions. This research used machine learning to produce robust data. Then, we used a statistical difference-in-differences analysis to estimate the causal relationship between lockdown and increased online aggression. The application of machine learning technologies in social science research can provide new information in a much broader scope at a much higher speed.

Related Works

Negative Impacts of Lockdown

At the individual level, studies have shown that lockdown is associated with suicidal ideation, anxiety disorder, nightmares, depression, loneliness, and poor mental health [7-12]. At the societal level, a lockdown's adverse effects are manifested through significant increases in divorces, sexual violence [13], and domestic violence [14]. All these effects pose considerable threats to the stability and well-being of individuals and society. Therefore, it is an urgent task to understand these harmful actions under COVID-19 lockdowns.

Other research in psychology has focused on the deterioration of mental health before and under lockdown [7]. The authors observed an increase in certain health behaviors 1 month into lockdown by comparing prelockdown and postlockdown survey data. However, the authors did not analyze the causal relationship between lockdown and these behaviors.

Emotion is one of the main drivers of human action. It is reasonable that a more aggressive state of mind leads to aggressive behaviors like domestic and sexual violence. The influential frustration-aggression theory [15] suggests that aggressive behavior results from frustration caused by thwarting individual goals. In the early months of the pandemic, lockdown led to many canceled plans and unaccomplished goals. Therefore, a causal relationship between lockdown and increased aggression is reasonable.

Notably, a study investigated the correlation between lockdown and increased aggression [2]. Killgore et al conducted a questionnaire survey [2]. They used the Buss Perry Aggression Questionnaire to measure aggression levels in patients under and not under lockdown during the initial months of the pandemic in the United States. They found a statistically significant increase in the following 4 kinds of aggression between lockdown and nonlockdown groups: physical aggression, verbal aggression, anger, and hostility. However, owing to limitations in traditional questionnaire methods, such as the lack of data before the pandemic, this research could not assess the causal relationship between lockdown and increased aggression. Furthermore, because of practical limitations in survey administration, the authors had to survey different participants in every sampling, which provides an additional source of uncertainty.

COVID-19 Twitter Sentiment Analysis

Online analysis of tweets using natural language processing (NLP) has provided valuable information in health-related research. General sentiment analysis has been performed to examine people's emotions under lockdown [16,17].

Some are related to specific topics, such as vaccination [18-20], while others are related to specific regions or countries [21]. However, most studies did not analyze the relationship between lockdown and emotions to the best of our knowledge. Su et al [22] analyzed the psycholinguistic features in 2 different cities going into lockdown. While this can capture specific rising trends in tweet words, the lexicon frequency analysis method does not capture each word's context. Thus, it cannot predict emotions as accurately as neural network models [23].

Our Study

This paper addresses the weaknesses of the current psychology and NLP research. Most of the recent literature in psychology has not offered meaningful evidence to the causality between lockdown and aggressive emotions. On the other hand, current NLP research in sentiment analysis mainly focuses on optimizing methods for machines to capture emotions in vast volumes of digitalized human discourse. However, the current body of NLP literature in the public health area rarely probes into causal relations of social phenomena.

We used new NLP technology to conduct a virtual longitudinal study of online Twitter users and their tweets to investigate the impacts of lockdowns on the following 3 kinds of aggression: anger, offensive language (offensive), and hate speech (hate). Our infoveillance method allows us to discover trends in aggression levels that can provide important information for policy makers and health professionals. Moreover, data before and after lockdown allows us to estimate the potential causal relationship between lockdown and increased aggression using the difference-in-differences analysis, an established econometric method to understand the causal relationship in nonexperimental time-series data [24]. This interdisciplinary method yields robust results in understanding the relationship between lockdown and increased aggression, and it opens up new potentials for applying NLP and internet technology to support medical research.

Methods

Overview

First, we sampled a group of Twitter users across the United States as our subjects of analysis. Then, we used Twitter's application programming interface to obtain all the tweets the sampled users posted between January 1, 2019, and October 1, 2020. Our objective was to use a neural network model to detect different levels of aggressive emotions during different periods in these tweets. We selected the Bidirectional Encoder Representations from Transformers (BERT) model, a state-of-the-art language model that can understand the meanings of emotions through contexts and nuances better than previous lexicon-based models [23,25]. To train the BERT model for emotion detection, we collected training data based on established data sets [26-28]. Afterward, we classified the tweet emotions using our trained BERT model. We conducted an observational analysis to compare and contrast aggression levels between different geographies, lockdown statuses, and times. After observing an increase in aggression after lockdown, we measured the relationship between lockdown status and aggression levels using the Poisson regression as a difference-in-differences estimation.

Twitter Data Sampling

In the United States, states retain the power to implement lockdown policies. Therefore, this research used the state lockdown status to determine whether an individual user was under lockdown at a particular time. We randomly sampled Twitter users geographically tagged with the states in the United States as our longitudinal internet study participants. After sampling the users, we sampled every tweet they posted in 2019 and the first 6 months after President Trump declared a national emergency in March 2020. Our sampling yielded a spatiotemporal data set of 1,281,362 tweets posted from January 1, 2019, to October 1, 2020, by 11,455 Twitter users. The sampled users came from all across the United States, including users from all 50 states. In this study, we used these tweets to investigate the relationship between lockdown and social media aggressiveness. All tweets followed a data preprocessing protocol [29] before being analyzed by the BERT model for emotion detection.

Training Data Collection

In order to detect aggressive emotions in the tweets, we trained a BERT neural network binary classification model for each of the 3 aggressive emotions. For each model, we collected different training data sets. Our definition of each emotion is identical to that of the training data set. Table 1 contains the definitions for the 3 aggressive emotions, with Table 2 providing sample text for each.

Table 1. Definition for each emotion.

Aggressive emotion	Definition
Anger	A strong feeling of displeasure or antagonism [26]
Offensive language	Speech that contains unacceptable language (profanity) and is potentially harmful to a disadvantaged group [27]
Hate speech	Language that expresses hatred toward a targeted group and is intended to be derogatory, insulting, and humiliating [27,28]

Table 2. Sample text containing each aggressive emotion.

Aggressive emotion	Sample text
Anger	I hope this all ends soon. This is hell
Offensive language	Are people really this stupid?
Hate speech	@user The rot starts from the top......Trumps wankers are all racist......F*ck them all!

Anger

We selected the GoEmotions data set to train the anger classification model [26]. It is one of the largest manually annotated data sets of 58,000 English Reddit comments. In the data set, each sentence is annotated to identify the presence of 28 relatively common emotions. To train the BERT model for binary classification, we selected the 6000 sentences that contain anger and a random sample of 6000 other sentences that do not contain anger. We selected 1000 other annotated comments for testing. Based on GoEmotions, anger is defined as "A strong feeling of displeasure or antagonism."

Offensive Language

Offensive language is speech that contains unacceptable language (profanity) and is potentially harmful to a disadvantaged group. We selected the "Automated Hate Speech Detection and the Problem of Offensive Language" (AHSD) [27] data set as our training data set, which contains 24,802 human-labeled tweets. We randomly sampled 7750 sentences for training and 613 for testing. The study distinguishes hate speech with real harmful intentions from general offensive lexicons. For example, many teenagers often use terms like f*ck and b*tch in a casual manner that does not intend harm. AHSD provides annotated data for offensive language and more harmful hate speech.

Hate Speech

Unlike general offensive language, hate speech is a more specific language that causes intentional harm. To train our hate model, we merged the AHSD data set, as mentioned earlier, with the Large Scale Crowd Sourcing [28] data set, which provides an additional 2067 tweets labeled hateful by humans. We randomly sampled 6450 sentences for training and 639 for testing. Both of these data sets identify hate speech as the language that expresses hatred toward a targeted group and is intended to be derogatory, insulting, and humiliating. This definition has been widely used in previous research [30-32].

Model Training

We used the BERT model [29] to identify emotions in tweets. This pretrained neural network model is one of the most powerful models in emotion understanding. With its abundant pretraining data from the entire English Wikipedia, the model already had a basic understanding of the English language before we conducted the final fine-tuning. The model's contextual embedding allows it to understand words regarding context, taking its language understanding ability beyond traditional lexicon analysis. Our model architecture is constructed under python modules pytorch 1.8.1 and transformer 4.11.0. Using the training data, we obtained great performing models for all 3 of our target emotions (specific statistics are shown below).

Model Evaluation

We first tested our model predictions on the testing set (train-test split). The results are shown in Table 3, along with the confusion matrices in Figure 1. Then, we tested our model on the sampled Twitter data set used for further analysis. To evaluate the model performance on our self-sampled Twitter data, we selected 1080 tweets, 540 from people under lockdown and 540 from people not under lockdown, with 5-6 tweets randomly selected from each week. Then, 2 native English speakers annotated the tweets based on the definition for each emotion above. The Cohen kappa values between annotators and our model's performance are reported in Tables 4 and 5, respectively. Through this, we can validate our model competence on Twitter data used in further down-stream analysis.

Table 3. Model performance on the testing set.

Model	Precision	Recall	F1
Anger	0.869	0.826	0.847
Offensive language	0.953	0.988	0.970
Hate speech	0.956	0.920	0.933

Figure 1. Confusion matrices for our models: anger (A), offensive (B), and hate (C). The bottom-right and top-left quadrants are where the models predicted correctly, which represent true negatives and true positives, respectively. A darker quadrant color indicates greater prediction.

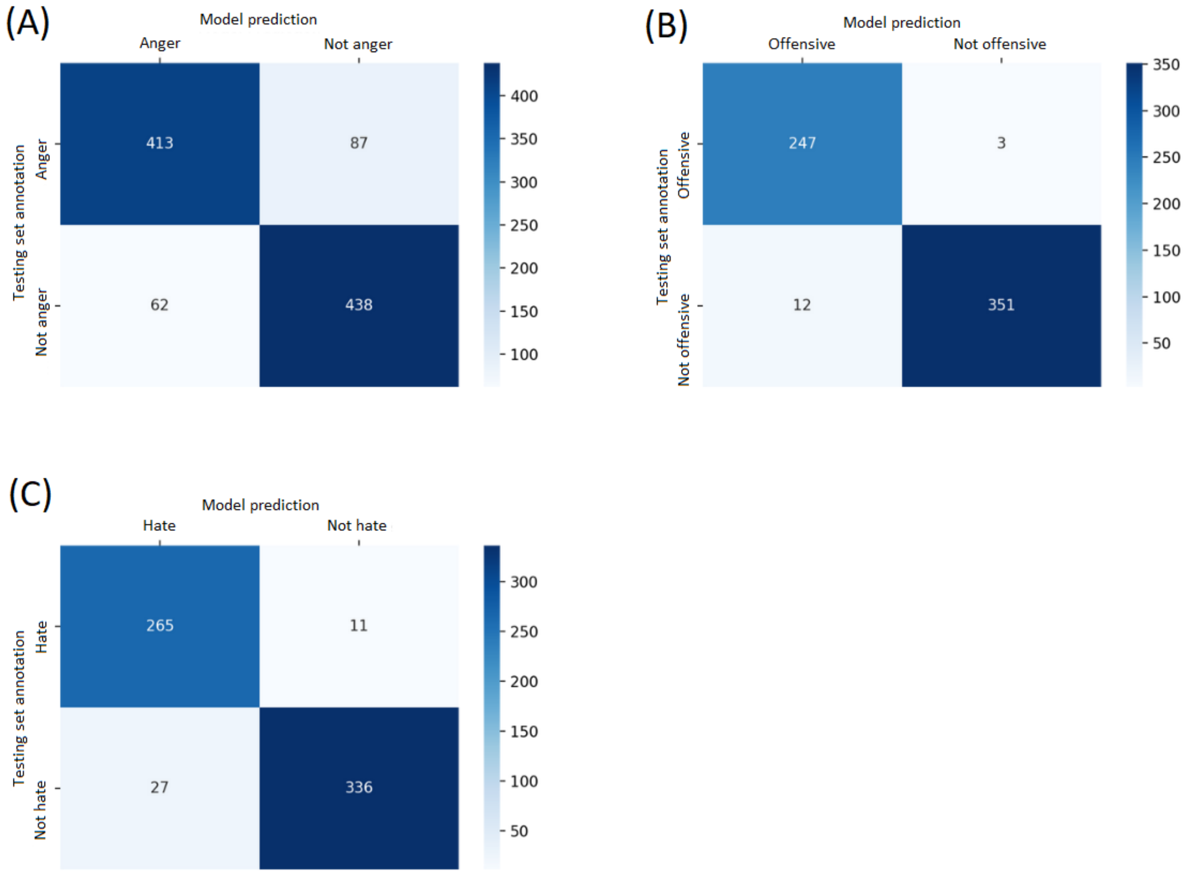

Table 4. Cohen kappa interrater agreement between the raters.

Emotion	Kappa
Anger	0.928
Offensive language	0.937
Hate speech	0.890

Table 5. Model performance on the sampled Twitter data set.

Model	Precision	Recall	F1
Anger	0.795	0.888	0.839
Offensive language	0.843	0.922	0.880
Hate speech	0.810	0.872	0.839

Data Analysis Methods

Overview

To understand aggression levels in tweets, we measured the proportion of tweets that contain aggression among all randomly sampled tweets. First, we used separate BERT models for each aggressive emotion (ie, anger, offensive, and hate) to analyze our sampled Twitter data. The analysis resulted in 3 data sets, one for each aggressive emotion. In each data set, for each of the 50 states, we calculated the percentage of tweets containing the aggressive emotion for the 92 weeks from January 2019 to October 2020. This analysis resulted in 3 data sets with 4600 data points each.

Although our data consist of aggressive tweet counts in different spatiotemporal settings, we analyzed the proportion of aggressive tweets among total tweets, rather than the count of aggressive tweets, to investigate the aggression level on Twitter. This is because an increase in aggressive tweet counts may be due to an increase in total tweets posted, which does not necessarily indicate a higher level of aggression. Measuring the proportion of aggressive tweets more accurately depicts the aggression level on Twitter.

Over 3 stages of observation and analysis, we looked at the data from different perspectives. In the first part, we compared aggression levels between groups of different lockdown statuses in the first 6 months of the pandemic. After that, we focused on the states that had undergone lockdown, and we looked at their aggression levels before and after lockdown. Finally, we used difference-in-differences analysis to estimate the impact of lockdown on the increase of aggression.

Observing the Difference in Aggression Levels Between Groups Under and Not Under Lockdown

To understand the impact of lockdown on aggressive emotions, we investigated the aggressive tweet proportions for each specific time and location, and compared the proportions in people under and not under lockdown. For that purpose, we designed our first objective. For each week in the 92 weeks from January 1, 2019, to October 1, 2020, we separated states under lockdown from those not under lockdown into 2 groups. Then, we separately aggregated the number of aggressive tweets and total tweets. We calculated the aggressive tweet percentage for each of the 2 groups every week for 92 weeks based on the combined data. Note that the users in each state represented the patients under lockdown and not under lockdown based on the state's current lockdown status.

Observing Aggression Trends in States That Had Undergone Lockdown From the Weeks Before and After Lockdown

In the previous section, we observed and compared aggressive emotions between groups under and not under lockdown. In this section, we focused on understanding the trends in states that had undergone lockdown. More specifically, we looked at the increase in aggression after lockdown by comparing data before and after lockdown. We chronologically aligned the data in each lockdown state based on the initial week of lockdown. More specifically, for every state that had ever undergone lockdown, the week that lockdown started was denoted as week 0. Other weeks were numbered accordingly (ie, the first week after week 0 was week 1, the week before week 0 was week −1, and so forth). Using this method, we visualized the increase in aggression after the lockdown. Note that this was solely an observation of aggression trends before and after lockdown. It did not measure the net impact of lockdown status on aggression levels. To specifically measure the impact and investigate the causal relationship, we applied the difference-in-differences estimation in the next section to quantify the difference in aggression levels between the lockdown and nonlockdown groups in a statistical manner.

Difference in Differences Using Poisson Regression

The traditional way to investigate a causal relationship is an experiment conducted on randomly assigned subjects, in which participants are randomly separated into 2 groups. One group receives treatment, and the other does not. However, in many cases, including ours, an experiment is not viable owing to practical or ethical reasons. For example, we cannot randomly assign people and put them under lockdown for an extended time. Some social scientific researchers use multivariate regression to solve this problem, when the independent variable of interest, X, and other correlated variables, Z_1, …, Z_k, act together to determine the outcome, Y. Although this method can control for the effect of the selected Z variables, some other potentially relevant variables might be lacking in data or difficult to identify, leaving a possibility that important variables are not considered. To address this problem, scientists have used the difference-in-differences method.

As Callaway and Sant'Anna indicated, "Difference in differences (DID) has become one of the most popular research designs used to evaluate causal effects in policy interventions" [33]. Difference in differences compares the difference between the treatment group and the control group at a particular time (T1) with that between them at another time (T2), with the 2 times separated by a particular intervention. This method compares the difference at T1 (D_{T1}) with the difference at T2 (D_{T2}) and measures whether the difference between D_{T1} and D_{T2} (difference in differences) has causal relations with the intervention. In short, difference in differences measures whether the intervention causally impacts the difference between D_{T1} and D_{T2} [34]. In this research, the treatment group refers to those Twitter users under lockdown, and the control group refers to those not under lockdown. The intervention is lockdown. Our objective was to compare the difference in the level of aggression between these 2 groups (D_{T2}) with that between the 2 groups before lockdown (D_{T1}) and measure whether the difference between D_{T1} and D_{T2} is causally related to lockdown.

To implement the difference-in-differences estimation in time-series data, we use fixed effect models. Fixed effect models address unseen variables by controlling for the average in each geographic and temporal data group (data group, in short). The average in each data group is constituted by many factors, including those Z variables that we may or may not know. In other words, the effects of the Z variables we need to control are captured in the average of each data group. By subtracting the average from the outcome in each data group, fixed effect models control for the influence of miscellaneous Z variables and measure the net increase in the Y variable to which the X variable contributes. Taking "fixed effect of the states" as an example, the difference in aggression levels caused by different political tendencies and racial compositions was captured in the average aggression level in each state. After subtracting the average, we now measured how aggression levels increased with respect to each state's norm. Models with fixed effects used in this research "come closer than does ordinary regression analysis to achieving unbiased estimates of causal effect" [35].

To implement the fixed effect model above, we needed to add the fixed effects to a regression model best suited for our data. Because our original observation was the number of aggressive tweets posted in a specific spatiotemporal setting, our data represented a type of count data. Therefore, we selected the classic Poisson model for count data with fixed effects [36]. The following equation was initially used:

$$\ln(\mathit{Aggressive\ Tweet\ Count}_{s,t}) = \alpha_0 + \alpha_1 \mathit{under\ lockdown} + \mu_{state} + \sigma_{time} + \varepsilon \quad \mathbf{(1)}$$

In this case, *Aggressive Tweet* $Count_{s,t}$ is the number of aggressive tweets in a specific state (s) under a specific time (t). α_0 is the constant in standard regression models. Variable α_1 signifies the treatment effect of *under lockdown* on the aggressive tweet count. *Under lockdown* is a binary variable (the explanatory variable in this experiment) that has a value of 0 for not under lockdown and 1 for under lockdown. The model also included state and time fixed effects as follows: μ_{state} and σ_{time}. These 2 variables do not have a specific range but rather represent the average of their corresponding groups of data (eg, data in a state or in a specific week). ε is the error term included in all statistical regressions.

As aforementioned, however, an increase in aggressive tweet counts may be due to an increase in the total tweets posted, which does not necessarily indicate a higher level of aggression. Measuring the proportion of aggressive tweets more accurately depicts the aggression level on Twitter. Therefore, to measure the proportion of aggressive tweets using this count-based model, we exposed the estimation to the total number of tweets by adding the term ln(*Total*), with the coefficient fixed to 1, to the equation. This action is designed for situations like ours and is supported by the *exposure()* option in Stata 17 software [37]. More specifically, our equation was now as follows:

$$\ln(Aggressive\ Tweet\ Count_{s,t}) = \alpha_0 + \alpha_1 under\ lockdown + \mu_{state} + \sigma_{time} + \varepsilon + \ln(Total_{s,t}) \quad \mathbf{(2)}$$

To understand the mechanism of how adding $\ln(Total_{s,t})$ allows us to estimate the proportion rather than the count, we can look at the equation in the following way: when we subtract $\ln(Total_{s,t})$ on both sides of the equation, the estimation is equivalent to modeling the proportion of aggressive tweets. The equation is as follows:

$$\ln(Aggressive\ Tweet\ Count_{s,t} / Total_{s,t}) = \alpha_0 + \alpha_1 under\ lockdown + \mu_{state} + \sigma_{time} + \varepsilon \quad \mathbf{(3)}$$

Our model comes closer to capturing the unbiased causal effect of the independent variable of interest on the dependent variable in observational data [35]. Since most other independent factors that might affect the result, such as seasonal and regional factors, have been absorbed by time and state fixed effects, a significant result in this difference-in-differences analysis can not only indicate a concrete positive correlation but also strongly suggest a causal relationship. All analyses were conducted using Stata BE Edition 17.0 (StataCorp).

Results

Observing the Difference in Aggression Levels Between Groups Under and Not Under Lockdown

This analysis compared aggression levels between states under and not under lockdown. The United States declared a state of emergency on March 13, 2020. Among 42 states that had ever imposed lockdown, 40 started lockdown in the 2 weeks between March 20 and April 4, 2020. Figure 2 shows data from April to October 2020, when the pandemic was getting severe in the United States and some states began lockdown. It illustrates the weekly difference in aggression levels between groups under and not under lockdown. Figure 3 zooms out the timeframe to include data from 2019, putting data under the pandemic into a broader perspective.

Figure 2. Weekly aggressive tweet percentages since April 1, 2020, for all 3 aggressive emotions: anger (A), offensive (B), and hate (C). States under lockdown (magenta) and not under lockdown (cyan) are indicated.

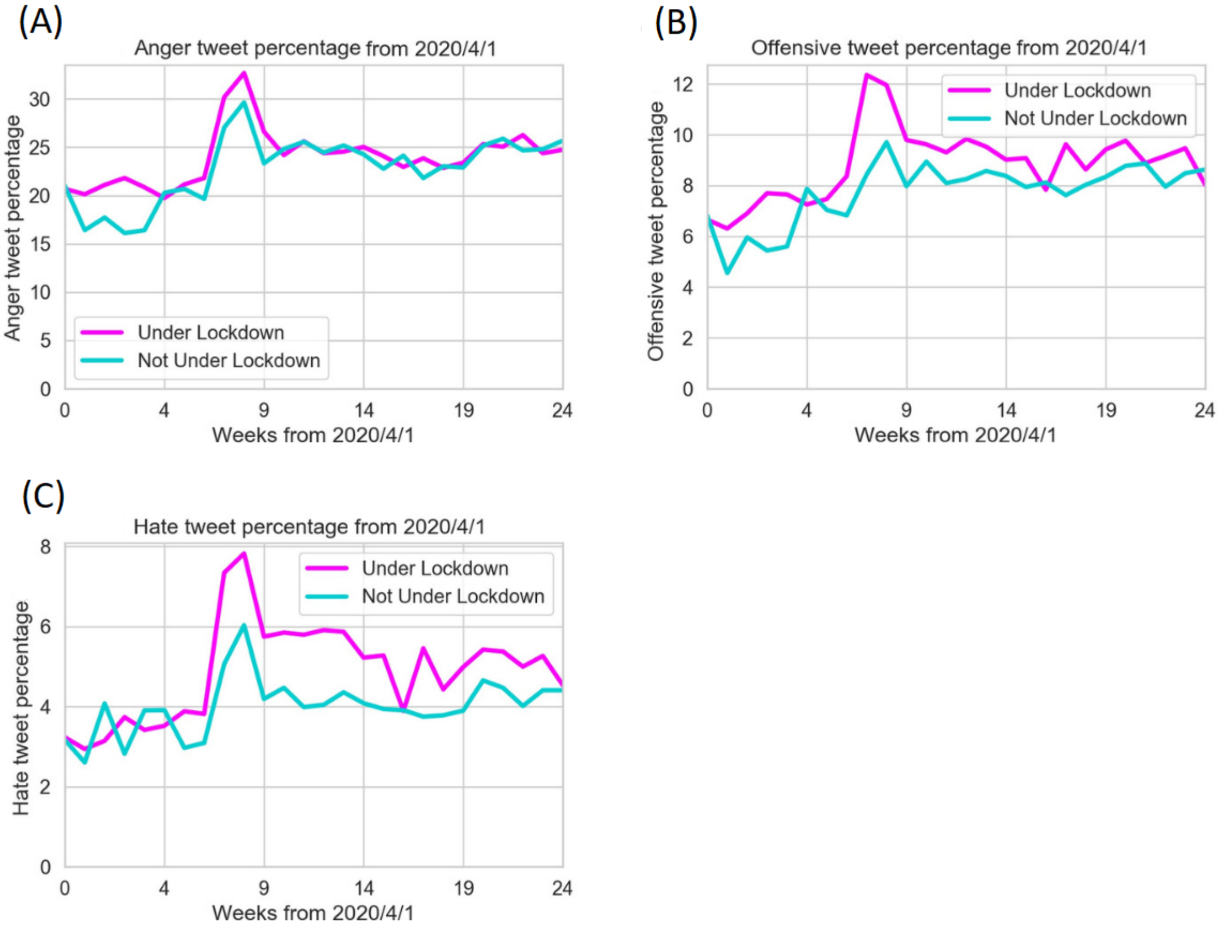

Figure 3. Weekly aggressive tweet percentages since January 1, 2019, for all 3 aggressive emotions: anger (A), offensive (B), and hate (C). States under lockdown (magenta), states not under lockdown (cyan), and data before any lockdown started (yellow) are indicated.

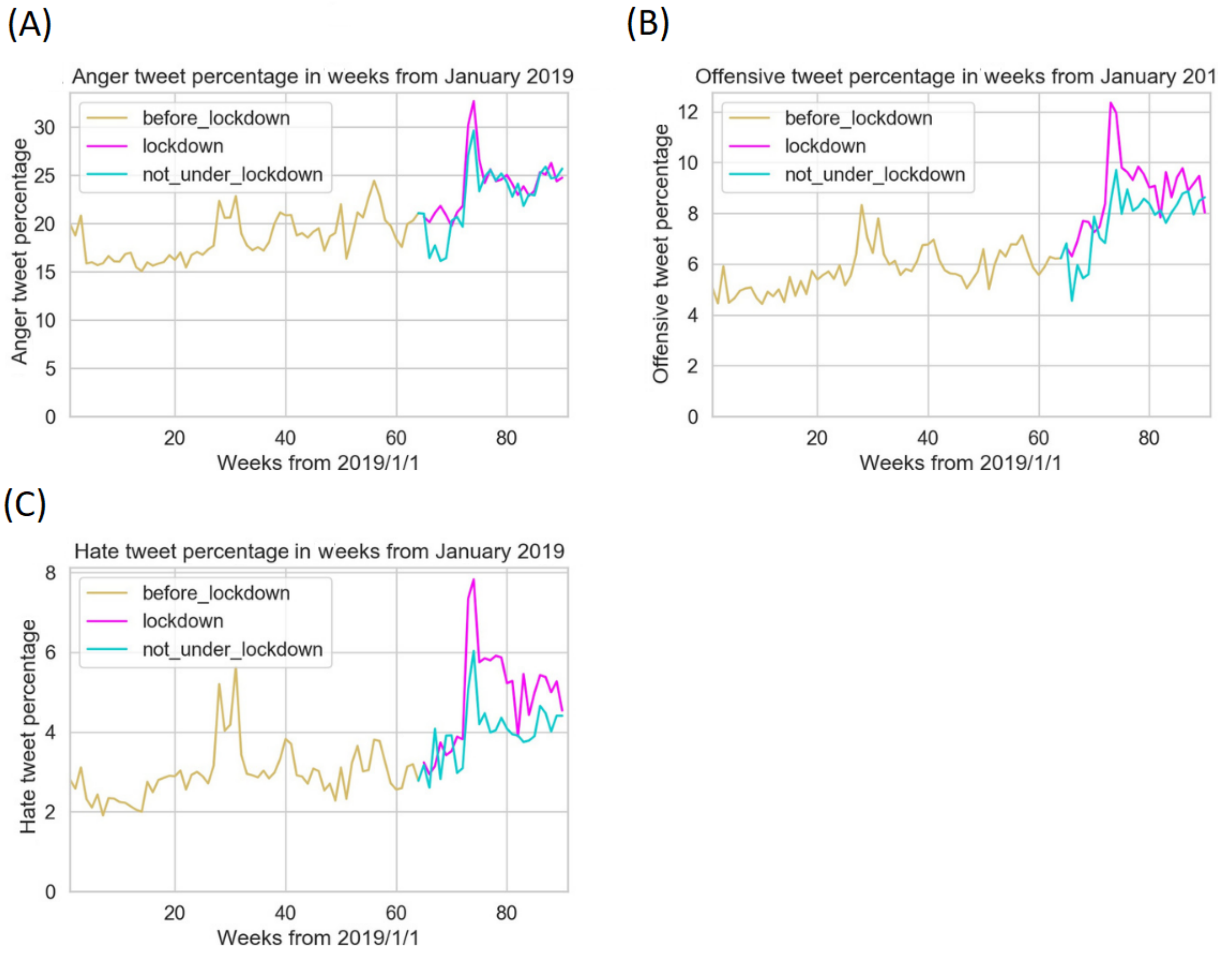


Anger

In terms of the intense feeling of displeasure or antagonism, there was a sudden increase in tweet count in May 2020, particularly evident in those under lockdown. In the first 9 weeks since April, average anger levels were 2%-3% higher in the group under lockdown than in the other group. Figure 3 shows that the percentage of angry tweets fluctuated around 20% in 2019. Coming into May 2020, the percentage rose to as high as 34%. In the summer of 2020, anger levels decreased, and the 2 groups demonstrated similar angry tweet percentages.

Offensive Language

For unacceptable language that can potentially harm a disadvantaged group, tweet proportions increased sharply for 7 weeks since April 2020 (Figure 2). Offensive levels fluctuated around 6% in 2019 (Figure 3). In the 7th week, offensive tweet percentages in under and not under lockdown groups surged to 12.2% and 9.8%, respectively. Afterward, the numbers started to gradually decrease. Although similar trends were seen in both the under and not under lockdown groups, the tweet percentages under lockdown were consistently 2%-3% higher than the values in the other group.

Hate Speech

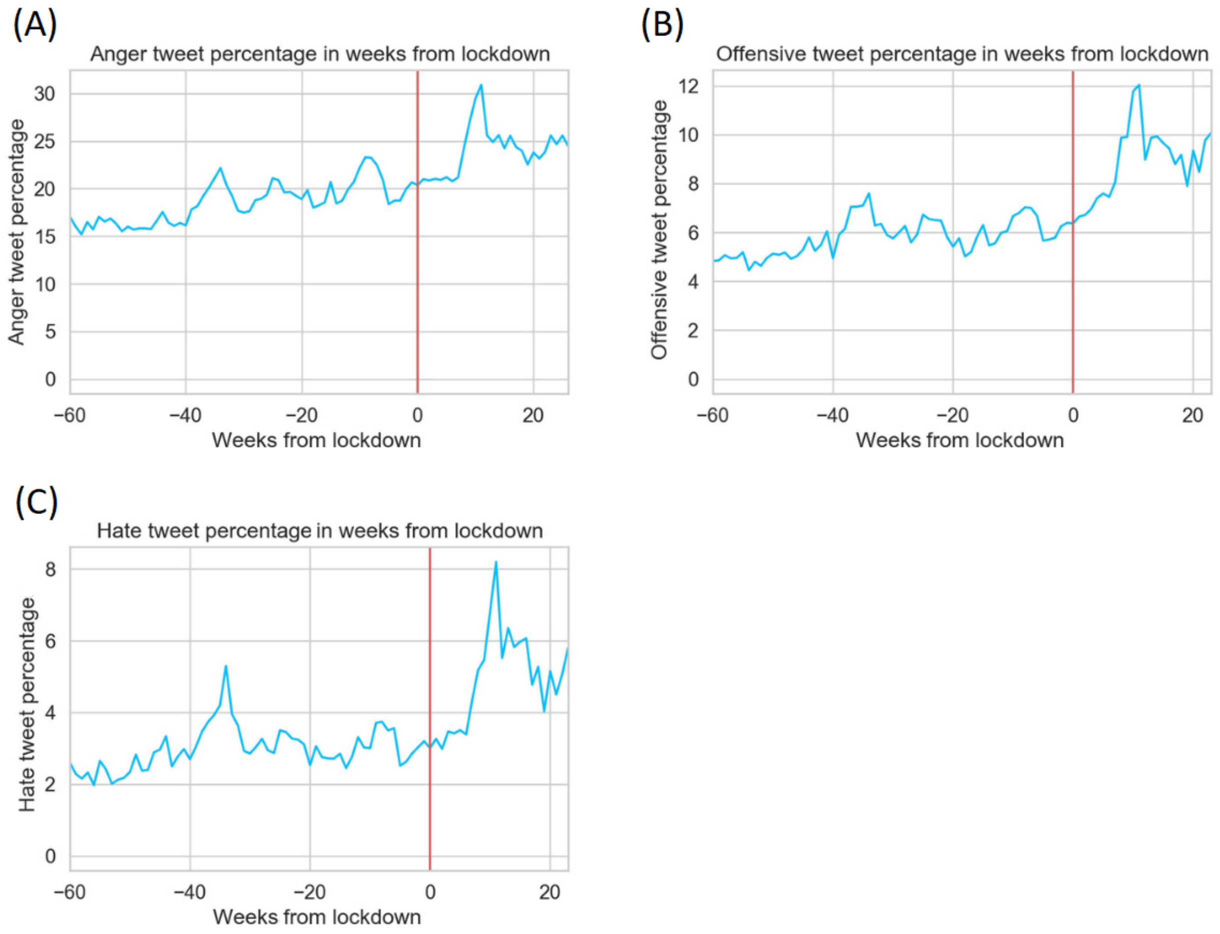
For derogatory, humiliating, and insulting speech intended to express hatred to a targeted group, tweet proportions reached the peak in the 8th week from April 1, 2020 (Figure 2). Hate speech percentages surged from around 3% when the pandemic started to 8% and 6% for people under and not under lockdown. Percentages decreased in the summer of 2020, gradually stabilizing in the months thereafter. Similar to trends in offensive language, hate tweet percentages were considerably greater than the values in 2019 after the decrease (Figure 3). After the initial surge, hate speech percentages under lockdown were 1%-2% higher than the values in the other group.

Aggression levels surged in all 3 kinds of aggressive emotions, reaching the peak around 6-8 weeks from April 1, 2020 (Figure 2). People under lockdown demonstrated a more aggressive tendency throughout the process than those not under lockdown. People who were not under lockdown experienced similar trends to those under lockdown, but to a less drastic degree. After the initial peak of increased aggression, all 3 kinds of emotional tweet percentages decreased to a relatively stable plateau. This stabilization might suggest that people are gradually getting used to the situation, and emotions are relatively eased compared with the sudden displeasure in the early days of lockdown. Despite the temporary decrease, aggressive tweet percentages were considerably higher than the values in 2019 (Figure 3).

Observing Aggression Trends From the Weeks Before and After Lockdown

We selected states that had undergone lockdown and compared their aggression levels before and after lockdown. We visualized the increasing trends of aggression after lockdown. Figure 4 shows the weekly changes in tweets containing the target emotions. In all 3 kinds of aggressive emotions, there was a visible surge in tweet percentage within 10 weeks after lockdown. The table below shows the average weekly tweet percentages (60 weeks before lockdown and 22 weeks after lockdown). In all 3 emotions, the percentage rose after lockdown (anger, 18.51% to 23.77%; offensive, 5.80% to 8.79%; hate, 2.97% to 4.85%). These descriptive data give us a basic grasp of the potential connection between lockdown and increased aggression. Note that this part does not conclude the increase is totally caused by lockdown but rather shows the general trends of aggression before and after lockdown that might be caused by multiple factors. In the next part, we conducted a difference-in-differences analysis to precisely estimate the net impact of lockdown on the increase of aggression.

Figure 4. Aggressive tweet percentages for anger (A), offensive (B), and hate (C) before and after lockdown. The vertical red line at week 0 denotes the start of lockdown. Note that because states might have started lockdown at different times, week 0 can differ in different states. Nevertheless, states generally started their lockdown between March 20, 2020, and April 4, 2020.



Difference in Differences Using Poisson Regression

In this section, we conducted a difference-in-differences analysis using a Poisson regression model. Lockdown was associated with an increase in aggressive tweet proportions for all 3 kinds of aggressive emotions. In a log-linear model, the original coefficient, α_1, between X and Y denotes the increase of ln(Y) for every unit increase of X, which is difficult to interpret due to the presence of logarithm. The incidence rate ratio (IRR) is the exponentiated coefficient of the independent variable of interest, $e^{\alpha 1}$, that demonstrates the increase of Y for every unit increase of X. For all 3 aggressive emotions, the IRR between the aggressive tweet proportion and lockdown status was greater than 1 (anger, 1.049; offensive, 1.168; hate, 1.114), indicating that after the initial lockdown, there were on average 4.9%, 16.8%, and 11.4% increases in emotional tweets for anger, offensive, and hate, respectively. All 3 of the results demonstrated high statistical significance (anger: *P*=.002, offensive: *P*<.001, hate: *P*=.005). Difference-in-differences results are shown in Table 6. Under the control of state and time fixed effects, most possible factors that can lead to misinterpretation were nullified. Therefore, we could measure the net impact of lockdown status on aggression levels. Our estimation strongly suggested a causal relationship between lockdown and increased aggression in all 3 categories of aggressive emotions.

Table 6. Results of Poisson regression for emotional tweet proportion and lockdown status.

Lockdown status	Incidence rate ratio	Standard error	z	P value	95% CI
Under lockdown (anger)	1.049745	0.0163949	3.11	.002	1.018099-1.082375
Under lockdown (offensive)	1.168261	0.0319202	5.69	<.001[a]	1.107345-1.232529
Under lockdown (hate)	1.114432	0.0432653	2.79	.005	1.032780-1.202541

[a] STATA regression yielded *P*=.000.

Discussion

Principal Findings

Infoveillance Study on Aggressive Emotions Under Lockdown

Understanding the trends of aggressive emotions is the first step to understanding various social problems associated with aggressive behaviors during the pandemic. Inspired by the questionnaire study by Killgore et al [2], we used NLP as an infoveillance method to observe the trends of online aggression in the first few months of the pandemic. We hope this method can support traditional psychology surveys by utilizing computer technology to provide a more efficient way of understanding crowd emotions.

By using statewide lockdown status to analyze tweets, we can capture the peaks and valleys of aggression levels throughout a prolonged time period. We can also identify the difference in aggression levels between groups with different lockdown statuses. There were a few particularly noticeable peaks in aggression levels in the observed timeframe. These aberrations might be able to explain the effects of various social events on public sentiment. From the start of April 2020, when most states imposed lockdown, to the second half of May in the same year, aggression levels rose by a magnitude not found in 2019, with people under lockdown demonstrating a more acute rise than others. As the nationwide deaths from COVID-19 skyrocketed from below 100 per day in late March to over 2000 in mid-April, emotions and lifestyles were impacted unprecedentedly. Through lockdowns, death tolls steadily decreased in the next few months, reaching a lower equilibrium in June. The peaks of all 3 kinds of aggressive emotions were observed in the most severe month of the nationwide pandemic when states were experiencing high death tolls and civil unrest.

After a roughly 2-month period of lockdown, aggression levels reduced. This drop might be due to pandemic fatigue, making people feel less stressed and demonstrating less aggression [38]. According to a report by the World Health Organization, “At the beginning of a crisis, most *people* are able to tap into their surge capacity – a collection of mental and physical adaptive systems that humans draw on for short-term survival in acutely stressful situations. However, when dire circumstances drag on, they have to adopt a different style of coping, and fatigue and demotivation may be the result” [39]. Despite the decrease, those under lockdown still demonstrated a higher aggression level than those not under lockdown.

Although aggression trends roughly follow the same pattern in all 3 kinds of aggressive emotions, each has some slightly different characteristics that reveal the uniqueness of each emotion. Anger was the most common emotion among the 3 emotions. After the initial peak, the aggression lines between groups of different lockdown statuses intertwined in the next few months. Offensive and hate were seen less often than anger. However, offensive and hate levels among those under lockdown were consistently higher than the levels among those not under lockdown in the first 6 months of the pandemic.

Our infoveillance study captured the fluctuation of people’s emotions over a specific timeframe, providing vital information for policymakers and public health professionals.

Discovery of a Causal Relationship Between Lockdown and Increased Aggression

Our estimation suggested a causal relationship between lockdown and increased aggression. The Poisson regression analysis designated for count data is suited to estimate the number of aggressive tweets posted in a time period. Time and state fixed effects are able to address the undesired effects of factors other than lockdown status on the outcome. Using this rigorous statistical model, we can show the net impact of lockdown status on the increase of aggressive tweets. The highly significant results in all 3 kinds of aggressive emotions (anger: *P*=.002, offensive: *P*<.001, hate: *P*=.005) matched with the observation in our infoveillance study, that is, people under lockdown have higher aggression levels. Aggressive emotions under lockdown can cause social problems such as domestic violence and divorce. Our findings provide essential information for understanding the causes of aggressive emotions during the pandemic.

Potential Policy Implications

Statistics and scientific evidence play crucial roles in rational policymaking during the pandemic [40]. Using big data to detect potential causal relations between lockdown and aggression may guide governments to implement mental health support policies during lockdowns. In the past, mental health support has come in various different forms, including but not limited to domestic violence protection [41], school counseling [42], and psychological consulting [43]. We hope that our spatiotemporal detection of aggression trends may facilitate more efficient allocation of public resources to areas that are most in need. Moreover, we hope to inspire future researchers to use machine learning to detect social trends that invite proper policy responses. Moreover, we hope our causal analysis can raise social and political awareness of the importance of mental health policies during the pandemic.

Comparison With Prior Work

Killgore et al [2] discovered an increase in aggression levels after lockdown that was particularly evident among those under lockdown. Our research used the Poisson regression model with fixed effects to precisely measure the net impact of lockdown and aggression. This widely established econometric method points to a causal relationship between lockdown and increased aggression [33]. Compared with traditional questionnaire surveys that can only collect data for 1 subject at a time, our data from Twitter are much more versatile. They can be used in other subject research by adjusting the analysis method.

Previous NLP sentiment analysis studies focused on using machines to understand emotions in vast volumes of text [16,17]. However, few of them applied this technology to investigate causal relations of social phenomena in the public health area. Inspired by traditional questionnaire research in psychology, we applied NLP technology to a longitudinal internet study of emotions. This interdisciplinary effort provides crucial information to understand the factors contributing to increased aggression. It opens up new opportunities for NLP technology to make psychology and public health research efficient and timely.

Limitations and Future Work

Our research has several limitations as well as potential for improvement in future work. First, Twitter data overrepresent younger users who have better access to mobile apps and live in a culture that promotes social media. Such users might not accurately reflect the whole population, as certain groups of different demographic and socioeconomic statuses might be underrepresented [44,45]. However, this limitation is not unique to this study but is present in all studies involving Twitter data. Second, due to time and computational limits, the number of tweets we sampled was not very large considering the total number of available tweets. In the future, we can use this research procedure with an increased number of tweet samples to detect aggression levels in space and time at a more granular scale. Nevertheless, the current number of sampled tweets was sufficient for this research to show aggression fluctuations at the statewide scale and draw statistically significant claims. Third, to determine the lockdown status of each user, this research could only use the lockdown status of the geo-tagged US state of the user. Since we were unable to ask the users about their lockdown status at a personal level, this might have led to some inaccuracies in determining the lockdown status of users. This limitation is inherent to social event studies on the internet. Therefore, our study is conducted under the assumption that users followed the lockdown policies in their state. Furthermore, different types and stringencies of lockdown policies emerged in response to the rapidly changing pandemic circumstances. This research only measured the initial lockdown where people were restricted to staying at home. Future research is open to measuring the effect of lockdown policies at different levels and nuances on aggressive emotions and behaviors. Another source of uncertainty comes from the Twitter user location labels, since the location is per user rather than per tweet ("a user who moves from one city to another [and updates his location] will have all of his tweets considered as being from the latter location" [46]). Moreover, the studies by Gore et al and Frank et al showed that the sentiment of a tweet is highly correlated with the geographical area (ie, city) it was composed in [47,48]. Finally, our research method is not restricted to measuring aggressive emotions. Future research can easily apply our methodology to other emotions and research topics. Using NLP technology to help psychology and public health research has vast potential in the future.

Conclusions

Infoveillance studies can be immensely useful in the modern world. With recent advancements in NLP, models can be trained to accurately understand emotions in text. NLP technology can be applied to analyze emotions in large volumes of social media data. This large-scale spatiotemporal data of public emotions can be further analyzed to investigate the correlations and causal relations between emotional trends and certain policies like lockdowns. Applying computer technology to social scientific research has vast potential in the future.

Abstract

Background: Both clinicians and patients have increasingly turned to telemedicine to improve care access, even in physical examination–dependent specialties such as dermatology. However, little is known about whether teledermatology supports effective and timely transitions from inpatient to outpatient care, which is a common care coordination gap.

Objective: Using mixed methods, this study sought to retrospectively evaluate how teledermatology affected clinic capacity, scheduling efficiency, and timeliness of follow-up care for patients transitioning from inpatient to outpatient dermatology care.

Methods: Patient-level encounter scheduling data were used to compare the number and proportion of patients who were scheduled and received in-clinic or video dermatology follow-ups within 14 and 90 days after discharge across 3 phases: June to September 2019 (before teledermatology), June to September 2020 (early teledermatology), and February to May 2021 (sustained teledermatology). The time from discharge to scheduling and completion of patient follow-up visits for each care modality was also compared. Dermatology clinicians and schedulers were also interviewed between April and May 2021 to assess their perceptions of teledermatology for postdischarge patients.

Results: More patients completed follow-up within 90 days after discharge during early (n=101) and sustained (n=100) teledermatology use than at baseline (n=74). Thus, the clinic's capacity to provide follow-up to patients transitioning from inpatient increased from baseline by 36% in the early (101 from 74) and sustained (100 from 74) teledermatology periods. During early teledermatology use, 61.4% (62/101) of the follow-ups were conducted via video. This decreased significantly to 47% (47/100) in the following year, when COVID-19–related restrictions started to lift (*P*=.04), indicating more targeted but still substantial use. The proportion of patients who were followed up within the recommended 14 days after discharge did not differ significantly between video and in-clinic visits during the early (33/62, 53% vs 15/39, 38%; *P*=.15) or sustained (26/53, 60% vs 28/47, 49%; *P*=.29) teledermatology periods. Interviewees agreed that teledermatology would continue to be offered. Most considered postdischarge follow-up patients to be ideal candidates for teledermatology as they had undergone a recent in-person assessment and might have difficulty attending in-clinic visits because of competing health priorities. Some reported patients needing technological support. Ultimately, most agreed that the choice of follow-up care modality should be the patient's own.

Conclusions: Teledermatology could be an important tool for maintaining accessible, flexible, and convenient care for recently discharged patients needing follow-up care. Teledermatology increased clinic capacity, even during the pandemic, although the timeliness of care transitions did not improve. Ultimately, the care modality should be determined through communication with patients to incorporate their and their caregivers' preferences.

Introduction

In 2020, the COVID-19 pandemic drove telemedicine to the forefront of health care [1,2]; dermatology care was no exception. Prepandemic teledermatology had gained popularity in some specific use cases [3,4]; however, the pandemic gave rise to new policies that overcame previous restrictions to ensure continued access to care, facilitating a rapid pivot to telemedicine for outpatients, including patients transitioning from inpatient care [5-7].

The highly visual nature of dermatology is well suited for this cost-effective and efficient care modality [4,8-10], which is well received by clinicians and patients [10-14]. Although convenience and improved access to care are the primary benefits, especially for rural and underserved populations, teledermatology also boasts time and cost savings, greater flexibility for dermatologists and patients, fewer no-shows, and better continuity of care [4,5,10,15-25]. However, teledermatology has some shortcomings that affect care delivery, including suboptimal image quality, patient privacy, diagnostic accuracy, network connectivity, patient technological literacy, and access to digital devices [8,9,11,15]. In addition, the inaccessibility of in-clinic tools and treatments (eg, dermoscopy, biopsy, and cryotherapy) makes managing certain conditions challenging [9]. These limitations may disproportionally affect patients with low socioeconomic status, Medicare beneficiaries, older adults, and non–English-preferring patients [9,11], who may also be at risk for delayed care transitions.

Nevertheless, teledermatology may be particularly beneficial for patients transitioning from inpatient dermatology consultation services to outpatient dermatology care. Currently, high-risk patients who are hospitalized often experience numerous comorbidities and may experience difficulties accessing in-clinic follow-up care. As a result, they risk receiving fragmented care and being lost to follow-up, which could have serious health consequences [26-28]. Teledermatology may improve follow-up access for these patients by increasing the capacity of dermatology clinics and improving the efficiency of scheduling and care provision. As video visits become a fixture in health care expected by patients and clinicians, it is essential to understand whether teledermatology supports timely care transitions. We retrospectively evaluated teledermatology use and its impact on the clinic's capacity, scheduling efficiency, and timeliness of follow-up care for patients transitioning from inpatient to outpatient dermatology care and explored dermatology clinicians' and schedulers' perceptions of teledermatology for this patient population.

Methods

Setting

Stanford University's Department of Dermatology encompasses 13 outpatient clinics with 16 subspecialties and provides inpatient consultative services in a quaternary hospital; that is, consultation requests placed by the patient's admitting team, such as general medicine or oncology. Consultations are delivered by 5 dermatologists and 2 dermatology residents on monthly rotations. The team consults >1500 inpatients per year, many of whom have complex, high-risk skin conditions in immunocompromised states and have multiple clinical teams involved in their care. Approximately 40% of these patients require postdischarge outpatient follow-up.

Intervention: Teledermatology

The department rapidly implemented teledermatology across all ambulatory clinics in response to the statewide COVID-19 stay-at-home orders in March 2020 [10]. Clinicians were provided with video visit–enabled hardware to enable the remote provision of teledermatology. All clinicians and staff completed the web-based training developed for the institution's rollout. Initially, clinicians and staff were encouraged to convert all nonurgent or emergent in-clinic visits into video visits. Once in-clinic capacity began to expand in spring 2020, department-developed clinical criteria guided appropriate video visit use for all patients except (1) patients with high skin cancer risk requiring full skin examination, including melanoma; (2) patients requiring specialized examinations (scalp and genitals); and (3) patients requiring procedural interventions. As of July 2022, teledermatology had remained a fixture and was offered to patients transitioning from inpatient to outpatient care.

Mixed Methods

Overview

Outcomes derived from quantitative scheduling data and qualitative interviews are defined in Table 1. Data were consolidated throughout the analysis and interpreted in parallel to understand converging and diverging issues regarding teledermatology use and its impact on the clinic's capacity, clinical appropriateness, sustainability, and the remaining barriers for patients transitioning from inpatient to outpatient care.

Table 1. Outcomes, definitions, and data sources used to evaluate the use, impact, and sustainability of teledermatology for patients transitioning from inpatient to outpatient dermatology follow-up care.

Outcomes and definitions	Data sources
Clinic's capacity	
Number and proportion of patients after discharge	
Scheduled follow-up within 90 days after discharge	Patient-level scheduling data
Completed follow-up within 90 days after discharge	Patient-level scheduling data
Teledermatology use	
Number and proportion of follow-up visits completed over video within 90 days after discharge	Patient-level scheduling data
Acceptability of teledermatology for postdischarge follow-up patients among clinicians, residents, schedulers, and patients	Clinician and scheduler interviews
Clinical appropriateness	
Perceived fit or compatibility of teledermatology within this setting, particularly for patients transitioning from inpatient to outpatient dermatology care	Clinician and scheduler interviews
Teledermatology to support timely care transitions	
Scheduling efficiency	
Days from hospital discharge to initial scheduling for in-clinic and video visits	Patient-level scheduling data
Days from hospital discharge to finalized scheduling for in-clinic and video visits	Patient-level scheduling data
Perceived impact of teledermatology on scheduling efficiency	Clinician and scheduler interviews
Timeliness of follow-up visits	
Days from hospital discharge to follow-up visit completion for in-clinic and video visits	Patient-level scheduling data
Number and proportion of patients who attended follow-up within 14 days after discharge (local benchmark)	Patient-level scheduling data
Incomplete follow-up visits	
Number and proportion of patients who scheduled but did not complete a teledermatology or in-clinic visit	Patient-level scheduling data
Perceived impact of teledermatology on follow-up visit completion	Clinician and scheduler interviews
Remaining barriers to video visit coordination	
Perceived long-term sustainability of video visits and the barriers need to be addressed to improve clinician, scheduler, and patient experience	Clinician and scheduler interviews

Quantitative: Inclusion Criteria, Data Collection, and Analysis

Patients who received a dermatology consultation in the inpatient or emergency department settings were discharged in 1 of the 3 study periods and potentially needed follow-up with outpatient dermatology. The three study periods were (1) June 1 to September 30, 2019 (baseline [before teledermatology]); (2) June 1 to September 30, 2020 (early teledermatology); and (3) February 1 to May 31, 2021 (sustained teledermatology). Follow-up scheduling and care were recorded for 90 days after discharge; visits scheduled >90 days after discharge were likely unrelated to the patient's hospitalization. Eligible patients and relevant events were retrospectively identified using the electronic health records and scheduling data. Inpatient dermatology consults were identified using Current Procedural Terminology codes (Multimedia Appendix 1).

Teledermatology use and its impact on the clinic's capacity, scheduling efficiency, and timeliness of follow-up care were compared across periods and visit modalities (video and in-clinic) using the outcomes described in Table 1. Descriptive statistics were calculated to describe patient characteristics and assess differences across the 3 study periods and by visit modality. Statistical significance was assessed using the Kruskal-Wallis test for patient age, chi-square test for categorical (ie, proportional) outcomes, and generalized linear models for continuous outcomes (eg, days from discharge). Differences in teledermatology use by patient age and distance between patient residence and outpatient dermatology clinic were determined using chi-square tests. Clinically meaningful (<70 years vs ≥70 years) or median-based (<21 miles vs ≥21 miles) categories were used. *P* values were adjusted for multiple comparisons with an adaptive, 2-stage linear step-up procedure, and significance was set at *P*<.05 [29].

Qualitative: Data Collection and Analysis

We designed a semistructured interview guide to capture perceptions of teledermatology for follow-up care of patients transitioning from the inpatient setting. Clinicians and schedulers were eligible if they were involved in transitioning patients from inpatient to outpatient dermatology. All eligible clinicians and schedulers (ie, 5 dermatologists, 5 dermatology residents, and 13 schedulers) were invited via email (plus 2 reminders) to participate in a 30-minute phone interview. Ultimately, 15 interviews (5/5, 100% dermatologists; 5/5, 100% residents; and 6/13, 46% schedulers) were conducted between April and May 2021 by 2 experienced qualitative researchers (EAS-G and AA), ranging from 30 to 60 minutes. The interviews were audio recorded and subsequently transcribed.

Data were analyzed deductively and inductively using Microsoft Excel. Deductive codes were derived from the Proctor implementation outcomes [30]. We used multiphase matrix analysis by leveraging rapid analytic procedures to achieve consensus coding of transcripts and extract early themes [31]. EAS-G and AA independently summarized transcripts after each interview; summaries were reviewed, and consensus discussions were held. Summaries were then consolidated into a matrix to identify and compare themes across interviewees. To ensure anonymity, all identifiable information was removed from transcripts, summaries, and reports.

Ethics Approval

This retrospective quality improvement evaluation received a nonresearch determination by Stanford University's Institutional Review Board (IRB-60382). Interviewees provided informed verbal consent before initiating the interviews and were assured that all responses would remain confidential. Detailed interview notes were taken if consent for recording was not provided.

Results

Patient Characteristics

Patient characteristics are summarized in Table 2. Briefly, 194 patients, 218 patients, and 256 patients were discharged following an inpatient dermatology consultation during the baseline, early teledermatology, and sustained teledermatology phases, respectively. The median patient age was similar across the 3 periods (61.0, 60.5, and 55.5 years for baseline, early teledermatology, and sustained teledermatology, respectively; *P*=.11). Approximately half of the patients lived ≥21 miles from the dermatology clinic during each study phase, and most had public insurance.

Table 2. Characteristics of patients who potentially needed outpatient postdischarge follow-up dermatology care following an inpatient dermatology consultation during one of three periods: baseline (N=194), early teledermatology (N=218), and sustained teledermatology (N=256).

Patient characteristics	Baseline (before teledermatology; June to September 2019), n (%)	Early teledermatology (June to September 2020), n (%)	Sustained teledermatology (February to May 2021), n (%)
Patients with inpatient dermatology consultation	194 (100)	218 (100)	256 (100)
Sex			
Female	100 (51.5)	116 (53.2)	135 (52.7)

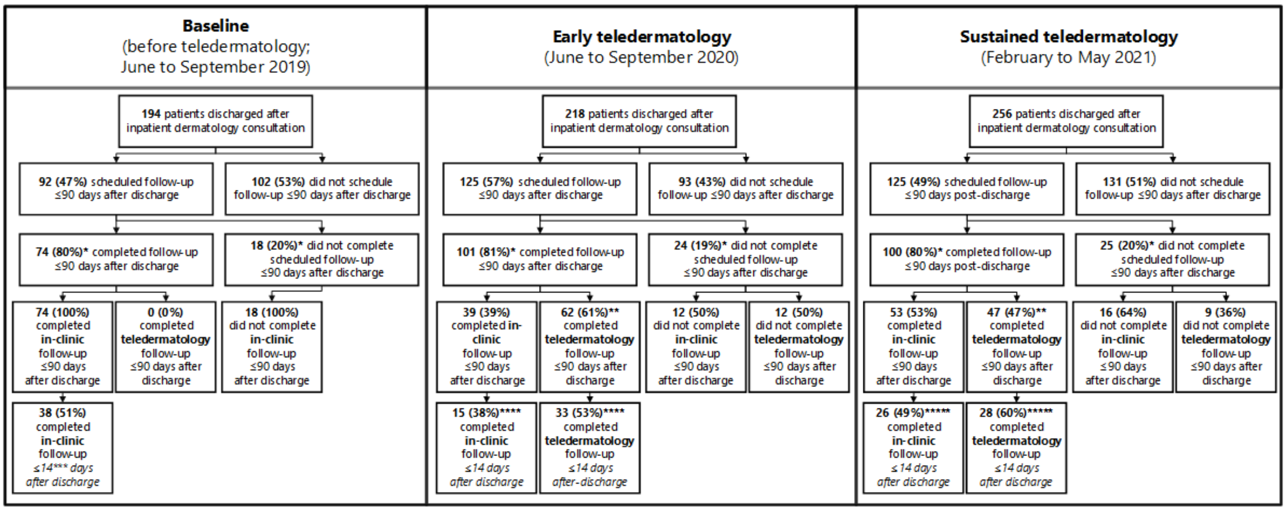
[a] Median distance between the patient's zip code and the primary dermatology clinic in Palo Alto, CA, United States, was 21 miles.

Clinic Capacity

More patients were scheduled for outpatient dermatology visits within 90 days after discharge during the early (n=125) and sustained (n=125) teledermatology phases than at baseline (n=92), indicating a 36% increase (n=125 from 92 and n=125 from 92 patients for early and sustained teledermatology, respectively) in the scheduling capacity (Figure 1). Similarly, the number of follow-up visits completed within 90 days after discharge was higher in the early teledermatology (n=101) and sustained teledermatology (n=100) than at baseline (n=74), indicating a sustained increase in capacity. The proportion of patients who completed their follow-up did not differ across the 3 evaluation periods, as shown in Figure 1.

Figure 1. Number and percentage of patients discharged following an inpatient dermatology consultation and who were scheduled for and completed an outpatient dermatology follow-up visit within 90 days after discharge in the clinic or via video. *P=.99 indicating no difference between baseline, early teledermatology, and sustained teledermatology phases. **P=.04 indicating significant difference between the early and sustained teledermatology phases. ***A local benchmark. ****P=.15 indicating no difference between the teledermatology and in-clinic follow-ups during the early teledermatology phase. *****P=.29 indicating no difference between the teledermatology and in-clinic follow-ups during the sustained teledermatology phase.



Teledermatology Use

Teledermatology use was highest in the early teledermatology period, with 61.4% (62/101) of follow-ups completed via video. This decreased significantly to 47% (47/100) of follow-ups in the sustainability period (P=.04), indicating a more targeted yet still substantial use (Figure 1). Interviewees remarked that patient acceptance of teledermatology and technology capabilities varied during early implementation; however, acceptance increased as it became the standard of care (see exemplary quotes in Textbox 1).

Clinicians and schedulers believed that older patients may prefer clinic visits, whereas patients residing farther from the clinic may favor video visits (Textbox 1). However, video visit use did not differ by patient age during the early or sustained teledermatology phase or by distance from the clinic during the early teledermatology phase (Table 3). However, in the sustained period, significantly more patients residing ≥21 miles away from the clinic had follow-up video visits (26/41, 63% patients) than those living closer (21/59, 36% patients; P=.01), confirming the interviewees' view that patients living farther away preferred video to in-clinic visits as teledermatology became optional (ie, no longer mandated because of the pandemic).

Textbox 1. Exemplary quotes from interviews with dermatologists, residents, and scheduling staff describing the use of teledermatology for patients transitioning from inpatient to outpatient dermatology care.

Teledermatology use

- “In the pandemic, people were frequently upset that they had to do a video visit. They wanted to be seen in person [...] Now that people are more used to the virtual world, they seem to be more okay with doing video visits. But I still think that for certain people, they just really don’t want anything to do with them [...]” [Resident 5]
- “...[video visits] made things a little bit easier because we are able to get over that hurdle of travel. So for a patient that maybe is hours away where they’re just never going to come back for a 15-30 minute, dermatology visit, where they’re just not able to do that. It has made us better able to at least connect with them.” [Dermatologist 3]

Clinical appropriateness

- “...for some patients video visits are totally fine, like a patient comes in with a drug rash, they’re totally better, you’re just checking it and making sure they’re not flaring again. It’s perfect. But when there’s an issue where they might need a culture or a lab, or they need a little more intensive care, like wound change or something like that, it’s very difficult. It’s challenging. Sometimes we just need in-person.” [Dermatologist 3]
- “...for some of our sick patients, maybe their skin isn’t their priority, and it isn’t a very complex thing that requires inpatient evaluation; it saves them so much time and stress, and also, kind of helps close the loop on our end as well.” [Dermatologist 2]
- “...medically, from our perspective, people that are in hospital tend to have certain conditions so a close follow-up where we can actually see all their skin, as opposed to pictures, is more helpful.” [Resident 4]
- “...a decent amount of the time we’ll do video visits, but we are leaving it up to patients. So even if it’s something that’s not really serious, they’d rather be seen in person, we’ll still accommodate them in person.” [Resident 5]

Teledermatology to support timely care transitions

- “A lot of the clinicians have more video visits than they do in person so it’s a lot easier just to get them in the video.” [Front office scheduler 2]
- “I think it [video visits] makes our work a little easier because we have more options to give the patient...[video visits] give the patient more options because sometimes patients don’t want to come into clinic, they’d rather do a video. [...] on top of that, with video visits, we can get the patients in sooner because with a lot of the video visits, there’s more video visits available where we can get the patients in sooner versus in-person that are booking months out.” [New patient coordinator 3]
- “The biggest difference for me is provider availability particularly for patients that live pretty far away because they’re able to be more flexible in terms of when they can schedule and then they can schedule sooner.” [Resident 3]
- “...it’s probably easier to schedule video visits. I think attendings can squeeze them in a bit faster than in-person. [...] having the option makes it a little easier to schedule in a timely manner. That’s really the only benefit I can think of.” [Resident 5]
- “...no-show rate is much higher for video visits ... significantly higher.” [Resident 5]
- “I find the video visits are a lot easier because they’re more likely to follow-up, because a lot of patients otherwise don't show when they have to come in-person.” [Dermatologist 5]

Remaining barriers to video visit coordination

- “...ideally, if they could leave the hospital with a follow-up appointment, that would actually help even more, but most of the time, that’s just not feasible.” [Resident 3]
- “I...prefer in-person visits to video visits just because you’re relying a lot on the patient uploading photos and then the photos they upload have to be good quality... I have definitely been fooled before where I see photos that a patient’s taken and thought one thing and then when you see them in person, it’s much different. So I think there definitely are limitations to video visit.” [Resident 5]
- “...we have a very large elderly group of patients and elderly people aren’t tech savvy. They’re a main group of people who are vulnerable during COVID but it made it really hard for them to do video visits.” [Front office scheduler 1]
- “...there are barriers, like if we’re not getting the best photos from the patient, or let’s say they have to do labs. There’s a lot of really tricky coordination. They need a lab slip and we have to get it to them somehow. Then they have to get to the lab and call us since we can’t call the lab for the results, and we’re really reliant on their primary care doctors, if they have one.” [Clinician 3]

Table 3. Completion of in-clinic and video outpatient dermatology postdischarge follow-up visits (by patient age and location) for patients who received an inpatient dermatology consultation and were discharged across 3 periods: baseline, early teledermatology, and sustained teledermatology.

Follow-up visit modality	Baseline (before teledermatology; June to September 2019)		Early teledermatology (June to September 2020)				Sustained teledermatology (February to May 2021)			
	Total visits, N	In-clinic, n (%)	Total visits, N	In-clinic, n (%)	Video, n (%)	*P* value[a]	Total visits, N	In-clinic, n (%)	Video, n (%)	*P* value
Patient age (years)						.32				.47
<70	56	56 (100)	72	30 (42)	42 (58)		71	36 (51)	35 (49)	
≥70	18	18 (100)	29	9 (31)	20 (69)		29	17 (59)	12 (41)	
Distance from clinic (miles)[b]						.15				.01
<21	36	36 (100)	47	19 (40)	28 (60)		59	38 (64)	21 (36)	
≥21	38	38 (100)	54	20 (37)	34 (63)		41	15 (37)	26 (63)	

[a] Differences in proportion between in-clinic and video visits were determined using chi-square tests.

[b] The median distance between the patient's zip code and the primary dermatology clinic in Palo Alto, CA, United States was 21 miles.

Clinical Appropriateness

Clinicians expressed interest in continuing to offer video visits to recently discharged patients who have ongoing stable conditions that are well-suited to teledermatologic care or limitations preventing in-clinic care (Textbox 1). Teledermatology was perceived to reduce barriers (eg, lack of time or resources to travel) to attending follow-up in person for high-risk patient populations who may need to attend several follow-up visits and may consequently deprioritize their dermatological issues. A video visit was perceived as better than no follow-up at all for patients who were too debilitated to travel, even if an in-clinic visit was clinically ideal.

Video visits were often considered ideal for quick, simple check-ins for postdischarge patients as they had recently been examined in person, whereas in-clinic visits were considered more appropriate for conditions requiring skin examinations or procedures, laboratory tests, or dressing changes. Nevertheless, a few residents believed that video visits were less suitable for postdischarge patients (Textbox 1). However, most agreed that the choice should ultimately be the patient's own. According to clinicians, patients appreciate having a choice that meets their priorities, needs, and preferences, and accommodating patients to complete the necessary follow-up is worthwhile.

Teledermatology to Support Timely Care Transitions

To understand the impact of teledermatology on the scheduling efficiency and timeliness of care transitions, differences in days from discharge to initial scheduling, finalized scheduling, and completion of an outpatient dermatology follow-up visit across each study period and visit modality were assessed (Table 1). The proportion of incomplete scheduled visits is also reported by the study period and visit modality.

Scheduling Efficiency

The average days from hospital discharge to initial scheduling of in-clinic visits increased from 4.2 (SD 7.2) days at baseline to 8.5 (SD 10.2) days during early teledermatology (*P*=.01; Table 4). This returned to 3.0 (SD 4.8) days in the sustained period, similar to baseline (*P*=.40). In contrast, the average number of days for initial scheduling of video visits was 4.3 (SD 6.8) days and 3.7 (SD 10.1) days for the early and sustainability periods, respectively, similar to the 4.2 (SD 7.2) days at baseline when only in-clinic visits were offered (*P*=.89 and *P*=.76, respectively; Table 4). The results were similar for the other efficiency measures; that is, days from discharge to final scheduling (Table 4). These results potentially reflect the decreased availability and increased difficulty in scheduling in-clinic visits in the early implementation period due to pandemic-related restrictions and concerns; however, the increased flexibility and appointment availability of teledermatology enabled comparable timeliness of follow-up scheduling during the pandemic as to before the pandemic, as reported by schedulers (Textbox 1).

Table 4. Days from inpatient discharge to initial scheduling, final scheduling, and completion of outpatient dermatological follow-up visits for patients who received an inpatient dermatology consultation and were discharged during 3 periods: baseline, early teledermatology, and sustained teledermatology.

Follow-up visit modality	Baseline (before teledermatology; June to September 2019)	Early teledermatology (June to September 2020)				Sustained teledermatology (February to May 2021)			
	In-clinic	In-clinic	*P* value[a]	Video	*P* value	In-clinic	*P* value	Video	*P* value
Patients who completed follow-up ≤90 days after discharge, N	74	39	N/A[b]	62	N/A	53	N/A	47	N/A
Days from inpatient discharge, mean (SD)									
Initial scheduling of outpatient follow-up	4.2 (7.2)	8.5 (10.2)	.01	4.3 (6.8)	.89	3.0 (4.8)	.40	3.7 (10.1)	.76
Final scheduling of outpatient follow-up	9.0 (13.5)	14.9 (17.8)	.02	6.4 (7.6)	.22	7.6 (11.2)	.51	5.7 (12.3)	.18
Completed outpatient follow-up	19.0 (14.8)	25.5 (21.9)	.19	17.3 (15.1)	.94	19.0 (17.7)	.99	18.4 (19.4)	.94

[a] Difference from baseline was determined using least squares means in generalized linear regression and was adjusted for multiple comparisons.

[b] N/A: not applicable.

Timeliness of Follow-up Visits

The average number of days from hospital discharge to completed follow-up visits did not differ across the periods or by visit modality (Table 4). A higher, although nonsignificant, proportion of patients was seen within 14 days after discharge, which is a local follow-up benchmark, via video than in the clinic (Figure 1). During the early teledermatology period, 53% (33/62) of follow-ups were conducted using teledermatology, whereas 38% (15/39) of follow-ups were conducted in the clinic (*P*=.15). Similarly, 60% (28/47) of follow-ups were conducted using teledermatology, whereas 49% (26/53) of follow-ups were conducted in the clinic (*P*=.29) during the sustained teledermatology period (Figure 1). Thus, although teledermatology follow-up visits were scheduled slightly faster (although not significant) than prepandemic in-clinic visits, this did not result in timelier follow-up care.

Incomplete Follow-up Visits

Relatively few patients missed their scheduled follow-up visits during the 3 periods (Figure 1). Of the 24 patients who missed their scheduled visit in the early teledermatology period, 12 (50% patients) had a scheduled teledermatology visit and 12 (50%) had scheduled in-clinic visits. A total of 25 patients did not complete their scheduled visit during the sustained teledermatology period, of whom 9 (36% patients) were scheduled for teledermatology and 16 (64% patients) for an in-clinic visit. This aligned with clinician and resident perceptions that teledermatology facilitated the completion of follow-up care but may not improve cancelation rates (Textbox 1). Some perceived that cancelation rates were higher for video visits, and others said they were higher for clinic visits; the small number of missed visits limits our evaluation of these perceptions.

Remaining Barriers to Video Visit Coordination

Interviewees acknowledged the benefits of teledermatology but indicated that care coordination and video visit setup were sometimes challenging (Textbox 1). Access to a smartphone and a means of taking a high-quality photograph were considered essential, especially for at-risk populations, including older adults, who were believed to benefit the most from improved access through reduced travel and risk during the pandemic. Schedulers perceived that these patients frequently needed help in setting up their devices and uploading their photographs before a visit. Despite this assistance, the photographs submitted sometimes lacked sufficient quality. Care coordination via video was further complicated if the patients required laboratory tests. Some interviewees suggested that this coordination should begin during hospitalization at the patient's bedside to integrate and prioritize the care needs of patients and caregivers in discharge planning and follow-up care scheduling.

Discussion

Principal Findings

Teledermatology was frequently used during the evaluation period; two-thirds of the visits were conducted via teledermatology early in the pandemic, whereas about half of the visits continued to be conducted using teledermatology later in the pandemic, indicating more targeted but nevertheless substantial use. Teledermatology availability increased the clinic's follow-up scheduling capacity for patients transitioning from inpatient to outpatient dermatology care. Teledermatology also provided a flexible option that increased overall clinic capacity while retaining comparable scheduling efficiency and timeliness of care as before the pandemic, even amid a pandemic and strained health care system. However, the scheduling efficiency and timeliness of care transitions did not improve, suggesting that a wider range of efforts are needed to improve these issues. Interviewees viewed teledermatology as an important care modality for providing accessible care, especially for patients with competing medical priorities and limited ability or availability to travel to the clinic, although important logistical and technological limitations were acknowledged for some patients. Ultimately, interviewees believed that patients should make the final choice between in-clinic or video visits.

Comparison With Prior Work

Teledermatology is an important tool for building clinic capacity, as well as improving scheduling timeliness and completion of care [17,18]. A study in an urban safety net hospital setting found that teledermatology implementation increased the total number of cases evaluated per month by approximately 20% and decreased the time to consultation for new patients from 84.6 days to 6.7 days before the COVID-19 pandemic [17]. Teledermatology has also been shown to increase access to and expedite care for patients in many settings, including referrals from primary to specialty care [19,20], within the Veterans Affairs system [21], in medically underserved populations [22,23], and for those needing inpatient consultations [24]. Our study builds on this literature by demonstrating a sustained increased clinic capacity of 36% after implementing teledermatology in the context of recently discharged patients needing follow-up care; the increase in clinic capacity did not come at the cost of less timely care. In addition, teledermatology services allowed safe access to care during the height of the pandemic when in-clinic care was delayed.

Nevertheless, our study was unable to detect improvements in the timeliness of care, which may be because of the urgency of our patient referrals (desired timeline from discharge to follow-up of only 14 days), as has been reported elsewhere [17-24]. Previous studies that found that video visit implementation improved care timeliness have been conducted in settings where patient referrals were nonurgent [17-24]. Although teledermatology supports increased access to outpatient care for patients of dermatology in general and those needing follow-up care after hospitalization, further research is needed to determine whether telemedicine itself supports more timely scheduling and care provision, particularly for care transitions.

Telemedicine has also been shown to promote visit completion and reduce patient cancelations and no-shows compared with in-clinic visits [16,25]. In the outpatient setting of a large academic health care system, 20% of telemedicine visits were canceled compared with 31% of in-clinic visits [16]. Similarly, a study focusing on dermatological care also showed that a lower percentage of virtual consults, specifically e-consults, were either canceled or not attended (ie, no show) than ambulatory consults (18% vs 39%) [25]. In this study, a few patients missed their scheduled follow-up, of whom 50% (12/24) missed a video visit in the early teledermatology period and 36% (9/25) missed a video visit in the sustained period. This latter result, although a different metric, suggests that recently discharged patients may be less likely to miss scheduled video visits than scheduled in-clinic visits, aligning with previous research [16,25]. However, the small sample size limits interpretability, and additional investigations are needed.

Teledermatology is well suited and highly accepted in dermatology, even for high-risk, recently discharged patients [10-14]. In this study, clinicians and scheduling staff recognized that teledermatology is convenient for patients experiencing difficulties related to their current health, with competing medical and care needs, or limited time and resources to access in-person care. In fact, even as in-clinic visits became more available, patients who lived farther from the clinic were significantly more likely to use teledermatology care than those living closer to the clinic, aligning with previous research reporting on the convenience of telemedicine for rural and underserved populations [10-14]. The widely reported flexibility of teledermatology [4,8-10] was recognized to support care transitions and continuity by interviewed clinicians and schedulers. Ultimately, telemedicine may be particularly well suited to this highly visual specialty, as reported here and elsewhere [4,8-10], perhaps even more so for follow-up care of patients recently physically examined and for whom the clinician expects but wants to confirm an improvement in their condition.

Although video visits are a well-accepted and widely used technology, some patients, clinicians, and schedulers still prefer in-person visits due to their limitations [32-34]. As reported here and previously, teledermatology continues to have shortcomings that affect care delivery, including incomplete previsit preparation, poor quality images, limited patient technological literacy, inability to access certain in-person tools and procedures, and patients’ lack of capabilities with digital devices [8,9,11,15]. Patient privacy concerns, diagnostic accuracy, and network connectivity are also well-recognized limitations [8,9,11,15]. The reported inequities in access to telemedicine care, known as the digital divide [9,11], compound the limitations of teledermatology. Although patients with complex medical issues may particularly benefit from the convenience and flexibility of teledermatology care, they may also lack access to a smartphone and the technological capacity to, for example, take and submit high-quality photographs. Thus, efforts to improve care transitions need to not only be attuned to patients who may benefit from teledermatology but also be able to assess whether such patients have access to the needed skills and technology; if not, alternatives or appropriate support for skills and technology must be provided to facilitate equitable access to care for all. Bedside communication for more patient-centered care [35] or employing dedicated care coordinator teams [28,36,37] to ensure that patients’ care needs are met could not only better support timely care transitions but also ensure high levels of patient and caregiver satisfaction, improved patient outcomes, and lower readmissions.

Limitations

This retrospective study has 3 main limitations. First, it was conducted in a single health care setting. Second, Current Procedural Terminology codes (Multimedia Appendix 1) associated with inpatient dermatology consultations were used as a surrogate to identify patients potentially needing follow-up care; ideally, such data would be based directly on clinical recommendations, including the follow-up timeline; however, such data were not systematically available. Third, 2 of the 3 study periods were during the COVID-19 pandemic. We considered many factors that could have influenced our findings, including seasonality, COVID-19 pandemic surges and restrictions, and the presence of other quality improvement initiatives, to identify comparable periods. However, this retrospective evaluation was not able to account for all potential confounding factors, including regular policy changes and vaccine availability.

Conclusions and Future Directions

Telemedicine has moved to the forefront of health care delivery and is anticipated to continue to expand. As telemedicine becomes an established care modality, additional evaluation of its quality, acceptability, and appropriateness for specific use cases and patient populations is needed to ensure the provision and sustainability of appropriate, high-quality care without continuing to widen the care access divide. Teledermatology was viewed as an important tool for maintaining accessible, flexible, and convenient care for patients transitioning from inpatient to outpatient dermatology care. Despite its shortcomings, including photograph quality and varying patient technological capabilities, teledermatology is predicted to be a standard option for patients. However, teledermatology alone does not completely solve care transition delays; it must be coupled with other efforts to improve communication between patients and care teams, patient access to and comfort with video technology, and workflows that support timely and equitable access to follow-up care. Care transitions are a vulnerable time for patients who may easily slip through the cracks and remain a challenge in health care systems [26,28,38-41]. Continued evaluation of alternate approaches to care delivery during care transitions, including telemedicine, as well as reporting of these efforts, is needed to understand their impact on this risky time in the patient care continuum.

Acknowledgments

The authors thank Melissa Dymock, MBA, formerly of Stanford Health Care, for her efforts in designing and executing the electronic health record data extraction and designing a dashboard to support the clinical team in tracking patient care transitions. This project was supported by Stanford Health Care as part of the Improvement Capability Development Program. The funder was not directly involved in the study design, data collection, data analysis, manuscript preparation, and publication decisions.

Abstract

Background: Although the COVID-19 pandemic has accelerated the adoption of telemedicine and virtual consultations worldwide, complex factors that may affect the use of virtual clinics are still unclear.

Objective: This study aims to identify factors associated with the utilization of virtual clinics in the experience of virtual clinic service implementation in Taiwan.

Methods: We retrospectively analyzed a total of 187,742 outpatient visits (176,815, 94.2%, in-person visits and 10,927, 5.8%, virtual visits) completed at a large general hospital in Taipei City from May 19 to July 31, 2021, after rapid implementation of virtual outpatient clinic visits due to the COVID-19 pandemic. Data of patients' demographic characteristics, disease type, physicians' features, and specialties/departments were collected, and physicians' opinions regarding virtual clinics were surveyed and evaluated using a 5-point Likert scale. Multilevel analysis was conducted to determine the factors associated with the utilization of virtual clinics.

Results: Patient-/visit-, physician-, and department-level factors accounted for 67.5%, 11.1%, and 21.4% of the total variance in the utilization of virtual clinics, respectively. Female sex (odds ratio [OR] 1.27, 95% CI 1.22-1.33, *P*<.001); residing at a greater distance away from the hospital (OR 2.36, 95% CI 2.15-2.58 if distance>50 km, *P*<.001; OR 3.95, 95% CI 3.11-5.02 if extensive travel required, *P*<.001); reimbursement by the National Health Insurance (NHI; OR 7.29, 95% CI 5.71-9.30, *P*<.001); seeking care for a major chronic disease (OR 1.33, 95% CI 1.24-1.42, *P*<.001); the physician's positive attitude toward virtual clinics (OR 1.50, 95% CI 1.16-1.93, *P*=.002); and visits within certain departments, including the heart center, psychiatry, and internal medicine (OR 2.55, 95% CI 1.46-4.46, *P*=.004), were positively associated with the utilization of virtual clinics. The patient's age, the physician's age, and the physician's sex were not associated with the utilization of virtual clinics in our study.

Conclusions: Our results show that in addition to previously demonstrated patient-level factors that may influence telemedicine use, including the patient's sex and distance from the hospital, factors at the visit level (insurance type, disease type), physician level (physician's attitude toward virtual clinics), and department level also contribute to the utilization of virtual clinics. Although there was a more than 300-fold increase in the number of virtual visits during the pandemic compared with the prepandemic period, the majority (176,815/187,742, 94.2%) of the outpatient visits were still in-person visits during the study period. Therefore, it is of great importance to understand the factors impacting the utilization of virtual clinics to accelerate the implementation of telemedicine. The findings of our study may help direct policymaking for expanding the use of virtual clinics, especially in countries struggling with the development and promotion of telemedicine virtual clinic services.

Introduction

During the COVID-19 pandemic, countries worldwide relaxed restrictions on the utilization of telemedicine to reduce the contagion, which has resulted in the expansion of telemedicine in various clinical applications [1-3]. Owing to the severity of the disease outbreak, many countries have implemented strict strategies to restrict movement, such as lockdowns, travel constraints, and quarantine, and have implemented extensive use of telemedicine in place of in-person clinic visits in order to reduce disease exposure and the risk of infection among patients and medical staff [4,5].

Although some initial research on the provision of health care via virtual clinics (virtual consultations, teleconsultations) in the United States and the United Kingdom during the COVID-19 pandemic reported generally high patient and provider satisfaction [6-8], the acceptance of virtual visits appeared to vary widely across different subspecialties and patient populations. A previous study reported that only 32% of patients with head and neck cancer chose to have a virtual visit, even during the COVID-19 pandemic [9]. In different countries, due to differing degrees of technology penetration and COVID-19 outbreak severity, the acceptance of virtual clinics seems to vary. For example, a study conducted in Australia showed that only 61.7% of patients were satisfied with virtual visits, and less than 50% of patients expressed the desire to continue to use it in the future [10]. In addition, research on whether patient demographics are associated with the willingness to use virtual clinics has revealed conflicting results. Although some studies have shown that patients who are female and younger than 65 years of age are more likely to use digital health services [11,12], others have found that female patients are less likely to use virtual clinics [13,14]. A large study analyzing 231,596 visits across 1652 primary and specialty care practices in the United States found that patient sex is not associated with differences in the use of video visits, whereas the type of practice and clinician specialty are the main drivers of variation in telemedicine usage [15].

The inconsistency among these preliminary findings suggests that further research is needed to better identify factors that potentially impact the utilization of virtual health care. In addition, factors beyond patient demographics may also play a role in the utilization of virtual clinics, including disease chronicity, physician characteristics, the physician's attitude toward virtual clinics, and the type of subspecialty. Understanding the impact of these factors may enable policymakers and health care providers to increase patients' receptiveness to virtual health care and to expand the utilization of virtual clinics in the postpandemic era. This study aims to identify factors associated with the utilization of virtual clinics in the experience of virtual clinic service implementation in Taiwan during the COVID-19 pandemic. The findings may help direct future policy for promoting and expanding the use of virtual clinics.

Methods

Background Information and Study Design

Prior to the COVID-19 pandemic, telemedicine regulations in Taiwan were restrictive. Before 2018, only residents of outlying islands or distant mountainous areas with insufficient medical resources were allowed to use telemedicine consultations in disease diagnosis and treatment. After 2018, a few specific patients, such as overseas patients or those admitted to a family physician integrated care plan, were added to the telemedicine project. Therefore, most physicians and patients in Taiwan had never used virtual consultations prior to the COVID-19 pandemic. The Cheng Hsin General Hospital is an 800-bed hospital located in Taipei City, Taiwan. In the pre–COVID-19 pandemic time, the average volume of our outpatient clinic was approximately 100,000 visits per month. Due to restrictive prepandemic telemedicine regulations, the number of telemedicine consultations was limited at approximately 10 visits per month. During the COVID-19 pandemic, the Taiwan government relaxed telemedicine regulations, and virtual clinic visits became reimbursed under the National Health Insurance (NHI) for all patients beginning May 16, 2021. Our institution rapidly responded to the change in policy and initiated virtual outpatient clinics conducted via an integrated user-friendly smartphone application platform beginning May 19, 2021. Both virtual and in-person clinic services were made available to all our outpatients, and patients could easily book an appointment for either type of visit through the smartphone application. This special background gave us a good opportunity to test the acceptance and demand for virtual outpatient clinics by the general public and physicians of various specialties. Thus, we conducted this retrospective, cross-sectional study to determine factors associated with virtual clinic utilization.

Data Source

Data were collected from 2 sources: (1) data from the hospital information system (HIS) and the electronic medical record (EMR) system of the Cheng Hsin General Hospital and (2) results of a physician survey. The data extracted from our HIS and EMR systems contained patient age, sex, and address of residence; visit date; visit type (in-person visit or virtual visit); insurance type (whether reimbursed by the NHI); principal diagnosis codes; the in-charge physician; and the age, sex, and medical specialty/department of the physician. The design and procedures of the physician survey are described in a separate section later.

Study Sample

We collected data of all outpatient visits of the Cheng Hsin General Hospital between May 19 and July 31, 2021. This study period was chosen because it was just after implementation of our virtual clinic platform and was the peak period of virtual visits during that year. To compare the usage of virtual clinics among various specialties, including pediatrics and geriatrics, we included patients of all ages in our study. Data from a total of 197,534 outpatient visits during the study period were collected. We excluded all visits from the Department of Emergency (n=3099, 1.6%), the Department of Health Examination (n=1623, 0.8%), and visits for COVID-19 vaccination (n=5070, 2.6%) because virtual clinic services were not available in those departments. After applying the exclusion criteria, the final data set included 187,742 visits, with 176,815 (94.2%) in-person visits and 10,927 (5.8%) virtual visits completed in the outpatient department of 30 subspecialties during the study period. For in-person visits, patients came to the hospital as usual because there were no lockdown restrictions in place in Taiwan during that period. For virtual visits, physicians conducted video calls with patients at the scheduled appointment time using the integrated platform. All virtual visits were booked by patients themselves and conducted by in-charge physicians using the same smartphone application platform. Audio-only visits occurred under the condition of insufficient internet bandwidth or poor Wi-Fi signals, which resulted in a video call without screen images and only audio signals being transmitted. Since the determination of video or audio visits mainly depended on the internet condition, further subgroup analysis between video and audio visits was not performed.

Physician Survey Design

To understand physicians' opinions on the implementation of virtual clinics and to evaluate the performance of our newly introduced virtual clinic platform to identify areas for future improvement, all full-time physicians who provide outpatient clinic services at our hospital were invited to complete an online service survey. The survey was conducted between September 9 and October 6, 2021.

In the current absence of a widely validated physician survey of telemedicine that met our purpose, we designed a service-specific questionnaire modified from previously published questionnaires [6,16-18] and followed recommendations on the use of telemedicine research surveys [19]. The survey evaluated the following elements: general attitude; reliability; confidence in diagnostic and therapeutic assessment; technique-specific elements, such as audio and video quality; platform-specific elements, such as function and design; efficiency; and satisfaction (see Multimedia Appendix 1). Physicians were asked to provide answers using a 5-point Likert scale (1=strongly disagree to 5=strongly agree). Finally, we allowed for comments and suggestions. A single question regarding each physician's general attitude toward virtual clinics was recorded, and the response was analyzed for the study.

Ethical Considerations

As this was a formal service evaluation, ethical approval was not required for this study. Nonetheless, all invited physicians were fully informed verbally of the aims of this survey and understood that their responses would be analyzed for the purpose of publication. Participation was voluntary, and consent from physicians was implied by participation in the survey. This study was approved by the Institutional Review Board of the Cheng Hsin General Hospital (#(916)110-62). The need for informed written consent was waived by the board, and approval was granted for informed verbal consent prior to data collection.

Study Measures

The outcome of interest in our study was visit type (in-person visit vs virtual visit). For patient-level variables, we included patient characteristics that have been previously demonstrated to influence telemedicine use, including age, sex, and distance between the patient's residence and the hospital. Sociodemographic variables, such as the marital status, highest education level, and income of the patient, were not included, because updated data of this type were not available in our HIS database. In addition, no data were available in our HIS database regarding the patients' race/ethnicity or spoken language. The distance between a patient's place of residence and the hospital was estimated using the patient address' zip code and then grouped as a categorical variable (<20 km, 20-50 km, >50 km, outlying islands, and traveled >5 hours to reach the hospital). We also collected visit-level variables, including insurance/reimbursement type and the coding of principal diagnosis based on the *International Classification of Diseases 10th Revision* (ICD-10) from our HIS and EMR databases.

To investigate the association between disease type and the usage of virtual clinics and to examine the association of major chronic diseases with virtual clinic service, we used the classifications of chronic diseases defined by the Ministry of Health and Welfare of Taiwan and the chronic condition indicator for ICD-10 developed by the Agency for Healthcare Research and Quality of America [20] to categorize the diseases. As defined by the Ministry of Health and Welfare of Taiwan, prescription refills are allowed for 101 chronic diseases in 16 categories (Multimedia Appendix 2). First, we removed certain disease groups that may involve complicated disease conditions, diverse prognoses, and various purposes for visits, including malignant neoplasm, brain tumor, polyneuropathy, nerve root and plexus disorders, trigeminal neuralgia, spinal cord injury, peptic ulcer, colitis, cholangitis, nephritis, arthritis, dermatomyositis, osteomyelitis, osteoporosis, autoimmune disease, ocular disease, skin diseases, ear diseases, blood diseases, prostate and urination diseases, infectious diseases, congenital malformations, hemorrhoids, follow-up after organ transplantation, and menopause syndrome. Next, we removed certain diseases that had few cases in our study cohort, including endometriosis, leprosy, blackfoot disease, and polychlorinated biphenyl intoxication. Finally, we defined 10 types of major chronic and stable diseases (Table 1) to compare with other diseases. The data of the dictionary of the specific ICD-10 codes used to categorize these diseases are provided in Multimedia Appendix 3. For physician-level variables, the physician's age and sex were obtained from the HIS database and the physician's general attitude toward virtual clinics was obtained from the physician survey, as described before. Department-level variables, such as the medical specialty/department of the visit, were collected from our HIS database as well.

Table 1. Major chronic diseases according to ICD-10[a].

Disease group	Visits (N=187,742), n (%)
1. Diabetes mellitus	30,680 (16.3)
2. Coronary artery disease	19,517 (10.4)
3. Hypertension	14,034 (7.5)
4. Chronic cardiac and arterial disease	11,387 (6.1)
5. Psychiatric disease and sleep disorder	9887 (5.3)
6. Cerebrovascular disease and other chronic neurologic diseases	7477 (4.0)
7. Chronic respiratory disease	5196 (2.8)
8. Chronic liver disease	3533 (1.9)
9. Thyroid and endocrine diseases	3408 (1.8)
10. Hyperlipidemia	2791 (1.5)

[a] ICD-10: International Classification of Diseases 10th Revision.

Statistical Analysis

Descriptive statistics were used to assess trends in the use of virtual visits and in-person visits. Continuous variables were described as the mean (SD). Categorical variables were described using frequencies and percentages.

Group comparisons (virtual visit vs in-person visit) were tested for differences using the Student t-test for continuous variables and the chi-square test for categorical variables. To determine the independent factors associated with the utilization of virtual clinics, all variables exhibiting a *P* value of <.01 on univariate analysis were entered into a multivariate binary logistic regression and a multilevel analysis. Multilevel analysis was conducted by using 3-level structure hierarchical linear modeling to incorporate variables at the patient/visit level, physician level, and department level in a statistically correct way.

All statistical analyses were carried out using commercially available software (IBM SPSS Statistics for Windows, version 28.0; IBM Corporation). The multilevel analysis was carried out using HLM version 8.2 (Scientific Software International). A two-sided *P* value of <.01 was considered statistically significant for all analyses.

Results

Visit Characteristics

Characteristics of all visits recorded during the study period are summarized in Table 2. Of 187,742 total visits, 10,927 (5.8%) were virtual visits during the study period. The mean age of patients in all visits was 61.48 (SD 16.86) years, and 96,884 (51.6%) visits were of female patients. In terms of the distance of the patients' residence from the hospital, 168,846 (89.9%), 12,623 (6.7%), and 5284 (2.8%) visits were by patients who lived <20 km, 20-50 km, and >50 km from the hospital, respectively. In addition, 449 (0.3%) visits were by patients who needed to travel extensively to reach the hospital, including 167 (37.2%) visits by patients who lived in the outlying islands of Taiwan and 332 (62.8%) visits by patients who traveled >5 hours to reach the hospital. Nearly all (n=175,881, 93.7%) of the visits were reimbursed by the NHI. For disease type, 107,910 (57.5%) visits were related to a major chronic disease. Regarding specialty, 129,504 (69%) visits were conducted by the heart center, the psychiatry department, or the internal medicine department.

Table 2. Characteristics of all visits.

Characteristics	Total visits (N=187,742)	In-person visits (n=176,815)	Virtual visits (n=10,927)	Virtual visit rate (%)= virtual visits/total visits
Age (years), mean (SD); *P*=.013	61.48 (16.86)	61.50 (16.84)	61.09 (17.22)	N/A[a]
Sex, n (%); *P*<.001

Physician Characteristics

Of 174 invited physicians, 165 (94.8%) responded to the survey, accounting for 179,857 (95.8%) of 187,742 outpatient visits during the study period. These physicians were from 30 subspecialties of 13 departments of our hospital. The characteristics of the 165 physicians who responded to the virtual clinic service survey are summarized in Table 3. Their mean age was 55.58 (SD 11.89) years, 25 (15.2%) physicians were female, and 115 (69.7%) physicians expressed a positive attitude toward virtual clinics by agreeing or strongly agreeing (Likert scale score≥4) that virtual clinics are practical and that they are willing to conduct virtual visits.

Table 3. Physician characteristics.

Characteristics	Participants (N=165)
Sex (female), n (%)	25 (15.2)
Age (years), mean (SD)	55.58 (11.89)
Attitude (Likert scale score≥4), n (%)	115 (69.7)
Department, n (%)	
Internal medicine	44 (26.7)
Surgery	37 (22.4)
Heart center	27 (16.4)
Obstetrics and gynecology	9 (5.5)

Ophthalmology	6 (3.6)
Dentistry	4 (2.4)
Dermatology	4 (2.4)
Pediatrics	4 (2.4)
Traditional Chinese medicine	2 (1.2)

Factors Associated With Virtual Clinic Utilization

In univariate analysis, the percentage of virtual clinic use was higher in female patients (6020/96,884, 6.2%, female patients vs 4907/90863, 5.4%, male patients, *P*<.001), in visits for major chronic diseases (8286/107,910, 7.7%, major chronic diseases vs 2641/79,832, 3.3%, nonmajor chronic diseases, *P*<.001), in visits reimbursed by the NHI (10,860/175,881, 6.2%, reimbursed visits vs 67/11,861, 0.6%, nonreimbursed visits, *P*<.001), and in visits performed by the heart center, the psychiatry department, or the internal medicine department (9416/129,504, 7.3%, visits in these departments vs 1511/58,238, 2.6%, visits not in these departments, *P*<.001). Patients who lived farther away from the hospital were more likely to use virtual clinic, with 69 (26.2%) of 332 visits by patients who needed more than 5 hours of travel time to reach the hospital, 34 (20.4%) of 167 visits by patients who lived in outlying islands of Taiwan, 677 (12.8%) of 5284 visits by patients who lived more than 50 km from the hospital, 1071 (8.5%) of 12,623 visits by patients who lived 20-50 km from the hospital, and 9059 (5.4%) of 168,846 visits by patients who lived within 20 km from the hospital (*P*<.001). There was no significant difference in the mean patient age between the in-person visit group (mean 61.50 years, SD 16.84 years) and the virtual visit group (mean 61.09 years, SD 17.22 years; *P*=.013).

Results of the 3-level structure multilevel analysis are shown in Table 4. The random part of the model represents the variance at each hierarchical level. Based on the formula of the intraclass correlation coefficient [21], physician-level factors accounted for 11.1% of the total variance and department-level factors accounted for 21.4% of the total variance in utilization of virtual clinics. Patient-/visit-level factors contributed to 67.5% of the total variance.

In multilevel analysis, patient-/visit-level factors associated with the utilization of virtual clinics included female sex (odds ratio [OR] 1.27, 95% CI 1.22-1.33, *P*<.001), distance from the hospital (OR 2.36, 95% CI 2.15-2.58 if distance>50 km, *P*<.001; OR 3.95, 95% CI 3.11-5.02 if extensive travel required, *P*<.001), visit for a major chronic disease (OR 1.33, 95% CI 1.24-1.42, *P*<.001), and visit reimbursed by the NHI (OR 7.29, 95% CI 5.71-9.30, *P*<.001). The physician's age and sex were not associated with the utilization of virtual clinics. The only physician-level factor associated with the utilization of virtual clinics was the physician's positive attitude toward virtual clinics (OR 1.50, 95% CI 1.16-1.93, *P*=.002). Department-level factors as represented by the different specialties were associated with the utilization of virtual clinics. The heart center, psychiatry department, and internal medicine department were more likely to use virtual clinics (OR 2.55, 95% CI 1.46-4.46, *P*=.004).

As shown in Table 4, combining all variables of different levels into a binary logistic regression model revealed that the physician's age and sex were significantly associated with the utilization of virtual clinics. Therefore, in our study, the results may be skewed if binary logistic regression analysis were used, and the role of physician- and department-level factors in the utilization of virtual clinics (ie, factors beyond the patient/visit level) could not be assessed with such a model.

Table 4. Results of the multilevel model.

Discussion

Principal Findings

In our study, results of the multilevel analysis showed that factors at different levels all contributed to the utilization of virtual clinics. In addition to patient-/visit-level factors (67.5%), physician-level (11.1%) and department-level (21.4%) factors also drove variation in virtual clinic use. Patients who were female and lived farther away from the hospital were more likely to use virtual clinics, whereas the patient’s age did not affect the utilization of virtual clinics in our study. Visit-level variables, including insurance type (reimbursed by the NHI) and disease type (major chronic disease), were positively associated with the utilization of virtual clinics. The physician’s positive attitude toward virtual clinics positively predicted the use of virtual clinics, while the physician’s sex and age were not major predictors. Certain medical departments/specialties (the heart center, the psychiatry department, and the internal medicine department) were positively associated with the utilization of virtual clinics. Even when in-person visits and virtual visits were equally available, the use of virtual visits was relatively low, accounting for 10,927 (5.8%) of 187,742 visits in our study period.

Comparison With Existing Literature

During the COVID-19 pandemic, a massive migration from in-person to virtual clinic visits was observed in many countries [2,4,22-24]. In prior reports from New York City, the epicenter of the pandemic during 2020, Mann et al [4] reported that telemedicine visits in a large academic health care system increased from less than 50 daily to more than 1000 daily, co-occurring with a decline of over 80% in in-person visits [4], and Ramaswamy et al [7] reported an 8729% increase in video visit utilization [7]. Various countries, including Italy, the United Kingdom, and India, reported virtual migration percentages between 60% and 95% of their usual practice [2,22]. However, during our study period, the COVID-19 outbreak in Taiwan was well controlled. No lockdown or shelter-in-place orders were enacted, and usual hospital outpatient services were not impacted. The use of virtual clinics was for individual health demand rather than for COVID-19–suspected diagnosis during our study period. Therefore, our hospital has not experienced a massive migration from in-person to virtual visits. Although there was a more than a 300-fold increase in the number of virtual visits compared to the prepandemic period, the majority (176,815/187,742, 94.2%) visits in our outpatient clinic were still in-person visits during the study period. This finding may imply that when both types of clinics are equally available, most patients still prefer in-person visits.

Earlier studies have reported that virtual clinics are associated with high patient/physician satisfaction [6-8,25,26], and findings have supported the effectiveness of virtual consultations in various practices [27-34]. Although teleconsultations or virtual clinics are not novel concepts, the growth of this type of health care service was slow in Taiwan owing to restrictive regulations prior to the COVID-19 pandemic. Our findings show that the utilization of virtual outpatient clinics was still limited even in the modern, high-income, capital city of Taiwan with a high penetration rate of smartphone use and broadband internet, implying that telemedicine may still have a long way to go to be widely accepted. Therefore, it is of great importance to investigate the factors impacting the utilization of virtual clinics in order to accelerate the implementation of telemedicine, especially in countries in which telemedicine services are currently underused.

Older age has been widely recognized as a barrier to adopting telemedicine in previous research [11,12,35-37]. However, no significant difference in patient age between the virtual visit and in-person visit groups was found in our study. Interestingly, some previous studies have found that age does not have a significant influence on a patient's willingness to conduct telemedicine consultations [38,39], which may explain our finding. There are several additional possible reasons for our finding. First, as is common in Asian cultures, elderly patients are commonly cared for by family members who can provide assistance in using the telemedicine platform. Second, since chronic diseases were shown to be positively associated with the use of virtual clinics in our study, the higher prevalence of chronic diseases in the elderly may have contributed to their seeking of virtual clinic services. Finally, with the advances of smartphone technology, telemedicine is easier to use and more accessible than ever. Prior studies have shown that smartphone device usage is high even in people of older age [37,40]. For elderly people, lack of appropriate equipment and lack of exposure to new technology have been identified as significant barriers to adopting telemedicine [35]; therefore, the ease of use of the smartphone platform used in our study may be beneficial for elderly patients to complete a virtual visit.

Although patient sex was not associated with the utilization of telemedicine in some prior research [6,9,15], a few studies did show that being female is negatively associated with the success rate or satisfaction of a video visit. Eberly et al [13,14] reported that female patients are less likely to complete video visits, and Ramaswamy et al [7] found that female patients have lower satisfaction with video visits compared to male patients. Our study found that female patients are more likely than male patients to use virtual clinics. The same finding has been reported in some previous research that showed female sex as a positive predictor of digital health engagement behaviors and telemedicine consultations [11,36,41].

Prior studies have shown that time- and cost-saving benefits of telemedicine consultations are largely affected by distance from the hospital or clinic [30,42-44]. Cannon et al [45] found that for every 23 miles a patient resides from their clinic, patients are 111% more likely to use telemedicine consultation [45]. Our study showed that patients who live farther away from the hospital are more likely to replace in-person visits with virtual visits, which is consistent with previous research. We also found that patients with chronic and stable diseases are more likely to seek care by using virtual clinics. Since patients with chronic diseases and those who need to travel extensively to access health care are more likely to be vulnerable individuals, the implementation of virtual clinics is particularly meaningful and beneficial for these patient groups. Virtual health care may be even more essential during the COVID-19 pandemic in protecting these patients from disease exposure and decreasing the risk of infection.

Previous studies in the United States have shown that patients who use video visits are more likely to be White, have private health insurance, and have a higher level of income [13,15,36]. However, since the health care system is quite different in Taiwan, having private insurance was not a positive predictor of the utilization of virtual clinics in our study. In Taiwan, almost all citizens are covered by the NHI, and private insurance seldom covers the expense of outpatient visits. Interestingly, we found that patients are less likely to use virtual visits if the expense is paid out of pocket, which suggests that if the medical expense related to a visit is to be self-paid, patients would prefer an in-person visit with the physician.

Provider resistance has been reported by studies from Ethiopia, the United Kingdom, Australia, Iran, and the United States as a barrier to adopting telemedicine [35]. In our study, the physician's age and sex did not influence the utilization of virtual clinics, but the physician's positive attitude toward virtual clinics did (OR 1.50, P=.002), which supported the findings of those prior studies. We also found that in our institution, physicians of specific departments and subspecialties, including the Department of Internal Medicine, the Department of Psychiatry, and the heart center, are more likely to utilize virtual clinics than others. Since physician-level factors accounted for 11.1% and department-level factors accounted for 21.4% of the total variance in the utilization of virtual clinics, an increase in the physicians' acceptance of virtual clinic services, particularly for physicians of certain departments, is important to further expand such service.

Limitations and Strengths

This study had some limitations. First, demographic characteristics, including marital status, income, race/ethnicity, spoken language, and educational level, were not available in our database, so we were unable to capture the influence of these sociodemographic variables. However, although patients' race/ethnicity and spoken language are common factors of patient inequities and disparities in telemedicine adoption, those factors may be not significant in Taiwanese society, as nearly all patients in Taiwan are ethnic Chinese. In addition, some prior studies examining various types of digital health utilization did not observe disparities in race/ethnicity [12,46].

Second, the practice and acceptability of telemedicine and virtual clinics may be strongly associated with the health care system structure and the pervasiveness of technology. The health care system of Taiwan is quite different from that in Western countries. A major difference is the lack of a well-established general practice and referral system in Taiwan. In large hospitals, physicians of various specialties also take on the role of primary care providers and have large volumes of outpatient visits for chronic diseases, such as diabetes, hypertension, hyperlipidemia, and coronary artery disease. The results of our study reflect this situation, with up to 107,910 (57.5%) of 187,742 visits during our study period having a principal diagnosis of a major chronic disease. However, our results may serve as a valuable reference for countries having a similar health care system structure, especially in East Asia.

Third, the study data were collected from a single hospital, limiting generalizability to different types of practices and organizations. However, to increase the relevance of study findings outside of the current institutional setting and practice, a multilevel analytic methodology was emphasized, which can be applied to different study cohorts and practice settings.

Despite these limitations, our study is unique in the following ways: First, unlike most of the virtual clinic studies conducted during the COVID-19 pandemic with lockdown or shelter-in-place orders and restrictions of regular medical services [6,7,12-15,36,47], our study was conducted with the background that virtual clinics and in-person clinics were both equally and easily accessible and the utilization of virtual clinics was not largely affected by the pandemic. Second, unlike most prior studies that focused only on patient-level variables that may affect the use of virtual clinics [12,13,36,37,48], we used multilevel analyses to show that insurance type, disease type, physician's attitude, and specialties are associated with the utilization of virtual clinics independent of patient demographic characteristics. Third, many prior telemedicine studies were small and focused on specific patient populations of 1 specific medical specialty [6,9,10,13,25]. Our study was performed across various specialties and departments, and the patient volume of each virtual clinic was controlled by individual physicians; therefore, physician-level variables could be investigated. Finally, all our virtual visits were conducted using a user-friendly smartphone application platform; thus, we could greatly reduce the impact of technology-related barriers that may strongly impact the utilization of virtual clinics.

Conclusion

In conclusion, our study demonstrates that factors at the patient/visit level, physician level, and department level all contribute to the utilization of virtual clinics. Female sex; residing at a greater distance away from the hospital; reimbursement by the NHI; seeking care for a major chronic disease; the physician's positive attitude toward virtual clinics; and visits within certain departments, including the heart center, psychiatry, and internal medicine, were positively associated with the utilization of virtual clinics in our study. The findings may help direct future policy for expanding the use of virtual clinics, especially in countries struggling with the development and promotion of telemedicine virtual clinic services. Further studies should be conducted to evaluate the trends in and utilization of virtual clinics in the postpandemic period in different countries and health care systems, to examine the effectiveness and acceptability of telemedicine as a routine alternative practice to in-person clinics, and to investigate the economic impact of telemedicine from the perspective of the provider, the health care system, and society.

Abstract

Background: Care coordination is challenging but crucial for children with medical complexity (CMC). Technology-based solutions are increasingly prevalent but little is known about how to successfully deploy them in the care of CMC.

Objective: The aim of this study was to assess the feasibility and acceptability of GoalKeeper (GK), an internet-based system for eliciting and monitoring family-centered goals for CMC, and to identify barriers and facilitators to implementation.

Methods: We used the Consolidated Framework for Implementation Research (CFIR) to explore the barriers and facilitators to the implementation of GK as part of a clinical trial of GK in ambulatory clinics at a children's hospital (NCT03620071). The study was conducted in 3 phases: preimplementation, implementation (trial), and postimplementation. For the trial, we recruited providers at participating clinics and English-speaking parents of CMC<12 years of age with home internet access. All participants used GK during an initial clinic visit and for 3 months after. We conducted preimplementation focus groups and postimplementation semistructured exit interviews using the CFIR interview guide. Participant exit surveys assessed GK feasibility and acceptability on a 5-point Likert scale. For each interview, 3 independent coders used content analysis and serial coding reviews based on the CFIR qualitative analytic plan and assigned quantitative ratings to each CFIR construct (–2 strong barrier to +2 strong facilitator).

Results: Preimplementation focus groups included 2 parents (1 male participant and 1 female participant) and 3 providers (1 in complex care, 1 in clinical informatics, and 1 in neurology). From focus groups, we developed 3 implementation strategies: education (parents: 5-minute demo; providers: 30-minute tutorial and 5-minute video on use in a clinic visit; both: instructional manual), tech support (in-person, virtual), and automated email reminders for parents. For implementation (April 1, 2019, to December 21, 2020), we enrolled 11 providers (7 female participants, 5 in complex care) and 35 parents (mean age 38.3, SD 7.8 years; n=28, 80% female; n=17, 49% Caucasian; n=16, 46% Hispanic; and n=30, 86% at least some college). One parent-provider pair did not use GK in the clinic visit, and few used GK after the visit. In 18 parent and 9 provider exit interviews, the key facilitators were shared goal setting, GK's internet accessibility and email reminders (parents), and GK's ability to set long-term goals and use at the end of visits (providers). A key barrier was GK's lack of integration into the electronic health record or patient portal. Most parents (13/19) and providers (6/9) would recommend GK to their peers.

Conclusions: Family-centered technologies like GK are feasible and acceptable for the care of CMC, but sustained use depends on integration into electronic health records.

Introduction

Defined by high service needs, high resource use, and functional disability, children with medical complexity (CMC) represent a disproportionately high share of pediatric care use but receive poor quality care when compared to their noncomplex counterparts [1-6]. CMC often require care coordination across multiple health care systems with a large care team that includes professional care providers, adult caregivers, and community agencies. Care coordination through multidisciplinary care teams centered around a patient-centered and family-centered medical home may improve outcomes for CMC but can be resource-intensive [7,8]. Moreover, many CMC access care across multiple health systems, receive care in resource-limited settings, and do not live adjacent to a tertiary pediatric center where many of these clinics are based, making scalability of these innovative teams difficult. Health care that is centered around shared goal-setting is a commonly proposed approach to coordinate care for CMC to improve clinical decision-making, family engagement, and health outcomes [9,10]. Although prior studies have deployed multidisciplinary teams to create shared care plans, few studies exist for effective and scalable tools to facilitate shared goal setting [8,11]. For children with noncomplex chronic conditions (eg, asthma, type 1 diabetes), mobile health technologies may provide efficacious ways to manage chronic medical conditions for children. These positive outcomes may translate to the care of CMC but to do so may also need to overcome additional challenges such as team hierarchies, loosely coupled teams, and asynchronous time scales among providers [12-14]. Many of these challenges affect the implementation of mobile health tools, which is essential for even the most efficacious tools.

In this study, we evaluated the implementation of an internet-based shared goal-setting tool (GoalKeeper) into the care of CMC. GoalKeeper is an internet-based tool developed by the study team to improve shared goal setting between parents and providers of CMC, and designed through interviews and iterative prototyping with this population. GoalKeeper consists of 2 modules: goal elicitation and tracking. The goal elicitation module is meant to be used jointly by parents and providers during a clinic visit to set family-centered goals and is shown in Figure S1 of Multimedia Appendix 1. During goal elicitation, parents and providers are prompted verbally and visually to share the screen and use verbal prompts on the screen to set goals. The first set of prompts asks for the parent's wishes/worries/concerns for their child's health care and the second set of prompts helps the parents and providers set specific, measurable, and timebound goals based on the wishes/worries/concerns. A third subsection of this module provides sample goals as inspiration. The tracking module includes customizable templates that providers could assign to parents to use to track their child's symptoms and daily progress relevant to the goals they set. After setting goals with their patient's parents, the providers could assign tracking templates relevant to these goals for parents to use in longitudinal symptom tracking during the trial. GoalKeeper was designed to be outside the electronic health record (EHR) to allow for rapid design modifications and to enable thorough assessment of effectiveness before potential future integration into the EHR. To facilitate the integration of the entered data into the EHR, the final screen of the goal-setting module also presents the data (ie, the wishes/worries/concerns and the goals) as a block text with a button to copy the text for easy pasting into the EHR. Parents and providers had distinct interfaces where they could view and input data. Providers could create new goals and tracking forms, while parents could view set goals and input data into the tracking templates. Additional details about GoalKeeper can be found in our forthcoming companion manuscripts (B Huber et al, unpublished data, 2022, and J Lin et al, unpublished data, 2021).

To illustrate how GoalKeeper works, we will consider a sample patient, Alex, a 7-year-old child with medical complexity who arrives at the clinic with his parents. In response to the first verbal prompt, his parents state they worry about Alex not attending school and not sleeping enough. At the next prompt, Alex's parents struggle to identify a specific goal; therefore, they turn to the sample goals for inspiration. After viewing sample goals focused on child development and discussion with their provider, they set a goal that, "Alex could be more awake during school based on adjustment of seizure medicines in the next two months." Alex's provider assigns a tracking template to measure school attendance and quality of sleep.

Nested within a larger effectiveness trial of the tool, this study aims to assess the barriers and facilitators of implementation of the GoalKeeper tool by using the Consolidated Framework for Implementation Research (CFIR) implementation framework. The CFIR is widely used to identify barriers and facilitators of implementation, including in health communication and adult and child chronic illness [15-18]. The CFIR contains 5 domains that interact to influence implementation effectiveness: inner setting, outer setting, characteristics of the individuals involved, intervention characteristics, and implementation process, with multiple constructs nested in each domain [15].

Methods

Study Design

This study is a prospective study of the implementation of a novel internet-based family-centered care plan called GoalKeeper nested under a prospective, stepped-wedge trial of GoalKeeper at a tertiary children's health system, Lucile Packard Children's Hospital Stanford. Details about the intervention design and results from the main trial are published in upcoming companion manuscripts (B Huber et al, unpublished data, 2022, and J Lin et al, unpublished data, 2021). Information about GoalKeeper is available through data-sharing requests directed to lsanders@stanford.edu. This study was conducted in 3 phases: preimplementation, implementation, and postimplementation. We selected a 3-phase approach, as the application of implementation science throughout intervention development is associated with increased success of implementation [18]. We selected the CFIR framework owing to its flexibility in assessing both the process of implementation and the barriers and facilitators to implementation, its use in formative evaluations at the preimplementation phase, and owing to the lack of effectiveness data of the novel tool used in the trial, as proven effectiveness is a key element of other implementation frameworks, whereas our trial evaluated the effectiveness of the tool with a secondary focus on implementation [16,19].

In the preimplementation phase, we conducted user testing in 3 stages of tool development: (1) early: parent and provider focus groups; (2) mid: individual role-play sessions and interviews using screen by screen feedback, hands-on, and think-aloud; and (3) late: pilot testing at Complex Primary Care Clinic (CPCC) with parents using GoalKeeper for a month after their clinic visit, instructing them to use GoalKeeper at least 3 times a week, followed by an exit interview. Focus groups and interviews used the CFIR interview guide questions to explore barriers and facilitators to the implementation of GoalKeeper. In the implementation phase, we implemented GoalKeeper at CPCC and pediatric neurology clinics by using implementation strategies informed by preimplementation focus groups. We recruited parent participants from the clinic of each enrolled provider for 3 weeks. Each parent was asked to use GoalKeeper with their provider at their enrollment clinic visit and for 3 months after the initial visit. At the end of the study, participants completed a postimplementation semistructured interview and survey.

Ethical Considerations

This study was approved by the Stanford University's Single Institutional Review Board (Protocol # 32161) and is registered on ClinicalTrials.gov (NCT03620071).

Study Population

For preimplementation focus groups and interviews, we recruited parents of CMC seen at Stanford by using a convenience sample of parents at CPCC. We selected providers from clinics planned for trial recruitment, CPCC and pediatric neurology, the hospital medicine team with specialization in caring for CMC, and a provider with expertise in clinical informatics for feedback on workflow integration. For the implementation phase, we recruited medical providers (physicians, nurse practitioners, physician assistants) from 2 clinical services that see the highest proportion of CMC: CPCC and pediatric neurology (2 clinics that historically care for many CMC). All providers at these clinics were eligible for recruitment. Based on prior work, goal setting was not routine practice in these clinics [14]. From the patients seen by enrolled providers, we recruited a convenience sample of primary caregivers (eg, parents). Parents were eligible if they were aged ≥18 years, English-speaking, and with a child with medical complexity <12 years presenting for a routine (not sick) visit. Parents who did not have home access to the internet were excluded. We excluded older children, who may have the capacity to participate in decision-making, since the tool was not designed for interaction with children [20]. We defined medical complexity as meeting all of the following criteria in the past 12 months: ambulatory visits with at least 2 subspecialty providers and functional impairment due to a chronic condition [21]. Recruitment occurred solely in-person, but due to the COVID-19 pandemic, recruitment was paused between March 13 and July 20, 2020. We did not pursue remote recruitment owing to concerns of intervention fidelity because GoalKeeper was designed to be used jointly by the provider and parents during a clinical encounter.

Measures and Outcomes

We focused on 3 of the 5 CFIR domains: intervention characteristics (GoalKeeper), inner setting (CPCC and pediatric neurology clinics), and characteristics of individuals involved (parents and providers of CMC). We used an adapted version of the CFIR interview guide focus groups and interviews to inform our approach for implementation of GoalKeeper [15,22]. The CFIR interview guide contains open-ended interview questions organized by the CFIR domain and construct. To limit interview length, the entire study team reviewed the interview guide together and selected questions based on constructs that we felt were the most relevant to our study. All focus groups and interviews were audio recorded and transcribed for subsequent review.

In the preimplementation phase, we conducted focus groups in person with study team members as observers. Focus groups included a project overview, a demonstration of the current intervention prototype, open feedback about the intervention, and semistructured questions. In the implementation phase, we collected user data from all participants, including number of goals set, types of goals set, and number of data entries after the encounter. We assessed feasibility based on the proportion of the intervention group who used GoalKeeper during the clinical encounter. In the postimplementation phase, we conducted individual exit interviews with parent and provider participants. We assessed acceptability by using a 5-point Likert scale to determine whether GoalKeeper was useful and fit into the clinic workflow.

Analysis

For preimplementation focus groups, all study team members collectively synthesized the key facilitators, barriers, and design considerations immediately after each focus group and interview and at weekly team meetings after reviewing the transcripts. Postimplementation exit interviews were analyzed using the CFIR qualitative analytic approach that starts with deductive coding to apply the CFIR as a coding framework and then applies inductive methods by using open, axial, and selective coding to create new codes and ultimately themes that arose from the data [23]. Three independent coders (authors JLL, KSR, and KMO) analyzed each transcript. After coding each transcript, the coders independently rated each represented CFIR construct on a scale of –2 (strong barrier to implementation) to

+2 (strong facilitator to implementation) based on the CFIR analytic approach and calculated the overall ratings for all transcripts based on the median rating. At serial coding reviews, we reviewed codes and CFIR ratings to reach consensus and generated themes based off the transcripts. We calculated means and SDs for the feasibility and acceptability measures and logged data. We compared participant characteristics between parents who were interviewed and those who were not by using chi-square tests for categorical variables and 2-sided Student *t* test for continuous variables with a significance level of $P \leq .10$.

Results

Preimplementation Results

For the preimplementation phase, in the early design stage, we conducted 1 provider focus group and 1 parent focus group. The provider focus group consisted of 3 physicians with specialties in general pediatrics, pediatric neurology, and clinical informatics. The parent focus group consisted of 2 parents of CMC. In the middesign stage, we conducted role-play sessions with 2 providers (1 complex care, 1 hospitalist) and interviewed 3 parents and 1 neurologist. In the late design stage, 2 parents pilot-tested GoalKeeper. From these focus groups and interviews, we devised 3 implementation strategies based on those previously tested by other studies: educational materials, individual technical assistance, and automated email reminders to parent participants [22].

Implementation Results

During the implementation phase, participants received educational materials, including paper and electronic copies of an instructional manual on GoalKeeper, with parent and provider versions. Parents also received a 5-minute in-person overview of GoalKeeper, while providers received a 30-minute overview, including a 5-minute educational video on using GoalKeeper during a clinic visit. A member of the study team was available for in-person individual technical assistance in clinic and reachable by email or phone outside of clinic but did not attend the clinic visit with intervention participants. Parent participants received automated weekly email reminders to log into GoalKeeper and track their progress on the goals that were set. Email frequency was set at 1 week by default, but the reminder frequency could be modified by parents, including turning reminders off.

We enrolled 11 providers and 35 parents (15 from complex care and 20 from neurology) in the intervention arm of the trial. The providers were mostly physicians (9/11, 82%), mostly female (7/11, 64%), and pediatric neurologists (6/11, 54%). Parents had a mean age of 38.3 (SD 7.8) years, were mostly female (28/35, 80%), primarily identified as White (17/35, 49%), almost half identified as of Hispanic ethnicity (16/35, 46%), with a mean household size of 4.1 (SD 1.0), were married (23/35, 66%), and had at least some college education (86%). Children of participants had a mean age of 5.9 (SD 3.8) years, 18 (51%) identified as White, 16 (46%) as Hispanic, 25 (71%) were followed by a neurologist, 20 (57%) had technology dependence, and 20 (57%) had neurodevelopmental delay. A total of 16 parents were lost to follow-up: 7 at the 1-month follow-up and 9 at the 3-month follow-up; 9 providers and 19 parents completed exit surveys, and 9 providers and 18 parents (7 CPCC, 11 neurology) completed exit interviews. Parent, provider, and child characteristics can be found in Tables 1-3, respectively.

During the initial clinic visit at the start of the study, 34 parent-provider dyads completed goal setting with GoalKeeper. For the 1 parent-provider dyad who did not complete goal setting, the provider decided in the visit that the parent was not a good fit to participate in the trial as the patient was revealed during the clinic visit to have an acute medical issue that needed to be the focus of the entire visit.

Postimplementation Results: Feasibility and Acceptability

Of the 19 parents who completed the exit survey, 13 (68%) parents responded that they would recommend GoalKeeper to other parents. Only 1 respondent would not, while others were undecided; 6 (67%) providers would recommend GoalKeeper to other providers. Providers commented that they would have wanted GoalKeeper integrated into the EHR. Parents would have wanted more options for reminders for use of the tool, 12 (86%) parents felt the tool was easy to use, 6 (75%) providers found GoalKeeper useful, and 4 (50%) providers felt GoalKeeper fit into their workflow. More details on the survey results are summarized in Table S2 of Multimedia Appendix 1.

From data use logs of participant use of GoalKeeper, parents and providers set a median of 2.5 (range 0-4) goals per initial clinic visit, and providers assigned a median of 3 (range 0-5) tracking templates to each parent participant. Each provider saw a median of 2.5 (range 0-10) parent participants. After the initial clinic visit, parents input information into GoalKeeper a median of 0 (range 0-19) times and providers viewed tracked data a median of 0.5 (range 0-2) times throughout the study period. The patterns of tool use based on the number of tracking templates created are summarized in Figure S3 of Multimedia Appendix 1. We conducted a post hoc analysis of correlation between the number of tracking templates used and the number of times parents entered data into the tracking templates and found a Pearson correlation coefficient of 0.41 (*P*=.01); 19 parents (8 CPCC and 11 neurology) did not enter any data into the tracking templates, while 13 parents (4 CPCC and 9 neurology) entered data 1-10 times, and 3 parents all from CPCC entered data over 10 times. Of the parents who were interviewed, 6 (1 CPCC and 5 neurology) did not enter any data, while 8 (2 CPCC and 6 neurology) entered data 1-10 times, and 3 (all CPCC) entered data over 10 times.

Postimplementation Results: Barriers and Facilitators

Participant exit interviews covered CFIR domains of intervention characteristics, inner setting, and characteristics of individuals involved and their related constructs. From these interviews, we categorized each barrier and facilitator under a CFIR domain and construct based on topic and rated each CFIR construct that was represented in the interviews. Participant knowledge and beliefs about goal setting were facilitators to implementation with a rating of +1 whereas adaptability and compatibility were barriers, with each receiving a rating of –1. The complete ratings are given in Table 4. Limited quotes are provided in the text with additional quotes found in Table 5. There were no statistically significant differences in parent or child characteristics between those who were interviewed and those who were not except for participants who were interviewed were more likely to have a child with a vagal nerve stimulator (*P*=.08).

Table 4. Consolidated Framework for Implementation Research ratings by construct and participant type.

Domain mean ratings (scale, –2: strong barrier; +2: strong facilitator)	Parents (n=19)	Providers (n=9)
Inner setting		
Tension for change: the degree to which stakeholders perceive the current situation as intolerable or needing change	1	0
Compatibility: the degree of tangible fit between meaning and values attached to the intervention by involved individuals, how those align with individuals' own norms, values, and perceived risks and needs, and how the intervention fits with existing workflows and systems	–1	–1
Characteristics of individuals		
Knowledge and beliefs: individual's attitudes toward and value placed on intervention as well as familiarity with facts, truths, and principles related to the intervention	1	1
Individual state of change: characterization of the phase an individual is in, as he or she progresses toward skilled, enthusiastic, and sustained use of the intervention	1	0
Intervention characteristics		
Relative advantage: stakeholder's perception of the advantage of implementing the intervention versus an alternative solution	0	0
Complexity: perceived difficulty of implementation, reflected by duration, scope, radicalness, disruptiveness, centrality, and intricacy and number of steps required to implement	1	0
Adaptability: the degree to which an intervention can be adapted, tailored, refined, or reinvented to meet local needs	–1	–1

Table 5. Sample quotes and main themes for implementation.

	Parents	Providers
Facilitators		
Parents and providers		
Goal-centered care is important to the care of children with medical complexity (tension for change)	"...I thought, 'This is interesting. I think this is going to be good.' Setting up the goals and giving me something on my side to kind of think about and work toward." (Parent 1227, age 57 years, some college)	"...I think it's important because sometimes the physician's goals are not the same as the family's goals. And so shared decision making doesn't always happen." (Provider 39, neurology)
Reminders are helpful, and more flexibility around reminder frequency would have improved use; providers wanted limited reminders (individual state of change)	"...Mostly when I get emails from you and stuff and it also reminds me too that I need to check her goals and everything I have on there." (Parent 1494, age 29 years, high school diploma)	"...And kind of the structured way of kind of connecting, whether it's weekly, or daily, or monthly, or whatever it is. To keep on something that is important for the family. I think it is important. So that might be useful." (Provider 33, complex primary care clinic)
The tool helped facilitate goal-centered care (knowledge and beliefs)	"...There are so many things I need to take care of. But then, when it comes to zeroing down to the main thing that matters, in that way, Goalkeeper was very helpful for me." (Parent 1510, age unknown, college degree)	"...And so in theory, this is a really great and I totally think that this is the way as a physician you should be thinking about it and trying to see what your family's goals are so that you can understand what it is that they want you to help with." (Provider 69, neurology)
Parents only		
The tool could be accessed from anywhere, but 2 parents still used other tools (relative advantage)	"...I always used to bring it in my own binder to the doctor and it's just a lot to carry rather than when I just have my cell phone all the time." (Parent 1476, age 38 years, some college)	N/A[a]
Providers only		
The tool should be used at end of visit to fit into clinic workflow (compatibility)	N/A	"...I mean sometimes if it worked out that I had to do it in the beginning of the visit because you were in the room to help me out and things like that, I found that less desirable than if I was able to time it toward the end of the visit." (Provider 50, complex primary care clinic)
The tool opens doors in patient care that providers otherwise would not explore (knowledge and beliefs)	N/A	"...So what the patient or their family values the most. So what they find most important to them, often times that comes into quality of life decisions, for example. So in that discussion about eating, they might value being able to eat some or having their child being able to eat some food more than a 50% reduction in their seizure frequency, or even being seizure free. Whereas by default, normally I would-- we're very focused on seeing if we can get to zero seizures. And knowing that that's the relative value that the family's putting on things is very, very important. Sometimes that would mean that maybe there is a reason why that is, or just as also just means important that there'll be something to work on because there can be trade-offs between those two things. For example, higher doses of antiseizure medications might cause more drooling or less ability to be awake to eat. Does that make sense? So both things are valuable, but which one is more valuable to that family? And so that you can-- it helps you prioritize between those two goals or two potential actions." (Provider 63, neurology)
Barriers		

	Parents	Providers
Parents and providers		
The tool would have been easier to access if it was embedded in the electronic health record/MyChart (compatibility)	"...I think the disadvantages is having another thing to log into. As is evidenced by the fact that I can't seem to get in right now I can barely keep all of my logins straight at the moment but MyChart is sticky. I have to use MyChart to keep track of-- my son has a complex medical condition, right? So between the insurance billings and keeping the appointments straight and dealing with all the different providers at Stanford, I'm tethered to MyChart." (Parent 1150, age 45 years, advanced degree)	"...The actual use of the application is a little awkward because it requires a separate login to the website. In terms of feedback, it would be nice if that could be embedded in the chart." (Provider 63, neurology)
Lack of feedback and closed loop communication hindered frequent use of the tool due to feelings that the other party was not using the tool (relative advantage)	"...So right now, being able to communicate with the doctor and having them understand that there is a communication between the two of you rather than on GoalKeeper it's only a one-way email and then they'd have to call you because there was no option for them to email." (Parent 1476, age 38 years, some college)	"...So I wouldn't want to use it if that kind of-- for some reason we're just not getting reliable feedback from families. If there's not a loop there." (Provider 50, complex primary care clinic)
Parents only		
Only providers could create and change goals, hindering parent engagement with the tool when goals became irrelevant (adaptability)	"...in the beginning when we first started, it was nice. But at the same time, as time goes by, it becomes a little bit more repetitive, especially when you're not able to change things unless you go to the provider's office or speak to the provider." (Parent 1490, age 33 years, some college).	N/A
Limited or unreliable internet access prevented constant use of the tool (adaptability)	"...I have limited internet data on my phone. The first time when I was able to access the first surveys, they were easy. The alert came. I was able to connect, and I was able to answer the questions with no problem. Again, in my case is not having access to technology when make this difficult for me." (Parent 1668, age 53 years, some college)	N/A
Providers only		
When providers perceived they were already practicing goal-centered care, they felt the tool was redundant even if they adopted aspects of the tool into their practice (relative advantage)	N/A	"...I think it is something that I do regularly as part of our visit. So I don't know that it's going to change my practice or very much in terms of goal-setting." (Provider 42, neurology)

[a] N/A: not applicable.

Intervention Characteristics

When compared to existing tools, parents and providers felt that GoalKeeper was a better way to start goals-of-care conversations. One provider shared:

> *I think, personally, I always phrased it in my own clinical practice, just as, "Tell me something that is most important to you or something that is a priority for us to work on for your child right now." Again, just trying to not actually always use the word "goal" itself. Or if you did ask what the parents' goals were, then providing just a little bit more of an explanation. So I did think that, again, the wording of "wishes and worries" I liked. It was something new for me that was not a wording choice I had used before* [Provider 57, CPCC]

Parents and providers also felt that GoalKeeper facilitated teamwork during and after clinic visits. Parents also liked that GoalKeeper could be accessed from anywhere they had internet access.

All providers and most parents felt a barrier to use of the intervention was difficulty accessing the intervention because the URL link was not user-friendly, and they had to access it through a previously received email from the study team. Home internet connectivity issues also prevented some parents from using GoalKeeper in the follow-up period. Two parents perceived that the goal-setting portal being provider-driven hindered their use of the intervention because their provider was unengaged about updating the goals after the initial visit.

Inner Setting

Almost all parents and providers felt there was a need for more shared goal setting in their current clinical care, which they felt promoted improved parent-provider engagement particularly for patients with more active complex medical issues. Providers overwhelmingly felt that parents of children who would need the provider's long-term care to be the ideal audiences for the intervention with some providers saying that the intervention allowed them to focus on parents' long-term goals. Parents also felt the intervention could fit parents of younger children who had developmental goals such as those with prematurity or other children with special health care needs. GoalKeeper was felt by both providers and parents to be incompatible with existing workflows because it was not integrated into the EHR and patient portal. Providers felt using the intervention during the middle or end of their visit fit better into their workflow, but that clinic time constraints make it hard to squeeze the intervention into the visit. Providers also wanted a Spanish-language form of the platform to target a population they felt is most in need of help setting goals for their child. When using the tracking module, parents overall desired provider feedback and communication about the information parents entered into the intervention with 1 parenting summarizing, “if there is no two-way communication or if there is no template or anything set up, then the value goes down” (Parent 1898, age 47 years, advanced degree). Parents admitted that at times, competing priorities for their child's health superseded the use of GoalKeeper such as when a child became hospitalized for an issue that was not captured in the goals they set in GoalKeeper.

Characteristics of the Individuals Involved

All participants felt that conversations centered around goal-setting were beneficial because they switched medical discussions to long-term and in the context of what is important to the family. Parents felt that the intervention shifted their mindsets by focusing them on the main concerns for their child. Parents felt that using the intervention made them more confident to articulate their concerns to their providers during the clinic visit and helped them identify to-do lists to achieve their goals for their child, with 1 parent remarking:

> *So I think that that's kind of the gift of motivation because it's like, “Oh, yes. We have some ability.” I think sometimes you look at a child who has a lot of needs and as a parent, you can get discouraged and then think, “Okay. We'll just do whatever the doctor say.”...so I guess that's a part of knowing that you can do some things to improve your child's life and to reduce their sort of future medical interventions is so helpful as a lot of parents can feel helpless with these kind of situations* [Parent 1368, age 37 years, college degree]

Parents also remarked that GoalKeeper helped them prioritize their child's short- and long-term goals. Parents felt supported and hopeful about the well-being of their child. However, most parents and providers did not adopt the intervention in its entirety with most participants only using the intervention during the initial clinical encounter. One provider shared that “like every habit, I think it might take many repetitions to start to want to use it regularly” (Provider 33, CPCC). Furthermore, providers were more motivated to use the intervention if they felt it opened new doors to insights about the patient that were not captured in their typical clinical practice. One provider remarked:

> *Well, I think there are some issues that came up and some questions I just hadn't asked before and a lot of it focused around happiness and joy and things like that that led to conversations with families I hadn't had before. So I think sometimes it'll open doors for me and the preset questions might even be more so. It'd opened doors for me that I might not have opened without Goalkeeper or without asking* [Provider 50, CPCC]

Two providers felt GoalKeeper was redundant to their practice even though they integrated part of GoalKeeper into their future practice.

Implementation Strategies

The 3 implementation strategies used during the study, that is, educational materials, individual technical assistance, and automated email reminders to parent participants, had varying success. The video tutorial provided to providers was found to be useful during the initial training, but few viewed the video after the training. No participant used the paper manual. Few participants used the individual technical assistant either virtually or in person, but for those who encountered technical issues during the visit, they found it useful with 1 provider commenting:

> *I always forgot the step where I was supposed to copy the goal and then go back to the page to add the template. So I just felt like each time you enrolled a patient, I was always turning back toward you to ask if I was clicking through it correctly to actually enter goals* [Provider 57, CPCC]

Parents overwhelmingly felt that the automated email reminders helped sustain their use of the intervention by reminding them of the goals they set for their child and to log into the system to use the tracking module with 1 parent remarking:

> *The email reminders were really great at making it easy to just log on and track it. And then it really was not time-consuming* [Parent 1352, age 28, some college]

Discussion

In this pilot clinical trial of a novel internet-based goal-setting tool, we successfully implemented the tool for use during ambulatory clinic visits to facilitate goal elicitation. However, we did not succeed in the sustained use of the tool after the initial clinic visit. A key facilitator to implementation was participant value for the intervention's stated aim: family-centered goal setting. A key barrier to implementation was inadequate integration with the EHR and patient portals. Provider use of the tool was also influenced by whether they felt the tool opened new doors to insights about the patient and their family that they were unable to get in their usual practice such as the relative priority of seizure control compared to appetite or wakefulness. Although automated email reminders were important to sustain tool use, they were insufficient. Parents and providers wanted a more dynamic way to communicate about goals through the intervention with most participants sharing that a feedback loop from the other party would have encouraged continued tool use. One aspect of the intervention design that is critically important is that the English-language and internet-based platform may exacerbate difference in care quality for minority and less-resourced populations.

Although our findings that automated email reminders and training are helpful implementation strategies are consistent with the implementation of digital health tools in adult chronic illness, we provide new insights for pediatric chronic illness care [24]. For example, we found that parents and providers both desired a feedback loop to sustain, which adds the caregiver perspective to prior studies of patient-generated health information where sustained use hinged on a tangible immediate benefit [25]. These findings also contribute practical considerations to the implementation of multidisciplinary care and family-centered care plans, particularly with regard to scalability and replicability across multiple institutions [11].

Our findings also contribute an implementation science perspective to practice transformation in digital health. We found that a lack of workflow integration hindered the compatibility of our intervention with the existing workflows of the providers. Future research should explore the use of clinical staff as mediators between providers and patients or caregivers for patient-reported information to facilitate intervention adoption and alleviate potential burdens that providers face with the introduction of a new intervention [26]. Furthermore, integration of our intervention into the workflow of clinical staff could address the needed feedback loop that our study participants desired but felt was lacking in the current form of the intervention. Having a tool that is well-integrated into clinic workflows would allow providers to revise and update goals as they evolve, the absence of which prevented parents from using the tool for a longer term in our study. A lack of workflow integration hindered other interventions across broad populations, including in advanced care planning for adults, pain management, and surgical safety [27-29]. Our intervention also was outside the electronic health portal, resulting in similar issues of workflow integration that have been observed in other digital interventions for populations with chronic conditions [30].

Although we purposefully built the intervention outside of the EHR to allow for rapid design improvements based on study results, future research should also explore integration of goal-setting tools within the EHR and patient portals to improve adoption. Recent efforts by payers to endorse the use of open application programming interfaces may help accelerate the integration of patient-generated health data into EHRs [31,32]. Such integration efforts should consider barriers found in our study, including how to represent patient-generated data and how to integrate goal-setting actions into the provider workflow [33,34]. As patients and parents gain access to provider notes, this research may guide efforts to improve patient and parent understanding, improve communication, and increase their empowerment [35,36].

Finally, language-related disparities must be addressed in any digital health intervention. Our participants emphasized the potential for an English-only internet-based intervention to exacerbate disparities in high-quality care coordination. Populations with low health literacy report lower use of digital health tools, which may widen the gaps in care quality they already experience owing to low health literacy [37,38]. Although 90% of the adults in the United States use the internet, fewer than 2 in 3 adults who identify as Hispanic or African American have broadband access at home with similar patterns based on lower income and education level [39]. Moreover, preference for languages other than English is associated with a decreased use of digital health tools for patient-provider communication [40]. Therefore, future work in implementation science of digital health tools should aim to understand the modifiable factors that influence the adoption by patients and families with preferences for languages other than English.

Our study should be interpreted in the context of a few limitations. The preimplementation phase used feedback from a small sample of parents and providers, which may have biased the selection of implementation strategies. Given the small number of providers practicing at each clinic, we limited feedback to a few providers to preserve an adequate provider sample for the trial. This study was conducted in a single academic medical center, which may not be reflective of the practice at other institutions caring for CMC. Not all parent participants participated in the exit interview, which may have introduced selection bias, but aside from the presence of the vagal nerve stimulator, there were no statistically significant differences in these 2 populations. Overall, our study period was quite short. Thus, the long-term use of our intervention, particularly on a repeat clinic visit, was not observed. The success of long-term implementation should be assessed with future studies.

Conclusion

Family-centered technologies like our intervention can be successfully implemented into ambulatory primary and subspecialty care. However, long-term adoption rests on integration into the EHR and patient portal as well as adaptation of tools for users who prefer languages other than English.

Abstract

Background: During the COVID-19 pandemic, video consultations became a common method of delivering care in general practice. To date, research has mostly studied acute or subacute care, thereby leaving a knowledge gap regarding the potential of using video consultations to manage chronic diseases.

Objective: This study aimed to examine general practitioners' technology acceptance of video consultations for the purpose of managing type 2 diabetes in general practice.

Methods: A web-based survey based on the technology acceptance model measuring 4 dimensions—perceived usefulness, perceived ease of use, attitude, and behavioral intention to use—was sent to all general practices (N=1678) in Denmark to elicit user perspectives. The data were analyzed using structural equation modeling.

Results: The survey sample comprised 425 general practitioners who were representative of the population. Structural equation modeling showed that 4 of the 5 hypotheses in the final research model were statistically significant ($P<.001$). Perceived ease of use had a positive influence on perceived usefulness and attitude. Attitude was positively influenced by perceived usefulness. Attitude had a positive influence on behavioral intention to use, although perceived usefulness did not. Goodness-of-fit indices showed acceptable fits for the structural equation modeling estimation.

Conclusions: Perceived usefulness was the primary driver of general practitioners' positive attitude toward video consultations for type 2 diabetes care. The study suggests that to improve attitude and technology use, decision-makers should focus on improving usefulness, that is, how it can improve treatment and make it more effective and easier.

Introduction

Background

Technological change and the use of new technologies in health care are driven by objectives to increase access to health care, reduce care costs, coordinate health care, and facilitate chronic disease prevention and management [1]. The COVID-19 pandemic, caused by SARS-CoV-2 infection, has spurred health care systems to rapidly change from delivering in-person care to using different types of web-based care [2-4] such as video consultations [5]. Within the primary care sector, the uptake of video consultations has increased [6], and general practitioners' use of the technology has internationally moved from being used in pilot projects to wider-scale use [7-9]. The care potential of using video consultations in general practice is considered high [10,11], and this technology holds the potential to disrupt how health care is delivered in the primary care sector [12].

The recent uptake of video consultations in general practice is intriguing as the use of new health care technology and its implementation typically takes years [5,13]. This is because digital-first approaches to primary care could increase general practice workload [14] or threaten professional autonomy [15]. Similar to the hospital sector [16,17], knowledge about the impact of video consultations on general practice is in its infancy, and the literature is particularly short on quantitative studies [18]. The nascent literature finds that offering video consultations constitutes a significant change in how health care professionals deliver and patients receive care [19]. Research into factors that influence the implementation of video consultations in routine practice finds that, for instance, training is an important facilitator [20], and hesitance to change is an equally important barrier [21]. Research suggests that general practitioner characteristics (eg, age and sex) do not influence use, although working in larger practices makes it more likely [22,23]. Interaction and communication between patients and general practitioners during video consultations are usually effective [24,25]. However, patients and practitioners report mixed user experiences but with the important point that user ratings depend on the context in which video consultations are used [26-31]. Younger patients were found to be more likely to request or be offered a web-based visit [32].

However, research has not systematically elicited general practitioners' attitudes toward video consultations or their perceptions of the ease of use or usefulness in general practice. This research gap is unfortunate as it is well established in IT literature that attitude and perception influence physicians' use of other types of health care technology such as electronic patient records or telemedicine [33-35]. The technology acceptance model (TAM) has proven to be a robust model through rigorous empirical testing within and beyond health care [36,37]. TAM is capable of studying user attitudes and perceptions and has good predictive power of health technology use [38]. Central to the original TAM [39] and later extensions [40] is that the behavioral intention (BI) to use technology is influenced by users' ratings of perceived usefulness (PU), perceived ease of use (PEOU), and attitude toward the technology. Importantly, BI to use predicts actual user behavior [41,42].

Using the insight that chronic disease prevention and management are key drivers of technological change, this paper studies the potential of using video consultations in general practice to manage type 2 diabetes for 3 reasons. First, type 2 diabetes is a chronic disease for which video consultation appears promising in general practice [43-45]. Second, previous research on the use of video consultations in general practice has mostly studied acute or subacute or out-of-hours care and, to a much lesser extent, the management of chronic care taking place during regular hours [17,25,31]. Third, it is important to find care models capable of delivering high-quality and efficient type 2 diabetes care in general practice [46,47] as the disease prevalence is increasing [48] and people living with type 2 diabetes are at higher risk of developing complications [49].

The aim of this paper is to use TAM to study general practitioners' technology acceptance of video consultations to manage type 2 diabetes in general practice. The hypotheses were that higher levels of attitude, PU, and PEOU positively affect general practitioners' BI to use video consultations to manage type 2 diabetes. Bringing to bear TAM on video consultations in general practice allows exploring the potential of using the technology for a type of chronic care where health care systems need to find new ways of increasing health care access and cutting care costs.

Research Model and Hypotheses

The research model (Figure 1) builds on TAM [39] and posits that general practitioners' perception of the degree to which video consultations used to manage type 2 diabetes are easy to use affects both perceptions of usefulness and attitudes toward using the technology. General practitioners' attitudes are also influenced by their perception of how useful the technology is. Ultimately, general practitioners' intention to use video consultations to manage type 2 diabetes can be explained by their attitude toward the technology and PU. The following develops 5 hypotheses by combining research insights on TAM, general practitioners, and the primary health care domain.

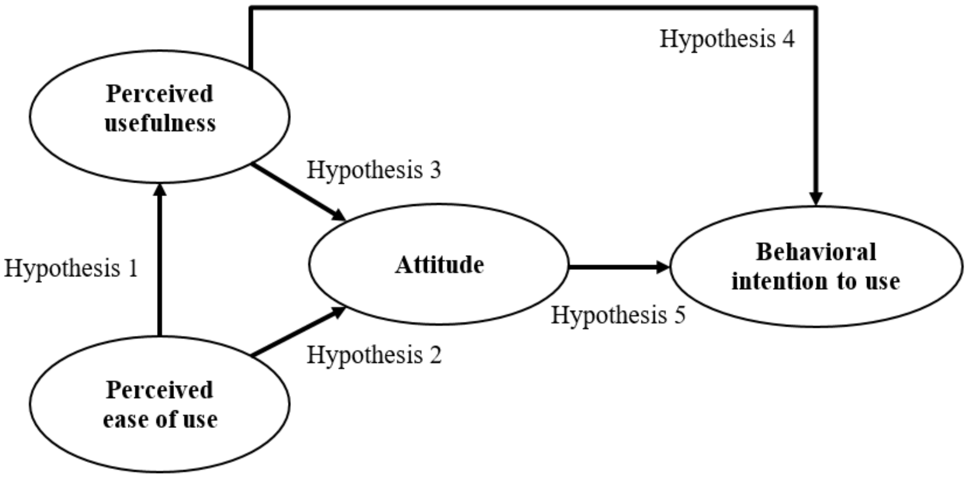
PEOU influences BI to use indirectly through both attitude and PU. A high PEOU represents the belief that using the technology will require little to no effort [39]. PU concerns the extent to which a user believes that the technology can improve or make their work more effective and easier and how it will be advantageous over the current practice. The relationship between PEOU and PU is expected to be positive as health care studies find that a higher level of PEOU leads to higher ratings of P [50-52]. Moreover, studies have shown that when a technology is perceived as easy to use, the attitude toward the technology is more positive [40,52]. The attitudinal component of the model measures an individual's affective response to adopting a new technology. Attitude concerns the extent to which a user finds that using the technology is a good idea, beneficial, or unpleasant for the way they work [39]. PU is considered particularly important in general practice [53,54], and research using TAM finds that physicians' PU influences attitudes toward health care technology [55,56]. Thus, 3 hypotheses about PEOU, PU, and attitude were formed:

- Hypothesis 1: PEOU has a positive impact on the PU of video consultations for type 2 diabetes care.
- Hypothesis 2: PEOU has a positive impact on attitudes toward video consultations for type 2 diabetes care.
- Hypothesis 3: PU has a positive impact on attitude toward video consultations for type 2 diabetes care.

The BI to use represents an individual's intention to use a new technology [41]. BI to use is an important component as it is a proxy capable of predicting subsequent actual user behavior in health care and beyond [33,41,42]. According to TAM, the extent to which users perceive a technology to be useful is directly influenced by their ratings of BI to use [38]. In the context of general practice, research has found a positive relationship between PU and BI to use [35,57-59]. Similarly, TAM suggests that the attitude of a user manifests itself as a positive or negative view of the BI to use technology. Research in the domain of primary health care finds that attitude influences the BI to use health care technology [23,60,61]. Thus, 2 hypotheses about PU, attitude, and BI to use were formulated:

- Hypothesis 4: PU has a positive impact on the BI to use video consultations for type 2 diabetes care.
- Hypothesis 5: Attitude toward video consultations for type 2 diabetes care has a positive impact on the BI to use the technology.

Figure 1. Research model based on the technology acceptance model.



Methods

Research Design and Setting

Data were collected through a cross-sectional web-based survey distributed to all general practitioners in Denmark (n=3326). The Danish health care system is mostly tax financed, and citizens can receive care from general practice free of per service charge. Danish general practitioners are self-employed but work on contracts for the public funder. Most general practitioners work in partnership practices, and their income is generated as a combination of fee for service and capitation [62]. The incentive for Danish general practitioners to use video consultations increased during the COVID-19 pandemic because of an agreement between the General Practitioners' Organization (negotiating on behalf of Danish general practitioners) and the Danish Regions (responsible for procuring health services), which agreed on a fee for service to general practitioners to provide video consultations to patients.

Survey Measures

The main measures (13 items) central to our hypotheses originated from TAM [39] and health care studies [55] to ensure the validity of the measures. The measures were adapted to the specific context of general practice and video consultations, translated into Danish, and repeatedly examined to ensure consistency. PU, attitude, and BI to use were measured using 3 items each, and PEOU was measured using 4 items (Textbox 1). An item each in the attitude and BI to use dimensions was negatively worded to reduce the risk of agreement bias [55]. All items were measured on 5-point Likert scales, with scores ranging from 1 (strongly disagree) to 5 (strongly agree). For PEOU, the items were worded according to the user status of the respondent (user vs nonuser of video consultations) to make the formulation relevant to the respondent. Respondents were able to skip questions or choose *do not know* (the latter being treated as missing data in subsequent analyses). Demographic measures (12 items) such as age and sex were collected to analyze the representativeness of the study sample in comparison with the total population of general practitioners. Before distribution and to test face validity, the survey was evaluated and revised according to inputs from 5 general practitioners working in each of the 5 Danish Regions.

Textbox 1. Items used in the research model.

- Perceived usefulness (PU)
  - PU1: can *improve* my treatment
  - PU2: can make my treatment more *effective*
  - PU3: can make my treatment *easier*
- Perceived ease of use (PEOU; worded differently for nonusers of video consultations as illustrated in brackets)
  - PEOU1: *learning* to use was (would be) easy
  - PEOU2: *(would be) easy to get* software to do what I need
  - PEOU3: (would be) easy to *master*
  - PEOU4: (would be) easy to *use*
- Attitude (ATT)
  - ATT1: using is a *good idea*
  - ATT2: using is *unpleasant*
  - ATT3: using is *beneficial*
- Behavioral intention (BI)
  - BI1: intend to use as *often as possible*
  - BI2: even when possible, *do not intend* to use
  - BI3: would *use to the extent possible*

Recruitment and Data Collection

The survey was administered using SurveyXact (Rambøll Management) [63]. To identify general practices, a list of all 1718 general practices in Denmark was obtained from MedCom (a provider of Danish public health care systems) [64] in January 2021. Of these 1718 practices, 44 (2.56%) general practices were excluded as they were managed by parties outside the target group of our study (eg, by Danish Regions). In total, 1674 general practices, representing 3326 general practitioners, were available for distribution [65].

The survey was distributed to general practices as an electronic letter on January 7, 2021, via the Danish public electronic mailbox system (e-Boks Business) using publicly available data from MedCom. The letter contained information about the study and a survey link. Participants were informed about data protection measures, anonymity of participation, and the option to be paid—DKK 276.72 (US $44) based on a General Practitioners'' Organization tariff—for the 20 minutes it maximally takes to complete the survey. The letter was addressed to the clinic, and all trained general practitioners were encouraged to participate. Unfortunately, it was not possible to contact each general practitioner directly as this information was not publicly available. The survey link was open and only available in a letter to ensure anonymity and availability for all general practitioners in a clinic. Data entry for payments was conducted in a separate survey to preserve anonymity. Two reminders were sent on January 21, 2021, and February 2, 2021. The data collection ended on February 7, 2021.

The Committee of Multipractice Studies in General Practice (journal number 25-2020) evaluated the study and recommended that general practitioners participate in the survey. This study was reported to the Danish Data Protection Agency (journal number 1-16-02-343-20).

Ethics Approval

The Research Ethics Committees for Central Denmark Region (1-10-72-181-20) concluded that the study could be conducted without approval from the committee as “According to the Consolidation Act on Research Ethics Review of Health Research Projects, Consolidation Act number 1083 of 15 September 2017, section 14(2) notification of questionnaire surveys or medical database research projects to the research ethics committee system is only required if the project involves human biological material.”

Data Analysis

Data were analyzed using Stata (version 17.0; StataCorp) [66]. To compare sample demographics with the population of general practitioners, we analyzed the latter using registry data made available by the Danish Health Data Authority [67]. The measures used in TAM were analyzed for normality distribution, internal consistency, convergent validity, and discriminant validity. Normality was examined by calculating skewness, kurtosis, and the Mardia multivariate kurtosis test. Internal consistency was assessed using Cronbach α with an acceptable threshold of .70 [68]. Confirmatory factor analysis was performed to determine model validity. Factor loadings of ≥0.7 were deemed acceptable [69]. Subsequently, we explored the research model using structured equation modeling [70], which is standard in the data analysis of TAM [37]. We used quasi-maximum likelihood as the estimator, with Satorra-Bentler adjustments because of our findings of nonnormality for some of the measures [71]. *P*<.05 was set as the threshold for statistical significance.

We report the unstandardized and standardized path coefficients from structured equation modeling. The unstandardized path coefficients reflect the expected (linear) change in the dependent variable with each unit change in the independent variable, given the other variables in the model. The standardized path coefficients express relationships in the same unit; that is, SDs. The interpretation is that when an independent variable (eg, PU) changes by 1 SD, then the dependent variable (eg, BI to use) changes by an SD as well. By placing all coefficients in the same unit, the SDs for different variables measured in different metrics become interpretationally equivalent.

Results

Demographic Characteristics

A total of 457 general practitioners answered the survey, from which 32 (7%) incomplete responses were excluded, resulting in 425 (93%) respondents. The sample represented 12.78% (425/3326) of all Danish general practitioners. The sample represented 18.82% (315/1674) of Danish general practices. Compared with the population of general practitioners, Pearson chi-square tests showed that the individual characteristics of the study sample (ie, sex and age groups) were representative of the population not participating (Table 1). The sample differed with regard to general practice characteristics (ie, clinic and municipality type) as general practitioners from more partnership practices participated than from solo practices, and a larger share of general practitioners working in practices in the capital area participated. The incomplete responses had similar demographics to the complete responses, with most (23/32, 72%) dropping out during or directly after the demographic items.

Table 1. Overview of respondents in sample and comparison with the remaining population.

Characteristics[a]	Survey sample (n=425), n (%)	Population not in the sample (n=2901), n (%)	Pearson chi-square (*df*)
Sex (female)[b]	226 (53.1)	1659 (57.1)	0.2 (1)

Measurements Based on the TAM

Table 2 presents the mean values (SD) of the 4 dimensions and the items from TAM. On a 5-point Likert scale, the highest mean value was PEOU 3.76 (SD 0.86) and ATT 3.48 (SD 0.92), thus indicating that respondents were confident that they, for instance, can use video consultations to manage type 2 diabetes and that the technology was a good idea. The mean values for PU 2.99 (SD 0.96) and BI to use 3.06 (SD 1.04) were similar, and the answers averaged around neither agreeing nor disagreeing. Across the studied dimensions and items, the data variability around the mean of the study sample was approximately 1 point on a 5-point Likert scale.

Table 2. Means and internal consistency of items in the research model (N=425).

Item	Participants, n (%)	Values, mean (SD)	Cronbach α
PU[a]			
PU1: can *improve* my treatment	389 (91.5)	2.70 (0.97)	.86
PU2: can make my treatment more *effective*	397 (93.4)	3.01 (1.07)	.78
PU3: can make my treatment *easier*	396 (93.2)	3.24 (1.13)	.85
PU: all usability items	379 (89.2)	2.99 (0.96)	.88
PEOU[b]			
PEOU1: *learning* to use was (would be) easy	417 (98.1)	3.99 (0.95)	.85
PEOU2: (would be) *easy to get* software to do what I need	401 (94.4)	3.81 (0.98)	.84
PEOU3: (would be) easy to *master*	412 (96.9)	3.91 (0.91)	.83
PEOU4: (would be) easy to *use*	372 (87.5)	3.28 (1.1)	.92
PEOU: all ease of use items	359 (84.5)	3.76 (0.86)	.89
ATT[c]			
ATT1: using is a *good idea*	409 (96.2)	3.29 (1.15)	.63
ATT2: using is *unpleasant*	398 (93.6)	2.04 (0.96)	.92
ATT3: using is *beneficial*	397 (93.4)	3.13 (1.09)	.68
ATT: all attitude items[d]	380 (89.4)	3.48 (0.92)	.83
ATT1+3: ATT excluding ATT2	393 (92.5)	3.21 (1.08)	.92
BI[e] **to use**			
BI1: intend to use as *often as possible*	403 (94.8)	2.66 (1.12)	.82
BI2: even when possible, *do not intend* to use	404 (95.1)	2.61 (1.2)	.88
BI3: would *use to the extent possible*	402 (94.6)	3.12 (1.12)	.78
BI: all intention items[f]	383 (90.1)	3.06 (1.04)	.88

[a] PU: perceived usefulness.

[b] PEOU: perceived ease of use.

[c] ATT: attitude.

[d] The mean represents all ATT variables with ATT2 reversed because of its negative wording.

[e] BI: behavioral intention.

[f] The mean represents all BI variables with BI2 reversed because of its negative wording.

The internal consistency of the items that comprise the 4 dimensions in TAM had Cronbach α >.8 (Table 2). Cronbach α values of ≥.7 indicate acceptable internal consistency. Although the internal consistency of attitude was .83, this value should be interpreted with caution. The right-hand column of Table 2 shows the effect of removing 1 of the 3 items on Cronbach α; that is, for the attitude dimension, the Cronbach α drops to .63 and .68 when removing items 1 and 2 and increases to .92 when removing item 3. In addition to attributing this change in internal consistency to this analytical finding, free-text remarks by some respondents indicated that the negative wording of item 3 could be confusing and challenging to answer. On the basis of logical reasoning [73] and to reflect the attitude dimension more accurately, we excluded item 2 from the subsequent analysis.

To determine the correct structural equation modeling estimation method, we calculated the skewness and kurtosis of all the measures to examine normality. The results showed a mild degree of skewness (ranging from −0.971 to 0.232) with moderate kurtosis (ranging from 2.134 to 3.841). Normality was further evaluated using the Mardia multivariate kurtosis test, in which all dimensions failed except attitude, thereby indicating nonnormally distributed measures (PU 20.4, χ^2_1=90.9, P<.001; PEOU 43.3, χ^2_1=694.6, P<.001; attitude 8.22, χ^2_1=0.3, P=.57; BI 17.9, χ^2_1=26.0, P<.001). As nonnormality invalidates the assumption for the maximum likelihood method of structural equation modeling estimation, we used Satorra-Bentler adjustments to relax the assumption of normality. The measures in TAM were also assessed for convergent validity and discriminant validity (Table 3).

The measures were further validated using a confirmatory factor analysis that showed factor loadings >0.7, except for the item PEOU4—*easy to use* (0.63). PEOU4 was also an outlier in terms of missing data, with 12.7% (53/425) of missing responses, leading to the suspicion that the data were not missing at random. We excluded PEOU4 from the analysis and ran a new confirmatory factor analysis, which had factor loadings ranging from 0.77 to 0.92, thereby confirming that the latent variables of TAM were explained by the observed variables. Goodness-of-fit indices confirmed that the confirmatory factor analysis was a good fit for the data (χ^2_{38}=51.5, χ^2/df=1.4; P=.07; root mean squared error of approximation 0.033 [recommended value <0.05]; standardized root mean square residual 0.024 [recommended value <0.08]; comparative fit index 0.995 [recommended value >0.95]) [74]. The final research model included data from 76.9% (327/425) of respondents.

Hypothesis Testing

We used structural equation modeling to analyze our hypotheses and the final research model. The goodness-of-fit indices model showed an acceptable fit (Table 4).

Analysis of the research model using unstandardized coefficients (Figure 2; Table 5) showed that the original paths of the model were significant (P<.005), except for the path from PU to BI to use (P=.84). PEOU had a positive influence on PU (β=.26, 95% CI 0.14-0.38) and attitude (β=.16, 95% CI 0.08-0.24). PU had a positive influence on attitude (β=1.22, 95% CI 1.09-1.36). The influence of attitude and PU on BI to use was also positive (β=.82, 95% CI 0.52-1.12; β=.04, −0.38 to 0.47); however, the latter was statistically insignificant. The calculated R^2 values (Figure 2) showed that 82% of the variance in BI to use was explained by attitude and PEOU, with attitude having the strongest influence. Standardized coefficients showed similar results (Figure 2; Table 6) and indicated that the strongest relationship existed between PU and attitude and between attitude and BI.

Table 4. Fit indices for structural equation modeling estimation.

Fit index	Structural equation modeling model with Satorra-Bentler	Recommended value [74,75]
Chi-square (*df*)	63.59 (39)	N/A[a]
Chi-square/*df*	1.63	<3.0
P value>chi-square (*df*)	0.008	>0.05
Root mean squared error of approximation	0.044	<0.05
Comparative fit index	0.991	>0.95
Tucker-Lewis index	0.987	>0.95
Standardized root mean square residual	0.036	<0.08

[a] N/A: not applicable (the literature on structural equation modeling does not recommend a value).

Discussion

Principal Findings and Comparison With Prior Work

To explore the potential of using video consultations to provide type 2 diabetes care in general practice, we used insights from technology adoption [36-40] to systematically elicit the technology acceptance of general practitioners. From our survey of Danish general practitioners, we found support for 4 of the 5 research hypotheses (standardized and unstandardized path coefficients).

First, our findings suggest that PU is the primary driver of a positive attitude toward using video consultations to provide type 2 diabetes in general practice (hypothesis 3 accepted: unstandardized β=1.22, 95% CI 1.09-1.36). Similarly, earlier research in general practice found that this relationship appeared to be highly important [53,54]. The unstandardized path coefficient indicates that increasing the PU of the technology by 1 unit will increase the attitude by 1.22 units, given the other variables in the model. The standardized coefficient (β=.89, 95% 0.84-0.94) shows that a change of 1 SD in PU leads to an increase by 0.89 SDs in attitude. Second, attitude toward the technology is positively influenced by general practitioners' PEOU (hypothesis 2 accepted: unstandardized β=.16, 95% CI 0.08-0.24); however, the impact is lower than that for PU (β=1.22 vs β=.16). This finding mirrors previous studies that found that PU, not PEOU, is the primary driver of users' attitudes toward health care technology. A reason is that ease of use is not necessarily a sufficiently large benefit to offset the difficulties of integrating new technology into established work routines [76]. Another reason is that the importance of a technology that is easy to use tends to decrease with general technology use [38,55,56].

Third, our analysis confirmed the expectation that general practitioners' PU of video consultations would be positively influenced by their ratings of PEOU (hypothesis 1 accepted: unstandardized β=.26,95% CI 0.14-0.38). This mirrors findings from studies of other types of health care technology [50-52]. The relatively small impact of PEOU may be attributed to the high education level of Danish general practitioners who use IT technologies daily to deliver care, such as electronic patient records, and thus have a basic level of IT skills that could be speculated to give them confidence in learning new technologies. Fourth, the BI to use video consultations to provide type 2 diabetes was positively influenced by the attitude toward the technology (hypothesis 5 accepted: unstandardized β=.82, 95% CI 0.52-1.12). This particular relationship has also been found in other studies in the domain of primary health care [23,60,61]. Attitude is a central driver that corresponds to other influential theories of behavior change, such as the theory of planned behavior [77]. Fifth, our research model links PU to BI to use; however, the positive influence was statistically insignificant (hypothesis 4 rejected: unstandardized β=.04, −0.38 to 0.47). Compared with the impact of attitude, the influence of the PU of video consultations was also less influential (β=.82 vs β=.04). Studies from general practice generally report that PU has a positive influence on BI to use [35,57-59]. However, these studies do not include the attitude dimension from the original model [39] in their research models and, thus, do not address the relative importance. Our findings indicate that the BI to use video consultations for type 2 diabetes care is primarily the result of the positive impact PU has on attitude.

By studying chronic care in our context—type 2 diabetes—our research findings contribute to an emerging literature on video consultations in general practice that has hitherto mostly studied acute or subacute or out-of-hours care [17,25,31]. A major strength of the study is that the findings build on TAM, which is a robust model [36,37] with good predictive power for health technology use [38]. The findings are also supported by goodness-of-fit tests, showing that the research model has an acceptable fit for structural equation modeling estimation. A strength of our analysis is that it did not rely on the assumption that the measures were normally distributed as we used the Satorra-Bentler adjustments in the structural equation modeling.

Practical Implications

The potential of using video consultations in general practice to deliver chronic disease management is promising [1,10,11] and could fundamentally change how the primary care sector delivers care [12,19]. Type 2 diabetes is a chronic disease for which video consultations in general practice are particularly relevant [43-45] because, as a new care model, it can deliver high-quality, efficient care [46,47] at a time when the prevalence of diabetes is increasing [48]. Our findings (standardized and unstandardized path coefficients in the research model) indicate that the strongest positive relationships are between PU and attitude and between attitude and BI to use. This suggests that if a policy maker wants to increase general practitioners' use of video consultations to provide type 2 diabetes care, they must ensure that the technology is useful in general practice as it will have a positive influence on their attitude, which, in turn, will positively affect their intention to use the technology. Policy makers interested in scaling up video consultations could benefit from looking into the items of the dimensions that constitute the research model. For example, to improve PU, policy makers should find solutions to three questions: how can it be ensured that video consultations (1) improve treatment, (2) make treatment more effective, and (3) make treatment easier?

Relatedly, our findings provide suggestions for mitigating change hesitance, which remains a barrier to implementing video consultations in routine practice [21]. As research shows that working in larger practices—but not individual characteristics such as age or sex—increases the likelihood that a general practitioner uses video consultation [22,23], it appears relevant to explore the perceptions of small and large practices separately. Using the example of PU, small and large practices may differ in the ways in which video consultations can improve and make treatment easier. These insights are important as data from, for example, the Danish Health Authority show a decrease in the use of video consultations in general practice from 2020 to 2021 [78], which suggests that general practitioners use the technology but also that it is not yet a regular work routine in general practice. Moreover, continuous improvement of the technology and its use in practice is central as there is a risk that this new care model increases general practitioner workload, and there may be a need to allocate more resources to implement digital-first pathways [14]. To the latter end, research finds that training facilitates the implementation of video consultations in routine practice [20].

Limitations

Two modifications were made to the original TAM, underlining the final research model. First, an item (attitude item 2) was removed as it decreased the Cronbach α of the attitude dimension. Another item (PEOU4) was dropped because of the low factor loading from the confirmatory factor analysis. To assess the extent to which removing these items changed the findings, a structural equation modeling estimation, including these items, was performed, which showed path coefficients very similar to our final model, thereby supporting the accuracy of the final structural equation model. Second, structural equation modeling estimations were not performed with all respondents as those skipping questions were omitted. Running a structural equation modeling estimation that included respondents with missing answers resulted in similar path coefficients but had poorer goodness of fit. The final research model met the recommended indices of the goodness of fit but failed the chi-square test. Failing the chi-square test is a known issue with structural equation modeling, which, similar to our study, has a high number of respondents and survey answers that are not normally distributed [75]. The issue of nonnormality was addressed using Satorra-Bentler adjustments.

With the widespread research validation of TAM in combination with acceptable goodness-of-fit indices, the final research model is considered valid. However, as this study surveyed general practitioners from a tax-financed health care system, the findings may be most generalizable to countries with similar health care systems such as the English National Health System. Some authors also raise the concern that the original TAM and later extensions lack precision in health care because of their inability to consider the influence of external variables and barriers to technology acceptance [36] such as psychological ownership of IT [79] or social norms [55]. Nevertheless, for the purposes of this study, the research model was kept simple for 2 main reasons. First, findings from health care that extend TAM only result in a relatively modest increase in explanatory power [55]. Second, getting general practitioners to answer surveys is difficult [43], and including other variables to increase the precision a little would likely come at the expense of a lower response rate. More questions also increased the risk of respondent fatigue and missing answers.

The relatively low response rate of 12.8% of all 3326 Danish general practitioners increased the risk of selection bias. Nevertheless, it improved confidence in the findings that the individual characteristics of the sample of general practitioners were comparable with the population, and the share of respondents in the sample who used video consultations was similar to that of other sources [78]. This finding supports the generalizability of our results. The difficulty in getting Danish general practitioners to participate in survey research is an explanation as they operate as for-profit firms and are often on a tight schedule [62]. The survey was also distributed during the COVID-19 pandemic when other surveys of general practitioners had similar low response rates [22,43,80]. It could be speculated that general practitioners with the strongest positive or negative attitudes toward technology were more likely to participate. Univariate normality tests of the items in the attitude dimension, as mentioned previously, showed that the respondents' attitudes were relatively normally distributed and did not only represent the most negative or positive attitudes toward video consultations used for diabetes care.

The study design was cross-sectional and, thus, only capable of capturing the views of general practitioners at the time of data collection. Although the cross-sectional design is standard in most studies on TAM [37,38], longitudinal studies are generally recommended to assess changes over time to make study findings more robust. Collecting data on the variables in TAM from the same source (ie, general practitioners) makes common method bias [81] a potential risk in the study. However, common method bias is of modest importance here as the research model asks about the intention to use rather than actual use.

Conclusions

This study explored the potential of using video consultations to provide type 2 diabetes care in general practice by eliciting the technology acceptance of a representative survey sample of Danish general practitioners. On the basis of TAM, our study suggests 2 main drivers: PU positively affects attitude toward using video consultations for diabetes care, and attitude positively affects the BI to use the technology. For policy makers interested in scaling up general practitioners' use of video consultations to provide diabetes care, our findings indicate that they should emphasize how the technology can improve treatment and make it more effective and easier. To this end, policy makers may need to explore what these aspects of usefulness mean to general practitioners working in different organizational contexts.

Acknowledgments

The authors are grateful for the insights provided by the reference group of 5 general practitioners from 5 Danish regions: Rasmus Dahl-Larsen, Michel Kjeldsen, Gitte Krogh Madsen, Janus Nikolaj Laust Thomsen, and Mogens Vestergaard. The authors thank Henrik Støvring, Lasse Bjerg Hansen, Daniel Witte, and Kasper Norman for their methodological comments.

The authors would also like to thank the Quality and Training Committees of North Denmark Region, Central Denmark Region, Region of Southern Denmark, Region Zealand, the Capital Region, and the Lundbeck Foundation Scholarship for General Practice. Support was provided by the Steno Diabetes Center Aarhus, Aarhus University Hospital, which is partially funded by an unrestricted donation from the Novo Nordisk Foundation.

Authors' Contributions

TP and AS conceptualized and designed the study. TP and DCT collected the data, conducted the statistical analyses, and wrote the first draft of the manuscript. All the authors critically revised the manuscript and approved the submitted version.

Conflicts of Interest

None declared.

Abstract

Background: Most smokers with chronic obstructive pulmonary disease (COPD) have not yet been diagnosed, a statistic that has remained unchanged for over two decades. A dual-focused telehealth intervention that promotes smoking cessation, while also facilitating COPD screening, could help address national priorities to improve the diagnosis, prevention, treatment, and management of COPD. The purpose of this study was to preliminarily evaluate an integrated asynchronous smoking cessation and COPD screening e-visit (electronic visit) that could be delivered proactively to adult smokers at risk for COPD, who are treated within primary care.

Objective: The aims of this study were (1) to examine e-visit feasibility and acceptability, particularly as compared to in-lab diagnostic pulmonary function testing (PFT), and (2) to examine the efficacy of smoking cessation e-visits relative to treatment as usual (TAU), all within primary care.

Methods: In a randomized clinical trial, 125 primary care patients who smoke were randomized 2:1 to receive either proactive e-visits or TAU. Participants randomized to the e-visit condition were screened for COPD symptoms via the COPD Assessment in Primary Care to Identify Undiagnosed Respiratory Disease and Exacerbation Risk (CAPTURE). Those with scores ≥2 were invited to complete both home spirometry and in-lab PFTs, in addition to two smoking cessation e-visits. Smoking cessation e-visits assessed smoking history and motivation to quit and included completion of an algorithm to determine the best Food and Drug Administration–approved cessation medication to prescribe. Primary outcomes included measures related to (1) e-visit acceptability, feasibility, and treatment metrics; (2) smoking cessation outcomes (cessation medication use, 24-hour quit attempts, smoking reduction ≥50%, self-reported abstinence, and biochemically confirmed abstinence); and (3) COPD screening outcomes.

Results: Of 85 participants assigned to the e-visits, 64 (75.3%) were invited to complete home spirometry and in-lab PFTs based on CAPTURE. Among those eligible for spirometry, 76.6% (49/64) completed home spirometry, and 35.9% (23/64) completed in-lab PFTs. At 1 month, all cessation outcomes favored the e-visit, with a significant effect for cessation medication use (odds ratio [OR]=3.22). At 3 months, all cessation outcomes except for 24-hour quit attempts favored the e-visit, with significant effects for cessation medication use (OR=3.96) and smoking reduction (OR=3.09).

Conclusions: A proactive, asynchronous e-visit for smoking cessation and COPD screening may offer a feasible, efficacious approach for broad interventions within primary care.

Introduction

Cigarette smoking remains the leading cause of preventable death globally and is responsible for more than 480,000 deaths each year in the United States [1]. A total of 21% percent of tobacco-related deaths are caused by chronic obstructive pulmonary disease (COPD), a progressive inflammatory lung disease that causes airflow obstruction and breathing-related problems [1,2]. Between 45% and 72% of smokers with COPD have not yet been diagnosed [3,4], a statistic that has remained largely unchanged for over two decades [4]. As noted in a recent viewpoint article by Yawn and Martinez [5], “COPD screening must develop better, more symptom-based tools and appropriate follow-up support.” A dual-focused intervention that simultaneously promotes smoking cessation, while also facilitating COPD screening, could address national priorities to improve the diagnosis, prevention, treatment, and management of COPD [6].

The vast majority (~70%) of adult smokers visit a primary care provider at least once per year, making primary care an ideal environment within which to identify smokers, provide evidence-based smoking cessation treatment, and screen for COPD [7-9]. Within the primary care setting, prior studies demonstrate up to a fourfold increase in COPD diagnosis when using screening tools to identify respiratory symptoms [10-12]. Although not COPD-specific, our team previously developed an asynchronous e-visit (electronic visit) to be delivered within the primary care environment to patients identified as smokers via the electronic health record (EHR) [13]. This e-visit was developed based on best practice guidelines [7] for smoking cessation treatment within primary care—the 5 A’s (ask, advise, assess, assist, and arrange). Results from an initial evaluation of the asynchronous smoking cessation e-visit as compared to treatment as usual (TAU) within primary care indicated high feasibility and acceptability with cessation outcomes that favored the e-visit condition at both 1 (odds ratios [ORs] 2.10-5.39) and 3 months (ORs 1.31-4.67) [13].

The purpose of this study was to preliminarily evaluate an integrated asynchronous smoking cessation and COPD screening e-visit that could be delivered proactively to adult smokers at risk for COPD, treated within primary care. Prior studies have evaluated the feasibility, acceptability, and validity of remote home spirometry and have found high test-retest reliability when compared to in-clinic assessments [14,15], high adherence rates [16], and high patient satisfaction [15,16]. As such, we opted to leverage our existing asynchronous smoking cessation e-visit platform and add to it remote, telehealth-facilitated COPD screening and completion of remote home spirometry for those eligible. The aims of this study were (1) to examine e-visit (for smoking cessation and remote home spirometry) feasibility and acceptability, particularly as compared to in-lab diagnostic pulmonary function testing (PFTs), and (2) to examine the efficacy of smoking cessation e-visits relative to TAU, all within primary care.

Methods

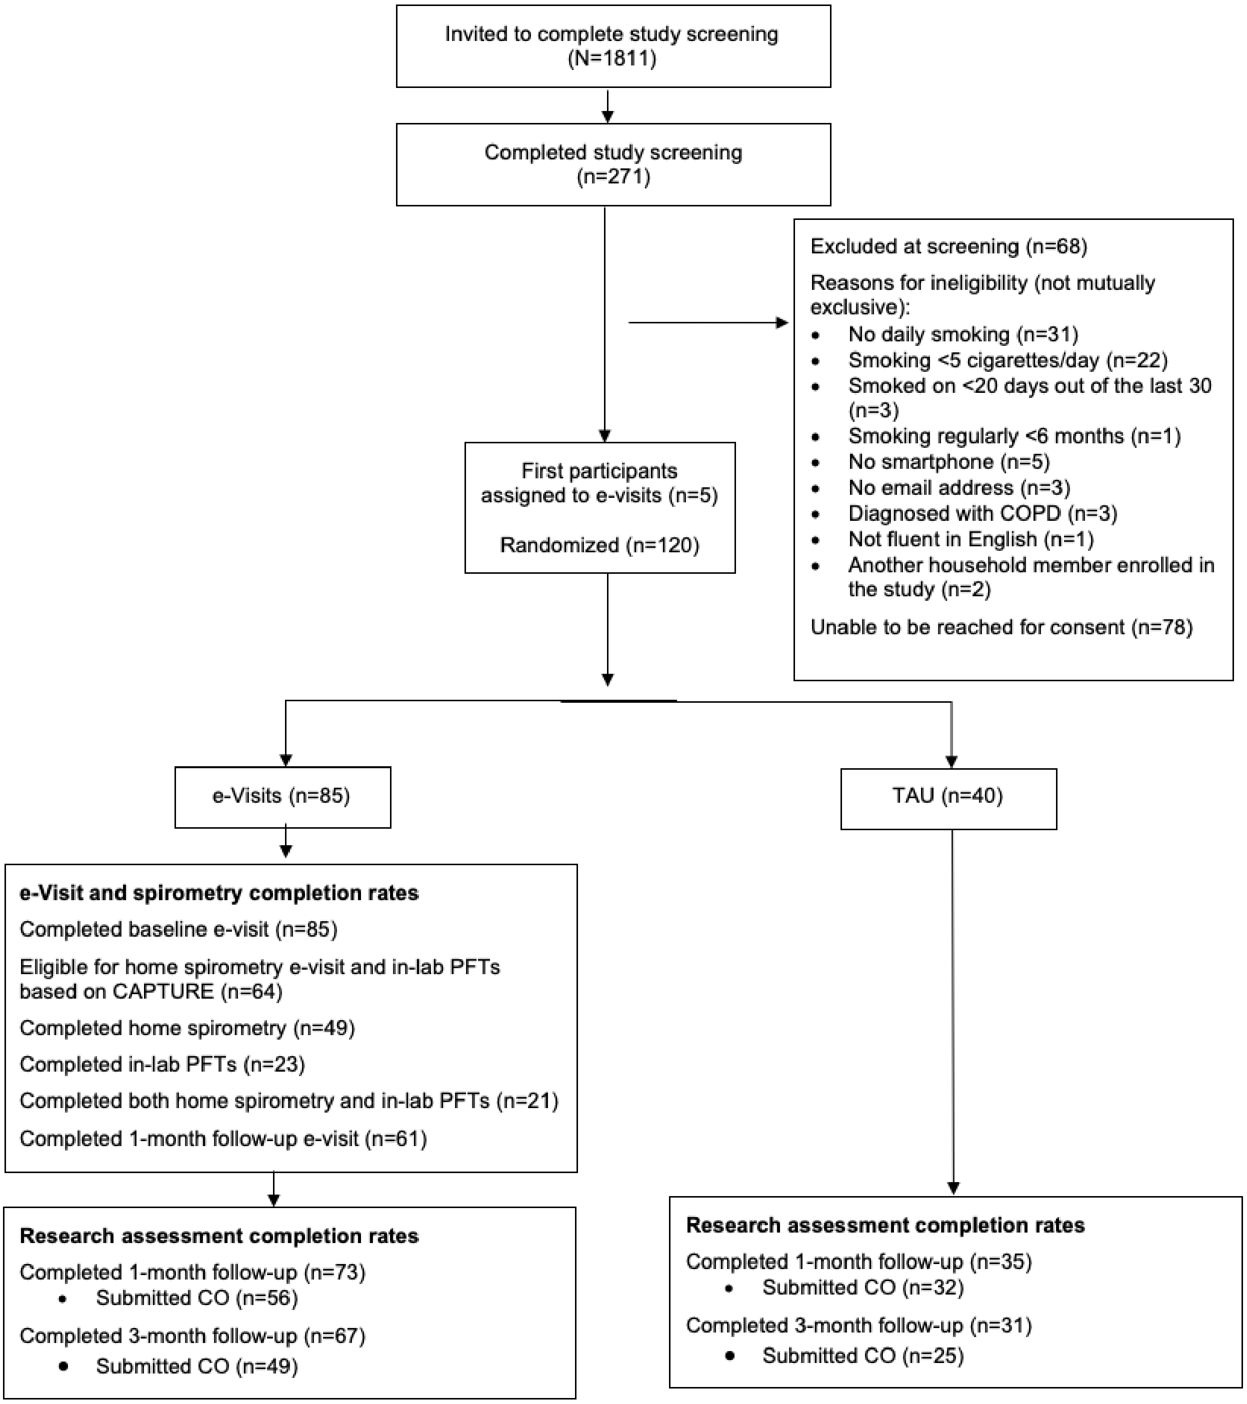
Ethics Approval

All study procedures were approved by the Medical University of South Carolina (MUSC) institutional review board (PRO00086016), and the trial was preregistered with ClinicalTrials.gov (NCT04155073). Eligible patients were scheduled to complete informed consent remotely with a member of the study team. Consent was completed either electronically or via mail, in both cases paired with a discussion with a member of the research team.

Participants

Participants were recruited from 13 primary care practices affiliated with MUSC between December 2019 and January 2021. Within our systemwide EHR, Epic, a study recruitment report was generated for all patients meeting the following criteria: (1) aged >40 years; (2) seen at an MUSC primary care practice in the last year; (3) current smoker; (4) no previous diagnosis of COPD (defined as International Classification of diseases, 10th revision codes J44.9, J44.1, J44.0, J43.9, or Z87.9) associated with any prior visit; and (5) access to MyChart, Epic’s patient portal. Via MyChart, 1811 patients meeting initial eligibility criteria were sent an invitation and link to study screening. Study invitations included introductory text highlighting the importance of quitting smoking and then continued with an invitation to participate in a research study to help change smoking behavior. All invitations noted that the study had been discussed with the patient’s primary care provider, who supported the study invitation. Patients were deemed eligible for the study if during the initial screening they met the following additional criteria: (1) current cigarette smoking, defined as smoking 5 cigarettes per day for at least 20 out of the preceding 30 days, for at least the last 6 months; (2) possess a valid email address, checked daily; (3) owner of an iOS or Android-compatible smartphone; and (4) fluent in English (study e-visits were only available in English, thus English fluency was required). In total, 271 patients completed study screening (ie, 15% of those invited), and 203 were deemed eligible following screening (Figure 1).

Figure 1. CONSORT flow diagram. CAPTURE: COPD Assessment in Primary Care to Identify Undiagnosed Respiratory Disease and Exacerbation Risk; CO: carbon monoxide; COPD: chronic obstructive pulmonary disease; PFT: peak expiratory flow; TAU: treatment as usual.



Study Procedures

Upon consent, enrolled participants completed baseline assessments via REDCap (version 11.2.1; Vanderbilt University) and then were randomized 2:1 to receive either the e-visits or TAU. The first 5 enrolled participants were all assigned to the e-visit condition to ensure that both smoking cessation and COPD e-visit components were functioning properly. All study participants were invited to complete follow-up research assessments at 1 and 3 months following baseline. To biochemically verify smoking status, participants were asked to submit an expired air carbon monoxide (CO) sample remotely via a smartphone-enabled CO monitor (iCO Smokerlyzer) at both follow-ups. iCO monitors were mailed to all enrolled participants following completion of the baseline visit, and mailings included information regarding how to submit CO readings. Participants were compensated up to US $250 total for all study procedures. Participants randomized to the e-visit condition were not separately compensated for completion of the e-visits or for completion of in-lab PFTs.

Interventions

Smoking Cessation and COPD e-Visits

Participants in this condition were automatically linked to initiate an asynchronous e-visit via MyChart. Smoking cessation components of the e-visit were similar to our team's prior work [13] but modified to include an additional focus on COPD screening. e-Visit functionality was similar to that of an electronic questionnaire, with participants answering 1 question per screen and then advancing to the next screen. The initial baseline e-visit gathered information about smoking history and motivation to quit, followed by an algorithm to determine the best Food and Drug Administration (FDA)-approved cessation medication (ie, nicotine replacement therapy [NRT], varenicline, and bupropion) to prescribe. This algorithm was based on prior research [17,18] and evidence-based guidelines [7], using branching logic to prioritize the most efficacious medications (ie, varenicline and combination NRT), while tailoring recommendations based on contraindications and participant preference. A medication recommendation was then displayed to the participant, with a personalized rationale, to which the participant could agree or request a different treatment. e-Visit results were then sent to the provider's electronic in-basket, who reviewed the e-visit, responded to the patient via MyChart with instructions, and e-prescribed (if indicated) medication. All medications were prescribed on label by 3 study physicians and were mailed to the patient at no cost. Responses from providers to participants also included information on the state tobacco Quitline, which participants could contact for additional behavioral support. Participants were subsequently invited to complete a follow-up smoking cessation e-visit 1 month following completion of the baseline session, consistent with the 5th A in the 5 A's guideline to arrange follow-up [7], at which time participants could request a refill of the medication prescribed at baseline, if needed, or could request a new smoking cessation medication. Results were sent to providers and reviewed in the same manner as the baseline e-visit.

In addition to smoking cessation content, the baseline e-visit included completion of the 5-item COPD Assessment in Primary Care to Identify Undiagnosed Respiratory Disease and Exacerbation Risk (CAPTURE) [19]. CAPTURE assesses the presence or absence of COPD symptoms, risk exposures, and recent history of acute respiratory illness. Responses are summed and scores of 2 or higher suggest a need for diagnostic assessment [5]. Thus, e-visit participants with a CAPTURE score ≥2 were subsequently invited to complete both remote spirometry and in-lab PFTs. For remote spirometry testing, participants were mailed a home spirometer (Vitalograph asma-1) and were sent a link to complete an additional e-visit in which they recorded themselves using the home spirometer. At the beginning of the home spirometry e-visit, participants reviewed an educational video, developed by our team, demonstrating how to use the device, while video recording themselves. Participants submitted 3 breath samples with accompanying videos for evaluation and were asked to enter peak expiratory flow (PEF) and forced expiratory volume in one second (FEV1) values into text boxes within the e-visit. Completed home spirometry e-visits and videos were reviewed by a study physician, who coded them for effort (ie, acceptable, unacceptable, and unable to determine), technique (coded similarly), and whether the participant correctly recorded PEF and FEV1 values from the home spirometer (ie, yes, no, or participant did not show values to the camera). For each participant, the percent predicted PEF was calculated from the highest acceptable PEF recorded, factoring in age, gender, and ethnicity, based on equations with standard values [20,21]. Participants with predicted PEF ≤80% were considered abnormal. Similarly, the highest acceptable FEV1 measurement was categorized as normal (≥80%), moderate (≥50%-<80% predicted), severe (≥30%-<50% predicted), or very severe (<30% predicted). After review, the physician sent a message to the patient via the EHR portal with results (normal or abnormal) along with a recommendation to complete in-lab PFTs previously ordered. These messages also included encouragement related to quitting smoking (eg, "we still recommend that you attempt to quit smoking. Quitting smoking now will help to prevent any further lung damage as well as reduce your risk of heart disease and cancer linked to tobacco use. We are here to continue helping you in those efforts"). No intervention for COPD was provided as part of this study.

All participants eligible for home spirometry testing were also referred for PFTs, regardless of the home testing results, to examine the comparative feasibility of home versus in-lab testing. To further remove barriers to completion of in-lab PFTs, all PFT costs were paid for by the study. Once completed, in-lab PFT results were communicated to the patient with recommendations for follow-up with their primary provider. Chart reviews were completed at 3 months following study enrollment for all study participants to determine whether PFTs were completed and whether the participant was subsequently diagnosed with COPD. PFT appointments for these participants were scheduled per usual practice (ie, a referral was placed by study coordinators, and central scheduling contacted participants to schedule testing).

Treatment as Usual (TAU)

TAU was designed to mimic existing standard cessation practices. Research staff provided participants in this condition with information on the state Quitline and a recommendation to contact their primary care provider to schedule a medical visit to discuss quitting smoking. Chart review was also completed at 3 months for these participants to determine whether they completed in-lab PFTs and whether they were diagnosed with COPD.

Measures

All participants at baseline completed a general assessment of demographics and health history. Primary outcomes for this trial include measures related to (1) e-visit acceptability, feasibility, and treatment metrics; (2) smoking cessation outcomes; and (3) COPD screening outcomes. Unless otherwise noted, participants self-input responses to study outcomes assessments in REDCap.

e-Visit Acceptability, Feasibility, and Treatment Metrics

To assess participant perception of the e-visits, during the 1-month research assessment, e-visit participants responded to the following items: (1) I found the e-visit easy to use; (2) I would use an e-visit again in the future; (3) during my e-visit, I felt I could trust my provider with my medical care; (4) I would recommend e-visits to other people; (5) It was as easy for me to state concerns through the e-visit as it would be in an in-person visit; (6) the e-visit was as good as an in-person visit with my doctor; and (7) I have experienced benefits from the e-visit. Response options ranged from strongly disagree to strongly agree.

To examine comparative feasibility of remote versus in-lab PFTs, completion rates for each were captured and compared. Feasibility of remote home spirometry was further assessed through clinician ratings of spirometry effort or technique, as described above. Feasibility of the smoking cessation component of the e-visit was captured via EHR chart reviews, as follows: (1) whether the patient opted for the medication recommended by the e-visit, (2) whether the physician prescribed the medication recommended by the e-visit, (3) whether the participant completed the 1-month follow-up e-visit, and (4) time to complete the 1-month follow-up e-visit.

Smoking Cessation Outcomes

All participants at baseline were queried for the number of cigarettes smoked per smoking day, incidence of quit attempts within the last year, and motivation or confidence to quit (0-10 on the visual analogue scale [22]) in the next month. During the 1- and 3-month follow-ups, all participants self-reported the following: (1) number of cigarettes smoked per day over the last 7 days, (2) incidence of 24-hour quit attempts since the prior assessment, and (3) use of an FDA-approved smoking cessation medication since the last assessment. Past-week smoking data allowed for a computed outcome to assess if participants reduced their smoking by at least 50% since baseline. Participants who reported smoking zero cigarettes over the last 7 days were coded as having self-reported 7-day point prevalence abstinence. Self-reported abstinence was biochemically confirmed via CO, using a cutoff point <6 ppm to define abstinence [23].

COPD Outcomes

COPD diagnostic status was ascertained for all participants via chart review at 3 months following study enrollment. Additionally, at baseline, all participants completed CAPTURE [19].

Statistical Analysis Plan

Chi-square and ANOVA analyses were used to determine baseline group differences in participant demographics as well as retention rates over time. Descriptive statistics were used to examine e-visit (for spirometry and smoking cessation) acceptability, feasibility, and treatment metrics. Binary logistic regressions were used to examine differences in cessation outcomes across treatment group, at both 1- and 3-month time points. For cessation outcomes, an intent-to-treat approach was used such that those who did not complete the assessment were coded as not having modified smoking [24].

Results

Participant Characteristics

In total, 125 participants were enrolled in the trial (e-visit=85 and TAU=40). The first 5 enrolled participants were all assigned to the e-visit condition, and the remaining 120 were randomized 2:1 to either e-visit or TAU. The first 5 enrolled participants did not significantly differ from those randomized, either in baseline characteristics or follow-up outcomes. There were no significant between-group differences in demographics or smoking history at baseline (Table 1), though participants in the TAU condition reported significantly greater COPD symptoms on CAPTURE ($F_{1,123}$=8.11, P=.005).

Study retention was generally high across both 1-month (86.4%) and 3-month (78.4%) follow-ups, with no significant differences in retention between treatment groups. Regarding demographic differences between those who completed follow-up assessments and those who did not, White participants were significantly more likely to complete the 1-month follow-up assessment compared to non-White participants (91% completion versus 75%; $\chi^2_{1,125}$=5.59; P=.02). There were no other significant demographic differences between those who completed follow-up assessments and those who did not, at either 1 or 3 months. Among 1-month respondents, 81.5% (88/108) also provided CO. Among 3-month respondents, 73.5% (72/98) also provided CO.

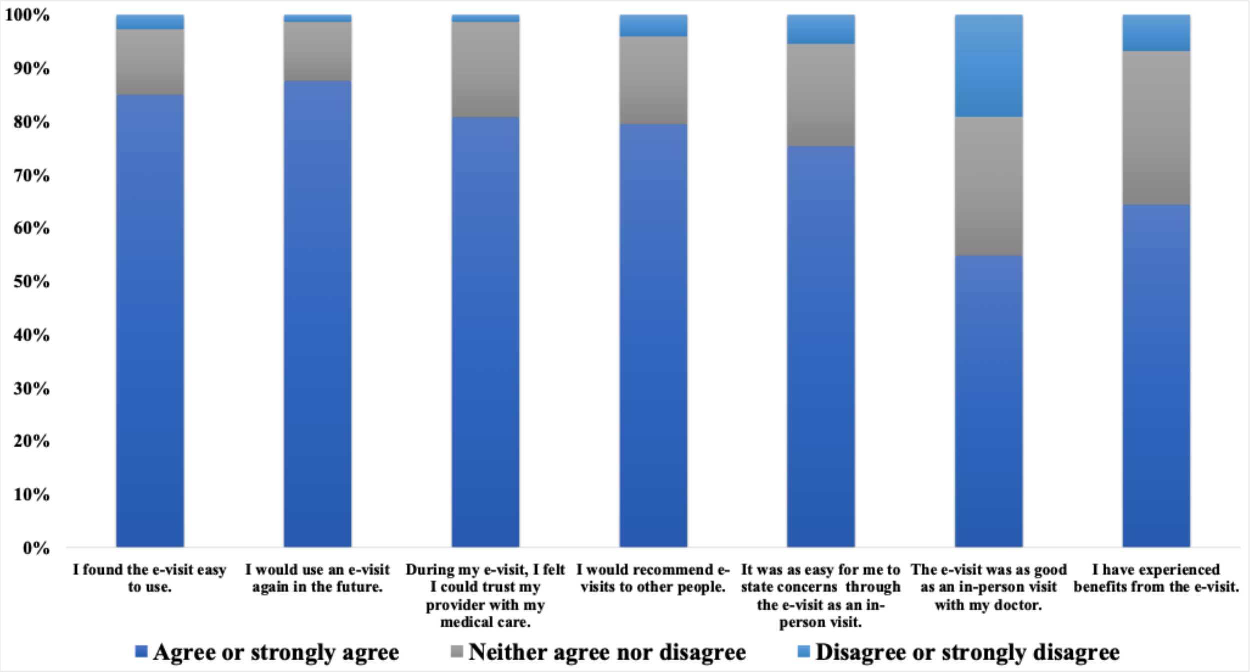
[a] CAPTURE: COPD Assessment in Primary Care to Identify Undiagnosed Respiratory Disease and Exacerbation Risk.

e-Visit Feasibility, Acceptability, and Uptake

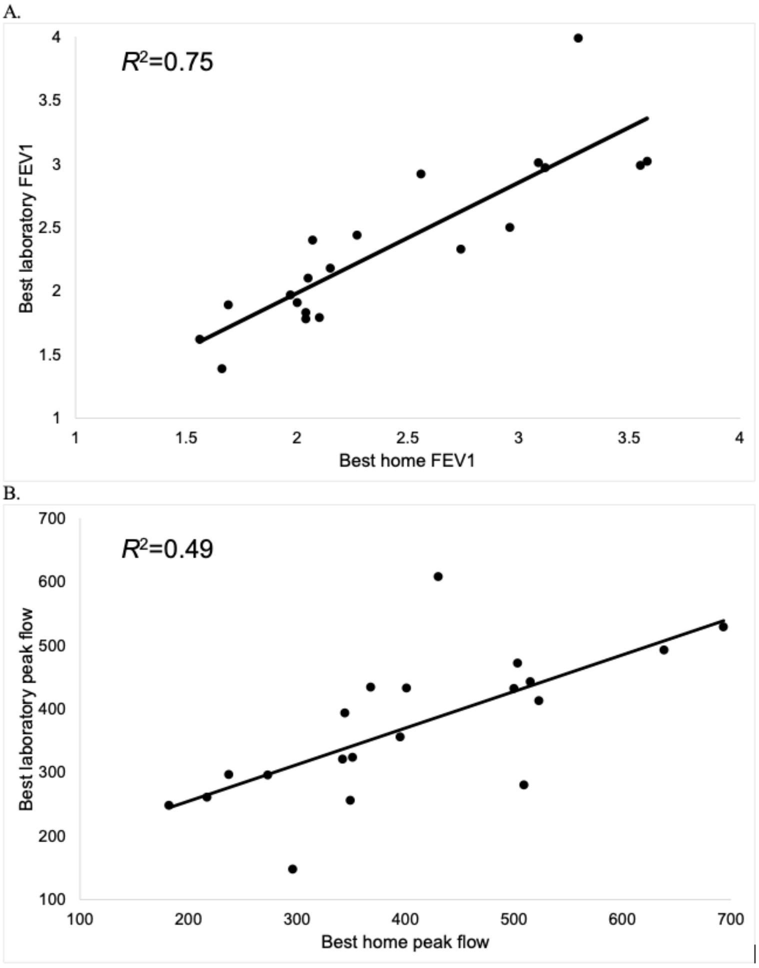
Participant feedback following completion of the baseline e-visit was generally positive (Figure 2). Of the 85 participants assigned to the e-visit condition, 64 (75.3%) were invited to complete home spirometry and in-lab PFTs because of a CAPTURE score of 2 or higher. Mean CAPTURE score among those eligible for spirometry was 3.7 (SD 1.4). Among those eligible for spirometry, 76.6% (49/64) completed home spirometry. Most of those (37/49; 75.5%) who completed home spirometry had acceptable effort; 79.6% (39/49) had acceptable technique, and 87.8% (43/49) correctly recorded values on at least 1 video. Two-thirds (33/49; 67.3%) of participants who completed home spirometry had at least 1 video with acceptable effort and technique.

Figure 2. e-Visit feedback.



Compared to completion rates for home spirometry, fewer participants in the e-visit condition completed in-lab PFTs (23/64, 35.9% of those eligible). Twenty-one participants completed both home and in-lab PFTs. Among these participants, concordance between home and in-lab PFTs was higher for FEV1 (R^2=0.75) compared to PEF (R^2=0.49; Figure 3). Among the sample completing both home spirometry and in-person PFTs, in-person spirometric diagnoses included normal spirometry (4/21, 19%), Global Initiative for Obstructive Lung Disease undifferentiated obstruction with FEV1 <80% but FEV1/forced vital capacity >0.7 (2/21, 9.5%), probable or confirmed restriction (5/21, 23.8%), mild obstruction (5/21, 23.8%) and moderate obstruction (5/21, 23.8%). No participant was found to have severe obstruction. Using a cutoff of home spirometry PEF <80% predicted, 5 participants who completed both home spirometry and in-person PFTs were considered to have abnormal home spirometry readings. Among these participants, in-person PFTs confirmed restriction (1/5, 20%), mild obstruction (1/5, 20%), moderate obstruction (2/5, 40%), and normal spirometry (1/5, 20%). In the TAU group, only 1 participant completed in-lab PFTs and that participant was subsequently diagnosed with COPD.

Figure 3. Home vs. In-Lab FEV1 and Peak Flow Among Participants Who Completed Both.



Smoking Cessation, Treatment, and Outcomes

The most common treatment recommendation as a result of the baseline e-visit was varenicline (65/85, 76.5%), followed by NRT patch (8/85, 9.4%), combination NRT (5/85, 5.9%), and NRT lozenge (3/85, 3.53%). Participants (73/85, 86%) and providers (72/85, 85%) agreed with recommendations from the medication algorithm. Three quarters (64/85, 75.3%) of e-visit participants completed the 1-month e-visit, on average within 2.7 (SD 6.9) days after invitation. During this follow-up e-visit, participants most often requested either a prescription for varenicline (20/64, 31.3%), combination NRT (11/64, 17.2%), NRT inhaler (10/64, 15.6%), or NRT gum (6/64, 9.4%), and providers abided by these preferences (63/64, 98.4%).

In general, smoking cessation outcomes favored the e-visit condition at both 1 and 3 months (Figure 4). At 1 month, all cessation outcomes favored the e-visit condition (ORs 1.6-4.1). At 3 months, all cessation outcomes except for 24-hour quit attempts favored the e-visit condition (ORs 1.1-5.8). Regarding significant effects, as compared to TAU, e-visit participants were 3.2 times more likely to have used a cessation medication at 1 month (95% CI 1.4-7.4; *P*=.006), and 4.0 times more likely to have used a cessation medication at 3 months (95% CI 1.7-9.0; *P*<.001). At 3 months, e-visit participants were 3.1 times more likely to have reduced their cigarettes per day by at least 50% (95% CI 1.2-8.2; *P*=.02), with a similar trend toward significance at 1 month (OR 4.1, 95% CI 0.9-18.8; *P*=.07).

Discussion

Study results preliminarily indicate feasibility, acceptability, and efficacy of a proactive, asynchronous e-visit for smoking cessation and COPD screening. Metrics of feasibility and acceptability were strong, with 88% (75/85) of participants indicating that they would use an e-visit again in the future. However, only a small majority (47/85, 55%) of e-visit participants reported preferring the e-visit to an in-person visit. Thus, although the e-visit may offer a scalable, feasible method to extend the reach of cessation treatment, it may not be preferred for all patients. Future research should examine which subgroups of patients may be most amenable to receiving cessation treatment via telehealth platforms such as e-visits.

Our study also confirms the feasibility of home spirometry, with promising compliance rates for submission of viable tests. This is consistent with prior research among other populations with obstructive lung diseases such as cystic fibrosis [25,26] and asthma [27]. Thus, home spirometry, completed via an e-visit and reviewed by a provider, may be a useful tool for COPD screening among high-risk smokers. A large body of literature has focused on both the potential utility and drawbacks of population-based screening for COPD, particularly among asymptomatic patients. Current US Preventive Services Task Force guidelines recommend against screening asymptomatic adults for COPD, citing lack of supportive data [28]. However, screening of individuals who self-report unaddressed respiratory symptoms, as implemented in this trial, can increase COPD diagnoses and facilitate treatment initiation [10-12]. Although a tool such as CAPTURE has broad reach and may help to identify those who are symptomatic, pairing CAPTURE with home-based spirometry could help further identify the subset of patients who should be strongly encouraged to complete diagnostic PFTs.

This study was not designed specifically to examine the validity of home spirometry; nevertheless, comparing home versus in-lab results for the small subset of participants who completed both suggests there are opportunities to improve validity. To maximize scalability of the e-visits, we opted to minimize the amount of training provided to participants. However, prior home spirometry trials have had success with incorporating synchronous coaching via video calls [29]. This approach may help improve the validity of home spirometry among adult smokers at risk for COPD, though it would limit scalability. In the future, it will be important to determine the appropriate amount of training needed for participants to submit valid samples and how best to embed this training in primary care.

To our knowledge, this is the first study to evaluate the CAPTURE, which was developed to be used in a broad population of primary care patients, in a population of smokers. We were surprised to see that 82.4% (103/125) of smokers in our full sample had a score of 2 or higher at baseline. Because smokers typically develop COPD after 10 pack years at a prevalence <20% [30], the CAPTURE instrument should be reevaluated among active smokers, as sensitivity may be too high. This is likely due to scoring 1 point for living or working in a place with smoke or secondhand smoke.

Our results further substantiate the potential of e-visits to promote smoking cessation. Results generally echoed those of our prior trial [13], supporting the efficacy of the e-visit approach. Whereas our prior trial did not provide free medications, the current study provided prescribed medications free of charge. Comparing intent-to-treat results across studies, the provision of free medication appears to have slightly increased the use of cessation medications (at 1 month: 44.1% vs 51.8%; at 3 months: 41.2% vs 60%). Thus, where possible, pairing the proactive e-visit with free medication may increase evidence-based cessation treatment uptake.

Results of this study should be interpreted with limitations in mind. The trial was largely conducted in the midst of the COVID-19 pandemic, which may have impacted rates of trial enrollment, engagement with the e-visits, and completion rates for in-lab PFTs. However, it is important to note that at MUSC, pulmonary function testing continued throughout the pandemic, thus all participants eligible for in-lab PFTs had the option to complete them. Future evaluation of proactive e-visits for COPD screening and smoking cessation outside the context of the COVID-19 pandemic will be important to determine whether e-visit acceptability and feasibility change as a function of the pandemic waning. Regarding generalizability, the Vitalograph asma-1 was used for remote home spirometry completion. Feasibility and validity results may not generalize to other remote monitors. Moreover, study inclusion criteria, including smartphone ownership and regular email use, may limit generalizability of results. Proactive study invitations were sent via MyChart, which may also decrease results' generalizability. However, this decision was made because the study e-visits were delivered via the MyChart patient portal. Given the preliminary nature of this trial and focus on feasibility and acceptability, resources to support deployment of both remote spirometry and in-lab PFTs were not comprehensively assessed. However, future cost-effectiveness analyses could help determine whether potential benefits of the e-visit approach are cost-effective or cost-saving at the health care system level. Finally, the completed e-visits were reviewed by study physicians. Implementation of the e-visits within routine clinical practice and with non–study-affiliated providers remains unclear but is an important avenue for future research.

In sum, a proactive, asynchronous e-visit for smoking cessation treatment and COPD screening may offer a feasible, efficacious approach for broad intervention within primary care. If validity of home spirometry can be improved over time, the e-visit platform may help not only promote uptake of evidence-based smoking cessation treatment but also provide an early screening mechanism to identify smokers with COPD or other important lung diseases.

Abstract

Background: Policy makers and practitioners in low- and middle-income countries (LMICs) are increasingly focusing on the effectiveness of digital devices in the delivery of medical and educational services to children under resource constraints. It is widely known that digital literacy can be fostered through exposure to and education regarding digital devices, which can improve children's academic performance as well as their search and communication skills in the digital era. However, the correlation between the cognitive function of children and exposure and intensity of the exposure to digital devices has rarely been studied, and the association between digital device exposure and the socioeconomic characteristics and cognitive development of children in LMICs is unknown.

Objective: This study examines the association among exposure to digital devices, socioeconomic status, and cognitive function in children aged 3 to 9 years in Cambodia.

Methods: We used a survey of 232 children that gathered data on familiarity with digital devices, demographic characteristics, and socioeconomic status, as well as a Cambridge Neuropsychological Test Automated Battery test for cognitive function, to examine the association between possible barriers and factors that may influence the cognitive function of children in 2 Cambodian schools from April 22, 2019, to May 4, 2019. A comparative analysis was performed with and without digital exposure, and an association analysis was performed among the variables from the survey and cognitive function.

Results: Significant differences were observed in demographic and socioeconomic characteristics such as school location, family type, and family income according to digital device exposure. The results of the Cambridge Neuropsychological Test Automated Battery tests, except for 1 test related to executive function, indicated no significant differences ($P>.05$) between group A and group B or among the 4 subgroups. Pretest digital device experience and amount of time spent using digital devices during the test had no significant impacts on the cognitive development of the children. Conversely, the multivariate analyses showed that cognitive function was associated with educational expenses per child, school (location), family type, and family income.

Conclusions: These results provide evidence to policy makers and practitioners on the importance of improving socioeconomic conditions, leading to investment in education by implementing programs for children's cognitive development through digital devices in LMICs.

KEYWORDS

low- and middle-income countries; digital device exposure; children; cognitive function; socioeconomic status

Introduction

Background

Resource-constrained health systems in low- and middle-income countries (LMICs) are considered a key obstacle to achieving sustainable development goals (SDGs), specifically SDG 3, to "ensure healthy lives and promote well-being for all at all ages," and SDG 4, to "ensure inclusive and equitable quality education and promote lifelong learning opportunities for all" [1-3]. As LMICs are experiencing an unprecedented increase in the number and use of digital devices such as mobile phones, digital health and education initiatives that capitalize on the widespread use of these devices are emerging [4,5]. A digital device is a physical piece of equipment that uses digital data in some way, such as sending, receiving, storing, or processing data [6]. Despite controversies over various digital initiatives and programs using digital devices, such as "One Laptop Per Child," policy makers and practitioners are still interested in the potential of digital technology to address issues such as the digital divide, the impact of resource constraints on cognitive development, and developmental disabilities in children [7-11]. However, will digital device exposure and intensity of the exposure affect cognitive development in children in LMICs? This question is difficult to answer because most of the research targets high-income countries, adolescents, and adults [12-14].

In addition to foundational skills such as literacy and numeracy, digital literacy and skills are also key to implementing the SDGs in this digital age [2]. Therefore, many have suggested using digital devices for children's cognitive development to improve information processing, communication skills, and educational attainment [10,15]. Studies have demonstrated that digital devices provide only short-term improvements in children's cognitive abilities during interventions [11,16-19]. A recent study on patients with an intellectual disability diagnosis showed significant improvement in cognitive function using digital devices [20]. Moreover, most studies have focused on the experience of high-income countries or different age groups and patient-only analyses [14,20-23]. The evidence provided by these studies may not be relevant to LMICs because of their different socioeconomic environments and cultures. Although socioeconomic characteristics of households, both within and without, are known to significantly affect cognitive development, few studies on digital device–using interventions, including on the impact of various levels of digital device exposure on children's cognitive development, have been conducted in LMICs [24].

This Study

This study addressed the following questions through a survey and cognitive function tests of children in LMICs:

1. Do demographic and socioeconomic characteristics differ according to digital device exposure in LMICs?
2. Do digital device exposure and intensity of the exposure affect cognitive function in children in LMICs?
3. Is there an association among digital device exposure, demographic and socioeconomic characteristics, and cognitive function of children in LMICs?

Methods

Study Design

This cross-sectional study was designed to identify and analyze the correlation between cognitive function and exposure to digital devices in children aged 3 to 9 years at 2 schools in Cambodia. The study focused on the following urban and rural regions in Cambodia to consider the effects of various conditions such as average literacy rates, wealth and income distribution, and educational environments: Sisophon in Banteay Meanchey (rural population: 24%-73%) and Sangkat Chaom Chaov in Phnom Penh (rural population: 6%-40%). Sisophon has a relatively small share of the nationally estimated high-wealth quintile (22.9%) and a lower average of schooling years than Sangkat Chaom Chaov (high-wealth quintile: 84.4%). The schools selected were Xavier Jesuit School (rural) and Mirero School (urban). Xavier Jesuit School has both kindergarten and elementary classes. In total, 4 classes—2 kindergarten classes, 1 first grade class, and 1 second grade class—were selected. As Mirero School has only elementary classes, we selected 2 classes each from the first and second grades.

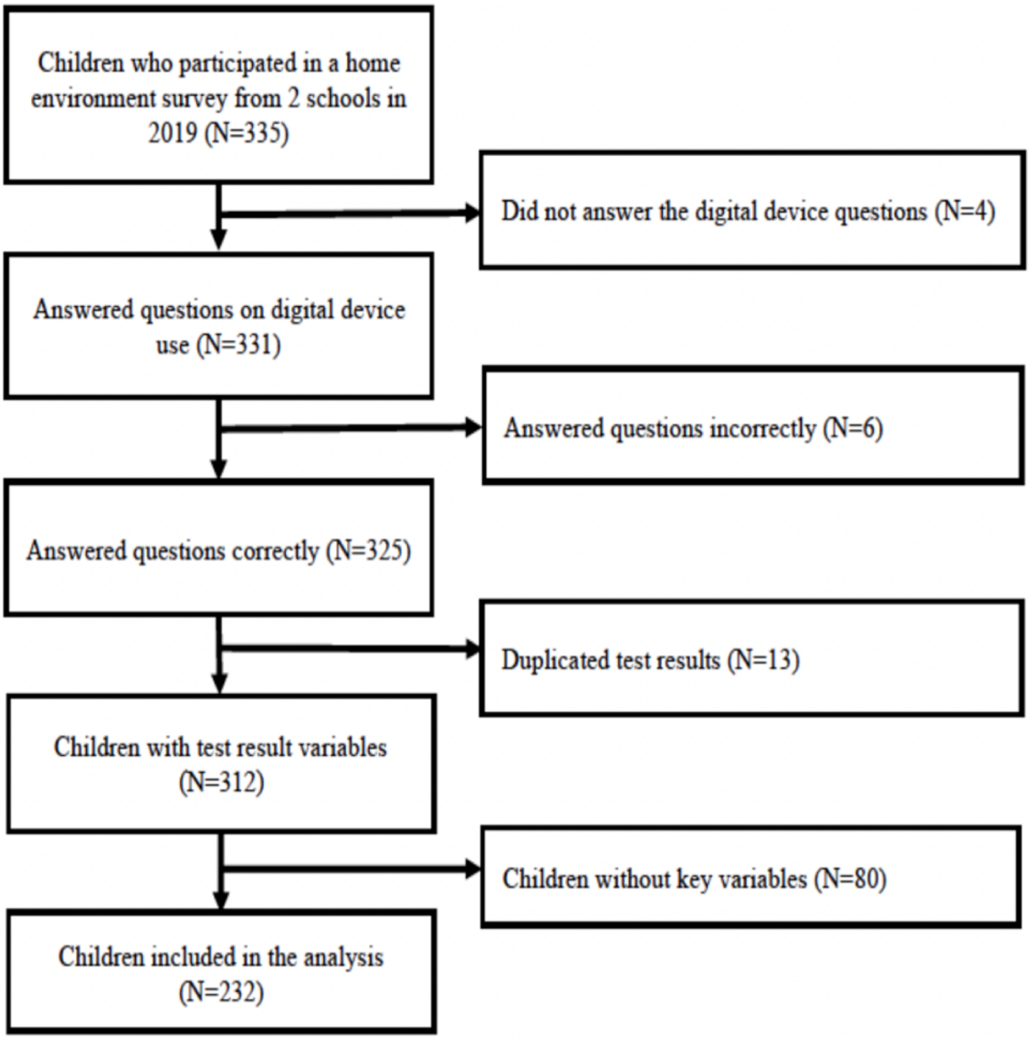
Participant Enrollment

To target children eligible for the cross-sectional study, we selected regions and schools with the advice of the Korea International Cooperation Agency Cambodia Office, which employs experts who are aware of the overall living environment, including education, in Cambodia. After the selection of areas and schools, classrooms and grades of age that met the inclusion criteria were selected.

Study participants were enrolled from 2 elementary schools in Cambodia's 2 regions: rural and urban. The inclusion criteria for children were as follows: (1) male and female students aged 3 to 9 years, (2) no environmental change in their home or school during the study, and (3) children who provided consent from their legal guardian or themselves. Students were excluded from the test if they could not use the study's digital device because of physical conditions or when legal guardians did not provide consent for the test. Figure 1 shows details of the participant selection flow.

The participants were divided into 2 groups based on their responses to the questionnaire about digital device experience: group A comprised children with digital device experience, and group B comprised those without digital device experience. The participants in group A were subsequently divided into 4 subgroups according to the duration (in minutes) of digital device use: group A-1: <30 minutes per day, group A-2: 30 to 60 minutes per day, group A-3: 60 to 90 minutes per day, and group A-4: >90 minutes per day. Of the 232 participants, 162 (69.8%) were in group A, with 95 (58.6%) in group A-1, 47 (29%) in group A-2, 10 (6.2%) in group A-3, and 10 (6.2%) in group A-4, whereas group B had 70 (30.2%) participants.

Figure 1. Participant selection flow.



Ethics Approval

All participants provided written informed consent before enrollment in the study. Consent was granted by their guardians after the study was explained in writing. Ethical clearance was obtained from the Ministry of Health's National Ethics Committee for Health Research in Cambodia (212).

Data Collection

We gathered data on demographic and socioeconomic characteristics through surveys and data on cognitive function using the Cambridge Neuropsychological Test Automated Battery (CANTAB) test. The survey targeted the basic socioeconomic characteristics and demographics of the participants and their guardians from April 22, 2019, to May 4, 2019. Most of the guardians were either the parents or grandparents. At both schools, the survey was delivered to the guardians living with the participant. The response rate was 82.9%. Most (335/404, 82.9%) of the participants returned the completed form to the school. In cases where the guardians could not read, schoolteachers assisted them in completing the survey at school. The questionnaire had 2 parts. The first elicited demographic information about the children, such as sex, age, and siblings, as well as digital device exposure and use. The second collected information about the family's socioeconomic status, including residential conditions, guardians' occupation and education level, household income, and educational expenditure (Multimedia Appendix 1). The participants' cognitive function, depending on their experience with digital devices, was evaluated through the CANTAB test using a tablet device. The CANTAB test includes highly sensitive, precise, and objective measures of cognitive function correlated with neural networks [25]. It includes tests that evaluate 4 cognitive areas: attention and psychomotor speed, executive function, memory, and social and emotional cognition. The participants were asked to perform 5 tests: motor screening task, reaction time, spatial working memory (SWM), pattern recognition memory, and spatial span. We collected 53 test result variables, including 11 key variables, for measuring the outcome of each test (Table 1 and Multimedia Appendix 2).

Table 1. Summary of the Cambridge Neuropsychological Test Automated Battery tests.

Cognitive function and text	Description	Key variable
Attention and psychomotor speed		
Motor screening	To evaluate response speed and pointing accuracy (selecting the cross), participants are asked to select the cross that appears on the screen as quickly and accurately as possible [26]	Mean latency from stimulus (MOTML[a])
Reaction time	Assesses simple reaction time and movement during simple and 5-choice reaction time trials	Median 5-choice reaction time (RTIFMDRT[b]); median 5-choice movement time (RTIFMDMT[c])
Executive function		
Spatial working memory	Test to find individual hidden tokens without returning to a box where one has previously been found [27]	Total between errors (SWMBE468[d]); between errors (4, 6, and 8 boxes; SWMBE 4,6, and 8, respectively); strategy score (SWMS[e])
Memory		
Pattern recognition memory	A 2-choice test of abstract visual pattern recognition memory [28]	Percent correct immediate (PRMPCI[f]); percent correct delayed (PRMPCD[g])
Spatial span	Test to recall the order in which a series of boxes was highlighted [28]	Longest successful sequence (SSPFSL[h])

[a] MOTML: motor screening task mean latency.

[b] RTIFMDRT: reaction time median 5-choice reaction time.

[c] RTIFMDMT: reaction time median 5-choice movement time.

[d] SWMBE468: spatial working memory between errors (4, 6, and 8 boxes).

[e] SWMS: spatial working memory strategy.

[f] PRMPCI: pattern recognition memory percent correct immediate.

[g] PRMPCD: pattern recognition memory percent correct delayed.

[h] SSPFSL: spatial span forward span length.

Statistical Analysis

To compare the demographic differences between groups A and B, a chi-square test was performed on categorical variables such as sex, and a Mann-Whitney *U* test was performed on continuous variables such as age. To compare the differences in cognitive function between the 2 groups, normality was tested for the variables using the Shapiro-Wilk test. Variables satisfying normality were examined using a 2-tailed *t* test, and those that did not satisfy normality were compared between the groups using the Mann-Whitney *U* test. For each comparison, the effect size was calculated for the 2 groups according to digital device exposure and for the 4 subgroups according to digital device use time, and the results of the normality test were compared for possible type 1 statistical errors. In comparing the 2 main groups, Cohen *d* was calculated for the *t* tests, and *r* was calculated using the Mann-Whitney *U* test. To compare the effect size among the 4 subgroups, eta squared (η^2) was calculated for ANOVA, and epsilon squared (^{2}) was used for the Kruskal-Wallis test. The threshold of statistical significance was set at $P<.05$, and an effect size greater than the small size, depending on its type (Cohen $d \approx \pm 0.20$: small, $r \approx \pm 0.10$: small, $\eta^2 \approx 0.01$: small, and $^2 \approx 0.01$: small), was considered significant for 2-tailed *t* tests. To confirm the association among demographic and socioeconomic characteristics, digital device familiarity, and cognitive function in children, univariate regression analysis was performed for 3 cognitive domains and 11 variables flowing from the CANTAB test. In the multivariate linear regression analysis, only variables that were statistically significant ($P<.05$) through univariate regression analysis were selected, and their effect on the cognitive function variable was evaluated with and without adjusting for age and sex. All statistical analyses were conducted using R (version 3.6.3; R Foundation for Statistical Computing) and Python (version 3.7; Python Software Foundation).

Results

Participant Flow

A total of 335 children participated in this study. Of these 335 children, 4 (1.2%) who did not answer the questions about digital device exposure and 6 (1.8%) who answered inconsistently (eg, talking about the purpose of the device, not the experience) were excluded from the data analysis; in addition, 13 (3.9%) children with duplicated test results and 80 (23.9%) without values for the key variables of each test were excluded. Ultimately, of the 335 children, 232 (69.3%) were included in the data analysis (Figure 1).

Overall Population

Of the 232 children, 162 (69.8%) were in group A, and 70 (30.2%) were in group B. The 162 students in group A comprised 110 (67.9%) Xavier Jesuit School students and 52 (32.1%) Mirero School students, a significant difference (*P*<.05). No significant difference between the groups was observed in terms of sex: in group A, 59.3% (96/162) of the participants were male students, whereas in group B, 56% (39/70) were male students (*P*=.72). The mean ages of the participants in group A and group B were 7.3 (SD 1.5) years and 7.6 (SD 1.3) years, respectively, without significant differences (*P*=.15). The proportion of participants with monthly family income of <US $150 was higher in group B (38/70, 54% vs 53/162, 32.7% in group A), with significant differences (*P*=.004). The proportion of participants with monthly family income of >US $350 was higher in group A (25/162, 15.4% vs 4/70, 6% in group B). The proportion of students whose mothers had secondary education and above was far higher in group A (73/162, 45.1% vs 17/70, 24% in group B), with significant differences (*P*=.01). The proportion of families who spent >US $30 per month on education per child was also higher in group A (24/162, 14.8% vs 4/70, 6% in group B), without overall differences between the 2 groups (*P*=.07; Table 2).

Table 2. Comparison of participants' demographic and socioeconomic characteristics according to digital device exposure[a].

Variable	Group A[b], n=162	Group B[c], n=70	Total, N=232	*P* value
School, n (%)				<.001
Xavier Jesuit (rural)	110 (67.9)	31 (44.3)	141 (60.8)

[a] Full table has been presented in Multimedia Appendix 2.

[b] Digital device exposure group.

[c] Digital device nonexposure group.

Digital Device Exposure

When comparing the results of the CANTAB test between the 2 groups, the SWM between errors (4 boxes; SWMBE4) variable of group A had a median of 2.0 (IQR 1.0-3.0), whereas that of group B had a median of 2.0 (2.0-3.0); there were significant differences (*P*=.01). However, the effect size was small (*P*=.02). The SWM strategy (SWMS) variable of group A had a median of 12.0 (IQR 10.0-58.3), whereas that of group B had a median of 10.0 (IQR 9.0-12.0); there were significant differences (*P*.002). The effect size was small (*P*=.04). There were no significant differences between groups A and B for the other variables. The smaller values for the motor screening task mean latency (MOTML) and reaction time median 5-choice reaction time (RTIFMDRT) variables were positive, but the median values of group A were 15.5 and 21.2 points higher, respectively, than those in group B. Conversely, the reaction time median 5-choice movement time variable for the exposure group was 13.5 points lower, without a significant difference in median values among the other variables (Table 3).

Table 3. Comparison of cognitive function according to digital device exposure.

[n] SWMS: spatial working memory strategy.

Digital Device Use Time

When comparing the differences in cognitive levels based on the duration of digital device use, the results showed no significant differences among the 4 subgroups, with all effect sizes being small. Although there were no significant differences, the median values of the 2 variables measuring attention and psychomotor speed in group A-4 were higher than those in group A-1. Regarding the visual memory variables, there were no significant differences among the 4 subgroups, and the distribution did not show a linear relationship. Regarding the executive function test, as use time increased, the number of errors decreased, leading to positive results. Regarding the SWM test, the distributions of the 4 subgroups were not different (Table 4).

Table 4. Comparison of Cambridge Neuropsychological Test Automated Battery test results according to digital device use time.

Cognitive function and variable	Digital device use time					*P* value	Effect size (ε^2)

Cognitive Function and Socioeconomic Status

All results of univariate linear regression analysis to determine the relationship between demographic characteristics and socioeconomic status and CANTAB test score have been presented in Multimedia Appendix 2.

The measures showed that the 3 variables MOTML, RTIFMDMT, and RTIFMDRT from the *Attention and psychomotor speed* cognitive function were significantly associated with *Age* (all *P*<.001), *School* (all *P*<.001), and *Education expense per child* (all *P*<.001) in the univariate model and multivariate model 1. However, in multivariate model 2, adjusted for age and sex, MOTML was significantly associated with *School*, and RTIFMDRT was significantly associated with *Family type* (Table 5).

Table 5. Univariate and multivariate regression models for relationship between cognitive function and survey variables.

Cognitive function and variable	Survey variable	Univariate model		Multivariate model 1		Multivariate model 2[a]

[a] Adjusted for age and sex.

[b] MOTML: motor screening task mean latency.

[c] Statistically significant data are shown in italics.

[d] RTIFMDMT: reaction time median 5-choice movement time.

[e] RTIFMDRT: reaction time median 5-choice reaction time.

[f] PRMPCI: pattern recognition memory percent correct immediate.

[g] PRMPCD: pattern recognition memory percent correct delayed.

[h] SSPFSL: spatial span forward span length.

[i] SWMBE468: spatial working memory between errors (4, 6, and 8 boxes).

[j] SWMBE4: spatial working memory between errors (4 boxes).

[k] SWMBE8: spatial working memory between errors (8 boxes).

[l] SWMS: spatial working memory strategy.

The 3 *Memory* cognitive function variables pattern recognition memory percent correct immediate, pattern recognition memory percent correct delayed, and spatial span forward span length were associated with *Age*, *Education expense per child*, *Family income*, *Family type*, and *School*. In the univariate model and multivariate model 1, pattern recognition memory percent correct immediate was significantly associated with *Age* (all *P*<.001), *Family type* (all *P*=.07), and *School* (all *P*<.05). However, in multivariate model 2, it was significantly related only to *Age* (*P*<.001) and *Family type* (*P*=.01). In the univariate model and multivariate model 1, pattern recognition memory percent correct delayed was significantly related to *Age* (all *P*<.001), *Education expense per child* (all *P*<.05), and *Family income* (all *P*<.05). However, in multivariate model 2, it was significantly associated only with *Age* (*P*<.001) and *Family income* (all *P*=.08). In all 3 regression models, spatial span forward span length was strongly related to *Age* (*P*<.001; Table 5).

The variables SWM between errors (4, 6, and 8 boxes), SWMBE4, SWM between errors (8 boxes), and SWMS corresponding to *Executive function* were related to *Age*, *Digital device exposure*, *Education expense per child*, *Family income per month*, *Family type*, *Sex*, and *School*. In the univariate model, SWM between errors (4, 6, and 8 boxes) was significantly related to *Education expense per child* (*P*=.03) and *Sex* (*P*=.05). However, in multivariate model 1, it was not associated with any variable. SWMBE4 was significantly associated with *School* (all *P*<.05) in the 3 regression models. Both *Age* (all *P*<.05) and *Sex* (all *P*<.05) had a significant association in the 3 regression analyses of SWM between errors (8 boxes). The SWMS variable showed a significant relationship with the 3 variables *Age* (all *P*<.05), *Digital device exposure* (all *P*<.05), and *School* (all *P*<.001) in all regression analyses (Table 5).

Discussion

Comparison With Prior Work

Since 2015, when the 2030 Agenda for Sustainable Development was adopted at the United Nations General Assembly, many initiatives for the application of digital technologies to policies and programs for development, particularly those associated with SDGs 3 and 4, emerged in various countries, particularly LMICs [5,29]. However, there is insufficient evidence on how digital device use affects children's cognitive improvement in LMICs [8,30,31]. This study focused on urban and rural Cambodian schools to provide a comprehensive perspective on the adoption and use of digital devices among children. We used a cross-sectional study to examine the cognitive level of 3 domains using the CANTAB, focusing on how exposure to digital devices affects cognitive development in elementary school–age children.

Principal Findings

Our study found significant differences in demographic and socioeconomic characteristics such as school location, family type, and family income according to digital device exposure. We found that children demonstrated neither superiority nor inferiority in cognitive scores on the CANTAB in 3 cognitive domains depending on digital device use. Given the lack of empirical research on the impact of digital device exposure on cognitive development, we offer two key findings that make a significant contribution to policies and programs for the application of digital devices to health care and education: (1) there is no significant association between exposure to digital devices and cognitive development; (2) however, socioeconomic conditions such as school location, family income, family type, and education expenditure are significantly related to cognitive function [31].

Strengths and Limitations

Several policy implications can be drawn from this study's findings. The first is the importance of an enabling environment that maximizes the impact of digital devices on cognitive function and development. The evidence demonstrates that socioeconomic factors significantly affect cognitive function and development in infancy, including memory and enforcement functions [24,27]. For example, US studies found that children from higher socioeconomic backgrounds had higher achievements in visuospatial, memory, and executive functions than those from middle or low socioeconomic backgrounds. Similarly, students from higher socioeconomic backgrounds in Brazil were found to have better memory and executive function results [24]. To what extent do socioeconomic conditions affect children's cognitive function and development in LMICs? The findings of our study demonstrate that these conditions, specifically education expenditure, enhanced cognitive function and development to a greater extent than did children's exposure to digital devices. Comments such as "we have higher priorities than laptops" expressed by many delegates to the 2005 World Summit on the Information Society, during which the "One Laptop Per Child" devices were introduced, were supported by our findings. Proper investment in education is a much more significant task than purchases of, and exposure to, digital devices, particularly in LMICs.

The second implication concerns the design and setting of digital devices. Many initiatives on the use of digital devices for children's cognitive function and development are based on a theoretical framework called the "brain's rearrangement capacity," which posits that children learn to associate what they see, hear, and know with symbolic characters [31]. Thus, we collected data indicating the symbolic characters that children see and hear on digital devices (Multimedia Appendix 1). Most children with digital devices experience a desire to play games and watch videos, such as those available on YouTube. By playing games and watching videos, children may not learn to associate what they see, hear, or know with symbolic characters. Our finding on the insignificant impacts of exposure to, or use of, digital devices on cognitive development suggests that the design and setting of the devices that children are exposed to should be effective enough to stimulate and accelerate the "brain's rearrangement capacity." Giving children access to digital devices with suitable designs and settings is more important than ever amid a pandemic such as the COVID-19 pandemic, during which almost all schools had closed for long periods worldwide [28].

Our study had several limitations. First, the levels of children's cognitive function and development were measured only during the survey; the long-term impact of digital device use on cognitive function and development was not assessed. This is a typical limitation of cross-sectional studies with a defined time frame. A longitudinal panel study based on groups of children with different socioeconomic backgrounds and levels of exposure to digital devices is needed to measure the long-term effects of digital devices on cognitive function and development. Second, our study was conducted in 2 areas of Cambodia. We focused on both rural and urban areas to examine the impact of differences in socioeconomic levels. However, this did not cover a sufficient area. Nevertheless, considering the lack of studies on the impact of digital device exposure on children's cognitive function and development in LMICs, particularly those focusing on both digital device exposure and socioeconomic conditions, our study expands the understanding of the enabling environment required for digital device–use initiatives aimed at children's cognitive function and development.

Acknowledgments

This work was supported by a grant from the Ministry of Education of the Republic of Korea and the National Research Foundation of Korea (NRF-2018S1A3A2075117), Republic of Korea; a grant from the Institute for Information & Communications Technology Planning & Evaluation (IITP 2022-0-00234) funded by the Ministry of Science and ICT, Republic of Korea; and a grant from the Korea International Cooperation Agency Creative Technology Solution program, Republic of Korea. The funders had no role in the study design, data collection, analysis, manuscript preparation, or decision to publish. The corresponding author has full access to all data and the final responsibility for the decision to submit the paper for publication.

Data Availability

The data set of anonymized individual participants collected during the study period, along with the data specification, is available upon request from the author with access to the data.

Authors' Contributions

H Heon Kim, SH, and YRP envisioned, planned, and supervised this study. H Heon Kim and SH drafted the paper, including the statistical analysis of the data, the effectiveness of digital devices, and educational expenditures. IY, SK, HSS, JK, and SY contributed to cognitive abilities, effectiveness of digital devices, and expertise in sustainable development goals. DRK and YC contributed to data collection through the implementation of the Cambodia Cambridge Neuropsychological Test Automated Battery. H Hyeon Kim and JHL analyzed the data and wrote and modified the paper at the revision stage. All authors reviewed, commented on, and approved the final manuscript.

Abstract

Background: During the COVID-19 pandemic, the shift to virtual care became essential for the continued care of patients. Individuals with rheumatic and musculoskeletal diseases (RMDs) especially require frequent provider visits and close monitoring. To date, there have been limited studies examining inequities in health technology use among patients with RMDs.

Objective: Our goal was to identify characteristics associated with patient portal use before and after the COVID-19 pandemic in a convenience sample of patients with RMDs from a large academic medical center.

Methods: In this cross-sectional study, Epic electronic medical record data were queried to identify established patients of the University of North Carolina Hospitals adult rheumatology clinic between November 1, 2017, through November 30, 2019. Demographic and clinical data were collected to compare MyChart (Epic's patient portal) users with nonusers before and after the COVID-19 pandemic. MyChart activation and use were modeled using logistic regression and adjusted odds ratios, and confidence intervals were estimated.

Results: We identified 5075 established patients with RMDs who met the inclusion criteria. Prior to the pandemic, we found that younger age (P<.001), suburban residence (P=.05), commercial/state insurance (P<.001), military insurance (P=.05), and median income >US $50,000 ($P$<.001) were associated with significantly higher odds of MyChart activation. Male sex (P<.001), being of Black or African American (P<.001) or "other" race (P<.001), Spanish as a primary language (P<.001), rural residence (P=.007), Medicaid insurance (P<.001), and median income of <US $25,000 ($P$=.01) were associated with lower odds of MyChart activation. Following COVID-19, younger age (P<.001), commercial insurance (P=.03), state insurance (P=.02), and median income of US $50,000-75,000 ($P$=.01) were associated with significantly higher odds of MyChart use. However, being of Black or African American (P<.001) or "other" race (P=.01), Spanish as a primary language (P=.002), male sex (P=.004), rural residence (P=.005), and having no insurance (P<.001) or Medicaid (P=.008) were associated with lower odds of MyChart use.

Conclusions: Residence in a rural area, being of minority race/ethnicity, older age, male sex, lower median income, Medicaid, being uninsured, and non-English primary language are associated with lower odds of patient portal activation and use. Future health policy and clinical practice measures should focus on reducing barriers to health technology adoption among these groups.

(J Med Internet Res 2022;24(8):e38802) doi:10.2196/38802

KEYWORDS

COVID-19; telemedicine; telehealth; health technology; health care disparities; patient portal; rheumatology; musculoskeletal diseases; chronic disease; digital health; MyChart; rural area; minority population; virtual care

Introduction

Rheumatic and musculoskeletal diseases (RMDs) are complex chronic conditions that require lifelong care. Patients may experience flares or acute complications related to their disease, requiring close communication with their rheumatologist. Patients with these conditions often take medications that require frequent monitoring and irregular dosing schedules. These aspects of RMD management require a high level of patient agency and open avenues for patient-provider contact and communication. Digital technology such as patient portals, health apps, and wearable technologies allow patients to manage and participate in their own care [1].

Many studies have shown positive effects on patient outcomes and satisfaction when patients are engaged in their own care through digital technologies [1-4]. In a systematic review by de Jong et al [2], patients who were able to communicate with their physicians had increased knowledge and self-management regarding their chronic condition, decreased health care visits, and improved psychosocial and clinical outcomes. In another study of patients with rheumatoid arthritis, patients who received weekly SMS text messages had better medication adherence than patients who did not receive the SMS text messaging intervention [3]. Participation in a web-based arthritis self-management program was associated with improved health status measures and self-efficacy in a study of patients with RMDs (ie, rheumatoid arthritis, osteoarthritis, or fibromyalgia) [4].

Health technology use became a necessity in early 2020 following the SARS-CoV-2 (COVID-19) outbreak, which forced health care systems around the world to adapt in the face of uncertainty. During this period, there has been a large shift to virtual care. Although this change has the possibility to close the gap in health care delivery in the United States, studies have shown that there are disparities in health technology use and the use of technology in general [5-11]. These studies have shown that low health literacy, lower educational attainment, residence in a rural area, being of minority race/ethnicity, and older age are associated with lower rates of health app and general technology use (ie, computer and cellphone ownership) [5-11].

To date, there have been limited studies examining inequities in health technology use among patients with rheumatologic conditions, and to our knowledge, none have looked at how COVID-19 has affected the patterns of health technology use among this patient population. Our goal was to identify the characteristics of patient portal users versus nonusers from a group of patients at a large hospital-based rheumatology clinic. We aimed to identify disparities and potential barriers to telehealth adoption among patients with rheumatologic conditions to help close the gap in health technology use.

Methods

Study Subjects

In this cross-sectional study, Epic electronic medical record data were queried to identify established patients of the University of North Carolina Hospitals (UNCH) adult rheumatology clinic between November 1, 2017, through November 30, 2019. "Established" patients were defined as patients who had at least one return visit during the 2-year study period. We specifically excluded "new" patients since these individuals may be seen for 1 consultative visit without further follow-up in the UNCH system. We felt that including these subjects could underestimate patient portal activation or use among our population.

Variables

Demographic and clinical data were collected from patient- and provider-entered information on Epic and used to compare the patients who activated Epic's patient portal (MyChart) to patients who did not activate MyChart at the time of the initial data acquisition. Additional data on MyChart usage were collected for the following year to compare MyChart use 8 months prior to the start of telemedicine visits at our clinic (from July 1, 2019, to March 30, 2020; "prepandemic") to the 8 months following the clinic's adoption of virtual care (from April 1, 2020, to December 2, 2020; "postpandemic"). MyChart "activation" indicates that the patient, or a patient proxy, has enrolled for patient portal access. MyChart "usage" was defined as the patient or patient-assigned proxy using MyChart to read or send patient-provider messages or manage appointments.

Demographic information collected included age, sex, race or ethnicity as documented in the electronic medical record (American Indian or Alaska Native or Native Hawaiian or Pacific Islander, Asian, Black or African American, Hispanic or Latino, White, or "other" race), primary language (English, Spanish, or "other"), zip code and county of primary residence, and primary insurance payor. Patients were grouped into generational categories based on age at the time of initial data collection (November 2019): born from 1997 to the present ("Gen Z," ages 17-22 years), born from 1981-96 ("Millennials," ages 23-38 years), born from 1965-80 ("Gen X," ages 39-54 years), born from 1946-64 ("Baby Boomers," ages 55-73 years), and born from 1928-45 ("Silent Generation," ages 74-91 years) [12]. North Carolina (NC) "rural," "suburban," and "urban" county designations were defined as average population densities of ≤250 people/square mile, 250-750 people/square mile, or ≥750 people/square mile, respectively, based on densities as reported in 2014 US Census population estimates [13]. Using individual income 2017 zip code data for NC from the Internal Revenue Service (IRS), we used the median gross income of each zip code to estimate individuals' annual median gross income. Estimated median adjusted gross income was grouped in quartiles as reported in the IRS data [14]. Income data were not available for all zip codes; income data was not reported for zip codes with a low number of returns or in cases of nonresidential zip codes [14]. Thus, patients with NC zip codes without income information and patients with out-of-state zip codes were excluded from analysis. The clinical data collected included the most recent outpatient visit date and number of clinic visits (≤2 vs ≥3) within the study period.

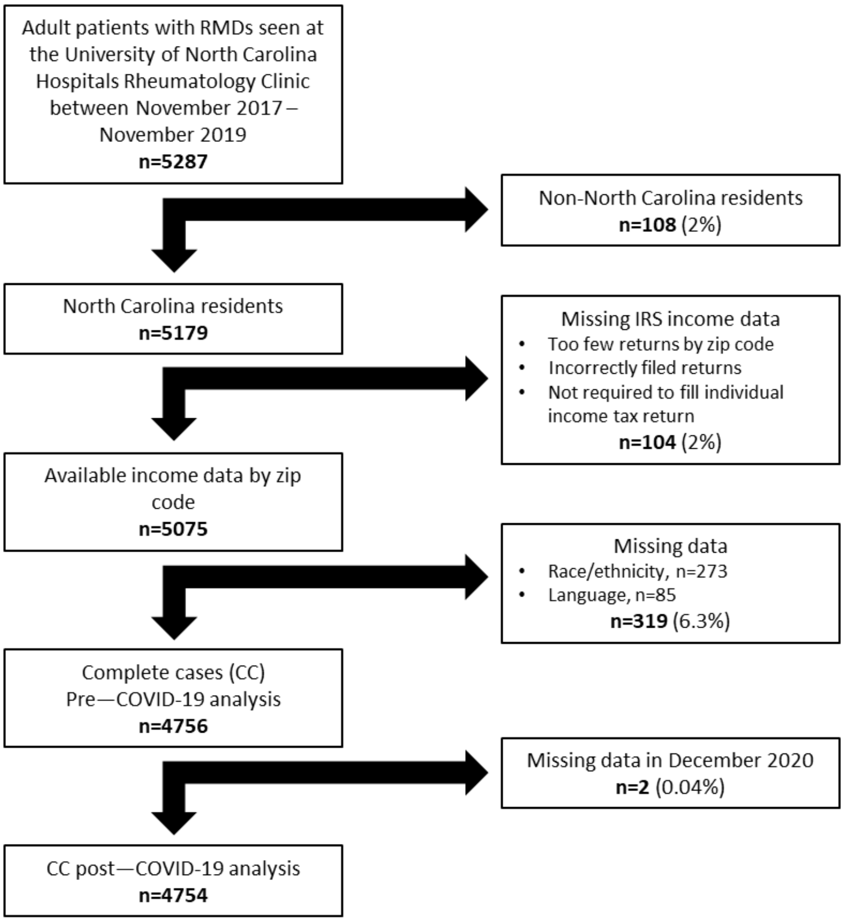
Statistical Analysis

Descriptive statistics were used to summarize study subjects and relevant variables. Counts and percentages were produced for categorical variables, whereas mean (SD) or median (IQR) were computed for continuous variables. Multivariable logistic regressions were separately modeled for the log odds of MyChart activation pre–COVID-19 (Model 1), MyChart use pre–COVID-19 and post–COVID-19 (Model 2), and MyChart use post–COVID-19 among nonusers pre–COVID-19 (Model 3). Model 2 used generalized estimating equations to account for the correlation between a patient's pre–COVID-19 and post–COVID-19 MyChart use and the interaction of pre–COVID-19 or post–COVID-19 time, with all covariables tested and retained if *P*<.05; otherwise, overall effects were shown for this model.

Models included all previously defined variables: visit date, the number of visits, age group, sex, race or ethnicity, primary language, county of residence, insurance, and median zip code–based income to produce adjusted odds ratios (aORs) and 95% CI. Complete cases were included for multivariable analyses, excluding subjects with missing variable items given that missing data rates (319/5075, 6.3%) were well below <10% (Figure 1) among NC residents with available IRS income by zip code.

Sensitivity analyses using multiple imputations of variables with missing information (race or ethnicity and primary language) were performed to assess the consistency of results. These variables were imputed using logistic regression by fully conditional specification methods for binary variables, which performs best for missing-at-random patterns and a missing proportion of less than 50%, to generate 10 imputed data sets for analyses [15]. Due to the exploratory nature of our study, corrections of statistical significance level were not performed [16]. All analyses were performed with SAS statistical software (version 9.4; SAS Institute Inc). Statistical significance was determined at *P*=.05.

Figure 1. Subject inclusion and exclusion. IRS: Internal Revenue Service; RMD: rheumatic and musculoskeletal disease.



Ethics Approval

Our study was reviewed and approved by the University of North Carolina's Institutional Review Board (protocol 19-3155) and adheres to the ethical principles of the Declaration of Helsinki. A waiver of informed consent was obtained due to the retrospective nature of our study.

Results

General Characteristics

We identified 5287 established patients who were seen at the UNCH rheumatology clinic during our study period, of whom 5075 patients were NC residents with available income data based on zip code. There were 4756 complete cases included in the pre–COVID-19 MyChart activation analyses and 4754 in post–COVID-19 MyChart use analyses (Figure 1).

Descriptive statistics for key characteristics are shown for the cohort of NC residents with income data (N=5075; Table 1). The mean age of the NC cohort was 54.7 (SD 15.4) years, and 73.9% (n=3749) were female. Of the 5075 established patients, 51% (n=2586) identified as White and 26.4% (n=1342) identified as Black or African American. In all, 88% (n=4478) identified English as their primary language, whereas 9.2% (n=469) reported Spanish as their primary language. Patients were almost evenly split between urban (n=1679, 33.1%), suburban (n=1506, 29.7%), and rural (n=1890, 37.2%) residences. Over two-thirds (n=3563, 70.2%) had a median adjusted gross income between US $25,000 to <US $50,000. Regarding insurance, 37% (n=1851) had Medicare, 25.1% (n=1276) had commercial insurance, 10.1% (n=512) had Medicaid, and 16.9% (n=859) were uninsured.

We examined MyChart activation among 3759 MyChart “activators” by patient characteristics (Table 2). We found that 74.1% (3759/5075) of our cohort had activated MyChart (Table 2). For age groups, 91% (111/122) of Gen Z patients had activated MyChart, whereas 69.7% (352/505) of those aged ≥75 years had activated MyChart. The rates of MyChart activation were 77.1% (2890/3749) among women and 65.5% (869/1326) among men. For race and ethnicity, 82% (2130/2586) of White patients and 87% (87/100) of Asian patients activated MyChart, whereas 63.6% (854/1342) of Black or African American patients and 65.4% (409/625) of Hispanic or Latino patients activated MyChart. MyChart activation was 76.3% (3416/4478) among English speakers and 57.4% (269/469) among Spanish speakers. The rates of MyChart activation among patients residing in a suburban county was 81.3% (1224/1506) and 65.4% (1237/1890) among patients residing in a rural county. Only 53.4% (86/161) of patients with an estimated median adjusted gross income of <US $25,000 activated MyChart, compared to 92.5% (124/134) of patients with a gross income of US $75,000 to <US $100,000. The rates of MyChart activation were high among individuals with commercial (1099/1276, 86.1%), state (319/350, 91.1%), and military (113/132, 85.6%) insurance, whereas 71.6% (1325/1851) of Medicare beneficiaries, 65.6% (336/512) of Medicaid recipients, and 65.3% (561/859) of uninsured individuals activated MyChart.

MyChart Activation Pre–COVID-19

Using data from complete cases among NC residents (n=4756), we calculated the aORs of MyChart activation by patient characteristics prior to the COVID-19 pandemic (Table 3). Compared to Baby Boomers, Gen Z patients were 5 times more likely to activate MyChart (aOR 5.39, 95% CI 2.67-10.9), followed by Millennials (aOR 2.86, 95% CI 2.22-3.69) and Gen X (aOR 1.72, 95% CI 1.42-2.08) patients. Male patients were significantly less likely to activate MyChart than female patients (aoR 0.61, 95% CI 0.51-0.71; *P*<.001). Compared to White patients, Black or African American patients (aOR 0.39, 95%

CI 0.33-0.47; *P*<.001) and patients of “other” race (aOR 0.44, 95% 0.27-0.70; *P*<.001) had significantly lower odds of MyChart activation. Spanish as a primary language was associated with significantly lower odds of MyChart activation (aOR 0.31, 95% CI 0.20-0.48; *P*<.001) than English. Suburban residence was associated with significantly higher odds of MyChart activation (aOR 1.22, 95% CI 1.00-1.49; *P*=.05), whereas rural residence was associated with significantly lower odds of activation (aOR 0.78, 95% CI 0.65-0.93; *P*=.007) than urban residence. Compared to patients insured through Medicare, there were significantly higher odds of MyChart activation among subjects with commercial insurance (aOR 1.77, 95% CI 1.41-2.23; *P*<.001), state insurance (aOR 2.67, 95% CI 1.76-4.05; *P*<.001), and military insurance (Tricare; aOR 2.20, 95% CI 1.19-4.10; *P*=.05), whereas Medicaid insurance was associated with significantly lower odds of MyChart activation (aOR 0.64, 95% CI 0.49-0.83; *P*<.001). Compared to thte median gross income level of US $25,000 to <US $50,000, median income of <US $25,000 was significantly associated with lower odds of MyChart activation (aOR 0.62, 95% CI 0.42-0.90; *P*=.01), whereas higher income levels were significantly associated with MyChart activation: US $50,000 to <US $75,000 (aOR 1.89, 95% CI 1.53-2.33; *P*<.001) and US $75,000 to <US $100,000 (aOR 3.61, 95% CI 1.74-7.47; *P*<.001). Results from the analysis using multiple imputed data were consistent with these results; thus, the results from complete case analyses are reported.

MyChart Use Pre–COVID-19 and Post–COVID-19

To determine changes in patient portal use during the COVID-19 pandemic, we calculated the aORs of MyChart usage in the 8 months prior to and the first 8 months following telemedicine adoption (Table 4). We also calculated the odds of becoming a MyChart user during the COVID-19 pandemic among those who were previously nonusers (Table 5).

Some disparities remained despite the rapid and nearly complete transition from in-person to remote care starting in April 2020 (Table 4; Model 2). The associations between MyChart use and sex, race or ethnicity, language, residency rurality, and insurance were similar to those observed with MyChart activation (Table 3; Model 1) and were not significantly different by pre–COVID-19 or post–COVID-19 timing. However, Gen Z patients had higher odds of MyChart use post–COVID-19 (aOR 2.52, 95% CI 1.63-3.89) than pre–COVID-19 (aOR 1.54, 95% CI 0.99-2.39). Interestingly, there was no difference in MyChart use after the pandemic between the highest earners (US $75,000 to <US $100,000) and the reference group (US $25,000 to <US $50,000), perhaps reflecting an increase in MyChart use among the reference group.

Among prior nonusers (n=3086; Table 5; Model 3), we observed that Gen Z was associated with significantly higher odds of becoming a MyChart user during the pandemic (aOR 2.80, 95% CI 1.32-5.94; *P*=.007). Prior male nonusers were less likely to become a MyChart user (aOR 0.58, 95% CI 0.41-0.83), as well as nonusers of rural residence compared to nonusers of urban residence (aOR 0.62, 95% CI 0.44-0.87).

Discussion

Principal Findings

We found that after the start of telemedicine visits at our institution, there was a significant increase in patient portal use among our youngest patients (Gen Z generation). However, MyChart usage following the implementation of telemedicine remained significantly lower among those of Black or African American race and “other” race, having Spanish as a primary language, being uninsured, and having Medicaid. Male sex and rural residence were also associated with lower odds of MyChart use post–COVID-19, and individuals in these groups were significantly less likely to become MyChart users during the pandemic. To our knowledge, this is the first study describing disparities in patient portal use among patients with RMDs and the first to evaluate changes in health technology use during the current COVID-19 pandemic.

Comparison With Prior Work

The results of our study build upon previous work, underscoring inequities in telehealth use and further highlighting that these disparities existed prior to the COVID-19 pandemic and continue to persist. A large cross-sectional study conducted prior to the COVID-19 pandemic showed that the most frequently cited barriers to patient portal adoption were preference for direct communication with providers and inexperience with computers, which were associated with lower income and older age. In this study, other commonly reported barriers included having no patient portal available or difficulty accessing the portal, lack of internet access, and privacy concerns [17].

Various studies examining disparities in telehealth use during the pandemic found similar results to ours. A study by Pierce and Stevermer [18] showed that those of non-White race and those who resided in rural postal codes had lower rates of telehealth use. Another study also showed that older age, living alone, and rural residence were associated with lower telehealth use [19]. However, these patterns are not restricted to rural populations. A study of New York City residents showed that Black and Hispanic patients, non-English speakers, and older patients were less likely to use telehealth for COVID-19–related care [20].

Some factors that may explain these inequities in telehealth use include limited access to affordable and reliable internet, low computer ownership, and low digital technology literacy among certain groups. It is estimated that 24 million Americans do not have access to affordable high-speed internet, with rural residents being disproportionately affected [21,22]. In a survey of NC residents, the cost and lack of access to broadband were the 2 most cited reasons for not having internet access [23]. Cellular phones offer an alternative method to access the internet and is sometimes the only option for certain individuals. A study of computer or laptop ownership among Americans showed that younger age, non-White race, lower educational attainment, and lower income were associated with "smartphone" dependency and a lack of computer or laptop ownership [24]. However, the ability to access the internet via cellular devices is subject to the availability of reliable cellular data networks.

In our study, we noted that men had lower patient portal activation and use before and during the pandemic. This finding may be explained by men's overall lower engagement with health care and hesitancy toward help-seeking behaviors compared to women [25,26]. Similar to our findings, Yang et al [27] found that Medicaid enrollees were less likely to adopt eHealth tools compared to the non-Medicaid population in part due to lower odds of internet access.

We found that Black or African American individuals were less likely to use the patient portal even after controlling for factors such as age, insurance, residence type, and income. Thus, although there are certainly social and economic factors tied to race that contribute to lower health technology use, there seem to be other elements that influence health technology use among Black or African American individuals. Some of these results may stem from poorer access to reliable internet, privacy concerns, or preference for speaking directly to their health care providers [28,29]. A qualitative study by Lyles et al [30] evaluating barriers to patient portal use among Latinx and Black patients showed that difficulty navigating the patient portal and concern that patient portal use would diminish the patient-provider relationship were 2 major themes observed across age, income, and geographical groups. Spanish and other non-English speakers are less likely to access health care or use telehealth modalities due to difficulty communicating with providers and using health technology platforms not available in their language [31,32]. UNCH MyChart is only available in English, which prevents non–English-speaking patients from using this resource.

Age is also a large factor in telehealth use. A study investigating health technology "readiness" among older adults showed that 41.4% of Medicare beneficiaries lacked access to a computer with high-speed internet access, 40.9% lacked a smartphone with a wireless data plan, and 26.3% lacked either form of digital access [33]. Other difficulties that older adults may face include age-related impairments (eg, hearing loss, vision loss, and dementia) or low overall use and unfamiliarity with using technology, and these barriers seem to be amplified in patients who are male; single; Black or African American or Hispanic or Latino; reside in a nonmetropolitan area; and have less education, lower income, and poorer self-reported health [34].

Strengths and Limitations

The strengths of this study include our large real-world cohort of patients with RMDs and the racial and socioeconomic diversity of our study population. We were also able to compare changes in health technology use pre–COVID-19 and post–COVID-19 in the same patients. Some of the limitations of our current study include our retrospective study design and the use of zip code as a proxy for socioeconomic variables, which risks homogenizing certain populations. Of the 5179 NC residents in our cohort, 104 were not included in the analysis due to lack of IRS income data. Of these individuals, 63% (n=66) were from rural counties, 23% (n=24) from urban counties, and 13% (n=14) from suburban counties. As expected, the majority of these individuals resided in rural counties. However, given the small percentage of the NC cohort that these patients represented (2%), excluding them from the analysis is unlikely to affect our results. We did not specifically assess remote telecommunication visits among our patients in this study and therefore cannot draw conclusions on whether there are disparities in telemedicine use among our patients. Additional factors that we did not include, but are possible confounders, include health literacy, smartphone ownership, computer or laptop ownership, broadband access, and cellular data access.

Conclusions

As technology is increasingly used for health care delivery, addressing disparities in health technology use has never been more important. A recently published perspective piece in the New England Journal of Medicine highlighted the scope of the issue and addressed the newly enacted Infrastructure Investment and Jobs Act. This law includes funding toward broadband infrastructure development and affordability, improving connectivity in rural and tribal communities, the creation of digital literacy programs, and preventing digital discrimination [35]. Although the Infrastructure Investment and Jobs Act does not specifically address digital inequities in health care, the potential changes that may occur as a result of this law will undoubtedly affect accessibility to health technology. Although many of the issues that contribute to inequitable technology access are multifaceted and cannot be changed immediately, we hope that increased research and resources are invested in making health technology accessible for all. Future studies should focus on ongoing barriers and potential solutions in avenues such as internet accessibility, health and digital literacy, and attitudes and perceptions toward health technology.

Acknowledgments

This research was funded by The Fund for Excellence in Lupus & Sjogren’s at the University of North Carolina Thurston Arthritis Research Center.

Editorial assistance was provided by Tessa Englund, PhD, MPH, Research Associate at the University of North Carolina Thurston Arthritis Research Center.

Authors' Contributions

EYS, CA, LFC, and SZS conceptualized, designed, and created the methodology of the study. EYS and CA performed data curation. CA completed the formal analysis and validation. EYS, CA, LFC, and SZS contributed to the original draft preparation, review, and editing. EYS and SZS provided supervision and project administration. SZS acquired the funding. All authors have read and agreed to the published version of the manuscript.

Conflicts of Interest

SZS has served as a consultant for GlaxoSmithKline, served on advisory boards for Aurinia Pharmaceuticals Inc and AstraZeneca, and received grant funding from Pfizer outside of this project. All other authors declare no other conflicts of interest.

Abstract

Background: Prior research on health information behaviors of people with dementia has primarily focused on examining the types of information exchanged by people with dementia using various web-based platforms. A previous study investigated the information behaviors of people with dementia within a month of their diagnosis. There is an empirical gap in the literature regarding the evolution of health information needs and behaviors of people with dementia as their condition progresses.

Objective: Our work primarily investigated the information behaviors of people with dementia who have been living with the condition for several (4 to 26) years. We also aimed to identify their motivations for changing their information behaviors over time. Our primary research questions were as follows: how do people with dementia get informed about their condition, and why do people with dementia seek information about their condition?

Methods: We adopted an action research approach by including 2 people with dementia as members of our research team. Collaboratively, we conducted 16 remote 1-hour contextual inquiry sessions with people living with mild to moderate dementia. During the study sessions, the first 40 minutes included semistructured interviews with participants concerning their information behaviors, followed by a 20-minute demonstration of their information-seeking strategies. Data from these interviews were analyzed using a constructivist grounded theory approach.

Results: Participants described their information needs in terms of managing the disrupted physiological, emotional, and social aspects of their lives following a diagnosis of dementia. They used various information behaviors, including active search, ongoing search, monitoring, proxy search, information avoidance, and selective exposure. These information behaviors were not stagnant; however, they were adapted to accommodate the changing circumstances of their dementia and their lives as they worked to re-establish equilibrium to continue to engage in life while living with a degenerative neurological condition.

Conclusions: Our research revealed the motivations, changing abilities, and chosen strategies of people with dementia in their search for information as their condition evolves. This knowledge can be used to develop and improve person-centered information and support services for people with dementia so that they can more easily re-establish equilibrium and continue to engage in life.

Introduction

Background

Information behavior refers to the ways in which people interact (and do not interact) with information [1]. Understanding health information behavior is important as decisions based on health information sources can influence a person's health trajectory, quality of life, and health outcomes [1,2]. Populations with unique health information needs may exhibit different health information behaviors. Therefore, researchers have studied the information behaviors of populations such as people with diabetes [3,4], breast cancer [5], and prostate cancer [6]. We studied the health information needs and behaviors of people with dementia as, similar to those with other health conditions, they want to be fully informed about their diagnosis [7-10]; however, the cognitive nature of their medical condition makes this inherently difficult. Therefore, we must identify the information that they seek, as well as find the most appropriate ways to provide it, to meet their needs.

To date, nearly all dementia-related information behavior research has analyzed data created by people with dementia using social media (eg, Twitter [11,12] and Facebook [13,14]), web-based dementia forums [15-17], and a web-based dementia advocacy platform to share their experiences [18]. These studies revealed the importance of web-based communities for information exchange among people with dementia, although they did not explore the broader information behaviors of people with dementia.

Most research on health information research on dementia has focused on informal caregivers' information behaviors. A recent scoping literature review of 20 studies found 4 studies on the information needs and information-seeking behaviors of people with dementia, with only 2 studies distinguishing the behaviors of people with dementia from those of caregivers [19]. Studies that delineate the unique information needs and information behaviors of people with dementia found that caregivers were more interested in searching for topics specific to dementia, whereas people with dementia predominantly searched for support groups and were generally disinterested in seeking information regarding dementia [20, 21].

Harland et al [10] found that perceptions of dementia were major factors affecting information-seeking behaviors immediately after diagnosis. For example, people with dementia avoided health information if they felt unable to influence their situation, whereas others valued and sought this information to "confirm their suspicions and provide explanations" [10]. Harland et al [10] called for further work to understand "how information needs and behaviors change over time and with the progression of the disease"—a call to which this paper responds.

Objective

The primary aim of this study was to discover the nature, content, and evolution of information behaviors of people living several years after a dementia diagnosis. Our secondary aim was to identify the motivations for changing information behaviors over time. Therefore, we sought to address the following research questions:

1. How do people with dementia stay informed about their condition?
2. Why do people with dementia seek information about their condition?

To answer these research questions, we adopted an action research approach [22], which included contextual inquiry sessions with 16 people with dementia to understand the factors that motivated them to initially seek information. We then examined their evolving information behaviors and investigated their motivations for adapting their information behaviors. In addition, our findings led to revelations beyond the scope of our original interview questions, which unveiled information behaviors in the realms of personal well-being and equilibrium. Equilibrium, defined as a state of balance between a person's mental framework (cognitive and emotional) and the environment [23], is a concept that has been applied in domains ranging from education to health sciences. Specifically, researchers have noted ways in which people strive for equilibrium when coping with a new medical diagnosis [24,25], which triggers disequilibrium, a state of disorder and imbalance in the mind [23]. Past research has noted how individuals with conditions such as cancer [24] and diabetes [25] actively search for information as a way of restoring equilibrium. In our study, several kinds of information behavior, including actively searching for information, played a key role in restoring equilibrium in participants with dementia. We compare our findings to prior research and discuss the implications of our findings for medical professionals who work with people with dementia, as well as health information resource providers such as web-based content developers interested in creating more accessible content.

Methods

Study Overview

Our research team comprised university researchers and 2 dementia advisers (people living with dementia who are knowledgeable and active in dementia advocacy). We selected an action research approach [22] that involved members of the target culture throughout the research process [22]. The 2 dementia advisers on our team served as empowered researchers and decision-makers. The participation of dementia advisers afforded the research team greater access to otherwise hidden truths in the population of people with dementia. The research team collaboratively determined the topic of the study, identified target questions, designed the study protocol, collected and analyzed the data, and wrote the final report.

A contextual inquiry approach [26] allowed us to collect data through participants' verbal explanations, as well as their demonstration of information-seeking behaviors. This strategy gives participants the chance to explain and attempt to perform their intentions, thereby not limiting data collection to recall or verbal descriptions of information behaviors [26,27]. This is particularly useful when conducting research with people with cognitive disabilities. We chose a qualitative approach rather than using a priori theories and methodologies to describe complex, dynamic participant experiences.

Recruitment

We recruited people with dementia through convenience sampling from our networks, which included members of peer support groups, large dementia advocacy organizations, and snowball sampling. To qualify for the study, participants had to self-report a clinical diagnosis of mild to moderate dementia and seek dementia information since being diagnosed. The research team first sent 30 potential participants an initial recruitment email with details outlining the study and the criteria for participation in the study. Of the 30 participants, 16 (53%) responded that they met the participation criteria and were interested and available to participate. Before scheduling each study session, the authors verified the eligibility of the participants by verbally inquiring about the participation criteria. Interview and observation sessions were scheduled and completed between July and September 2020.

Data Collection

The 16 contextual inquiries comprised 2 parts: an interview (about 40 minutes), followed by a 20-minute observation session. Sessions were conducted on Zoom videoconferencing (Zoom Video Communications Inc) because of pandemic-related research restrictions. The first 4 contextual inquiry sessions were conducted by a team of 2 (ED and JA) academic researchers. The remaining 12 contextual inquiry sessions were conducted by blended teams (1 academic researcher [ED teamed with DCB] and 1 dementia adviser [JA teamed with MLR]), with the dementia adviser leading each session.

Ethics Approval

We assumed consent capacity, which aligns with best practices when working with people having mild to moderate dementia [28] and is required by law in many countries [29]. As a precaution, we were attentive to a possible lack of capacity and were prepared to use the University of California Davis protocol [30] to determine whether the person was able to do the following: (1) make a choice to participate, (2) show an understanding of what the study entailed, (3) describe their rationale for participating in the study, and (4) show an appreciation of the potential risks and benefits of the study. This protocol was not used for any participants, as there was no indication that any participant might not have the capacity to consent.

In each contextual inquiry session, participants first provided verbal consent and then completed a short demographics form. In semistructured interviews, we asked questions such as “How do you typically obtain dementia-related information?” and “How would you improve your process of obtaining dementia information?” We subsequently followed up with probing questions to pursue topics raised by the informants (eg, conversations with their physicians). During each observation, the screen-sharing technology allowed participants to demonstrate their information-seeking strategies.

On the basis of our related work involving people with dementia, we created 8 scenarios as prompts for information seeking (see Multimedia Appendix 1 for scenarios), and then invited participants to select and conduct a search while describing their intentions. During this phase, we probed participants to reveal their thought processes using questions such as “Why did you choose this site?” Following each session, participants received US $20 Amazon gift cards as compensation.

Raw data comprised session transcriptions, screen videos of web-based searches, field notes, methodological memos, and Zoom video and audio recordings, which resulted in approximately 16 hours of recorded data. This was transcribed using Otter.ai (AISense, Inc) and reviewed and verified by an academic researcher. All procedures were approved by the University of Maryland institutional review board (approval number 1316631-40).

Data Analysis

We used a constructivist grounded theory approach to analyze the interview data [31] as it required taking into consideration and accounting for our own perspectives as researchers. This was critical, given that our research team included both dementia advisers and academic researchers.

Each of us open coded the transcriptions, creating early codes such as “offline information gathering strategies” and “vetting people/organizations.” We collaboratively discussed our codes and determined emergent themes, such as “information sources and systems,” “information gathering strategies,” and “motivations for seeking information.” Individual codes were merged into collaborative themes, resulting in a code book. The team then collectively edited, clarified, and refined the code book. The resulting code book was applied during the refining process of focused coding using the most significant initial codes to sift through large amounts of data to categorize the data incisively and completely [31].

Each transcript was focus coded twice—once by a dementia adviser and then by an academic researcher—to ensure that we correctly understood what each participant’s intended meaning. Through this process, our analysis led us to understand how individuals use different types of information behaviors, which has been previously defined in the literature (although, to the best of our knowledge, not in the context of dementia).

We followed an iterative process of engaging with the data, comparing codes, performing pattern recognition, and memoing for several months with weekly team meetings to build connections between codes and emergent theories that would explain the nature of participants’ health information–seeking behaviors. This process led to a dementia adviser connecting the concept of “finding equilibrium,” based on the theory of “optimizing re-equilibration” [23], to the motivation that participants described for their information-seeking strategies and their subsequent emergent changes in information behaviors, which we describe further in the results.

When studying the lived experiences of individuals or groups of people, we may (consciously and unconsciously) superimpose our own perspectives, cultures, and experiences onto the analyses [31]. Therefore, we explicitly reveal our beliefs and status as academics or people living with dementia, so that the reader may interpret our findings with a full understanding of our roles [31]. Although based at a research university, the academic researchers have also been informed by dementia activists who advocate for people with dementia and are known to practice self-determination well into the progression of the condition [32-34]. In addition, technology research has informed our practice of supporting people with dementia [35] and other disabling conditions to take an active role in their own health and well-being [36-39]. These perspectives have influenced the ways in which we conduct research on how people with dementia use information.

Participants

A total of 16 participants aged 57 to79 years self-reported at least one type of mild to moderate dementia with a range of 4 to 26 years since their diagnosis before the study (Table 1). Of the 16 participants, 15 (94%) identified ethnically as White and 1 (6%) as Asian. All participants reported employment statuses of retired, retired on disability, or volunteering. Nearly all claimed being “somewhat confident” using technology (Thomas was “not confident,” whereas Lila, Lucy, and Carter were “very confident”). All participants were dementia advocates and members of online peer support dementia groups.

Table 1. Participant demographics.

Pseudonym	Age (years)	Sex	Country of residence	Type of dementia	Years since diagnosis	Education	Technical confidence
Arnold	68	Male	Canada	Vascular dementia	≥10	Some college; no degree	Somewhat confident
Dawson	73	Male	United States	Early onset Alzheimer disease	2 to 5	Some college; no degree	Somewhat confident
Lucy	67	Female	United Kingdom	Early onset Alzheimer disease	5 to 10	Bachelor’s degree	Very confident
Carter	61	Male	United Kingdom	Vascular dementia	5 to 10	Some college; no degree	Very confident
Michael	61	Male	United States	Functional neurological disorder	5 to 10	Some college; no degree	Somewhat confident
Sadie	79	Female	United States	Alzheimer disease	≥20	High school diploma	Somewhat confident
Lila	Range 60-70	Female	Canada	Early onset Alzheimer disease with a Lewy body component	5 to 10	Multiple bachelor’s degrees	Very confident
Carly	62	Female	United States	Frontotemporal dementia	≥10	Master’s degree	Somewhat confident
Gale	71	Female	Australia	Frontotemporal dementia	5 to 10	Master’s degree	Somewhat confident
Eva	57	Female	United States	Lewy body dementia with behavioral disturbances	5 to 10	Bachelor’s degree	Somewhat confident
Levy	61	Male	No answer	Lewy body or Parkinson disease	2 to 5	Some college; no degree	Only a little confident
Velma	61	Female	Canada	Vascular dementia	5 to 10	Bachelor’s degree	Somewhat confident
Thomas	68	Male	United States	Variant of slow-moving Alzheimer disease	5 to 10	High school diploma	Not at all confident
Kevin	79	Male	United States	Frontotemporal dementia	≥10	Master’s degree	Somewhat confident
Toby	61	Male	United States	Early onset Alzheimer disease and Lewy body	5 to 10	Master’s degree	Somewhat confident
Donna	62	Female	Australia	Semantic variant of primary progressive aphasia	≥10	Master’s degree	Somewhat confident

Results

Overview

We discovered the information needs of people with dementia concerning the physiological, emotional, and social aspects of their life. These included the factors that motivated them to seek information on their condition to re-establish equilibrium, both initially after diagnosis and in evolving ways over the years (or decades, in some cases) through active searching, monitoring and ongoing searching, proxy information search, information avoidance, and selective exposure.

The Goal of Health Information Seeking: Re-establishing Equilibrium After Diagnosis

Overview

Disequilibrium is defined as a state of disorder and imbalance in the mind such that individuals cannot assimilate new information into their schema because of its contradictions or inconsistencies with their prior knowledge or experience [23]. In the instances described by the participants, disequilibrium arose with a medical diagnosis of dementia. After hearing that they had an incurable brain condition, participants described feeling sometimes relieved at receiving an actual diagnosis but also still feeling uninformed, confused, worried, sad, upset, or alone in terms of the physiological, emotional, and social aspects of life. As they strived to resolve this disequilibrium, they often did so by seeking relevant health information; however, just as often, they did not find what they needed.

Information Needs Concerning Physiological Aspects of Life

Upon diagnosis, participants usually expected physicians to satisfy their information needs regarding their physiological health. However, as nearly all respondents explained, most of their physicians (and even local dementia organizations) failed to provide adequate information regarding the origin, progression, treatment, and management of dementia, both initially and during the evolution of their condition. Arnold explained, “I wasn’t given any referrals, any information, who to talk to, where to go.” Donna, too, recounted as follows:

> *I was told, “The type of dementia you’ve got, there’s nothing I can do, and no medication available.”...And then, “See you in six months.”*

This lack of information at diagnosis led to a state of disequilibrium for participants, as they were unsure of the physiological factors related to what to expect out of life with their new dementia diagnosis.

Even after realizing that their questions might yield unpleasant answers (or none at all), several respondents persevered in researching the nature of their condition. Gale explains this as follows:

> *When I was first told the diagnosis, I didn’t really know anything...I really wanted to study [frontotemporal dementia], find out what it was, and confirm [to] myself that I thought the symptoms matched.*

Participants asked the following:

> *...medical, mental kinds of stuff...a cure* [Kevin]
>
> *Is this being caused by the [reduced] blood flow?* [Velma]
>
> *Have I taken the proper steps?* [Levy]

By educating themselves about the physiological aspects of dementia, some participants hoped to learn how to mitigate the effects of dementia on their lives as a way of re-establishing equilibrium. Lila explained the following:

> *I’ve come to realize that there are different forms [of dementia], and each form comes with a different set of problems. And if I know the problem, maybe I can avert the long term effects.*

Information Needs Concerning the Emotional Aspects of Life

The emotional toll of the information provided at diagnosis often left the participants hopeless or in an extremely low emotional state. When Velma received a diagnosis of vascular dementia, her physicians told her, “There was nothing that they could do, nothing that they really had for me, and that I needed to get my affairs in order to try to enjoy my window of time.” This led her to an emotional “state of numbness and shock for probably a good six months or so...I couldn’t even figure out what questions I needed to actually ask, because all that kept going through my head was three to eight years,” which is the reported average life expectancy for individuals with vascular dementia. Similarly, Thomas described his diagnosis as “excruciatingly painful to hear,” leading him to “go home, and then you put a blanket over your head, start having some very dark thoughts about...what’s the point of carrying on, if this is all I’ve got?” He added the following:

> *A lot of health practitioners...don’t practice good emotional care. And emotional care is every bit, if not more important, particularly when you're being told you have a fatal disease.*

Participants had previously expected a different trajectory for their lives. Therefore, the diagnosis of dementia was emotionally destabilizing.

Participants searched for encouraging health information to balance the negative news they had received with any positive news—sometimes just to find hope to re-establish equilibrium. However, Thomas realized he was not the best person to do the research:

> *We need...the wisdom of what to do with this new diagnosis as [physicians] give the diagnosis, not send people home and let them go looking for it.*

Disequilibrium upon diagnosis was compounded by failed expectations that physicians would not only fully address his physical and cognitive condition but also his emotional state of being, as it related to the changes he was undergoing.

Other participants experienced not only receiving pessimistic information from their physicians but also a dehumanizing delivery of their diagnosis. Lila’s neurologist “never looked at [her] once.” Instead, the physician announced to her husband, “‘Your wife has early onset Alzheimer's. You can bring her back when she can’t dress herself.’” Lila was furious:

> *I had to keep my mouth shut. I was biting my tongue so hard, I thought the blood was gonna start pouring out of my mouth...*

She later called her primary physician and was referred to another specialist. These kinds of interactions with physicians could last for years, which is explained by Donna as follows:

> *I had a very good rapport with [the doctor], but after the dementia diagnosis, he wouldn’t see me on my own. After about three years, I took a piece of paper with big type, big black font on it: “Talk to Me.”...He said, “What do you mean?” I said, “Well, before dementia, you used to talk to me about my health.*

> *Now you'll only talk to my husband; it's like I don't even exist in the room."*

Such dehumanizing interactions with physicians at diagnosis left at least one participant yearning for moral support and information "that touch the person's heart" (Thomas).

Information Needs Concerning Social Aspects of Life

Participants said that their social lives changed from the moment they shared their diagnoses, reporting an apparent lack of empathy from friends or family members who had no prior experience with dementia. Thomas explained the following:

> *When you finally work up the nerve to tell people what you're going through, the first thing out of their mouth, 95% of the time, isn't empathetic. It's like, "You don't look like you have dementia! At least you don't have cancer"...[A spouse] loves you dearly, but doesn't get the fear that courses through your veins*

Lacking a sense of belonging to a given community also contributed to the participants' state of disequilibrium, driving them to seek information that would help with the social aspects of their lives.

Participants described the need for social connections with other people with dementia and sought further information on their similar lived experiences:

> *I knew that I couldn't be the only one...So I was searching—where are these people? I have to find them. I know they're out there* [Velma]

Connecting to other people with dementia was key to understanding how to live well; knowledge from their lived experiences could not be gleaned from other relationships. Lila described the following:

> *We need to learn from each other. We need to hear how other people do things and what they've gone through.*

Given that many participants could not locate others with dementia nearby, they "had to go online" (Sadie) to accommodate information needs concerning social aspects of life to re-establish equilibrium.

Evolving Information Behaviors of People With Dementia

Overview

Although participants expressed the need for more health information immediately following the diagnosis of dementia, they also described changes in information needs as their medical condition progressed, as new medical discoveries occurred, and as access to different types of information became known. Their initial needs and formerly successful strategies to seek information no longer provided them with equilibrium; therefore, they adapted. At the time of the study, 31% (5/16) of participants had been living with dementia for >10 years, and one participant for even 20 years, and we learned about changes in their information needs and behaviors, along with those of the more recently diagnosed people.

Active Searching

Overview

The first information behavior most participants described following diagnosis reflected the Wilson active search technique, meaning they were "intentionally choosing to browse or search for information" [40]. Participants indicated that the goal of their active searching immediately after diagnosis aided them in recovering from initial postdiagnostic reactions such as depression or denial. Active searching also took place months and years later from digital resources and other people with dementia in online peer support groups.

Digital Resources

As many participants felt they were provided insufficient information at diagnosis, they described actively "searching out every little thing" (Levy) to satisfy their information needs. Carly described herself as "a questioning person...a thinking person," where she tries to clarify the things she's read by "immediately look[ing] [it] up."

Given the multiple types of dementia and their myriad of symptoms, participants had varied physiological information needs, which led them to actively search for web-based resources. Velma, who described herself as "always learning—everyday I'm learning," read "a lot of new reports that come out in JAMA...I'm learning how important things like nutrition, exercise, socialization and connections with people are, in staying well." When experiencing potential symptoms of dementia, Lila searched for "'dementia and left side brain' So, you know, because of the regions in the brain, depending on which side you have dementia attacks and the areas it attacks, it will also tell you what symptoms could be happening to you." Other participants wanted to understand whether symptoms, such as loss of smell and taste (Velma), were related to dementia or to another condition that they might need to treat.

Participants routinely conducted active searches on the internet as they knew that research is "evolving all the time" (Dawson). Even after 12 years of living with dementia, Donna looks up new information "all the time, because everything's changing so much...even stuff about diagnosing categories." Similarly, Dawson acknowledged that "what was in Google out there 10 years ago, 8 years ago, 5 years ago, 10 minutes ago, is always changing..."

For many participants, the sources of information they used were dependent on the type of information they were trying to find. Carly described: "I have many systems—dependent upon the question..." For basic information, Carly would use the Google search engine. When this was "not enough," she would turn to peers with dementia. These peer interactions during the process of actively seeking web-based information were typically synchronous and presented in a mutually beneficial manner, as discussed in the following section.

Counterparts in Peer Support Groups

Without exception, all participants said that they actively sought information about dementia from others with similar diagnoses in online support groups, citing this as one of the most important strategies for gathering useful information.

Several participants described actively seeking physiological information from other people with dementia who had been living with the disease longer, and seemingly better, through web-based synchronous communication using videoconferencing platforms such as Zoom. For example, Eva and Michael both referred to a web-based social group called "Dementia Mentors" [41], which provides a safe, nonjudgmental, stress-free environment several times a week. Through this program, people recently diagnosed with dementia can communicate with people who have lived with the condition for many years via web-based interactions.

The participants also mentioned organizations that offered online peer support groups, such as the Alzheimer's Association, Association for Frontotemporal Dementia, Lewy Body Association, Alzheimer's Society, Dementia Alliance International, and Dementia Australia. After joining a peer support group, Velma "started to have a better understanding of how much there was that we could do to help ourselves." For Toby, the group provided an opportunity to observe other group members, and "almost [see] a case study in what's going to happen to me vicariously," which satisfied his need for information to understand the physiological changes he might experience in the future. Similarly, Dawson explained the following:

> *You can see they've experienced it and you have faith and trust in that individual...if they've had a good experience with a particular medication or some activity that they've done, then it may be something I might want to consider...we share that information.*

Such online peer support groups helped participants identify, and often actually provided, the information necessary to re-establish equilibrium in their lives.

Online peer-to-peer support groups provide a place where participants "share your problems with people who get it...all the different nuances and fears," similar to "a foxhole connection you get when you're in war" (Thomas). Information sharing created a bond that "wasn't the social thing; it was much deeper than that...this connection is heartfelt, emotional, mental and spiritual" (Thomas). This connection helped Thomas to "overcome my own severe negative feelings about people with dementia, and recognize that there's still life worth living, because I was just like everyone else." Arnold expressed how "what we say stays in the group, and we're not pre-judged." Knowing that everyone is similarly vulnerable and that confidentiality is preserved seemed to make peer groups feel safe, even allowing for personal growth. These web-based communities seem to be highly valued resources for re-establishing equilibrium by meeting the information needs concerning the social and emotional aspects of life.

Monitoring and Ongoing Searching

Overview

Participants explained how an active search helped them build "a base of knowledge" (Toby) on dementia and re-establish equilibrium by meeting their physiological, social, and emotional information needs after diagnosis. With these needs met, and equilibrium restored, some shifted to searching less often, such as Gale:

> *In all honesty I tend not to look for anything specific nowadays, because I kind of feel that I've got all the basic information.*

These participants adopted the information behavior of ongoing search, "where active searching has already established the basic framework of knowledge, but where occasional continuing search is carried out to update or expand one's framework" [40]. To facilitate an ongoing search, participants set up what Ellis defines as monitoring strategies, which include any actions that enable someone to stay updated with new developments in their field [42]. For example, Gale explained that when "somebody has prompted me with a subscription or said something, I'd say, 'Oh yeah; I'll look that up and see.'" When new information was inconsistent with the existing knowledge base of the participants, they would slip into disequilibrium, prompting the need to conduct an ongoing search for further information to re-establish equilibrium.

Monitoring strategies included attending peer support groups, curating social media accounts, and receiving push notifications such as subscribing to newsletters, as discussed in the following sections.

Peer Support Groups

Monitoring and ongoing searches in peer support groups of people with dementia were important sources of health information for the participants when "someone else in the group may bring one [research article] forward and go, 'Hey, did you see this one?'" (Velma). Thomas believed that current clinical research "would come up in group, 'cause we have people in our group that are proactive about those kinds of things," alluding to peers who routinely conducted active searches. Arnold, who is in several peer support groups, explained, "I've been caught off-guard with some information...These groups are a tremendous source of information and help."

Lucy occasionally conducted ongoing searches:

> *I don't actually go online unless...a discussion has come up and I want to know more about it...I will go on Google Search and find out...a little bit more about what they're talking about.*

She monitors information in the "nine different groups that I'm involved in" with the goal of "shar[ing] all the information I've collected from others...[because] it's important, isn't it? Because they don't know, and that's something I'm still capable of...getting all this information and letting them know."

Social Media

Participants also used social media platforms such as Twitter to monitor rather than actively search for relevant health information. Arnold explained that "About 95% of the people that I follow are dementia-related," such as researchers and advocacy organizations. He elaborated that he is "not using Twitter to get information; it's more seeing what people in the dementia world are up to," reflecting a monitoring strategy. He "look[s] at everything that's posted. And then I'll click the heart, which means I like it. And sometimes I will make a retweet with a comment. But that's basically it."

Donna checks, "if I see something on Twitter, and there's a lot of chatter about it, I think, 'Oh, I better read that one,'" reflecting an ongoing search strategy. Carter curated a network on Twitter, although for the "vast majority" of people he followed, he had also "met personally...[and] can vouch for their credibility."

Push Notifications and Subscriptions

Many participants set push notifications from subscription providers to monitor the latest dementia information from organizations such as the Dementia Engagement and Empowering Program (Carter), Alzheimer's Disease International (Donna), Lewy Body Dementia Association (Levy), international health organizations (World Health Organization and United Nations [Donna]), medical journals (The Journal of the American Medical Association [Velma] and Neuroscience [Gale]), and medical organizations (the Mayo Clinic [Donna and Velma]). Velma described this strategy as, "just wait for them [newsletters] to show up," as she did not "know how to find a list of what I'm subscribing to or not," but did regularly read her email.

The participants remarked that these monitoring strategies resulted in a large volume of new information. Gale "subscribed to any new research...I probably get three or four emails a day that have information about what's going on with dementia." Donna subscribed to "loads" of blogs that "come into my inbox on a Monday morning...I very rarely go to them in my inbox" as "I just get too many emails, about 600 emails a day across my different emails." However, this offer of information did not usually create disequilibrium. Instead, as Donna explained, with certain research organizations, such as the Mayo Clinic, "I get their newsletter, but I rarely read it unless it really jumps out as something that might be super relevant." Therefore, these monitoring strategies only led to ongoing searches when participants were confronted with new information that was not already part of their existing knowledge base or conflicted with their own experiences.

Proxy Information Search

Proxy information search is when "one individual tries to find information on another person's behalf" [43]. Owing to the progression of dementia and changes in abilities, some participants described having to transition from active or ongoing search to proxy information search to continue having access to the kind of dementia-related information they needed. For example, Toby described decreases in "the speed at which I can assimilate information...and the extent to which I can recall information." Thomas finds actively searching for information difficult as "I don't retain stuff really good anymore." Given that so much information seeking related to dementia took place on the web, active and ongoing search became inaccessible to Carter because of his difficulty with "working on the PC" where "things that I used to be able to do, not that long ago, that I can't do anymore." As a result, the physiological, social, and emotional aspects of life were inadequately addressed, often leaving participants in a state of disequilibrium. To re-establish equilibrium, some participants found a proxy to help them search for dementia information, thus accommodating their progressive cognitive disabilities.

To reiterate, the participants' shift to using the strategy of proxy information search did not appear to be based on a waning interest in dementia information or a lack of questions. Toby explained the following:

> *I generally have the ability to ask the questions and to know the relevant questions and pose them. But I have lost the ability to do some of the deep research that I normally would have done.*

In such instances, several participants referred to their spouses as assuming the role of proxy information seeker by "look[ing] stuff up for me" (Thomas) and being "a conduit for information flow" (Toby). Others relied on mentors (Arnold) and family members (Levy). Thomas also relied on people from his support groups.

The participants expressed much gratitude for the proxy searchers. However, some participants were deterred by the need to transition to greater dependency on information. Levy explained his reluctance to use a proxy but also recognized his own limitations:

> *I don't really go out looking. I used to...when I first got diagnosed...*

However, giving up the power to search for information was a "struggle...because you feel you're going to lose everything. And it's like, now I gotta give this up [searching on his own]. It's killing me" (Levy).

People with dementia often have activities slowly taken away because of their own changing cognitive abilities [32] or from well-intentioned carers to relieve them from certain responsibilities. In either case, the transition to a proxy search may be seen as yet another activity being taken from them. Although participants noted their disappointment and dissatisfaction with having to rely on others to assist with information search, they retained an active role in choosing when to engage in a proxy search.

Some participants described serving as proxy researchers for their peers. When Dawson gave dementia-related talks, people asked him questions about specific types of dementia or how to get tested for dementia. Hence, he would do "a little more digging," then "usually I'll share with them at a very high level what I have been able to learn, but I will also ask them to check with their own doctor or check with an association to get specific[s]." By contrast, Gale did not simply conduct searches for people but rather "show[ed] them how to do it [look up information] and where to look," demonstrating for those capable of looking up dementia information but in need of training on where and how to find it.

Information Avoidance and Selective Exposure

Some participants expressed how, after a certain point, continuing to search for dementia information led to a state of disequilibrium rather than providing a means to reach equilibrium. Michael said, "I'm burned out. I'm burned out on looking at that stuff—I get it. I get it—it is what it is." In response, participants chose information avoidance, or "the human tendency to avoid, ignore, and deny information, particularly in the context of health care" [44], to maintain their equilibrium. When Eva experienced degenerative changes because of dementia, she admitted, "I just let it slide by; I don't care. I don't want to know." In these instances, a participant may experience changes inconsistent with prior knowledge or experiences but still choose not to seek information that would help "go beyond his current state and strike out in new directions" [23]. Instead, some participants described avoiding dementia information or only selectively exposing themselves to dementia information, specifically to maintain their equilibrium.

However, information avoidance did not necessarily signify the end of participants' information seeking but was used more as a mitigation strategy to avoid shifting into disequilibrium because of information overload at a particular moment. Thomas occasionally used proxy search or information avoidance to focus on life and relationships because of the following:

> *What's the point? I mean I know there are some people, they're going to spend the rest of whatever is left of their life worrying about it, stressing over looking stuff up, and I'd rather go play with my dog and go camping and do what I can, while I can, with what time I've got left.*

Information avoidance allowed participants to deflect negative emotions and, instead, as Thomas explained, engage in "trying to be a person who's positive and happy and full of joy. And that's the way I want to live my life; that's the way I want to be known."

The perceived high volume of web-based dementia information was also a contributing factor to some participants' choices to engage in information avoidance. Eva described being overwhelmed and frustrated:

> *You get too much information sometimes, and you just don't want to know any more facts and information.*

She also expressed dissatisfaction with not being able to find answers to questions, sometimes simply as there were no answers. Thomas was more fatalistic:

> *What's the Internet gonna tell me about how you improve your memory?...As far as I know, there's no real way to improve your memory; you either have it or you don't.*

For some, the response to overwhelmingly negative dementia information was not avoiding it all but rather avoiding only emotionally triggering stories, which is a practice called selective exposure, wherein conscious decisions are made to consume only certain information [45]. Lila minimized information related to the stages of dementia to manage her anxiety:

> *Once you're diagnosed...Well, you know, I have dementia, I'm going to decline. I know that...I'm not going to even think about that. You know I have enough to worry about...Why add something else on my plate that could potentially make me more anxious?*

However, she continued to actively search for physiological information on her symptoms. In an observation session, Eva declined to explore the scenario to find information on coping with anxiety caused by dementia, saying, "I don't need to read it. I live it...I live a lot of my life in paranoia and worry and fear." She then chose a less sensitive scenario and demonstrated her technical skills without having to lose her equilibrium because of the potential emotional toll of the information content.

Discussion

Principal Findings

Our findings, based on the semistructured interviews with 16 participants with dementia recruited through convenience sampling, unveiled how the postdiagnostic information needs of people with dementia concerning their physiological, emotional, and social aspects of life motivated participants to actively search for information on their condition. Participants also used the information behaviors of the ongoing search, monitoring, proxy search, information avoidance, and selective exposure as they worked to re-establish equilibrium. These information behaviors were not stagnant but adapted to accommodate the changing circumstances and needs of their lives with dementia to continue to engage in life while living with a degenerative neurological condition.

Comparison With Prior Work

Past research examining how information behaviors change over time has included people with cancer [46] and diabetes [47]. Eheman et al [46] also specifically investigated how information-seeking strategies change from active to passive searching after people receive cancer treatment. Although cancer causes 10 million deaths a year, and diabetes 1.5 million, dementia now affects >55 million people worldwide, with >10 million new annual cases [48]. This fast-growing population merits investigation into its information-seeking behaviors, especially as there are several forms of dementia. with even those in the medical field being often unfamiliar with the dozens of diseases that can cause this condition. The result is that people diagnosed with dementia have had to learn about their complex symptoms for themselves while trying to live fulfilling lives.

Prior research on the information behaviors of people with dementia found that caregivers were more interested in searching for topics specific to dementia. On the other hand, people with dementia were more interested in finding support groups but appeared altogether disinterested in seeking dementia information [20,21]. Although our research validates the importance of support groups (and provides evidence for their role in filling physiological, social, and emotional information needs), our findings refute this claim of disinterest. Our findings are more aligned with the recent Harland et al [10] study, which highlights the interests of some people with dementia to seek information 4 weeks after diagnosis, whereas others avoided it as they felt they could not affect their situation [10]. Similarly, we found that some individuals, such as Velma, practiced information avoidance for up to 6 months after diagnosis. Some participants' justification for information avoidance was because they felt emotionally "numb" (Velma) rather than powerless to affect their situation, as reported in the study by Harland et al [10], and even reported the decisions to engage in various information behaviors, including actively seeking dementia information later in their lives. Because of our semistructured interviews with 16 participants with dementia recruited through convenience sampling, we were able to discover the transitions that many participants underwent in their information behavior.

Even participants who described intentionally avoiding dementia information or only exposing themselves to certain topics many years after diagnosis (because of the emotional toll they anticipated) illustrated conscious choices to maintain equilibrium. Such acts of self-preservation and self-care are perhaps a vital stage of effective dementia information seeking because of the pessimistic, overwhelming, and unsatisfactory extant dementia information. This finding provides a contrasting narrative to the typical assumption that people with dementia are incapable of self-regulation [49]. In fact, participants were able to recognize that searching for dementia information at times led them to an unhealthy state of mind; therefore, they adjusted their actions to avoid disequilibrium.

Thus, information avoidance may be worth exploring in future research, as it may inform physicians and support and advocacy organizations in their efforts to deliver more person-centered, positive dementia-related information. When participants chose to seek dementia information, they developed and used their own systems to monitor advances in research, including regular scrolling through curated social media accounts, which is an avenue for the dissemination of self-narratives by people with dementia [11,12]. Our findings also contribute to the field by demonstrating that some people with dementia use social media in the hopes of hearing about new breakthroughs in medical research regarding dementia. Future studies should consider using social media as an additional platform for disseminating information about support services for individuals with dementia.

Our findings depict that the information behaviors of a group of people with dementia differ from those studied in previous research, which found that people with mild cognitive impairment and dementia underuse social media and push notifications to access health information [50]. Although prior research reported apathy toward technology in the search for web-based dementia resources [51,52], individuals in this study demonstrated a wide range of technology savviness and interest, not only in finding web-based dementia resources but also in setting up monitoring strategies through social media and subscriptions.

We also discovered that participants regularly used web-based platforms to seek out peers with dementia on Twitter [11,12], Facebook [13], dementia advocacy websites [18], and web-based forums [15-17], echoing the importance of web-based communities. Notably, we found that people with dementia seek peers who have lived with the diagnosis longer than they had in synchronous support groups such as "Dementia Mentors" [41]. However, participants also leveraged technology to support others as friends and mentors, with one participant (Gale) teaching newly diagnosed people how to search for dementia information instead of merely serving as a proxy. Such mentors fit the concept of "Dementia Trailblazers" outlined by Johnson et al [17] in 2020—people with dementia who were "extremely active" and knowledgeable in web-based dementia forums in providing information support. Thus, our findings provide evidence of the value of creating support services that incorporate peer mentors to teach people newly diagnosed with dementia how to search for information to meet their physiological, social, and emotional information needs.

Our research on the evolving information behaviors of people with dementia has shown that their search strategies change over time, not only because of the degenerative nature of their condition but more importantly because they remain motivated to re-establish a sense of equilibrium in their lives. Past work has described how people living with cancer [24] and diabetes [25] strive for equilibrium while coping with their diagnosis. It is noteworthy that our study has shown that people with cognitive disabilities are motivated by the same human need for equilibrium in the physiological, social, and emotional aspects of life. To the best of our knowledge, our work is the first to theorize how information behaviors, and the transitioning between them, are motivated by the need to re-establish an equilibrium for people with dementia. Although past work has largely focused on the various motivational factors for information seeking or information avoidance [4,46,47], our findings enrich the health information behavior literature by illustrating a single cross-cutting motivational factor for the range of information behaviors—equilibrium.

Implications

Revelations from this research will serve to inform medical professionals and web-based content developers about the information needs of the 55 million people with dementia worldwide [48], not only to help them regain equilibrium after the initial diagnosis of a serious brain disease but also to continue supporting them throughout the progression of their condition as they undergo changes in physiological, emotional, and social aspects of their lives.

Medical Professionals

Participants described their initial diagnosis of dementia as the trigger to disequilibrium, a finding consistent with prior research that revealed the overwhelmingly negative manner used by physicians to inform patients of their condition, which led to multiple calls for physicians to adjust the language they use to communicate a diagnosis [10,53,54]. Therefore, we add our voices to the call for physicians to convey information in a way that is emotionally reassuring [10] and to "instill hope in the context of a dementia diagnosis" [54].

Left in an information desert after diagnosis, participants were forced to go in search of answers about their type of dementia on the web using only their random technological skills, general education, and access to computers to sift through approximately 1.2 million TB of internet content (as of 2021). Although many participants eventually found health information on the web, it was often not exactly what they needed, took an inordinate amount of time, and was easily lost because of the complexity involved in saving digital information. To combat these challenges, we join in the call of previous work for interprofessional education [55] and multidisciplinary care teams [56] to provide more effective postdiagnosis support to people newly diagnosed with dementia [55]. Our findings demonstrate the necessity of providing such information upon diagnosis in multiple formats and languages (eg, printed, web-based, verbal, pictorial, audio, and video) and when the newly diagnosed individual is emotionally more ready for it. Further work is needed to identify the full range of barriers that people with dementia may encounter when searching for health information on the web.

Web-Based Content Developers

In pursuit of dementia information on the web, participants described using social media platforms, search engines, dementia advocacy websites, medical organizations, journal websites, and online peer support groups, although they encountered challenges with each. To address some of these challenges, we ask content developers to better support the information needs of people with dementia in the following areas.

As many participants wanted to actively, although selectively, search for dementia information (to limit their exposure to certain dementia-related topics), we would suggest improving signposts to the content of pages, so that end users can more easily avoid their personal informational triggers to disequilibrium.

Furthermore, the nuisance of subscriptions was frequently discussed, despite the participants' stated desire to stay informed about health information. A potential solution could be to filter more finely any available web-based content, such as excluding paid advertisements, providing only open-access articles, or showing only reports whose accuracy has been academically verified.

Finally, because of executive function challenges (eg, speed of retrieval, recall, and retention), people with dementia sometimes resorted to proxy searches, which often led to negative emotions around the sense of losing agency. Therefore, we refer to web-based content developers to learn and address the cognitive accessibility needs of neurodiverse end users [57]. These include but are not limited to providing clear and understandable text, using simplified layouts to facilitate the locating of needed information, reducing extraneous material such as advertising and flashing notifications to maintain focus, and offering support for different ways of understanding content [57].

Limitations

In designing a study involving people with dementia, we were cognizant of the need to respect the time commitment and amount of work we should require. Therefore, we limited the scope of data collection to a single, approximately 1-hour session. We realize that a longitudinal study of participants' information-seeking behaviors would yield much more data; thus, we hope that future ethnographic or autoethnographic studies will follow the progression of people with dementia, as well as the evolution of their information behaviors.

Participants in this study were limited in racial, geographic, linguistic, and age diversity because of the nature of our convenience sampling recruitment strategy and access to volunteers. All but 1 participant identified as White, and all resided in the United States, the United Kingdom, Canada, or Australia and spoke English, which does not represent the global population currently living with dementia. Prior research shows a higher prevalence of dementia in the United States in African American and Latinx communities [58]. Therefore, future work is needed to ensure that our understanding of information behavior is more representative.

Given that 50% (8/16) of our participants were aged ≤65 years, we also acknowledge an overrepresentation of people with younger onset dementia [59], which only accounts for 9% of global diagnoses [48], although this number may be an underrepresentation of actual cases. Recruiting this relatively younger group of participants may have resulted from the hesitation of the older generation to reveal their diagnoses because of stigma [32,60,61] and misinformation about dementia, which leads to an unwillingness to discuss personal experiences with researchers [62]. The overrepresentation may also have been because participants were recruited using convenience sampling from the most visible peer support and advocacy groups that regularly expressed an interest in helping dementia researchers. Finally, most participants in this study used technology confidently, which may not be representative of the general population with mild to moderate dementia, although this is trending upward: 54.14% of people with mild cognitive impairment or dementia report using their smartphones and tablets almost daily [63].

Conclusions

Using an action research methodology with 2 dementia advisers and academic researchers, we collaboratively identified the motivations and evolution of the information behaviors exhibited by people with dementia after diagnosis. Participants demonstrated their ingenuity and changing abilities to search for information themselves, shifting their information behaviors (eg, from active to monitoring or proxy searches and from ongoing searches to information avoidance and selective exposure), and discussing such changes to maintain and re-establish their sense of equilibrium in life.

Participants also demonstrated and reflected on their abilities, challenges, and frustrations when seeking dementia information on the web. We found that people with dementia (similar to people with cancer, diabetes, and other conditions that trigger disequilibrium) were motivated to adapt their information behaviors not only to meet their evolving cognitive needs but also to address the physiological, emotional, and social aspects of their lives to re-establish equilibrium when faced with inconsistent or conflicting information, even as their condition progressed.

By informing physicians, support organizations, web-based health resource developers, and other factors that influence information behaviors of people with dementia, we aim to see innovation in communication technologies and media platforms to facilitate their use by a neurodiverse population. In face-to-face interactions, we hope that groups will incorporate peer mentors to teach people newly diagnosed with dementia how and where to search for trustworthy health information on the internet, as well as from their medical providers. We also anticipate that our findings will guide readers newly diagnosed with dementia and who are experiencing disequilibrium to try some of the participants' strategies to search for the web-based health information that they need to re-establish equilibrium in their own lives.

Acknowledgments

We thank the participants, Beth St Jean, and the anonymous reviewers who provided feedback on versions of this paper. Abstract

Background: Lack of knowledge of systematic reviews (SRs) could prevent individual health care professionals from using SRs as a source of information in their clinical practice or discourage them from participating in such research.

Objective: In this randomized controlled trial, we evaluated the effect of a short web-based educational intervention on short-term knowledge of SRs.

Methods: Eligible participants were 871 Master's students of university health sciences studies in Croatia; 589 (67.6%) students who agreed to participate in the trial were randomized using a computer program into 2 groups. Intervention group A (294/589, 49.9%) received a short web-based educational intervention about SR methodology, and intervention group B (295/589, 50.1%) was presented with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist. The participants' knowledge of SRs was assessed before and after the intervention. The participants could not be blinded because of the nature of the intervention. The primary outcome was the difference in the percentage of correct answers about SR methodology per participant between the groups after the intervention, expressed as relative risk and 95% CI.

Results: Results from 162 and 165 participants in the educational intervention and PRISMA checklist groups, respectively, were available for analysis. Most of them (educational intervention group: 130/162, 80.2%; PRISMA checklist group: 131/165, 79.4%) were employed as health care professionals in addition to being health sciences students. After the intervention, the educational intervention group had 23% (relative risk percentage) more correct answers in the postintervention questionnaire than the PRISMA checklist group (relative risk=1.23, 95% CI 1.17-1.29).

Conclusions: A short web-based educational intervention about SRs is an effective tool for short-term improvement of knowledge of SRs among health care studies students, most of whom were also employed as health care professionals. Further studies are needed to explore the long-term effects of the tested education.

Introduction

Background

Evidence-based medicine (EBM), which is interchangeably also called evidence-based practice (EBP) or evidence-based health care (EBHC) [1], is credited with a major impact on health care [2]. Systematic reviews (SRs) are considered the gold standard evidence that helps in making decisions about health within the concept of EBM [3].

However, multiple studies have shown a low level of knowledge of EBM among health care professionals. Low awareness of EBM was reported by Novak et al [4] among physicians in Croatia, and limited knowledge but a positive attitude toward EBM was reported by Ulvenes et al [5] among Norwegian physicians. A study conducted by Munroe et al [6] showed that only 3% of nurses evaluated their knowledge of EBP as very good.

Knowledge of SRs is considered important for health sciences and medical students as well because it is important that clinicians know how to find and appraise evidence [7]. Knowledge of SRs in trainees can help not only in developing useful skills in critical appraisal but also in addressing important clinical questions and serve as a strong basis to design new, original research studies that will fill the gaps and answer relevant and unsolved clinical questions [8].

The importance of medical students' exposure to EBM was shown by Vrdoljak et al [9], who reported that knowledge and attitudes of mentors toward EBM in general practice can be influenced by using medical students as academic detailers. It has been shown that better knowledge and more positive attitudes toward EBM among medical students are associated with the exposure to the vertical subject on research in biomedicine and activities of The Cochrane Collaboration [10]. Glass et al [11] reported that summarized research evidence delivered in a poster format can increase student nurses' access to the evidence base. This intervention has increased their knowledge to guide their clinical practice. Thus, knowledge of EBM is a variable that can be influenced. A lack of knowledge of SRs and EBM could prevent individual health care professionals from using SRs as a source of information in their clinical practice or discourage them from participating in such research. Several studies have shown the effectiveness of educational programs on changing the beliefs on and attitudes toward EBM of health care professionals and their readiness to use evidence from EBM sources such as the Cochrane Library or SRs to solve clinical problems [12-15].

Web-based educational interventions are low-cost, easy to implement, easily refined and stored for later use, and easily accessible by health care professionals. Educational interventions conducted via the internet related to various topics in medicine have been shown to be effective [16,17]. Several studies have also proved the effectiveness of web-based educational interventions among health care professionals on knowledge of EBP [12-14].

A 2017 Campbell SR on the effectiveness of e-learning in improving knowledge of EBHC showed that, compared with no learning, pure e-learning improved knowledge of and skills regarding EBHC but not attitudes and behaviors [18]. Varnell et al [12] showed that an accelerated 8-week training program influenced a statistically significant positive change in beliefs on and attitudes toward EBP. A controlled trial examining the effect of an educational intervention on knowledge of EBM among physicians in Israel [14] reported a significant improvement in the level of knowledge of and attitudes toward EBM but not a significant impact on clinical practice [14].

Objectives

We were not able to find studies evaluating the effectiveness of educational interventions dedicated to learning about SRs and SR methodology. In this randomized controlled trial (RCT), we evaluated the effect of a short web-based educational intervention about SRs on short-term knowledge of SR among students of health sciences studies in Croatia.

Methods

Ethics Approval

The study protocol was approved by the Ethics Committee of the Catholic University of Croatia on March 1, 2021 (Klasa: 641-03/21-01/03; Urbroj: 498-03-02-06-02/1-21-02). Subsequently, the ethics committees of all participating institutions also approved the study protocol. The participants provided written informed consent to take part in the study.

Guidelines for Reporting

The manuscript was reported in line with the CONSORT (Consolidated Standards of Reporting Trials) checklist [19]. The CONSORT checklist for this manuscript is available in Multimedia Appendix 1. The educational intervention was reported in line with the Guideline for Reporting Evidence-based Practice Educational Interventions and Teaching (GREET) checklist [20].

Trial Registration

The study protocol was prospectively registered (ie, before enrolling the first participants) on the Open Science Framework website [21]. There were no differences between the protocol and the conducted trial.

Study Design

We conducted an RCT with 2 parallel groups and 1:1 participant allocation.

Participants

Inclusion Criteria

The participants were students of Master's university health sciences studies in Croatia. The study programs available at the participating universities were Nursing, Radiological Technology, Clinical Nutrition, Physiotherapy, and other programs. Full-time and part-time students were eligible to take part in the study. Many of these students were already employed in health care; students were eligible for participation regardless of their employment status.

Institutions

There were 8 eligible institutions in Croatia for this study, and we invited all of them. The following 7 institutions accepted the invitation to participate: Catholic University of Croatia; University Department of Health Studies Split; University Department of Health Studies Zadar; University of Dubrovnik, Nursing Studies; University North, Faculty of Dental Medicine and Health; University of Osijek, Faculty of Health Studies; and University of Rijeka. One institution declined the invitation to participate in the study (University of Zagreb School of Medicine).

Contacting the Students

Students from eligible institutions were contacted via email by coauthors (MC, MN, KI, DA, NS, SZ, and SM) employed in these institutions and invited to participate in the study on brief web-based education about SRs of the literature. Students who agreed to participate were randomized by simple randomization using the Randomizer website. After randomization, they were sent an email invitation to access the web-based platform on which materials for participants from the educational intervention and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist groups were available.

The text of the email provided information about the study and provisions related to the anonymity of the participants according to the General Data Protection Regulation, and students were invited to click on the link to further participate in the study. For this study, 2 separate interfaces for the participants were created on the SurveyMonkey platform (Momentive Inc). One interface was created for participants in the educational intervention group and the other for participants enrolled in the PRISMA checklist group. Each group accessed their interface using a separate link.

The link in the email took the participants to their respective SurveyMonkey web-based interface. The text of the email to the participants is presented in Multimedia Appendix 2. In the SurveyMonkey interface, the participants were initially asked to confirm that they voluntarily took part in the research and that they were providing informed consent to participate in the study by entering the next page.

Intervention Group A

In the web-based interface, intervention group A received a newly developed intervention created by the authors of this study with expertise in medical and health sciences education and research methodology. The educational intervention was written in the Croatian language. It consisted of 11 short educational texts on the methodology of producing SRs. A module describing the forest and funnel plots contained figures of those 2 graphs. The content of the educational intervention was an abbreviated version of the information contained in Cochrane's educational materials for web-based learning about SRs of the literature (Cochrane Interactive Learning). The complete content of the educational intervention, translated into English, is presented in Multimedia Appendix 3.

The learning objectives of the educational intervention anticipated that the participants would be able to define EBM, recognize different levels of evidence, define an SR, ask a clinical question, define the steps for preparing and registering an SR protocol, describe literature search and screening, explain the risk-of-bias assessment, and describe the process of data analysis and interpretation in SRs. In addition to theory, there was a practical learning objective: the participants were expected to be able to differentiate between an abstract of an SR and of a narrative literature review.

The first version of the educational intervention was iteratively revised within the team. Before conducting this trial, the web-based interface with the educational intervention was evaluated in a qualitative study among health care workers via semistructured interviews (Krnic Martinic et al, unpublished data, November 2021). The results of the users' feedback obtained in the qualitative study were used to revise the educational intervention.

The intervention was delivered as an asynchronous web-based education that did not include any components of live education or interaction.

The participants were able to go back and forth through the web-based interface with the educational modules and respective questions without a time limit.

Intervention Group B

Intervention group B was presented with the PRISMA checklist [22] for reporting on SRs (Multimedia Appendix 4) in their web-based interface, and the participants were asked to read it. It was presented to the participants in 11 separate sections to be as similar as possible to the number and form of the educational texts in intervention group A.

Pre- and Postintervention Questionnaires

Both groups completed a preintervention questionnaire containing questions about demographic characteristics and their knowledge of SRs before the presentation of the intervention (educational intervention or PRISMA checklist group; Multimedia Appendix 5). We were unable to find questionnaires on this topic and purpose in the literature. Thus, we designed the pre- and postintervention questionnaires specifically for this study. The pre- and postintervention questionnaires were not validated. Questions evaluating knowledge of SRs were based on the questions used in our previous studies on knowledge of SRs [23] and the definitions of SRs [24].

At the end of the educational intervention or PRISMA checklist presentation, the participants were asked to answer the postintervention questionnaire (Multimedia Appendix 5). The questionnaire contained the same questions on knowledge of SRs as in the preintervention questionnaire as well as questions about whether they agreed with the proposed characteristics of the definition of SRs. Finally, they were presented with 4 abstracts of published articles and asked to assess whether they were abstracts of SRs.

As part of the postintervention questionnaire, the participants were asked to express the level of their agreement on whether an SR should have 6 characteristics proposed earlier by Krnic Martinic et al [24]. They were asked to express their agreement with a number on a Likert scale ranging from 1 to 5 that best suited their opinion, where 1 meant *I do not agree at all* and 5 meant *I completely agree* (Multimedia Appendix 5).

After those questions, the participants were presented with 4 abstracts of published scientific articles, of which 2 (50%) were abstracts of SRs [25,26] and the other 2 (50%) were abstracts of narrative reviews of the literature [27,28]. They were chosen based on a nonstructured literature search of SRs where we tried to find SR abstracts that were simple to understand and appropriate for the target population. The abstracts did not contain any mention of the study design used. If the abstract reported that it was an abstract of an SR or if a systematic search was mentioned, that part of the abstract was removed. The participants were asked to assess whether the abstracts were abstracts of SRs. The 4 abstracts used for this assessment are presented in Multimedia Appendix 6 [25-28].

On the last page of the interface in both intervention groups A and B, the participants were invited to optionally leave their first and last name and email address if they wanted to receive a certificate of participation in the educational intervention. The certificate was prepared by Cochrane Croatia.

The entire questionnaire we administered to the participants was a survey and not a psychological instrument. Thus, we did not perform any psychometric calculations. For the 6 before-and-after questions about the opinion regarding SRs, we calculated that, at the first measurement (before the intervention), reliability was .89, expressed using Cronbach α.

Outcomes

The primary outcome was the difference in the percentage of correct answers per participant in the postintervention questionnaire between intervention groups A and B.

Secondary outcomes were the difference in the percentage of correct answers per participant in the pre- and postintervention questionnaires for the intervention group, the proportion of participants who correctly recognized an abstract describing an SR of the literature (percentage), and the proportion of participants who correctly recognized an abstract describing a simple narrative review of the literature (percentage).

Participant Timeline

After we obtained permission from the ethics committees, the participants were invited to take part. After collecting the names of students who agreed to participate and randomizing them, the invitation to participate in the study containing the link to the intervention A or intervention B interface was sent on June 7, 2021. The links were inactivated on June 20, 2021. The knowledge assessment was conducted immediately after the intervention.

Sample Size

The expected effect size was a difference of at least 20% for the primary outcome between intervention groups A and B. The calculation of the sample size to compare the proportions, predefining an α of .05 and β of .20, assuming a difference of at least 20% for the primary outcome between intervention groups A and B, determined that a sample size of 182 participants (91 participants per group) would be required. To compensate for the possible loss of participants after the beginning of the survey (incomplete answers) or the possibility that participants who initially agreed to take part might eventually choose not to take part, the plan was to include at least 20% more participants than calculated as necessary (n=218).

Encouraging the Inclusion of Participants (Recruitment)

After the initial email was sent to the participants with the link to their respective study arm, 3 more reminders were sent to the participants 4 days apart.

Randomization of Participants

The participants were randomized by simple randomization using the Randomizer website.

Allocation Concealment

After randomization, the participants were allocated to the study arms using a randomization sequence by a third person who was not included in other parts of the study.

Blinding

Blinding of Participants and Personnel

The intervention was of such a nature that the participants could not be blinded.

Blinding of Outcome Assessors

Only the first author (MKM) and the principal investigator (LP) had access to the complete raw data set generated by SurveyMonkey, which included the names and email addresses of the participants who wanted the certificate. MKM removed the participants' names and email addresses before the outcome assessor (IB) analyzed the data; thus, anonymized data were analyzed.

Data Management

One author downloaded Microsoft Excel worksheets from SurveyMonkey, which were anonymized in case any participant left a name and email address to obtain the certificate. The SurveyMonkey interface was configured not to collect any information about the participants, including IP addresses. The data were stored on a secure server until the time of analysis.

Statistical Analysis

To determine the normality of the variables' distribution, we used the Kolmogorov-Smirnov test. Categorical data were presented as frequencies and percentages, and numerical values were presented as medians with IQR for variables not following normal distribution and as arithmetic means with IQR for variables following normal distribution. Differences between intervention groups A and B for categorical variables were tested using the chi-square test. To express the difference between groups, numerical values were tested with 2-tailed *t* tests for independent samples (for variables following normal distribution) and Mann-Whitney tests (for variables not following normal distribution). Pre- and postintervention differences were evaluated using the chi-square test for categorical variables and the *t* test for independent samples for numerical variables. The effect size for the primary outcome (the difference between the percentage of correct answers between groups in the postintervention questionnaire) was expressed using relative risk (RR) and 95% CI, as was the difference between the number of correct answers in the pre- and postintervention questionnaires in both groups. The effect size for the secondary outcome was expressed using odds ratio with 95% CI.

We assessed the participants' opinions before and after using parametric procedures on Likert-type scales, which are usually analyzed using a nonparametric test. This was done because, after the initial analysis where we used nonparametric statistics, the results were not interpretable. When we presented results using median and 95% CIs, the results were similar in both groups, although there were significant differences after the intervention. Therefore, we proceeded with parametric testing, which gave the same results but was more precise as it enabled us to interpret the direction of the difference clearly.

All analyses were performed using the computer program JASP (version 0.14.1.0; JASP Team). Statistical significance was set at *P*<.05.

Results

Participant Flow

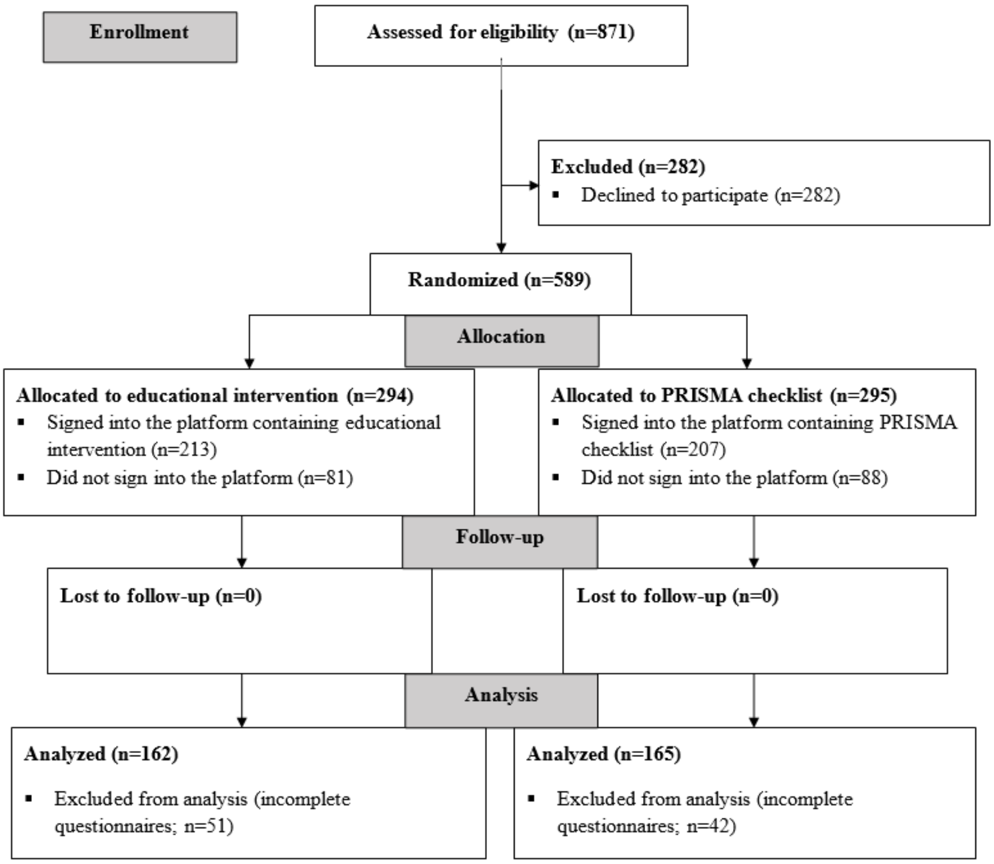
In this trial, 871 potential participants met the inclusion criteria, of whom 282 (32.4%) indicated that they did not want to participate in the study. Thus, 67.6% (589/871) of students were randomized: 31.1% (183/589) from University North; 23.1% (136/589) from the Catholic University of Croatia; 22.4% (132/589) from the Faculty of Health Studies, University of Rijeka; 14.3% (84/589) from the University Department of Health Studies Split; 6.6% (39/589) from the University Department of Health Studies Zadar; 1.7% (10/589) from the University of Dubrovnik, Nursing Studies; and 0.8% (5/589) from the Faculty of Dental Medicine and Health, University of Osijek.

Recruitment and Access to the Educational Platform

The link to participate in the study was sent via email to the addresses of the 589 students on June 7, 2021. The students were sent 3 reminders 4 days apart, and access to the web-based platforms was inactivated on June 20, 2021. A detailed participant flow diagram is shown in Figure 1.

The average time the participants took to complete the entire interface with questionnaires and educational materials was 21 (SD 9.00) minutes in the educational intervention group and 19 (SD 3.96) minutes in the PRISMA checklist group.

Figure 1. Participant flow diagram. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.



Baseline Participant Characteristics

The demographic participant data are presented in Table 1. More than 40% of the participants (educational intervention group: 66/162, 40.7%; PRISMA checklist group: 64/165, 38.8%) were from 1 institution (University North), >80% of the participants (educational intervention group: 134/162, 82.7%; PRISMA checklist group: 138/165, 83.6%) studied nursing, and >50% of the participants (educational intervention group: 97/162, 59.9%; PRISMA checklist group: 85/165, 51.5%) attended the second year of study. More than 80% of the participants (educational intervention group: 136/162, 84%; PRISMA checklist group: 138/165, 83.6%) were employed while studying for their Master's degree. Most participants were employed as health care workers (educational intervention group: 130/162, 80.2%; PRISMA checklist group: 131/165, 79.4%). The median length of working in health care was 9.9 years among participants who received the educational intervention and 9.8 years in the PRISMA checklist group. The median age of the participants in both groups was approximately 30 years, and >85% of the participants in both groups were women (educational intervention group: 140/162, 86.4%; PRISMA checklist group: 146/165, 88.5%; Table 1).

Participants in both groups rated their knowledge of SRs with a median grade of 3 (range 1-5). All participants (327/327, 100%) stated that they had heard of SRs, and approximately three-quarters of the participants in both groups (educational intervention group: 124/162, 76.5%; PRISMA checklist group: 123/165, 74.5%) stated that they had read an SR. In our sample, 17.3% (28/162) of the participants from the group that received the educational intervention and 18.2% (30/165) of the participants from the PRISMA checklist group stated that they had participated in producing an SR (Table 1).

Table 1. Demographic characteristics of the participants included in the analysis (N=327).

Variable and level	Educational intervention (n=162)	PRISMA[a] checklist (n=165)

[a] PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

[b] EBM: evidence-based medicine.

Numbers Analyzed

Of the 420 participants who accessed the interface, 327 (77.9% response rate) completed the questionnaires, and their results were included in further analysis (Figure 1).

Owing to incomplete questionnaires, we excluded the results of 23.9% (51/213) of participants from the educational intervention group and 20.3% (42/207) of participants from the PRISMA checklist group. The results of 54.9% (162/295) of participants from the educational intervention group and 56.1% (165/294) of participants from the PRISMA checklist group were finally included in the analysis. There were no transfers of participants from one group to another.

Primary Outcome

In the postintervention questionnaire, of the 1458 potential correct answers, there were 1086 (74.49%) correct answers to knowledge questions in the educational intervention group (162/327, 49.5%). In the PRISMA checklist group (165/327, 50.5%), of the 1485 potential correct answers, there were 900 (60.61%) correct answers (Table 2). Thus, the effect size for the difference in the number of correct answers to knowledge questions between groups was an RR of 1.23 (95% CI 1.17-1.29); that is, the educational intervention group had 23% (relative risk percentage) more correct answers in the postintervention questionnaire than the PRISMA checklist group.

Table 2. Knowledge of systematic reviews (SRs) among participants who completed pre- and postintervention assessments (N=327).

Questionnaire and items	Educational intervention (n=162)	PRISMA[a] checklist (n=165)	*P* value[b]
Preintervention questionnaire (correct answer)			
It is sufficient to search one database to produce an SR (no), n (%)	128 (79)	139 (84.2)	.22
SRs must be produced by one author only (no), n (%)	103 (63.6)	98 (59.4)	.44
SRs must contain meta-analyses (no), n (%)	17 (10.5)	21 (12.7)	.52
SRs must have duplicate screening and data extraction (yes), n (%)	87 (53.7)	83 (50.3)	.54

[b] Comparison between educational intervention and PRISMA checklist groups. Chi-square test was used for categorical variables, and 2-tailed *t* test was used for independent samples for numeric variables.

[c] Comparison before and after the intervention. Chi-square test was used for categorical variables, and 2-tailed *t* test was used for dependent samples for numeric variables.

Secondary Outcomes

Difference in the Number of Correct Answers per Participant in the Pre- and Postintervention Questionnaires for the Educational Intervention Group

Both groups performed better on the postintervention questionnaire than on the preintervention questionnaire (Table 2). In the educational intervention group, the total number of correct answers was 53.16% (775/1458) in the preintervention questionnaire and 74.49% (1086/1458) in the postintervention questionnaire (RR=1.40, 95% CI 1.32-1.48; Table 2). In the PRISMA checklist group, the total number of correct answers was 51.58% (766/1485) in the preintervention questionnaire and 60.61% (900/1485) in the postintervention questionnaire (RR=1.17, 95% CI 1.10-1.25; Table 2).

Independent of the group, in the pre- and postintervention questionnaires, the smallest number of correct answers was to questions related to the concept of meta-analysis, whereas, in both groups, the highest number of correct answers was to the question about the necessity to assess the quality of research included in the SR (Table 2).

There was no difference in the overall results of the questionnaire assessing knowledge of SRs (the exact number of answers to all 9 knowledge questions) between the educational intervention and PRISMA checklist groups before the intervention (Table 2).

Proportion of Participants Who Correctly Recognized SR Abstracts

The first 2 presented summaries were identified accurately as summaries of SRs by 65.4% (106/162) and 74.1% (120/162) of participants from the educational intervention group and 71.5% (118/165) and 72.7% (120/165) of participants in the PRISMA checklist group, respectively (Table 3). There was no statistically significant difference between the groups in the ability to correctly detect an SR summary (Table 3).

The third and fourth summaries were recognized as a summary of a simple narrative review by 22.2% (36/162) and 46.3% (75/162) of participants from the educational intervention group and 34.5% (57/165) and 47.9% (79/165) of participants from the PRISMA checklist group, respectively (Table 3). There was no statistically significant difference between the groups in the recognition of summaries of narrative reviews (Table 3).

Table 3. Comparison of answers to questions on sources of information needed to answer a clinical question and recognition of a systematic review (SR) abstract (N=327).

Variable and level	Educational intervention (n=162), n (%)	PRISMA[a] checklist (n=165), n (%)	*P* value[b]
If you needed to search for information to solve a clinical problem, what would be the preferred information source for you?			
Colleagues	65 (40.1)	65 (39.4)	.98
Books	59 (36.4)	61 (37)	.98
Scientific literature	120 (74.1)	132 (80)	.25
SR of the literature	135 (83.3)	136 (82.4)	.93
Internet search engine (Google)	29 (17.9)	30 (18.2)	.98
Is this an SR abstract?

[e] A total of 8 answers missing.

[f] A total of 10 answers missing.

Additional Analyses

There was no statistical difference in the choice of information sources between the educational intervention and PRISMA checklist groups in the postintervention questionnaire, with multiple possible responses about where the participants would look for answers to a clinical question from their own clinical practice (Table 3). More than 80% of the participants in both groups (educational intervention group: 135/162, 83.3%; PRISMA checklist group: 136/165, 82.4%) stated that they would look for answers in an SR. Most participants (educational intervention group: 120/162, 74.1%; PRISMA checklist group: 132/165, 80%) responded that they would look for answers in scientific literature in general (Table 3). A third of the participants in both groups would look for an answer to a clinical question in a textbook (educational intervention group: 59/162, 36.4%; PRISMA checklist group: 61/165, 37%) or ask a coworker for an answer (educational intervention group: 65/162, 40.1%; PRISMA checklist group: 65/165, 39.4%). Less than one-fifth of the participants in both groups would search for an answer on an internet search engine such as Google (educational intervention group: 29/162, 17.9%; PRISMA checklist group: 30/165, 18.2%; Table 3).

In the preintervention assessment in both groups of participants, there was no significant difference in agreement with the proposed characteristics of an SR (Table 4). After the intervention, there was more agreement with these characteristics in the educational intervention group than in the PRISMA checklist group (Table 4).

Table 4. Responses regarding the characteristics of a systematic review in the pre- and postintervention questionnaires (N=327)[a].

Questionnaire and items	Educational intervention (n=162), mean (95% CI)	PRISMA[b] checklist (n=165), mean (95% CI)	*P* value[c]
Preintervention questionnaire			
Research question is defined	4.5 (4.4-4.7)	4.4 (4.2-4.5)	.09
Listed sources of literature searched, with repeatable search strategy (naming of databases, naming of search platforms, search date, and complete search strategy)	4.4 (4.2-4.5)	4.2 (4.0-4.3)	.08

[c] *t* test (2-tailed) for independent samples.

Discussion

Principal Findings

This RCT demonstrated that a brief educational intervention conducted on the web about SRs significantly increased knowledge of SRs in the target population. To the best of our knowledge, this is the first trial conducted for this purpose. Relatively successful learning models about EBM have been reported in the literature [15,29-31], but we could not find any publications on the effectiveness of educational interventions focused exclusively on knowledge of SRs.

Comparison With Prior Work

The participants from the educational intervention group (162/327, 49.5%), who were presented with a new educational intervention designed for this study, needed an average of 21 minutes to go through the entire interface. The interface included multiple sections beyond educational intervention: pre- and postintervention questionnaires and the evaluation of 4 scientific abstracts. However, the web-based platform used for this study did not allow for the measurement of the time spent on specific items or pages in the interface. Thus, we cannot know how long the participants read the educational texts prepared for the educational intervention and PRISMA checklist groups. However, if we consider the time to read and answer the questions, the participants probably needed 15 minutes or less to read the educational intervention itself. Such an intervention is very short. Therefore, the intervention should be suitable for health professionals who usually state that their lack of time is a major obstacle to practicing EBM [32-34] and implementing the EBM curriculum during education [35].

Initially, participants in both groups rated their knowledge of SRs with a median grade of 3 out of 5. This is comparable with the self-assessed knowledge of EBP among nurses evaluated in the study conducted by Munroe et al [6]. In that study, only 3% of the nurses said that they were very familiar with EBP [6].

Three-quarters of the participants (educational intervention group: 124/162, 76.5%; PRISMA checklist group: 123/165, 74.5%) stated that they had read SRs. We were surprised with the result that 17.3% (28/162) and 18.2% (30/165) of the participants in the educational intervention and PRISMA checklist groups, respectively, stated that they had participated in developing a SR, which is a high percentage [6]. SR methodology is very complex. Thus, it is questionable whether the students have actually participated in the development of SRs in such large numbers. Health students may have participated, for example, in translating Cochrane's plain language summaries into Croatian [36,37]. However, without the possibility of further clarifying what the participants really meant, it is not possible to discuss this topic in further detail. In the study by Olsson et al [38], which focused on nursing PhD programs and candidatures, in the analyzed 135 nursing dissertations made according to the Scandinavian model of integrated research, only 5 published SRs were found (ie, only 4% of the included nurses—dissertation authors—participated in developing an SR). This number is much lower than the percentage of our participants who stated that they had participated in the production of an SR, and our students were not PhD students but Master's-level students.

The primary outcome of this study was the difference in the percentage of correct answers collected from the educational intervention and PRISMA checklist groups when answering questions evaluating knowledge of SRs on the postintervention questionnaire after the participants had read the educational materials. After the training, the educational intervention group had 23% more correct answers than the PRISMA checklist group (ie, the size of the effect expressed in RR was 1.23). In addition, comparing the pre- and postintervention questionnaire results in the educational intervention group, there were significantly more correct answers on the postintervention questionnaire than on the preintervention questionnaire, with an RR of 1.40. The RR of correct answers comparing the pre- and postintervention questionnaires in the PRISMA checklist group was 1.17.

An RCT by Sánchez-Mendiola et al [15] showed a significant effect of EBM education on the final knowledge of EBM among medical students, with a 25.9% increase in correct answers in the knowledge test about EBM [15]. This is comparable with our primary outcome results. However, it should be emphasized that their intervention was very different in terms of content and duration. Sánchez-Mendiola et al [15] tested an EBM course with 14 two-hour weekly sessions during 1 semester. The course was a formal part of the medical school curriculum; it was delivered by 6 experienced professors and included different content compared with ours. Their course covered 15 topics, including clinical decision-making, uncertainty and probability in medicine, the Bayes theorem, and clinical guidelines [15].

Rohwer et al [18] evaluated the effectiveness of e-learning in improving EBHC in a Campbell SR. The study included 24 trials, of which 20 were RCTs and 4 were observational studies, with a total of 3825 participants including physicians, nurses, physiotherapists, physician assistants, and educators at all levels of education. It demonstrated that, compared with nonlearning, pure e-learning improved EBHC knowledge and skills with similar outcomes to face-to-face learning for any observed primary outcome.

In 2021, needs assessments and expectations regarding EBP knowledge acquisition and training activities were explored among frontline health care providers, including postgraduate medical and nursing students who were working or living in China. The results indicated that the respondents expressed a high need for education on evidence quality appraisal, interpretation of SRs or meta-analyses, and knowledge translation [39]. However, it may not be sufficient to only strive for the improvement of knowledge among the targeted individuals. Nursing education at the undergraduate level is starting to teach the process of research integration through EBP implementation with active learning strategies, which is endorsed by the students [40].

To advance the knowledge and application of evidence in daily practice, ultimately, health institutions will also need to recognize the need to foster such topics [41].

Our educational intervention, implemented via a web tool, is particularly suitable in the current time of the COVID-19 pandemic. Owing to containment measures, many parts of the world have switched to web-based education during the COVID-19 pandemic. Bond et al [42] published a living systematic mapping review on August 30, 2021, calling the web-based teaching experience during the pandemic the "first global online semester." Although such teaching was initially seen as a distance learning response to emergency remote teaching [43], the educational experience gained during a pandemic is very valuable for evaluating the distance learning experience. Our study provides a further test of a remotely delivered educational intervention targeting students and health care workers.

Many studies have evaluated experiences with virtual continuing medical education during the pandemic [44-48]. The SR education evaluated in our study could be incorporated into continuing medical education programs for health care professionals. Owing to the short format and the possibility of distance learning, such education could be of interest to health care professionals who want to learn more about the basics of SRs.

In addition to showing the efficacy of our newly designed educational intervention, our study also indicated areas where the target group of participants significantly lacked knowledge. Independent of the group, in the pre- and postintervention questionnaires, the smallest number of correct answers was to questions related to the concept of meta-analysis and questions about graphical representations of meta-analyses (funnel plot and forest plot). Very modest improvements were observed in those questions in the postintervention questionnaire. In a study on knowledge of the basic methodological components of SRs conducted by Puljak and Sapunar [23] among the directors of postgraduate programs at European universities, only 31% of the participants answered correctly that an SR does not necessarily contain a meta-analysis.

There were few correct answers to questions about graphical presentations of meta-analyses. In the educational intervention group, before the training, 20% of the participants correctly answered what a funnel plot and a forest plot represented. In the PRISMA checklist group, only 8% of the participants correctly answered what a funnel plot represented, and 16% correctly answered what a forest plot depicted. In the postintervention questionnaire, in the educational intervention group, 40.7% (66/162) to 49.4% (80/162) of the participants correctly answered the question about the use of the forest plot or funnel plot, whereas, in the PRISMA checklist group, only a fifth (37/165, 22.4%) to a quarter (44/165, 26.7%) of the participants correctly answered these questions. However, after the educational intervention, more than half of the participants did not know the correct answer to the questions regarding the graphical representations of meta-analyses.

Poor knowledge of graphical representations in meta-analyses has been described elsewhere. A survey conducted on psychologists in Italy found that less than a fifth of psychologists estimated that they had sufficient knowledge of the forest plot [49]. Less than 15% of psychologists stated that they had sufficient knowledge of the funnel plot [49]. A survey conducted on psychologists in Spain showed that only approximately 10% of the participants said that they had satisfactory knowledge of the forest plot. Only 7% of the participants said that they had satisfactory knowledge of the funnel plot [50]. Only 10% of PhD program directors accurately recognized the purpose of funnel plots, and 11.3% recognized the purpose of the forest plot [23]. Poor knowledge of graphical representations of meta-analyses may be the best indicator of generally poor knowledge of SR and meta-analysis methodology.

In this study, we also included a practical knowledge test that involved the recognition of journal abstracts of SRs after the intervention. The accuracy of journal abstract recognition was 22% to 72% in the educational intervention group and 46% to 74% in the PRISMA checklist group, without a statistically significant difference between the groups. This was the final test of understanding and pragmatic application of the knowledge acquired in our trial. We found that the educational intervention did not significantly affect the recognition of abstracts of SRs. It is possible that a time lag or longer systematic learning is needed for the acquired knowledge of SRs to influence the practical application of the knowledge itself. It is also possible that it is necessary to further adjust the educational intervention to enable the practical application of the acquired knowledge.

In the postintervention questionnaire, the participants were asked which sources of information they would use in searching for an answer to a question from their clinical practice, and most participants from both groups opted for scientific literature (educational intervention group: 120/162, 74.1%; PRISMA checklist group: 132/165, 80%) or SRs (educational intervention group: 135/162, 83.3%; PRISMA checklist group: 136/165, 82.4%). Compared with the results of a study conducted by Sánchez-Mendiola et al [15] on medical students in Mexico, in our study, a significantly higher percentage of students chose to search for answers in SRs and scientific literature. In the study by Sánchez-Mendiola et al [15], most participants from the group that attended EBM classes stated that, in solving a certain health problem, they looked for answers in review articles or the Cochrane Library only occasionally, whereas very often they would look for the answer to a health problem in textbooks or search engines or they would ask their teachers. Nevertheless, the number of students who would seek answers in the Cochrane Library or scientific articles was higher than in groups of students who did not attend classes on EBM [15]. Evidently, education about EBM—or, in our case, about SRs—has the express intention to use these data sources more often in solving clinical problems.

Strengths and Limitations

The strength of this study is the appropriate sample size and a high number of fully completed questionnaires, with three-quarters of the participants (327/420, 77.9%) completing the questionnaire in full and almost equal numbers of unfinished questionnaires in the educational intervention and PRISMA checklist groups, allowing for comparable results. Furthermore, we tested the practical application of the acquired knowledge of SRs by asking the students to recognize summaries of SRs or narrative reviews.

A limitation of this study is a highly homogeneous sample that does not allow for significant analyses by sociodemographic subgroups. We acknowledge that there is a potential self-selection aspect in our final sample. We do not have data about nonparticipants among the eligible students and, theoretically, there could be some differences between responders and nonresponders. However, this is an inherent problem of any trial—the eligible participants are invited to take part, and they can choose whether they want to participate.

The study was conducted in only 1 country but in multiple institutions across the country. We did not measure the time spent in the intervention; some participants may not have spent much time reading the text. Furthermore, we measured the outcomes immediately after the reading of the educational texts. Such short-term follow-up does not allow for monitoring of the long-term retention of knowledge of SRs among the participants. Longer-term research will make it possible to verify the long-term effectiveness of the intervention on the knowledge of the target group.

Finally, we would like to note that, in this manuscript, when referring to the studies of other researchers, we used the terms EBM, EBP, and EBHC as they were reported in those manuscripts.

Conclusions

A short web-based educational intervention about SRs is an effective tool for short-term improvement of knowledge of SRs among health care studies students, most of whom were employed as health care professionals. This education can be further studied, modified, and used in the continuing medical education of health care professionals.

Acknowledgments

This study was conducted as a part of the Professionalism in Health: Decision-making in Practice and Science project (IP-2019-04-4882) funded by the Croatian Science Foundation, whose principal investigator is Professor Ana Marušić, MD, PhD. This study was part of the PhD thesis of the first author, MKM. The thesis was written and defended in the Croatian language at the University of Split School of Medicine in Croatia. The authors are grateful to the thesis committee members, professors Ozren Polasek, Zarko Alfirevic, and Damir Roje, for their constructive feedback on this study.

Data Availability

The raw data from this study were published on the Open Science Framework website [21] and made publicly available.

Authors' Contributions

MKM, MC, AM, DS, TPP, IB, RT, and LP contributed to study design. MKM, IB, RT, S Malisa, MN, KI, DA, NS, SZ, S Miksic, DC, and LP contributed to data collection and analysis. MKM, IB, DC, and LP wrote the first draft of the manuscript. MKM, MC, AM, DS, TPP, IB, RT, S Malisa, MN, KI, DA, NS, SZ, S Miksic, DC, and LP critically revised the manuscript. MKM, MC, AM, DS, TPP, IB, RT, S Malisa, MN, KI, DA, NS, SZ, S Miksic, DC, and LP approved the final version of the manuscript.

Conflicts of Interest

Multiple authors of this study are members of Cochrane Croatia (AM, TPP, IB, RT, and LP), but this was not an official research project of the global Cochrane organization.

Editorial Notice

This randomized study was retrospectively registered. The authors published the protocol for the trial [21] before it commenced instead of registering it with a trial registry. As the trial does not involve a study of the cause-and-effect relationship between a health-related intervention and a health outcome, it does not meet the definition of a clinical trial. The editor granted an exception from ICMJE (International Committee of Medical Journal Editors) rules mandating prospective registration of randomized trials because the risk of bias appears low and because the publication of a protocol is equivalent to trial registration and meets all of the purposes listed by the ICMJE regarding transparency.

Abstract

Background: Eating disorders and other forms of disordered eating cause significant complications and comorbidities in patients. However, full remission with current standard treatment remains low. Challenges to treatment include underdiagnosis and high dropout rates, as well as difficulties in addressing underlying emotion dysregulation, poor impulse control, and personality traits. Serious video games (SVGs), which have the advantages of being highly engaging and accessible, may be potential tools for delivering various forms of treatment in addressing the underlying psychopathology of disordered eating.

Objective: This review aims to provide an overview of the possible mechanisms by which SVGs may affect the clinical course of disordered eating, while evaluating the outcomes of studies that have assessed the role of SVGs in the treatment of disordered eating.

Methods: A systematic search was performed on PubMed, PsycINFO, and Embase, using keywords related to SVGs, disordered eating, and eating disorders. A narrative synthesis was subsequently carried out.

Results: In total, 2151 papers were identified, of which 11 (0.51%) were included. Of these 11 studies, 10 (91%) were randomized controlled trials, and 1 (9%) was a quasi-experimental study. The types of SVG interventions varied across the studies and targeted different mechanisms of disordered eating, ranging from addressing problem-solving and emotion regulation skills to neurocognitive training for inhibitory control. Most (10/11, 91%) of the studies showed some benefit of the SVGs in improving certain physical, behavioral, or psychological outcomes related to disordered eating. Some (4/11, 36%) of the studies also showed encouraging evidence of the retention of these benefits at follow-up.

Conclusions: The studies included in this review provide collective evidence to suggest the various roles SVGs can play in plugging potential gaps in conventional therapy. Nonetheless, challenges exist in designing these games to prevent potential pitfalls, such as excessive stress arising from the SVGs themselves or potential gaming addiction. Further studies will also be required to assess the long-term benefits of SVGs as well as explore their potential preventive, and not just curative, effects on disordered eating.

Introduction

Background

At least 9% of the world's population is affected by eating disorders [1], with adolescents and young adults being the most likely to be diagnosed with eating disorders [2,3]. Besides their implications for mental health, eating disorders also cause multisystemic medical complications [4]. *Disordered eating* is a term that encompasses eating disorders that were formally defined by the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, such as anorexia nervosa (AN), bulimia nervosa (BN), and binge eating disorder (BED) [5]. However, besides the aforementioned eating disorders, disordered eating may also refer to pathological eating behaviors, including restricting, bingeing, purging, or other compensatory behaviors, without fulfilling the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, criteria for eating disorders [6]. Disordered eating attitudes can be driven by underlying body dissatisfaction or body image concerns (for restricting and purging), as well as an impairment of inhibitory control (for bingeing) [7,8].

Treatment of eating disorders hinges on early recognition and intervention, which is associated with better response to therapy as well as long-term outcomes [9]. According to guidelines from the National Institute for Health and Care Excellence, treatment of eating disorders such as AN, BN, and BED generally involves multidisciplinary effort, including psychoeducation, dietary rehabilitation, and monitoring and treatment of physical complications, as well as psychological treatment. Although eating disorder–focused cognitive behavioral therapy (CBT) is commonly perceived to be the first-line treatment and has the strongest and most rapid effects, evidence of its efficacy has been scarce for persistent AN as well as AN in adolescents [10]. Of note, a review published in 2002 revealed that only 46.8% of the patients with AN reached full recovery, 33.5% improved, and in 20.8% the disorder became chronic [11]. Treatment is also often limited by high rates of patients dropping out, ranging from 20.2% to 49.6% [12]. Mortality rates of these illnesses are still high, with those who received inpatient treatment for AN having more than 5 times increased mortality risk [13].

Challenges to the treatment of disordered eating are multifold. To start with, disordered eating is often underdiagnosed and undertreated because of a lack of awareness or feelings of shame associated with its diagnosis [14-16]. Obstacles to treating disordered eating can then be broadly considered in terms of patient- and clinician-related factors. Clinician-related factors that prevent use of evidence-based therapies include lack of training and individual beliefs regarding the effectiveness of certain forms of therapy, as well as over- or undervaluing certain elements of therapy [17]. There may also be difficulties in establishing a therapeutic alliance with the patient who is required to become vulnerable and give up some sense of control during the course of treatment [18]. Patient-related factors for poor treatment response can be examined through the underlying psychopathology of eating disorders. In patients with AN or BN, for instance, an underlying ego-syntonic pursuit of thinness or body dissatisfaction may be difficult for the patient to give up [18,19]. Furthermore, core features seen in disordered eating, such as the lack of impulse control, poor emotion regulation [20], and high reward-seeking behavior [21], are often difficult to address even with established forms of psychotherapy [22,23]. These comorbidities can also in turn affect motivation and compliance to psychological treatment [18]. In addition, traits of narcissistic, borderline, obsessive-compulsive, and avoidant personalities, which may be common in patients with disordered eating, may also negate treatment adherence and effectiveness [18,24]. The limitations of current conventional treatment as well as difficulties arising from the aforementioned factors necessitate a consideration of alternative treatment options or treatment options complementary to existing ones.

Technology is increasingly harnessed in the treatment of psychiatric conditions [25]. One example is the use of virtual reality (VR) to target clinical features of eating disorders such as binge eating, cravings, and body dissatisfaction through VR-mediated cue exposure and reference frame shifting [26]. According to a recent meta-analysis, VR-enhanced CBT has been shown to display better efficacy than CBT alone in reducing the frequency of binges and situation-induced body dissatisfaction [27]. VR has also been shown to be a feasible intervention to improve inhibitory control and thereby reduce binge eating episodes [28]. Internet-based CBT is another innovation that circumvents certain limitations of traditional CBT, such as high costs, long waiting time, and perceived stigma associated with seeking help for psychiatric disorders [29]. However, the challenges of high dropout rates and poor compliance remain [30].

This review is interested in the possible role of serious video games (SVGs) in addressing disordered eating. Games are by definition an activity in which "independent decision makers seek to achieve their objectives in a limiting context" [31]. Serious games can be simply viewed as games with a *serious* objective, often for education, vocational training, or problem-solving [32]. Nonetheless, the line between serious and entertainment games is sometimes blurred because certain entertainment games are sometimes repurposed for an educational purpose as well [33]. Serious games have been used in various fields, ranging from education and military applications to interpersonal communications training [32]. A key feature of these serious games is that besides delivering knowledge or skills to the player, they stimulate an environment through narrative story, gameplay, or encounters that is safe and controlled for users to be able to practice new learned skills or behaviors [34,35]. In today's landscape, serious games are increasingly available on digitized platforms, ranging from mobile apps [36] to VR devices [35].

Serious games have had some early success in treating a range of psychiatric conditions and have been deemed to be highly feasible and acceptable to both patients and clinicians [34]. Psychiatric conditions in which serious games have been used to address symptoms include depression [37] and addiction problems such as substance abuse [38] and internet addiction [39]. It is noteworthy that these psychiatric conditions happen to be comorbidities commonly associated with disordered eating. One example of serious games being used in treating psychiatric conditions is Smart, Positive, Active, Realistic, X-Factor Thoughts (SPARX), a participative game based on CBT that targets depression in adolescents. The treatment outcomes of SPARX were shown to be comparable with those of conventional treatment despite its being a predominantly self-guided resource [40,41]. Dropout rates for this intervention were also low at approximately 9%, suggesting that such games may have an advantage in engaging patients belonging to the adolescent age group [41].

Serious games as a treatment can be highly engaging [42]. It has been shown that being appropriately challenged has positive effects on both engagement and learning, with the challenge of the game being a strong predictor of learning outcomes [43]. In serious games, players can advance through individualized game difficulty levels and be constantly challenged, allowing for personal growth [35]. By contrast, this may be difficult to replicate in traditional CBT. Furthermore, the potential of serious games in improving impulse control [44] and emotion regulation [45], which are core features in the psychopathology of disordered eating, would be one of their key foreseeable advantages. However, current studies examining the therapeutic effects of serious games on persons with disordered eating are sporadic. Hence, there is a need to systematically consolidate and critique such available studies to understand the effectiveness of serious games as a therapeutic medium for disordered eating behaviors.

Objectives

This study aimed to answer the question regarding the effectiveness of SVGs in reducing disordered eating behaviors and addressing their underlying psychopathology. The review will provide an overview of the possible mechanisms by which SVGs can affect the clinical course of disordered eating, while evaluating the effectiveness of SVGs and their potential role in complementing current treatment options for disordered eating.

Methods

Search Strategy

The systematic review and meta-analysis were reported according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. Three databases (PubMed, Embase, and PsycINFO) were last searched on March 29, 2022, with no restrictions on publication dates. The following search terms were applied in the search strategy, with the use of relevant controlled vocabulary such as Medical Subject Headings, Emtree, and PsycINFO Thesaurus terms: *((serious gaming) OR (game) OR (computer-assisted therapy) OR (gamification) OR (gaming simulation) OR (video game) OR (applied game) OR (mobile game) OR (gamified application) OR (digital game)) AND ((eating disorder) OR (anorexia) OR (bulimia) OR (binge eating) OR (impulsive eating) OR (body image) OR (body dissatisfaction) OR (self-control) OR (inhibitory control)).*

Selection of Articles

The inclusion criteria were as follows: studies (1) needed to be peer-reviewed randomized controlled trials (RCTs) or quasi-experimental design studies; (2) involved interventions delivered on a digital platform with gaming elements; (3) assessed the efficacy of SVGs in terms of their therapeutic benefit for eating disorders, disordered eating behaviors, and underlying body image concerns or inhibitory control; (4) involved populations prone to disordered eating; and (5) were in English.

Studies assessing the effects of gamified food-related inhibitory control training (ICT) were included because of evidence suggesting that interventions targeting food-related impulsivity have the potential to reduce binge eating frequency as well as address food cravings [46,47]. This is because disordered eating behaviors such as overeating have been linked to lack of inhibitory control, which is an underlying trait seen in eating disorders [8,48]. Studies examining the use of video games originally designed for entertainment purposes and not for their therapeutic effect were also included.

Studies were excluded if (1) the intervention was related to web-based CBT, web-based counseling, or guided self-help without elements of gamification; and (2) it involved VR-mediated interventions. Studies with VR-mediated interventions were excluded to isolate the effect of non–VR-related gamification on disordered eating as much as possible because of the extensive evidence of the efficacy of VR-mediated interventions [26-28].

The selection of articles was conducted by 3 authors (JZAW, TJYN, and WSWT). The selection was performed over 2 phases. In the first phase, articles were screened depending upon their relevance to this review based on their title and abstract. Shortlisted articles from the first phase of screening subsequently underwent full-text assessments for their eligibility to be included in this review. Disagreements on the selection process were resolved by discussion among the aforementioned authors as well as consultation with the senior author (CSHH).

Review and Quality Assessment

The quality of each included study was independently evaluated by 2 separate authors (TJYN and WSWT) with any disagreements resolved through discussion. The RCTs were assessed using the Cochrane Risk-of-Bias 2 tool, whereas the noncontrolled experimental study was assessed using the Joanna Briggs Institute Critical Appraisal Checklist for Quasi-Experimental Studies [49,50].

Data Extraction and Evaluation

After finalizing the selection of studies, the following information was extracted from the papers: (1) publication details (eg, title, authors, and country), (2) details of the SVG intervention (eg, type of platform, game objectives, and gameplay), (3) details of the studied population (eg, population type, sample size, and gender ratio), and (4) type of outcomes measured and the respective results. The studies were then categorized by the posited mechanisms by which the SVG intervention affected disordered eating.

The interventions used in the included studies were collectively assessed by adapting a framework developed by Murray et al [51] for evaluating the potential benefits of digital health interventions. The following factors were considered: (1) the accessibility of SVGs to populations with disordered eating, (2) causal explanations for how SVGs can treat disordered eating, (3) the key components required for SVGs to affect positive outcomes on disordered eating, (4) how target populations should be supported in the use of SVGs to treat or prevent disordered eating, (5) the possible harms of SVGs and the likelihood of their risks, (6) the costs of using SVGs incurred by users and the health system, and (7) the overall utility of SVGs. The evaluation of the SVGs was aided by a framework developed by Liverpool et al [52] that highlights key components contributing to engagement in digital mental health interventions among young people. This involves assessing the SVGs for intervention-specific factors, including suitability, usability, and acceptability, as well as user-specific factors, including motivation, opportunity, and capability [52].

Results

Search Results

Our search strategy yielded 2916 articles. Hand searching did not uncover other relevant studies. From the 2916 articles, 765 (26.23%) duplicates were removed. Of the remaining 2151 articles, we excluded 2108 (98%) after title and abstract screening because they did not include serious gaming as an intervention, or they focused on a disease unrelated to eating disorders. After full-text screening of the 43 remaining articles, 32 (74%) were excluded. Reasons for the exclusion of articles after full-text screening include not reporting outcomes related to eating disorders, assessing SVGs that were not run on digital platforms, and interventions not having gamified elements. Thus, of the initial 2916 articles identified, 11 (0.38%) were included in the systematic review. The PRISMA flowchart is presented in Figure 1. The main outcomes of the included articles are summarized in Table 1, whereas the details of the SVG intervention of each study are summarized in Table 2. The characteristics of the included studies are presented in Multimedia Appendix 1 [53-63], and the assessments of the risk of bias are presented in Multimedia Appendix 2 [54-63] and Multimedia Appendix 3 [53]. Of the 11 included studies, 10 (91%) were deemed to be at a low overall risk of bias, with the exception of 1 (9%) study, regarding which concerns were raised over the suitability of the outcome measures.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram showing the selection of the studies.

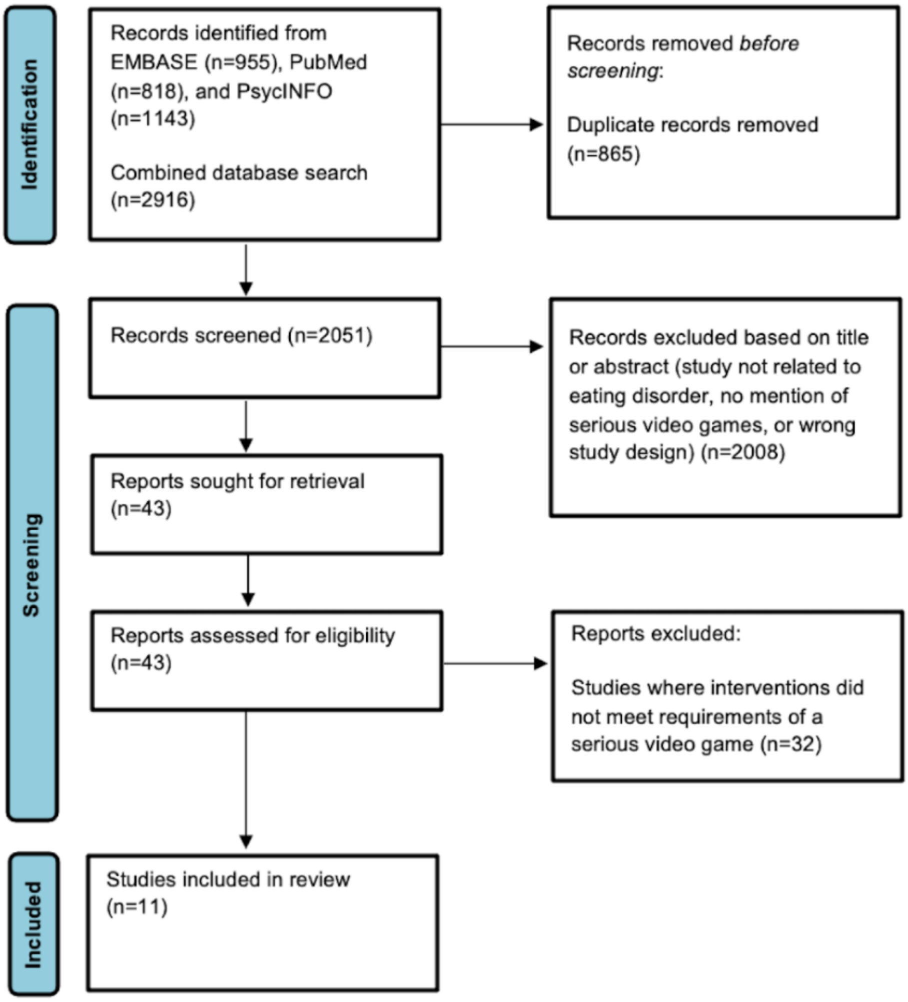

Table 1. Characteristics and outcomes of the included studies.

Serious video game category and title	Study, year	Outcome measures (physical, behavioral, and psychological)	Main outcomes
Serious video games for emotion regulation skills			
The Use of Videogames as Complementary Therapeutic Tool for Cognitive Behavioral Therapy in Bulimia Nervosa Patients	Fernandez-Aranda et al [53], 2015	• Frequency of bingeing and purging • Dropout rates • Eating disorder psychopathology • Anxiety and anger • Remission rate (partial or complete)	• Intervention group achieved nonstatistically significant higher rates of total remission than the control group (50% vs 28%, respectively; *P*=.22) • Intervention group had lower treatment attrition rates than the control group (20% vs 44%, respectively; Cohen d=0.54) and displayed improvements in emotion regulation, whereas the control group showed persisting emotion dysregulation
Serious video games for body image concerns			
An App-Based Blended Intervention to Reduce Body Dissatisfaction: A Randomized Controlled Pilot Study	Kollei et al [54], 2017	• Eating disorder psychopathology • Depressive symptoms • Body dissatisfaction	• Intervention group showed significantly greater reduction in body dissatisfaction (Cohen d=–0.62; *P*=.001) and a medium-sized effect in reduction of eating disorder symptoms (Cohen d=–0.46; *P*=.007) which persisted at 1-month follow-up • No significant effect on depressive symptoms was noted
A Brief Mobile Evaluative Conditioning App to Reduce Body Dissatisfaction? A Pilot Study in University Women	Kosinski [55], 2019	• Depressive symptoms • Eating disorder psychopathology • Self-esteem • Body dissatisfaction and drive for thinness	• No significant reduction of body dissatisfaction between the evaluative conditioning and control conditions was noted, but body dissatisfaction fell across conditions with a small effect size (*r*=0.27; *P*<.005). Similar patterns presented for the drive for thinness (*r*=0.67; *P*<.001) and self-esteem (*r*=0.29; *P*<.05) • No statistically significant effects were observed for bulimia and restraint scores
An Interactive Training Programme to Treat Body Image Disturbance	Gledhill et al [56], 2017	• Eating disorder psychopathology • Self-esteem • Body size perception and body image concerns	• Study 1 • The intervention succeeded in shifting the thin-fat categorical boundary for individuals with body size concerns, as well as improved eating restraint (day 14 difference z score=0.92, 95% CI 0.33 to 1.51; *P*=.003), body weight (day 14 difference z score=1.15, 95% CI 0.58 to 1.72; *P*<.001), and body shape concerns (day 14 difference z score=1.04, 95% CI 0.45 to 1.64; *P*=.001) • Study 2 • The intervention succeeded in shifting the thin-fat categorical boundary significantly in participants with anorexia nervosa. Eating disorder symptoms also improved for at least a month (Eating Disorder Examination Questionnaire score day 1 vs day 30 difference z score=0.74, 95% CI 0.20 to 1.28; *P*=.008) • The degree of body size category boundary shift was significantly correlated with changes in the eating disorder symptoms

Serious video game category and title	Study, year	Outcome measures (physical, behavioral, and psychological)	Main outcomes
When You Exercise Your Avatar in a Virtual Game: The Role of Avatars' Body Shape and Behavior in Users' Health Behavior	Joo and Kim [57], 2017	• Exercise and eating behavior	• No significant effects of the avatars' lifestyle on the participants' exercising or eating behaviors were observed • There was a significant positive effect of the normal-weight body shape of the avatars on the participants' exercising behaviors (*P*=.02). No difference was noted for players who used the obese avatars
Serious video games for neurocognitive training to influence eating behaviors			
App-Based Food-Specific Inhibitory Control Training as an Adjunct to Treatment as Usual in Binge-Type Eating Disorders: A Feasibility Trial	Keeler et al [58], 2022	• Food valuation on palatability of high- and low-energy–dense foods • Eating disorder psychopathology • Depressive symptoms • Anxiety • Impulsivity	• Intervention did not reduce binge eating frequency but showed greater reduction in eating disorder psychopathology (SES[a]=–0.57, 95% CI –1.12 to –0.03) and valuation of high-energy–dense foods than usual treatment (SES=–0.61, 95% CI –0.99 to –0.24). These effects were lost and reduced, respectively, at 8-week follow-up • At 8 weeks, the intervention group showed greater reduction in food addiction symptoms and lack of perseverance with a small effect size (SES=–0.23, 95% CI –0.81 to 0.34)
Gamified Working Memory Training in Overweight Individuals Reduces Food Intake but Not Body Weight	Dassen et al [59], 2018	• BMI • Food intake and healthy eating • Self-control • Dropout rate • Executive function • Eating disorder psychopathology	• WM[b] training did not result in significant additional weight loss • WM training resulted in a significant reduction in caloric intake after training, especially at high levels of craving • Both groups showed improvements in self-reported emotional eating and self-control
Gender Differences in the Effect of Gamification on Weight Loss During a Daily, Neurocognitive Training Program	Forman et al [60], 2021	• Weight • Enjoyment of game and compliance to treatment • Inhibitory control	• Gamification had a significantly stronger effect on weight loss for men than for women • No significant differences were observed between genders for the effect of gamification on enjoyment, compliance, and impulse control
A Serious Game to Increase Healthy Food Consumption in Overweight or Obese Adults: Randomized Controlled Trial	Blackburne et al [61], 2016	• Eating behavior • Cognitive restraint • Go–No-Go performance	• Inhibitory control improved with the intervention, which was associated with increased consumption of healthy foods and reduced consumption of unhealthy foods. Cognitive restraint also improved
Computerized Neurocognitive Training for Improving Dietary Health and Facilitating Weight Loss	Forman et al [62], 2019	• Weight • Frequency of food consumption • Implicit preference for sweets	• ICT[c]—both gamified and nongamified—were deemed acceptable and feasible • Only participants with higher baseline implicit preference for sweets experienced weight loss benefits from ICT. However, gamification marginally reduced the impact of ICT
Executive Function Training With Game Elements for Obese Children: A Novel Treatment to Enhance Self-regulatory Abilities for Weight-Control	Verbeken et al [63], 2013	• BMI • Treatment feasibility and acceptability • Executive function • Visuospatial WM • Stop-signal task performance	• The intervention showed significant effects in WM and meta-cognition and displayed significant improvements in weight loss maintenance at 8 weeks, although the effect was lost at 12 weeks • No significant effects were observed for inhibition and the stop-signal task

[a] SES: standardized between-group effect sizes.

[b] WM: working memory.

[c] ICT: inhibitory control training.

Table 2. Characteristics of the serious video gaming interventions.

Game category and study	Game title	Serious game genre	Platform	Objectives	Gameplay
Serious video games for emotion regulation skills					
Fernandez-Aranda et al [53], 2015	PlayMancer: Islands	Goal oriented and problem-solving	PC	To increase emotion–self-control skills and self-control over users’ general urgency to act	• Players are immersed in the setting of an island and are required to overcome challenges by achieving therapeutic targets • Biosensors and a camera that continuously tracks the emotional state of the player are used to monitor physiological changes in response to the players’ emotional state
Serious video games for body image concerns					
Kollei et al [54], 2017	Mindtastic Body Dissatisfaction app	Cognition and brain training	Mobile app	Approach-avoidance training to foster approach of functional stimuli and avoidance dysfunctional stimuli	• Players are shown (1) pictorial stimuli of their own bodies as well as that of their ideal bodies and (2) positive and negative body-related statements. They are required to pull the positive statements and pictures of themselves toward themselves and swipe away the negative statements and idealized pictures
Kosinski [55], 2019	Executive conditioning app	Cognition and brain training	Mobile app	Evaluative conditioning	• The player’s photographs are taken to act as conditioned stimuli. Positive photographs that elicit a positive affective response and do not correspond to feminine ideals were used as unconditioned stimuli. Players are shown 3 conditioned stimuli and unconditioned stimuli pairings at the start and are required during the game to pick out their conditioned stimuli and unconditioned stimuli pair as quickly as possible
Gledhill et al [56], 2017	Perceptual training with two-alternative forced-choice decisions	Cognition and brain training	PC	Evaluative conditioning	• Participants are presented with a series of computer-generated imagery images of women’s bodies and trained to judge the respective body size. Feedback was given to the participants on whether their responses were accurate. “Inflationary” feedback was given with the intent to shift their categorical boundary of a “fat” body shape by 2 body shape variations higher
Joo and Kim [57], 2017	The Sims 4	Goal oriented and problem-solving	PC	To increase emotion– self - control skills and reduce general impulsive behaviors	• A web-based life simulation game, The Sims 4, was used • Players were assigned to either a normal weight or obese avatar. Players were then instructed to operate their avatars in a healthy (exercise and fresh foods) or unhealthy lifestyle setting (sedentary lifestyle and unhealthy foods)
Serious video games for neurocognitive training to influence eating behaviors					

Game category and study	Game title	Serious game genre	Platform	Objectives	Gameplay
Keeler et al [58], 2022	FoodT, an inhibitory control training app	Cognition and brain training	Mobile app	To increase inhibitory control	• Players are presented with pictorial stimuli consisting of high-energy foods, low-energy foods, and filler items, accompanied by "Go," or "No Go" cues. Participants are required to tap on the "Go" items and avoid tapping on the "No Go" items
Dassen et al [59], 2018	WM[a] training	Cognition and brain training	Tablet computer or PC	Psychoeducation and WM training	• Each session comprises 3 WM tasks in the setting of a restaurant involving visuospatial memory, backward digit span, and object memory
Forman et al [60], 2021	Go–No-Go training	Cognition and brain training	PC	To increase inhibitory control	• Players are presented with pictorial stimuli consisting of healthy and unhealthy foods, accompanied by "Go," and "No Go" cues, respectively. Participants are required to tap on the "Go" items and avoid tapping on the "No Go" items
Blackburne et al [61], 2016	"NoGo," a Go–No-Go inhibitory control training app	Cognition and brain training	Mobile app	To increase inhibitory control	• Players are shown stimuli of healthy and unhealthy foods. Each game consists of (1) Go–No-Go trials where the reaction timer starts counting down next to the image after it is shown and (2) stop trials where the timer counts down while the images change between categories
Forman et al [62], 2019	Go–No-Go training	Cognition and brain training	PC	To increase inhibitory control	• The gamified inhibitory control training involved the task of moving in a grocery store as quickly as possible while choosing the correct foods. This required players to respond to frequently presented stimuli (healthy foods such as fruit and vegetables) and inhibit their responses to nonfrequent stimuli (high-sugar food)
Verbeken et al [63], 2013	"Braingame Brian," an executive function training game	Cognition and brain training	PC	To increase executive function (inhibitory control and WM)	• The game is set in a game world with a storyline where the character, Brian, is required to complete tasks involving (1) WM training where the player has to reproduce correctly a random sequence of rectangles lighting up and (2) inhibitory control training in the setting of a factory, including both go trials and stop trials

[a] WM: working memory.

Physical Outcomes

Of the 11 studies, 4 (36%) measured the effects of the gamified interventions on physical outcomes such as weight or BMI. All interventions were used in the context of treating overeating in individuals who were overweight [59,60,62,63]. Among the 4 studies, only 2 (50%)—the gamified ICT in the study by Forman et al [60] and the executive function (EF) training in the study by Verbeken et al [63]—reported statistically significant reduction in BMI after the serious game intervention. This effect, achieved in the study through an intervention centered on ICT was noted to be more significant in men than in women [60]. However, in another study by Forman et al [62], it was reported that gamification slightly reduced weight loss benefits compared with normal ICT [62].

Of note, the other studies in which a healthy increase in BMI would have been an ideal outcome in the context of undereating did not measure weight or BMI as a study outcome likely because of the short duration of their interventions.

Behavioral Outcomes

In terms of behavioral outcomes, the studies reported a variety of outcomes such as frequency of binges and purges; food intake; enjoyment in using, and compliance to, the intervention; dropout rates; nonverbal communication; and drive for exercise. However, the reporting on the type of behavioral outcomes among the studies was not consistent.

Varying outcomes have been obtained in terms of eating habits and attitudes toward food. CBT coupled with a role-playing problem-solving SVG achieved neither a statistically significant increase in the reduction of bingeing or purging episodes nor an increase in the rates of total or partial clinical remission of BN [53]. In addition, an avatar-based SVG based on social cognitive theory was unable to influence the short-term eating behaviors of participants [57].

However, the study by Dassen et al [59] showed that gamified working memory (WM) training helped in reducing caloric intake, especially at high levels of craving [59]. In a different vein, the study by Blackburne et al [61] showed that a gamified ICT app improved inhibitory control that was associated with increased consumption of healthy foods and reduced consumption of unhealthy foods. Similarly, an app-based food-specific ICT in the study by Keeler et al [58] showed small-sized effects on a greater reduction in food addiction and medium-sized effects in participants' valuation on the palatability of high-energy–dense food. However, the latter effect was diminished at later follow-up. The intervention also did not show greater reduction in binge eating frequency than usual treatment [58].

Dropout or attrition rates were measured in 27% (3/11) of the studies. The study by Fernandez-Aranda et al [53] showed that conventional CBT coupled with an SVG (*PlayMancer:Islands*) resulted in lower treatment attrition rates than CBT alone (20% vs 44%, respectively) [53]. In a different setting, the gamified WM training in the study by Dassen et al [59] demonstrated a participant dropout rate of 23% (21/91) across the interventional training and sham training groups using the same game. Gamified ICT in the study conducted by Forman et al [62] demonstrated an attrition rate of 14.8%, which did not differ significantly from the attrition rate in the nongamified ICT group.

Psychological Outcomes

Overview

Across the studies included in the review, a variety of instruments were used to assess the features of eating disorders and their psychiatric comorbidities. Commonly applied questionnaires in the field of eating disorders, namely the Eating Disorder Inventory-2, Symptom Checklist–Revised, State-Trait Anxiety Index, and State-Trait Anger Expression Inventory-2, were used. In some (2/11, 18%) of the studies, throughout the duration of the treatment, patients kept a daily food and purging diary. Assessments were made before and after group therapy. The frequency of binges and purges was reported in the study by Fernandez-Aranda et al [53]; however, no statistically significant differences were found between the 2 clinical groups.

Eating Disorder Psychopathology

Of the 11 studies, 6 (55%) reported on participant scores on the eating disorder questionnaires [53-56,58,59]. Of these 6 studies, 4 (67%) displayed statistically significant improvements in eating disorder symptoms [54,56,58,59], although these effects were not always maintained at follow-up after a longer period [54,58].

Body Dissatisfaction and Body Size Perception

As it is an important psychopathological factor driving disordered eating, body dissatisfaction was reported on by 18% (2/11) of the studies, involving 113 participants in total. Both studies involved university students: Kollei et al [54] focused on students with significant body dissatisfaction, whereas Kosinski [55] focused on female students. Both interventions were based on approach-avoidance training aimed at fostering the avoidance of dysfunction stimuli and approach of functional stimuli. This was done by pairing participants' photographs with positively conditioned stimuli. In both studies, participants in the intervention group reported significant reductions in body dissatisfaction, although the study by Kosinski [55] did not display a significant difference compared with the control group where neutral stimuli were used.

Although the study by Gledhill et al [56] did not measure body dissatisfaction directly as an outcome, it showed that a gamified perceptual training paradigm with inflationary feedback was successful in modifying perceptions on body size (measured by their thin-fat categorical boundary) in both individuals with body size concerns and patients with AN.

Gender Differences in Outcomes

Forman et al [60] assessed the associations between gender differences (between men and women) and the effectiveness of a gamified neurocognitive intervention program on weight loss and inhibitory control. Although gamification significantly enhanced weight loss in men more than in women, the association between overall effectiveness on inhibitory control and gender differences was unclear. The study also assessed participant enjoyment of the daily neurocognitive training program. Although there was no significant difference due to gender in the effect of enjoyment, women generally reported, with a small effect, higher enjoyment scores. By contrast, gamification did not seem to enhance men's enjoyment of the intervention. The study also examined compliance to the treatment regimen with gamification. Although statistically nonsignificant, compliance to treatment regimen as a result of gamification improved in men but decreased in women [60].

Discussion

Principal Findings

The results of the review show an overview of the possible ways that SVGs or gamification of CBT interventions can effect change in the symptoms of disordered eating or its underlying psychopathology. These effects can be classified into physical, behavioral, and psychological outcomes. Among the papers that reported physical outcomes of BMI or weight change, it was found that the SVGs and gamified interventions potentially had some effect in improving weight. However, it may not be clear whether this effect can be truly attributed to the inclusion of gamification elements or whether it would still be retained in the nongamified intervention of the same type [62]. The duration of the interventions was also likely to be too short to identify the long-term effects of these SVGs on the participants' weight. Behaviorally speaking, there were mixed results on the effect of the SVGs on desired changes in eating behavior. However, it is noted that gamified versions of neurocognitive training such as WM or ICT seemed to report more positive behavioral changes than the role-playing or avatar-based games. Psychologically speaking, it was observed that SVGs of different types such as those targeting body dissatisfaction, inhibitory control, or WM were all able to produce improvements in eating disorder symptoms or psychopathology [54,56,58,59]. This informs developers of future SVGs for disordered eating on potential game mechanisms and types.

Key Components of SVGs and Their Mechanisms in Treating Disordered Eating Behaviors

The studies (n=11) included in this review comprised 11 different SVGs. As seen in Table 2, the characteristics of the SVGs examined in this review were varied and addressed different aspects of disordered eating with different mechanisms. Of the 11 SVGs, 2 (18%) were gamified adaptations of approach-avoidance and evaluative conditioning training based on the cognitive behavioral model of body satisfaction, aimed to foster approach of functional stimuli and avoidance of dysfunctional stimuli in body dissatisfaction [54,55]. In a similar vein, the SVG in the study by Gledhill et al [56] was also based on cognitive training and worked by calibrating participants' perception of categorical definitions of body shape. Of the 11 SVGs, 4 (36%) aimed to improve inhibitory control regarding unhealthy foods through ICT with *Go–No-Go* (GNG) food stimuli [58,60-62], whereas in the study by Fernandez-Aranda et al [53], the SVG was an immersive role-playing game that required players to solve problems by using emotion regulation skills and achieving impulse control. Interestingly, Dassen et al [59] and Verbeken et al [63] recognized the role of WM and EF, respectively, in behavioral self-regulation and sought to assess the effect of gamified WM and EF training on food intake [59,63,64]. Finally, it is noted from the paper by Joo and Kim [57] that commercially available simulation games, such as *TheSims 4*, may potentially be helpful in influencing real-life health behaviors of users through their avatars' body shape and health behaviors.

The paper by Fernandez-Aranda et al [53] was the only one that examined the effects of an SVG and CBT on eating disorders, specifically BN. The study examined the role the SVG was able to play in addressing the limitations of CBT in treating the underlying traits of eating disorders (namely emotion regulation and impulsivity) while harnessing its gamified elements to ensure compliance and increased accessibility. *PlayMancer:Islands* is an SVG specifically designed for this purpose. The gameplay is unique in that the facial expressions and physiological markers such as heart rate and respiratory rate were monitored as responses to the players' emotional states. Undesirable emotional states would then correspond to increased difficulty in completing tasks. Through the game, participants are required to learn and demonstrate emotion–self-control skills. Although the intervention had limited effect on clinical remission of BN, it was successful in addressing eating disorder psychopathology and in reducing treatment dropout rates. This is corroborated by case studies and case series, which, although not included in this review, showed positive effects of *PlayMancer: Islands* on the intervention group participants' impulse control, emotion regulation, anxiety, and novelty seeking, as well as various physiological measures, including a functional magnetic resonance imaging scan comparing engagement of brain areas, compared with those of healthy controls [65-67]. The case study by Giner-Bartolomé et al [66] even reported changes in eating behavior, such as the number of bingeing episodes. Although SVGs such as *PlayMancer: Islands* cannot be considered an alternative to replace conventional therapy, it is likely that they can be used effectively to supplement the limitations of CBT in addressing emotion regulation and personality traits underlying eating disorders [24]. Nonetheless, stronger evidence for this intervention may be required in studies with a larger sample size and longer duration of follow-up. It will also be worth assessing the effect of *PlayMancer: Islands* on eating disorders other than BN with common psychopathological features, such as AN or BED. The feasibility and accessibility of the SVG intervention would also be a future practical consideration, given the use of biosensors and facial recognition technology.

It is interesting to note that the majority (10/11, 91%) of the other SVGs reviewed differ from *PlayMancer: Islands* in that these other games seek to provide cognitive response training to modify and address the underlying perceptions that drive disordered eating as opposed to the goal-oriented and problem-solving nature of gameplay used in *PlayMancer: Islands*. Of note, body dissatisfaction, ICT, and WM were the main concepts targeted by the SVGs studied.

The studies by Kollei et al [54] and Kosinski [55] both showed significant effects of SVGs in improving symptoms of body dissatisfaction. The Mindtastic Body Dissatisfaction app in the study by Kollei et al [54] used approach-avoidance training where participants are conditioned to perform approach actions (swiping toward themselves) and avoidance actions (swiping away) in response to specific stimuli such as positive and negative body-related statements, respectively. This approach has previously been shown to modify biases toward food and alcohol and in reducing their consumption [68-70]. By contrast, the mobile app intervention in the study by Kosinski [55] used evaluative conditioning, a form of Pavlovian conditioning, where a change in behavior or response is induced when conditioned stimuli (participants' own photographs) are paired to unconditioned stimuli (positive body image photographs). The evaluative conditioning approach is supported by the work of Aspen et al [71], whose study showed that pairing participants' bodies with positive social stimuli and pairing other bodies with neutral stimuli resulted in improvements in body shape concerns and self-esteem, as well as reduced food restriction. Kollei et al [54] and Kosinski [55] collectively show the potential of gamified mobile app interventions in providing remote cognitive training to modulate adaptive body image attitudes, which can be seen to be highly feasible and accessible. As both studies examined the effects of the interventions on university students, it would be useful to understand the generalizability of these effects on other demographics, as well as persons formally diagnosed with eating disorders. Given the use of these mobile app interventions in university students not diagnosed with eating disorders, it may also be interesting to assess the potential role of SVGs in preventing eating disorders in populations considered to be at high risk who have not yet been formally diagnosed. Studies with a longer follow-up duration may be helpful to inform whether such games can reduce the incidence of eating disorder diagnoses.

Commonly compared with approach-avoidance training, GNG training is another form of motor response training aimed at changing behaviors. GNG training was the modality that was gamified in the *FoodT* app in the study by Keeler et al [58]; this app, when used by patients with BN and BED, showed a reduction in eating disorder pathology and diminished the perceived palatability of high-energy–dense foods. GNG training was also used in the intervention in the studies by Forman et al [60,62] and Blackburne et al [61]. Although used in different populations, the effect size on eating disorder pathology of the *FoodT* app was similar to that of the Mindtastic Body Dissatisfaction app in the study by Kollei et al [54]. Although the meta-analyses conducted suggested that GNG training may be more effective than approach-avoidance training in influencing food behaviors [72,73], it is difficult to compare the usefulness of both SVGs because they address different psychopathological drivers of disordered eating (poor inhibitory control and body dissatisfaction). The *FoodT* app also lends support to the feasibility of cognitive training for disordered eating through gamified mobile apps, and it may be interesting to see whether a combination of features from these cognitive training apps can lead to better outcomes.

Accessibility and Feasibility of Using SVGs

In addition to the benefits SVGs may have in the treatment of disordered eating, they may have other advantages. Compared with conventional treatment, SVGs are likely to be more accessible to patients with disordered eating. First, there is a high degree of correspondence between the demographics of video game players and patients with disordered eating; 38% of the video game players in the United States fell within the age range of 18 to 34 years, whereas 20% were aged <18 years [74]. It is hence likely that SVGs will appeal more to patients with disordered eating. Furthermore, with more SVGs using mobile apps as a platform coupled with increasing smart device ownership, SVGs have the potential to reach more persons with disordered eating. Finally, SVGs have relatively low barriers to use and also offer users the option of being by themselves, which may help circumvent issues of trust with the therapist or personality-related comorbidities such as avoidance in patients with disordered eating [18,75]. Hence, these factors may address certain challenges in the treatment of disordered eating such as low treatment uptake rates or high dropout rates.

Further Tailoring of SVGs and Supporting Their Use

The study by Forman et al [60] compares gender differences in the effect of gamification on weight loss. Eating disorders tend to affect women more than men; however, disordered eating can affect men as well. In general, most studies have samples that consist predominantly of women. The study provides a different perspective on gender differences in the effect of SVGs. Most video game users tend to be men [76], and men are reported to be more motivated by gaming elements than women, which is supported by Hassouneh and Brengman [77], whose study indicates that the effects of SVGs on women and men can differ. The study also found that compliance to SVG interventions tends to be higher in men than in women. In addition, it was reported that the gamification elements had more positive outcomes for men. This may inform future recommendations on the potential use of SVGs for the treatment of disordered eating based on gender, as well as expectations regarding their subsequent clinical effectiveness. However, the SVG assessed by Forman et al [60] used a gamified GNG training modality; hence, it is not clear whether the trend noted in this study would apply to other SVG genres. As discussed by Forman et al [60], it is plausible that the inclusion of other gaming elements such as more elaborate backstories, incentives, and components that require collaboration with other participants in these SVGs may contribute to their appeal to women [78-81]. Such features may serve to enhance user motivation as well as foster a sense of connection with peers facing similar struggles with disordered eating. This may further promote user engagement with the SVGs.

Although not explicitly addressed by the included studies, it is important to consider the concerns over privacy and confidentiality that users may have regarding such SVGs, especially in the context of treating disordered eating behaviors. A review by Borghouts et al [82] showed that concerns over the safety and privacy of disclosed information can act as a barrier to engagement in such digital mental health interventions [82]. On the flipside, assurance of anonymity in the use of the digital intervention encouraged engagement [52,82]. Hence, in the design and implementation of such SVGs, it would be necessary to make sure that appropriate safeguards are in place to protect sensitive user data. It has also been suggested that the use of trusted brand names and transparency as well as evidence of credibility would serve to increase engagement of young users with digital mental health interventions [52].

Possible Risks and Adverse Outcomes

Despite the many benefits an incorporation of SVGs may confer to the treatment of disordered eating, it is important to note potential pitfalls where SVGs may complicate treatment. One such instance would be the situation where the inclusion of serious gamification elements such as player scores may inadvertently cause additional stress or cognitive load because of the participant's drive to do well in the game and distract participants from the therapeutic intentions of the game [83,84]. This could also potentially cause further insult to the self-esteem of the participant or further diminish confidence and motivation in complying with treatment. This is supported by the study by Mekler et al [85], which suggests that gamification elements such as scores and leader boards may function more as an extrinsic source of motivation that increases performance quantity but do not have a significant relationship with competence or intrinsic motivation; for example, players may attempt the game multiple times for the simple object of passing a particular level while not necessarily improving in competency. This may be apparent in the study by Forman et al [62] where gamified ICT actually reduced the weight loss benefits derived from conventional ICT. This was posited by the authors to possibly be due to distraction from the core stimuli by gaming elements such as visuals, music, and sound effects, which may have reduced prepotent reward response, hence affecting inhibitory response.

Nonetheless, among the other SVGs assessed in this review, scoring systems and leader boards are not key elements and may not necessarily cause the aforementioned effect. Furthermore, games such as *PlayMancer: Islands*, which uses biosensors to track physiological and facial expression responses to emotional states, will be able to pick up states of distress in participants as well as obtain an objective measure of progress [53]. Hence, as more research is being conducted to assess the effects of gamification elements on motivation, careful design and implementation of gamification will be crucial.

Given the relatively short duration of the implementation of the SVGs studied in this review, it may be a concern that the effects of gamification such as the participants' enjoyability, compliance, and improvements in psychopathology may be due in part to the novelty of the gamification experience [86,87]. This implies that the usefulness or effectiveness of an SVG can be lost over time as the novelty effect of gamification wears off. This may not be a significant problem if the gamified intervention is meant to be used only in the short term, but it will have to be taken into account if the serious game is expected to be part of a patient's long-term treatment. As discussed by Hamari and Kovisto [88], the addition of social networking and community elements to the gamification process may be helpful in enhancing effectiveness as well as the participants' willingness to use the service. These effects are positively related to positive recognition and reciprocity. Hence, it is plausible that implementation of SVGs in the setting of support groups for disordered eating could enhance and prolong their benefits, while promoting a sense of connectedness.

There may also be concerns over SVGs fueling other problems such as gaming addiction. This is because impulsivity traits such as urgency and lack of perseverance are both associated with eating disorders such as binge eating as well as with problems of addiction [89]. At the same time, problematic internet use has been shown to act as a predictor of eating disorders in a meta-analysis [90]. However, none of the SVGs (n=11) assessed in the review have reported addiction as an adverse effect. This is likely to be due to the short duration of the intervention, making addiction unlikely. However, this may have to be taken into consideration if the SVGs are implemented for a longer duration, and countermeasures such as additional supervision or imposing appropriate limits on the use of the games may be warranted.

Overall Utility and User Engagement

Taking the aforementioned considerations into account, although most of the outcomes measured in the individual papers were different, they collectively provide evidence to suggest the various roles SVGs can play in plugging potential gaps left by conventional therapy. Fitting the aforementioned factors into the framework developed by Liverpool et al [52] to evaluate user engagement, SVGs fare well in intervention-specific factors such as suitability, usability, and acceptability. In terms of person-specific influencing factors, young users likely have ample capability to engage in the use of SVGs. Furthermore, the novelty of SVGs also contributes to good user motivation, although its sustainability requires further examination. Opportunities for the adoption of SVGs may also be limited by confidentiality concerns as well as a lack of a sense of connectedness with others.

Strengths and Limitations

The strength of this study is that it provides a broad overview of the various ways in which gamification may be imbued in different types of interventions to address different psychopathological and clinical aspects of disordered eating; for instance, SVGs that address body dissatisfaction, which may be more prevalent in AN, and those that target inhibitory control, which may be associated more strongly with overeating, BED, or BN [7,48]. Furthermore, this study provides insight into the effectiveness of SVGs not only in eating disorders but also in disordered eating, which encompasses pathological eating behaviors beyond the strict diagnoses of eating disorders.

The limitations of this study are that only a small number of studies were included for analysis, providing limited amount of data and evidence for the assessment of the effectiveness of SVGs in disordered eating. Furthermore, the outcomes of the studies were varied, making it difficult to compare effect sizes among them. In addition, given the small sample sizes in the studies, there is a higher risk of bias and potential lack of representativeness. It was also observed that not all the included studies addressed populations who had received formal diagnoses of disordered eating but instead included participants from the general population or those who had other characteristics such as obesity, which may not be accurate proxies for disordered eating. Hence, it may be difficult to extrapolate the effects of the studied interventions to apply in populations with formal diagnoses of disordered eating behaviors. However, the studies in the review do show the promise that SVGs hold for effecting change in eating behaviors. Hence, it may be helpful for more studies to validate this effect on populations with disordered eating. It is also noted that the SVGs reviewed in this paper targeted a predominantly young population such as university students, with a large proportion of participants being women. As such, more evidence may be required to advance knowledge on the effectiveness of SVGs in disordered eating in other age groups as well as in men, given the knowledge that eating disorders in men also face significant underdiagnosis and undertreatment [15].

Further Studies and Recommendations

We have identified some gaps in current research that could be addressed in subsequent studies. First, more RCTs need to be conducted to expand the evidence pool. The World Health Organization's global strategy on digital health includes the recommendation that research is important in ensuring safety and accountability in the implementation of digital health interventions [91]. Hence, it is important to solidify our understanding of the efficacy of SVGs as a treatment intervention for disordered eating. Pending studies, such as the one pertaining to the Self-help, Integrated, and Gamified Mobile-Phone Application intervention for patients who were overweight with maladaptive eating behaviors, will add to our current understanding of gamified mobile apps for disordered eating [92]. Studies investigating the effectiveness of SVGs for disordered eating in different socioeconomic backgrounds, levels of computer literacy, genders, and ages may also be helpful.

As mentioned earlier, the longest study in this review was held only over 8 weeks. Hence, the long-term impact of the interventions and the retention of its beneficial effects might not be well understood and can be explored further. Learning about the long-term impact of SVGs in the context of disordered eating may then also provide clues to their potential role not only in treatment but also in prevention of disordered eating in persons with high-risk factors.

Some of the SVGs discussed were computer applications. However, in recent years, computer sales have been declining, and other devices such as smartphones are increasingly being used [93]. As such, it will be prudent for future studies to study games supported on such platforms, which promise greater accessibility.

Conclusions

In conclusion, this review supports the effectiveness of SVGs in complementing the current standards of care in treating disordered eating. Although more research is needed to gain a better understanding of the long-term effects of SVGs on disordered eating and their effectiveness across different demographic groups, SVGs have shown that they are able to provide measurable short-term benefits by addressing the underlying psychopathological processes that drive behaviors of disordered eating. Nonetheless, challenges exist in developing effective SVGs for disordered eating such that while having to keep the games appropriately challenging and engaging, caution has to be taken in the game design to prevent potential adverse outcomes.

Abstract

Background: Opioid addiction is currently one of the most pressing public health issues. Despite several treatment options for opioid addiction, the recurrence of use episodes during remission remains high. Research indicates that meaningful membership in various social groups underpins the successful transition from addiction to long-term remission. However, much of the current literature focuses on online peer-support groups for individuals in remission from substance use, sometimes also called recovery groups, a term we will use in line with the terminology used by the online community we studied. In contrast, online group memberships that promote substance use and groups that are unrelated to substance use and remission (non–drug-related groups) are rarely studied.

Objective: This study aims to understand whether engagement with a variety of Reddit subforums (subreddits) provides those in remission from opioid use disorder (OUD) with social capital, thereby reducing their risk of a use episode over several years. More specifically, it aims to examine the different effects of engagement with substance use, recovery, and non–drug-related subreddits.

Methods: A data set of 457 individuals in remission from OUD who posted their remission start date on Reddit was collected, of whom 219 (47.9%) indicated at least one use episode during the remission period. Using a Cox proportional hazards model, the effects of the number of non–drug-related, recovery, and substance use subreddits an individual had engaged with on the risk of a use episode were tested. Group engagement was assessed both in terms of the absolute number of subreddits and as a proportion of the total number of subreddits in which an individual had posted.

Results: Engagement with a larger number of non–drug-related online communities reduced the likelihood of a use episode irrespective of the number of posts and comments made in these forums. This was true for both the absolute number of non–drug-related communities ($P<.001$) and the proportion of communities with which a person engaged ($P<.001$). The findings were less conclusive for recovery support and substance use groups; although participating in more recovery support subreddits reduced the risk of a use episode ($P<.001$), being part of a higher proportion of recovery support groups relative to other subreddits increased the risk ($P=.01$). A higher proportion of substance use subreddits marginally increased the risk of a use episode ($P=.06$); however, the absolute number of substance use subreddits significantly reduced the risk of a use episode ($P=.002$).

Conclusions: Our work indicates that even minimal regular engagement with several non–drug-related online forums may provide those in remission from OUD with an opportunity to grow their social capital and reduce the risk of a use episode over several years.

online communities; opioid addiction; recovery capital; social identity; Reddit; social media

Introduction

Background

In recent years, research on remission from addiction has shown the importance of social groups [1,2] and recovery capital [3] more widely. This trend builds on recent findings in the health and well-being literature, which suggest that the joining of new groups can act as a *social cure* [4]. The social cure hypothesis states that a higher number of memberships in social groups is associated with better mental and physical health outcomes, better resilience, and higher well-being. With regard to substance use disorders, much of the literature focuses on the benefits of peer-support groups for remission. Overall, this literature suggests that highly structured, peer-led support groups, both offline and online, support remission [5-10]. Few studies have examined the impact of social groups beyond such peer-support groups, and these tend to focus on a small number of offline groups or individuals (eg, family, friends, and coworkers) [11,12], thereby overlooking the potential of *online communities* as social capital for managing the remission process.

Understanding the impact of online community memberships beyond the direct effects of online peer-support groups can help tailor support for those with limited access to offline social networks. Access to a face-to-face support network can be limited by geographical location (eg, rural areas), difficulties with mobility (eg, lack of transport and failure of groups to accommodate mobility impairments), or significant caring responsibilities (eg, childcare availability) [13,14]. In some cases, the stigma surrounding addiction can also make it harder for those in remission to access offline help [15]. More recently, lockdowns during the COVID-19 pandemic have severely limited face-to-face interactions for those in remission, not only with peer-support groups but also with a wider support network of family, friends, and health care professionals [16]. Therefore, it is not surprising that online communities play an increasingly important role in providing social support, advice, and information [17,18] and may act as an additional source of social capital during remission.

Social Groups and Recovery

Overview

Research on the social cure provides mounting evidence that membership in several social groups increases health, well-being, and resilience [4,19]. For instance, research shows that a higher number of self-reported group memberships is associated with lower levels of smoking and drinking [20]. A recent study of online communities found that the number of subreddits an individual posted in and the evenness of participation in these different online communities reduced the risk of use episodes over several years for those in remission from opioid use disorder (OUD) [21]. Being part of various social groups is thought to provide members with psychological and physical resources such as a sense of connectedness, meaning, purpose, and worth as a member of a positively valued group [4]. Furthermore, groups also provide direct and indirect social support, a sense of personal control through the group's ability to affect change, and the social power and agency that the opportunity for collective action brings [4,22]. Similarly, recovery capital can be built by developing and strengthening links with those who are in recovery (*bonding*) and the wider community that may provide support (*bridging*) [3,23,24].

The Social Identity Model of Recovery (SIMOR) [1] integrates these 2 strands of research and suggests that meaningful membership in various social groups underpins the successful transition from addiction to long-term recovery. Rather than focusing on a few strong interpersonal bonds, the SIMOR suggests that being a part of several social groups is among the key factors associated with remission from substance use. Group membership becomes part of an individual's self-concept—their social identity—once the individual sees themselves, and is seen by others, as belonging to a particular social group or category [25,26]. When an individual identifies themselves as a group member, as well as begins to feel part of the group, group norms become internalized and guide attitudes, emotions, and behavior [27].

On the basis of this approach, being a member of a community that endorses substance use can be expected to increase substance use as this behavior is a normative expression of this particular group membership. In contrast, the model suggests that membership in recovery support groups shifts the identity away from an *addiction* identity toward a *recovery* identity. A *recovery* identity is thought to promote remission, such as a reduction in substance use or abstinence, through its norms and by providing (social) resources. In the longer term, gaining or regaining membership in groups that are not associated with substance use or remission (ie, non–drug-related groups) should help the individual build a social identity that increases health and well-being and is resilient to life changes [28,29]. Hence, the SIMOR conceptualizes remission from substance use disorder as a long-term transformation of social relationships and, correspondingly, the social self. The self is transformed from an *addiction* identity to a *recovery* identity toward a range of non–drug-related social identities (eg, parent, employee, and volunteer) that the individual gains or regains during their recovery journey [1].

Recovery Communities

Joining and participating in traditional support groups, such as Alcoholics Anonymous (AA) or Narcotics Anonymous, have shown significant promise in assisting individuals with a substance use disorder in maintaining their abstinence [30] by providing an encouraging and supportive community and by facilitating programs for addiction management and remission. An AA intervention designed to change an individual's social network—away from network members encouraging substance use toward abstinence-supporting network members—found positive effects on behavioral and attitudinal support for abstinence [5,31].

Similarly, positive effects on sustained remission have been found for online peer-support networks. For example, research found that engagement in online recovery support communities on Reddit reduced the risk of recurring use episodes in those who were in remission from smoking or from alcohol use disorders [8]. Similarly, a qualitative study showed that participation in the online recovery support group *Soberistas* was related to an offline commitment to changing drinking behaviors [32]. Studies on recovery from OUD show that online recovery groups are supportive [33] and promote remission despite a high chance of a recurring use episode among group members [34].

Active participation has been shown to be an important component [8]. For instance, a recent study found that those who participated more on a Facebook page dedicated to supporting those with a substance use disorder in the early stages of remission were more likely to remain in the program [9]. Here, the level of participation was assessed through the number of received *likes* and increased use of the word *we*.

Non–Drug-Related Communities

Further evidence from the field of addiction highlights the important role of a wider social network beyond recovery support groups. Much of this literature examines the effect of peer support on the decision to "quit" substance use and start therapy [35,36] or the reverse effect of the decision to quit on the composition of the social network [37]. However, a few studies have shown that social network composition affects subsequent substance use.

A longitudinal social network study across 32 years found that alcohol consumption tends to follow the behavior of individuals in a person’s social network [38]. These effects were mostly driven by interpersonal relationships with family members and close friends rather than groups (eg, coworkers or neighbors). The study also did not differentiate between problematic alcohol consumption and general alcohol consumption.

Furthermore, a self-report study with residents in a therapeutic community found that a higher proportion of non–drug-related group memberships decreased substance use at the 6-month follow-up [11]. In this study, the number of group memberships and categorization into non–drug-related (or *low-risk*) and substance use (or *high-risk*) groups were based on a mapping exercise. Participants were asked to group their social relations into different categories (eg, family, friends, coworkers, and recovery peer groups). Participants also indicated the number of people in each *group* who regularly used substances. Groups in which most individuals used substances regularly were then labeled as *high-risk* groups and those in which most of the members were abstinent, in remission, or whose drug use was unknown to the participant were then labeled as *low-risk* groups, with more mixed groups remaining uncategorized. As a result, recovery support groups were not considered in their own right but were classified as high risk, low risk, or uncategorized based on the perceived substance use of its members and not based on the norms of the group. This method also does not clearly differentiate between interpersonal relations (eg, family and friends) and group membership (eg, work team). Surprisingly, participants indicated only a very small number of *group memberships* (median 4). This suggests that small groups were mostly considered by participants rather than wider social categories (eg, parent and Christian) or shared interest groups (eg, volunteer and rugby fan) that form an individual’s social identity [27].

In summary, current research suggests that face-to-face interactions with individuals and groups who are not engaging in substance use are more likely to support remission than interactions with individuals who are known to continue to use substances. However, there appears to be very little, if any, research examining the effects of a wide variety of (online) communities that are concerned with non–drug-related interests, such as video games, literature, sports, and politics. Instead, current literature focuses on small groups and interpersonal social networks.

Substance Use Communities

In line with the SIMOR, a few studies indicate that a higher proportion of individuals engaging in substance use—or substance use groups—in an individual’s network tends to be related to higher substance use [11,38], although others have found no statistically significant effect [39]. However, these studies also indicate difficulties in neatly categorizing a group as a *substance use group* as opposed to a *non–drug-related group*. The use versus nonuse binary has been challenged by several researchers (eg, [40,41]) as adding a burden on those in remission. For instance, qualitative research suggests that severing ties with groups that continue to engage in substance use can result in the loss of trusted and emotionally significant relationships, particularly for young people [40]. Importantly, those who continue to engage in substance use do not necessarily seek to undermine remission in others and may provide information and emotional support. Similarly, the suggestion that the "bad company" of substance use groups undermines remission has been criticized as being based on relatively sparse empirical evidence [41]. Specifically, for online communities, we are not aware of any research examining the effect of participation in communities that actively promote or endorse substance use on the risk of recurring use episodes for those in remission.

In summary, there appears to be some empirical support for the positive effects of recovery support groups and offline non–drug-related groups on remission from substance use disorders. However, evidence is surprisingly sparse regarding the effects of groups that promote substance use and non–drug-related online interest groups. Looking closely at the research also reveals a mix of approaches in determining the type of group—often revealing a focus on the perceived behavior of known individuals rather than the norms that the wider social group is promoting. It is also unclear from the current literature whether it is close interpersonal network members (eg, family, friends, and coworkers) or interactions with wider communities (eg, parents, volunteers, sports fans, and Christians) that support remission. Finally, the current literature is limited to separately examining the effects of substance use, recovery, and non–drug-related groups.

Aim and Hypotheses

This study aimed to extend a previous study [21] on the effects of multiple online group memberships on remission from OUD. More specifically, this study tested the effects of substance use, recovery, and non–drug-related online communities separately in terms of absolute numbers of memberships and as a proportion of all memberships. Differentiating between the effects of different types of communities is both theoretically and practically important. In addition to testing the wider social cure hypothesis, this approach will test the SIMOR, which suggests that substance use groups affect remission differently from recovery and nonusing groups. Although several studies have tested parts of the SIMOR, only one study that we are aware of has tested all 3 types of groups together [11], and none has done so in an online environment. Understanding how different types of online communities affect remission also has practical implications by allowing those in remission to make more informed choices about their online community engagement. Furthermore, by examining data across several years, the study also sheds light on the longitudinal effects that these 3 different types of social groups have on the risk of a use episode over time, thereby considerably extending the knowledge about the long-term effects of social group membership.

In line with the SIMOR, we expected that a higher number (and proportion) of online community memberships actively supporting recovery will decrease the risk of a use episode over time (*hypothesis 1*). Similarly, a higher number (and proportion) of non–drug-related online groups were predicted to reduce the risk of a use episode (*hypothesis 2*). In contrast, a higher number (and proportion) of memberships in online communities that advocate substance use were expected to increase the risk of a use episode in those in remission from OUD (*hypothesis 3*).

Methods

Data Selection

The online forum platform Reddit provides a unique opportunity to study the effects of membership and activity patterns in various online communities on the risk of recurring use episodes [8,18,21]. Reddit is a public social news and discussion website where user-created content is organized into topic-based boards called *subreddits*. It accommodates >100,000 different subreddits where content is shared within a community of interest, such as about politics, business, parenting, medical conditions, sports, literature, music, video games, and life choices. This abundance of social groups allows us to simultaneously examine the effects of substance use, recovery, and non–drug-related online communities on the risk of a use episode during remission.

The subreddit r/OpiatesRecovery has >31,000 members and has provided individuals who wish to recover from OUD with recovery information and peer support since 2012. Some members make statements about their remission status on a regular basis by announcing the number of days they have not been using opioids. In combination with statements announcing a use episode, this provides us with information about the point in the recovery journey when a community member had a recurring use episode. Furthermore, anonymous but unique user IDs allow us to gather data on community members' activities across the entire Reddit platform, providing behavioral information on engagement with online communities. Using behavioral information, problems with memory bias and differences in the definition of what is meant by a *group membership* can be circumvented. This is particularly important in light of the recent finding that online interactions are not spontaneously self-reported as social contact [42].

Ethics Approval and Privacy Considerations

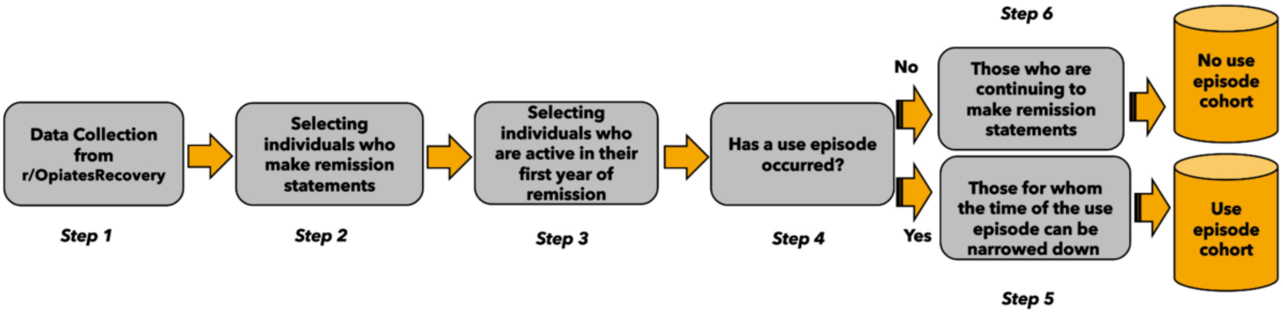
Before work commenced, the study received ethics approval from the University of Exeter's institutional review board (eCLESPsy001576), in line with the guidelines of the British Psychological Society and the American Psychological Association. This study used publicly accessible Reddit data for the analysis. Reddit usernames were used to collect quantitative data across different subreddits and were then replaced with anonymous participant numbers in the working data set. In this study, we do not report any user identifiable information to protect user privacy (eg, direct quotations and usernames); instead, we paraphrase quotations to illustrate our method.

Data Collection and Preparation

The steps involved in the data collection and preparation processes are illustrated in Figure 1. The study used publicly accessible data from r/OpiatesRecovery between February 2012 (when the group started) and June 2019 (the month of data collection).

After cleaning the data from adversarial content, bots, and so on, the initial data set contained 295,232 posts and comments from 18,125 individuals (step 1). Among these posts, we identified statements in which individuals announced their remission status (eg, "I'm 21 days clean") and found 2950 instances of remission being announced by 1651 individuals (step 2). As we wished to study the activity of those in remission from OUD from the beginning of their current remission period, individuals whose self-reported time in remission exceeded their time on Reddit by >1 year were excluded from the analyses (eg, an individual who joined in 2015 but said in a post that they have been in remission since 2012). To allow sufficient information about each individual in our data set, we only retained data from those who posted at least 10 posts and comments in any subreddit for a minimum of 3 different months during the first year of remission. This resulted in 1081 individuals (step 3).

Figure 1. Diagram of data collection and preparation for identifying use episode and no use episode cohorts.



To identify which individuals had experienced a use episode, we examined statements commonly used to report such an episode (eg, "I started using again last night"). As we aimed to include as wide a sample as possible, we used inconsistent reporting of abstinence to identify those with a use episode. Where an inconsistent number of days without a use episode was reported (eg, "5 days without using" after announcing "21 days clean" a week earlier), a trained psychologist individually inspected remission status statements and found 51 additional individuals with a likely use episode. On the basis of statements and inconsistent reporting, we identified a *use episode* cohort of 335 individuals (step 4) among the 1081 individuals that regularly announced their remission progress. To ensure that survival analysis can estimate time correctly, we excluded those individuals for whom the time of the use episode could not be narrowed down to a specific month. For individuals whose remission statements only indirectly indicated a use episode, we used the month between the last report of a consistent period without a use episode and the announcement of a new period of remission (step 5). Individuals who had a consistent increase in remission days and did not make any statements about a use episode were grouped into the *no use episode* cohort. To ensure *noninformative* censoring, we only kept data from individuals in the *no use episode* cohort who were still active in r/OpiatesRecovery by the end of our data collection period in June 2019 (step 6). In total, our sample comprised 457 individuals from r/OpiatesRecovery, of whom 219 (47.9%) reported a use episode during remission, and 238 (52.1%) did not report a use episode.

Labeling of Online Communities

To study the impact of distinct types of online groups on recovery progress, we categorized them into 3 types in line with the literature on the SIMOR: substance use, recovery, and non–drug-related groups. We considered subreddits that actively promoted substance use or discussed safe use as *substance use groups* (eg, r/Drugs, r/trees, and r/fentanyl). These also included legal substances such as alcohol consumption and tobacco smoking (eg, r/Cigarette, r/juul, and r/alcohol). Groups that discussed and supported recovery from addiction to any substance were considered recovery support communities (eg, r/narcoticsanonymous, r/quittingsmoking, and r/leaves). Both the description of the subreddit and posts within the community were considered when categorizing. Overall, 2 research assistants labeled the data, with the 2 authors providing guidance and reviewing the labels.

The participants in our data set were part of >4500 subreddits, which makes it impractical to label all of them. Therefore, we used a snowball approach where we started with r/Opiates and r/OpiatesRecovery, found similar subreddits to each of these, and then identified their category based on the content posted on the subreddit. We followed the same procedure for the newly identified subreddits, limiting our search to 4 rounds. We used Sayit [43], an online tool for finding subreddits similar to a specific one based on the number of mutual members. This procedure led to 1247 subreddits. Of these 1247 subreddits, 151 (12.11%) were labeled as substance use communities, 38 (3.05%) were labeled as recovery support communities, and 1058 (84.84%) were labeled as non–drug-related communities. Given that non–drug-related subreddits had a much higher prevalence, although we explicitly searched for subreddits on substance use and recovery support, we tested whether those who had not been labeled could be considered non–drug-related communities. To do so, we randomly selected 500 subreddits that had so far not been labeled and categorized them into substance use, recovery, and non–drug-related groups. Only 3.2% (16/500) were found to be substance use or recovery support groups. Therefore, it was decided that the risk of categorizing the remaining unlabeled forums as non–drug-related groups to the quality of the data was negligible.

To assess the effect of different types of groups on remission outcomes, researchers used 2 different operationalizations: the absolute number of groups of a particular type [20] and the proportion of a particular type of group relative to the total number of groups [11]. Assessing the absolute number of group memberships is in line with much of the social cure research that tends to find that a larger absolute number of group memberships is beneficial to health, mental health, and resilience [4]. In contrast, the SIMOR suggests that recovery from addiction is affected by the balance between substance use, recovery, and non–drug-related groups (ie, the proportion). Here, we use both operationalizations to examine the SIMOR and the wider social cure hypothesis.

For each participant, we counted the number of different subreddits in which they had posted at least once for each month from their self-reported remission start date until the first use episode or the last remission status announcement. On the basis of a labeled list of subreddits, we assessed the number of substance use, recovery, and non–drug-related group memberships for each month. In addition, we calculated the proportion of these group memberships by dividing membership into 1 of 3 categories (substance use, recovery, or non–drug-related) by the total number of group memberships in the same month (eg, number of substance use groups divided by number of all groups an individual has posted in). For each month, we also collected the number of posts and comments that a participant had contributed to the different online communities. Summary statistics for the sample are provided in Table 1, showing that participation in online communities far outstrips the number of groups that individuals who are in remission from a substance use disorder report in the offline world [11].

Table 1. Summary statistics of no use episode and use episode cohorts (N=457).

	All	No use episode	Use episode
Total sample, n (%)	457 (100)	238 (52.1)	219 (47.9)
Total posts, n (%)	237,435 (100)	137,030 (57.7)	100,405 (42.3)
Total subreddits, n (%)	4582 (100)	3513 (76.7)	2268 (49.5)
Posts per individual, median (range)	158 (1-15,805)	157 (1-15,805)	160 (3-7184)
Subreddits per individual, median (range)	14 (1-532)	18 (1-522)	11 (1-532)

Data Analysis

The availability of longitudinal data up to a maximum of 6 years in an individual's remission journey allowed us to predict the risk of a use episode as an outcome variable in a survival analysis (the step-by-step R code for the survival analysis is provided in Multimedia Appendix 1). The absolute number of substance use, recovery, and non–drug-related communities that an individual posted in at least once, as well as the proportion of these communities, served as predictor variables in our models. The number of posts and comments that an individual provided to these communities was statistically controlled for. This allowed us to test whether it is the number of group memberships, or an individual's posting behavior, that is related to the risk of a use episode.

Survival analysis is a type of time-to-event analysis that has been widely adopted when the research interest is a combination of *whether* the event has occurred (binary outcome) and when it has occurred (continuous outcome). It provides unbiased survival estimates by using the information provided by individuals who have experienced the event (here, a use episode), as well as by those who have not (here, no use episode; so-called censored data). To explore the effects of various factors on the time to relapse, we used an extended Cox model [44]. This survival analysis regression method explores the relationship between the event of interest (the use episode in our study) and factors that affect the time at which the event occurs. This allowed us to study how survival probabilities change with changes in the studied factors. Unlike the basic Cox model, the extended version is designed to accommodate time-dependent variables; that is, variables whose values for a given participant may differ over time. Cox modeling does not make any assumptions about the statistical distribution of survival times, unlike most other statistical models, which makes it an appropriate choice for our research problem.

The data used in the study, the activity of individuals in terms of Reddit group membership over time, is provided as a supplementary file in Multimedia Appendix 1.

Results

Preliminary Results

Summary statistics (Table 2) of the number of substance use, recovery, and non–drug-related groups that individuals participated in at least once show that participation in non–drug-related groups is common among individuals in remission from OUD. They also indicate that those in the *use episode* cohort show significantly less engagement with non–drug-related groups than those in the *no use episode* cohort. Interestingly, there were no significant differences in the number of substance use and recovery groups, respectively, between the *no use episode* and the *use episode* cohorts.

Table 2. Summary statistics and significance tests for online community types by use episode and no use episode cohorts.

Communities	No use episode, median (range)	Use episode, median (range)	Significance test	
			U test	*P* value
Substance use	1 (0-10)	0 (0-28)	24,414.00	.20
Recovery	2 (1-11)	2 (1-11)	27,946.50	.16
Non–drug-related	16 (0-507)	8 (0-493)	22,036.00	.004

Absolute Number of Group Memberships

In line with our hypotheses, we tested whether the absolute number of memberships in substance use, recovery, and non–drug-related groups affected the risk of a use episode during OUD remission. In line with SIMOR, we expect recovery and non–drug-related groups to decrease the risk of a use episode over time (hypotheses 1 and 2) and substance use groups to increase the risk of a use episode (hypothesis 3). The number of posts within these communities was controlled statistically. The statistics for the 3 separate survival analyses and the combined analysis are presented in Table 3.

Table 3. Effects of the absolute number of memberships in recovery, non–drug-related, and substance use online forums on the risk of a use episode during opioid use disorder remission.

Variable	*b* (SE)	*P* value	Odds ratio (95% CI)
Separate models			
Recovery models			
Number of posts (recovery)	0.002 (0.0008)	.04	1.0017 (5.61×10^{-5} to 0.003)
Recovery memberships	−0.20 (0.08)	.009	0.8182 (−0.352 to −0.049)
Non–drug-related			
Number of posts (non–drug-related)	0.0004 (0.0002)	.005	1.0004 (0.0001 to 0.0006)
Non–drug-related memberships	−0.05 (0.008)	<.001	0.9499 (−0.066 to −0.036)
Substance use models			
Number of posts (substance use)	0.002 (0.002)	.11	1.0020 (−0.0006 to 0.0046)
Substance use memberships	−0.22 (0.07)	.002	0.8024 (−0.361 to −0.078)
Combined model			
Number of posts (total)	0.0004 (0.0001)	.001	1.0004 (0.0001 to 0.0007)
Recovery memberships	0.02 (0.07)	.73	1.02 (−0.108 to 0.154)
Non–drug-related memberships	−0.06 (0.01)	<.001	0.94 (−0.073 to −0.040)
Substance use memberships	0.08 (0.05)	.12	1.08 (−0.020 to 0.172)

In line with hypothesis 1, survival analysis showed that the number of online recovery groups an individual is a part of is negatively and significantly related to the risk of a use episode (*P*=.01), irrespective of the number of posts. Similarly, the higher the number of memberships in non–drug-related online groups, the lower the risk of a use episode (*P*<.001), supporting hypothesis 2. However, in contrast to hypothesis 3, we found that the higher the absolute number of substance use group memberships, the lower (rather than higher) the risk of a use episode over time. The individual models also showed that the number of posts or comments made in each type of forum tends to increase the risk of a use episode. This effect was statistically significant for recovery and non–drug-related online forums.

When all 3 predictors were included in the same survival analysis, only the effect of the absolute number of non–drug-related online communities remained significant. Membership in non–drug-related groups has significant potential for reducing the risk of a use episode by 6% per additional non–drug-related group that an individual joins. Importantly, this effect is found when controlling for the number of posts or comments made, showing that the effect is not because of more active engagement in online communities. In fact, the total number of posts or comments was significantly and positively related to the occurrence of a use episode during remission, indicating a higher risk for those who contributed more frequently.

Proportion of Group Memberships

Next, we tested the same 3 hypotheses but with the number of group memberships in a particular type of group (substance use, recovery, or non–drug-related) relative to the number of total Reddit communities in which an individual participated (ie, the proportion). Again, we statistically controlled for the total number of posts or comments that contributed to the respective type of group. The statistics for the 3 separate survival models are presented in Table 4.

Survival analysis showed an unexpectedly positive and significant effect of the proportion of recovery group memberships on the risk of relapse. Being part of a higher proportion of online recovery subreddits significantly increases the likelihood of an individual reporting a use episode over time (*P*<.001). This finding does not support hypothesis 1. The model also showed a marginally significant positive effect of the proportion of substance use groups on the risk of a use episode (*P*=.06). In line with hypothesis 3, this finding suggests that a higher proportion of substance use groups may increase the risk of a use episode during remission. In contrast, being part of a higher proportion of non–drug-related groups significantly decreases the risk of a use episode (*P*<.001), in line with hypothesis 2.

Table 4. Effects of the proportion of memberships in recovery, non–drug-related, and substance use online forums on the risk of a use episode during remission.

Variable	*b* (SE)	*P* value	Odds ratio (95% CI)
Recovery models			
Number of posts (recovery)	0.001 (0.001)	.29	1.00 (−0.0008 to 0.0027)
Recovery memberships (%)	1.61 (0.20)	<.001	5.00 (1.219 to 2.002)
Non–drug-related models			
Number of posts (non–drug-related)	−0.001 (0.001)	.30	1.00 (−0.003 to 0.0009)
Non–drug-related memberships (%)	−1.39 (0.26)	<.001	0.25 (−1.900 to −0.879)
Substance use models			
Number of posts (substance use)	−0.004 (0.002)	.38	1.00 (−0.011 to 0.004)
Substance use memberships (%)	1.16 (0.60)	.06	3.20 (−0.062 to 2.387)

Discussion

Principal Findings

Using naturally occurring data from the popular online platform Reddit, we examined the risk of a use episode over several years of remission from OUD. Our study tested predictions by the SIMOR that recovery and non–drug-related group memberships sustain remission, whereas substance use groups undermine it. Here, we specifically tested the SIMOR in an *online* environment to provide empirical evidence for the effects of online community memberships that go beyond membership in a single online recovery support group.

Our findings show that a higher number of memberships in non–drug-related online groups are associated with a lower risk of use episodes during OUD remission. The more online non–drug-related groups an individual recovering from OUD becomes part of, the lower the risk of a use episode over time. This effect persisted when membership in recovery and substance use groups was accounted for. These findings support the SIMOR's focus on building non–drug-related group memberships to sustain remission [1]. They also support predictions by the wider social cure literature, which suggests that social groups deliver health benefits and create resilience [4].

In contrast to much of the literature, we found mixed support for membership in recovery support groups. The results indicate that a higher absolute number of memberships in recovery support groups is associated with a reduction in the risk of a use episode but only when other types of group membership are not controlled for. Furthermore, we found a significant increase in the risk for those with a higher proportion of recovery groups among all their Reddit groups.

We offer 2 explanations for this result. First, engaging with several recovery support forums unrelated to opioid remission may indicate that the individual is dealing with polysubstance dependence or has been using multiple substances to self-medicate health issues (eg, chronic pain) or underlying mental health problems (eg, depression and anxiety). Recovering from multiple substances in addition to opioids may increase the chances of a use episode because of the higher risk to mental and physical health [45]. However, this explanation cannot account for the finding that the absolute number of recovery support group memberships reduced the risk of a use episode (or was unrelated to risk when other group memberships were accounted for). A second possible explanation is that a narrow focus on online recovery support groups may be detrimental to sustained remission when online activities do not include participation in non–drug-related groups. Investing primarily in recovery support groups (ie, having a high proportion of recovery support group memberships relative to other memberships) appears to undermine building a resilient social self that incorporates a variety of social identities derived from valued group membership in different spheres of life. This points toward a need for future research to examine the extent to which membership in (online) recovery support groups may reduce engagement with non–drug-related communities and the effects of this on the risk of recurring use episodes and other remission outcomes. Examining the effects of recovery support group membership in isolation may risk missing wider, potentially detrimental effects.

Furthermore, our analysis uses data across several years, thereby examining a longer period of recovery than is usually investigated in the literature, which tends to focus on 6 months to 1 year after treatment. Therefore, it is possible that our findings reflect the importance of non–drug-related identities that replace a *recovery* identity in the long term, as suggested by the SIMOR [1]. Hence, our work provides the first indication that the recovery journey needs to continue beyond building recovery support group memberships and that online communities can play a part in providing a diverse range of non–drug-related group memberships.

We also found inconsistent support for the proposed detrimental effect of substance use groups on the risk of a use episode during remission. Memberships in online communities that promote substance use did not show the expected effect of increasing the risk of a use episode. Instead, we found a significant negative effect of the absolute number of substance use communities on the risk of a use episode. This effect disappeared when other group memberships were controlled for. However, we also found a marginally significant effect that a higher proportion of substance use community memberships increases the likelihood of a use episode. Together, this inconsistent pattern does not unequivocally support the assumption by the SIMOR that substance use group memberships undermine long-term remission.

This finding is surprising as substance use groups on Reddit share pictures of drugs and paraphernalia. Such pictures have been linked to cravings in individuals with substance use disorder [46]. However, our study did not exclusively focus on substance use groups linked to opioids. Those who participate in substance use communities may seek alternative treatments to avoid opioid use [47]. Furthermore, some researchers have challenged the assumption by the SIMOR, as well as similar models, that substance use groups are necessarily detrimental. For instance, qualitative research has shown that groups (and individuals) associated with continuing substance use can provide significant recovery support through information [48] and trusted and emotionally significant friendships [40]. Future research is needed to provide a clearer, as well as a more differentiated, picture of substance use group memberships and their part in the recovery journey.

Importantly, we controlled for posting activity throughout to test whether the number of group memberships or the activity level drives effects. Interestingly, posting activity was positively related to the risk of a use episode, suggesting that those who posted, or commented, more frequently were more likely to report a use episode. Surprisingly, this effect was significant for both recovery and non–drug-related online communities, indicating that this effect was not because of an increased discussion of drug-related issues. Future research should examine whether posting frequency is an early warning sign of recurring use episodes or whether other variables related to posting activities act as risk factors.

Limitations and Future Research

To test the SIMOR and extend previous research on the effects of online community memberships on the risk of a use episode during OUD remission [21], we categorized subreddits into substance use, recovery, and non–drug-related groups. Our discussion of the effects of recovery groups and substance use groups indicates that such a classification might be too simplistic to capture the effects of specific groups on the risk of recurring use episodes. The supposedly neat categorization into these 3 types of groups by the SIMOR has already been criticized elsewhere [40,41,49]. Although such labeling of groups provides some benefits in terms of public health messaging, it may not adequately reflect the complexities on the ground.

Another limitation is the lack of demographic information and other relevant information in our sample. As a result, we cannot statistically control for potential confounding variables such as previous opioid use severity, treatment uptake, comorbidity, and other relevant variables. For instance, individuals who manage to join more online groups during their remission from OUD may have personal skills (eg, self-confidence) and privileges (eg, free time and unrestricted internet access) that allow them to engage with more online communities.

The sample size of our study was smaller than those of other studies that used computational approaches. However, the sample size is still larger than that of the vast majority of studies in the area of social group effects on remission outcomes. Furthermore, sample size is not an indicator of the validity of the findings. It is increasingly being recognized that an important challenge when using online data for clinical or social research questions is that validity is established across all components: a high-quality sample, valid measures, and appropriate statistical methods. As outlined in the *Methods* section, the sample size was determined by methodologically justified steps to ensure valid conclusions. For instance, rather than including all individuals who posted in r/OpiatesRecovery and did not report a use episode into the *no use episode* cohort, we ensured that we had a clear indication from remission status statements that no use episode had occurred where inconsistent remission status statements were made, and a trained psychologist reviewed the case. Similarly, we invested time in labeling a large number of subreddits not only based on their name or mission statement but also by taking the posts in the subreddits into account.

Importantly, our research found that the activity level in communities was unrelated to the risk of a use episode or increased risk rather than lowering it. However, we do not have data for individuals who are entirely passive members of a community; that is, those who read posts but never or rarely post themselves (sometimes referred to as *lurkers*). The CEO of Reddit, Steve Huffman, estimates that two-thirds of the members may fall into this category [50]. Recent research shows that active participation in face-to-face groups is not an attractive or viable option for everyone [14]. Therefore, understanding whether *lurking* is enough to provide a person with a sense of social identity and group resources (eg, advice and shared experience) is a relevant (although technically challenging) avenue for future research.

Practical Implications

Online communities provide a new methodological way of studying remission from substance use disorders. The public and anonymous nature of online communities allows us to examine longitudinal data of those who are in remission over several years, including data from individuals that may be difficult to recruit for traditional surveys or interview studies (eg, those who do not access therapy through the health care system). Much of the literature on social group effects on remission relies on cross-sectional data, with only a few studies testing longitudinally, rarely for more than 6 months or a year at best. Sample sizes tend to be small (often N=20-50 for smaller, cross-sectional studies, with N=200-350 for large studies) and often stem from therapeutic communities or peer-support groups (eg, AA or Narcotics Anonymous), thereby limiting findings to those who already successfully access formal support. Examining online community behavior, such as participation in different online forums, also allows us to observe real-world behavior rather than having to rely on the memory and subjective definitions of participants in survey studies and interviews.

Online communities have the potential to benefit those who are in remission from substance use disorder by providing relatively easy access to social groups. Our findings suggest that fairly minimal engagement with non–drug-related groups can increase resilience during recovery over a long period. Although online communities are not universally accessible because of the requirement for an internet connection and basic literacy and computer skills, they create fewer barriers than many offline groups [14]. They may also provide a sense of continuity to those who need to move their location.

Importantly, our research indicated that an exclusive or narrow focus on recovery support communities may increase the risk of recurring use episodes. Platforms and mutual help communities that offer online support to those in substance use remission but are not part of a wider platform (eg, Reddit) may wish to flag non–drug-related online communities to their members to enable them to build wider social group memberships and avoid a narrow focus on recovery support groups, particularly in the longer term.

Conclusions

Opioid addiction is one of the most pressing public health issues of the day and was declared a national health emergency by the US government in 2017 [51], with an average of 128 overdose deaths from opioids every day in the United States alone [52]. Worldwide, 118,000 deaths in 2015 were directly associated with OUD [53]. Access to therapy and recovery support groups can prove difficult for several reasons, such as a lack of funding, stigma, and personal circumstances. Online groups, such as forums on popular platforms like Reddit, may provide a lifeline for those who are in remission from OUD. Providing evidence-based support for the use of online groups during OUD remission is an important public health task. Here, we provide the first evidence that online forums that are unrelated to substance use and recovery advice can provide social capital that significantly reduces the risk of a use episode across several years significantly—by as much as 6% per additional non–drug-related online community. Our results also suggest that more research is needed to understand the circumstances under which ties with substance use groups may not pose a risk to sustained remission from OUD. Similarly, further research is needed to understand the circumstances under which a narrow focus on online recovery support groups may be harmful during OUD remissions.

Acknowledgments

Abstract

Background: Patients struggling with rare diseases may face challenges caused by care providers being unfamiliar with their condition. The life span of people with rare diseases may be the same as that of healthy people, but their quality of life is different. Patients with chronic pain are constantly looking for ways to mitigate their pain. Pain killers are not a permanent solution. In addition to the medical and nonmedical costs of rare diseases for both patients and health care providers, there is a need for sustainable sources of information that are available to help with pain and improve their quality of life, with the goal of reducing physician visits and hospital admissions.

Objective: This study investigated the challenges that patients with genetic disorders face in managing their health conditions and finding disease-related information as well as the effect of online peer support groups on pain mitigation and care management.

Methods: Interviews were conducted via Zoom between July 2021 and December 2021. Eligible participants were those who were aged >18 years, had a medical diagnosis of any type of Ehlers-Danlos syndrome (EDS) with chronic pain, and were members of any support group. Participants were recruited through an announcement in the research and survey section of The Ehlers-Danlos Syndrome Society web page. Interviews were analyzed using the framework approach. Data were systematically searched to identify patterns, analyze them, and identify themes. Interview audio files were transcribed and independently coded by two researchers (SA and AT). Through an iterative process, a final coding table was agreed upon by the researchers and used to thematically analyze the data.

Results: We interviewed 30 participants (mean age 37.7, SD 15 years; n=28, 93% were women; n=23, 77% were residing in the United States). Thematic analysis revealed that participants (patients with EDS) were constantly in pain and most of them have not received accurate and timely diagnoses for many years. They expressed their challenges with health care providers regarding diagnosis and treatment, and complained about their providers' lack of support and knowledge. Participants' main sources of information were web-based searches, academic journals, The Ehlers-Danlos Syndrome Society web page, and online peer support groups on Facebook, Reddit, Twitter, and Instagram. Although pain killers, cannabis, and opioids are providing some pain relief, most patients (28/30, 93%) focused on nonmedical approaches, such as hot or ice packs, physical therapy, exercises, massage, mindfulness, and meditation.

Conclusions: This study highlights the information gap between health care providers and patients with genetic disorders. Patients with EDS seek access to information from different web-based sources. To meet the needs of patients with genetic disorders, future interventions via web-based resources for improving the quality of care must be considered by health care professionals and government agencies.

KEYWORDS

online peer support group; genetic disorders; pain management; Ehlers-Danlos syndrome; EDS; chronic pain; health care provider; pain mitigation techniques

Introduction

Background

More than 400 million people (30 million Americans) are living with one or more of the 7000 identified rare diseases. Rare diseases encompass many different disorders and symptoms, but approximately 72% of rare diseases are genetic [1]. In this study, our focus was on Ehlers-Danlos syndrome (EDS), a genetic disorder. It is an inherited connective tissue disorder that causes problems in the skin, blood vessels, bones, and other organs. Patients with EDS have to cope with complications such as joint hypermobility or dislocations and damaged skin for their entire life [2]. Similar to other rare diseases, a lack of scientific knowledge and information regarding EDS causes delays in diagnosis. On average, it takes 6 to 8 years for patients to obtain an accurate diagnosis of their disease. There are no Food and Drug Administration–approved drug treatments for >95% of all rare diseases [3]. Therefore, patients with genetic disorders are under considerable pressure to learn about their disease and how they can manage their pain [4]. On the basis of the recent survey results, compared with other diseases such as cancer, patients with genetic disorders did not feel sufficiently supported with issues related to mental health, navigating the health system, physical and daily living, patient care, and sexual needs [5]. The life span of people who are diagnosed with genetic disorders is often the same as that of healthy people, but the quality of their life is usually very different. There are no cures for genetic disorders; therefore, patients cope by mitigating pain and maximizing their quality of life [6].

The availability of health information on the web has increased dramatically over the past decade. A study in 2018 showed that adults in the United States looked on the web for health information 59% more than in 2013 [7]. The study also revealed that, currently, 55% of health care information seekers are relying more on the internet and web-based resources for their health-related information than 5 years ago. More than 67% of American health care information seekers mentioned that they look for health information on social media. The importance of online support groups has been studied among different people [8] with different diseases such as Parkinson disease [9], psychiatric disabilities [10], amyotrophic lateral sclerosis [11], breast cancer [12], chronic diseases [13,14], neuromuscular disorders [15], and alcoholism [16]. Several studies [12,13,17] have discussed the positive impact of online support groups and how patients can benefit from the emotional and community support obtained from such groups. Online support groups are also used for information support. People who faced similar problems can share possible solutions, suggest how to cope with symptoms, and provide information about their disease to other members of the group [11,18].

Objective

This study investigated the approaches followed by patients with EDS to gain information about their disease, find solutions and treatments, and discover pain mitigation techniques. In addition, the effects of online peer support groups on pain mitigation and care management were examined. Information about the challenges faced by patients with genetic disorders with their health care providers is crucial for governments, researchers, health care regulations, and policy makers to be able to improve health care and population health management.

Methods

Overview

This study comprised qualitative, individual, semistructured interviews with patients with EDS to gather perspectives on the care management. Interviews were conducted to investigate the effectiveness of online peer support groups in managing the health conditions of patients with genetic disorders. Transcripts were analyzed using thematic analysis approach, which allows for both inductive and deductive themes to be explored using an iterative, constant comparative coding process.

Ethics Approval

All research activities were approved by the institutional review board of the Sacramento State University (protocol number IRB-19-20-173).

Participants

A total of 30 participants were recruited by advertising the study on The Ehlers-Danlos Syndrome Society web site. Eligible participants were those who were aged >18 years, had a medical diagnosis or a suspected case of any type of EDS with chronic pain, and were members of an online support group.

Recruitment

The recruitment flyer and announcement letter were posted on The Ehlers-Danlos Syndrome Society website. Volunteers for the study were instructed to email the primary investigator to express their interest and learn more about the study. In response to those volunteers, the primary investigator (SA) of the study emailed the e-consent form, study details, time window for the appointment (in PST), and a request for their availability for a 30-minute interview. From July 2021 to December 2021, we received 57 emails and eventually scheduled appointments with 30 (53%) of them. The remaining volunteers (27/57, 47%) did not respond regarding their availability. The interviews were conducted via Zoom, with the participants' permission to record the session.

Data Collection

The semi-instructed interviews were conducted by the first author of the study (SA), using the question guide presented in Multimedia Appendix 1. The discussion began by sharing the experiences of the researcher (SA) as a patient with genetic disorder along with chronic pain and further discussions about the origins of this study. Participants could ask questions at any point during the interview. After explaining the background of the study, participants were asked several demographic questions, leading to questions about their experience with pain and EDS. Participants themselves tended to guide the conversation, and they explained in detail about their journey toward learning more about EDS. The interviewer provided prompts to pursue more detailed discussions on selected topics and help keep the discussions on track.

The main focus of the discussions, along with the research questions, was on (1) pain management techniques, (2) different sources of information about patient's health, (3) use of online support groups in managing one's health condition, and (4) health care providers' roles. The average length of each interview was 45 minutes.

Data Analysis

The interviews were audio-recorded and transcribed verbatim. The research team used inductive thematic approach to develop themes from the interview transcripts. In total, two authors (SA and AT) independently read the 30 transcripts several times to familiarize themselves with the data and identify themes. The 2 authors met to discuss their findings to resolve differences. After this analysis, the authors developed a thematic framework. They also coded all the transcripts using this thematic framework independently. The main topics from the interview guide were used to create the initial deductive codes. Deductive and inductive codes were identified and used, respectively, in our analysis. Then, the authors discussed the results to reach consensus and refine the main themes. NVivo (version 12.2.0; QSR International) was used in this study to organize the transcripts and facilitate analysis.

Results

Overview

Following our template analysis, seven main themes were identified based on patients' experiences of living with genetic disorders and participating in online support groups and their efforts to find solutions for their pain and health conditions. Our themes include (1) patients with EDS disorders are constantly in pain; (2) challenges with health care providers regarding diagnosis and treatment; (3) lack of health care provider support; (4) searching for different sources of information; (5) collection of different pain management techniques; (6) finding disease treatments, lifestyle solutions, and shared experiences in online peer support groups; and (7) changes in health management as a result of participating in online support groups.

Participant Characteristics

A total of 30 English-speaking participants were interviewed in 2021. Participant characteristics are reported in Table 1. Participants had a mean age of 37.7 years. Most participants (28/30, 93%) identified as women, with most of them residing in the United States (23/30, 77%). Our demographics reflect that of the general population with EDS, which is 73.9% women and 26.1% men [19,20]. Most participants (28/30, 93%) were White. In total, >65% of the participants had some college and graduate degree; however, <45% of them were currently working. Owing to chronic pain and health conditions, most of them (17/30, 57%) were temporarily disabled or can no longer work.

Table 1. Participants' characteristics (N=30).

Patients With EDS Disorders Are Constantly in Pain

Patients with EDS are constantly in pain. They expressed their pain frequency as every day and all the time. The level of pain and its location varied among patients. All quotes are presented verbatim, but to improve readability, some filler words such as *like* and *um* were removed. In addition, the information in the bracket at the end of each quote refers to the interviewee's information that we deidentified and coded. A participant described her pain as follows:

> *Every day, I would say that my normal pain level is probably a three to four that's like my normal, but then whenever I'm having a really bad flare it could be up to like seven sometimes eight.* [H-CA]

The participants also showed their frustration of being in constant pain and their desperation to find a cure or treatment:

> *I am in pain everyday all the time, it's pretty ridiculous.* [E-CA]
>
> *I am in pain every minute, every second, every hour, every day, non stop.* [SH-U]
>
> *I probably suffer about 20 to 30 sublocations and dislocations a day, I mean, I've always been in pain.* [El-U]

Challenges With Health Care Providers Regarding Diagnosis and Treatment

Participants shared their difficulties in receiving timely and precise diagnosis from their health care providers. Most of them (25/30, 83%) declared that their disease remained as a mystery for many years before they were diagnosed with EDS:

> *I've always known there's something different about me, but I was not formally diagnosed until February of this year. I've been regressing pretty steadily since March of 2019, but I did not have a formal diagnosis and so. I go to a lot of different doctors to try different things.* [AM-CO]
>
> *I live in a really rural area as well, so our medical care is pretty limited. You know I don't think there's any doctors here that really too familiar.* [SA-TE]
>
> *I'm so used to managing it on my own. Since I was diagnosed over 100 different doctors specialists in*

> *different areas. Doctors are completely useless, most of the time when I start listing my medical conditions I'll get to the third or fourth one and their eyes glaze over and it's like they just assume.* [SA2-CA]

Several participants (8/30, 27%) were misdiagnosed and had to visit different providers to understand their actual problem:

> *I've been hyper mobile since I was a young child and it got misdiagnosed as various things along the way, until we finally landed on what we now know.* [PA-MI]

> *The diagnosis was only recent probably within the last six months, but up until then everyone thought it was fibromyalgia, but I had been tested for Parkinson's and for multiple sclerosis and for arthritis and every other kind of immunological disease that they could think of.* [CH-NA]

> *It's actually more recent diagnosis. I was mistaken as with lupus for a long time.* [EL-U]

Given that participants had to deal with chronic pain for most of their life, they were eager to learn about their disease and treatment solutions through a trusted source such as a health care provider. Lack of knowledge and awareness among physicians and family members has made the life of patients with EDS more difficult:

> *My biggest pain problem was like my legs, and I remember at being two years old crying on the floor of a gas station and my mom's like come on get up. You know because she didn't believe me, and throughout my whole life I've had these leg pains that would come and go, and just nobody knew what it was you know, and I was 46 years old, when I first got diagnosed.* [SA-SC]

> *I have known about it all my conscious life. I have been working on trying to figure out what this hypermobility means and trying to get doctors and medical professionals help me understand what it means, and it's been a long journey. I did the research myself and looked up medical articles. I took that to my doctor, and I said, "I think I have this" and she read it, looked at it and said, "you know, you are probably right." So, I did it myself, that was in probably 2006, 2007.* [KA-CA]

Lack of Health Care Provider Support

One of the main complaints from participants was the lack of support from their health care providers. Many participants (26/30, 87%) mentioned that their medical team was not supportive and did not trust them when they said they were in pain:

> *I've had issues and it's kind of like, you may have this but it doesn't really matter anyway because it's having a lot of other issues that they couldn't put together, so I've known about it for a long time but been diagnosed for about a year. Because that's one of the biggest things right it's like you have doctors that just don't believe you or they don't believe in EDS. And they'll tell you it's all in your head.* [JU-KE]

> *Just that fear of you know, having a doctor be like Oh, this is all in your head you're just looking for attention you're just a girl Blah Blah Blah like everything that I heard from like age seven. My friend said to do stuff to get doctors to take you seriously.* [JE-BO]

Several participants (10/30, 33%) expressed helplessness in their current situation and desire to find a way to manage their health in a less stressful manner:

> *I distinctly remember being kicked out of Tuft's Ehlers-Danlos because I had been fainting left and right and they're like you should try acupuncture or yoga and we think that this is a psychiatric problem.* [JE-BO]

> *I am scared that it is never going to heal right, and I will never have the strength that I used to have.* [ER-U]

Searching for Different Sources of Information

Participants reported searching different sources for disease information and pain mitigation techniques. Approximately all participants (29/30, 97%) were actively searching the internet to learn about their problem and find solutions to manage their health. Among these resources, online peer support groups hosted by Facebook, Instagram, Twitter, Reddit, and Inspire were the most popular. Each of these platforms has its own tools and methods for distributing information:

> *I find the Facebook group very helpful because they are like people chain, for example one kind of antibiotics that we should not use they shared a name, so I know right now. I'm in local EDS group in Italy.* [DA-IT]

> *The nice thing about doing the Instagram awareness thing was a bunch of people were in my group message but I'm already friendly with them and they are like oh hey I have this too, and let's chat and you know so I'll go to them now and be hey have you tried blah blah blah.* [JE-BO]

> *It's been helpful to be able to talk to other people that have it, too, because they go through what you go through, as opposed to like a medical professional that doesn't go through it and they're trying to help you arguing.* [HA-CA]

> *The subreddit for Ehlers-Danlos and be like hey does anybody know of a thing that's useful for like this type of pain Has anybody had any luck with X or Y or Z.* [JE-BO]

Most participants (25/30, 83%) described their approaches to finding information about their disease. As a first step, they searched symptoms and problems on Google. Most of the time, Google directed them to scientific and scholarly pages from medical journals:

> *I go straight to the internet because that's what my doctors are doing, you know even my doctors don't*

> *know what they're up against so there's really no better.* [CH-NA]
>
> *I'll just Google what the issue is and research that and then I usually bring that to my doctor, and I look more than often and look on PubMed for actual research.* [AM-CO]

Another trusted source of information is The Ehlers-Danlos Syndrome Society website. Participants rely heavily on the disease information found in that website:

> *I also usually go to the Ehlers-Danlos society. They have a lot of information and videos and stuff about EDS so I can usually find stuff there. The Ehlers-Danlos society has an LGBT support group and I go to that one exclusively because it's so much better.* [MI-SE]
>
> *The Ehlers-Danlos society that is a really good place to get information.* [KA-U]

Collection of Different Pain Management Techniques

Participants discussed the nonmedical pain management techniques that they learned through online support groups, web searches, and reading other patients' experiences. Many nonmedical pain mitigation techniques that they use include hot and cold packs, mental therapy and meditation, topical creams, diet, braces, distraction, and salt baths:

> *Ice and heat are my best friend.* [PA-MI]
>
> *My greatest tool for dealing with the pain is mindfulness.* [ME-DC]
>
> *I also have some over the counter muscle rub that's a help, I take a muscle relaxer every day because a lot of the pain that I have is from my muscles being so tense because they're doing the job of my joints.* [LY-NA]
>
> *One thing that I am trying to do is take a look at my own nutrition and figure this out. You know, what is helpful, what should I avoid, and it's been a long journey, but I think I am getting closer. Certain foods are irritating, some fruits make me inflamed and retain water and gain weight. The blood type diet is very helpful.* [KA-CA]

Participants shared their experiences with physical therapy, exercises, dry needling, and acupuncture for reducing their pain. They had both positive and negative experiences with physical therapy. They mentioned that the knowledge of the physical therapist and their familiarity with EDS are necessary for achieving a good result in pain reduction:

> *I'm going to physical therapy for the EDS and that's been helping me a ton in terms of the pain. She started me in the pool which was super helpful.* [JE-BO]
>
> *When I first got diagnosed my doctor sent me for physical therapy. After about a month they said you're not getting any better, so we can't help you so that ended, because at the time they did not know how they can help me.* [SA-SO]
>
> *I get dry needling done. It makes such a difference to my functionality and my pain. It's definitely worth finding the right person to do it.* [SA-AU]

Several participants (4/30, 13%) talked about pain management classes that they attended through their health care provider, but the result was not very satisfactory:

> *I was going to the pain management program. They do a lot of stuff like learning how to meditate and calm your system down. They don't use any kind of painkillers. It's all like the mind and body. The only issue with the pain management program is they're not very educated on people with EDS, and so they were having me do everything that everybody else was doing and that could be very harmful to those of us with EDS.* [HE-CA]

Many participants (28/30, 93%), through trial and error and web-based research, found body positions that gave them less pain and great relief. They tried taping, stretching, moving, sitting, and resting in different positions:

> *I move myself every day. To start the circulation in the blood system, because then I don't get stuck. Sleeping well it's good.* [LO-SW]
>
> *It's very important that I listened to my body and lay down when it says lay down.* [LY-NA]
>
> *What position can I put my body in to quiet it and so slowly but surely, I found things, to do the trick. When I got into where I had to keep moving around...* [SU-NY]

Approximately half of the participants (16/30, 53%) mentioned that they had used different drugs such as opioids and cannabis. However, many of them (10/30, 33%) expressed their concern about addiction or developed drug tolerance and could not receive the same relief in the long term:

> *The topical medical marijuana stuff with cannabidiol in it and essential oils, some of those are amazing.* [SA-CA2]
>
> *I don't take any pain medication I had a very, very bad experience over multiple years of being on progressive levels of opioids.* [SA-CA]
>
> *I was taking opioids when I first got diagnosed. I took those for about three years, and I got off of them two reasons, first, I could tell my body was becoming too used to them, and you know I had to take more and more, but also it actually made my pain worse because you know my body got used to it.* [SA-SO]

Although participants named 23 different nonmedical pain mitigation techniques, pain killers were still on everyone's list. For most of them (20/30, 67%), pain killers and anti-inflammatory medication were not sufficient. They have to use multiple techniques to reduce their pain and frustration. Several pain killers were being used: naltrexone, celecoxib, ibuprofen, meloxicam, carprofen, tylenol, and amitriptyline. They also mentioned using antidepressant medicines such as fluoxetine and diazepam or similar products for sleeping problems caused by their persistent pain.

Finding Pain Solutions, Lifestyle Tips and Tricks, and Community Support Through Online Peer Support Groups

Most interviewees (24/30, 80%) were participating in online peer support groups to find pain management solutions, physician and product referrals, natural remedies, or tips and tricks that can make their life easier. They also benefited from sharing their experiences and hearing other patients' stories:

> *I like when people have recommendations or like what works for them. Different kind of tips and tricks, I guess.* [JE-AL]
>
> *Information about my disorder like you dislocate your shoulder What do you do when your shoulder dislocates do you wear a brace like this do you tape it, how did you tape it yourself, do you use YouTube videos learning it like What do you do you know I mean.* [MI-SE]
>
> *I usually go on them like the Amazon recommendations I find those really helpful, especially when I'm trying to buy furniture. I have asked in the past about assistive devices, so you know it's getting hard for me to turn door handles, anybody got a suggestion.* [SA-AU]

Several participants (7/30, 23%) mentioned their gratitude for being able to help and support other people:

> *I am able to help people because I see these people that are just starting on their journey or they are much younger than me and they've been diagnosed, so I can give them these tips that are all my best practices that you know.* [SA-CA]

Another reason why patients are participating in online peer support groups is the discovery of an empathetic community of people with the same health issues. They stated that being part of the EDS community improves their mental health:

> *It's been helpful to be able to talk to other people that have it, too, because they go through what you go through, as opposed to like a medical professional that doesn't go through it and they're trying to help you.* [HE-CA]
>
> *I was like I'm normal within my subset of people, I'm the majority here, so that was kind of cracking me up because you've been the outcast or that you were the outlier, I guess your whole life.* [SA-CA]

Changes in Health Management as a Result of Participating in Online Support Groups

Approximately all participants (29/30, 97%) reported that their health care management changed as a result of participating in online peer support groups. They agreed that they learned more about their condition and how to handle it after using online support groups. Being part of a group made them feel less alone, reduced their stress, and eventually helped with their pain reduction:

> *You know they're a blessing and a curse I think they're invasive at times and they're a little demanding but they're also incredibly helpful I don't think I would have gotten as far along on my own journey with figuring out what was going on with me, it's definitely helped me to take better care of myself really.* [CH-NA]
>
> *It makes me feel less alone, especially you know, being in you understand, you're in your 30s and you're dealing with all this chronic pain. These groups have also made me feel valid.* [HE-CA]
>
> *They help me remember that I am not a normal person. I cannot do some of the things that other people do, and I do have limits and those are good reminders of that. That oh yeah, I do have limits and oh yeah I shouldn't feel bad that I could not eat pizza with all that cheese and gluten and you know, there is a reason why I am choosing to eat the way I eat, and exercise the way I exercise.* [KA-CA]

They described that their participation in online peer support groups helped them to be more vocal about their needs and start taking better care of themselves:

> *If I didn't have the support group I wouldn't be managing my health, the way that I am.* [JU-KE]
>
> *I'm a lot more proactive I know a lot more. I learned so much.* [LO-UK]
>
> *I've learned to be much more advocate for myself because before you know I found out about it, that I had a rare disorder, it was just you have pain, you know you have to kind of deal with it.* [PA-MI]

Discussion

Principal Findings

Overall, this qualitative study provides strong insights from patients with genetic disorders into the challenges of receiving quality care from health care providers, managing their health condition, and finding pain mitigation techniques.

To the best of our knowledge, this study is among the first to explore the challenges faced by patients with genetic disorders with health care systems and their efforts to find solutions and treatments from the internet via online support groups. The results demonstrate that most patients with genetic disorders are disappointed with the help they receive from their health care providers and actively looking for solutions through different academic and web-based resources. Among all resources, most participants agree that online peer support groups have changed the way they were managing their health previously and helped with care management improvement. The findings from this study can be used to inform future studies on the development of new or improved online support groups. In addition, the findings can be used to reduce the gap of information between patients and health care providers.

Comparison With Previous Studies

This study distinguished the utility of traditional physician-patient relationships versus online support groups in obtaining helpful information for the management of EDS symptoms. The focus of this study was to explore the relationship between people and the medical community when the medical community has limited knowledge of a person's disease. We focused on EDS as a representative of the large community of people with genetic disorders and other rare diseases.

All participants (30/30, 100%) reported experiencing consistent pain, which had major impact on their daily life. Interacting with members of the medical community—general physicians, specialists, chiropractors, and physical therapists—left the study participants dissatisfied with the information they were receiving. From inaccurate diagnoses to lack of knowledge about EDS to recommending treatments that would only worsen the symptoms, trust in health care providers was generally lacking. Owing to frustration, these participants turned to alternative sources of information that they were able to find in online support groups. They found these groups to be helpful places for finding information to manage their conditions. Our findings from this study appear to be consistent with those of previous studies regarding the positive effects of support groups in pain education and the increase in the patient's knowledge about their disease [21-24].

Primarily, study participants were looking for information in 4 categories. First, they wanted to know more about their disease and were interested in any new study that was available in medical journals and publications. Second, they were interested in referrals for effective care providers and products such as braces or topical creams. Third, participants were seeking advice for dealing with everyday challenges such as driving or sleeping comfortably. Finally, participants were looking for emotional support from other people with EDS. Previous studies have demonstrated that patients use support groups to write about their pain and express their feelings. Researchers have found that patients were learning about pain management techniques and reducing their dependence on pharmaceutical pain management tools such as opioids [25-27].

All study participants (30/30, 100%) were very actively engaged in managing their health, and most of them (28/30, 93%) had found that the way they managed their health had been positively affected by participating in online support groups. Participants cited emotional support in using a mobility device, discovery of new bracing techniques, learning self-advocacy in relation to care providers, and generally improved self-reliance as some of the ways online support groups helped them to manage their health.

Study participants mainly resided in the United States, but were also residents of Italy, Canada, Sweden, the United Kingdom, Australia, and the Netherlands. Participants in the United States were slightly more likely to have a positive experience within the health care system, but attitudes toward caregivers and online support groups were similar and independent of country.

Although overall opinions of online support groups were positive, most study participants (24/30, 80%) had significant reservations about them. A common experience was the ineffective ways in which information was presented. Many participants (23/30, 77%) expressed dismay at the amount of information they would have to screen to find the specific information they were looking for. Most participants (25/30, 83%) expressed concern about the veracity of the information they were finding and the lack of citation of a trustworthy source. Many participants (20/30, 67%) found the tone of the support groups to be negative, either owing to self-pity or unwarranted criticism of other group members. Most participants (15/30, 50%) also expressed concern about security and privacy and often preferred to be anonymous. Our findings from this study are compatible with those of previous studies regarding patients' lack of privacy and the need for better information dissemination formats [28,29]. Several other studies have focused on the design and technical aspects of online support groups. They stated that web-based platforms should be more user-friendly and help patients to navigate and access information easily [30,31].

Most study participants indicated that health care professionals did not assist them with or direct them toward the online support groups they ended up using. Health care providers were not aware of the benefits of the information available on these sites. Providers were also not aware of the vast amounts of clinical information that users were compiling on online support groups that would be useful in studying EDS. Given that the economic burden of 379 rare diseases in the United States in 2019 was estimated to be approximately US $1 trillion, health care providers can help to reduce these high medical and nonmedical expenditures by referring patients to online support groups [32]. On the basis of the Centers for Disease Prevention and Control, the total costs of top three chronic diseases such as diabetes [33] (US $327 billion in 2017), cancer [34] (US $157 billion in 2020), and heart disease and stroke [35] (US $214 billion in 2018) are far less than the costs of rare diseases.

Future investigations into online support groups will focus on the ways these sites can be structured to directly meet the needs of patients who are chronically ill.

Limitations

A key limitation of the study was the small sample size and self-selection of participants through one website (The Ehlers-Danlos Syndrome Society). Most participants were women (28/30, 93%), and most were White (28/30, 93%). All the participants (30/30, 100%) were English speakers. In addition, we focused only on one rare disease. A study that includes a broad sample of rare diseases using multiple survey instruments across time can provide valuable insights regarding the role of online support groups in the management of rare diseases. Our findings demonstrated the potential value of online support groups in helping patients in managing their health conditions. Further studies may focus on the existing features of current support groups' platforms, *missing* features, and how developers, with the help of health care providers, can improve their platforms to reduce the spread of misinformation and increase the credibility of contents.

Conclusions

Professionals providing care to patients with EDS and other patients with long-term debilitating conditions should consider online support groups as a source of information for assisting their patients with their conditions. By participating in the same sites as their patients, professionals will be able to provide context to the information being posted, and they will add some trustworthiness to the content. These professionals will also gain insight into the needs of their patients that are not being met in the clinical environment.

Abstract

Background: In recent years, an increasing number of users have joined online health communities (OHCs) to obtain information and seek support. Patients often look for information and suggestions to support their health care decision-making. It is important to understand patient decision-making processes and identify the influences that patients receive from OHCs.

Objective: We aimed to identify the posts in discussion threads that have influence on users who seek help in their decision-making.

Methods: We proposed a definition of influence relationship of posts in discussion threads. We then developed a framework and a deep learning model for identifying influence relationships. We leveraged the state-of-the-art text relevance measurement methods to generate sparse feature vectors to present text relevance. We modeled the probability of question and action presence in a post as dense features. We then used deep learning techniques to combine the sparse and dense features to learn the influence relationships.

Results: We evaluated the proposed techniques on discussion threads from a popular cancer survivor OHC. The empirical evaluation demonstrated the effectiveness of our approach.

Conclusions: It is feasible to identify influence relationships in OHCs. Using the proposed techniques, a significant number of discussions on an OHC were identified to have had influence. Such discussions are more likely to affect user decision-making processes and engage users' participation in OHCs. Studies on those discussions can help improve information quality, user engagement, and user experience.

KEYWORDS

influence relationship; decision-making threads; online health communities; patient engagement; deep learning; text relevance measurement

Introduction

Background

In recent years, online health communities (OHCs) such as the Cancer Survivors Network (CSN), MedHelp, DoctorLounge, WebMD, and Health-boards message boards have become one of the most important resources that patients leverage [1]. An OHC is defined as an asynchronous web-based message board system for patients that contains multiple message boards, each of which typically focuses on 1 disease. OHCs provide a web-based channel that enables information exchange, facilitates communication, and provides support to patients and caregivers [2-4]. They are especially valuable for patients with chronic diseases to learn about their conditions and seek social support [5,6].

Empowering and supporting patients to make informed health care decisions is a key component of patient-centered health care and is a social, economic, and technical necessity [7,8]. A lot of patients seek information and advice on OHCs. Existing work has found that nearly half of the threads in a breast cancer forum [9] are related to patient decision-making [1]. Studies have also shown that patients are often influenced by web-based sources and social media in their health care decision-making [10,11].

Objectives

The goal of this study was to identify the influence relationship of posts in discussion threads related to health care decision-making. Specifically, we defined the influence relationships and identified post replies that influenced the initial author, who had questions posted on OHCs.

The outcomes of this study are important for health care professionals to help patients make informed decisions for several reasons. First, analyzing the writing style and pattern of posts that have influence may help explain why they have influence and provide insights to health care professionals on effective communication with patients. Second, if the information provided by posts that have an influence is not accurate, it will mislead patients. It is important to check the information quality in such posts to improve the quality of influence. Furthermore, a patient who has questions but does not receive any replies that have an influence may need further help.

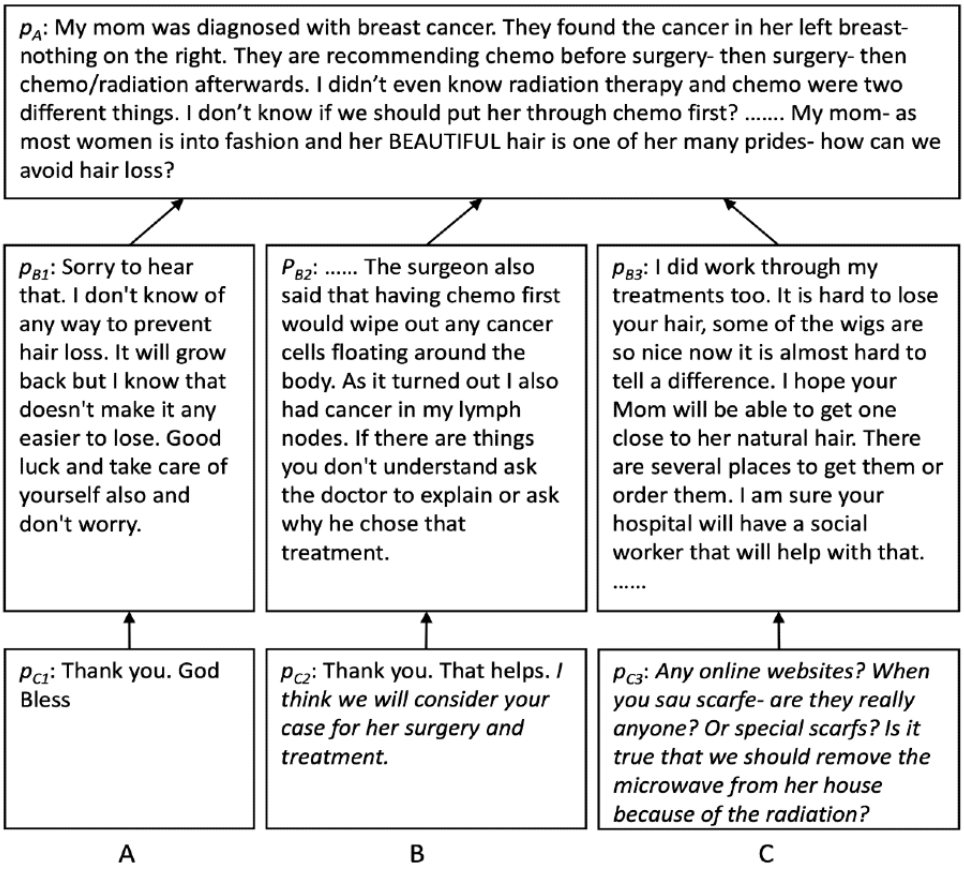
Literature Review

There is a lot of research conducted on OHC analysis, although with limited study on identifying influence relationships of posts. Several studies have been conducted on analyzing the reciprocal patterns between users' replies in discussion forums [12-14]. There is also work on analyzing the patterns between post views and post replies [15]. Many studies have been conducted on identifying influential users in a community [16-20]. In those applications, a post, blog, or tweet typically expresses an opinion of the author, and the replies are considered as an indication of being influenced by the opinion of the original post. That is, the reply relationship is considered as an influence relationship. The focus is on judging the influential power of an author based on activeness of post writing [21] and social network features [17,18] such as PageRank-like algorithms or clustering algorithms.

Finding influence relationships among posts in discussion forums is different from finding influential users and requires different techniques. In an OHC, the initial author of a thread typically expresses a question, not an opinion. The influence happens when a reply to the question affects the initial author. There are only 2 existing studies that consider the influence of the replier on the initial author [21,22]. This influence is identified when the sentiment of the initial author is changed to be similar to that of the replier. However, this definition may not be accurate.

Let us look at an example of a discussion thread related to patient decision-making, shown in Figure 1. An OHC user initialized a thread asking for advice on whether to have chemotherapy before surgery for her mother's treatment plan in post p_A.

Figure 1. Example of a discussion thread.



p_A: My mom was diagnosed with breast cancer. They found the cancer in her left breast- nothing on the right. They are recommending chemo before surgery- then surgery- then chemo/radiation afterwards. I didn't even know radiation therapy and chemo were two different things. I don't know if we should put her through chemo first? .... My mom- as most women is into fashion and her BEAUTIFUL hair is one of her many prides- how can we avoid hair loss?

p_{B1}: Sorry to hear that. I don't know of any way to prevent hair loss. It will grow back but I know that doesn't make it any easier to lose. Good luck and take care of yourself also and don't worry.

P_{B2}: ...... The surgeon also said that having chemo first would wipe out any cancer cells floating around the body. As it turned out I also had cancer in my lymph nodes. If there are things you don't understand ask the doctor to explain or ask why he chose that treatment.

p_{B3}: I did work through my treatments too. It is hard to lose your hair, some of the wigs are so nice now it is almost hard to tell a difference. I hope your Mom will be able to get one close to her natural hair. There are several places to get them or order them. I am sure your hospital will have a social worker that will help with that. ......

p_{C1}: Thank you. God Bless

p_{C2}: *Thank you. That helps. I think we will consider your case for her surgery and treatment.*

p_{C3}: *Any online websites? When you sau scarfe- are they really anyone? Or special scarfs? Is it true that we should remove the microwave from her house because of the radiation?*

In Figure 1A, a user replied by comforting her in post p_{B1}. The reply was not informative. Even though the initial author expressed gratefulness to the author of post p_{B1}, with sentiment changing to be positive in post p_{C1}, she was not influenced by post p_{B1}. Indeed, studies show that 75% to 85% of CSN forum participants change their sentiment in a positive direction through web-based interactions with other community members [23]. A change in sentiment is not necessarily an indicator of being influenced.

In contrast, in Figure 1B, a user shared her experience in a similar situation suggesting to have chemotherapy before a surgery in post p_{B2}. The initial author expressed her gratitude and indicated that she would consider this suggestion in determining her mother's treatment plan (the sentences in italics) in p_{C2}, showing her being influenced.

Contribution

Instead of considering sentiment changes, we propose using questions or future actions on relevant replies as an indicator of being influenced, as illustrated in the aforementioned example. There are 2 major challenges in identifying influence relationships. First, we need to define influence relationships of posts. We examined the semantics of post content to define influence relationships. Unlike influential users, who are defined by network features in the existing work [16-20], text content is the key to determine whether posts have influence. Second, it is hard to identify influence relationships. Unlike typical text classification problems, influence relationships involve multiple posts with reply relationships rather than a single paragraph of text. In addition, influence is an abstract concept. It is challenging to extract relevant features to capture the influence patterns considering both content and the reply relationship.

This study makes novel contributions to identifying influence relationships in discussion threads in OHCs related to patient decision-making. Specifically, (1) we defined the influence relationship between the posts based on the semantics of the post content, (2) an extensible deep learning model that extracts and combines both sparse and dense features was proposed to identify the influence relationships in OHC decision-making threads, and (3) the proposed model achieved good performance in identifying influence relationships in empirical evaluation.

Methods

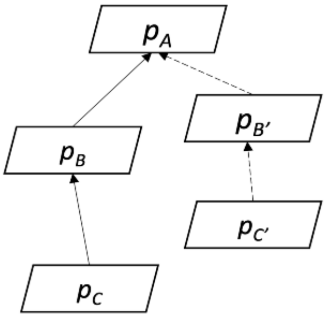
In this section, we first model the OHC data and define the influence relationship in discussion threads. We then propose a deep learning–based model to identify the influence relationships.

Problem Definition

Definition of Discussion Threads

Figure 2 presents an overview of the OHC data structure. We modeled an OHC as a set of discussion threads $T = \{t_1, t_2,..., t_n\}$. Each thread t_i is composed of a set of posts and a function R that represents the reply relationship. For example, Figure 2 illustrates a thread that contains a set of 5 posts $\{p_A, p_B, p_C, p_{B'}, p_{C'}\}$. One of the reply relationships, $R(p_B) = p_A$, represents that post p_B replies to post p_A. Each post p_i consists of a sequence of sentences $p_i = \{s_1, s_2,..., s_l\}$. Each post has an author. We denoted the author relationship using a function U. $U(p_i)$ represents the author of post p_i. Note that a post only has a single author; however, an author may write ≥0 posts in a thread. We used p_A to present the first post of a thread and named it the *initial post*. The author of the *initial post*, $U(p_A)$, is referred to as the *initial author* of the thread.

Figure 2. Data structure of an online health community.



Existing work [1] has studied the thread discussions in OHCs and identified that a subset of threads is related to *patient decision-making*. Such a thread is characterized by questions in the initial post and replies with suggestions of options. Techniques have been developed to identify decision-making threads in OHCs.

In this paper, we study how to identify the cases where the initial author of a decision-making thread is influenced by a reply post. Note that our study is general to any thread discussions related to decision-making. The definition and identification of decision-making threads can be handled using the approach developed in existing work [1] or other approaches. In the rest of this paper, we use *threads* to refer to decision-making threads for simplicity. The defined influence relationship may not be applicable to discussion threads that are not related to decision-making, such as discussion threads for casual communication or experience-sharing threads providing social support.

Definition of Relationships

Overview

Before introducing the definition of *influence relationships*, we first introduce relationships. A relationship is defined on a triple of posts in a thread with reply relationships: an initial post, a reply to the initial post, and the initial author's subsequent reply.

Definition 1 (Relationship)

We define the relationship among three posts p_A, p_B, and p_C, in a thread as $r_i = (p_A, p_B,$ and $p_C)$, where post p_A is the initial post of the thread, post p_B replies to p_A, post p_C replies to p_B, and the authors of p_A and p_C are the same person. That is, $R(p_B) = p_A$, $R(p_C) = p_B$, and $U(p_A) = U(p_C)$.

We used $r_i = (p_A, p_B, p_C)$ to denote the relationship among p_A, p_B, and p_C. Note that there are many such relationships in a thread, and we considered all such triples. For instance, Figure 2 shows a thread with 2 relationships, $r_1 = (p_A, p_B, p_C)$ and $r_2 = (p_A, p_{B'}, p_{C'})$.

Also, note that existing work on identifying influential users [16-20] does not consider the relationships among post triples but only considers the reply relationship between 2 posts.

Definition of Influence Relationships

Intuition

Now, we discuss how to define *influence relationships* on relationship (p_A, p_B, p_C), where post p_B has an influence on the initial author $U(p_A)$.

First, intuitively, if post p_B influences the initial author $U(p_A)$, then the content of these 3 posts must be relevant.

Second, we referred to the definition of *influence* in Merriam-Webster [24]—"to affect or alter by indirect or intangible means"—and the reaction of *being influenced* is to *sway* rather than being convinced. If the initial author considers the suggestion given in post p_B, even if she eventually does not take the suggestion, she is considered to have been influenced by post p_B. On the basis of this definition, we observed 2 indications that the initial author, $U(p_A)$, was influenced by p_B.

An observation of being influenced is that the initial author may ask questions in p_C based on the suggestions in p_B. Curiosity is a motivator for learning and influential in decision-making [25]. An existing study [26] used a statistically large sample of learning forum posts to investigate whether student participation in the forum could be influenced. They observed that students who were influenced by others' interesting answers were more likely to ask follow-up questions. This indicates that asking further questions is a sign of being influenced. The same pattern also exists in OHCs. Let us look at the example in Figure 1C. The initial author expressed concerns about hair loss in p_A. Another user replied in post p_{B3} suggesting the use of wigs. The initial author then replied in post p_{C3} with questions (the sentences in italics) for more details about the suggestion given in post p_{B3}. These questions indicate that the initial author was thinking about the suggestion given in post p_B; that is, being influenced.

The second indication that the initial author was influenced by a post p_B is that she expressed her intention to take action in post p_C. Adjei et al [27] found that member-to-member communication in web-based brand communities greatly influenced the members' future purchase behavior. Similarly, the communication through discussion threads in OHCs may also affect the initial author's future actions. Let us look at the example in Figure 1B again. For the treatment question asked in p_A, a forum user shared her experience and discussed the treatment in post p_{B2}. The initial author then replied with a planned action (the sentence in italics) in p_{C2}. The intention of future action based on the communications in the thread is an indicator of the influence relationship.

On the basis of these observations, we define influence relationships in decision-making threads in the following section.

Definition 2 (Influence Relationship)

A relationship $r_i = (p_A, p_B, p_C)$ is considered as an influence relationship—that is, $U(p_A)$ is influenced by p_B—if and only if the following conditions are met: (1) the content of p_B is relevant to post p_A, (2) the content of p_C is relevant to post p_B, and (3) p_C contains questions or indicates future actions.

To identify influence relationships, we modeled it as a classification task. Given a set of relationships $R = \{r_1, r_2,..., r_n\}$, for each relationship r_i, we predicted its label to be either 1 or −1, where label 1 indicated that r_i was an influence relationship and label –1 indicated that r_i was not an influence relationship. The goal was to learn a model from the labels of known relationships and predict the labels for unlabeled relationships.

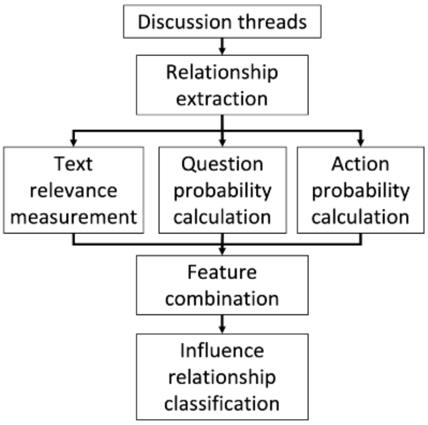
Model Design

Overview

In this section, we present the method to identify the influence relationships in decision-making threads in OHCs. Figure 3 presents the framework of the proposed method.

Given a set of discussion threads as the input, we first extracted the triple relationships using the relationship extraction module. Text relevance features, question probability features, and action probability features were then calculated using the text relevance measurement module, the question probability calculation module, and the action probability calculation module, respectively. Finally, all the features were combined using a deep learning model in the feature combination module to generate the probability of a relationship being an influence relationship.

Figure 3. Workflow of influence relationship identification.



Relationship Extraction Module

In this section, we introduce the relationship extraction module, which extracted all relationships defined in definition 1.

In the first step of relationship extraction, we built the reply tree structure based on the indented format in html files. For each adjacent post pair, the post that was posted earlier was treated as the parent of the latter post. The ancestor-descent distance between a post and the initial post was represented by the number of tab characters. The reply structure of a thread is illustrated in Figure 2. Each post is a node in the thread tree, and each edge represents a reply relationship. The root of the thread tree is the initial post (ie, p_A) in definition 1.

Existing work observes that, in some forums, the reply structure in a discussion thread may not be fully available and proposes techniques to construct full reply structures [28]. The OHCs used in our experiments had a full reply structure. Existing techniques can be leveraged if needed for other forums.

We then navigated the thread tree to extract all relationship triples, as defined in definition 1. Each triple started with the initial post followed by a reply to the initial post written by another author and then a subsequent reply by the initial author, all of which were on the same path in the thread tree. For example, $r_1 = (p_A, p_B, p_C)$ and $r_2 = (p_A, p_{B'}, p_{C'})$ are 2 relationships in the thread tree in Figure 2.

Text Relevance Measurement Module

The text relevance measurement module measures the content relevance, or text semantic similarity, of 2 posts using a relevance score between 0 and 1.

There are mainly 2 types of deep learning–based methods in the literature that measure text relevance. The first type of method extracts content feature vectors of 2 input texts and then combines them to make a prediction, such as the Deep Structured Semantic Models (DSSM) [29], the Convolutional DSSM [30], and Architecture-I (ARC-I) [31]. The intuition of this method is to highlight the important information of the original texts so that irrelevant content can be removed before the feature combination phase. However, the drawback of this type of method is that it runs the risk of losing detail [32].

The second type generates the word-level relevance first and then uses neural networks to learn the hierarchical interaction patterns for content-level relevance, such as DeepMatch [33], Architecture-II (ARC-II) [31], and MatchPyramid [34]. The motivation is that making a good relevance judgment requires considering the interactions in the text relevance measurement process, starting from the interactions between words to patterns in phrases and those in whole sentences [34]. However, the training process for the second type is much more expensive than for the first one.

We evaluated both approaches to measure text relevance in experiments. We chose 2 state-of-the-art representative methods for the text relevance measurement module in the evaluation. For the first type, we chose ARC-I [31], which uses a multilayer perceptron to combine relevance feature vectors. It shows better performance than the DSSM [29] and Convolutional DSSM [30], both of which use cosine similarity [34]. We chose MatchPyramid [34] to represent the second type of method as it exhibits better performance than the other 2 methods (DeepMatch [33] and ARC-II [31]) in experiments on multiple data sets [34].

We further proposed the adaptation of Bidirectional Encoder Representations from Transformers (BERT) [35] as the embedding layer in the ARC-I and MatchPyramid models. BERT is a state-of-the-art embedding method for word representation in many natural language understanding tasks, trained on BookCorpus and English Wikipedia. We considered both BERT (trained on Wikipedia) and word2vec (trained on the training data set) as the embedding methods for both ARC-I and MatchPyramid. Different variations of the text relevance measurement module are evaluated in the *Text Relevance Evaluation* section.

Question Probability Calculation Module

We now discuss how to calculate the probability of a post containing a question using the question probability calculation module.

There are 2 types of methods to identify question sentences in forums: a rule-based approach and a learning-based approach. In a rule-based approach, question marks and 5W1H words (what, who, when, where, why, and how) are used to identify question sentences [36]. A learning-based approach uses sequential question patterns to train a binary classifier on labeled data [37-40]. Liu and Jansen [37] used the question mark to extract question posts from Sina Weibo. In the studies by Ranganath et al [38,39], frameworks were proposed to identify rhetorical questions by modeling the motivation of the user for posting them. In the study by Ojokoh et al [40], questions from ResearchGate were identified based on the maximum probability value of a naïve Bayes classification with part-of-speech tag features.

Both rule-based and learning-based approaches can achieve excellent performances. A study shows that a rule-based approach can outperform complicated learning-based approaches [36]. Thus, we followed a rule-based method [36] to identify question presence in the posts. In total, 2 types of rules were considered: question marks and 5W1H words. We made adaptations of this approach for OHCs. As a question mark is the most significant sign of a question, we gave a higher confidence score to a sentence with a question mark. We also set some constraints on 5W1H words to simulate the pattern of question sentences. First, 5W1H must appear at the beginning of a sentence. Second, auxiliary words were added to the original words for more specific patterns. For example, we considered *what is*, *what are*, *what does*, and *what do* instead of *what*.

After the question probability of each sentence in a post p_i was calculated, the maximum probability was used as the likelihood of post p_i containing at least one question, denoted as $Q(p_i)$.

Action Probability Calculation Module

This section presents the action probability calculation module, which generated the probability of action presence in a post.

The indication of a future action can be captured by the presence of verbs and appropriate sentence tense. The Natural Language Toolkit (NLTK) [41] tagger module defines a standard interface for augmenting each token of a text with supplementary information, such as its part of speech or its WordNet synset tag, and provides several different implementations for this interface. We leveraged the NLTK tagger module to assess the likelihood of a post containing future actions by checking the existence of words with a future tense verb tag (eg, *will consider* in Figure 1B) or a modal auxiliaries tag (eg, *can*, *could*, *may*, and *must*). To count on the cases where future tenses may not be identified because of forum users' typos or informal writing, we set the probability of future action to be 0.5 when the rules failed to identify future actions. Equation 1 shows the calculation formula to generate the action probability of a post p_i.

Note that we did not consider negation in the action probability calculation module. For example, in post p_C, the initial author disagrees with the suggestions proposed in p_B and decides to do something different. For those cases, the overall meaning of p_B and p_C would be the opposite and, therefore, would be captured by the relevance vectors generated in the text relevance measurement module. Thus, we did not consider negations in this phase to avoid double counting.

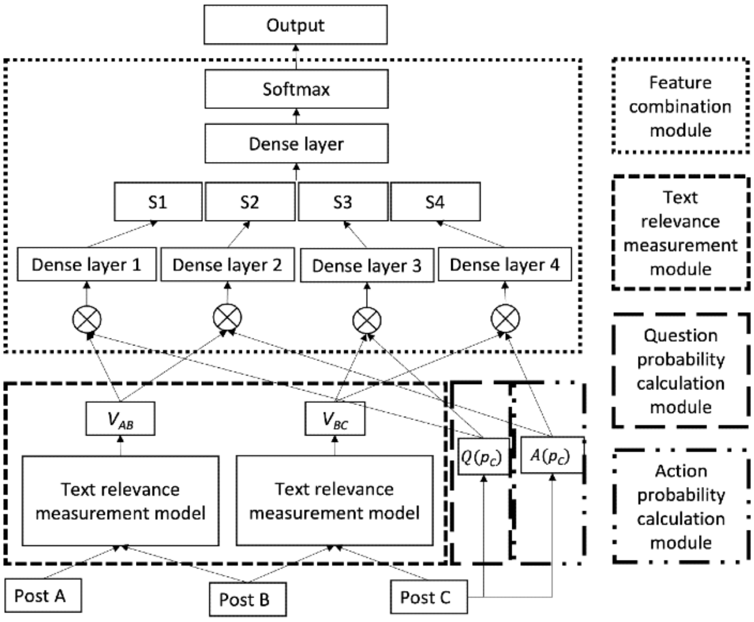
Feature Combination Module

Overview

Referring to Figure 4, the text relevance measurement module calculated P_{AB}—the relevance score between p_A and p_B—and P_{BC}—the relevance score between p_B and p_C. The question probability calculation module and action probability calculation module calculated the question probability $Q(p_C)$—or Q in short—and action probability $A(p_C)$—or A in short—based on the text of p_C.

We now discuss the feature combination module that measures the influence score based on these features. We discuss 2 alternative methods: *a baseline approach* and *a deep learning model*.

Figure 4. Architecture of the feature combination module.



Baseline Approach

Recall that, according to definition 2, the presence of an influence relationship requires the relevance between post p_A and post p_B, the relevance between post p_B and post p_C, and the presence of a question or action in post p_C. We started with an intuitive method to detect influence relationships based on the definition using Equation 2.

$$P_{baseline} = P_{AB} \times P_{BC} \times \max\,[Q(p_C), A(p_C)]\ \mathbf{(2)}$$

We set the thresholds to 0.5, 0.5, and 0.9 for each component.

Deep Learning Approach

We further proposed a deep learning model that combines the text relevance, the likelihood of question presence, and the likelihood of future action presence to identify influence relationships. The architecture of this model is shown in Figure 4.

Compared with the *baseline* approach, there are 3 major benefits of using a deep learning model. First, it is labor-intensive, time-consuming, and difficult to determine appropriate thresholds for cutting off the probabilities using a rule-based approach such as the *baseline* approach. A threshold that works well for one data set may not be optimal for another. Both a rule-based approach and a deep learning model require different thresholds for different data sets. A rule-based approach requires manual parameter tuning for each data set. In contrast, a deep learning approach learns thresholds from the ground truth and, thus, can easily adapt to a new data set with minimal human intervention [42]. Second, the question and action features may have different interactions with the relevance features. We observed that questions are often relevant, but actions are not necessarily. People typically express appreciation in post p_C or sometimes even mention actions totally irrelevant to post p_B, such as the plan to travel or shop. Being relevant is more important to consider in the presence of actions compared with in the presence of questions. However, in the *baseline* approach, the question and action features are merged before being combined with the relevance features, resulting in the loss of important information. Furthermore, we used relevance vectors as inputs to the deep learning model to calculate the influence score. Compared with the *baseline* approach, which uses the relevance scores as input to measure the influence score, relevance vectors provide much richer information. This can be especially helpful when there are several topics involved in the discussion. The relevance information is also leveraged during the phase of combining the relevance features with the question or action features.

Let V_{AB} denote the relevance vector between p_A and p_B and V_{BC} denote the relevance vector between p_B and p_C. We generated V_{AB},V_{BC} from p_A, p_B, and p_C and calculated Q and A from p_C.

These features were then connected. The question or future action in p_C must be related to the content of p_A and p_B. Thus, we combined V_{AB} and V_{BC} with Q and A using one of the following two operators: (1) *cat* (concatenating each relevance vector with question or action probability) and (2) *dot* (multiplying each relevance vector with question or action probability).

There are 2 major differences between these 2 operators for connecting the features: *cat* and *dot*. First, *dot* makes sure that Q and A affect each dimension in the relevance vectors, whereas *cat* cannot guarantee this as some neurons or nodes are dropped out. Some interactions between questions or actions and text relevance may be ignored by the *cat* operator. Second, the training process of the *cat* is more expensive than that of the *dot* because, for each dense layer 1 to 4, there is an additional dimension for the *cat* compared with for the *dot*.

In Figure 4, we use ⊗ to present the combination operator, which can be either *cat* or *dot*. The combination step produces 4 feature vectors: $V_{AB} \otimes Q$, $V_{AB} \otimes A$, $V_{BC} \otimes Q$, and $V_{BC} \otimes A$. To extract the key information from these combined feature vectors, 4 dense (fully connected) layers were used to populate the summarized feature vectors (S_1, S_2, S_3, S_4). The concatenation of these 4 summarized feature vectors was passed through 2 dense layers. The first one was used to further combine the summarized feature vectors. The second one aimed to generate the probability distribution over the labels. To avoid gradient vanishing and exploding [43], we chose the *Relu* function as the activation function for all the dense layers except the output layer, which uses the *softmax* function to populate the probabilities.

We trained the model using the binary cross-entropy loss function defined in Equation 3, which minimizes the distance between the probability distributions of the ground truth and those of the predicted score.

Where y_i is the ground truth label of the ith training sample and s_i is the score predicted by the model. The Adam optimizer [43] was leveraged for optimization because of its advantage of processing sparse features and obtaining faster convergence compared with the normal stochastic gradient descent with momentum.

Ethics Approval

All materials were obtained from anonymous open-source data. Thus, ethics approval was not required.

Results

Experiment Setting and Evaluation Metrics

We implemented a prototype system for influence relationship identification on discussion threads. The prototype system and data sets used in the evaluation are publicly available at GitHub [44].

For empirical evaluation, we collected 25,208 threads that were publicly available in the CSN breast cancer forum [9]. The webpages were collected and processed by a web crawler we developed leveraging the Spider Crawler library [45]. There were 321,000 posts with 1.9 million sentences in total. We applied the classifier proposed by Li et al [1] on all 25,208 threads to identify the ones that were related to patient decision-making and obtained 11,815 (46.87%) such threads. Note that other models for classifying decision-making threads can also be plugged in.

We then extracted relationships from the decision-making threads using the relationship extraction module and obtained 9053 relationships. We randomly picked 853 (9.42%) of them to label. A total of 4 PhD students worked on the manual labeling. All the relationship triples and post pairs were first independently labeled. In case of disagreement, a consensus was reached after discussion. A total of 261 relationships were labeled as influence relationships. Recall that, per definition 1, each relationship is presented as a triple (p_A, p_B, p_C). We also labeled whether posts p_A and p_B were relevant (ie, P_{AB}) and whether posts p_B and p_C were relevant (ie, P_{BC}). We observed some reply posts with content expressing only comfort or wishes. Although they express care about the initial author's conditions and seem relevant, they are generic. After discussion, we reached an agreement that, when the initial post and reply post shared similar medical terms (such as *chemotherapy* and *chemo*), we would label them as relevant. All 1706 post pairs (p_A, p_B) and (p_B, p_C) of the 853 relationships were labeled. Of the 1706 pairs, 1210 (70.93%) were relevant pairs, and the remaining 496 (29.07%) were irrelevant. We split the set of relationships into a training set (90%) and a testing set (10%). The post pairs in the aforementioned training and test sets were used for text relevance training and testing, respectively.

The metrics used for evaluation included precision, recall, F_1 score, accuracy, area under the receiver operating characteristic curve (ROC AUC), and area under the precision-recall curve (PR AUC). They evaluated the effectiveness of a system using different aspects: (1) *precision*, also known as positive predictive value, is the fraction of relevant instances among the retrieved instances; (2) *recall*, also known as sensitivity, is the fraction of relevant instances that are retrieved among all relevant instances; (3) *F_1 score* measures a model's performance by calculating the harmonic mean of the precision and recall, as shown in the following equation: **(4)**; (4) *accuracy* is a common evaluation metric for binary classification problems and is defined as the fraction of corrected predictions among the total number of predictions; (5) *ROC AUC* is a common evaluation metric for binary classification problems and is created by plotting the true positive rate against the false positive rate at various threshold settings; and (6) *PR AUC* is commonly used to evaluate the performance of a model on data sets with imbalanced labels.

Text Relevance Evaluation

Table 1 presents the classification results of the text relevance measurement module. In total, 2 observations were made. The first observation was that the models using BERT achieved high recall but low precision, whereas the models with word-embedding vectors trained on OHC data obtained balanced precision and recall values. There are 2 reasons for these results. First, OHC data are domain-sensitive and can benefit from domain-specific word representation. Second, the BERT transformer tends to link words in adjacent sentences by mistake. In the text relevance measurement module, precision was more important than recall as the accuracy of influence relationship identification depended on the precision of relevance classification. Thus, we used the word vectors trained on OHC data instead of BERT in the following experiments.

Table 1. Text relevance measurement module results.

	Precision	Recall	F_1	Accuracy	ROC AUC[a]	PR AUC[b]
MatchPyramid with BERT[c] (trained on Wikipedia)	0.578	*0.992*[d]	0.730	0.512	0.502	0.583
MatchPyramid with word2vec (trained on the training data set)	0.781	0.820[d]	*0.806*	0.692	0.763	0.854
ARC-I[e] with BERT (trained on Wikipedia)	0.523	0.890[d]	0.659	0.503	0.493	0.554
ARC-I with word2vec (trained on the training data set)	*0.832*	0.747[d]	0.785	*0.784*	*0.848*	*0.903*

[a] ROC AUC: area under the receiver operating characteristic curve.

[b] PR AUC: area under the precision-recall curve.

[c] BERT: Bidirectional Encoder Representations from Transformers.

[d] The P value is statistically significant at P=.05.

[e] ARC-I: Architecture-I.

The second observation was that, with word vector embedding, ARC-I achieved a better performance than MatchPyramid in most of the evaluation metrics. In the ARC-I model, each input text goes through an embedding layer, a convolution layer, and a max pooling layer, and the extracted feature vectors are then concatenated together as the input to a fully connected layer that calculates the predicted relevance scores. MatchPyramid populates the local word relevance matrix first. Each cell of the matrix presents the dot product of the word-embedding vectors of the words in the text input. The patterns of these interactions are then extracted using a convolutional neural network [46]. Thus, ARC-I focuses on checking relevance based on the meaning of the whole text, whereas MatchPyramid focuses on summarizing the important relevance features based on local word similarity. For OHC data sets, posts were relatively long and often contained noisy information; thus, considering the meaning of the entire post text was more important than focusing on adjacent words. This is why the performance of ARC-I was better than that of MatchPyramid in our evaluation. We also observed that *ARC-I* with word2vec outperformed *MatchPyramidwith word2vec* in both *ROC AUC* and *PR AUC* but had an inferior *F_1 score*. Note that F_1 averages the performance of all the samples by combining the precision and recall, whereas the ROC AUC and PR AUC cumulate the precisions among all samples with different recall thresholds. This indicates that the average performance of *MatchPyramidwith word2vec* was better, but the overall performance of *ARC-Iwith word2vec* was better.

Question and Action Probability Evaluation

Now, we present the evaluation of the question probability calculation module and the action probability calculation module. The performance is shown in Table 2. Good performance was achieved for question identification. For future action identification, a high score was achieved on recall but not on precision. The following are a few examples of posts that are classified as containing future actions but actually do not have action intent: *I will tell you though I hated my silicone* or *I would worry about it*. These sentences have verbs in the future tense, but those verbs only convey opinions or feelings rather than taking action on health care. We plan to improve action detection by training action sentence models as future work.

Recall that in the *deep learning* approach, question and action probabilities are considered as input features instead of imposing a strict requirement on their presence. We conducted an analysis on the test data in terms of their presence. All positive cases either had a probability of action presence of 1.0 or had a high probability of question presence, with an average probability of 0.986 (SD 0.033). This indicates that the *deep learning* approach captures definition 2 well, ensuring the high likelihood that either a question or a future action is present.

Table 2. Question and action calculation module results.

	Precision	Recall	F_1	Accuracy	ROC AUC[a]	PR AUC[b]
Question probability calculation module	*1.000*	*1.000* [c]	*1.000*	*1.000*	*1.000*	*1.000*
Action probability calculation module	0.771	*1.000* [c]	0.871	0.810	0.733	0.771

[a] ROC AUC: area under the receiver operating characteristic curve.

[b] PR AUC: area under the precision-recall curve.

[c] The *P* value is statistically significant at *P*=.05.

Influence Relationship Classification Evaluation

Table 3 shows the performance of the *baseline* and *deep learning* approaches with alternative ways to combine text relevance vectors, question features, and action features. Recall that, for the feature combination module, *baseline* combines the text relevance score, the likelihood of question presence, and the likelihood of future action presence to identify influence relationships. *MatchPyramid+cat Q/A* represents the model using *MatchPyramid* to calculate the text relevance score and *cat* as the combination operator ⊗, whereas *MatchPyramid+dot Q/A* uses *dot* as the combination operator ⊗. *ARC-I+cat Q/A* represents the model using *ARC-I* to calculate the relevance score and *cat* as the combination operator ⊗, whereas *ARC-I+dot Q/A* uses *dot* as the combination operator ⊗.

Table 3. Influence relationship classification results.

	Precision	Recall	F_1	Accuracy	ROC AUC[a]	PR AUC[b]
Baseline	0.300	0.231[c]	0.261	0.595	0.495	0.307
MatchPyramid+cat Q/A[d]	0.667	0.154[c]	0.25	0.714	0.560	0.442
MatchPyramid+dot Q/A[e]	0.633	*0.577* [c]	*0.603*	0.667	0.634	0.481
ARC-I+cat Q/A[f]	0.667	0.154[c]	0.25	0.714	0.637	0.515
ARC-I+dot Q/A[g]	*0.750*	0.462[c]	0.571	*0.786*	*0.724*	*0.631*

[a] ROC AUC: area under the receiver operating characteristic curve.

[b] PR AUC: area under the precision-recall curve.

[c] The *P* value is statistically significant at *P*=.05.

[d] MatchPyramid+cat Q/A: model using *MatchPyramid* to calculate the text relevance score and *cat* as the combination operator ⊗.

[e] MatchPyramid+dot Q/A: model using *MatchPyramid* to calculate the text relevance score and *dot* as the combination operator ⊗.

[f] ARC-I+cat Q/A: model using *Architecture-I* to calculate the relevance score and *cat* as the combination operator ⊗.

[g] ARC-I+dot Q/A: model using *Architecture-I* to calculate the relevance score and *dot* as the combination operator ⊗.

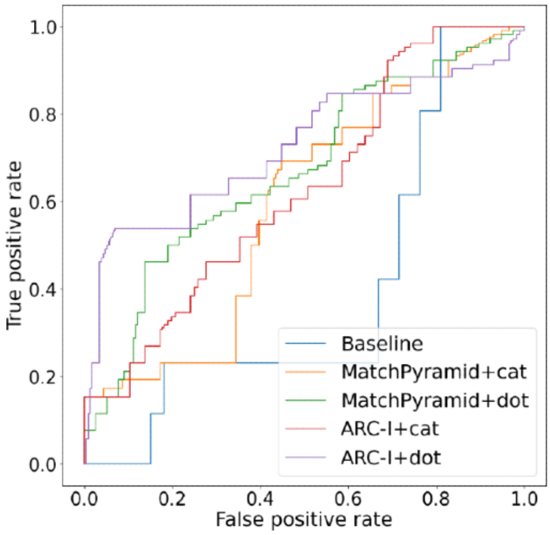
We also visualized the operating characteristic curves of all methods, as shown in Figure 5. From Table 3 and Figure 5, we have the following observations.

First, all proposed *deep learning* methods, which use relevance features and consider the interaction between relevance and the presence of questions or actions, significantly outperformed the *baseline* approach. This indicates that the relevance feature vectors generated by the text relevance measurement module were effective in capturing relevant content. Combining these feature vectors with the features of question presence and action presence helped capture their interactions and achieved good performance in influence relationship classification. In contrast, the *baseline* approach, which directly follows definition 2, did not perform well. This was due to the inability to capture the interactions between text relevance and question or action presence and the challenge of manually setting an appropriate cutoff threshold for each module.

Second, the models using the *dot* operator performed better than those using the *cat* operator. There are mainly 2 reasons for this. First, question probability and action probability may interact with V_{AB} and V_{BC} relevance vectors, which can be captured well by the *dot* operator. Figure 1B shows an example in which the action in p_C is related to the discussion in p_A and p_B. The action in p_{C2} is related to *chemo*, which is the common content of p_A and p_{B2}. In this case, the action probability needs to be combined with V_{AB}. Although, in another case, the action refers to an option mentioned in p_B, the interaction between p_B and p_C is more likely to be the context of the action and, thus, the action probability needs to be combined with V_{BC}. In contrast, the *cat* operator ignores some interactions between questions (actions) and the context because of the dropout of some neutrals. Therefore, the *cat*-based methods had a much lower recall than the *dot*-based methods. The results show that interactions between action and context are important for influence identification.

Furthermore, the *ARC-I+dot Q/A* had a much better precision, accuracy, ROC AUC, and PR AUC than *MatchPyramid+dot Q/A* but had lower recall and slightly lower F_1. This is because ARC-I achieved a better performance than MatchPyramid in the text relevance measurement module. *ARC-I+dot Q/A* was stricter than *MatchPyramid+dot Q/A* when fitting the model to the relevance factor. For applications that want to analyze the writing style and patterns of posts that have influence, precision is critical. *ARC-I+dot Q/A* is effective for locating such discussions. In contrast, for applications that want to check the information quality of the posts that have influence to prevent and mitigate the spread of misleading information, *MatchPyramid+dot Q/A* is more suitable because of its higher recall.

Figure 5. Influence relationship classification.



A Case Study

Figure 1 shows an example of 3 relationships, (p_A, p_{B1}, p_{C1}), (p_A, p_{B2}, p_{C2}), and (p_A, p_{B3}, p_{C3}), where (p_A is the initial post of the thread. The scores of these 3 relationships calculated using our system were 0.282, 0.793, and 0.622, respectively. Our system identified (p_A, p_{B2}, p_{C2}) and (p_A, p_{B3}, p_{C3}) as each containing an influence relationship, and (p_A, p_{B1}, p_{C1}) does not. As we can see from the post content, p_{B2} provides suggestions to the initial author regarding the treatment decision. In post p_{C2}, the initial author expresses actions to take based on the suggestions in p_{B2}. In post p_{B3}, the replier recommends that the author use wigs. The initial author then asks further questions about the wig information. Both relationships indicate that the initial author was influenced. In contrast, p_{B1} discusses general information and comforts the initial author, and the initial author expresses thanks in p_{C1}, but there is no indication of being influenced.

Discussion

Principal Findings

To the best of our knowledge, this is the first study that defines the influence relationships of discussion posts related to decision-making in OHCs. We proposed a deep learning–based natural language processing prototype to identify influence relationships. We then applied the developed techniques to identify the influence relationships in an OHC, the CSN breast cancer forum. There were 2 major observations.

First, we found that there is a significant amount of influence relationships in the OHC. Of the 9052 relationships in decision-making threads identified by Li et al [1], 3069 (33.9%) were identified as influence relationships. That is, approximately one-third of the communications influence the initial authors on their decision-making. Furthermore, of the 5143 decision-making threads, which have at least one relationship, 2417 (47%) contain at least one influence relationship. Owing to the prevalence, it is important to study posts that have influence.

Second, we also observed that posts that have influence may contribute to engaging users in discussions. The average number of posts in threads containing at least one influence relationship was 15.5, whereas the average number of posts in threads containing no influence relationship was 12.6. Our conjecture is that posts that have an influence likely provide helpful information or good reasoning, which are thought-provoking and help engage users in discussions.

On the basis of these observations, there are several applications that can benefit from the identification and analysis of influence relationships.

First, analyzing the quality of posts that have influence helps improve the quality of the influence. As discussed in the first observation, influence relationships are common. Quality checking of those posts is more critical than that of other posts in terms of improving the effect of influences and mitigating the spread of misleading information.

On the basis of the identification of influence relationships, we can further identify influential users in OHCs. We can use existing techniques that analyze the network features to identify influential users [16-20], where this work calculates the edge weights (ie, the influence of a post). Identifying and checking influential users contributes to high-quality information dissemination.

Second, based on the second observation, analyzing the writing style of posts that have influence provides insights to health care professionals about effective communication for patient engagement.

Furthermore, identifying influence relationships contributes to effective information recommendations for addressing the information overload problem. When a user searches for information in OHCs, it is important to rank discussion threads and posts and recommend to users the most relevant and helpful discussions. On the basis of the analysis of influence relationships and the second observation, discussions that contain influence relationships are more likely to provide helpful information and encourage patient engagement. Thus, the presence of influence relationships is a positive factor in ranking.

Limitations

Our results are not without limitations. First, our definition of relationship was based on 3 posts, including the initial post in the thread. Therefore, we only identified the posts that had an influence on the initial author. However, any 3 posts that have a sequential reply relationship with the first and third posts from the same author can represent a relationship. We conjecture that the proposed techniques can be used to identify influence relationships among the generalized relationships and plan to study that problem in the future. Second, in this study, we considered text relevance between the posts in the relationship. Sometimes, even though 2 posts, p_B and p_C, are relevant overall, the specific sentence that has a question or future action indication in p_C may not be relevant to the suggestions in p_B. In addition, the current technique for future action detection sometimes generates false positives. To address these issues, we will investigate how to leverage part-of-speech and reference resolution techniques [47] to improve natural language understanding.

Conclusions and Future Work

We studied the problem of identifying influence relationships of web-based discussions and developed techniques and a prototype system for identifying influence relationships in OHCs. The proposed deep learning model demonstrates the performance advantage of the compared methods. As future work, we will address the aforementioned limitations to improve the generality and accuracy of the proposed techniques.

Abstract

Background: The widespread secondary use of electronic medical records (EMRs) promotes health care quality improvement. Representation learning that can automatically extract hidden information from EMR data has gained increasing attention.

Objective: We aimed to propose a patient representation with more feature associations and task-specific feature importance to improve the outcome prediction performance for inpatients with acute myocardial infarction (AMI).

Methods: Medical concepts, including patients' age, gender, disease diagnoses, laboratory tests, structured radiological features, procedures, and medications, were first embedded into real-value vectors using the improved skip-gram algorithm, where concepts in the context windows were selected by feature association strengths measured by association rule confidence. Then, each patient was represented as the sum of the feature embeddings weighted by the task-specific feature importance, which was applied to facilitate predictive model prediction from global and local perspectives. We finally applied the proposed patient representation into mortality risk prediction for 3010 and 1671 AMI inpatients from a public data set and a private data set, respectively, and compared it with several reference representation methods in terms of the area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), and F1-score.

Results: Compared with the reference methods, the proposed embedding-based representation showed consistently superior predictive performance on the 2 data sets, achieving mean AUROCs of 0.878 and 0.973, AUPRCs of 0.220 and 0.505, and F1-scores of 0.376 and 0.674 for the public and private data sets, respectively, while the greatest AUROCs, AUPRCs, and F1-scores among the reference methods were 0.847 and 0.939, 0.196 and 0.283, and 0.344 and 0.361 for the public and private data sets, respectively. Feature importance integrated in patient representation reflected features that were also critical in prediction tasks and clinical practice.

Conclusions: The introduction of feature associations and feature importance facilitated an effective patient representation and contributed to prediction performance improvement and model interpretation.

Introduction

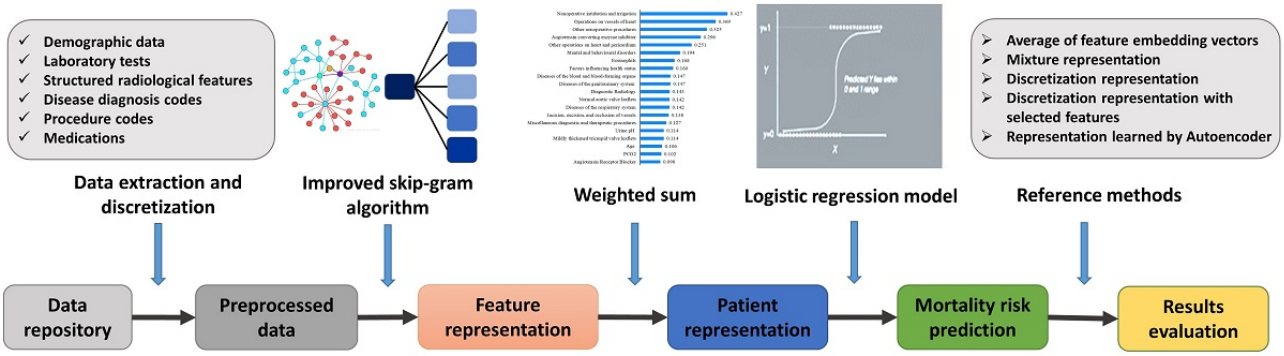
Electronic medical records (EMRs) contain diverse and heterogeneous information, such as demographic data, disease diagnoses, laboratory tests, radiological findings, examinations and procedures, and medications. EMR data can be used to not only reflect the health status of patients and record the treatment trajectory, but also help doctors in making clinical decisions [1-6] and improving the efficiency of diagnosis and treatment [1,7,8]. One of the most prevalent and practical tasks of the secondary use of EMR data is building models to predict the disease status [8-10] and treatment outcomes [11-17] for a patient, using machine learning algorithms.

However, the high dimensionality, sparsity, and heterogeneity of EMR data [12,18] pose many obstacles for directly inputting the raw data into machine learning–based predictive models. Some manual and data-driven feature engineering methods [15,19], though time-consuming and laborious, were used to select important features or extract useful information for predictive tasks. Moreover, the performance of predictive models relies heavily on the representation of data. It was reported that effective representation methods could make the downstream modeling simpler and more flexible, and greatly improve the predictive performance [18,20]. By transforming raw features into compact vectors, representation learning can make it easier to automatically extract useful information when building predictive models [16,21,22]. One widely used representation method for EMR data is the skip-gram algorithm [23], a distributed embedding method that treats patient records as sentences and medical concepts as words. An inevitable problem in the skip-gram algorithm is that contrary to words within a sentence, medical concepts in a patient's record do not have a natural order, making it difficult to learn meaningful representations of concepts that have potential associations. One solution for this problem was randomly shuffling the concepts within a record to learn concept embeddings [12,24-26]. It could reduce the impact of the disorder attribute of medical concepts on the algorithm to some degree, while associations among these concepts were still not taken into consideration.

Acute myocardial infarction (AMI) is an acute ischemic heart disease and is the second leading cause of death. One in every 6 deaths is caused by ischemic heart disease, where AMI accounts for the majority of deaths [27,28]. Mortality risk prediction for AMI patients plays a crucial role in clinical work, helping doctors identify potential clinical factors, take early intervention measures based on timely alerts of patients' adverse health statuses, and reduce the burdensome expenditure of related health care expenses. Therefore, researchers [19,29-31] have focused on building machine learning models for the outcome prediction of AMI patients, and most of them used specific clinical features, such as laboratory test results (eg, albumin), comorbidities (eg, diabetes), and demographic data (eg, gender).

In this study, we aimed to represent various structured features extracted from EMR data as fixed-length embedding vectors, which were then used to improve the performance of predictive models for the death risk of AMI patients. Specifically, we introduced the association strengths into the skip-gram algorithm to learn more informative representations of features. We also introduced the Shapley additive explanations (SHAP) [32] technique to facilitate representation at the patient level and enhance the interpretability of the predictive model. An overview of our proposed representation learning framework and its application is shown in Figure 1.

Figure 1. Overview of the proposed representation learning method for patients' mortality risk prediction. First, feature representations were learned by the skip-gram algorithm using an adaptive context window. Then, patient representations were constructed based on feature representations weighted by the feature importance. Finally, the proposed patient representation was applied in the mortality risk prediction for acute myocardial infarction in-patients from a public data set and a private data set, and compared with reference methods.



Methods

Skip-Gram–Based Patient Representation

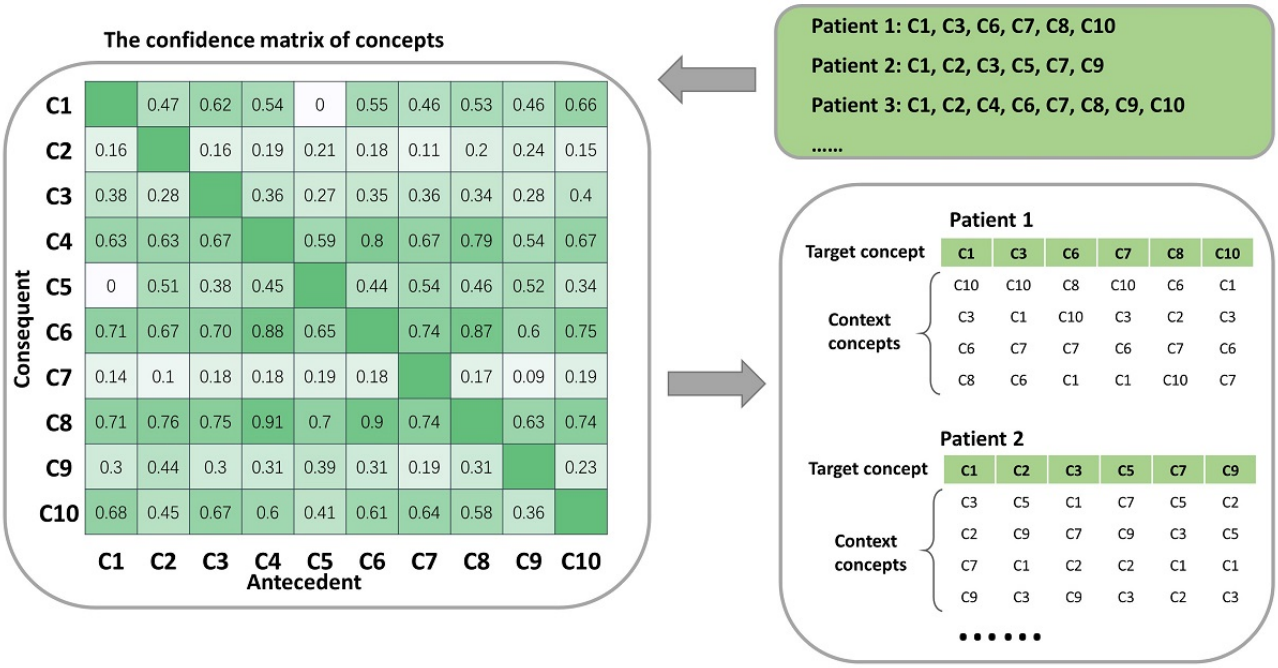
The representation was learned hierarchically at the following 3 levels: the concept, feature, and patient levels. At the concept level, we employed the improved skip-gram algorithm [23] to represent a concept as an embedding vector. In the natural language processing domain, the basic idea of skip-gram was to maximize the occurrence probabilities of the target words and the context words in the predefined context window, making the words that appear in the same context window closer in the embedding space. Unlike words with natural orders in a sentence, medical concepts appeared out of order in a patient record for a certain hospital stay. This made it difficult to determine the context window that contained relevant concepts for the target concept, especially when the number of concepts in a record was far larger than the size of the context window.

Thus, for a concept within a record, we identified relevant concepts using its association strength with a candidate concept in the same record. The association strength was defined as the confidence (equation 1) of an association rule with one candidate concept as the unique antecedent (or consequent).

$$\text{Confidence}\ (C1, C2) = |C1 \cap C2| \,/\, |C1| \quad \textbf{(1)}$$

where C1 and C2 are the antecedent and consequent concepts, respectively, of an association rule C1→C2, and |C1| and |C1∩C2| are the numbers of patient records containing C1 and both C1 and C2, respectively. The greater the confidence, the stronger the association between the 2 concepts. Antecedent (or consequent) concepts in association rules with the top N highest confidences were included in the context window of the target concept. We called these selection schemes of context concepts *antecedent-based* (or *consequent-based*) embeddings. Figure 2 provides an example of the consequent-based selection scheme of context concepts.

Figure 2. An illustration of context concept selection for the skip-gram algorithm using association strengths. All records are composed of 10 concepts (C1, C2, ……, and C10). In the confidence matrix, element Cij was the confidence of the association rule with Cj as antecedent and Ci as consequent. For patient 1 with 6 concepts (C1, C3, C6, C7, C8, and C10), the included concepts in C1's 4-concept context window were selected from the remining 5 candidate concepts, whose confidences were 0.66 (antecedent, C10), 0.62 (C3), 0.55 (C6), 0.53 (C8), and 0.46 (C7). Therefore, C10, C3, C6, and C8 were selected to construct the context window for C1.



The confidence matrix of concepts

••••••

Moreover, to reduce the high dimensionality and sparsity of a large number of concepts, while preserving the clinical information as much as possible, we aggregated the concepts of disease diagnoses and procedures into several clinically meaningful feature groups according to International Classification of Diseases, 10th revision (ICD-10) codes and International Classification of Diseases, 9th revision (ICD-9) codes, and with the help of clinical experts. For example, disease diagnoses of type 1 diabetes mellitus and type 2 diabetes mellitus were grouped into the feature group of diabetes mellitus. The average of all embedding vectors of concepts from the same feature group in a patient record was treated as the representation at the feature level for the patient.

The representation at the patient level was the weighted sum of feature-level representations. The feature weights were obtained under the guidance of the predictive task, indicating the importance of each feature involved in the patient representation. In this study, we used SHAP values as the feature weights. The SHAP framework is a machine learning interpretation technique based on the idea of game theory. It approximated a trained prediction model with a different but simple model that could easily calculate the contribution in the form of a SHAP value for each feature in the prediction model and performed additive feature attribution to explain the combination of features [32]. A positive or negative SHAP value reflected a positive or negative influence on the prediction. A feature's importance was then computed as the average of its absolute SHAP values from all samples.

Experiments and Evaluations

Data Sets and Data Preprocessing

In this study, we used a public data set, the freely accessible critical care database Medical Information Mart for Intensive Care III (MIMIC-III data set [33]), and a private data set for the experiments.

The MIMIC-III data set was collected between June 2001 and October 2012, and involved 46,520 patients admitted to intensive care units at the Beth Israel Deaconess Medical Center in Boston, Massachusetts. It includes patient health information, such as demographics, vital signs, laboratory test results, medications, procedures, diagnosis codes, and clinical notes. The informative MIMIC-III data set was widely used in some medical machine learning modeling and algorithm evaluations, providing strong data support for researchers to establish models and evaluate algorithms [14,18].

The private data set was derived from the EMR system of a tertiary hospital, Xuanwu Hospital, Capital Medical University, Beijing, China, between January 2014 and December 2016. Patient features included hospital admission and discharge information, demographic data, disease diagnoses, laboratory tests, examinations and procedures, medications, and radiology reports of chest X-ray or color sonography examination.

We extracted the records of all 3010 and 1671 AMI patients from the public and private data sets, respectively. The diagnosis of AMI was confirmed with the ICD-9 codes 410.01 to 410.91 or ICD-10 codes I21 and I22. There were 254 (8.1%) and 103 (6.2%) patients who died in the hospital from the public and private data sets, respectively.

We maintained patients' first hospitalization data to evaluate the proposed method. Demographic data (age and gender) and the following AMI-related features were maintained in both data sets: AMI-relevant items of laboratory tests that at least 95% of patients carried out, AMI-relevant radiological features extracted from radiology reports [34], 7 commonly prescribed medications, and all recorded disease diagnoses and procedures. For laboratory tests performed more than once, only the results obtained in the first test (usually at admission) were retained, which could reflect a patient's health status and the severity of illness.

Since initially proposed in the field of natural language processing, the skip-gram algorithm was used to train embeddings for discrete words or symbols. Therefore, to use the skip-gram algorithm for the embedding representation of the structured data, all patient features should be categorical, where each discrete value is treated as a concept. For example, male and female were 2 concepts for gender. Different from raw categorical features, such as gender, disease diagnoses, procedures, and medications, that might remain unchanged, the continuous variables age and laboratory test results had to be discretized into two or more concepts. Age was discretized into 2 concepts (>60 years and ≤60 years). Each laboratory test result was also discretized into 2 concepts (normal and abnormal with reference to clinical standards). In total, 3326 and 1073 medical concepts were identified and further aggregated to 104 and 108 feature groups in the public and private data sets, respectively (Table 1). All feature groups of the private and public data sets are listed in Multimedia Appendix 1 and Multimedia Appendix 2, respectively.

Table 1. Concepts and feature groups of both the public and private data sets.

Feature category	Public data set		Private data set		Concept examples
	Feature groups (n=104), n	Concepts (n=3326), n	Feature groups (n=108), n	Concepts (n=1073), n	
Age	1	2	1	2	>60 years and ≤60 years
Gender	1	2	1	2	Male and female
Laboratory tests	19	38	40	80	Abnormal serum triglyceride and normal serum creatinine
Radiological features	34	34	36	36	Cardiac image enlargement and sharp costophrenic angle
Disease diagnoses	24	2600	15	739	Hypertension and brainstem infarction
Procedures	18	643	8	207	Coronary stenting and pericardiocentesis
Medications	7	7	7	7	Angiotensin-converting enzyme inhibitor and heparin

Representation Evaluation

To evaluate the effectiveness and advantages of the proposed representation, we used 2 additional kinds of simple reference representation methods, namely, the 3-layer autoencoder with learning and the feature selection method without learning. Table 2 describes the details of the proposed and reference representation methods.

The proposed representation method was first evaluated at the concept level. Cluster analyses were used to cluster laboratory test concepts into 2 clusters for the quantitative evaluation. The adjusted Rand index (ARI) [35] (ranging from −1 to 1) was used to evaluate the cluster solutions. Greater ARI values indicated higher ability of discriminating from categories with different real labels (normal and abnormal). We also applied the t-distributed stochastic neighbor algorithm to project the embedding vectors of laboratory test concepts into a 2-dimensional space to visually observe the distribution of embeddings.

The proposed representation method was then evaluated at the patient level with a downstream prediction task using the logistic regression model. The predicted outcome was the in-hospital death of AMI patients during hospital stay. The input for prediction was the patient representation derived from the entire feature set listed in Table 1. We also extracted a treatment-free feature subset that excluded medications and procedures from the entire feature set, trying to clarify that the performance of the proposed patient representation was related to the features that were involved in the representation and that the treatment-related features played a crucial role in predicting patient outcome even if they had been represented as embedding vectors.

Table 2. Descriptions of the proposed and reference representation methods.

Representation method	Descriptions	Representation examples
Mixture	The mixture of discretization codes for original discrete features and original values for continuous features. The missing values in the laboratory tests were interpolated using the mean of the corresponding laboratory tests.	(0,1,1,0,0,0,1,12,8.5,3,8) for a patient with 11 features
Discretization	The 0-1 vector where the digit 1 represented the patient having the specific disease, procedure, radiological feature, and medication, and 0 otherwise. Age of 1 meant >60 years and 0 meant ≤60 years, gender of 1 meant male and 0 meant female, and a laboratory test item of 1 meant abnormal and 0 meant normal. Missing values for laboratory tests were interpolated by the corresponding mode.	(0,1,1,0,0,0,1,1,0,1,1) for a patient with 11 discretization features
DIS_FS[a]	The selected features with discretization representations were statistically different between patients with and without the label "death."	(0,0,1,0,0,1,0,1) for a patient with 8 selected features
DIS_AE[b]	The hidden-layer vector of a 3-layer autoencoder with discretization vectors as inputs and outputs. The dimension of the hidden layer was set to 64.	(0.7,1.9,0.5,−1,−3.1,2.4) for a patient with a 6-dimensional vector
RAN_EM_AVE[c]	The average of feature embedding vectors learned from the skip-gram algorithm using the random selection method to determine the context window.	(1.6,−0.5,1.1,0.1,−1.3,0.6) for a patient with a 6-dimensional embedding vector
RAN_EM_WGT[d]	The weighted sum of the feature embedding vectors learned from the skip-gram algorithm using the random selection method to determine the context window.	(1.2,−0.9,1.3,0.4,−1.9,1.0) for a patient with a 6-dimensional embedding vector
ANT_EM_AVE[e]	The average of the feature embedding vectors learned from the skip-gram algorithm using the confidence with the target concept as the antecedent.	(0.9,−0.6,1.2,1.4,−1.9,0.6) for a patient with a 6-dimensional embedding vector
ANT_EM_WGT[f]	The weighted sum of the feature embedding vectors learned from the skip-gram algorithm using the confidence with the target concept as the antecedent.	(1.2,−1.5,1.1,0.1,−0.6,0.6) for a patient with a 6-dimensional embedding vector
CON_EM_AVE[g]	The average of the feature embedding vectors learned from the skip-gram algorithm using the confidence with the target concept as the consequent.	(1.6,−0.8,2.1,1.6,−1.4,1.5) for a patient with a 6-dimensional embedding vector
CON_EM_WGT[h]	The weighted sum of the feature embedding vectors learned from the skip-gram algorithm using the confidence with the target concept as the consequent.	(1.1,−0.4,−0.7,1.6,−0.3,0.9) for a patient with a 6-dimensional embedding vector

[a] DIS_FS: discretization representations with feature selection.

[b] DIS_AE: hidden vector of an autoencoder-based representation.

[c] RAN_EM_AVE: average of the random selection–based embedding representation.

[d] RAN_EM_WGT: weighted sum of the random selection–based embedding representation.

[e] ANT_EM_AVE: average of the antecedent-based embedding representation.

[f] ANT_EM_WGT: weighted sum of the antecedent-based embedding representation.

[g] CON_EM_AVE: average of the consequent-based embedding representation.

[h] CON_EM_WGT: weighted sum of the consequent-based embedding representation.

We randomly split samples into training and test data sets by the ratio of 7:3. The training samples were first represented in the discretization vectors and used to build a predictive model for calculating all features' SHAP values for the further patient embedding representations of all study samples. After being represented as embedding vectors, the training and test samples were used to build and validate a logistic regression-based predictive model, respectively. The area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), and F1-score were the main evaluation metrics. Other relevant performance metrics from the confusion matrix included precision, recall, and accuracy. To eliminate the performance bias introduced by the initialization of a skip-gram model and the training/test data set split, we performed the comparative experiment 100 times. In each experiment round, the above processes were repeated. The mean with its 95% CI of each performance evaluation metric was reported.

In the skip-gram algorithm, the size of the context window and the dimension of the embedding vector were determined by trial and error. We conducted a group of predictive experiments on the public data set, using possible combinations of window sizes of 5, 10, 15, and 20, and vector dimensions of 50, 100, 200, and 300. Experimental results (listed in Multimedia Appendix 3) showed that the skip-gram algorithm with the combination of a window size of 10 and a vector dimension of 300 had the highest representation performance. Therefore, the size of the context window and the dimension of the embedding vector were set to 10 and 300, respectively. We applied the negative sampling mechanism (20 negative samples in this study) to accelerate the concept embedding training process. Other parameters were as follows: learning rate, 0.001; number of iterations, 50; batch size, 64. The gradient calculation method was Adam. We implemented representation learning, SHAP value computation, and prediction modeling in Python 3.7 and TensorFlow 2.0. In the step of patient representation, we used the L2 regularization penalty with "liblinear" solver for the logistic regression model, and the inverse of regularization strength was set to 0.1.

Ethics Approval

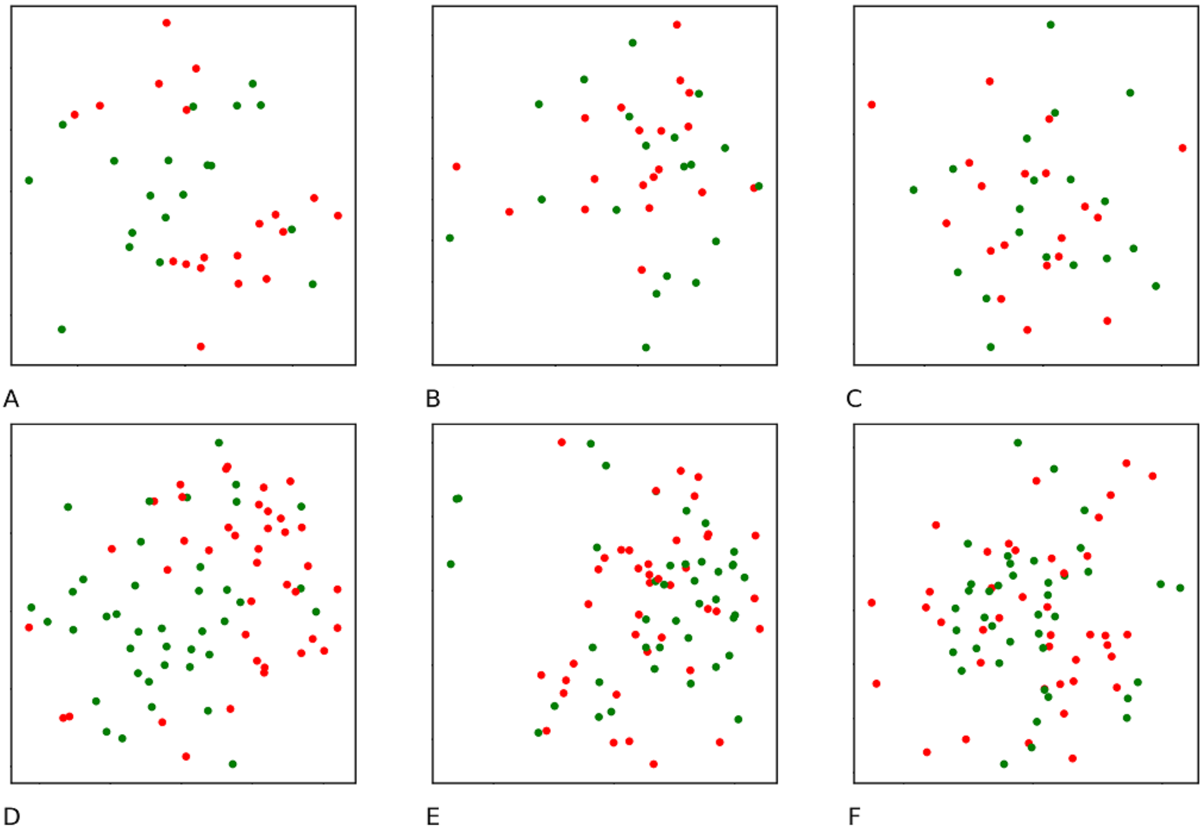
The study was approved by the Human Research Ethics Committees of Xuanwu Hospital, Capital Medical University (approval number: Clinical Scientific Research 2020-070).

Results

Concept Representation Evaluation

Embedding vectors for laboratory test concepts were visualized in a plane space (Figure 3). Concepts of normal and abnormal laboratory tests (Figure 3) were farther away when they were represented by the consequent-based embeddings (Figures 3A and 3D) than by the antecedent-based embeddings (Figures 3B and 3E) and the random selection–based embeddings (Figures 3C and 3F). In cluster analyses for laboratory tests, the consequent-based embeddings achieved higher ARIs (0.317 and 0.520 on the public and private data sets, respectively) than the antecedent-based embeddings (0.112 and 0.149, respectively) and the random selection–based embeddings (0.043 and 0.028, respectively). The best cluster performance of the consequent-based embeddings among the 3 embeddings indicated that the consequent-based embeddings might contain more feature association information.

Figure 3. Visualization of the embedding laboratory tests using different selection schemes for contextual concepts in the skip-gram algorithm (the t-distributed stochastic neighbor embedding algorithm was used). Dots in red and green represent abnormal and normal laboratory test results, respectively. A to C for the public data set: the contextual concepts of a target concept consist of its consequent concepts (A) or antecedent concepts (B) in association rules, or randomly selected concepts (C). D to F are the counterparts of A to C on the private data set.



Predictive Performance

Table 3 and Multimedia Appendix 4 list the predictive performances using various representation methods on the private and public data sets, respectively. The proposed representation method, the weighted sum of the consequent-based embedding representation (CON_EM_WGT), showed the highest predictive performances, with maximum AUROCs of 0.878, 0.973, and 0.926 using all features of the public data set and the entire and treatment-free feature sets of the private data set, respectively. When the performance was measured by AUPRC and F1-score, the proposed representation method outperformed all the other methods regardless of the data sets and feature sets.

Compared with the reference representations, most of the embedding-based representations on both data sets showed a performance improvement. The average AUROC, AUPRC, and F1-score of the 6 representation methods with embeddings were greater than those of the 4 reference methods without embeddings (0.855 vs 0.831, 0.203 vs 0.185, and 0.354 vs 0.328, respectively) on the public data set with the entire feature set. Further, among the 6 representations based on the skip-gram algorithm, representations with algorithm improvement based on the association strength achieved superior performance than those without.

When assembling feature representations into a patient representation, the assembling method and the involved features did matter. Representations based on the idea of weighted sum outperformed those based on the idea of average, on either the public data set with the entire feature set (AUROC, 0.863 to 0.878 vs 0.834 to 0.850) or the private data set with the entire feature set (0.967 to 0.973 vs 0.948 to 0.957). On the other hand, consistently superior predictive performance was achieved on both data sets with the entire feature set compared with the treatment-free feature set. Multimedia Appendix 5 shows the average predictive performance of patient representation methods on the public and private data sets with and without treatment feature sets.

Table 3. Predictive performance of patient representation methods on the private data set.

Predictive Model Interpretation

Figure 4 illustrates the global feature attributions for the top 20 most important features from the private data set when predicting in-hospital death risk. The treatment-related features played an important role in the mortality prediction. These features included other surgery (mean absolute SHAP value: 0.413), diagnostic ultrasound (0.279), contrast agent cardiovascular angiography (0.197), etc (Figure 4A). Moreover, comorbidity diseases like hypertension (mean absolute SHAP value: 0.252) and heart disease complications (0.236), and laboratory tests like serum glucose (0.188) and serum lactate dehydrogenase (0.139) had strong associations with in-hospital death (Figure 4B). SHAP values of features in the public data set are shown in Multimedia Appendix 6.

In addition to the feature's global importance in the specific predictive task, SHAP values were helpful in distinguishing the feature's local importance, that is, the importance for an individual sample. Figure 5 illustrates how the mortality risk was predicted with SHAP values for a patient who died during hospital stay and another patient who did not die. The positive SHAP values of most features of the patient who died during hospital stay increased the total SHAP value from an average value of −3.739 to a final value of −0.499 (Figures 5A and 5C), meaning that the patient had a higher risk of in-hospital death than the average. In this incremental process, gender as female, for example, contributed a SHAP value of +0.21 (Figures 5C). On the contrary, the negative SHAP values of most features of the patient who was discharged alive decreased the total SHAP value from −3.739 to −6.169 (Figures 5B and 5D), indicating a lower death risk. In this decremental process, male gender contributed a SHAP value of −0.09 (Figures 5D). We have shown 2 examples of patients from the public data set in Multimedia Appendix 7.

Figure 4. The mean absolute Shapley additive explanations (SHAP) values of the top 20 features of the private data set within the entire feature set (A) and the treatment-free feature set (B).

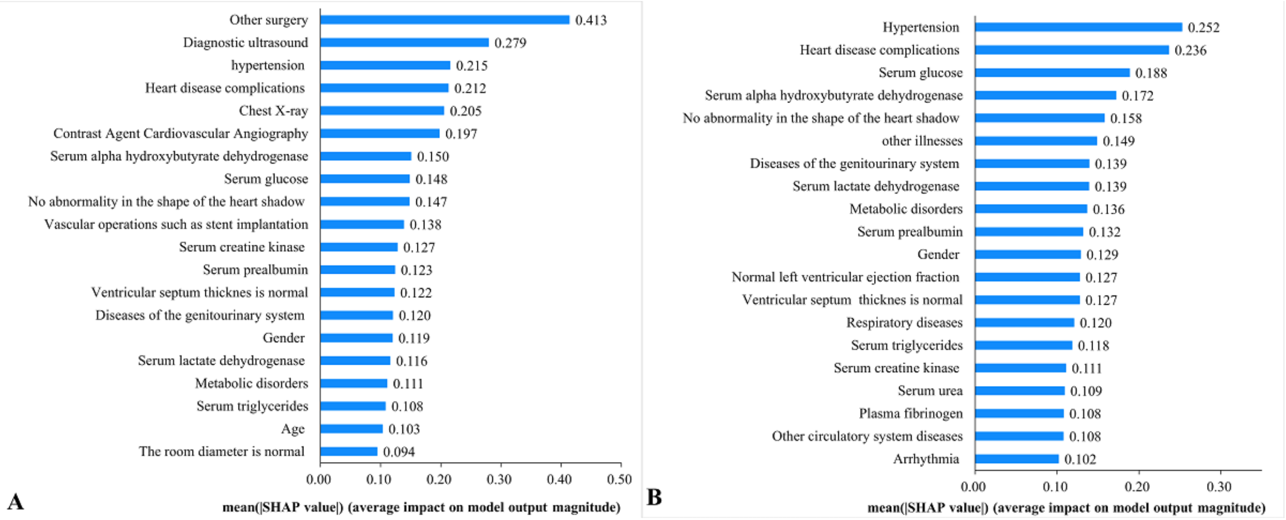

Figure 5. Shapley additive explanations (SHAP) values for a patient who died during hospital stay (A and C) and another patient who did not die (B and D). Both patients were selected from the private data set with the entire feature set. A and B, all features with their SHAP values. C and D, 20 features with the greatest absolute SHAP values. Features in blue tend to reduce the possibility of a patient being classified as positive (death in this study), while features in red do the contrary. The meaning of each abbreviated feature name can be found in Multimedia Appendix 1.

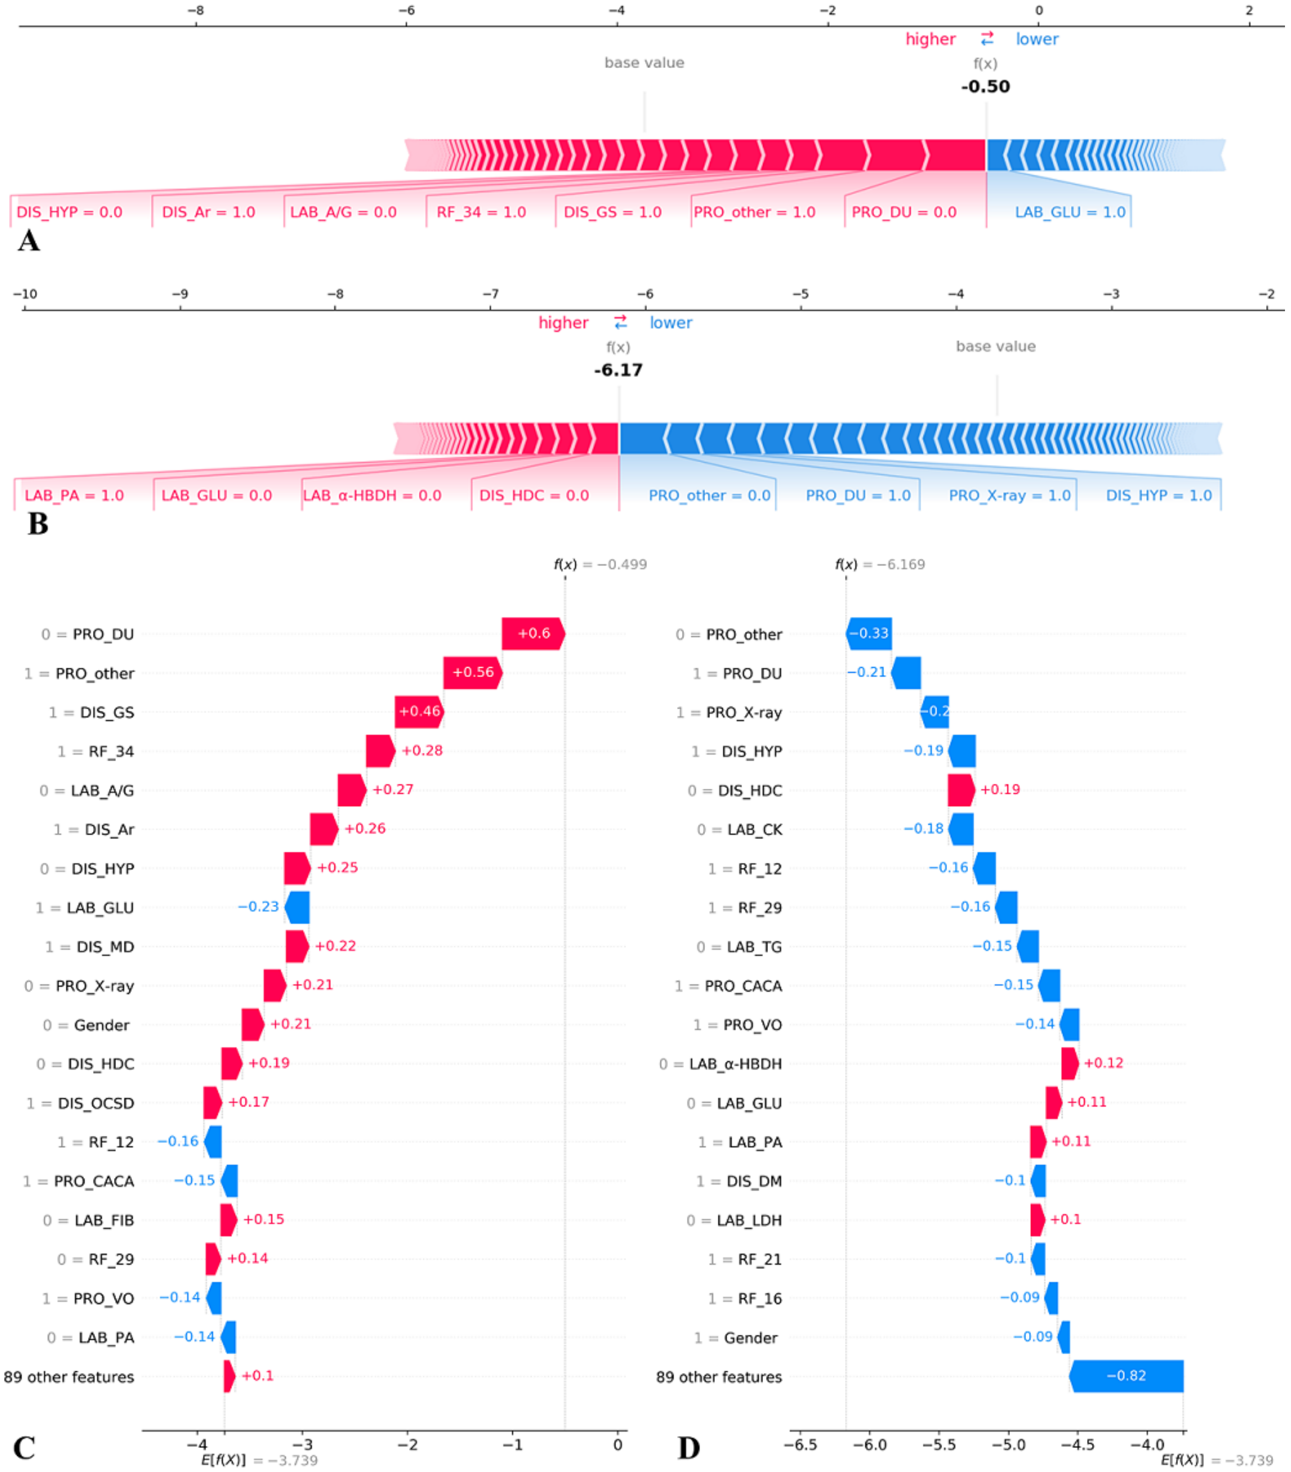

Discussion

Principal Findings

With the widespread adoption of EMR data in building machine learning–based predictive models, one of the most fundamental research challenges was learning proper patient representations that might capture hidden semantic associations among medical concepts [18]. In this study, we proposed an improved skip-gram–based patient representation method where the association strength among medical concepts and the task-specific feature importance were integrated. Compared with other representation methods, the proposed patient representation improved the performance of the mortality risk prediction for AMI patients.

In previous studies, deep learning models [9,10,12,25,36] were used in training embedding representations of medical concepts for the subsequent patient representation. When using the skip-gram algorithm, the order of medical concepts that was independent of feature relevance hindered the algorithm from learning high-quality representation. Prior work recommended the shuffling mechanism for medical concepts in a patient record to reduce the impact of the out-of-order characteristics on the algorithm [12,24-26]. In this study, we introduced the association strength between 2 concepts that was defined as the confidence of an association rule involving just the 2 concepts. Experiments from various aspects indicated that this ingenious improvement was effective in revealing potential associations among medical concepts and further enhancing the performance of downstream prediction tasks.

In addition to the representation algorithm, features used to represent a patient were also critical. Many previous studies focused on some features in the original form of medical codes, such as disease diagnoses, procedures, and medications [1,11,14,37]. For laboratory tests that contained much diagnosis and prognosis-relevant information about patients, we included the normal status of the laboratory tests into the feature sets, rather than simply using the number of laboratory tests and test co-occurrences [12,38]. We further extracted radiological features from free-text radiological reports. Admittedly, richer features may lead to a feature representation with more information, even if the dimension of patient representation remains unchanged. In this study, predictive models using more features to represent a patient did reflect more information about the patient and showed higher performance than those using fewer features. Our finding is similar to the results of other studies [39,40].

Prior studies employed neural networks to train predictive models for clinical outcomes using EMR data [2,16,22]. They focused on end-to-end prediction models built on large data sets, where the last hidden layer of the neural network was regarded as the patient representation. Although the deep end-to-end neural network–based patient representation improved the predictive accuracy, the lack of interpretability could not be ignored. Some studies [26,41] constructed patient representations using the average of concept representations learned by word embedding methods, which did not make full use of the importance of different clinical features for patients. As an advanced interpretability method, the SHAP value [32] was successfully used to analyze and explain the predictive models in some previous studies [40,42-44]. We introduced SHAP values as feature importance into the patient representation, and further explained the predictive model with SHAP values. SHAP values can be used to not only rank the overall importance and identify the important factors for the prediction task, but also explore the key factors for predicting the mortality risk for a specific patient. In our predictive task for AMI patients, the most important features identified by SHAP values were really closely related to AMI [45-47], such as serum glucose and serum creatine kinase, which are 2 critical laboratory tests for AMI diagnosis and prognosis in clinical practice.

In our predictive task, the model that took all available patient characteristics represented by the proposed patient representation method as inputs showed a higher performance than other models on the same task in previous studies (AUROC, 0.973 vs 0.905 to 0.935 [19,29-31,48]). This may be because the embedding representation contained a large number of diverse features extracted from a general EMR system, while many researchers selected AMI-related features with the assistance of clinical experts. For example, basic demographic data and few laboratory tests, as well as several specific features of AMI like Killip classification and left ventricular ejection fraction [19,30] were directly added into the machine learning model to predict mortality risk. Further, compared with other simple feature extraction methods like Principal Component Analysis [29] and the 3-layer autoencoder model, the proposed method took the association strength and feature importance into consideration, achieving higher predictive performance.

Limitations

This study had some limitations. First, only patients' laboratory tests for the first time during hospital stay were included in this study, while many patients took two or more laboratory tests. Since temporal data, especially multiple laboratory tests, may reflect the dynamic health status and the treatment effect of a patient over time, the lack of temporal characteristics of laboratory tests in the patient representation may lead to performance loss in downstream tasks. A future study will focus on integrating this uneven and irregular temporal data into the current patient representation. Second, the skip-gram algorithm was used in training concept embeddings. The algorithm is popular in the natural language processing domain, possibly having a limited ability to represent structured and disordered EMR data. A transformer-based pretrain model, Med-Bert, has been trained to represent disease diagnoses originally expressed in ICD-10 and ICD-9 codes, showing higher performance with AUROCs of 85.39% and 82.23% in heart failure and pancreatic cancer prediction tasks, respectively [49]. Therefore, more complicated deep learning methods will be adopted for a more informative patient representation in the future. Lastly, we carried out only internal validation of the predictive model built on the proposed patient representation. External validation of high quality will be more convincing and will help in continuous algorithm improvement. Moreover, the chosen reference methods for the performance comparison were simple feature selection methods and a 3-layer autoencoder. Comparison with state-of-the-art methods is needed to evaluate the performance and potential use of our proposed method.

Conclusions

In this study, we improved the embedding-based patient representation with the association strength of medical concepts and importance of patient features. After further training and fine-tuning, the model based on the proposed patient representation will hopefully be used to assist in prognostic prediction for AMI inpatients. This study puts forward a meaningful direction for the development of more effective and efficient clinical prediction models using EMR data. It is desirable for patient representation learning to serve as an essential part of building a predictive model for clinical outcomes.

Abstract

Background: The rapid implementation of virtual care (ie, telephone or video-based clinic appointments) during the COVID-19 pandemic resulted in many providers offering virtual care with little or no formal training and without clinical guidelines and tools to assist with decision-making. As new guidelines for virtual care provision take shape, it is critical that they are informed by an in-depth understanding of how providers make decisions about virtual care in their clinical practices.

Objective: In this paper, we sought to identify the most salient factors that influence how providers decide when to offer patients video appointments instead of or in conjunction with in-person care.

Methods: We conducted semistructured interviews with 28 purposefully selected primary and specialty health care providers from the US Department of Veteran's Affairs health care system. We used an inductive approach to identify factors that impact provider decision-making.

Results: Qualitative analysis revealed distinct clinical, patient, and provider factors that influence provider decisions to initiate or continue with virtual visits. Clinical factors include patient acuity, the need for additional tests or labs, changes in patients' health status, and whether the patient is new or has no recent visit. Patient factors include patients' ability to articulate symptoms or needs, availability and accessibility of technology, preferences for or against virtual visits, and access to caregiver assistance. Provider factors include provider comfort with and acceptance of virtual technology as well as virtual physical exam skills and training.

Conclusions: Providers within the US Department of Veterans Affairs health administration system consider a complex set of factors when deciding whether to offer or continue a video or telephone visit. These factors can inform the development and further refinement of decision tools, guides, and other policies to ensure that virtual care expands access to high-quality care.

KEYWORDS

virtual care; decision-making; qualitative; virtual visits; web-based; carer; video; telephone; telemedicine; appointments; caregiver

Introduction

The COVID-19 pandemic spurred rapid and widespread implementation of virtual care, including both video- and telephone-based visits, to address acute and chronic needs of patients. Many welcomed the availability of virtual care given benefits such as increased access to care, less travel time for patients, and often lower costs for both patients and health care systems [1]. Providers and patients have also reported unexpected advantages such as greater convenience and the ability to assess patients in their home environments [2].

While in-person care delivery has largely resumed, virtual care continues to play a major role in how health care systems deliver care to patients [3]. Because of this, identifying optimal approaches to virtual care delivery that ensure patient safety, satisfaction, quality of care, and equitable access will remain a critical challenge facing health care organizations [4,5]. Due to the rapid implementation of virtual care during the pandemic, many providers were asked to provide virtual care with little or no formal training and without clinical guidelines and tools to assist with decision-making. Currently, these guidelines and tools are beginning to take shape, and it is critical that they are informed by an in-depth understanding of *how* providers make decisions about virtual care in their clinical practices.

Currently, there is a plethora of qualitative studies describing provider and patient attitudes toward virtual care, as well as perceived barriers and facilitators to virtual care implementation and adoption [2,6-8]. Well-known barriers include lack of institutional support and the infrastructure to support the technology needed for virtual care, low levels of digital literacy among both patients and providers, and poor integration of virtual modalities into existing clinical workflows, to name a few [2,8,9]. Though these studies may improve uptake and implementation of virtual care, they sometimes lack specifics on how and when to provide virtual care as a substitute or adjunct to in-person care. Fewer studies have examined how non–mental health care providers more generally make decisions about when to use virtual modalities [10,11]. Systematic identification of the factors that providers consider when assessing the suitability of virtual care for a given patient and clinical need may inform the aforementioned tools and guidelines necessary for accessible, high-quality care.

The US Department of Veterans Affairs (VA) has been a leading health care organization in the use of virtual care modalities, even before the onset of the COVID-19 pandemic [12,13]. Through a qualitative assessment of VA providers from diverse clinical settings, we sought to identify the most salient factors that impact providers' decisions about when to offer patients virtual care.

Methods

Participants and Study Design

As part of a study of VA's implementation of virtual care and distribution of video-enabled tablets to veterans with access barriers, we conducted a qualitative study of a national sample of VA clinicians. We used a combination of administrative data and provider referral to purposefully sample participants. A majority of providers had only begun offering virtual care in the last 1 to 2 years at the time of interviews. Rather than focus on a single specialty, we strove for variation in our interview sample [14] and selected providers from the following 4 diverse areas of clinical practice: primary care, cardiology, spinal cord injury, and palliative care. With guidance from VA's Office of Connected Care, these specialties were chosen due to higher use of virtual care. Additionally, they offer diverse types of services offered during a clinical visit. Through administrative data, we identified practitioners who had frequently used video visits in the previous calendar year relative to their peers in similar clinical practices. Providers were recruited from several US geographic regions—West, Midwest, South, and Northeast. The participants were sent messages to their institutional email addresses explaining the purpose of the study and asked if they would like to participate. A total of 26 physicians and 2 nurse practitioners agreed to participate in an interview, for a total of 28 providers. Participant characteristics are summarized in Table 1.

Table 1. Characteristics of health care providers (N=28).

Characteristics	Values, n (%)
Clinical specialty or practice	
Primary care	11 (39)
Cardiology	7 (25)
Spinal cord injury	5 (18)
Palliative care	5 (18)
Gender	
Women	16 (57)
Men	12 (43)
Setting	
Rural	5 (18)
Urban or suburban	23 (82)
Years of practice	
Less than 5 years	4 (14)
Over 5 years	24 (86)

Ethics Approval

This quality improvement initiative was reviewed and designated as nonresearch by the supporting VA program office, the Stanford University Institutional Review Board, and VA Research Administration.

Data Collection

Two researchers, a medical sociologist with expertise in qualitative methods (CG) and an internist with qualitative training (RT), conducted interviews with the providers to learn about their experiences offering virtual care prior to and during the COVID-19 pandemic. The interviews took place between December 2020 and June 2021, with each specialty interviewed consecutively to ensure greater consistency. The interview questions focused on circumstances under which providers choose to offer virtual care, preferences for virtual care or in-person care, and perceptions of scenarios where virtual care was inappropriate or less optimal. The providers were also asked to reflect on needed skills and training around virtual care and perceived barriers to providing virtual care more frequently. The interviews were conducted using Microsoft Teams, which lasted approximately 30 minutes, and with permission from interview participants, they were videorecorded and transcribed by a professional transcription service.

Data Analysis

To identify the primary factors informing provider decision-making around virtual care, we employed a qualitative descriptive approach [15], using constant comparison [16,17] to further reduce and synthesize data. First, the research team inductively reviewed 5 transcripts and identified emergent codes, combined these codes with deductive codes derived from the interview questions, and created a codebook used to code all transcripts. The transcripts were uploaded into Atlas.ti (ATLAS.ti Scientific Software Development GmbH), a software that facilitates qualitative data analysis, and coded according to the codebook. After transcripts were coded, the codes and their associated text were reviewed collectively by the team and then grouped together into larger categories. During this process, we identified themes by assessing for repetition and emphasis of specific points. Finally, all team members participated in selecting exemplary quotes and sorting themes into 3 categories of factors that appeared to most impact provider decision-making.

Results

Clinical, Provider, and Patient Factors Impacting the Decision to Use Virtual Care

Thematic analysis revealed that provider decisions about whether to continue with or initiate a virtual visit is driven by clinical, patient, and provider factors (Textbox 1). Although we observed some variation related to specific aspects of the different clinical focus areas, the factors discussed here were noted across all 4 specialties.

Textbox 1. Thematic categorization of factors influencing provider decision-making.

Clinical factors

- Patient acuity
- Need for additional tests or labs
- Change in patient’s status or overall stability
- First visits and patients with no record of recent medical examination

Patient factors

- Patient’s ability to articulate symptoms or needs
- Availability and accessibility of technology
- Preferences regarding virtual visits
- Access to caregiver assistance

Provider factors

- Comfort with and acceptance of virtual technology
- Knowledge about how to conduct physical exam and assessment virtually

Clinical Factors Impacting the Decision to Use Virtual Care

The providers described clinical factors that impact their decisions about whether to see a patient virtually or in person. The common clinical factors cited include patient acuity, a need for additional tests or labs, changes in the patient’s status and overall stability, and a visit with a patient who is new or has no record of recent medical examination.

Patient Acuity

The providers indicated that acute, newly emergent conditions proved most difficult to assess virtually. In particular, they noted that patients’ reports of pain were often challenging to assess virtually, since they were unable to physically examine sensitive areas to help in making a diagnosis. On the other hand, chronic conditions were better suited for virtual management, particularly if patients had already been diagnosed and had an established medical plan. Blood pressure and blood sugar management were characterized as 2 examples of chronic conditions that may be easily managed using virtual care. Elaborating on this observation, a spinal cord provider explained as follows:

> *Most of the time, you cannot [make a diagnosis] without laying hands on the patient. But [when it's] just blood pressure management, blood sugar management, you don't have to have a patient face-to-face encounter. You can do only virtual.*

Need for Additional Tests or Labs

Conditions that required lab draws or imaging to accurately diagnose were described as difficult to manage. The providers noted that patients who were able to have tests performed prior to their virtual visit were much more likely to have a productive visit, but because tests are often completed at the time of the in-person visit, previsit workups were reportedly uncommon. Hence, the providers noted that if a patient needed lab tests, additional virtual visits were often necessary to complete their assessments and ultimately make a diagnosis.

Changes in Health Status

The providers noted that patients who reported changes in clinical status and overall well-being were less appropriate for virtual care. These changes often signaled to providers the need for a comprehensive, in-person physical examination rather than a virtual exam. Some examples of health status changes that clinicians felt warranted an in-person visit included unexpected weight gain or weight loss and fluctuating or inconsistent symptoms accompanying a diagnosed chronic condition. For example, a cardiologist noted the following:

> *[If] I have a visit with a patient that's either a telephone or a [video visit] and identify that there are some factors that are starting to concern me——in general it's weight, shortness of breath, new symptoms that I wish I could have a physical exam or be able to examine the patient—then I will follow those telephone visits … with an in-person visit generally in the next couple of weeks and sometimes more urgently.*

Conversely, the providers indicated that patients who reported a stable and consistent health status made for better candidates for virtual care.

New Patients and Individuals With No Recent Visit

Providers across all specialties maintained the view that first visits and new patients should be seen in person if possible. This view held steady despite the wide variety of conditions being assessed and treated among the providers who participated in the interviews. For example, a physician who treats patients with spinal cord injury stated the following:

> *In terms of pain, you have to have at least the first encounter in person, because you have to do a special test, you have to examine to see specificity, to palpate, to see joints, range of motion.*

Additionally, patients who had not been seen in person for an extended period (2 or more years) were considered less ideal virtual care candidates. However, providers noted that they felt more comfortable offering virtual care when the patients had been recently seen by other providers within the medical system and for whom extensive notes were available.

Patient Factors Impacting the Decision to Use Virtual Care

While the providers largely focused on the clinical needs and circumstances of patients when determining whether a virtual visit would be appropriate, they also described several patient-related factors that influenced decision-making, including a patient's ability to articulate their symptoms and needs, ability to use the technology associated with virtual visits, general preferences for in-person visits, and access to a caregiver to assist with the virtual visit.

Ability to Articulate Symptoms or Needs

The providers explained that patients who were able to communicate their symptoms or needs in a robust and reliable way made for the best virtual visit candidates. Patients who had challenges describing their symptoms, difficulty recalling the timing of certain events or the onset of specific symptoms, or challenges describing physical changes or abnormalities left providers less confident in their virtual assessments. For instance, a primary care provider described how she imparts this advice to residents:

> *I tell the residents as we're seeing patients, one of our first decisions to make is, "Can I safely continue this visit in this fashion, or is there no way I'm going to get enough data by history that I can end at a point where I feel like I've safely cared for the patient?"*

The providers admitted that relying on patients' accounts rather than their own hands-on assessments required a comfort level with virtual assessments, which often took time to develop. In response to this, the providers noted that they had to hone their history taking skills to feel confident with the information patients were relaying to them.

Availability and Accessibility of Technology

The providers indicated that patients needed both personal technology (eg, home computer, tablet, or smart phone) and reliable broadband access to participate in virtual visits. They described many instances of initiating virtual encounters with patients, only to discover that the video or sound quality was poor, and subsequently wasted valuable clinical time troubleshooting these technology-based problems with patients. In such cases, they would either try to follow up by telephone or simply reschedule in-person visits. The providers also noted that individuals with specific clinical or physical characteristics frequently had challenges with virtual visits (eg, older patients with cognitive disabilities such as dementia or patients who experienced sensory loss, namely hearing and visual impairments). A quote from a primary care provider illustrates this point:

> *Like hearing can become a huge problem. If hearing difficulties are too severe, it's really hard to have an appropriate visit. There's something with the tech, the video that I feel like people just can't hear you as*

> *well. I'm not sure if it's the delay and it throws off the mouth reading or something.*

However, despite these challenges, the providers cautioned against assuming that all older patients or patients with sensory loss were inappropriate for virtual care, since they could think of many exceptions to this general observation.

Access to Caregiver Assistance

Finally, the providers noted that having another individual available to assist the patient, typically a caregiver or family member, increased their likelihood of conducting a virtual visit. Particularly among patients with mobility issues, sensory loss, or cognitive impairment, a caregiver was often able to help the veteran troubleshoot technology issues, assist with physical exam maneuvers, or help capture images providers needed to fully assess the patient. Underscoring this point, a palliative care provider explained how they suggest involving caregivers in assessing pain in areas that may be difficult for patients to reach:

> *I always ask the patient "Does it hurt to touch?" And if there's a spouse or another person or a family member or any other person there, I might ask them to touch it.*

Preferences Regarding Virtual Visits

The providers reported that some patients preferred in-person visits to virtual visits and were therefore reluctant to engage through virtual care if an in-person visit could be conducted in a timely manner. They noted that some patients crave face-to-face interactions with their providers and report that the video format fails to replicate that connection. For others, this preference was also attributed to a lack of digital literacy skills and inadequate patient support to help facilitate their use. With additional instruction and digital familiarity, some of these patients could grow more accepting of virtual care.

Nevertheless, the providers speculated that patient's preferences were unlikely to change and that they would continue to opt for in-person visits when given the choice. For instance, a primary care provider reflected as such:

> *My perception of my patients is they're not entirely comfortable never seeing me in person, especially new patients who I've never met. I think most of them feel like, "I'd like to meet you at some point." I think that's always going to be a need there.*

In these scenarios, the providers noted that they would often comply with patients' preferences and opt to see the patient in person rather than virtually. The COVID-19 pandemic, however, necessitated at times that visits be virtual, even when patients preferred in-person care.

Provider Factors Impacting the Decision to Use Virtual Care

While playing less of a role in real-time decision-making around virtual care, the providers also described how factors related to their own acceptance of and comfort with virtual care modalities impacted their decision-making. In addition, they noted that acquiring training on how to assess patients virtually would likely lessen their discomfort and encourage them to provide virtual care more often and to more patients with diverse clinical needs.

Comfort With and Acceptance of Virtual Technology

First, the providers argued that assessing patients virtually required a general acceptance of the format and a recognition that it necessitates a different approach to patient assessment and evaluation. While the providers in our sample largely appreciated virtual care, they described colleagues who lamented the shift to virtual care and found it challenging to adapt their clinical care to the new format. This acceptance provided a foundation for providers to improve their virtual diagnostic skills and increase the likelihood of engaging in a virtual visit with a patient. A primary care provider elaborated on this point as follows:

> *You have to accept the strengths and deficits of video [visits] and don't try to make it into a total replacement for a face-to-face visit, because if you're more comfortable listening to their symptoms, listening to what they tell you and they can relate to you pretty well how much edema they have and where it was before, and if you accept that, then you can get more done.*

Virtual Physical Exam Skills

In most instances, the providers described learning to provide virtual care as a process of "just figuring it out," while also drawing on the fundamentals of their clinical training. In this process, many acquired new skills and adopted new strategies for conducting virtual physical exams, including asking patients to engage in specific maneuvers or provide information not typically asked for in a face-to-face visit. The providers described how conducting virtual exams increased their awareness of the observations they make about patients and their physical health during in-person exams. Virtual exams required deliberate attention to those missing elements. For example, one primary care provider explained:

> *You're assessing the speed they're getting up and moving around, so you have to make sure to ask them to walk around. And so, I think that there is a potential to miss things if you haven't gone through the process of saying, okay, what are the things that I'm likely to miss as a provider given this particular modality, and then how can I try to counter those with just some things on your internal checklist that you want to make sure to ask about?*

In this last example, asking patients to stand and walk around while on video was one way to assess gait and movement. The providers' confidence in and acquisition of these skills increased the likelihood that they would opt to treat and assess a patient virtually.

Discussion

Principal Findings

In this qualitative study of VA providers, we found that a complex set of clinical, patient, and provider factors influences a provider's decision about whether to provide care virtually or in person. Many of the providers in our study referenced scenarios where virtual visits had already been scheduled and initiated, but through examination of patients, they realized an in-person visit would be more clinically appropriate. Such instances added an additional visit for both patients and providers, contributing to potential waste and redundant services. This highlights the value for providers of knowing a priori which scenarios and which patients might be more appropriate for virtual care. Here, we detail several ways that these findings may be used to optimize the use of both virtual and in-person care.

First, the providers noted that, in many cases, a high-quality virtual visit requires some collection of information or data from the patient. As the providers have made the leap to virtual care, many have mourned the loss of data that would be more easily accessible in a traditional in-person visit, such as vital signs and physical exam findings [18]. Some providers have found solutions in home devices such as blood pressure cuffs, blood glucose monitors, pulse oximeters, and scales, all of which can help them to form a more complete picture of patients' vital signs and other important information for decision-making [19,20]. The increasing availability of wearable and other patient-facing digital technologies, including exercise monitors (eg, FitBits and Apple Watches), smartphone-associated portable electrocardiograms, and home-based lab testing may offer additional opportunities to collect key information outside the in-person visit, although there is still a need for evidence about the reliability and consistency of data in different circumstances [21,22]. Augmenting a virtual visit with these technologies may mitigate the risks that the providers in our study noted when they must rely on imperfect or incomplete patient-provided histories.

Second, specific skills and training are required to conduct effective virtual visits and spare providers from "figuring it out as [they] go." Several efforts are underway to develop and disseminate training and instruction on virtual care and to integrate these domains into standard medical school and residency curricula [7,23]. Additional training resources should target mid- or later-career clinicians, since they are less likely to be exposed to interventions geared toward medical trainees. The American Medical Association as well as other organizations and societies have developed resources to help clinicians build telemedicine physical exam skills [24] and communication skills such as "digital empathy" [25]. These resources include guidebooks as well as informational webinar series and videos. Others have created helpful guides for conducting patient-assisted physical exams [26].

Third, there is a need for guidelines to help determine whether a specific visit should be scheduled in person or virtually. The providers largely maintained that patients without recent visits or presenting with new or higher acuity problems might not be best served by virtual visits. Both for building patient rapport and for ensuring a more complete mental model of a patient's condition, it may well be best for an initial patient visit to occur in person for most patients and clinical situations [25]; some have suggested newly diagnosed patients should always be seen in person, at least initially, until medication regimens can be safely established [27]. Nevertheless, there is mounting evidence that with proper training and protocols in place, even high-acuity clinical circumstances can be safely assessed virtually and may even decrease overall rates of emergency care use. For example, Wray et al [28] demonstrated how a "tele-urgent care program" that provided care for a variety of clinical scenarios was safe, effective, and led to the decreased use of emergency departments. Such findings may provide further confidence to virtual care providers that virtual care can provide safe access to care in a variety of clinical scenarios.

Finally, attention to equity is needed to ensure that all patients have opportunities to build digital literacy skills [29], have access to the technology and receive the support they need to participate in virtual visits. Failure to attend to these issues may contribute to further inequity in health care provision and outcomes [30]. Health care organizations have attempted to respond to this digital divide in a variety of ways. For instance, the VA initiated a tablet distribution program, in which at-risk, high-need patients are provided with video-enabled tablets equipped with internet service. This program has resulted in improved access and continuity of care, with high satisfaction rates among Veterans [31,32]. In addition, studies have found that providing patients with hands-on instruction on how to use new technologies may further ameliorate a lack of digital literacy skills [33]. Moreover, functional limitations (eg, loss of eyesight and hearing as well as dementia) also created barriers to patients' use of virtual care in this study. Incorporating principles of universal design, which advocates for designing products and services that can be used by all individuals to the greatest extent possible, may abet some of these issues and ensure accessibility for all patients [30,34,35].

Even with the array of tools and strategies described above, it is unlikely that all combinations of providers, patients, and clinical scenarios will ultimately prove ideal for virtual care. Given the dramatic expansion of virtual care since the onset of the COVID-19 pandemic, the existence of virtual care is effectively a foregone conclusion; what is essential to uncover at this stage is how and when to best use the various visit modalities at provider and patients' disposal. The observations providers shared in this study are useful for generating hypotheses on how to integrate virtual and in-person care.

Limitations

This study has several limitations. First, the sample was limited to providers at the VA; thus, provider experiences may not apply to other settings, particularly those with different reimbursement models. Fee-for-service systems, the predominant mode of health care delivery in the United States, may reimburse virtual visits differently from in-person visits and pose additional incentives or disincentives to use virtual care. However, we were able to assess a broad array of providers across a variety of geographic regions, improving the transferability of our findings. Second, this qualitative study about provider perceptions does not assess the impact of these factors on quality of care and patient outcomes, which would provide value in discussions about the degree to which these criteria should inform guidelines and protocols. For example, while the providers noted that remote monitoring devices and other technology increased their comfort and confidence in virtual examination, the actual impact of this factor on quality and safety of care warrants further evaluation. A final and perhaps most significant limitation is that this study does not assess decision-making in real time and instead relies on providers' reflections on their decisions, an inherent limitation of qualitative interviews. Though challenging to carry out, direct observations of clinical practices may offer a more realistic account of provider decision-making around virtual care.

Conclusion

This qualitative study found that providers within the VA consider a complex array of factors when deciding whether to offer or continue with a virtual visit. Clinical factors were the most dominant, but patient and provider factors also influenced the decision process. These findings can inform health system policies to ensure accessible, high-quality care, as well as policy maker considerations when adjudicating reimbursement levels for virtual care visits. Further development of tools, resources, and guidelines is needed to facilitate real-time provider decision-making about when to offer a patient virtual care.

Abstract

Background: Musculoskeletal disorders negatively affect millions of patients worldwide, placing significant demand on health care systems. Digital technologies that improve clinical outcomes and efficiency across the care pathway are development priorities. We developed the musculoskeletal Digital Assessment Routing Tool (DART) to enable self-assessment and immediate direction to the right care.

Objective: We aimed to assess and resolve all serious DART usability issues to create a positive user experience and enhance system adoption before conducting randomized controlled trials for the integration of DART into musculoskeletal management pathways.

Methods: An iterative, convergent mixed methods design was used, with 22 adult participants assessing 50 different clinical presentations over 5 testing rounds across 4 DART iterations. Participants were recruited using purposive sampling, with quotas for age, habitual internet use, and English-language ability. Quantitative data collection was defined by the constructs within the International Organization for Standardization 9241-210-2019 standard, with user satisfaction measured by the System Usability Scale. Study end points were resolution of all grade 1 and 2 usability problems and a mean System Usability Scale score of ≥80 across a minimum of 3 user group sessions.

Results: All participants (mean age 48.6, SD 15.2; range 20-77 years) completed the study. Every assessment resulted in a recommendation with no DART system errors and a mean completion time of 5.2 (SD 4.44, range 1-18) minutes. Usability problems were reduced from 12 to 0, with trust and intention to act improving during the study. The relationship between eHealth literacy and age, as explored with a scatter plot and calculation of the Pearson correlation coefficient, was performed for all participants (r=–0.2; 20/22, 91%) and repeated with a potential outlier removed (r=–0.23), with no meaningful relationships observed or found for either. The mean satisfaction for daily internet users was highest (19/22, 86%; mean 86.5, SD 4.48; 90% confidence level [CL] 1.78 or –1.78), with nonnative English speakers (6/22, 27%; mean 78.1, SD 4.60; 90% CL 3.79 or –3.79) and infrequent internet users scoring the lowest (3/22, 14%; mean 70.8, SD 5.44; 90% CL 9.17 or –9.17), although the CIs overlap. The mean score across all groups was 84.3 (SD 4.67), corresponding to an *excellent* system, with qualitative data from all participants confirming that DART was simple to use.

Conclusions: All serious DART usability issues were resolved, and a good level of satisfaction, trust, and willingness to act on the DART recommendation was demonstrated, thus allowing progression to randomized controlled trials that assess safety and effectiveness against usual care comparators. The iterative, convergent mixed methods design proved highly effective in fully evaluating DART from a user perspective and could provide a blueprint for other researchers of mobile health systems.

Introduction

Background

Musculoskeletal disorders (MSDs) are prevalent across all ages, have shown an increase in the global disease burden over the past decade [1-3], and are associated with increased life expectancy and reduced activity [4,5]. MSDs are leading contributors to years lived with disability, early work retirement, and reduced ability to participate socially [5]. In many countries, they present the most significant proportional reason for lost productivity in the workplace, leading to significant impacts on the Gross Domestic Product and health care costs [6,7].

In the United Kingdom, the MSD burden of care poses a significant financial challenge to the National Health Service (NHS), costing £4.76 billion (US $3.84 billion) of resources and using up to 30% of primary care physician visits annually [8,9]. A freedom of information request has revealed that the average waiting times for NHS musculoskeletal outpatient physiotherapy services exceeded 6 weeks in the year to April 2019, with some patients waiting 4 months for routine physiotherapy appointments [10]. Longer waiting times can result in delays to physiotherapy services, with detrimental effects on pain, disability, and quality of life for waiting patients [11,12], highlighting the need for a targeted policy response [3,13].

Reducing inconsistency in clinical pathway delivery, including unwarranted secondary care consultations and investigations, forms part of the “Getting It Right First Time (GIRFT)” national program implemented within the UK NHS and has demonstrated cost reduction across the musculoskeletal pathway, particularly relevant in overburdened health care systems [14] Musculoskeletal triage as a single point of entry is effective in improving user satisfaction, diagnostic agreement, appropriateness of referrals, and reduction in patient waiting times [15], where it has been demonstrated to be effective using several methods by a range of clinicians [16-18]. However, using clinicians to provide MSD triage carries its own challenges [19].

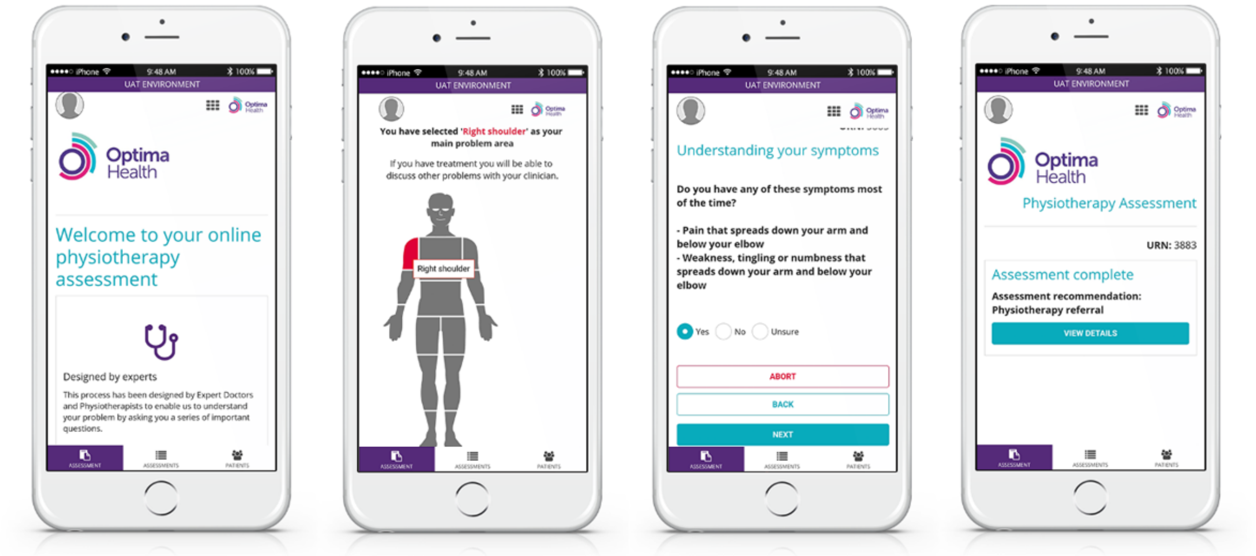
Mobile health (mHealth), defined by the World Health Organization as a medical or public health practice that is supported by mobile devices [20], has seen rapid evolution and adoption, and currently, smartphone apps have the potential to make the treatment and prevention of diseases cost-efficient and widely accessible [21,22]. Optima Health has developed the mHealth Digital Assessment Routing Tool (DART) specifically for triaging MSDs, delivering a narrower but deeper assessment than that found with more generic symptom checkers. A digital alternative to clinician-led triage, which is able to replicate the same stratification of care and reduction in costs, is a desirable objective, although some mHealth tools have not demonstrated cost-effectiveness or have merely shown a shift in spending to another part of the health system [23]. It is also recognized that many mHealth apps fail to scale up from a prototype to successful implementation, with inattention to usability during the design and testing phases being identified as a potential cause of the high abandonment rate [24-27]. Although acknowledging usability is crucial in the design, development, testing, and implementation of mHealth apps [28-32], a consistent approach to testing has not yet been established, with researchers using a combination of different study methodologies [33].

An iterative, convergent mixed methods design was used to assess the usability of DART, using cyclical evaluation and improvement plus mixed methods to provide richness while quantifying use, maximizing usability, and therefore supporting system adoption [34]. The testing protocol for this study has been described in detail in a previous publication [35].

DART Overview

DART is a first contact mHealth system comprising an algorithm distinguished by 9 body areas, providing the patient with a recommendation for the most appropriate level of intervention based on their responses (Figure 1). Screening for serious pathologies is completed at the start of the assessment, with less urgent medical referrals being identified as the patient passes through the questioning. The referrals recommended by the algorithm are configured to match the service provider’s local MSD pathways. DART typically signposts emergency or routine medical assessments, specific condition specialists, physiotherapy, self-management programs, and psychological support services.

Figure 1. The Digital Assessment Routing Tool mobile health system.



Welcome to your online physiotherapy assessment

Designed by experts

This process has been designed by Expert Doctors and Physiotherapists to enable us to understand your problem by asking you a series of important questions.

You have selected 'Right shoulder' as your main problem area

If you have treatment you will be able to discuss other problems with your clinician.

Understanding your symptoms

Do you have any of these symptoms most of the time?

- Pain that spreads down your arm and below your elbow
- Weakness, tingling or numbness that spreads down your arm and below your elbow

● Yes ○ No ○ Unsure

Physiotherapy Assessment

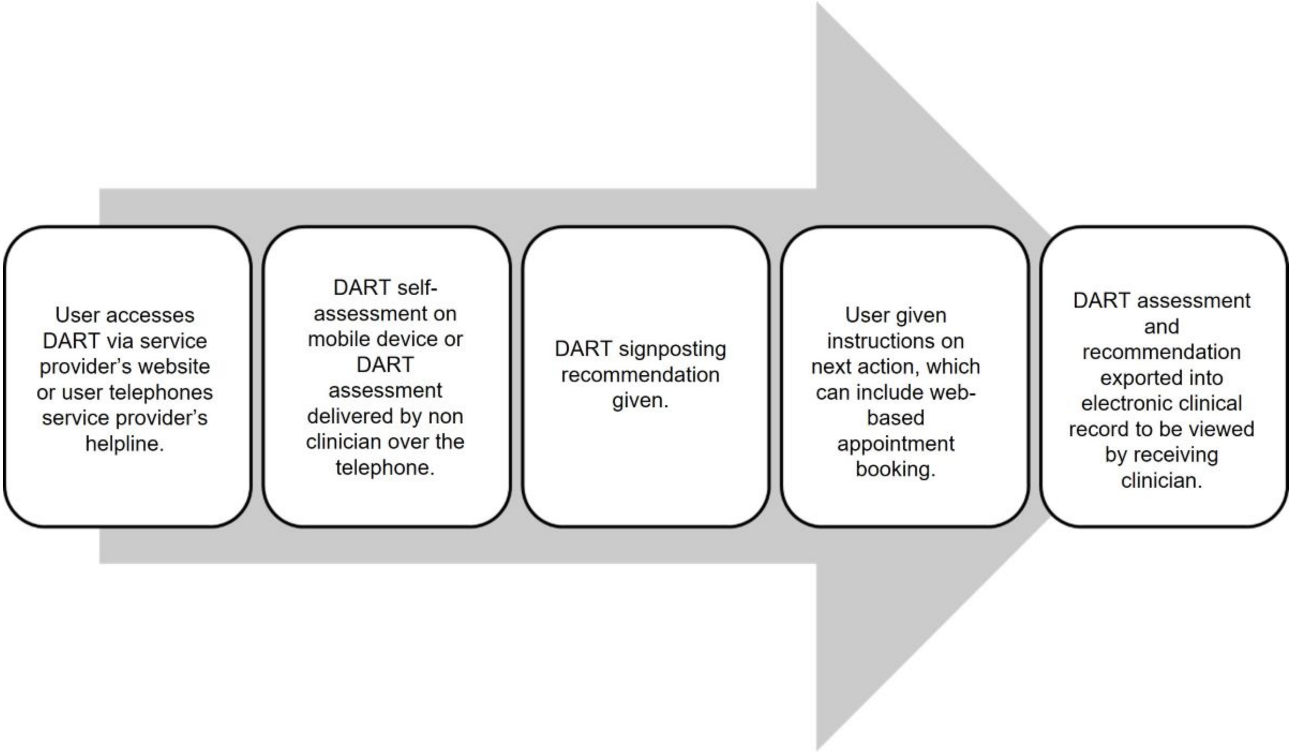
URN: 3883

Assessment complete

Assessment recommendation: Physiotherapy referral

Integration of DART with the provider's clinical record system means that assessment data and recommendations can be made instantly available to the receiving clinician. Using a link on the clinical provider's website, DART can be accessed 24/7 using a mobile device or computer, directing users to care at an earlier stage of their injury than would be possible via a traditional clinician-led triage process (Figure 2). Alternatively, DART can be delivered over the telephone by a nonclinician. Reduction in treatment waiting times and reallocation of triage clinical resources to more complex assessments and management could hold significant benefits for the user and health care system.

Figure 2. Integration of the DART mobile health system within an existing musculoskeletal disorder pathway. DART: Digital Assessment Routing Tool.



Previous Work

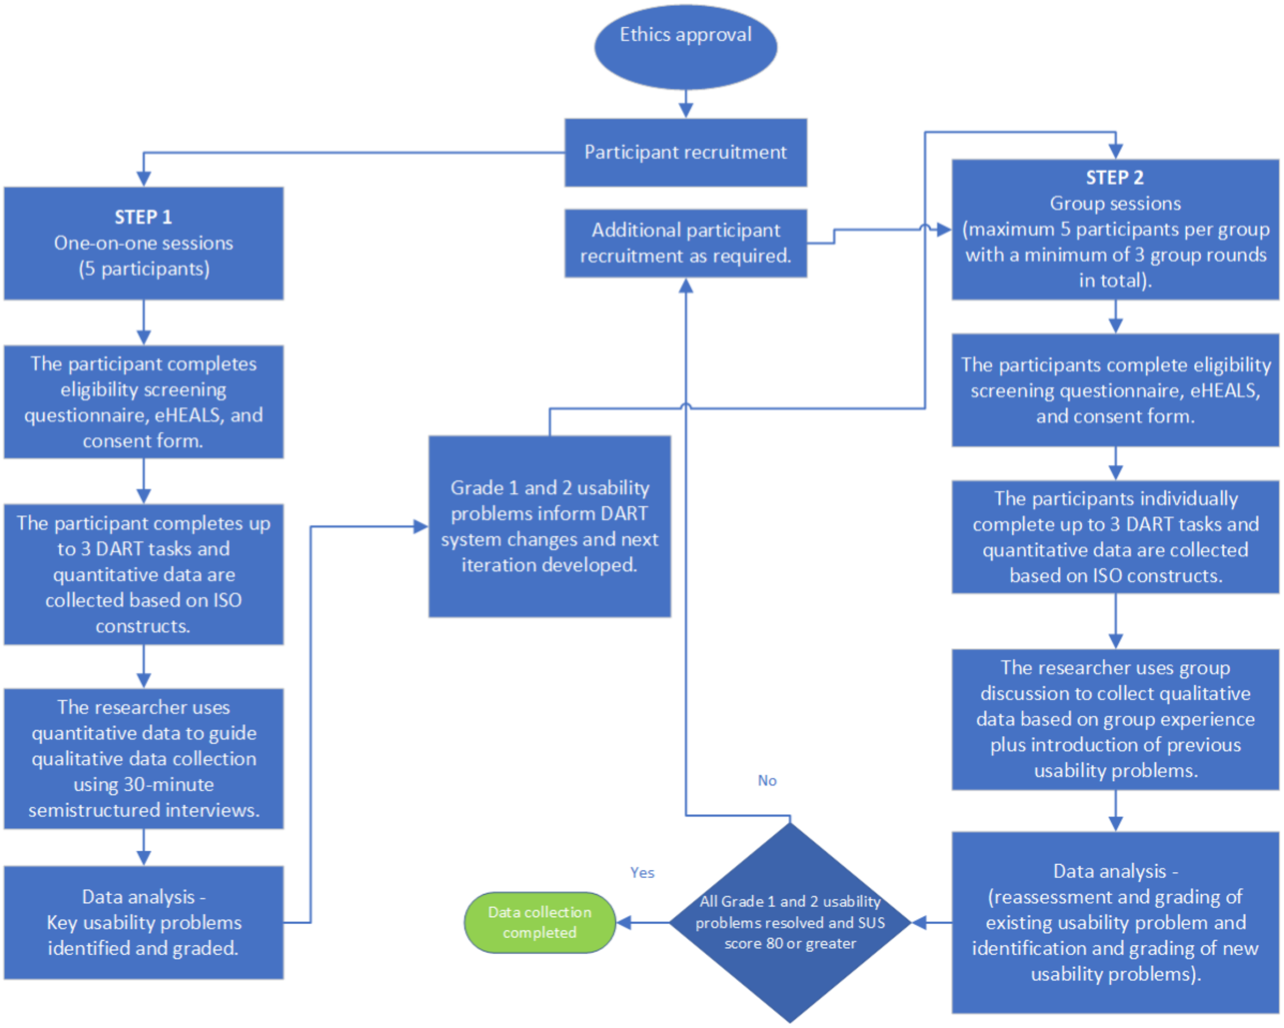
This usability study is part of a larger project, bringing DART from concept to implementation through a series of clinical and academic research work packages. Clinical algorithm validity was assessed by a panel of clinical experts using vignettes incorporating common MSD presentations, as well as red flags and complex presentations, with the panel deeming the validity to be sufficient to allow DART to proceed to further research studies. The protocol devised for this usability study went through a series of iterations within an internal review process, comprising the research project team and DART system developers to arrive at the final version [35]. The objective of this study was to optimize usability before evaluating the safety and effectiveness of DART through a randomized controlled trial, the pilot protocol for which has been published [36].

Methods

Study Design

This study used an iterative, convergent mixed methods design, the protocol for which has been published elsewhere [35]. Step 1 involved in-depth interviews with 5 participants to identify key usability issues, followed by step 2, where group sessions captured greater diversity of data from a potential DART user population (Figure 3). Quantitative data collection was defined by the constructs of effectiveness, efficiency, and satisfaction within the International Organization for Standardization (ISO) 9241-210-2019 standard [30] and provided researchers with a focus for qualitative data collection during both steps. Accessibility was monitored throughout the testing process following the principles described in ISO 30071-1-2019 for embedding inclusion within the design process [31]. Mixed methods data collection and analysis continued cyclically through all rounds of testing until the fourth DART mHealth system iteration was found to perform according to the agreed criteria and the study end points of all grade 1 and 2 usability problems being resolved, as well as a mean System Usability Scale (SUS) score of ≥80, were achieved. The relationship between the likelihood to recommend a system and the mean SUS score has been found to be strongly correlated, and a score of ≥80 was chosen as a study end point as achievement of this threshold is considered to increase the probability of users recommending the system to a friend, therefore positively affecting adoption [37].

Figure 3. DART usability study iterative, convergent mixed methods design. New participants were recruited for each testing round. Participants raising specific issues in previous rounds were invited individually to review and provide feedback on changes. DART: Digital Assessment Routing Tool; eHEALS: eHealth Literacy Scale; ISO: International Organization for Standardization.



Participant Recruitment

A stratified purposive sampling method was used to gather information from participants by using a sampling matrix and quotas [38], categorized by participant age, internet use, sex, and English for speakers of other languages (ESOL) groups—all of which are subgroups that have shown to contribute small differences in internet use [39]. For this study, “daily internet users” were defined as individuals who access the internet every day or almost every day, and “infrequent internet users” were those who were not daily users but had accessed the internet within the past 3 months [39]. Recruitment was conducted via flyers and emails to local community groups, Optima Health's existing client base of employers and staff, and Queen Mary University of London students, as well as via social media. In the latter stages, snowballing yielded participants with characteristics of interest; study recruitment continued throughout the study process until the study end points were reached. Potential participants expressing an interest were sent a patient information sheet and consent form and had the opportunity to review this material before consenting to join the study. A total of 33 individuals expressed an interest in participating, of whom 22 (67%) enrolled in the study after meeting the screening criteria.

Inclusion and Exclusion Criteria

The study participant inclusion criteria were as follows: (1) adults aged >18 years; (2) able to speak and read English; (3) living in the United Kingdom; (4) accessed the internet at least once every 3 months; (5) access to a smartphone, tablet, or laptop; and (6) current or previous experience of a musculoskeletal condition.

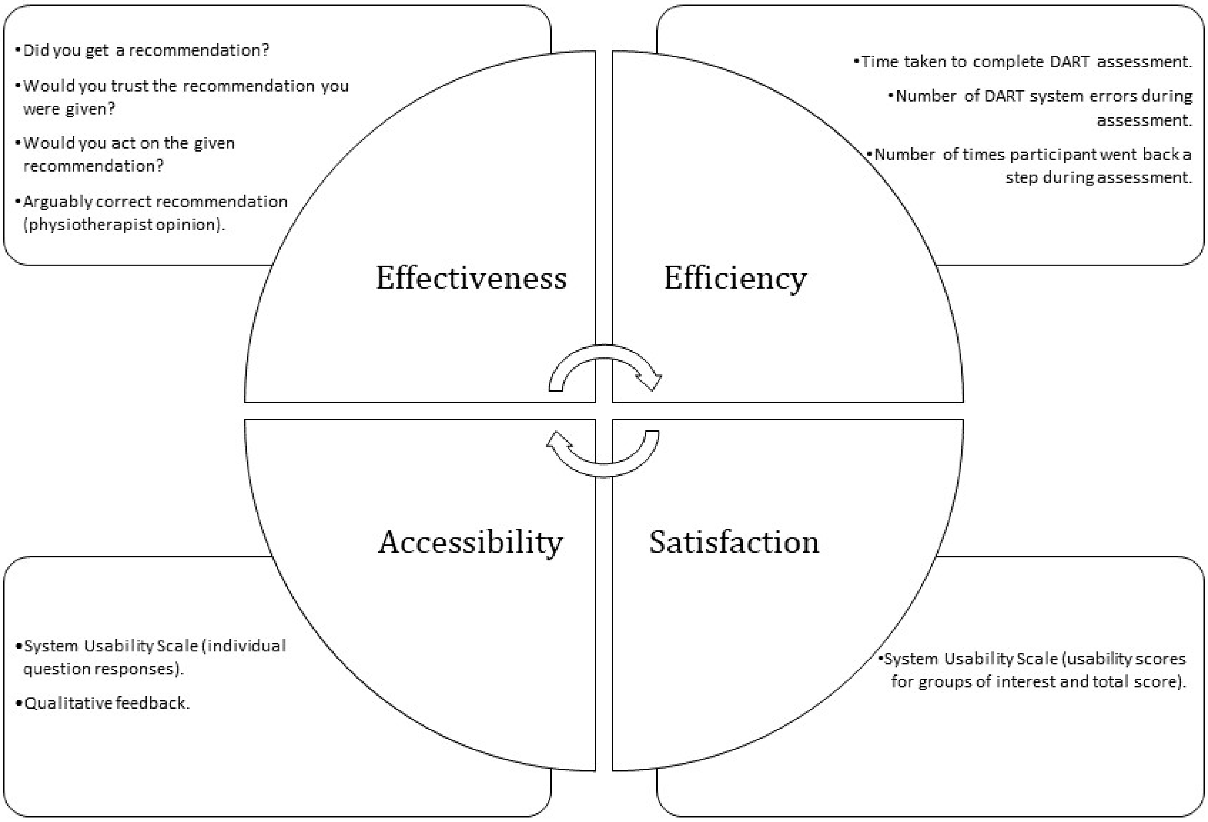
The study participant exclusion criteria were as follows: (1) significant visual or memory impairment sufficient to affect the ability to answer questions and recall information in an individual or group discussion setting; (2) medically trained musculoskeletal health care professional, such as a physician or physiotherapist; (3) relatives or friends of the researchers; and (4) Optima Health employees.

Data Collection

Following the attainment of consent, participants completed a short questionnaire, including the eHealth Literacy Scale (eHEALS) [40], to provide demographic data and were given instructions by the researcher on how to log into the DART system test site. The first 5 participants in step 1 attended one-on-one video call interviews lasting up to 60 minutes where they could choose up to 3 existing or previous musculoskeletal conditions to complete assessments while being encouraged to give feedback using the concurrent think-aloud method [41]. Participant choice was not limited to specific body sites as usability features were synonymous across all 9 body sites. The participants in step 2 tested DART individually and then attended 30-minute video call group discussion sessions facilitated by the researcher.

Assessing DART performance using satisfaction scales alone was not considered adequate; thus, data collection parameters were defined using the ISO constructs (Figure 4). Following their DART assessments, all participants completed a questionnaire and the SUS [42-44]. The researcher (physiotherapist with postgraduate MSD qualifications) assessed the clinical accuracy of the DART recommendation based on the diagnosis the participant had been given by their treating clinician. Quantitative data were also taken from the DART system itself.

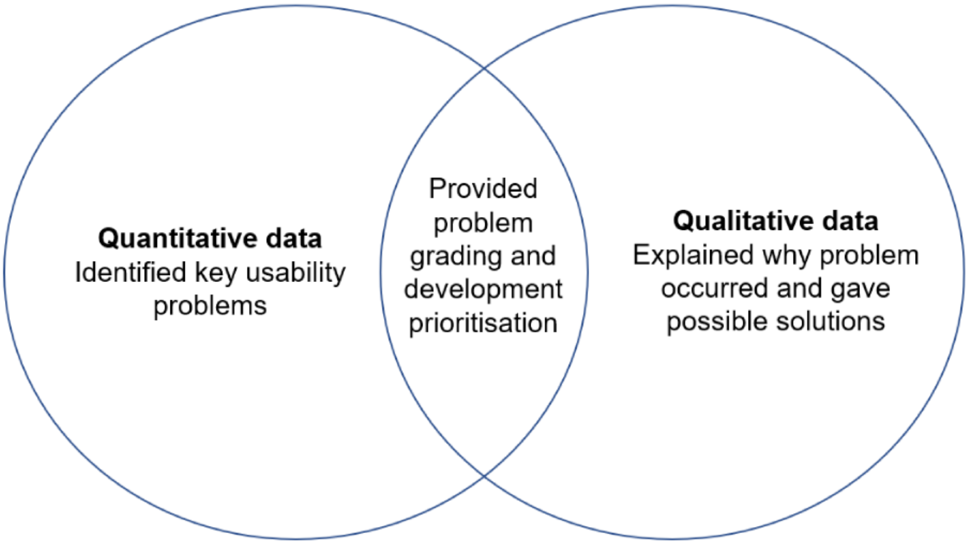
Figure 4. Data collection methods used to assess DART performance against the International Organization for Standardization 9241-210-2019 and International Organization for Standardization 30071-1-2019 standards constructs of effectiveness, efficiency, and satisfaction [30] and accessibility [31]. DART: Digital Assessment Routing Tool.



Quantitative data aligned to the ISO 9241-210-2019 standard constructs were generated from participant questionnaires and DART system data, as shown in Figure 4. These informed the researcher's qualitative data collection, aided by the use of a visual joint display, merging both types of data to illuminate not only usability problem themes but also potential system improvements (Multimedia Appendix 1). Qualitative data recorded during the interviews and group sessions were transcribed verbatim using the Otter transcription software (Otter.ai; automated video and audio transcription software) and checked for accuracy against the original recording. During group sessions, previous usability problems were introduced to participants to assess the impact of changes made to the previous iteration. In addition, users who raised specific issues in previous rounds were invited individually to review and feedback on changes. In addition to usability problems, any participant feedback on accessibility or positive aspects of DART was recorded.

Data analysis occurred after each round of testing and leveraged the strengths of the convergent mixed methods design to identify usability issues and inform the changes required for subsequent DART iterations (Figure 5). Of particular importance was the thematic analysis of qualitative data provided by real-world users, which ensured their views were included in the DART system development to improve usability.

Figure 5. The convergent mixed methods design, where both data types are collected simultaneously to allow the analysis and grading of usability problems, thus informing the next system iteration.



Data analysis was performed to identify the overall satisfaction score and differences between groups (mean score, SD, and confidence level [CL]). Statistical analyses examined the relationship between participant age and eHealth literacy using Pearson correlations.

Restrictions imposed during the COVID-19 pandemic led to all data collection sessions being conducted remotely using Microsoft Teams videoconferencing software and web-based questionnaires.

Ethics Approval

This study received approval from the Queen Mary University of London Ethics of Research Committee (QMREC2018/48/048) in June 2020.

Data Analysis

Extending the convergent mixed methods design from data collection to analysis, the reporting used a weaving approach where usability problems were brought together on a theme-by-theme basis and presented through joint displays [45].

Quantitative data from web-based questionnaires and measures of efficiency from the DART system were analyzed and reported to identify key usability issues. Participant SUS raw scores were converted and analyzed by groups of specific interest (daily internet users, infrequent internet users, and ESOL), and the amalgamated mean score across all participants was converted into a percentile score to provide benchmarking against other web-based systems [46].

To minimize bias, quantitative data were collected by an independent researcher during the initial 5 semistructured interviews, and web-based questionnaires were used for the group sessions. Using a thematic analysis approach, qualitative data derived from transcripts of interviews and group sessions were reviewed and analyzed systematically by the 2 researchers independently. Patterns and clusters of meaning within the data were identified and labeled according to the area of system functionality. Data not directly related to the overall research question were excluded. The 2 researchers then worked together to agree and create a thematic framework with higher-order key usability themes able to address the research objective [47,48]. Data were indexed into usability problems of key importance to the study and quotes extracted for each subtheme, thus providing the details required to make the system changes needed to remove or mitigate grade 1 and 2 usability issues. The researchers, working independently initially and then together, arrived at a consensus and allocated a problem severity grade to each usability problem. This was obtained by considering the impact and frequency of the problem, leading to a decision on the risk of not addressing the problem versus the reward of correcting it [49] (Table 1). Once problems had been graded, matched system developments were passed to the DART system developers to guide the next iteration. Actions to address all grade 1 and 2 usability problems were completed for the next iteration, together with closely associated grade 3 and 4 problems if they fell within the scope of the development work. All usability problems remained on record and were reassessed after each round and, if necessary, regraded. Positive feedback about the system was also reported.

Table 1. Usability problem grading criteria, adapted from guidance issued by The Food and Drug Administration [49].

Grade	Impact	Frequency	Implications	Action
1	High	High, moderate, or low	Prevents effective use of the system	Address in next study iteration
2	Moderate or low	High or moderate	Affects the quality of system delivery	Address in next study iteration
3	Moderate or low	Low or moderate	Minor issues for several users or a small number of users highlighting concerns important to them	Document and address in later development
4	Low	Low	Small issues that, if resolved, could improve user satisfaction	Document and address in later development

Statistical Analysis

The relationship between participant age and eHealth literacy was analyzed using Pearson correlations in Microsoft Excel (a spreadsheet with statistical analysis functionality) to identify user groups less likely to use DART successfully.

Differences in satisfaction scores were present between groups, with expert internet users having the highest mean score (mean 86.5, SD 4.48; 90% CL 1.78).

Results

Overview

A total of 22 participants were enrolled and completed the study (Table 2). The first testing round comprised 23% (5/22) of participants who completed qualitative "think-aloud" data collection led by a researcher familiar with the system and with training in the use of the method. It has been suggested that this relatively small number of participants is sufficient to expose 75% of usability issues, including all catastrophic problems, with further testing of subsequent iterations using new participants to identify less serious problems [50]. This proved to be the case, and data sufficiency was achieved. This was supported by a narrow study aim and the quality of dialog with the first 5 participants. The final sample size was not predefined and was re-evaluated after each round of results [51].

There was representation from all the groups of interest; however, not all quotas were met, and small sample sizes, especially infrequent internet users, resulted in a skew of data in favor of daily internet users. This compromised detailed statistical analyses across groups (Table 3).

Table 2. Participant characteristics (N=22).

Characteristic	Daily internet users	Infrequent internet users	ESOL[a,b]	All groups
Total sample, n (%)	19 (86)	3 (14)	6 (27)	22 (100)
Age (years)				
Values, mean (SD)	47.6 (15.7)	55 (11.4)	41 (8.5)	48.6 (15.2)
Values, range	20-77	47-68	31-55	20-77
Sex (male), n (%)	9 (41)	1 (5)	3 (14)	10 (46)
eHEALS[c] score				
Values, mean (SD)	29 (8)	25 (4)	26 (12.3)	28.8 (7.8)
Values, range	8-38	21-29	8-37	(8-38)

[a] ESOL: English for speakers of other languages.

[b] All ESOL participants were also daily internet users.

[c] eHEALS: eHealth Literacy Scale.

Table 3. Recruitment matrix showing minimum quotas and number of participants recruited by characteristics of interest (N=22)[a].

Characteristic	Daily internet user (n=19)		Infrequent internet user (n=3)	
	Quota	Enrolled, n (%)	Quota	Enrolled, n (%)
Age (years)				
18-54	2-4	7 (37)	1-3	2 (67)
55-74	2-4	10 (53)	1-3	1 (33)
≥75	1-3	1 (5)	2-4	0 (0)
Sex				
Male	Minimum 6	7 (37)	Minimum 4	1 (33)
Female	Minimum 6	10 (53)	Minimum 4	2 (67)
ESOL[b]				
Non-ESOL	Minimum 6	15 (79)	Minimum 6	3 (100)
ESOL	Minimum 2	6 (32)	Minimum 2	0 (0)

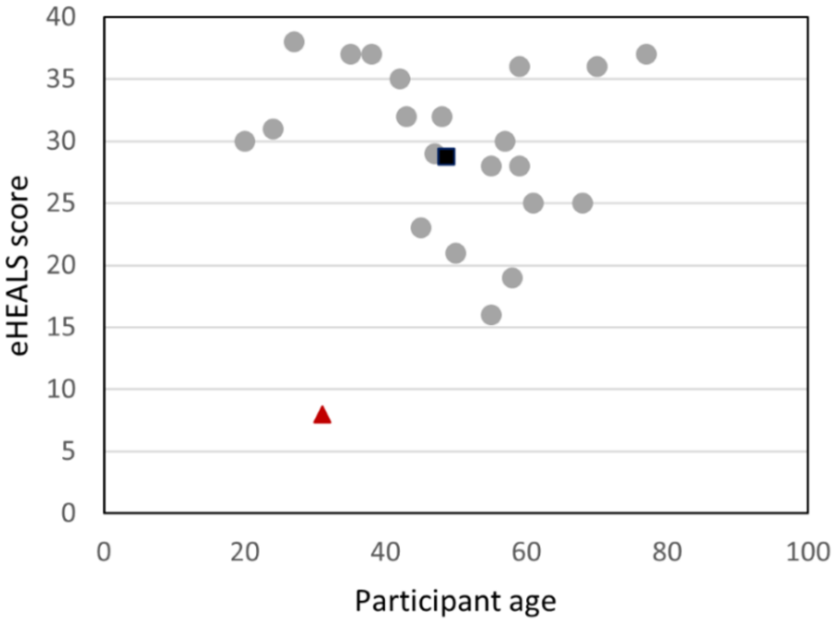
[a] Total study participants quota was 20.

[b] ESOL: English for speakers of other languages.

We were interested to know whether the frequency of internet use, age, eHealth literacy, or being a speaker of English as a second language would affect DART usability, as these factors have been highlighted as potential variables in mHealth adoption [39]. There was a wide range of eHEALS scores across participants (mean 28.8, SD 7.8; 95% CI 25.1-32.3), with the highest score of 38/40 achieved by a daily internet user aged 27 years and the lowest score of 8/40 achieved by an ESOL daily internet user aged 31 years. The oldest participant (aged 77 years) achieved a score of 37/40, and the youngest participant (aged 20 years) scored 30/40.

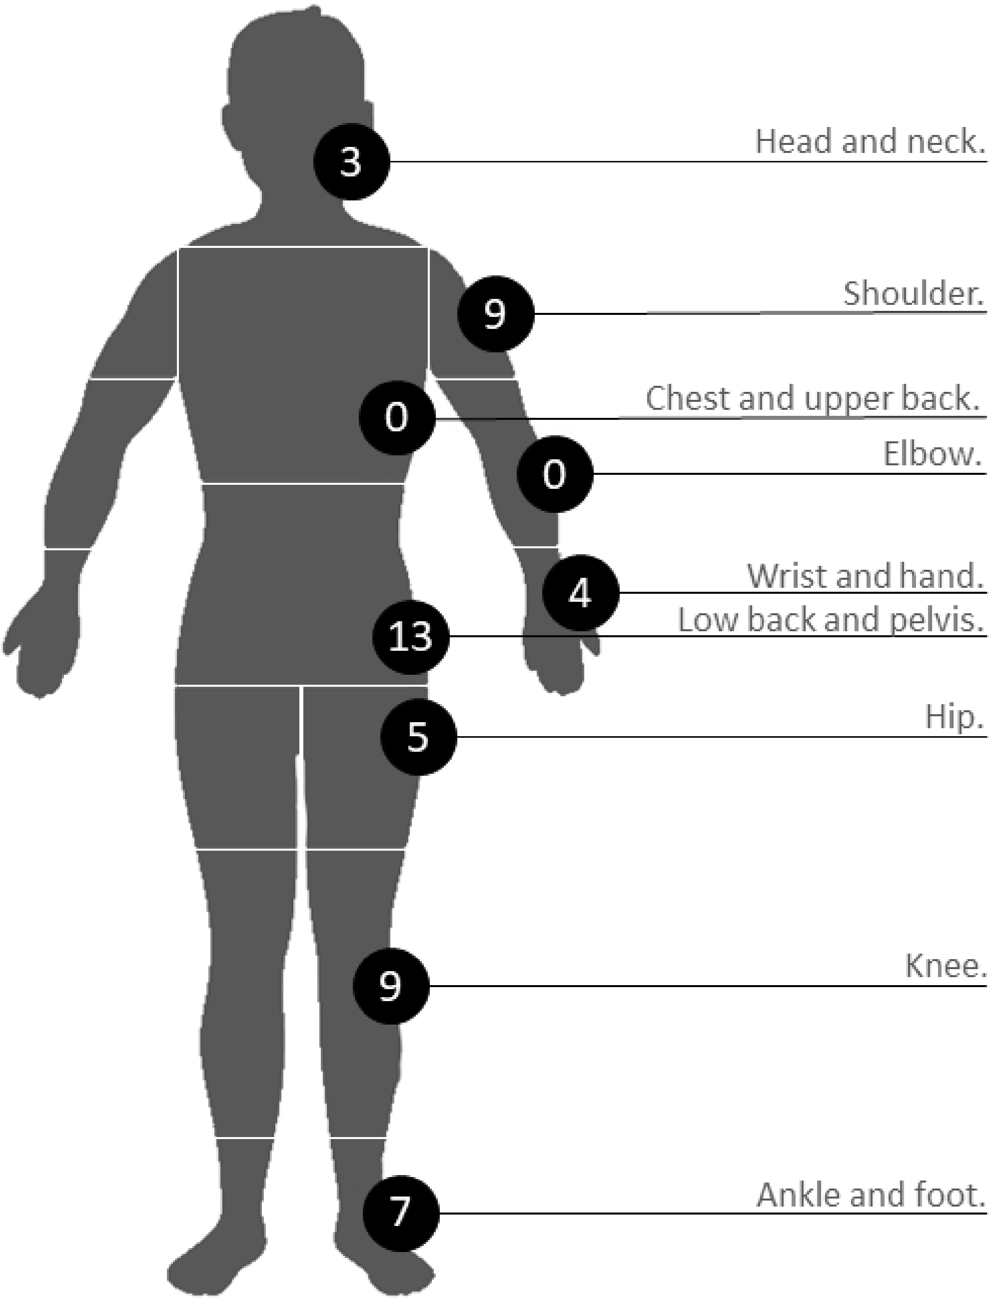
The relationship between eHealth literacy and age, as explored with a scatterplot and calculation of Pearson correlation coefficients, was performed for all participants (20/22, 91%; *r*=–0.2) and repeated with the potential outlier removed, as indicated in Figure 6 in red (19/22, 86%; *r*=–0.23), with no meaningful relationship observed or found for either.

Figure 6. Relationship between age and eHealth literacy scores across all participants. (eHEALS scores range from 0 to 40 scale, with higher scores being better). eHEALS: eHealth Literacy Scale.



A total of 50 assessments were completed by the 22 participants across a possible 9 body sites (Figure 7). The most frequently chosen body site was the low back and pelvis (13/22, 26%), followed by shoulder and knee (both 9/22, 18%). Two body sites were not selected by participants for testing: chest and upper back and elbow. Within a typical MSD triage service, these are often the least occurring body sites. However, the usability features are consistent with those of the other body regions; thus, it is unlikely that any new problems would have been identified through the selection of these pathways.

Figure 7. Body sites selected by participants. The number of selections represents the total of the front, back, and either side of a given body site. The Digital Assessment Routing Tool algorithms are designed to assess for musculoskeletal disorder conditions that occur or refer to pain in the selected body site.



Usability Problems

A total of 19 individual usability problems were identified across all 5 rounds of testing, of which 12 (63%) were initially classified as grade 1 or 2. These grades were either reduced or resolved over the iterations. DART iteration 4 was reviewed by participants during testing round 4, and no grade 1 or 2 usability problems were found. This was validated during testing round 5, and the study end points were achieved (Figure 8).

Within the grade 1 and 2 usability problems, 3 main themes and 7 contributory subthemes were identified (Figure 9).

Over each of the 5 testing rounds, grade 1 and 2 usability problems were discussed with the participants and regraded (Table 4).

Figure 8. Number of usability problems across testing rounds by grade. The incidence and problem grading changed over the 5 rounds of testing, with grade 1 and 2 problems being negated or reduced to a lower grade. All grade 3 and 4 issues were documented, reviewed, and prioritized for future Digital Assessment Routing Tool development.

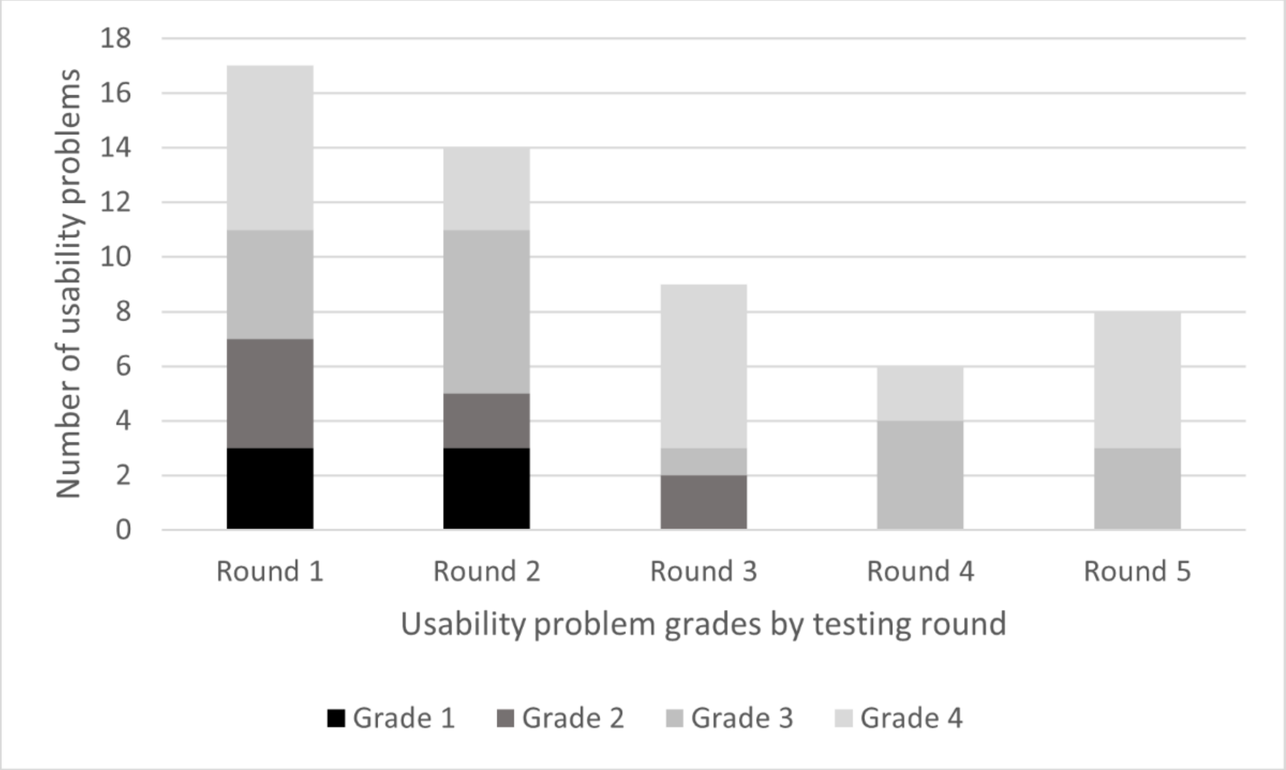


Figure 9. Grade 1 and 2 usability problem themes and underlying subthemes. MSD: musculoskeletal disorder.

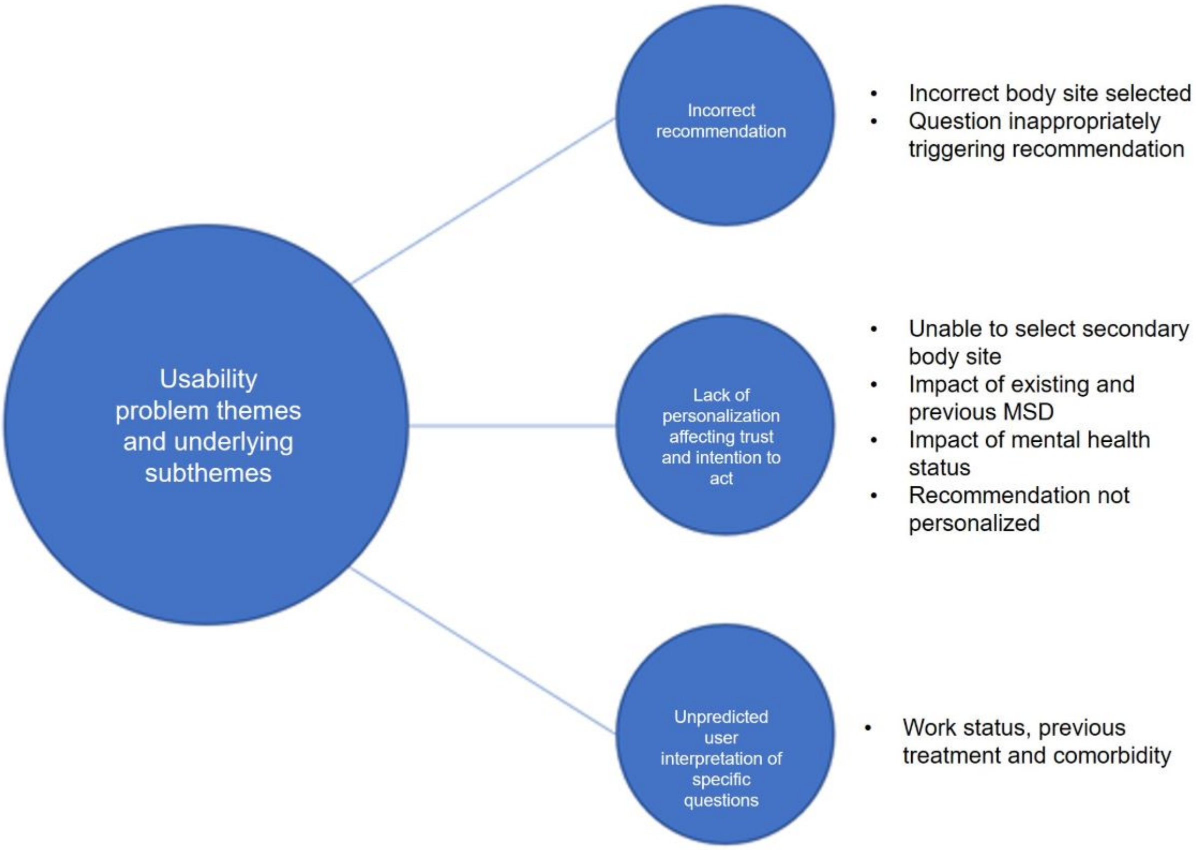

- Incorrect body site selected
- Question inappropriately triggering recommendation

- Unable to select secondary body site
- Impact of existing and previous MSD
- Impact of mental health status
- Recommendation not personalized

- Work status, previous treatment and comorbidity

Table 4. Grade 1 and 2 usability problem themes, subthemes, and participant quotes over 5 rounds of testing[a].

Underlying theme and subthemes	Usability problem grade of subtheme (testing round)	Participant quotes
Theme 1: incorrect DART[b] recommendation compared with expert opinion		
Incorrect body site selected	• 1 (1) • 2 (2) • 2 (3) • 4 (4) • 4 (5)	• "If people are like me, they don't read things properly, especially at the beginning. Was there an option to start again, because people might mess up?" [DART005] • "The only time that I felt slightly lacking in confidence was on the body site. That was the only time I wasn't sure the system would grab the information I clicked." [DART002]
Question inappropriately triggering recommendation—systemic inflammatory disease and central nervous system condition	• 1 (1) • 1 (2) • 0 (3) • 0 (4) • 0 (5)	• "I think that came because I said that I'm stiff in the morning, that eight minutes or whatever." [DART006] • "So I read weakness, not severe weakness. So, I can stand on it and support my weight, but it just hurts like hell, rather than not being able to support myself." [DART015]
Theme 2: lack of personalization affecting participants' trust and intention to act		
Unable to select secondary body site	• 0 (1) • 2 (2) • 2 (3) • 0 (4) • 0 (5)	• "I think if I could have put more evidence in, then I'd be more likely to follow the recommendation at the end because I think it was relevant to me." [DART006] • "I suppose you could differentiate slightly more between the source point of the pain and the consequences for your other limbs like, you know, I knew very well that it was bad at the back that was causing my inability to walk. So maybe distinction between primary pain and a secondary or referred pain might be useful." [DART010]
Impact of existing and previous MSD[c]	• 2 (1) • 0 (2) • 0 (3) • 0 (4) • 4 (5)	• "I don't want to waste the GP's time or my time waiting for an appointment to be told what I already know. So, in my two cases, it wasn't so much about diagnosis is more of an okay, this has returned. We know the course of action." [DART019] • "I wasn't sure whether sometimes we're talking about what it's like when it's really bad, or what it's like in general." [DART005]
Impact of mental health status	• 0 (1) • 2 (2) • 3 (3) • 3 (4) • 3 (5)	• "I think one way of making it better is also seeing how it affects someone psychologically as well. I think that this is something which can sometimes be overlooked, but I think it's important to see how it is impacting on someone's emotional wellbeing?" [DART001] • "When you seek sort of medical advice, or you have a condition that gives you worry and anxiety, probably you expect a little bit more than just sort of self-treatment." [DART016]
Recommendations not sufficiently personalized	• 4 (1) • 2 (2) • 0 (3) • 0 (4) • 0 (5)	• "I guess, it might need to be a little bit more personalized recommendations depending on what people choose." [DART001] • "I suppose the only thing that might dissuade people, would be that if they were users of it, and it came up with the same sort of end page every time." [DART002]
Theme 3: participant difficulty in interpreting questions		
Specific questions (work status, previous treatment, and comorbidities)	• 2 (1) • 3 (2) • 4 (3) • 0 (4) • 4 (5)	• "You were distinguishing between people who were employed, and people who are not employed. It just seemed to me as though there was quite a large category of people lumped together in that one box and maybe it would be better to differentiate them a bit more, so that they did actually tick retired or they ticked student" [DART010] • "Where you were asked whether you'd had surgery or physio, it just was rather a broad question. I thought maybe it should have been a tick box for that to show which one you'd had." [DART004] • "You're a little bit unsure about whether it's really registered to your osteoporosis." [DART010]

---

[a] Usability problems were clustered into subthemes based on specific areas of DART functionality. Problem grades were reduced in severity over testing rounds as problems were negated or reduced during DART iterations (grade 1 is the most severe, and grade 4 is the least severe).

[b] DART: Digital Assessment Routing Tool.

[c] MSD: musculoskeletal disorder.

Construction of a joint display showed how different types of data were combined to assess performance against the ISO 9241-210-2019 constructs (Tables 5, 6, and 7).

Table 5. Display of qualitative data by International Organization for Standardization 9241-210-2019 standard constructs (effectiveness, efficiency, and satisfaction)[a].

Construct and goal	Participant quotes
Construct 1: effectiveness	
Assessment results for a recommendation being given	• "I found it really user friendly and I found I could read the questions quite quickly and just give an answer and move on." [DART018]
Assessment results for a correct clinical recommendation;	• "I expected the area [selected body part] that I chose to change color, I would do it a different color, red or something like that." [DART005]
Assessment of whether the participant would trust	• "It might be easier if you just say have a secondary field to sort of like give your secondary issues as well. You know, sometimes it's just not, it's like the neck runs into the arm and lower parts, but it can be different things as well." [DART014] • "It might make people feel a bit more confident that they've done it right." [DART015]
Assessment of whether the participant would act upon	• "I think if I could have put more evidence in, then I'd be more likely to follow the recommendation at the end, because I think it was relevant to me." [DART006]
Construct 2: efficiency	
Time taken to reach recommendation (minutes)	• "It was very quick. And I quite like that it has one thing for one page, which is a very short question, it gives you a few options, and then you answer so you don't have to go through long text questions, one after the other. So, it just takes you very quickly step by step. And it's quite, I don't know, for me, it was super easy and clear to answer questions." [DART017]
DART[b] system errors	• "I found it really simple system to use very, very easy and had no problems at all." [DART010B]
DART system backsteps	• "That was a question about whether I'd been off work for a long time and if I'm employed or self-employed, something that I didn't find quite straightforward." [DART020]
Construct 3: satisfaction	
System Usability Scale score per round	• "If I had this actual system, I would have saved £150 in cash and probably three months of pain had I been able to access it when I had my problems with my back." [DART013] • "It's done me a favor actually, because I was in two minds whether to try and get a private injection, whether to go to an osteopath or physio. I think it might save me money in the long run." [DART014]

[a] Participant quotes provide a deeper understanding of system performance and usability problems.

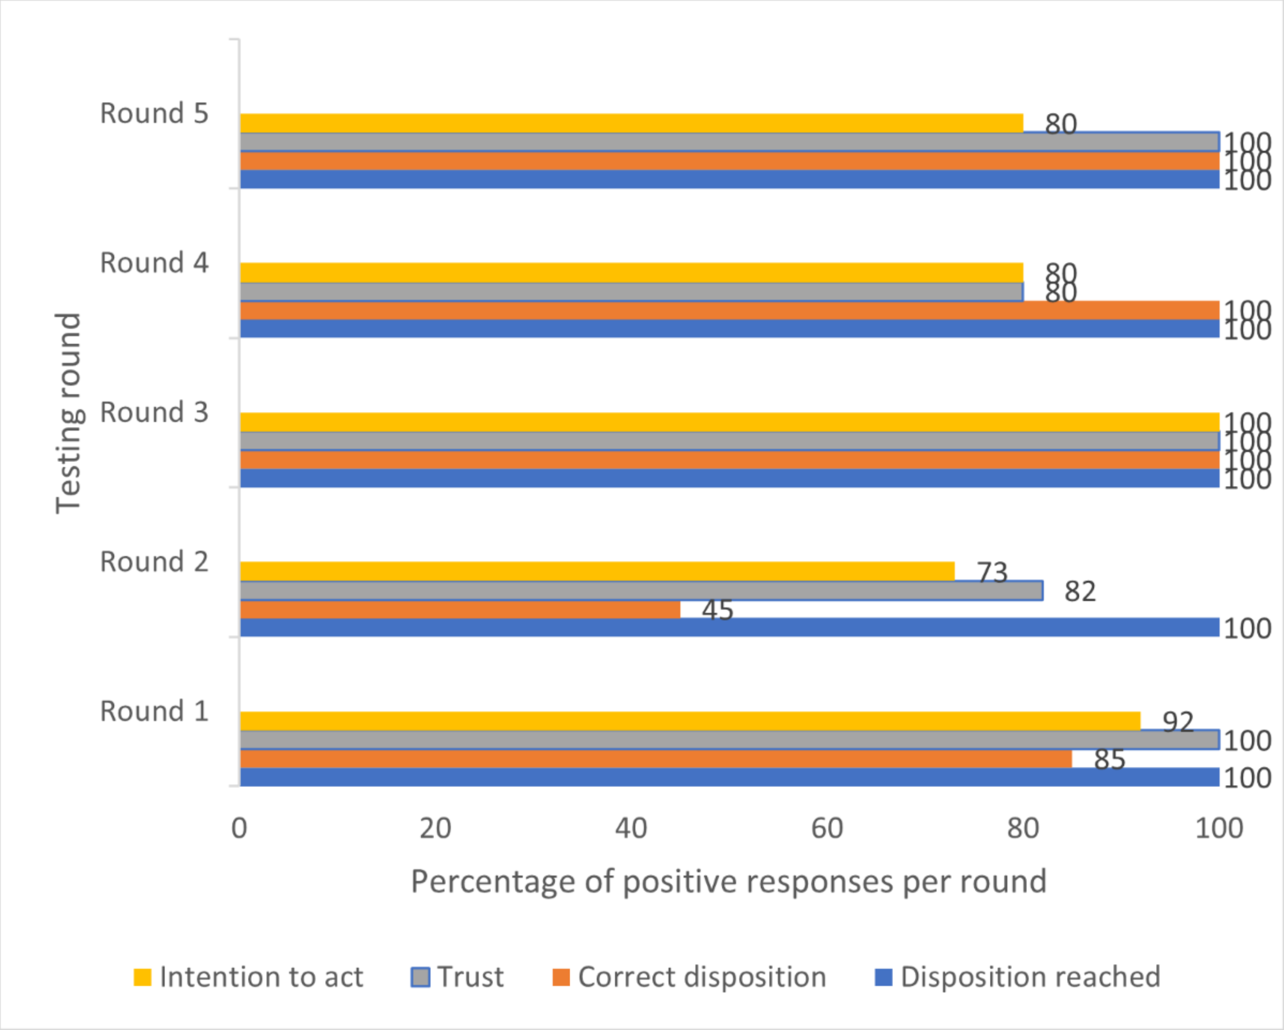
[b] ESOL: English for speakers of other languages.

Effectiveness

All assessments resulted in a recommendation. Other measures of effectiveness improved over the DART iterations, culminating in a high degree of efficiency being reached (Figure 10).

Of the 50 assessments, 8 (16%) resulted in an incorrect recommendation being given, equating to a grade 1 usability issue. Qualitative data revealed that the selection of the incorrect body site at the start of the assessment was responsible for one of these errors. A total of 7 inappropriate clinical escalations were triggered by 2 specific screening questions for systemic inflammatory disease (SID) and central nervous system conditions. Both were reviewed against the evidence base, rewritten, and incorporated into iteration 3. Subsequent testing rounds, including inviting the participants who revealed this problem to retest, confirmed that this usability issue was solved. Participants said their trust and willingness to act would increase if all their symptoms are considered, and this could be achieved by adding a text box on the body site page where they could enter information about problems in other body areas. A related theme was participants wanting to personalize their assessment by adding additional information, and DART iteration 3 included the addition of a free text box at the end of each page. This improved both trust and intention to act, with all participants during testing round 5 arriving at a correct recommendation that they would trust, with just one assessment where the participant said they would not act on the recommendation related to their previous experience of their MSD resolving spontaneously. A small number of participants felt that the lack of personalization of the DART recommendation page made them less likely to act on the advice. This was a result of a test version being used for the study, containing a simple generic recommendation rather than the detailed advice and next actions that would be found on a production version. However, the importance of this feedback was noted and will guide the final DART version to be deployed.

Figure 10. Combined measures of effectiveness by testing round. Results are displayed as the percentage of total assessments to allow comparison, as there were different numbers of participants and assessments in each round. The percentage of assessments in each round resulted in a positive response to the following queries: (1) whether a disposition was achieved, (2) whether it was a clinically correct disposition, (3) whether the participant would trust the disposition, and (4) whether the participant would act on the disposition.



Efficiency

Quantitative indicators of efficiency remained high throughout testing, reinforced by qualitative data.

Round 5 had a larger number of ESOL participants, and it was noted the mean time for this group was slightly longer (6 minutes). The longest time (18 minutes) taken to complete an assessment was by an ESOL participant (Figure 11). All participants without exception said that the time taken to complete an assessment was acceptable and that the format of the questions was clear and supported their ability to make decisions easily.

System errors were defined as DART technical errors, such as presenting the user with an error message or the system timing out. No system errors were encountered during any testing rounds.

The number of times a participant moved back in the pathway to review the previous question remained consistent across the first 4 testing rounds, even with the introduction of participants who used the internet less frequently and ESOL users. Backsteps increased to 6 in round 5 and were linked to one of the ESOL participants, who had the lowest recorded eHEALS score (Figure 12). He told us some of the questions were more challenging to answer and required him to reread them.

Figure 11. Efficiency (time to complete an assessment). Time taken for participants to complete assessments. A total of 16 participants completed 34 assessments in total across rounds 2 to 5. Time was not recorded in round 1, as participants were encouraged to use the “think-aloud” technique.

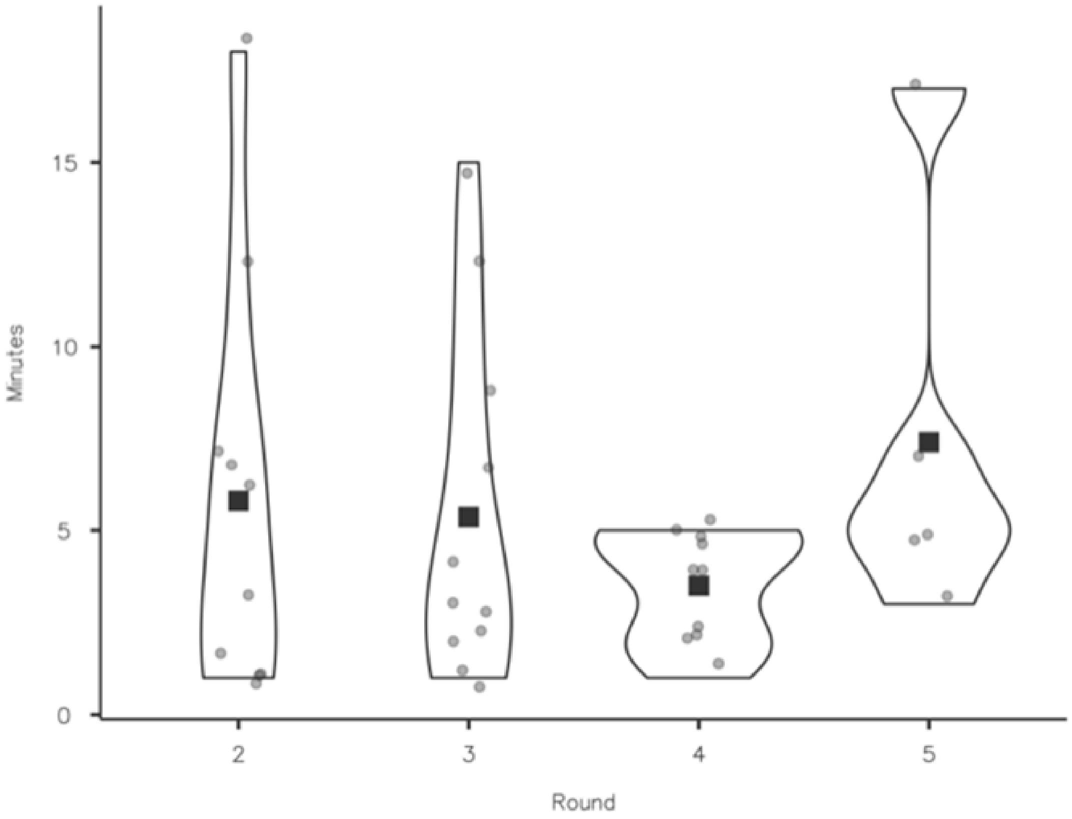


Figure 12. Measures of efficiency (backsteps) by testing round. Number of times a participant moved back a step in the question set to review their previous question and response, with backsteps shown as a percentage of the total number of questions in the assessment.

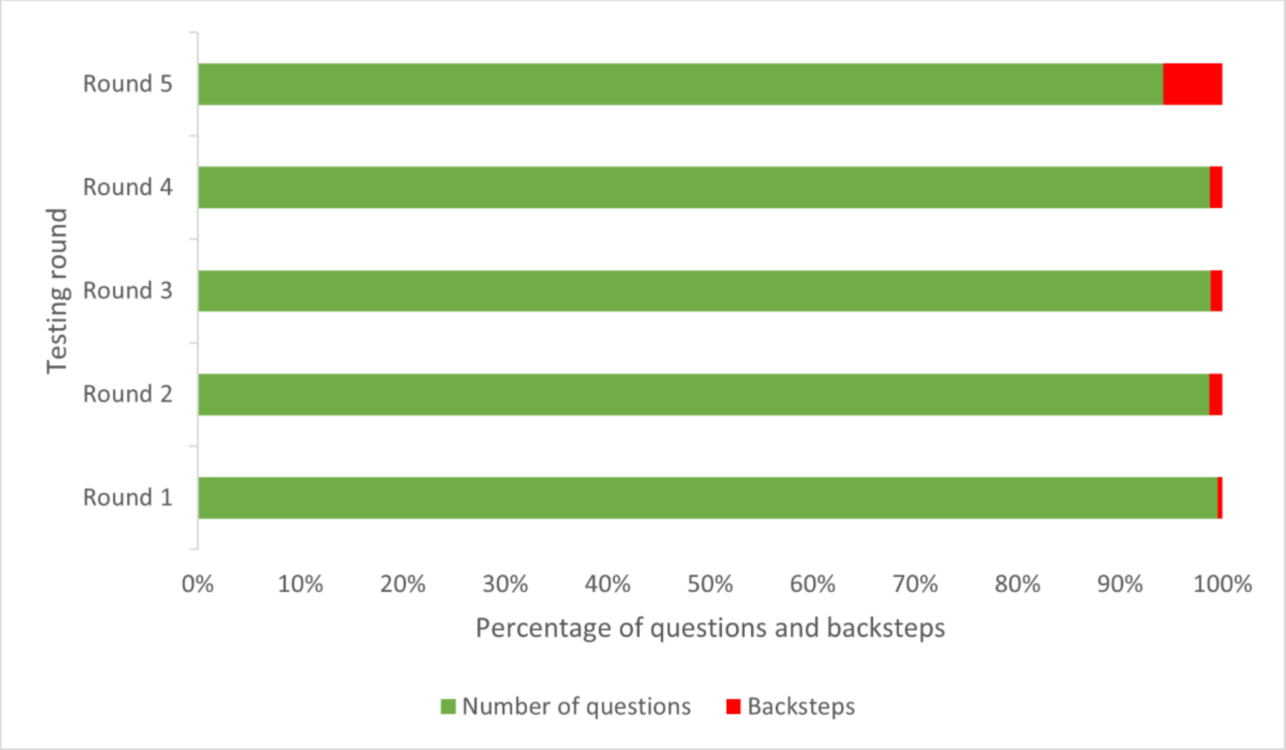
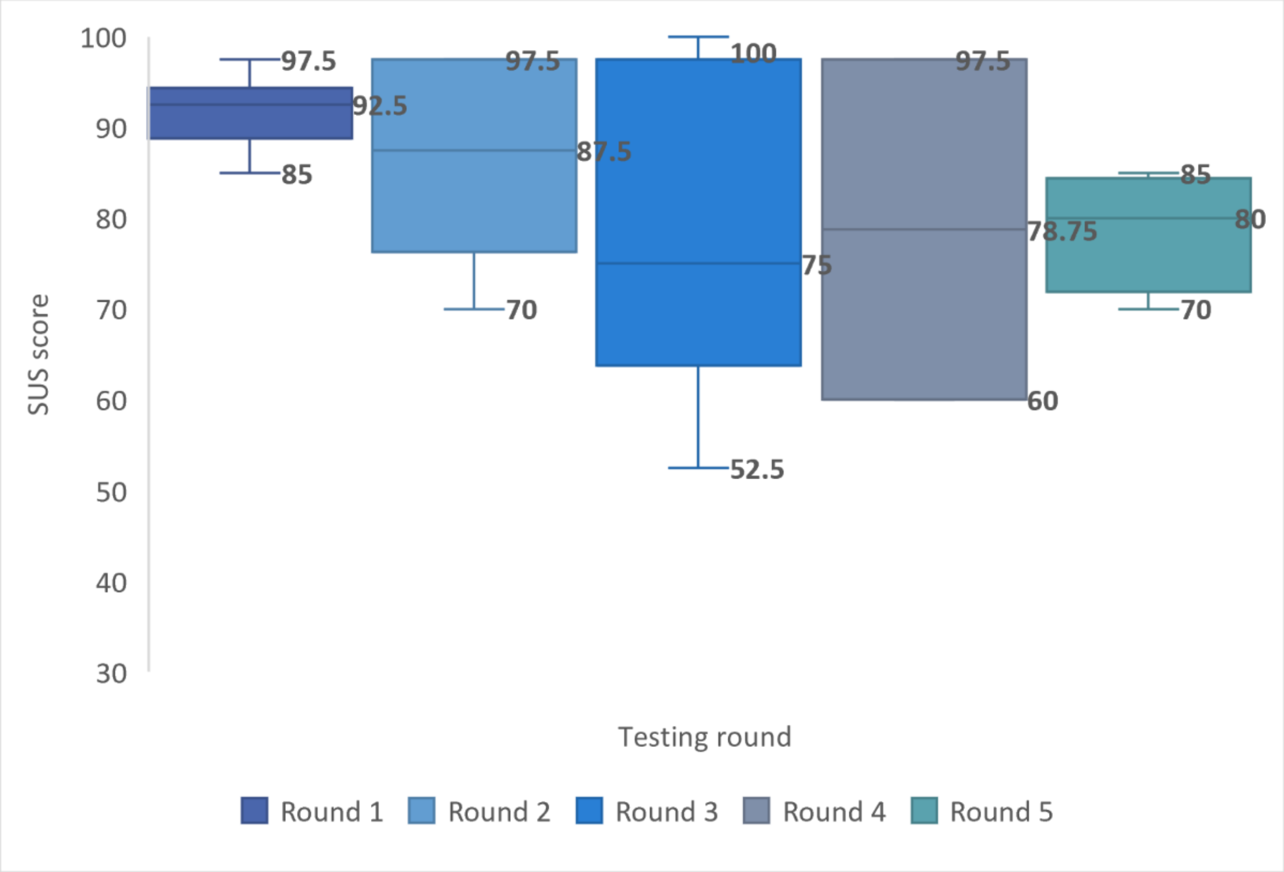


Satisfaction

Satisfaction was measured quantitively across all groups using the SUS, with qualitative data providing deeper insights into specific question responses. Although high levels of system satisfaction were prevalent throughout testing, cumulative satisfaction scores reduced with each round as infrequent internet users and ESOL participants were recruited (Figure 13). However, the final mean SUS score of 84.3 (SD 12.73; 90% CL 4.67) across all groups achieved the predefined study end point of a score of ≥80, representing a “good” or better system and associated with an increase in the probability that users would recommend DART to a friend [37].

Figure 13. Measure of satisfaction by testing round. SUS: System Usability Scale.



Differences in mean satisfaction scores were present between groups, with daily internet users scoring highest (19/22, 86%; mean 86.5, SD 4.48; 90% CL 1.78 or –1.78), and nonnative English speakers (6/22, 27%; mean 78.1, SD 4.60; 90% CL 3.79 or –3.79) and infrequent internet users scoring the lowest (3/22, 14%; mean 70.8, SD 5.44; 90% CL 9.17 or –9.17), although the CIs overlap.

Although care should be taken in examining individual SUS item responses as external validity only exists on aggregated scores [51], analysis of the highest scoring questions did reveal some useful insights. All participant groups scored highest when saying that they would not need to learn many things before they could use DART. Both daily and infrequent internet users agreed they would not need technical support to use DART, with ESOL participants agreeing to a slightly lesser extent.

All groups did not feel they would use DART frequently or that the functions in the system were well integrated. This was not an unexpected finding as DART is intended for single-time use to determine the correct level of intervention for the user’s MSD and, therefore, would not be used frequently. In contrast to most other mHealth systems, DART is not designed to provide an MSD intervention, with no requirement for the user to navigate to additional features within the system.

Satisfaction adjectives were associated with each participant’s individual total score to aid in explaining the results to non–human factor professionals [52], with 91% (20/22) of participant scores equating DART as a “good,” “excellent,” or “best imaginable system.” The remaining 2 (8%) participants rated DART as “fair,” with none rating it as “poor” or “worst imaginable.”

Using the normalizing process described by Sauro [46], DART ranks within the 96th to 100th percentile (SUS score 84.1-100) of systems tested using the SUS, with an associated adjective rating of “Excellent” [53]. Benchmarking of the DART SUS score against the mean score of 67 (SD 13.4) from 174 studies assessing the usability of public-facing websites utilizing the SUS revealed that DART was among the highest scoring systems assessed in this way [46].

Accessibility

Accessibility has been central to the design of the DART user interface, and the Appian platform on which DART is constructed includes features supporting accessibility for a wide range of users, including those with disabilities who use assistive technologies such as screen readers.

DART's simplicity of use was recognized in the qualitative data by all participants from all groups, who felt that it was sufficiently simple to use and liked the fact that all assessments resulted in a disposition being given. This supports the theory of a low barrier to entry for DART, provided users have internet access:

> *It is so simple, its one most simple of the things, websites, I've engaged with.* [DART016]
>
> *It was very quick. And I quite like that it has one thing for one page, which is a very short question, it gives you a few options, and then you answer so you don't have to go through long text questions, one after the other. So, it just takes you very quickly step by step. And it's quite, I don't know, for me, it was super easy and clear to answer questions.* [DART017]

We asked participants whether they could think of anyone who may not be able to use DART:

> *I wonder how somebody like my mom's age would cope with it and I actually thought there wouldn't be too many who wouldn't.*

One of the ESOL participants tested DART with the help of her daughter, which she told us was her normal practice when she needed to use the internet and common practice within her community:

> *No it's easy to do. My daughter is helping me. Little bit, I understand most of the things, but little bit some questions, what can I say? So, my daughter guides me and help me.* [DART012]

When asked how other ESOL users would use DART, she said the following:

> *I think they need somebody's help, their partner or their children, somebody, or some of their friends, some can help them and then they can do it.*

Overall, participants felt that DART would be easily accessible to people who are familiar with using the internet but that a telephone-delivered alternative would be required for some users. Additional benefits of reducing the time to receiving a diagnosis or treatment and financial savings were also mentioned:

> *If I had this actual system, I would have saved £150 in cash and probably three months of pain had I been able to access it when I had my problems with my back.* [DART013]

Discussion

Principal Findings

The use of the iterative, convergent mixed methods design proved effective; rich data provided objective measures of system performance together with identification of serious usability problems and solutions by real-world users. The results from this study indicate that through a series of iterations, DART usability reached a sufficiently high standard to proceed to further safety and effectiveness trials.

Theme 1: Factors Leading to an Incorrect Recommendation Being Given

Selection of the appropriate body site is crucial to driving matched clinical algorithms within DART, and failure to do so accounted for 8 incorrect recommendations. In addition, participant confidence in DART being able to recognize their body site selection was considered important to most participants, being related to their wider trust in the system and associated intention to act on the recommendation they received. As a result, the body site diagram was refined across all iterations.

A specific DART question designed to screen for SID triggered false-positive recommendations for participants describing mechanical pain. Correct identification of SID can be problematic for primary care clinicians because of varied symptom presentation and overlap with more common osteoarthritic joint conditions [53-55]. A study using patient-entered responses showed that osteoarthritis was diagnosed in 38% of SID cases [56], a result that is clinically significant, given the interdependency of early recognition of SID, minimizing a poor patient outcome [57,58]. During DART testing, these participants prioritized the presence of pain characteristics of osteoarthritis over the hot and swollen multiple joint symptoms presented in SID. This problem was addressed by a detailed review of the literature on the differential diagnosis of SID, rewriting, and inclusion of new questions within all algorithms with associated linked age logic. Subsequent testing rounds, including participants who revealed this problem, confirmed success in negating this usability issue. The implications of creating false positives are often underestimated, with most symptom checker development taking a conservative approach, resulting in systems typically being more risk averse than health care practitioners [59-61]. However, the failure to provide an accurate routing decision can affect user trust and system adoption [62], as well as the creation of unnecessary referrals to urgent or emergency services.

Theme 2: Impact of Assessment Personalization on Participant Trust and Intention to Act on the Given Recommendation

Personalization of assessments was perceived by some participants as a key advantage of a patient-clinician triage interaction over an mHealth system. It has been shown that lack of personalization can affect trust and intention to act, with implications for system adoption [63]. Our participants wanted to "tell their story," not feeling involved in the assessment process unless they could provide information personal to them, including entering details of secondary body site areas. It has been estimated that 8% of patients with MSD presenting to a primary care physician have a problem in >1 body site [64]; thus, an additional comment box was added to the body site diagram page, inviting users to enter other problem areas, something our participants said would address this problem.

In all but 1 assessment, participants who said they would trust DART also said that they would act on the recommendation they were given. A direct correlate of eHealth user trust is information quality, defined by knowledgeable, impartial, and expert sources. These are important factors that lead users to believe the system is acting in their best interest, as they feel a clinician would do [65].

Trust factors have a significant direct effect on user intention to act [66], a key requirement for successful DART introduction into an MSD digital pathway and system adoption. However, we found other factors may be at play, such as previous experience in MSD management. One of the participants told us that they would trust the DART recommendation for physiotherapy but would have waited to see whether their problem improved without treatment, as it had before. It has been recognized that when users of eHealth make decisions on system trust and intention to act, especially those with high eHealth literacy, they will often corroborate information using other web-based content to “triangulate” advice, particularly if the primary source is not familiar to them [63,66]. Interestingly, it has been shown that eHealth users in the United Kingdom with access to free NHS health care are less likely to use health corroboration than users in other countries with private health systems [66]. The NHS website is considered a trusted source of information for many citizens in the United Kingdom, and deploying DART within an NHS pathway may enhance a user’s trust in the given recommendations.

Qualitative data revealed a usability problem that was not considered during development—that serious condition-screening questions on DART had the potential to cause user anxiety in some individuals, who otherwise would not have considered the potential for their problem to be serious. On the basis of this feedback, we placed these less frequently occurring conditions in the context of their incidence to allay unnecessary user anxiety. This is an important consideration for developers of mHealth triage systems, as although the creation of false positives is well recognized and largely accepted as a prudent conservative approach to medical risk management [62], it is also suggested that a significant proportion of potential users would reject using a symptom checker for fear of receiving a wrong diagnosis or an assessment that could cause them anxiety [60].

Theme 3: Impact of User Interpretation When Answering Specific DART Questions

A small number of questions provoked some unexpected participant responses attributable to individual interpretation, likely influenced by their personal experiences. This theme was not identified during previous validation work completed by the panel of expert clinicians. It was only possible to reveal and understand this important usability factor by using a convergent mixed methods design with real-world users, reinforcing the advantage of this methodology over the common practice of using vignettes constructed or delivered by clinicians. An expert clinician recognizes conditions by virtue of pattern recognition, bypassing the conscious, effortful cognitive requirements demanded of a nonclinician user to interpret questions and make decisions on how to respond [67]. Moreover, clinicians are highly educated and not representative of a real-world system user population, including people with eHealth literacy challenges. This study concluded that diversity of user personal experiences can influence how real-world users respond to questions presented by an mHealth system and, ultimately, the recommendation they receive, thus presenting a challenge to developers. For this reason, it is suggested that clinical testing of mHealth systems using vignettes is best used as a precursor to real-world usability testing comprising a representative sample of potential system users.

We found no relationship between age and eHealth literacy, with older participants equally able to arrive at a recommendation as the younger participants. Although this finding should be treated with caution because of the small number of older participants, it could suggest that the perceived ability to seek and use health information is more related to the frequency of internet use rather than age and that differences in eHealth literacy are less likely to be between user group demographics but rather socioeconomic variables between individuals within them [68]. A recent report showed continued growth of internet use in the United Kingdom, with a 6% increase in households with internet access between 2018 and 2020. In the same period, the increase in the number of households with a single adult aged >65 years who accessed the internet within a 3-month period rose from 59% to 80% [39], challenging perceptions about potential mHealth user demographics. An ESOL participant who had assistance from her daughter told us she often sought help from family or neighbors to use the internet, that this was common practice within her community, and that DART could be used effectively in this way. Web-based “surrogate seeking” is now a widespread practice, with significant numbers of internet health information seekers accessing advice on behalf of someone else [69]. However, some studies still link the use of web-based symptom checkers to younger and more highly educated populations [60] and self-referrals for the assessment of musculoskeletal conditions generally [70].

Limitations

Recruitment during the COVID-19 pandemic proved challenging, particularly for people who were not daily users of the internet, as they typically do not engage with social media or advertisements sent via email. All data had to be gathered remotely, affecting the recruitment of people not confident in using web-based video call technology. Although the full recruitment quota was not met for infrequent internet users, this was partially addressed, and the feedback from these participants was particularly valuable in highlighting usability problems. This recruitment challenge could be an indicator of self-selection for DART user adoption related to internet use.

During the DART tests, most participants recalled past conditions that had been resolved or that had been present for some time and had changed since the first onset. At times, this created a problem for participants regarding how to respond to questions; for example, current symptoms versus symptoms they had at the beginning of their problem when they first sought clinical advice. This could be addressed in future studies by only recruiting participants with current problems who had not received medical advice; however, this could potentially exclude participants with chronic MSDs and more complex conditions, thus limiting generalizability.

Although a generic internet system assessment tool, the SUS was chosen as a measure of DART user satisfaction in the absence of a more specific validated mHealth usability measure. As a result, not all the questions were matched to DART in its role as a single-use assessment system with no additional integrated functionality. Other usability assessment tools were considered, including those that measure domains such as loyalty, trust, credibility, and appearance; however, these were designed for the assessment of transactional business systems and included questions inappropriate for DART, such as purchasing and confidence in concluding business [37]. Other tools measured the usability of mHealth systems that support the therapeutic management of conditions over time, with repeated patient use and different integrated functions and features, meaning that the domains assessed were not directly applicable [71].

Future Work

The purpose of this usability study was to optimize usability before proceeding to a trial evaluating the safety and effectiveness of DART against a usual care comparator. A protocol for an initial pilot study has been published and will explore the key aspects of the trial methodology; assess the procedures; and collect exploratory data to inform the design of a definitive, randomized, crossover, noninferiority trial to assess DART safety [36]. DART is currently deployed in a controlled live clinical environment where we use system data, as well as user and clinician feedback, to further refine the algorithms and system usability. A quality improvement study, where DART is integrated into an existing public health service, is also in the design phase.

Conclusions

This study suggests the DART mHealth system has the potential to be offered as an alternative to primary care physician–led or physiotherapist-led triage as part of an MSD pathway. Participants found DART easy to use and would trust and act on the routing recommendation they were given. With all significant usability problems addressed, DART can proceed to the next stage of validation—a randomized controlled trial to assess the safety and effectiveness against a usual care comparator. The inclusion of real-world participants revealed important usability problems and solutions that were not identified during the development or expert panel review stages and highlights the importance of a more sophisticated approach to mHealth system usability testing. The iterative, convergent mixed methods design proved to be highly effective for system development and evaluation and could provide a blueprint for other researchers of mHealth systems.

Acknowledgments

This study was funded by Optima Health.

Authors' Contributions

CL and DM designed the study. MB collected quantitative data, whereas CL collected qualitative data, and both performed data analysis and interpretation. CL drafted the manuscript. DM and WM reviewed the manuscript and provided the final approval. CL takes responsibility for the integrity of the data analysis.

Conflicts of Interest

Optima Health has developed the Digital Assessment Routing Tool system and is the owner of the associated intellectual property. The principal investigator (CL) is an employee of Optima Health and a PhD research student at Queen Mary University of London.

Abstract

Background: Patients with cancer undergoing cytotoxic chemotherapy face an elevated risk of developing serious infection as a consequence of their treatment, which lowers their white blood cell count and, more specifically, their absolute neutrophil count. This condition is known as neutropenia. Neutropenia accompanied by a fever is referred to as febrile neutropenia, a common side effect of chemotherapy with a high mortality rate. The timely detection of severe neutropenia (<500 absolute neutrophil count/µL) is critical in detecting and managing febrile neutropenia. Current methods rely on blood draws, which limit them to clinical settings and do not allow frequent or portable monitoring. In this study, we demonstrated the usability of PointCheck, a noninvasive device for neutropenia screening, in a simulated home environment without clinical supervision. PointCheck automatically performs microscopy through the skin of the finger to image the blood flowing through superficial microcapillaries and enables the remote monitoring of neutropenia status, without requiring venipuncture.

Objective: This study aimed to evaluate the usability of PointCheck, a noninvasive optical technology for screening severe neutropenia, with the goal of identifying potential user interface, functionality, and design issues from the perspective of untrained users.

Methods: We conducted a multicenter study using quantitative and qualitative approaches to evaluate the usability of PointCheck across 154 untrained participants. We used a mixed method approach to gather usability data through user testing observations, a short-answer qualitative questionnaire, and a standardized quantitative System Usability Scale (SUS) survey to assess perceived usability and satisfaction.

Results: Of the 154 participants, we found that 108 (70.1%) scored above 80.8 on the SUS across all sites, with a mean SUS score of 86.1 across all sites. Furthermore, the SUS results indicated that, out of the 151 users who completed the SUS survey, 145 (96%) found that they learned how to use PointCheck very quickly, and 141 (93.4%) felt very confident when using the device.

Conclusions: We have shown that PointCheck, a novel technology for noninvasive, home-based neutropenia detection, can be safely and effectively operated by first-time users. In a simulated home environment, these users found it easy to use, with a mean SUS score of 86.1, indicating an excellent perception of usability and placing this device within the top tenth percentile of systems evaluated for usability by the SUS.

Introduction

Background

One of the most serious side effects of cytotoxic chemotherapy and immunotherapy is neutropenia—a decrease in neutrophils, the most common type of white blood cell (WBC) and the most important cell needed to prevent bacterial infection. The primary clinical consequence of neutropenia is an elevated risk of life-threatening bacterial infection that typically requires immediate admission to the emergency department, hospitalization, and treatment [1-3]. Every year, approximately 850,000 patients with cancer start chemotherapy treatments in the United States [4], and 140,000 (17%) [5] will endure at least one episode of febrile neutropenia (FN), or neutropenia accompanied by a fever. FN typically requires an admission of over 1 week, costing approximately US $30,000 per episode [6,7], with associated mortality rates between 7% to 10% [8]. The timely detection and awareness of severe neutropenia (ie, <500 absolute neutrophil count/µL) [9] can be crucial to prevent and manage FN in the outpatient setting [10,11] and the emergency department [12,13].

In the current standard of care, the risk of FN is evaluated by using a priori scores, such as the Multinational Association for Supportive Care in Cancer score [14], to indicate primary prophylaxis with growth colony stimulating factors or by patients regularly monitoring their temperature at home to seek emergency care when fever ensues [15]. Despite these existing methods, FN still has an important economic and clinical impact in cancer care. The early detection of neutropenia could be used to prevent FN by triggering an early administration of granulocyte colony-stimulating factor or antibiotics [16-19]. Unfortunately, current neutropenia-monitoring options rely on venipunctures in the clinical setting or finger-prick blood samples at the point of care [20]. These technologies either require laboratory infrastructure limited to the hospital setting or are impractical as they cannot be operated by minimally trained users to achieve accurate and reliable results [21-24]. To address this unmet need, this paper presents a usability evaluation of a novel, noninvasive technology that allows automated and frequent neutropenia monitoring by patients from the home setting with minimal training.

Assessing the usability for this kind of technology is crucial in ensuring the accuracy of the results, driving adoption, and improving patient compliance and adherence [25]. According to the International Organization for Standardization (IEC 62366-1:2015), usability is defined as a “characteristic of the user interface that facilitates use and thereby establishes effectiveness, efficiency and user satisfaction in the intended use environment” [26]. These metrics can be measured by gaining insight into patient perspectives regarding user performance, satisfaction, and acceptability while using an intervention [27]. For this study, the standardized System Usability Scale (SUS) survey was chosen as a quantitative method of assessing subjective usability due to evidence that it can be used to assess any technology [28] and has successfully been used in the medical domain to assess home medical devices [29-31].

The early detection of FN risk is essential as it can be associated with a higher chance of survival, more successful treatment, and improved quality of life. Therefore, the need for these technologies to be user friendly to the majority of the patient population subsequently increases, as this can impact the patients’ perception of the technology and their decision to take the test [32]. Additionally, technology-based solutions such as the one presented in this paper can help strengthen the relationship and communication between patients and their doctors, empower the patients’ well-being, and help doctors make better and more informed decisions [33].

Study Objectives

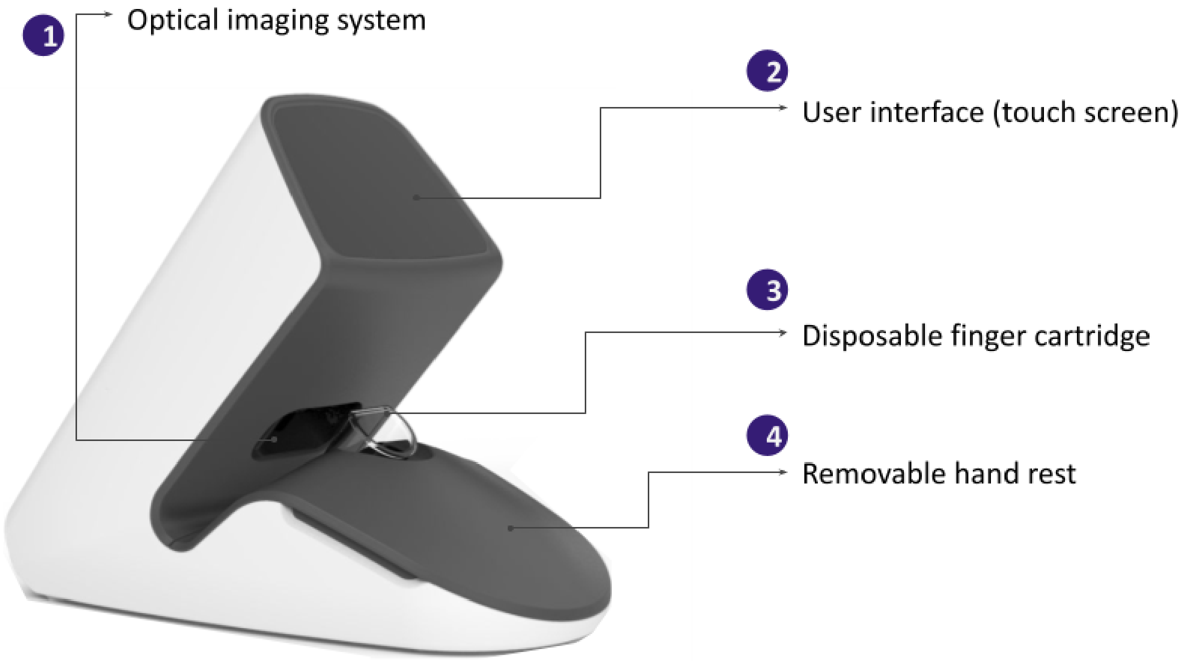
We hypothesized that novice users will consider PointCheck (Leuko Labs), the first noninvasive optical technology for screening severe neutropenia, to be easy to use. The primary study objective was to evaluate the usability of PointCheck with the goal of identifying potential user interface (UI), functionality, and design issues from the perspective of untrained, first-time users in a simulated home environment. The primary end point for the study, defined a priori, was a group mean score of 80.8 on a standardized SUS, indicating a favorable perception of usability and a higher likelihood of adoption.

Methods

Device Description

PointCheck is the first noninvasive device (Figure 1) designed to screen for severe neutropenia in the home setting [34]. By imaging the blood flowing through the capillaries in the finger, PointCheck enables real-time remote monitoring of WBC levels based on optical imaging and without a blood draw [35,36].

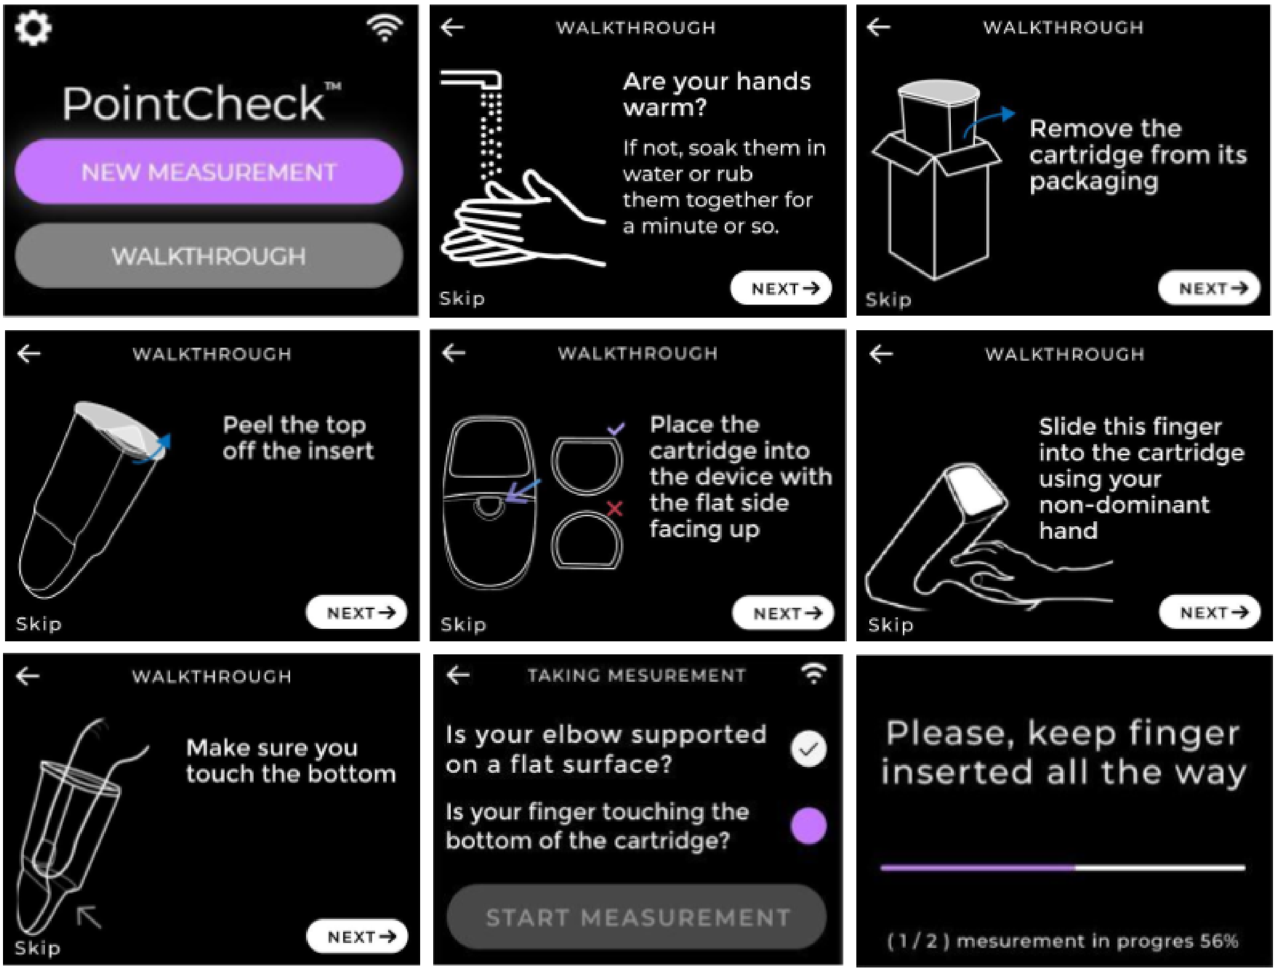
Figure 1. The PointCheck device and its main components.



The device consists of an optics and illumination system, on-board computing electronics, an 8.9-cm touch screen UI, a power cord, and disposable finger cartridges (Figure 1). It uses a camera microscopy system and LEDs to image capillaries in the nailfold region of the finger—typically the nondominant 4th (ring) finger, which has been shown by previous literature to contain the most intact and visible capillaries when compared to other fingers [37]. The finger cartridge is a disposable component that is prefilled with mineral oil and allows for effective optical refractive index coupling to ensure transdermal imaging quality [38,39]. The finger cartridge is designed for 1-time use. The hardware system design resembles the methods used in standard nailfold video capillaroscopy, which is an established technique used by rheumatologists to evaluate capillary morphology and microcirculation [40].

The UI on the touch screen provides a guided walk-through to facilitate the correct use of the device. It prompts the user to warm their hands; open up a new, unused cartridge; properly place the cartridge into the device; and insert their nondominant 4th (ring) finger all the way into the cartridge while properly supporting their arm on a flat, stable surface (Figure 2). A final checklist ensures that the most critical steps have been completed and the user is able to start the 1-minute measurement. The version of the device used in this study was a beta prototype (version 4).

Figure 2. Screenshots of PointCheck’s user interface depicting the user walk-through tutorial in English for taking a measurement and device function via the touch screen interface. Language support for Spanish- and Haitian-speaking populations was implemented to translate the instructions.



Are your hands warm?

If not, soak them in water or rub them together for a minute or so.

Remove the cartridge from its packaging

Peel the top off the insert

Place the cartridge into the device with the flat side facing up

Slide this finger into the cartridge using your non-dominant hand

Make sure you touch the bottom

Is your elbow supported on a flat surface?

Is your finger touching the bottom of the cartridge?

Please, keep finger inserted all the way

(1 / 2) mesurement in progres 56%

Participants and Setting

Usability data was gathered from a cohort including both healthy volunteers and outpatients with cancer receiving chemotherapy. Patients were recruited at both the Boston Medical Center and Hospital Universitario 12 de Octubre before their routine chemotherapy administration. The healthy volunteers were recruited at the Massachusetts Institute of Technology’s Center for Clinical and Translational Research via advertisements displayed on Massachusetts Institute of Technology’s campus and social media and via email lists. The study visits took place in a simulated home environment, and testing was conducted without supervision from a medical professional. No participants had prior experience with the tested device.

A total of 154 participants (85 patients and 69 volunteers) participated in this study. According to standard usability sample size models, this sample size provides a 99% chance of detecting errors with the probability of occurrence of 3% at least once [41].

To ensure the generalizability of the results, we included younger (aged <65 years) and older (aged ≥65 years) adults, patients with diverse cancer types (lymphoma, leukemia, and myeloma, among other tumor types), men and women, and different education levels (≥8th grade or <8th grade). This allowed us to better understand the links between certain characteristics of the potential patients (ie, age, education, technophilia, and health literacy) and the usability [42,43].

Ethics Approval

Institutional review board (IRB) approvals were obtained from the Boston Medical Center IRB (H-39964), Hospital Universitario 12 de Octubre IRB (20/049), and the New England IRB (1290027) to conduct the study prior to recruitment. Participants provided written consent before agreeing to participate in the study according to good clinical practice guidelines (ICH E6:R2) [44].

Study Design

We used a mixed method approach to gather usability data through (1) user observation, (2) a short-answer qualitative e-questionnaire, and (3) a standardized quantitative SUS to assess perceived usability and satisfaction.

Regarding user observation, study coordinators observed participants while they used the device to document any errors that could potentially lead to imaging errors on the device. For example, an unsupported arm or incorrect hand placement could result in too much movement during a measurement and cause an error in the reading. Study coordinators also observed participants to identify and document any points of confusion during the walk-through steps that could be improved. All documented observations were collated into a list to be manually categorized by the type and frequency of occurrence (see Qualitative Results).

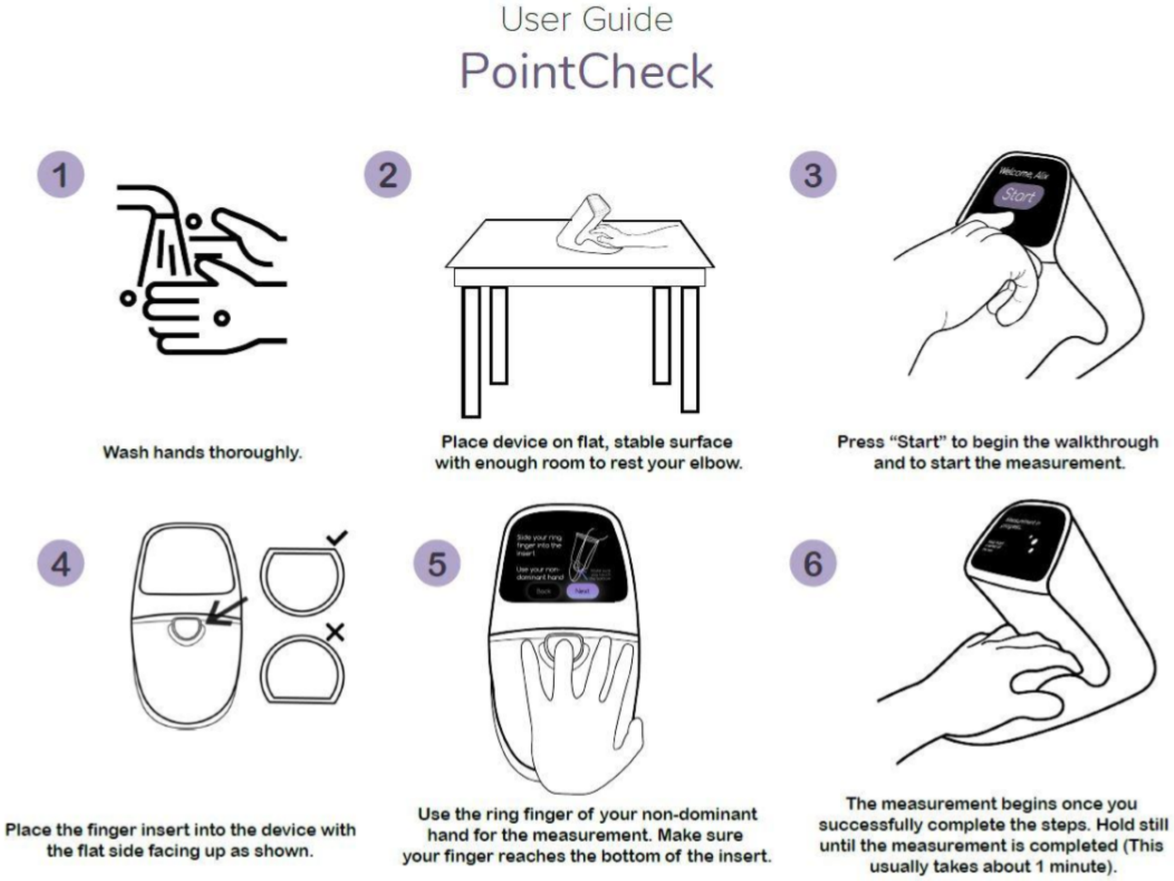
A subset (n=120) of the participants were given the opportunity to give feedback and document their thoughts, feelings, and experience using the device through an e-questionnaire containing 4 questions (Multimedia Appendix 1). We used this questionnaire to assess any potential confusion or difficulties participants may have had using the device or the UI, their attitude toward the product, and any potential features they would like to see added to improve user friendliness. The feedback from the questionnaires was collated into a spreadsheet to be manually categorized into themes (see Qualitative Results).

Finally, the SUS survey was used as a method of assessing subjective usability. The SUS is a Likert-type questionnaire comprising 10 questions with 5 response options ranging from “strongly disagree” to “strongly agree,” allowing for a subjective assessment of usability [45]. Scores range from 0 to 100 with higher scores indicating favorable user perceptions of the device and lower scores indicating low usability. The success criterion for a favorable evaluation in the SUS was defined by a mean group score of greater than 80.8 (see Quantitative Results). This threshold was selected based on previously published cutoffs to define the promoters of a technology [46].

Usability Testing Procedure

Baseline assessments conducted by research staff included a brief physical examination and collection of demographic information. Study coordinators read a short script that provided the participants with information about how to use the device and emphasized that the aim of the study was to test the user friendliness of the device and not the participants’ ability to use the device correctly (Multimedia Appendix 2). In addition, the participants were provided with a 1-page guide containing device instructions before attempting to take a measurement on their own (Figure 3).

Figure 3. One-page quick start guide provided to participants before attempting to take a measurement on their own.



Participants were then asked to follow the instructions presented to them on the device screen, guiding them through the critical steps required to obtain high-quality measurements. The study coordinators did not intervene or answer questions related to device use to reproduce the conditions of unsupervised home use. A second observer monitored and recorded a subset of visits either in person or through the Zoom teleconferencing platform (Zoom Video Communications). Observers documented participant errors, feedback, and tendencies. After completing the initial measurement, participants were immediately asked to complete the SUS and questionnaire to evaluate their first impressions about the user friendliness of the system to prevent any bias introduced from repeating measurements and becoming familiar with the measurement process. Participants performed additional trials, each lasting about 1.5 minutes (1-minute measurement plus 30-second setup and walk-through) for a total of 2 to 6 repeat measurements to evaluate the device precision. These subsequent trials were not used for the perceived usability evaluation and are not reported here.

Data Analysis

Basic demographic characteristics were summarized using descriptive statistics. A final SUS score was computed in accordance with Brooke [47], and responses to the e-questionnaire were tokenized for their content and categorized into themes for qualitative analysis. Statistical comparisons were made between the different group categories stratified by age and literacy to evaluate usability differences using nonparametric techniques (Mann-Whitney *U* test). All quantitative data were processed using RStudio (version 1.3.1093; RStudio Team) [48].

Results

User Statistics

Table 1 represents the breakdown of study participant characteristics by age, education level, gender, and race. Of the 154 participants, 118 (76.6%) were aged <65 years, with an average age of 44.8 (range 18-88) years. A majority (n=102, 66.2%) of the participants had an education level exceeding 8th grade, whereas 43 (27.9%) participants had an education level below 8th grade, and 9 (5.8%) did not provide educational level information.

Table 1. Basic demographics of participants. Educational, race, and ethnicity level data were missing for 9 (5.8%), 11 (7.1%) and 10 (6.5%) out of 154 participants, respectively.

Demographic	Participants (N=154)
Age (years)	
Mean (SD)	44.8 (20.5)
Median (range)	38.3 (18.0-88.5)
Gender, n (%)	
Male	67 (43.5)
Female	87 (56.5)
Educational level, n (%)	
<8th grade	43 (27.9)
≥8th grade	102 (66.2)
Missing	9 (5.8)
Race, n (%)	
American Indian or Alaska Native	1 (0.6)
Asian	28 (18.2)
Black or African American	28 (18.2)
More than 1 race	5 (3.2)
Unknown	11 (7.1)
White	81 (52.6)
Ethnicity, n (%)	
Hispanic or Latino	49 (31.8)
Not Hispanic nor Latino	95 (61.7)
Unknown	10 (6.5)

Quantitative Results

The average SUS score across all participants was 86.1. In total, 70.1% (108/154) of the participants scored above the goal of 80.8 (Tables 2 and 3), which indicated that they would be early promoters and more likely to recommend the device to a friend [49]. When stratifying the SUS results by education level, we found that participants exceeding the 8th grade level scored slightly higher than those with an 8th grade level education and below—but only by a margin of 2.5 points, which was not found to be statistically significant (*P*=.27; Table 4). When stratifying SUS results by age categories, we found that participants aged <65 years also scored higher than participants aged ≥65 years by a margin of 3.4 points, showing a nonstatistically significant trend (*P*=.06). Both groups had a mean score above the predefined threshold of 80.8 (Table 5). When evaluating the SUS results by the individual survey questions, we found that 96% (145/151) of the participants that completed the survey found PointCheck easy to use and felt that they could learn to use it very quickly (Figure 4).

Table 2. Quantitative System Usability Scale (SUS) results across all participants. SUS surveys were incomplete for 3 participants and could not be computed.

SUS score (range 0-100)	Overall (N=154)
Mean (SD)	86.1 (12.2)
Median (range)	87.5 (20.0-100)
Missing, n (%)	3 (1.9)

Table 3. Total percent of promoters (defined as participants scoring >80.8 points on the System Usability Scale). System Usability Scale surveys were incomplete for 3 participants and could not be computed.

Cutoff used (points)	Overall (N=154), n (%)
≤80.8	43 (27.9)
>80.8	108 (70.1)
Missing	3 (1.9)

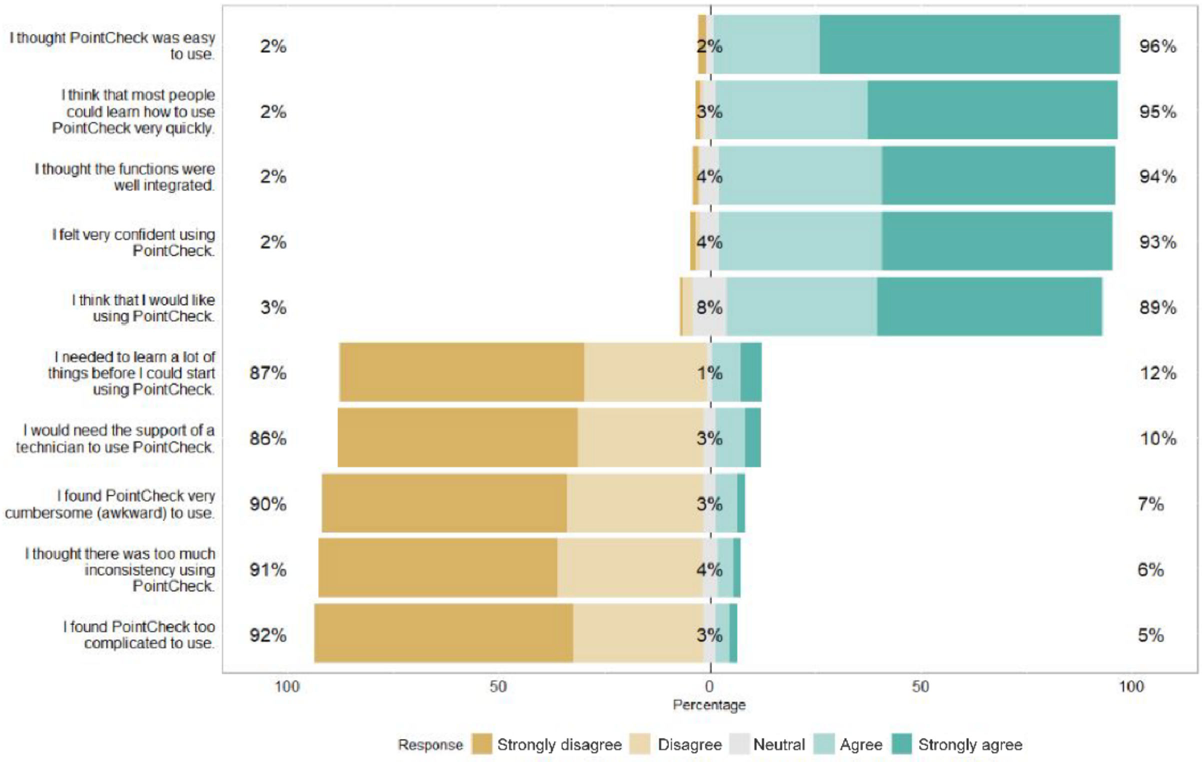
Table 4. System Usability Scale (SUS) results stratified by educational level (<8th grade and ≥8th grade). The results were generated using the data available from a total of 145 participants. Educational level data was missing for 9 participants (N=154, 5.8%).

SUS score (range 0-100)	<8th Grade (N=43)	≥8th Grade (N=102)	Overall (N=154)
Mean (SD)	84.0 (12.7)	86.5 (12.2)	86.1 (12.2)
Median (range)	85.0 (57.5-100)	87.5 (20.0-100)	87.5 (20.0-100)

Table 5. System Usability Scale (SUS) results stratified by age category (<65 years and ≥65 years).

SUS score (range 0-100)	<65 years (N=118)	≥65 years (N=36)	Overall (N=154)
Mean (SD)	86.9 (12.5)	83.5 (11.0)	86.1 (12.2)
Median (range)	90.0 (20.0-100])	82.5 (57.5-100)	87.5 (20.0-100)

Figure 4. SUS survey responses assessed individually. Percentage values are calculated using available data from a total of 151 participants. SUS surveys were incomplete for 3 participants. SUS: System Usability Scale.



Qualitative Results

User Observation

Error observation notes were collated into a list and then manually categorized by the type and frequency of occurrence. The primary error sources included skipping or misreading instructions and on-screen instruction accessibility. The majority (70/86, 81%) of these errors occurred only on the first use and were shown to be correctable by interventional guidance. Such guidance was given after the SUS survey had been completed, and improvement in most cases was demonstrated in subsequent trials. This shows that although the device performs well in independent use, the monitoring of first use by an experienced operator may have further benefit for catching usability errors.

e-Questionnaire Feedback

The feedback from the questionnaires was collated into a spreadsheet and then manually categorized into the following themes: UI/user experience, aesthetic design/logical design, hand rest, cartridge, cleaning/sanitation, and software/bugs. The themes were then broken down into the following subthemes: confidence in use, training effectiveness, UI design/clarity of UI instructions, ergonomic design, foreseeable home use issue, and accessibility. The instances of feedback falling within these subthemes were counted and generated the 3 overarching themes: pretraining effectiveness, user friendliness of PointCheck (related to ease of use, accessibility, and clarity of UI elements), and ergonomic design.

Pretraining Effectiveness

A portion of participants initially expressed some uncertainty when using the device for the first time (Participants #38 and #18; Table 6). With repeated use, however, most participants felt that they could catch on quickly (Participant #40; Table 6).

Table 6. Illustrative quotes for the 3 overarching themes.

Theme/category	Illustrative quote
Pretraining effectiveness	• "Would like a YouTube channel/clip to watch in advance that will explain the device." (Participant #38) • "The most difficult step was probably removing the cartridge from the box. I was not sure if I had to keep the cartridge clean for measurements and the instructions did not tell how I should be holding the cartridge or if I should even be careful or not about touching it too much and getting it dirty" (Participant #18) • "The device was cumbersome (awkward) to use because it was the first time. After the first time, it would be easier to use." (Participant #40)
User friendliness of PointCheck	• "Others can't see as well, may need others to help them if they have dementia or are forgetful." (Participant #53) • "Could not read font of the three step instructions." (Participant #65) • "If I were to use the device on a daily basis, I would be relatively annoyed by the fact the three repeat questions are timed lag to press yes." (Participant #15) • "One thing I was confused about was checking off 'was my finger in all the way.' It was just a circle and I was confused what I was supposed to do on this step." (Participant #21) • "The cartridge lid is shown to be peeled from the flat side (facing down) but then needs to be rotated to be put in with the flat side up. If the peel could be opened in the right orientation, that would have helped." (Participant #24) • "Very crisp, and clear how to start using it...the screen has good contrast, good font choice given resolution and size, and the purple/grey color scheme is also calming." (Participant #30) • "Even though I knew beforehand that I should rest my elbow, I forgot to do so after inserting my finger because that was my main focus, so I really appreciated the reminder to have my elbow rested right after the step where I inserted my ring finger." (Participant #34)
Ergonomic Design	• "The display seems angled a little high, considering that the machine needs to be placed a considerable distance to rest my arm. The steps were fairly intuitive." (Participant #3) • "I was expecting the device to be a bit smaller. I think the device is designed for a very big hand, I think it would be probably better to try to make it the size closer to a computer mouse." (Participant #16) • "My fingers are pretty small and narrow but the soft spiked insides of the capture cylinder still left marks on my finger afterwards. This was completely non-painful but just noting this here for other users who might have thicker fingers! It was a bit bigger than I expected (the size of the device) but it doesn't impact usability. It also produced quite a loud hum but again, doesn't impact usability." (Participant #11) • "I liked the brush-like texture inside the tube. It helped me feel that I had my finger in the right position." (Participant #33) • "My first impression was that it looked pretty compact and that it's very straight to the point in its features--nothing fancy, just functional." (Participant #34)

User Friendliness of UI Design

Older participants (aged ≥65 years) discussed the need for improved screen readability, mentioning increasing the font size or needing additional assistance (Participants #53 and #65; Table 6).

There were mixed opinions on the overall design of the UI, but the majority (145/151, 96%) of the participants found the overall system to be easy to use and that they could learn quickly. Some participants did comment on the elements of UI design, such as buttons, on-screen instructions, or color choices, that made them feel frustrated, confused, or uncertain about whether they were performing the measurement correctly (Participants #15, #21, and #24; Table 6). Other participants expressed satisfaction with the UI design (Participants #30 and #34; Table 6).

Ergonomic Design

Finally, participants also addressed the changes they wished to see in the ergonomic design to better meet the needs of end users (Participants #3, #16, and #11; Table 6). Other participants expressed satisfaction with the ergonomic design (Participants #33 and #34; Table 6).

Discussion

In this study, we aimed to evaluate the usability and design of PointCheck, a novel technology for noninvasive, home-based neutropenia detection. Through a mixed method approach of user observation, questionnaires, and a SUS survey, we have validated the hypothesis that PointCheck is easy to use by first-time users in a simulated home environment with a mean SUS score of 86.1 (Table 2), classified as a score of A (ie, excellent; net promoter score: promoter level) [50,51] and falling within the top tenth percentile of systems as evaluated by the SUS [49].

Although the majority of first-time users expressed high satisfaction with the overall design and user friendliness of PointCheck (Table 3), a number of areas for improvement were identified through the feedback and observation of users and will be implemented into future designs. The main changes to be implemented to enhance the usability of the device and reduce instances of errors include the addition of a tutorial video and walk-through image animations as additional training methods, improved screen readability, improved button design to make them easily identifiable to users, and a modification of the cartridge to be more size inclusive.

In observing the use of the device in context, correct positioning during the use of the device may be more difficult for nonambulatory patients. Ideally, patients will have a training session with their health care professional prior to bringing this device home for normal use. This training would allow patients to familiarize themselves with the device beforehand, ask any questions related to use, and receive the support needed to ensure confidence in using the device alone for weeks at a time.

It is to be noted that a majority of study participants were aged <65 years and have an educational level of ≥8th grade level, both of which are factors that increase the likelihood of technological proficiency and willingness to adopt new technology [52]. Emerging technologies such as smartphones and tablets have raised concerns about their ease of use in older and untrained populations [53]; however, we found that it did not affect the perceived usability of PointCheck, considering that there was no significant differences in the SUS scores among users across educational levels and age categories (Tables 4 and 5). This is consistent with prior literature which has demonstrated that older populations are interested and capable of using modern technologies for managing health and can learn how to use a touch screen after a few tries [53,54]. Although all participants in the study had no previous training or experience using PointCheck, all of them were able to become proficient after 1 or 2 measurements guided by experienced clinicians through repetition by the end of the study visit. This is an indication that training, while necessary for building intuition and confidence when using the device [55], does not need to be extensive and the on-screen walk-through is effective in guiding the user through a measurement alone.

Although this study aimed to evaluate a variety of usability factors in a simulated home environment, a single study cannot claim to assess these factors in all use cases and situations. The perceived usability of PointCheck should be tested further in real-world home environments with users who receive prior training to identify context-related issues in the future.

Overall, this study demonstrated that PointCheck, a novel digital device for noninvasive WBC monitoring, can be easy to use for unsupervised patients in the home setting. By enabling continuous home-monitoring for severe neutropenia, PointCheck has the potential to change the standard of care for patients with cancer and substantially improve their clinical outcomes.

Acknowledgments

Funding for the study was supported through the National Cancer Institute Small Business Innovation Research program (grant R44CA228920), the National Institutes of Health (grant U54HL143541), the Massachusetts Technology Collaborative Digital Health Sandbox Program, and the Centro de Desarrollo Tecnológico e Industrial in Spain (grant SNEO-20191188). We are also grateful to Catherine Ricciardi, DNP, ANP-BC (Nurse Director and Clinical Operations); and Tatiana Urman, RN, MSN (Clinical Research Nurse Coordinator) at the Massachusetts Institute of Technology Center for Clinical and Translational Research. We extend a special thank you to all volunteers and patients who participated in this study.

Conflicts of Interest

GL, APT, IB, NB, RB, AB, ASF, and CCG are current employees and holders of stock options in a privately held company, patents, and royalties of Leuko Labs, Inc. Abstract

Background: Participation in case-control studies is crucial in epidemiological research. The self-sampling bias, low response rate, and poor recruitment of population representative controls are often reported as limitations of case-control studies with limited strategies to improve participation. With greater use of web-based methods in health research, there is a further need to understand the effectiveness of different tools to enhance informed decision-making and willingness to take part in research.

Objective: This study tests whether the inclusion of an animated decision aid in the recruitment page of a study website can increase participants' intentions to volunteer as controls.

Methods: A total of 1425 women were included in a web-based experiment and randomized to one of two experimental conditions: one in which they were exposed to a simulated website that included the animation (animation; n=693, 48.6%), and one in which they were exposed to the simulated website without the animation (control; n=732, 51.4%). The simulated website was adapted from a real website for a case-control study, which invites people to consider taking part in a study that investigates differences in purchasing behaviors between women with and without ovarian cancer and share their loyalty card data collected through 2 high street retailers with the researchers. After exposure to the experimental manipulation, participants were asked to state (1) their intention to take part in the case-control study, (2) whether they would be willing to share their loyalty card for research, and (3) their willingness to be redirected to the real website after completing the survey. Data were assessed using ordinal and binary logistic regression, reported in percentages (%), adjusted odds ratio (AOR), and 95% confidence intervals.

Results: Including the animation in the simulated website did not increase intentions to participate in the study (AOR 1.09; 95% CI 0.88-1.35) or willingness to visit the real study website after the survey (control 50.5% vs animation 52.6%, AOR 1.08; 95% CI 0.85-1.37). The animation, however, increased the participants' intentions to share the data from their loyalty cards for research in general (control 17.9% vs animation 26%; AOR 1.64; 95% CI 1.23-2.18).

Conclusions: While the results of this study indicate that the animated decision aid did not lead to greater intention to take part in our web-based case-control study, they show that they can be effective in increasing people's willingness to share sensitive data for health research.

Introduction

One of the most effective methods to test for exposure in epidemiological research is to conduct a case-control study in which people who have an illness are compared retrospectively with a matching population without the outcome [1]. Although it is a reliable methodology to test for associations, poor recruitment of population representative controls often undermines such studies [2].

Previous research reports the most common methods of recruiting control participants for case-control studies as follows: door-to-door recruitment, postal invitation, and random digit dialing [1,2]. More recently, with greater access to the internet, many cohort studies have moved their participant management and recruitment online (using unique websites), providing new opportunities to recruit participants, potentially improving diversity and ease of data collection [3,4]. Despite several advantages, however, caution needs to be exercised with the opportunistic recruitment of participants to web-based studies. For example, a recent study reported less than 4% of participants who visited a study recruitment website, after clicking on a targeted social media advertisement campaign, went on to sign up to the research [5]. This indicates that while individuals may be forming some interest to take part in research studies by clicking on a recruitment advertisement, their intention does not always translate to survey completion after they land on the research website.

Evidence on the barriers and facilitators of web-based survey completion primarily relates to the completion of stand-alone web-based surveys, rather than the use of unique websites to recruit participants to case-control studies [6-11]. These studies suggest that individuals' trust in the organization carrying out the research, whether they are early adopters of technology and high in literacy, and whether the research is in line with the individuals' values and beliefs are positive predictors of individual participation. Recommendations to achieve better outcomes include clear communication of the research goals, transparency about how data will be used, and shorter survey length.

Clinical trials have attempted to address some of the above (eg, transparency about how data will be used), using audio-visual decision aids to supplement the process of obtaining informed consent [12]. Communicating information via these mediums (enabled through web-based recruitment strategies), have the potential to reduce the associated cognitive load, facilitate further engagement with the research aims, generate positive attitudes toward the targeted behavior, and subsequently motivate engagement in the behavior itself [13-16]. To our knowledge, the potential impact of animated decision aids on intentions to take part in a web-based case-control study has not previously been investigated. This study aims to measure the effectiveness of an animated decision aid as a supplementary tool on a simulated website of a case-control study to encourage participation.

Methods

Setting

This study comprised a randomized web-based experiment, which assessed the effectiveness of adding an animated decision aid to a simulated website. The simulated website the animation was designed for (or added to) was the recruitment website for the case-control study: Cancer Loyalty Card Study (CLOCS) [17].

Cancer Loyalty Card Study

CLOCS is an observational case-control study that aims to investigate the self-care behaviors of patients with ovarian cancer prior to their cancer diagnosis. It seeks to do this by investigating differences in transactional data (such as medication purchasing) between women with and without ovarian cancer (the transactional data are collected through the loyalty cards of 2 UK-based high street retailers). Cases (ie, women with ovarian cancer) are recruited through participating National Health Service sites, while controls are recruited through the study website. Full details for CLOCS have previously been reported in the study protocol [17].

Animated Decision Aid

A key challenge for CLOCS recruitment has been communicating the research aims clearly, and our previous research highlights that the public often needs further explanations for how individual transactional data can be used in health research [18]. To improve public understanding and engagement with the aims of CLOCS, an animated decision aid was jointly prepared by Science Animated Limited, 2 patient representatives, and the CLOCS research team prior to the initiation of this web-based experiment. It aimed to convey key facts on ovarian cancer, the potential contribution of CLOCS in informing earlier diagnosis, as well as how women in the general population can play a role to aid its efforts (based on the participant information sheet tailored and approved by a National Health Service Research Ethics Committee [19/NW/0427-SA1], included in Multimedia Appendix 1). However, it should be noted that the animation was designed as a supplement to the main study materials, not as a key participant communication material to prompt informed decision-making. The animation features English subtitles and is 123 seconds (2 minutes and 3 seconds) long [19].

Procedure

The randomized web-based experiment was programmed in Survey Monkey. In July 2020, women who were eligible to take part in CLOCS as a control(ie, between the ages of 18 and 70, living in the United Kingdom, and without an ovarian cancer diagnosis) were recruited through a survey vendor (Dynata Limited). For those who were interested in taking part, information about the experiment, including a brief description of CLOCS, was presented and followed by the completion of the study consent form. If participants consented and were eligible, they were randomized (in a 1:1 ratio) to one of the following two experimental conditions: the simulated CLOCS website without the animation (control), or the simulated CLOCS website with the animation (animation) (Multimedia Appendix 2 and 3).

Once everyone viewed the simulated website, they were asked to complete the survey, where they were required to indicate their intention to take part in CLOCS using a 4-point Likert scale (definitely yes, probably yes, probably not, and definitely not) adapted from previous research [20-22]. The study participants were then asked to indicate their loyalty card use by selecting from a list of high street retailers' loyalty cards and whether they would be willing to share their loyalty card data for research purposes. The latter question was adapted from research on willingness to share electronic health data, which uses 4 commonly used models of consent for the use of data [23].

In the next step, the study participants were asked about their educational level, annual household income, and health literacy. For the latter, the eHealth Literacy Scale was used. This scale assesses individuals' retrieval and judgement of health information on the internet [24]. It consists of 8 items rated on a 5-point scale, ranging from 1 to 5, and has demonstrated considerable reliability and validity [24]. The participants' scores across the 8 items on the scale were summed and calculated for a sample mean. Individual scores below and above (or equal to) this sample mean were defined as low and high health literacy, respectively [25,26].

The final survey item was included as a behavior *proxy*. The participants were asked whether they want to be redirected to the actual CLOCS website for more information on how to take part. Those who responded that they would like to visit the website were provided with a link to the CLOCS website at the final page of the survey [22]. The website opened in a new tab for participants who clicked on the link. No data were collected from the study participants for their direct participation in CLOCS associated with the experiment.

Ethics Approval

Ethics approval for this study was granted by the UCL Research Ethics Committee (Project ID: 17823/001).

Data Analysis

A pilot study has been conducted beforehand for the purpose of sample size calculations. Based on the findings from the initial sample of 359 participants, with a 10% difference in intention to take part (definitely yes or probably yes versus definitely no or probably no), we determined the number of participants needed to achieve 95% certainty and 80% power was 650 per trial arm. Data from participants in both the pilot and final sample were combined for analysis.

Sample characteristics were assessed using descriptive statistics (Table S1 in Multimedia Appendix 4). To aid interpretation, the participants' income and educational levels were dichotomized in inferential analyses. For income, we used £30,000 (US $37,000) as the cut-off point, based on the average household income in the United Kingdom (reported by the Office for National Statistics, 2020) [27]. For education, we categorized participants into those with General Certificate of Secondary Education or A Levels and those with a university degree [20-22].

Differences in intentions to take part in CLOCS were assessed using univariate and multivariate ordinal logistic regression. Willingness to visit the actual website and willingness to share loyalty card data for research purposes, between groups, were assessed using univariate and multivariate binary logistic regressions. Odds ratios (ORs), 95% confidence intervals, and P values are presented in the results, with P values below .05 regarded as statistically significant. Participants who spent a short amount of time completing the survey (ie, *survey speeders*) were excluded from the analysis (Multimedia Appendices 5-8, based on the 50% cut-off points provided from previous research using median values) [28]. We report the analysis for the whole sample in Table S2 (Multimedia Appendix 9) and the distribution of the time spent on the survey before and after the exclusion of the *speeders* in Multimedia Appendices 5-8 [29]. Additional analyses for interaction between the intervention and health literacy led to null results and were not reported due to the unbalanced proportion of those with low health literacy and high literacy in the study population.

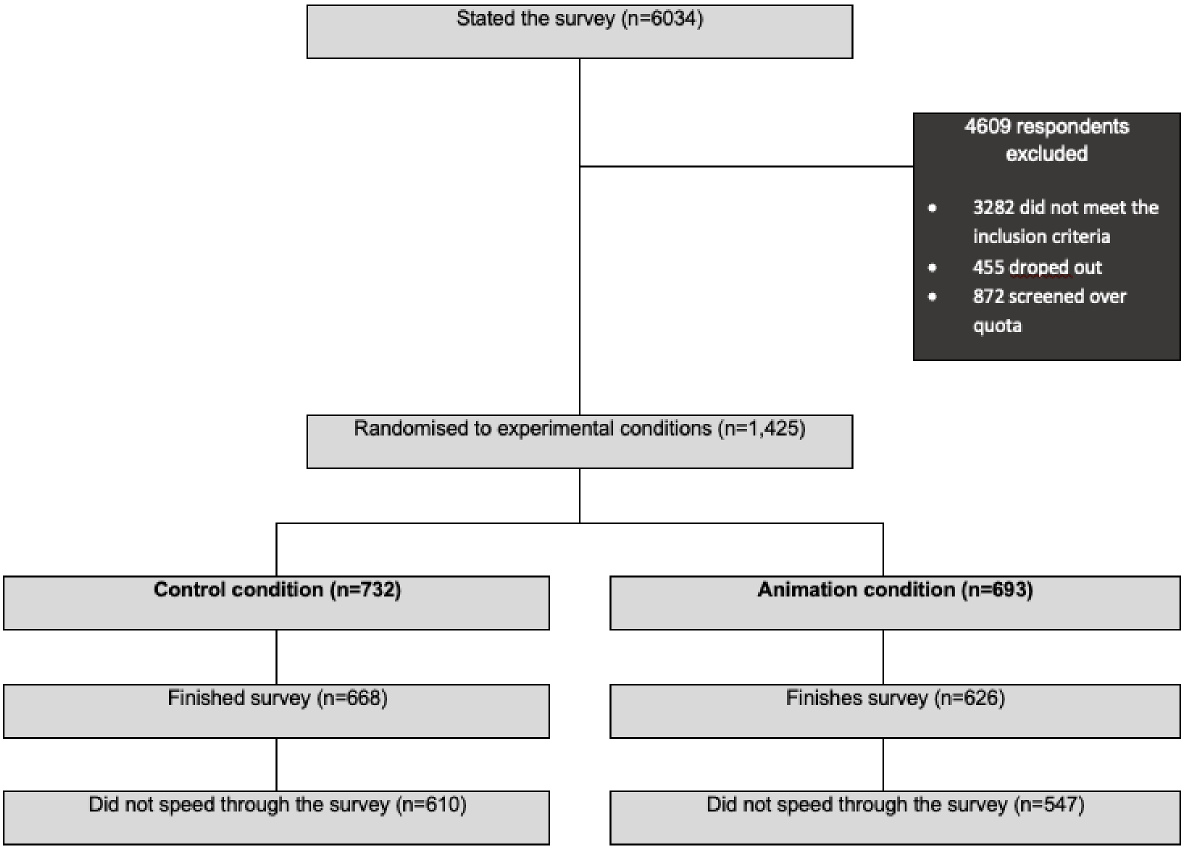
Results

Study Sample

Figure 1 demonstrates the flow of participants through the study. In total, 6034 women were invited to participate, of which 4609 (76.4%) were excluded as they were not eligible, dropped out, or discontinued the initial screening. The remaining 1425 (23.6%) were then randomized to one of the following two experimental conditions: 732 (51.4%) were randomly allocated to the control condition, and 693 (48.6%) to the animation condition. Across conditions, 131 (9.2%) did not finish the survey after randomization. Furthermore, 137 (9.6%) were excluded as they spent less than 50% of the median time. The analytical sample consisted of 1157 women—610 (52.7%) participants in the control condition, and 547 (47.3%) in the animation condition.

Most women in the analytical sample were aged between 55 and 70 years (n=417, 36.9%), did not have a university degree (n=686, 59.3%), and had an annual household income of less than £30,000 (US $37,000; n=622, 53.8%). The mean eHealth Literacy Scale score for the participants was 30.3 out of 40; thus, those who scored below this mean were classified as having low health literacy [20,21]. Post hoc comparisons revealed that sociodemographic characteristics were comparable between the two experimental conditions (Table S1 in Multimedia Appendix 4).

Figure 1. Flow through the study.



Intentions to Participate in CLOCS

Intentions to participate in CLOCS were generally very high, with 69.7% (n=807) of women stating that they would probably or definitely participate. Figure 2 shows the distribution of the intentions to participate in CLOCS after exposure to the simulated website. The ordered logistic regressions in Table 1 show that the inclusion of the animation did not affect participation intentions (OR 1.12; 95% CI 0.90-1.39 and AOR 1.09; 95% CI 0.88-1.35). The regression further shows that older women aged 55-70 years stated lower intentions to participate (OR 0.56; 95% CI 0.42-0.74), while those with an income above average (OR 1.36; 95% CI 1.06-1.63), one or more existing loyalty cards (AOR 2.05; 95% CI 1.16-3.62), and low health literacy (AOR 1.26; 95% CI 1.01- 1.58) had higher intentions to take part in CLOCS.

Willingness to Share Loyalty Card Data for Research

Most study participants stated that their data should be used but that they should have the option of saying no (control condition: n=246, 40.3%; and animation condition: n=181, 33.1%; Figure 3). However, significantly more participants in the animation condition, compared to control, indicated that they would be willing to provide the data if they were needed—as shown in the binary logistic regressions in Table 2 (control: n=109, 17.9% vs animation: n=142, 26.0%; OR 1.61; 95% CI 1.22-2.14 and AOR 1.64; 95% CI 1.23-2.18). Similarly, as with the intentions to participate in CLOCS, women aged 55-70 years were again less likely to state that their data should be used if needed compared to those aged 18-34 years (n=71, 17% vs n=72, 24.8%; AOR 0.62; 95% CI 0.43-0.89).

Willingness to Visit the CLOCS Website After the Survey

A slight majority of the study participants (n=596, 51.5%) indicated that they would like to visit the CLOCS website after the end of the survey (Multimedia Appendix 10). Table 3 shows that there was no difference between the two experimental conditions (control: n=308, 50.5% vs animation: n=288, 52.6%; OR 1.09; 95% CI 0.87-1.37 and AOR 1.08; 95% CI 0.85-1.37). Women with low health literacy, in comparison to those with high health literacy (n=111, 60% vs n=485, 49.9%; AOR 1.43; 95% CI 1.03-1.98), and women aged 35-44 years, in comparison to those aged 18-34 years, were more interested in visiting the study website (n=145, 60.4% vs n=148, 51%; AOR 1.49; 95% CI 1.05-2.12).

Discussion

Key Findings

This randomized web-based experiment examined the effectiveness of an animated decision aid to increase the willingness to participate in a case-control study. The results show that the animation did not increase intentions to participate in a real-world case-control study (CLOCS), or willingness to visit the real study website after the survey. However, the animation increased the participants' willingness to share data from their loyalty cards for research. Interestingly, immediately after the completion of this web-based experiment, there was a spike in activity within the case-control study, with over 100 people signing up to participate in CLOCS.

Comparison With Previous Literature

Our findings reflect the mixed evidence currently available in the literature. While there has been some support for the effectiveness of animated decision aids in the context of health behavior research, many studies have focused on how the interventions can improve participants' knowledge of the health behavior concerned, as their main outcome. When assessing participant intention to engage in the behavior (or an objective measurement of the behavior itself), the findings have been more inconsistent [30,31].

An interesting finding in our study is that, among all participants, those with lower health literacy scores were more interested to find out about the study compared with those with high health literacy scores. Our sample size calculations were based solely on the primary outcome; thus, we might have been underpowered to detect the interaction effects of health literacy and outcomes on the behavior *proxy*. However, the previous studies indicate that multimedia interventions are not always significant in individuals with lower educational levels [14] and low health literacy [15,16]. It has been previously shown in the cancer screening literature that gist-based supplementary materials could be used to enhance engagement with the main literature among people with low numeracy [32], and perhaps using animation and other easy-to-read materials could enhance participant recruitment in health research [33]. Furthermore, the positive association between low health literacy and willingness to visit the website may be explained by factors such as wanting to find more information, the salience of the research topic, and other factors that were not included in this web-based experiment. As such, future studies focusing on the comprehension of the materials among people with low health literacy using a think-aloud methodology could explain this outcome.

Strengths and Limitations

This study has some important limitations, which call for follow-up research. First, we did not include a comprehension assessment to check if participants fully understood or watched the animation. Second, we did not measure attitudes toward the simulated website and CLOCS. A recent systematic review on participant comprehension and informed consent in health research further highlighted that while there are efforts to improve participation rates using various methods, there is a lack of assessment of participant readability, literacy, and standardization of recruitment methods in health research for informed consent procedures [33]. While all the participant-facing CLOCS research materials have been reviewed by patient and public representatives, further assessment of participant comprehension prior to the animation experiment would have strengthened our methodology. However, the rationale for the exclusion of these measures was based on the assumptions that people often form immediate decisions about whether something is relevant to them using heuristic decision-making before establishing deliberative decisions [34]. As such, by excluding cognitive measures in our assessment to minimize judgement and bias, we tried to capture individuals' potential reactions to the website as close to their reaction in real life. In this context, further studies using eye-tracking experiments on the simulated website will be highly informative to build a better understanding of the interaction with the website and the contents [35].

On the other hand, exposure to the animation increased the intentions to share loyalty card data for research in general, but not for intentions to participate in the CLOCS study; this suggests that there are study-specific characteristics that did not appeal to individuals (eg, actively signing up to provide information) or that the study participants were not eligible. However, a recent study also shows that only half of the population is willing to share shopping data for health research, highlighting the differences in sociodemographic characteristics of people who are willing to share their data for health research [36]. The characteristics of the participants who are willing to take part in CLOCS in this study mirror the results of this age-stratified survey employed in England, with older women less willing to take part. While self-sampling bias will continue to be a concern of case-control studies based on the differences in characteristics of the people who are willing to take part, recruitment strategies could be stratified and tailored to engage different populations who are less willing to take part in health research based on this evidence and the validation of public acceptability. Our results support this evidence further using experimental design with greater internal validity for potential barriers in recruiting participants to a case-control study.

Implications for Policy and Future Research

While such questions of generalizability are warranted, this study still poses important relevance and implications to current research contexts. Due to the COVID-19 pandemic, many research studies have been forced to consider the possibility of being adapted online. This may require researchers to derive additional strategies to reach web-based samples with different characteristics. Underrepresentation in health research is already an issue for minority populations, people with low literacy, and those with greater deprivation using traditional methods of recruitment, unless they are specifically targeted [37,38]; thus, there is a further need to ensure that web-based strategies can provide means for researchers to attract representative samples.

Future studies should therefore continue exploring web-based methods to facilitate complex decision-making processes for potential participants of health research. The CLOCS animation has not been actively disseminated for participant recruitment following this dearth of evidence; however, unique findings might be obtained for research of a different nature. Other multimedia formats or mediums such as social media can be further explored in future studies, along with the consideration of potentially important variables such as participants' willingness to share data for research purposes.

Conclusion

The results of this study indicate that the animated decision aid did not influence the participants' intention to take part in CLOCS or visit the study website. The animation, however, increased the probability of individuals stating that they would share their loyalty card data for research. Future research should continue exploring methods that can effectively engage participants with low health literacy to participate in complex health research.

Acknowledgments

The authors would like to acknowledge Deborah Tanner and Fiona Murphy who have acted as representatives to patients with ovarian cancer since the inception of the CLOCS project and helped us inform the design and contents of the animation. This study was funded by Cancer Research UK Early Detection and Diagnosis project grant (C38463/A26726).

Authors' Contributions

JHL, STS, RK, and YH developed the study concept and design. YH, HRB, and JMF designed and developed the animation aid for the Cancer Loyalty Card Study (CLOCS). JHL, STS, and YH performed the data analysis and interpretation. JHL, STS, and YH drafted the manuscript. All authors provided critical revisions and approved the final version of the manuscript for submission.

Abstract

Background: Sexual dysfunction is a private set of disorders that may cause stigma for patients when discussing their private problems with doctors. They might also feel reluctant to initiate a face-to-face consultation. Internet searches are gradually becoming the first choice for people with sexual dysfunction to obtain health information. Globally, Wikipedia is the most popular and consulted validated encyclopedia website in the English-speaking world. Baidu Encyclopedia is becoming the dominant source in Chinese-speaking regions; however, the objectivity and readability of the content are yet to be evaluated.

Objective: Hence, we aimed to evaluate the reliability, readability, and objectivity of male sexual dysfunction content on Wikipedia and Baidu Encyclopedia.

Methods: The Chinese Baidu Encyclopedia and English Wikipedia were investigated. All possible synonymous and derivative keywords for the most common male sexual dysfunction, erectile dysfunction, premature ejaculation, and their most common complication, chronic prostatitis/chronic pelvic pain syndrome, were screened. Two doctors evaluated the articles on Chinese Baidu Encyclopedia and English Wikipedia. The Journal of the American Medical Association (JAMA) scoring system, DISCERN instrument, and Global Quality Score (GQS) were used to assess the quality of disease-related articles.

Results: The total DISCERN scores (P=.002) and JAMA scores (P=.001) for Wikipedia were significantly higher than those of Baidu Encyclopedia; there was no statistical difference between the GQS scores (P=.31) for these websites. Specifically, the DISCERN Section 1 score (P<.001) for Wikipedia was significantly higher than that of Baidu Encyclopedia, while the differences between the DISCERN Section 2 and 3 scores (P=.14 and P=.17, respectively) were minor. Furthermore, Wikipedia had a higher proportion of high total DISCERN scores (P<.001) and DISCERN Section 1 scores (P<.001) than Baidu Encyclopedia. Baidu Encyclopedia and Wikipedia both had low DISCERN Section 2 and 3 scores (P=.49 and P=.99, respectively), and most of these scores were low quality.

Conclusions: Wikipedia provides more reliable, higher quality, and more objective information than Baidu Encyclopedia. Yet, there are opportunities for both platforms to vastly improve their content quality. Moreover, both sites had similar poor quality content on treatment options. Joint efforts of physicians, physician associations, medical institutions, and internet platforms are needed to provide reliable, readable, and objective knowledge about diseases.

(J Med Internet Res 2022;24(8):e37339) doi:10.2196/37339

KEYWORDS

sexual dysfunction; digital health; Baidu Encyclopedia; Wikipedia; internet; health information; DISCERN instrument

Introduction

Knowledge regarding health and well-being is cobbled together from health care professionals, family, friends, books, newspapers, magazines, educational pamphlets, radio, television, and pharmaceutical advertisements [1]. However, we are increasingly heading online for answers rather than pursuing information through these other avenues [2]. Approximately 6% of all internet searches in the United States are health-related [3], and it is believed that internet searches have become people's first choice of method to seek information regarding health issues [4]. In addition, the population of netizens in mainland China reached 1011 million in 2021, and the number of online medical users in China had reached 239 million by June 2021, accounting for 23.7% of total internet users [5]. Information quality, emotional support, and source credibility have significant and positive impact on the likelihood of health care information adoption, and among these factors, information quality has the biggest impact on patients' adoption decisions [6]. Given the large amount of inaccurate information online, users are very easily misinformed [1]. Previous studies showed that the quality of online health information is problematic [7,8]. Thus, the assessment of source reputability and the veracity of information is a crucial and urgent task.

As the most common male sexual dysfunctions, erectile dysfunction (ED; the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance) and premature ejaculation (PE; poorly controlled and rapid ejaculation) greatly affect the quality of life of patients [9,10]. Furthermore, sexual dysfunction is closely associated with chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS; urologic pain or discomfort in the pelvic region associated with lower urinary tract symptoms) and is the most common complication [11,12]. The prevalence of CP/CPPS in men is about 8.2%, and men with CP/CPPS are more prone to ED and PE than the general population [13]. A previous study found that nearly half of patients with a self-reported diagnosis of CP/CPPS reported mild to severe ED [14]. A meta-analysis of 24 studies suggested that the overall prevalence of sexual dysfunction in patients with CP/CPPS was 0.62 [15]. In particular, our previous study found that "prostate" and "prostatitis" were the most queried terms by Chinese users with PE [16], which highlighted the stigma and preferences of these patients [17]. In addition, the complex and unclear etiology of CP/CPPS and sexual dysfunction not only challenges clinicians in the choice of treatment but also seriously affects the quality of life of patients. Previously, public interest and the change over time in the search volume for sexual dysfunctions and lower urinary tract symptoms were analyzed [16,18,19]. People tended to consult Dr. Internet in a combined manner on these issues for treatment decision-making. Therefore, the issue of sexual dysfunction is commonly investigated with CP/CPPS.

Wikipedia, the most popular and consulted encyclopedia website in English, is a web-based encyclopedia that provides valuable web-based health information [20]. Previous studies have shown that Wikipedia is a reasonably reliable medical resource and it was ranked higher on search engines than other general websites [21,22]. Unfortunately, on May 19, 2015, "Chinese Wikipedia" announced that mainland Chinese servers would be shut down because of violation of mainland China's laws due to the attack and destruction of the internet. As the equivalent Wikipedia for Chinese internet users, the Baidu platform and its Encyclopedia service is the most popular and frequently consulted encyclopedia site in mainland China [23,24]. In mainland China, with 766 million users actively using the Baidu search service, its usage in relation to health inquiries and symptom confirmation accounts for 66.83% of use, and health and medical topics ranked first among science topics [24]. Our previous research on the Baidu search index showed that the search demands by its users for sexual dysfunction and lower urinary tract symptoms are huge. However, users often get irrelevant online medical information, and there is little evaluation of the quality of Baidu-related content [16,19]. The purpose of this paper was to assess the reliability, readability, and objectivity of Wikipedia and Baidu Encyclopedia content on ED, PE, and CPPS/CP for the advancement of internet medicine.

Methods

Data Sources

The contents analyzed in this study are available on Chinese Baidu Encyclopedia and English Wikipedia. The Chinese Baidu Encyclopedia and English Wikipedia were investigated for articles on ICD-10 version 2016 codes. All possible synonymous and derivative keywords for each term were screened. Two doctors evaluated the articles on Chinese Baidu Encyclopedia and English Wikipedia. Any disagreement was reviewed by and arbitrated by a third reviewer who was an expert on sexual dysfunction. All authors have many years of experience in andrology and urology and are competent in the diagnosis and treatment of male sexual dysfunction and urinary disorders. These reviewers have professional knowledge of male sexual dysfunction and urinary disorders and can make professional evaluations.

Assessment of the Quality of the Research Articles

The Journal of the American Medical Association (JAMA) scoring system [25], DISCERN instrument [26], and Global Quality Score (GQS) [27] were used to assess the quality of disease-related articles. The contents of these scoring tables are shown in Multimedia Appendix 1. The JAMA scoring system is a well-known tool for evaluating the quality of information obtained from health-related websites. It includes 4 evaluation dimensions: author, attribution, disclosure, and currency. If it meets the requirements of each dimension, it will get 1 point, and the deimension with the highest quality will get 4 points. The DISCERN instrument has been developed to judge the quality of written health information [26]. To more comprehensively determine the quality of information in the article, the DISCERN tool consists of 15 questions plus an overall quality rating, and each is scored on a scale from 1 to 5. The first section of the DISCERN instrument is commonly used to evaluate the quality of published information, and the second section focuses on the quality of treatment choices offered to patients. The total score can range from 16 to 80, where a score of 63 to 80 suggests excellent quality, 51 to 62 indicates good quality, 39 to 50 indicates fair quality, and 16 to 38 indicates poor quality [26]. Experienced health information users and providers can use the DISCERN instrument to distinguish between high-quality and low-quality publications, so as to promote the generation of high-quality, evidence-based patient information. The GQS is a 5-point Likert scale that can subjectively rate the overall quality of each reviewed website. In addition to evaluating the overall quality of the website, GQS also considers the flow and ease of use of each website [28].

Statistical Analysis

All databases were constructed with Excel 2019 (Microsoft Corporation, Redmond, WA). The Shapiro-Wilk test was used to test the normality of the data. Descriptive analyses are reported as means and SDs for normally distributed variables. Medians and IQRs are reported for non-normally distributed variables. To ensure the quality of these scores, the intraclass correlation coefficient (ICC) was used to evaluate interobserver reliability. ICC values range from 0 (untrusted) to 1 (fully trusted), and any concordance values less than 0.75 were discussed by the research team to clarify the discrepancy. For nonparametric tests, the Mann-Whitney *U* test was conducted to test the significance of different ranks by using SPSS, version 22.0 (IBM Corp, Armonk, NY). The Fisher exact test was used to test the difference in the frequency distribution of DISCERN scores. We used Prism 8 for macOS, version 8.4.0 (455; GraphPad Software Inc, San Diego, CA) to conduct statistical analyses and create figures. For the statistical analysis, $P<.05$ was considered significant.

Results

Content Characteristics

We searched for “erectile dysfunction,” “premature ejaculation,” “chronic prostatitis/chronic pelvic pain syndrome,” and similar keywords on English Wikipedia and Chinese Baidu Encyclopedia. The search results are shown in Table 1. Wikipedia has only 1 entry for a disease, corresponding to a specific article. In Baidu Encyclopedia, a disease may have multiple entries and multiple articles. The information sources of these articles are different, and the number of views varies greatly. In Wikipedia, an article about a disease is constantly supplemented by different registered individuals. However, Baidu Encyclopedia's content providers are official organizations or unregistered individuals. Moreover, some of the recently updated articles in Baidu Encyclopedia show that the information is more often provided by organizations or institutions and is certified by experts. In addition, both Baidu and Wikipedia provide links to external information, including videos, articles, and images, while some links are unrelated advertisements. The latter especially appear in Baidu Encyclopedia. Furthermore, Wikipedia provides its own features for assessing the quality of articles, and all Wikipedia articles included in this study were rated as grade C.

Table 1. Characteristics of the search results from 2 online platforms.

Number of references, median (IQR)	53.5 (19.3-84.0)	0 (0.0-0.8)	.002

[a] A Mann-Whitney *U* test was conducted to test the significance of different ranks.

[b] CP/CPPS: chronic prostatitis/chronic pelvic pain syndrome.

[c] N/A: not applicable.

[d] ED: erectile dysfunction.

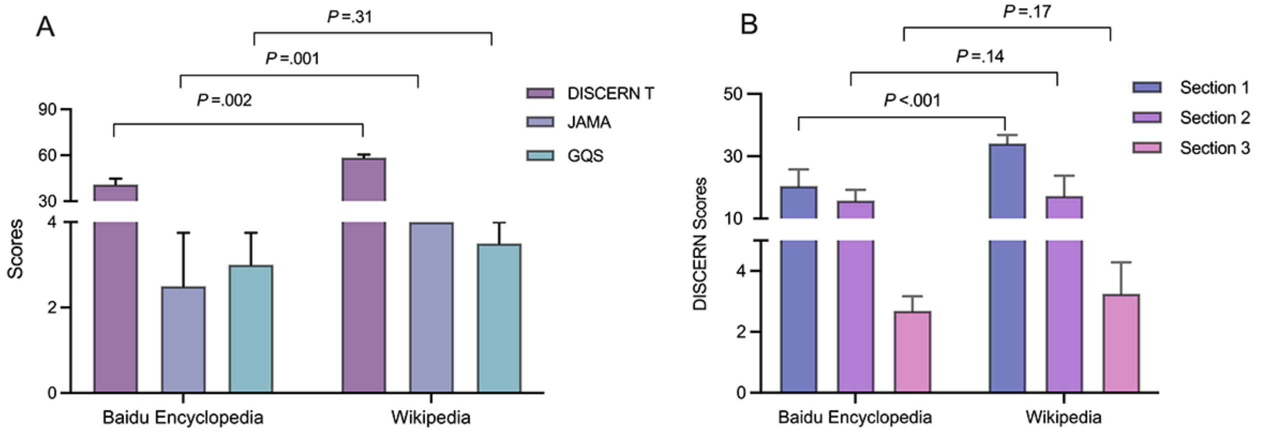
[e] PE, premature ejaculation.

Overall Scores for Baidu Encyclopedia and Wikipedia

A 2-way mixed/random effects model was used to analyze the consistency of the ratings by the 2 independent reviewers. The ICC results showed good consistency between the 2 reviewers for the GQS scores (ICC=0.87), JAMA scores (ICC=0.91), and DISCERN scores (ICC=0.82).

Comprehensively, the scores for Wikipedia were higher than those for Baidu Encyclopedia (Figure 1A). The contents in Wikipedia were significantly higher rated by the DISCERN tool and JAMA tool than those in Baidu Encyclopedia, suggesting that Wikipedia provides higher quality information. Although there was no statistical difference between the GQS scores for these websites, a numerically higher score on Wikipedia indicates that Wikipedia may provide better reading fluency and ease of use. In order to distinguish the differences between the 2 websites in more detail, we compared the DISCERN section scores for Baidu Encyclopedia and Wikipedia (Figure 1B). The DISCERN Section 1 score for Wikipedia was significantly higher than that for Baidu Encyclopedia, suggesting that Wikipedia provides more reliable and more objective information. The DISCERN Section 2 evaluates “How good is the quality of information regarding treatment choices?” There was no statistical difference between the DISCERN Section 2 scores for these websites, suggesting that they may have a similar impact on patients’ choice of treatment options. Section 3 is the overall rating of the publication, and the lack of statistical difference revealed that the overall quality of the publication as a source of information about treatment choices was similar for these websites.

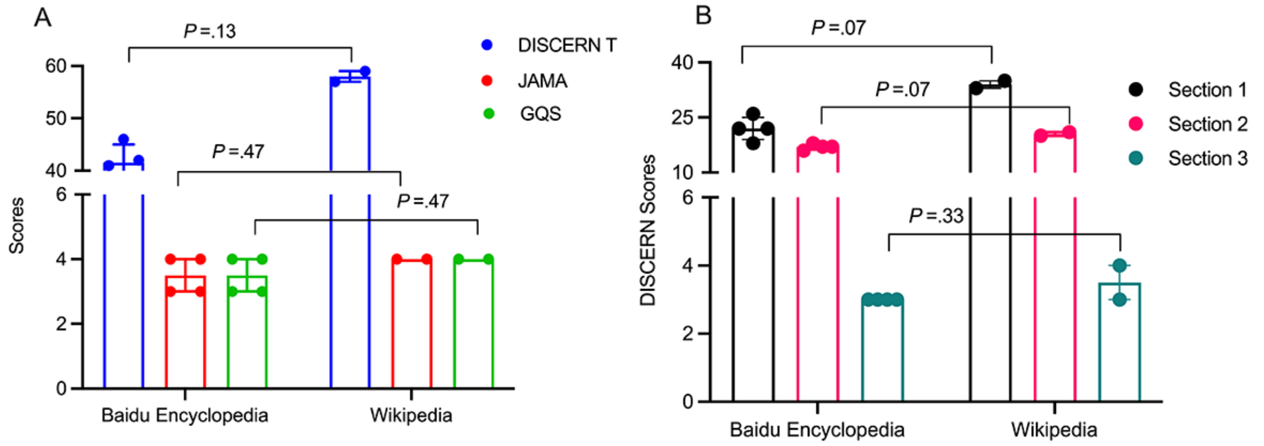
Figure 1. Overall comparison between Baidu Encyclopedia and Wikipedia: (A) median and IQR for DISCERN total scores, Journal of the American Medical Association (JAMA) scoring system scores, and Global Quality Score (GQS) scores; (B) median and IQR for the 3 DISCERN sections.



Overall Quality Comparison Between Wikipedia and Baidu Encyclopedia for the Theme of ED

ED is one of the most common male sexual dysfunctions. By comparing the content scores for ED articles on Baidu Encyclopedia and Wikipedia, Wikipedia appeared to have numerically higher total DISCERN scores, JAMA scores, and GQS scores, but there were no statistically significant differences (Figure 2A). Furthermore, the 3 DISCERN section scores for Baidu and Wikipedia were also compared separately (Figure 2B). Wikipedia appeared to have numerically higher DISCERN Section 1 and 2 scores. In addition, they had similar DISCERN Section 3 scores. These results suggest that there is no statistically significant difference between Wikipedia and Baidu Encyclopedia scores for ED content.

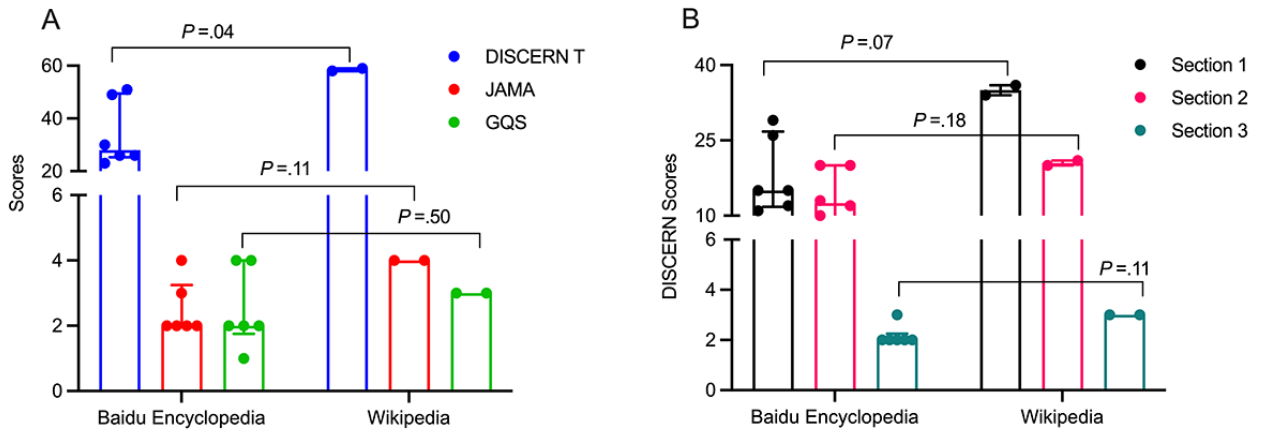
Figure 2. Comparison of erectile dysfunction (ED) scores between Baidu Encyclopedia and Wikipedia: (A) median and IQR for total DISCERN scores, Journal of the American Medical Association (JAMA) scoring system scores, and Global Quality Score (GQS); (B) median and IQR for the 3 DISCERN sections.



Overall Quality Comparison Between Wikipedia and Baidu Encyclopedia for the Theme of PE

A comparison of the scores for PE, the other most common sexual dysfunction disorder, showed that Wikipedia had a significantly higher total DISCERN score than Baidu Encyclopedia (Figure 3A). Although Wikipedia seemed to have higher JAMA and GQS scores than Baidu Encyclopedia (Figure 3A), this difference was not statistically significant, and all DISCERN section scores showed a similar trend (Figure 3B), which may be related to the great intragroup variability of Baidu Encyclopedia.

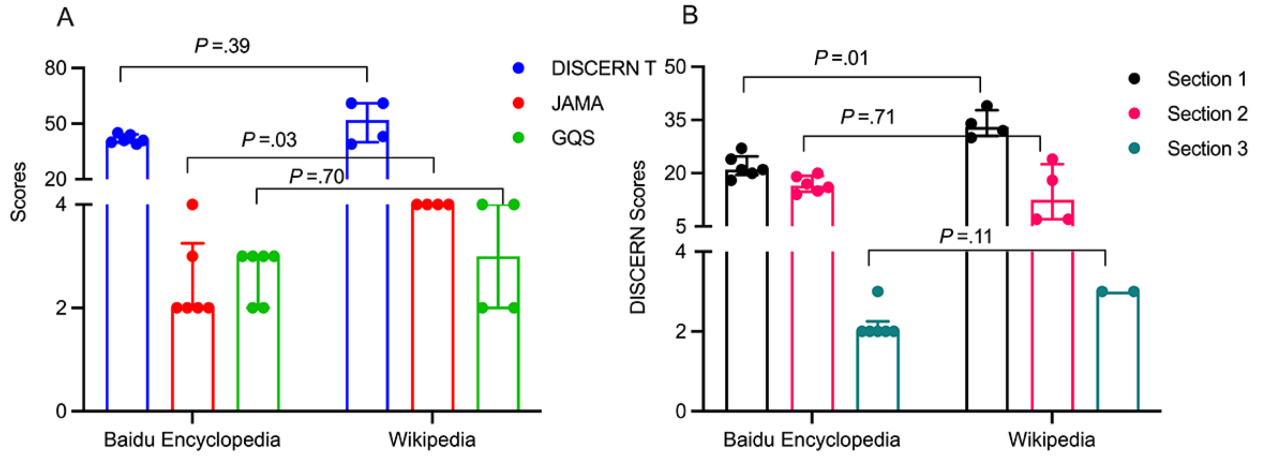
Figure 3. Comparison of premature ejaculation (PE) scores between Baidu Encyclopedia and Wikipedia: (A) median and IQR for total DISCERN scores, Journal of the American Medical Association (JAMA) scoring system scores, and Global Quality Score (GQS); (B) median and IQR for the 3 DISCERN sections.



Overall Quality Comparison Between Wikipedia and Baidu Encyclopedia for the Theme of CP/CPPS

CP/CPPS, as one of the most common concomitant diseases of sexual dysfunction, seriously affects the quality of life of male patients. By comparing the overall scores for Wikipedia and Baidu encyclopedia on CP/CPPS, we found that the scores of Baidu Encyclopedia were mostly fair quality, while the scores of Wikipedia ranged from fair quality to good quality (Figure 4A). Meanwhile, Wikipedia showed statistically higher JAMA scores, but there were no statistical differences between total DISCERN scores and GQS scores (Figure 4A). Furthermore, the DISCERN Section 1 score for Wikipedia was statistically significantly higher than that of Baidu Encyclopedia, while the DISCERN Section 2 and 3 scores for both sites were not significantly different from each other (Figure 4B).

Figure 4. Comparison of chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) scores between Baidu Encyclopedia and Wikipedia: (A) median and IQR for total DISCERN scores, Journal of the American Medical Association (JAMA) scoring system scores, and Global Quality Score (GQS); (B) median and IQR for the 3 DISCERN sections.



Distribution of the DISCERN Scores

After comparing the overall quality of the information for different diseases on Baidu encyclopedia and Wikipedia, the overall scores for Wikipedia seemed to be higher than those of Baidu encyclopedia, but some scores only showed numerical differences without statistical significance. Nevertheless, the differences in the distribution of scores that had numerical differences were seemingly obvious. Therefore, we performed further statistical analyses of the score distributions for Wikipedia and Baidu Encyclopedia. As aforementioned, according to the DISCERN standard, a total DISCERN score <50 (near 60%) is fair or poor quality, while a score >50 is good or excellent quality [26]. Based on this rule, we took a score of 3 for each question as the cutoff value; that is, a score higher than 3 points was defined as good quality.

The score distributions for each disease are shown in Table 2. Wikipedia had a higher proportion of total DISCERN and Section 1 scores distributed above 3 points, whether compared with the overall score or the score for each disease, and was significantly better than Baidu Encyclopedia. However, Baidu Encyclopedia and Wikipedia had low Section 2 and 3 scores, and most of these scores were ≤3, which are defined as low quality.

Table 2. Distribution of the DISCERN scores for each disease and comparisons via the Fisher exact test.

DISCERN	Overall			CP/CPPS[a]			ED[b]			PE[c]		
	Wikipedia, n (%)	Baidu Encyclopedia, n (%)	*P* value	Wikipedia, n (%)	Baidu Encyclopedia, n (%)	*P* value	Wikipedia, n (%)	Baidu Encyclopedia, n (%)	*P* value	Wikipedia, n (%)	Baidu Encyclopedia, n (%)	*P* value

Discussion

Principal Findings

Internet-based information is playing an increasingly important role in the diagnosis and treatment of patients, especially for privacy-sensitive conditions such as sexual dysfunction and related concomitant diseases. Comprehensive and objective information can help patients understand their condition, choose the right time to visit a doctor, and then improve their prognosis. However, incorrect or incomplete information may leave patients vulnerable to misdiagnosis, leading to delays in treatment and considerable health risks [1]. As a consequence, at a time when internet health care is booming, there is an urgent need to evaluate the credibility, readability, and accuracy of online resources. This study evaluated the reliability, readability, and objectivity of Baidu Encyclopedia and Wikipedia in terms of ED, PE, and CP/CPPS content. Overall, the total DISCERN scores and DISCERN Section 1 scores for the content provided by Wikipedia were significantly higher than those of Baidu Encyclopedia. Also, Wikipedia had a higher proportion of total DISCERN and Section 1 scores distributed within the high-quality range than Baidu Encyclopedia. Combined with higher JAMA scores, the results suggest that Wikipedia provided more reliable, higher quality, and more objective information than Baidu Encyclopedia. Baidu Encyclopedia and Wikipedia had low DISCERN Section 2 and 3 scores, and most of these scores were low quality. Similar DISCERN Section 2 and 3 scores for Wikipedia and Baidu Encyclopedia indicated that they had an analogic and mediocre impact on patients' choice of treatment options. Although not statistically different, Wikipedia had numerically higher GQS scores, suggesting that Wikipedia might provide relatively better flow and be easier to use.

By June 2021, the number of online medical users in China was 239.33 million, and the utilization rate of the internet was 23.7%, an increase of 11.4% over December 2020 [29]. In an analysis of internet search trends in China, some scholars found that only 43.74% of the search results for PE were related to PE [16]. In another study on lower urinary tract symptoms, 1.13%-93.92% of the retrieved content was found to be irrelevant to lower urinary tract symptoms [19]. The study also found similar problems in the contents about these diseases in Wikipedia and Baidu Encyclopedia. Wikipedia provides more standardized and unified content, with standard templates for almost every disease, which allows readers to find the information they need quickly and accurately [30]. In contrast, the quality of content provided by Baidu Encyclopedia varies widely, with some recently updated articles providing more comprehensive content than Wikipedia, but the overall trend is a lack of standardization and formality. In Baidu Encyclopedia, the same disease may correspond to multiple entries and corresponding articles, which compare poorly with each other, and different articles may provide users with contradictory information, which can cause great confusion to users. The diversity of the content formats presented by Baidu Encyclopedia is consistent with the great variability of its overall score. The total DISCERN scores and JAMA scores for Wikipedia were significantly higher than those for Baidu Encyclopedia, and the proportion of Wikipedia scores within the high-quality distribution was also higher than those for Baidu Encyclopedia. These results suggest that Wikipedia provides higher quality information than Baidu Encyclopedia. In addition to the lack of a standard content presentation format, the low quality of Baidu Encyclopedia is also related to other features of its website, such as information sources and references. The contents of Baidu Encyclopedia are mostly sourced from official organizations or unregistered individuals, while information on Wikipedia is provided by registered users. The comparison shows that the quality of contents provided by unregistered individuals is always rated as "poor quality." Accurate citation of high-quality references is an important guarantee for the reliability of a paper [31]. The contents provided by these unregistered individual users are almost always without references and extended information. By contrast, the quality of contents provided by registered users or official organizations are almost rated as "good quality," with accurate references. These characteristics of the website are closely related to DISCERN Section 1 scores, and significantly higher DISCERN Section 1 scores for Wikipedia indicate that its publications are more reliable than those of Baidu Encyclopedia. The other 2 main focuses of the quality assessment are "How good is the quality of information regarding treatment choices?" and "the overall quality of the publication as a source of information about treatment choices." Similar scores on DISCERN Sections 2 and 3 for Wikipedia and Baidu Encyclopedia indicated that they had an analogic and mediocre impact on patients' choice of treatment options. Recent updates to Baidu Encyclopedia also show an increasing number of medical professionals involved in reviewing or writing the content, also significantly improving the DISCERN and JAMA scores. This comparison suggests that the inconsistency of disease presentation formats and differences in information sources may account for the lower Baidu scores.

CP/CPPS is characterized by localized pain or discomfort in the abdomen, pelvis, and genitals, usually with lower urinary tract symptoms, psychosocial disorders, and sexual dysfunction [11,12]. The relationship between sexual dysfunctions and CP/CPPS has been studied more extensively [32]. Previous studies have shown a good correlation between the severity of symptom scores between the 2 clinical conditions, CP and PE, and that approximately 49% of male patients with CP have concomitant sexual dysfunction [33]. It addition, "prostate" and "prostatitis" were the most queried terms by Chinese users with PE [16]. The complex and heterogeneous pathophysiology of CP/CPPS makes the management of this troublesome situation very challenging both for clinicians and patients, and approximately 50% of older patients experience recurrence [34]. The UPOINT System classifies CP/CPPS patients into 7 different subgroups based on symptoms: urologic, psychosocial, organ-specific, infectious, neurologic, tenderness (pelvic floor tenderness), and sexual dysfunction; then, it proposes specific treatment plans based on the different subgroups [35]. There is growing evidence that the addition of second-line therapies, such as 5-phosphodiesterase inhibitors, antidepressants and muscle relaxants, according to the UPOINT System approach, can significantly improve patients' CP/CPPS symptoms [36]. These results showed that CP/CPPS and sexual dysfunctions can directly or indirectly increase the economic burden of health care and seriously affect patients' quality of life. Patients with CP/CPPS or sexual dysfunction may feel too embarrassed to discuss their problems with doctors due to the influence of the Chinese culture, and they are likely more willing to look for disease-related information, such as symptoms, diagnosis, treatment methods, prognosis, and hospital rankings, on the internet first. There is no doubt that the information these patients access from the internet affects their perception of their health status, which in turn affects treatment choices and disease prognosis.

By comparing the contents for ED, PE, and CP/CPPS on Baidu Encyclopedia and Wikipedia, we found that the consistency of Wikipedia is better, with almost all content rated as "good quality," while the scores for Baidu Encyclopedia were mostly "fair quality." Take PE-related articles in Baidu Encyclopedia as examples. Both reviewers rated "早发性射精" (early-onset ejaculation) as “poor quality.” After analyzing the content on the web page for “early-onset ejaculation,” we found there was no introduction to “examination, diagnosis, and treatment,” and the content in the article was not objective and scientific. Contrary to the lack of effective information, there are more than 25 irrelevant advertising links and only one reference on this web page. The content on the “早泄” (premature ejaculation) page on Baidu Encyclopedia was rated as “good quality,” and the information was more comprehensive and objective than that for “early-onset ejaculation.” Corresponding to the quality grades for “early-onset ejaculation” and “premature ejaculation,” there was a huge difference in page views (early-onset ejaculation/premature ejaculation: 33,506/25,747,398). The discrepancy may be related to the inconsistent identity of content providers. The irrelevant advertising links or misleading information obtained by users using Baidu Encyclopedia may be related to the fee-based editing service. There are many third-party underground industries that charge fees to write Baidu Encyclopedia entries on their behalf, so as to insert advertisements and achieve the purpose of attracting patients. In order to improve the quality of the health information, Baidu Encyclopedia announced the “rainbow plan” on December 9, 2012, wherein all medical entries could only be edited and revised by certified medical experts [37]. This is consistent with the findings of this study that an increasing number of medical professionals are involved in reviewing or writing content for Baidu Encyclopedia. Consequently, attracting, encouraging, and even recruiting more medical professionals to draft or proofread the content about disease presentation provided on these websites may ensure the content is objective and comprehensive. At the same time, the Baidu Encyclopedia platform should strengthen content regulation and establish a review mechanism to remove interest-related content.

In contrast, Wikipedia has its own content quality evaluation system, such as the “Wiki-Project article quality grading scheme” and the “Wiki-Project priority assessments” [38,39]. In this study, all included Wikipedia articles were rated as grade C, which means “Useful to a casual reader, but would not provide a complete picture for even a moderately detailed study” and “Considerable editing is needed to close gaps in content and solve cleanup problems.” The “Wiki grading” for these Wikipedia articles is similar to the grading by the 3 grading tools applied in this paper. That is, the quality of these Wikipedia articles is almost “good quality” but far from “excellent quality,” and all articles needed further improvement. Despite this fact, the formality and drafting on Wikipedia are better because of the clear attribution and disclosure it provides. As mentioned earlier, there is a lack of uniform standards for writing Baidu Encyclopedia content, many of the information sources are not supported by academic references, and external links are mostly related to advertisements. Hence, though the content on both sites leaves much to be desired, as a source to popularize science, the content on Wikipedia could at least guide interested individuals to the right source of informations, while Baidu Encyclopedia is more likely to provide misleading information.

In the era of rapid internet development, more patients have started to try online consultations [40]. This change in mode of treatment has presented new opportunities and challenges for doctors, medical institutions, physician associations, internet platforms, and patients. In this study, we evaluated the objectivity, reliability, and readability of the content on sexual dysfunction and CP/CPPS on Baidu and Wikipedia and found that the quality of the content provided by both sites was not “excellent quality” and needed to be improved. This study is only a microcosm of the vast amount of information available in internet-based health care. Considering the increasing coverage of the internet, more users will be influenced by internet-based information, and incorrect or incomplete information will have a negative impact on users’ decision-making. Therefore, we believe that, in the era of the internet information explosion, physicians, physician associations, and medical institutions should make full use of their expertise and become more involved in the construction of internet-based health care by providing objective and comprehensive content. Internet platforms, on the other hand, should strengthen the regulation and review of medical-related content and remove false or irrelevant content. Wikipedia already has a relatively complete self-censorship system and self-evaluation system, but Baidu Encyclopedia has almost no achievements in this regard. In China, the country with the world’s largest population, the importance of popular science education for the whole society and the world is self-evident. Baidu Encyclopedia, as the largest platform for online science education in China, still needs to be greatly enhanced to take up the corresponding social responsibility. Through the joint efforts of physicians and the platform, we hope to achieve the goal of providing users with timely access to correct, objective, comprehensive, and valid information when seeking medical advice or searching for health science content on the internet.

Limitations

Some limitations must be addressed in this study. This study only presents the results of medical professionals’ evaluations of health-related science content on the internet, and further research is needed on the specific impact of this information on the audience and readers. Since information on the internet is updated quickly, there may be some bias between the study results and the actual situation, and the data need to be updated in real time to ensure that the findings are true and valid. In addition, the difference in the number of Chinese and English entries indicates the information received by users will be significantly different because of the entries they choose to click. Therefore, our “combined” evaluation cannot fully represent the quality of the information they really receive. Fortunately, with the availability of infodemiology research, academics can combine content analysis and infodemiology search trends to better elucidate the impact of health-related information on the internet on users, society, and the health care industry.

Conclusions

Internet medicine, as a new medical model in the new era, provides strong support for users to understand disease information and choose the timing of treatment in a timely manner. Although it is more formally composited, Wikipedia also provides more reliable, higher quality, and more objective information than Baidu Encyclopedia. They also have a similar impact on patients' choice of treatment options, and the websites are similar in terms of flow and ease of use. To promote the healthy and sustainable development of internet health care, the joint efforts of physicians, physician associations, medical institutions, and internet platforms are needed to provide more reliable, accessible, and comprehensible disease knowledge to the public.

Acknowledgments

This research was supported by the National Natural Science Foundation of China (grant numbers 81870513, .81600584, 81470980), 1.3.5 project for disciplines of excellence, West China Hospital, Sichuan University (grant number ZY2016104).

Authors' Contributions

This study was conceptualized by MM and TL. The methodology was designed by MM, YF, and TS. The investigation was carried out by MM and YF. MM and SY carried out the data statistics and interpretation. MM and MZ wrote the original draft. MM, YF, TS, and TL reviewed and edited the draft. Funding was acquired by TL. All authors approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Secondary use of clinical data for biomedical research purposes holds great potential for various types of noninterventional, data-driven studies. Patients' willingness to support research with their clinical data is a crucial prerequisite for research progress.

Objective: The aim of the study was to learn about patients' attitudes and expectations regarding secondary use of their clinical data. In a next step, our results can inform the development of an appropriate governance framework for secondary use of clinical data for research purposes.

Methods: A questionnaire was developed to assess the willingness of patients with cancer to provide their clinical data for biomedical research purposes, considering different conditions of data sharing and consent models. The Cancer Registry of the German federal state of Baden-Württemberg recruited a proportionally stratified random sample of patients with cancer and survivors of cancer based on a full census.

Results: In total, 838 participants completed the survey. Approximately all participants (810/838, 96.7%) showed general willingness to make clinical data available for biomedical research purposes; however, they expected certain requirements to be met, such as comparable data protection standards for data use abroad and the possibility to renew consent at regular time intervals. Most participants (620/838, 73.9%) supported data use also by researchers in commercial companies. More than half of the participants (503/838, 60%) were willing to give up control over clinical data in favor of research benefits. Most participants expressed acceptance of the broad consent model (494/838, 58.9%), followed by data use by default (with the option to opt out at any time; 419/838, 50%); specific consent for every study showed the lowest acceptance rate (327/838, 39%). Patients expected physicians to share their data (763/838, 91.1%) and their fellow patients to support secondary use with their clinical data (679/838, 81%).

Conclusions: Although patients' general willingness to make their clinical data available for biomedical research purposes is very high, the willingness of a substantial proportion of patients depends on additional requirements. Taking these perspectives into account is essential for designing trustworthy governance of clinical data reuse and sharing. The willingness to accept the loss of control over clinical data to enhance the benefits of research should be given special consideration.

Introduction

Background

Secondary use of clinical data for biomedical research purposes has great potential for various types of noninterventional, data-driven studies. We define secondary use of clinical data as the collection and reuse of clinical data in data gathering, noninterventional biomedical research, or learning activities; clinical data are collected during and for the purpose of patient care [1]. Research using clinical data has the ethical and efficiency advantages of not requiring additional physical interventions or collection of additional data. Although secondary use aims at improving biomedical knowledge and, in turn, medical care, it does not imply a direct benefit for the patient who has released their data.

The blurring of the boundaries between research and care, as envisaged in concepts of learning health care systems, is currently visible only in few areas [1,2]. The endeavor to merge these different system logics is faced with emerging challenges such as limited utility of specific consent models for research or false expectations regarding their benefits on the part of patients [3]. The goal of this paper was to contribute the patients' perspective to the debate and potential solutions to the current challenges of secondary use of clinical data in the context of learning health care systems.

Previous studies with citizens and patients have already shown that certain aspects seem to be crucial for supporting secondary use, such as who conducts the research (eg, academic or commercial), whether data are transferred to other countries, and what consent model is applied [2-9]. However, owing to varying research designs, for example, by examining different study units, applying different survey instruments, and being conducted in diverse health care systems, these studies, taken together, have heterogeneous results.

Consent is a crucial component of respecting patient autonomy and building trust in health research. However, the specific consent paradigm of clinical trials cannot easily be applied to the secondary use of clinical data because most scientific questions are unknown at the time consent is obtained, that is, when the patient receives care. Newly applied models for secondary use of clinical data, such as broad consent or data use by default (with the option to opt out any time), facilitate research with clinical data, but are criticized from an informational self-determination perspective for offering patients insufficient control over their clinical data. However, previous studies have identified patients' and citizens' openness toward these new models [5,10-12]. Other empirical studies show that, to increase research benefits, participants seem willing to accept the loss of control over their data [13-16]. However, no studies have yet been conducted to assess the acceptance of consent models in light of the trade-off between the control of clinical data and research utility.

Aim

The objective of this study was to assess (1) patients' general willingness and relevant requirements to share pseudonymized clinical data for research purposes, (2) acceptance of different consent models including characteristics of data control and research utility, (3) preferences regarding the setting to provide consent, and (4) general expectations toward data use and other stakeholders.

Methods

Survey Development

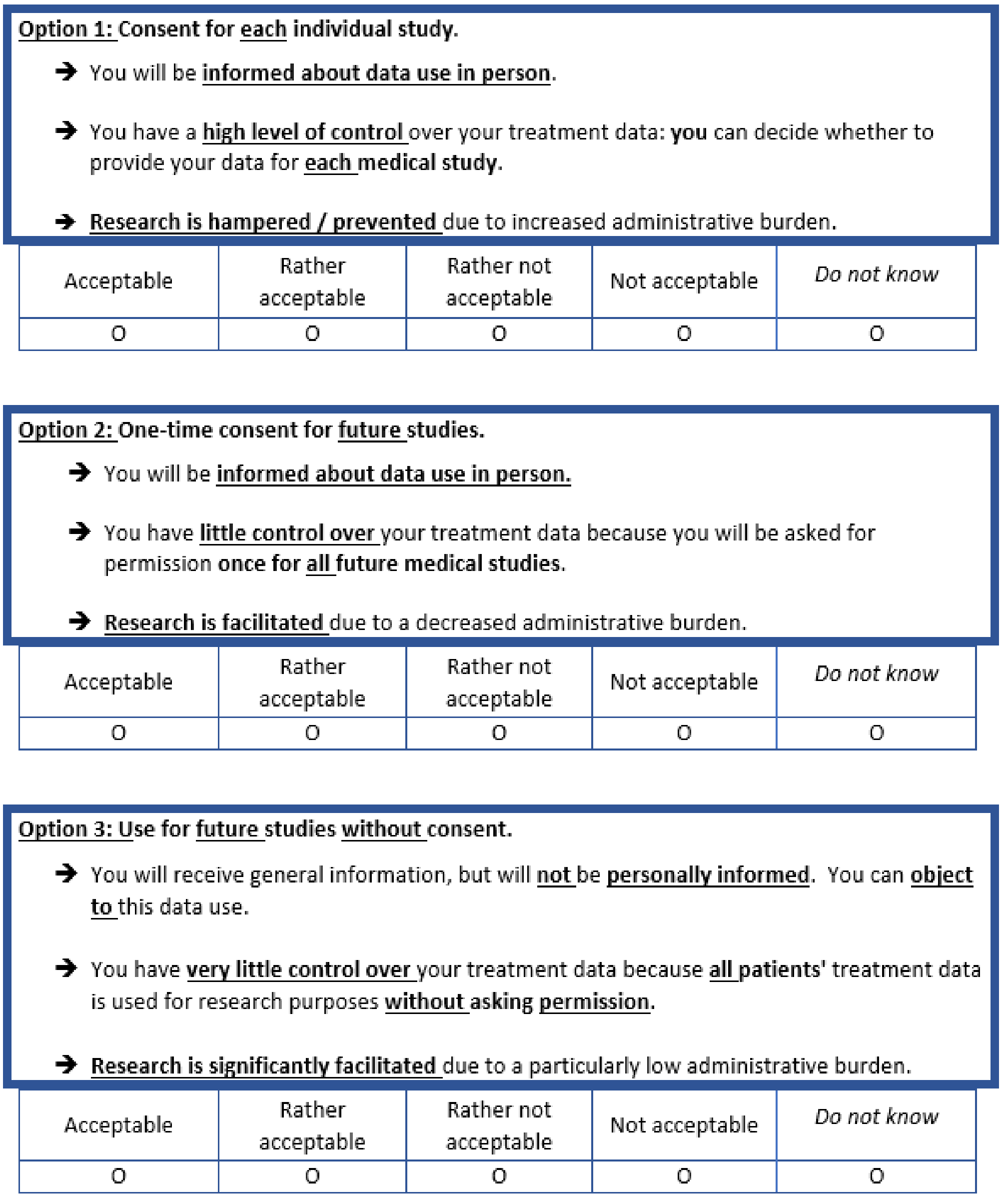
The questionnaire (Multimedia Appendix 1) was based on a review of the relevant scientific literature and a preparatory expert interview study among stakeholder groups engaged or affected by the planned secondary use of clinical data in Germany [17]. In total, 2 representatives for patient interests were included in the expert sample. The questionnaire was developed through several discussion and feedback rounds by the international and interdisciplinary project team, consisting of social scientists; ethicists; legal scholars; and clinicians with expertise in social, ethical, legal, or practical aspects of secondary use of clinical data. To ensure comprehensibility and technical functionality of the questionnaire, cognitive interviews (n=5) with patients with cancer and survivors of cancer who had provided consent were conducted in the pretest phase, resulting in minor adaptions.

To allow participants to develop an informed opinion, the survey included background information about risks and benefits associated with the secondary use of clinical data. The survey consisted of 33 items on the following topics: sociodemographic and disease-related information, expectations and risk perception toward secondary use, willingness to provide clinical data under certain requirements, and acceptability of consent models and procedures. Attitudinal questions were designed as 5-point Likert scale. The survey was approved by the data protection officer of the Heidelberg University Hospital.

Operationalization of Consent Scenarios

In total, 3 vignettes were developed to measure the acceptability of 3 consent scenarios: *specific consent*, *broad consent*, and *data use by default* (with the option to opt out at any time). Acceptance was measured using a 4-point Likert scale (Figure 1).

Figure 1. Display of the 3 consent scenarios in the questionnaire (English translation).



Option 1: Consent for each individual study.

➔ You will be **informed about data use in person**.

➔ You have a **high level of control** over your treatment data: **you** can decide whether to provide your data for **each medical study**.

➔ **Research is hampered / prevented** due to increased administrative burden.

Acceptable	Rather acceptable	Rather not acceptable	Not acceptable	*Do not know*
○	○	○	○	○

Option 2: One-time consent for future studies.

➔ You will be **informed about data use in person.**

➔ You have **little control over** your treatment data because you will be asked for permission **once for all future medical studies**.

➔ **Research is facilitated** due to a decreased administrative burden.

Acceptable	Rather acceptable	Rather not acceptable	Not acceptable	*Do not know*
○	○	○	○	○

Option 3: Use for future studies without consent.

➔ You will receive general information, but will **not** be **personally informed**. You can **object to** this data use.

➔ You have **very little control over** your treatment data because **all patients'** treatment data is used for research purposes **without asking permission**.

➔ **Research is significantly facilitated** due to a particularly low administrative burden.

Acceptable	Rather acceptable	Rather not acceptable	Not acceptable	*Do not know*
○	○	○	○	○

Previous studies have reported that participants made a trade-off between research utility and data control [13]. Hence, 3 consent scenarios were designed with information about research utility and control over data. In the process of operationalization, we further reduced the complexity of the theoretical concept to ensure good comprehensibility of the survey material:

1. By *specific consent*, we understand that consent is provided for each individual study (option 1 in Figure 1), as currently performed in clinical trials. Consistent with our preliminary studies [1,17], we inform about high degree of control over the secondary use of clinical data and low research benefit owing to the administrative burden on researchers.
2. In the case of the *broad consent* scenario, 1-time consent is provided for future medical studies with clinical data; moderate control and research utility are presumed (option 2 in Figure 1).
   This vignette refers to the implementation of a broad consent process for the German Medical Informatics Initiative; the development of a unified template for broad consent was accompanied by the German Working Group of Research Ethics Committees [18]. In practice, this model involves safeguards such as the review of each individual research project by a research ethics committee and data access committees, organizational measures to protect patient data, and comprehensive information for patients [18]. To ensure comprehensibility, the details of these safeguards are not provided to the participants of this study.
3. *Data use by default* is use of data for secondary research by default (comparable with Denmark or Estonia) without individual informed consent process, but with the possibility to opt out at any time. This scenario is associated with low degree of data control for patients and facilitation of research as no individual consent needs to be obtained (option 3 in Figure 1).
   Regarding law, the European Union (EU) data protection regulation provides some scope for this scenario of data use based on a legal basis other than informed consent if

> the potential research benefit clearly outweighs the right to informational self-determination (Art. 9, Paragraph 2, lit. j [19]). Compensating efforts such as ambitious security and privacy measures and extensive general public education about data use and data governance are likely to be ethically and legally necessary. To ensure comprehensibility, the details of these safeguards are not provided to the participants of this study.

Sampling and Recruitment

The Cancer Registry of the German federal state of Baden-Württemberg sent postal invitations to a random sample of patients with cancer and survivors of cancer, proportionally stratified by age and gender, requesting study participation (n=4219). The sample frame consisted of all registered patients in Baden-Württemberg, Germany, with a diagnosed tumor disease who were aged ≥18 years. Participants had the option of either completing an anonymous and self-administered web-based survey (the hyperlink was provided in the cover letter) or returning an envelope by mail, consenting that their address may be forwarded to the research group to subsequently receive a paper-and-pencil questionnaire. Survey instruments were adapted to the requirements of a mixed-mode survey [20].

Individuals who completed the survey were not compensated.

Data collection occurred from May 2021 to July 2021.

Analysis

Descriptive statistics were used to express the categorical variables as counts and percentages. Differences in proportions were assessed for statistical significance ($P<.05$) using chi-square tests. The 2-tailed Pearson correlation coefficients were computed. All analyses were performed using SPSS (version 28; IBM Corp).

Ethics Approval

The study obtained ethics approval from the University of Heidelberg's research ethics committee (reference number S-361/2018). Informed consent was obtained from the individuals who participated in the study pretest measurement and the written survey.

Results

Demographics of Participants

Of the 4155 patients with cancer approached by the Cancer Registry Baden-Württemberg, 838 (20.17%) participants completed the survey. Approximately half of the participants who answered the respective question were women (389/820, 47.4%; Table 1). Of 832 participants, 390 (46.9%) participants were aged between 60 and 74 years, and of 826 participants, 541 (65.5%) participants were retired. In total, 29.8% (247/830) of the participants had a university degree. The most common types of cancer were breast cancer (204/826, 24.7%), prostate cancer (187/826, 22.6%), and gastrointestinal cancer (79/826, 9.6%). The distribution of age, gender, and cancer entity mirrored that of the general distribution of patients with cancer in the Cancer Registry Baden-Württemberg, with minor deviation.

Table 1. Demographics of participants.

Characteristics	Values, n (%)
Gender (n=820)	
Women	389 (47.4)
Men	431 (52.6)
Age groups (years; n=832)	
18-59	186 (22.4)
60-74	390 (46.9)
≥75	256 (30.8)
Highest educational degree (n=830)	
Elementary school diploma	84 (10.1)
Secondary school diploma	398 (47.9)
Qualification for university entrance	97 (11.7)
University degree	247 (29.8)
No school diploma	4 (0.5)
Employment status (n=826)	
Employed or self-employed	219 (26.5)
Not employed owing to health reasons	45 (5.4)
Retired	541 (65.5)
Not employed owing to other reasons	21 (2.5)
Type of cancer (n=826)	
Breast	204 (24.7)
Prostate	187 (22.6)
Gastrointestinal	79 (9.6)
Skin cancer	63 (7.6)
Non-Hodgkin lymphoma	39 (4.7)
Lung	31 (3.8)
Leukemia	22 (2.7)
Kidney	22 (2.7)
Head and neck	22 (2.7)
Uterine or endometrial	21 (2.5)
Urinary bladder	18 (2.2)
Stomach	16 (1.9)
Pancreas	9 (1.1)
Other	93 (11.3)

General Willingness to Provide Clinical Data for Biomedical Research Purposes and Requirements for Data Provision

Most participants indicated that they are generally willing to make their clinical data available either without restrictions (527/838, 62.9%) or under certain conditions (283/838, 33.8%). Only 0.7% (6/838) of the participants generally refused to provide clinical data.

Then, the participants who indicated general willingness were asked about certain requirements under which they would provide their clinical data. When asked about the general requirements they deemed relevant, most participants stated the highest possible data security standards (482/838, 57.5%), followed by use of their data for as many research projects as possible (254/838, 30.3%), and being informed about the most important research results (208/838, 24.8%; Multimedia Appendix 2).

Most participants (591/832, 70.5%) stated that they would support research with their data in countries with high level of data protection comparable with German standards; 17.9% (149/832) of the participants stated that they would restrict data use to domestic research projects; and 8.8% (73/832) of the participants agreed to support international projects, independent of the level of data protection (Multimedia Appendix 3).

When asked how long their initial consent should be valid, 38.5% (320/832) of the participants set no time limit and approximately half of the participants demanded to renew consent either after 3 years (181/832, 21.8%), 10 years (227/832, 27.3%), or 30 years (10/832, 1.2%), respectively. In total, 10.2% (85/832) of the participants favored renewal of consent each time their data are used for specific research projects (Multimedia Appendix 4).

A large proportion of participants (532/832, 63.4%) said that they would grant access to researchers, independent of their affiliation; however, 22.7% (189/832) of them did not want to share their data with researchers at for-profit companies that conduct medical research (Multimedia Appendix 5). Only a small proportion opposed the secondary use of their clinical data by their physicians (56/832, 6.7%) or researchers at universities and university hospitals (48/832, 5.8%).

Acceptance of Consent Models

The questionnaire provided information about 3 consent models that correspond to specific consent, broad consent, and data use by default (with the option to opt out at any time), including the trade-offs of each model between control over clinical data and the facilitation of medical research (Table 2). For each consent model, the participants rated the level of acceptance on a 4-point Likert scale. Each of the 3 consent models showed a medium degree of acceptance with significant mean differences. Of the 838 participants, 491 (58.6%) accepted the broad consent model, 421 (50.2%) accepted data use by default (with the option to opt out at any time), and 323 (38.5%) accepted the specific consent model. Of the 323 participants accepting the specific consent model, 102 (31.6%) did not accept any other model (102/838, 12.2% of the total sample). Sociodemographic characteristics were not significant, except for older participants being more likely to accept data use by default (Pearson coefficient, 2-tailed: r=0.138; P<.001).

Table 2. Acceptance rates of 3 consent models: broad consent, data use by default, and specific consent (N=838)[a].

Model	Description	Accepted, n (%)	Not accepted, n (%)	Do not know or not answered, n (%)
Broad consent	One-time consent for future studies, informed in person, low level of control, and research is facilitated	491 (58.6)	230 (27.4)	117 (13.9)
Data use by default	Use for future studies without consent process, not personally informed, very low level of control, and research is significantly facilitated	421 (50.2)	347 (41.4)	70 (8.4)
Specific consent	Consent for each study, informed in person, high level of control, and research is hampered	323 (38.5)	372 (44.4)	143 (17.1)

[a] Acceptance was measured using a 4-point scale; results were collapsed into 2 groups (*not acceptable*: not acceptable and rather not acceptable; *acceptable*: acceptable and rather acceptable).

Preferences Regarding the Setting for Providing Consent

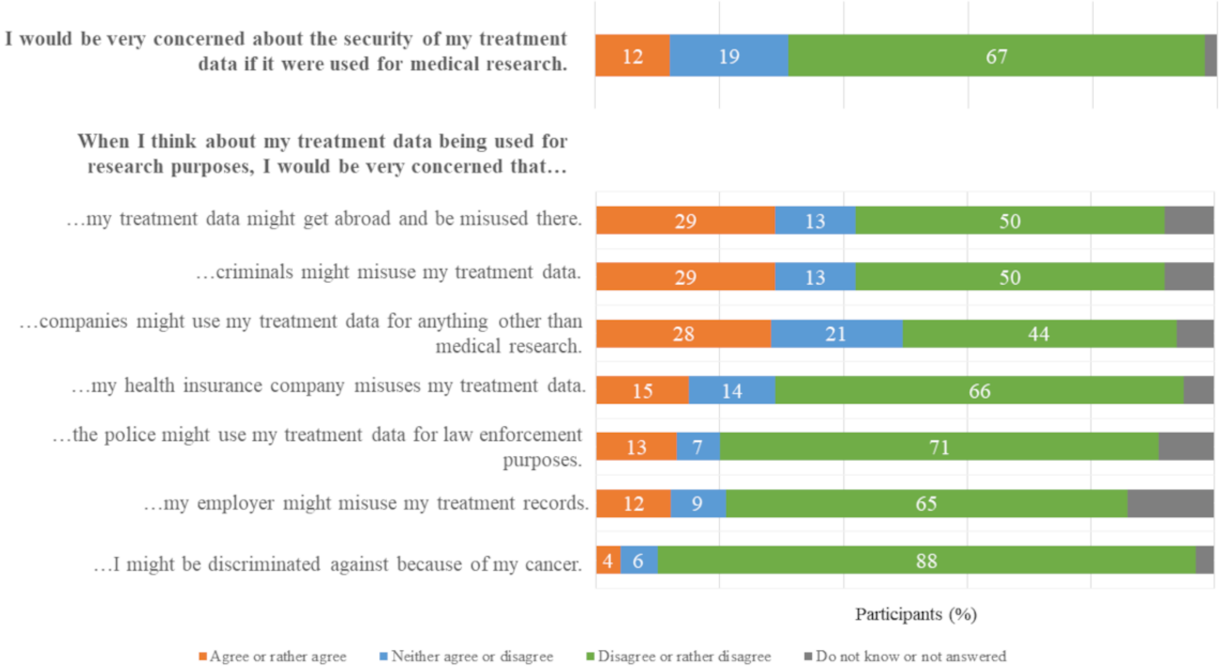
Participants were asked about the most appropriate setting for providing consent for the secondary use of their clinical data for research purposes. Most of them preferred to decide at their general practitioner's practice (528/838, 63%), and a small proportion of participants preferred to decide during the admission to a hospital (174/838, 20.8%; Multimedia Appendix 6).

When asked about preferred information formats, most participants selected a brief written summary of key points in easy-to-understand language to learn more about secondary use (616/838, 73.5%), followed by face-to-face consultation with physicians (347/838, 41.4%; Multimedia Appendix 7). Participants were asked about who should decide about data access and use by individual research projects: most participants (393/838, 46.9%) favored committees with experts in which the opinion of patients is represented, for example, by patient representatives, whereas a small proportion of participants preferred to leave the decision to an expert committee (without patient representation; 185/838, 22.1%) or to decide for themselves (200/838, 23.9%; Multimedia Appendix 8).

Concerns in the Event of Data Use

A small proportion of the participants (99/838, 11.8%) showed major general concerns regarding their clinical data being used for research purposes (Figure 2). Then, all participants were asked about more specific concerns: the largest proportion of participants were worried about the data being misused in countries other than Germany (246/838, 29.4%), data being misused by criminals (244/838, 29.1%), and data being used by companies for something other than medical research (235/838, 28%). Concerns about participants being discriminated against because of cancer were very low (32/838, 3.8%).

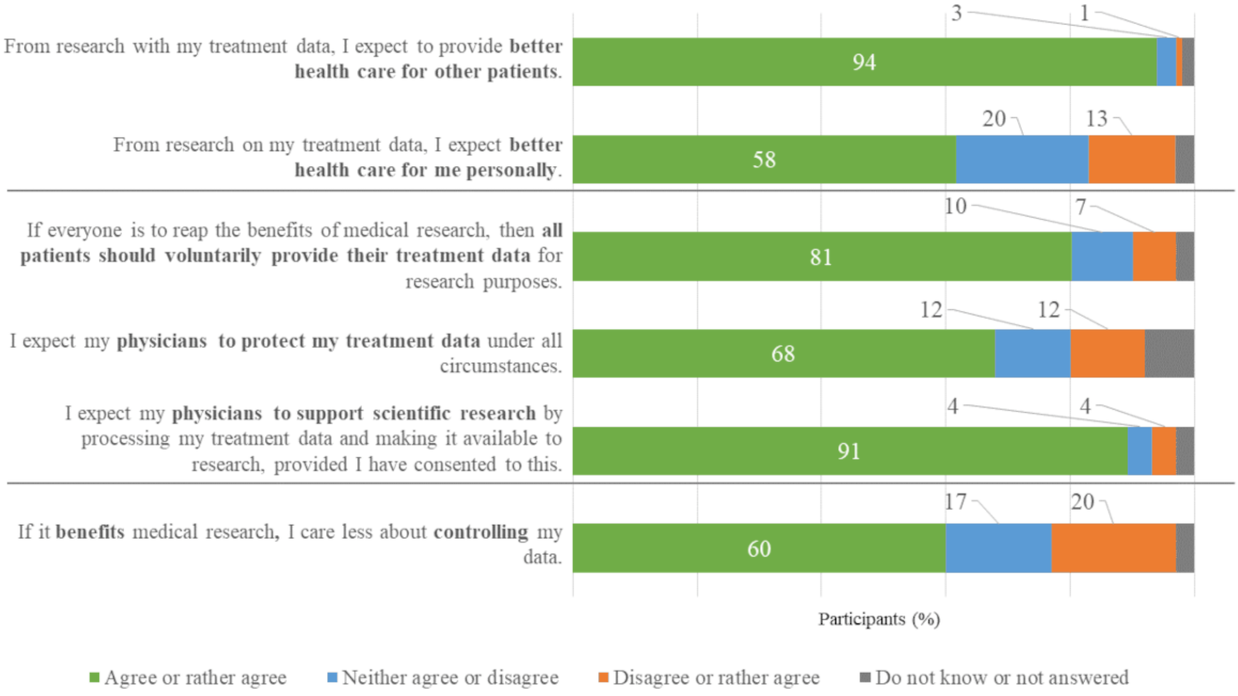
Figure 2. Concerns in the event of data use (N=838).



Expectations Toward Benefits, Other Patients, and Physicians

Approximately all participants (788/838, 94%) expected a benefit for other patients from making their clinical data available for research purposes (Figure 3). More than half of the participants (482/838, 57.5%) mistakenly expected a personal benefit, even though the explanatory text explicitly stated the opposite. Of the 838 participants, 676 (80.7%) participants supported the claim that all patients should voluntarily make their clinical data available for research purposes. In total, 68.3% (572/838) of the participants expected their physicians to protect the participants' clinical data in all circumstances, and approximately all participants (758/838, 90.5%) expected their physicians to support research, if consent was provided, by making their patients' clinical data available for research.

Figure 3. Expectations toward physicians and other patients (N=838).



Discussion

Principal Findings

Information about the requirements under which patients would make their treatment data available for research is important for any form of policy that regulates the secondary use of such data. This paper provides the results of a representative sample of German patients with cancer on general willingness and decisive requirements for sharing their data for research purposes and on the acceptance of consent models and expectations toward relevant stakeholders. The following are the main findings. First, we found an unprecedentedly high general willingness (810/838, 96.7%) to make clinical data available even after being informed about the potential risks of secondary use; however, relevant requirements included the following: ensuring a high level of data security, comparable data protection standards for data use abroad, and renewed consent at regular time intervals. Second, in contrast to previous studies, three-fourths of respondents (620/838, 73.9%) supported data use also by researchers in commercial companies. Third, the highest acceptance rate was found for a broad consent model (494/838, 58.9%), followed by data use by default (419/838, 50%); and specific consent for every study (327/838, 39%). Fourth, high expectations for physicians and fellow patients to support data sharing for research purposes were found.

To the best of our knowledge, this is the first representative study on attitudes toward the secondary use of clinical data and acceptance of consent models in combination with characteristics of data control and research utility.

High General Willingness to Provide Clinical Data

Overview

An important finding of our study was the high willingness of patients with cancer to make their clinical data available for research purposes (810/838, 96.7%), either without any restrictions (527/838, 62.9%) or under certain conditions (283/838, 33.8%). Only 0.7% (6/838) of the participants generally refused to provide clinical data. A population-representative study in the United States found low proportions of general willingness (76%) [21], similar to representative studies in Germany in the contexts of the COVID-19 pandemic (65%) [22] and medical data including genetic data (56%) [13]. These different results suggest that patients with cancer are more willing to provide clinical data for medical research because they may either have benefited or hope to benefit from research. As potential beneficiaries of past studies, they may also feel greater responsibility than citizens and other patient groups to support research to help future generations of patients [11,23-25]. Although patients with cancer are not representative of all patients, we assume that they can hint well at the attitude of other patient groups with severe or rare diseases, such as leukodystrophies [26]. A study conducted in the United States shows slightly lower willingness among patients with cancer and survivors of cancer (71%) [27] than among the general population (76%) [21], which may point toward country-specific factors in the context of health systems and trust in institutions.

General Requirements: Data Security, Maximizing Data Use, and Transparency

The most relevant general requirements for supporting the secondary use of clinical data for research were high data security (486/838, 57.9%), maximizing data use (251/838, 29.9%), and information about research results that made use of patients’ clinical data (210/838, 25.1%). These findings indicate the relevance of the ability of data governance to protect clinical data, maximize accessibility (and usability) of data for research, and report transparently on the results of data use. These findings are largely consistent with previous literature that describes secure data use, public benefits through effective use by researchers, and transparency as important requirements for data sharing [3,8,14]. It may well be that participants value the reporting of results as an act of recognition and reciprocity. Suggestions for future set up of governance for secondary use of data to respond to the abovementioned requirements include appropriate safeguards to protect patient data; high degree of transparency regarding data use and benefits to society; and technical, organizational, and legal data infrastructure that enables researchers to maximize research benefits. Involving patients to better understand their concrete needs in designing these requirements for secondary use seems advisable [28].

Data Transfer Only to Countries With Comparable Data Protection Standard

Most participants stated that they would restrict their data to research in countries with data protection standards comparable with those in Germany (737/838, 87.9%), and a small minority of the participants was willing to provide data to other countries (75/838, 8.9%). This resonates with another German study with outpatients who generally support data donation in favor of public research institutions in EU countries with similar data protection standards (92%); only a minority of the participants approved data access to countries outside the EU (24%), which is a large share compared with our findings [6]. The high relevance of this aspect is consistent with studies of Canadian citizens [8,9]. However, further studies are needed to explore the exact kinds of misuse that make people fearful about international data transfers. Our study suggests that comparable data protection standards are a decisive requirement for patients. A suggestion to address this need is that policy makers and data initiatives explain well to patients what the additional benefit of multinational research is, what the specific risks are (eg, foreign government access and less ability to enforce rights), and how risks to data protection in these countries are mitigated. They are well advised to give patients the choice of whether to consent to data transfer to countries with low data protection standards.

Most Participants Support Data Use by Corporate Researchers

Low willingness of citizens to share data with the private industry has been reported in several studies [3,4]. This finding poses challenges to the biomedical research landscape, as many studies are conducted by companies or in cooperation with companies. In contrast, our results show that approximately three-fourths of the participants (620/838, 73.9%) were willing to make their clinical data available to company researchers.

This is a much higher acceptance than in studies with German citizens [5] and outpatients [6], which reported that only a minority of those participants who agreed to data donation were willing to provide data to the industry (17% and 29%, respectively). A cross-country study found particularly low support for medical and genetic data sharing with for-profit researchers among German participants (22% compared with 32% on average across all countries) [29]. We hypothesize that willingness to share data with company researchers may change owing to experiences with a severe illness: patients with cancer may develop strong awareness of contributions by corporate researchers, possibly based on their experiences during their therapy. In addition, our questionnaire item included a brief explanation of the relevant contribution of industry to medical research and of industry as an important collaborator with public research institutions. We suppose the explanation increased the participants' understanding and willingness to provide clinical data to the industry, which is consistent with a study examining public attitudes toward commercial data access, in which provision of information and deliberative methods increased willingness to share data [15]. In addition, our findings indicate that low willingness to share data with corporate researchers can be addressed through collaboration with public research institutions in public-private partnerships.

Renewed Consent Within Certain Time Intervals

The participants' stance was divided on the duration of data use after initial consent is provided. Most participants (408/838, 48.7%) preferred to renew consent for broad research use after a period of 3 or 10 years. Only approximately one-third of the participants (243/838, 28.9%) preferred 1-time consent with unlimited duration of consent validity. In contrast, in a representative study of German citizens, more than half of the participants favored unlimited validity of consent (56%), and a minority favored consent validity of 5 years (17%) [5]. Our reported relatively high proportion of participants preferring renewed consent may have resulted owing to the following reasons. First, patients with cancer experience changing health conditions, leading to a subjective sensitivity to release clinical data without time limit. Second, our questionnaire explicitly mentioned risks of data release, possibly reducing the approval of unlimited data use. Third, the abovementioned study among German citizens asked for unlimited use for "data donation," which can be understood as irrevocable by definition. To address this potential need for patients to renew consent, further studies should investigate the preferences using neutral wording.

Broad Consent and Data Use by Default Was More Accepted Than Specific Consent—Research Benefits Partially Outweigh Loss of Control

Overview

Participants were presented with general information about 3 consent models (specific consent for every study; broad consent; and data use by default, with the option to opt out at any time). Specific consent is related to maximum informational control for patients, but less utility for research projects, whereas data use by default is associated with less informational control, but maximum utility for research projects. The broad consent model features moderate control and research utility (Table 2). The opportunity of being personally given information by health personnel is not available in the case of data use by default. Participants rated the level of acceptance for each consent model. The broad consent model received the highest acceptance rate (491/838, 58.6%), followed by data use by default (421/838, 50.2%) and the specific consent model with only a moderate acceptance rate (323/838, 38.5%). The relatively high acceptance rate for the broad consent model is consistent with the results of previous studies. Different study designs and minor deviations regarding the definition of consent procedures apply; therefore, comparisons should be considered cautiously. In total, 2 studies with a German patient sample and a large sample of Dutch patients found even higher acceptance rates in the context of health care–embedded biobanking and data donation (92%-93%) [5,10]. An earlier study of German patients (87%) [11] and a study of a smaller sample of US citizens (96%) [12] showed similar results. Our acceptance rates for each of the presented consent models were lower than those in other studies. This may be a consequence of the choice among 3 different models, rather than only 1, as presented in other studies. The low acceptance rates may also result from a trade-off decision between support for research and control over one's clinical data. Previous studies have described this trade-off between control and research benefits as a relevant influencing factor in decision-making [12-16]. Accordingly, in our study, most participants (520/838, 62.1%) agreed to give up control if it increased the benefits of research. This finding is significant because most participants (804/838, 95.9%) believe in the benefits of secondary use for other patients. Evidence from other studies [11,23-25] and our findings not only suggest that research benefits partially outweigh the loss of control but also that they are a critical motivational aspect of making data available for research.

As none of the models achieved wide-ranging acceptance in our study, it is worth discussing whether a meta-consent model that allows participants to choose their preferred consent variants [30] accounts best for individual ways of balancing control and research benefits regarding consent models.

Preferred Framework Conditions for Providing Consent and Data Release

When asked for consent, participants expected brief and understandable written information (616/838, 73.5%) about data use and preferred their primary care physician as a venue for informed consent (528/838, 63%) over providing consent upon hospital admission (174/838, 20.8%). This finding is underpinned by a qualitative study in which support by health care professionals was seen as an important facilitator [8].

Our findings indicate that, regarding place and time (ie, where and when patients are informed and asked for consent), consent in the clinical context is preferred over consent before becoming a patient. This is consistent with the finding that patients prefer providing consent at hospitals (64%-76%) over providing consent outside the clinic [6]. However, another study concluded that the decision about making data available for research should be separated from the clinical context and anchored in everyday life [31]. Owing to possible age and disease effects, further studies should investigate the differences between the general population's and patients' acceptance.

When asked who should decide on data release when individual research projects apply for using participants' clinical data after having personally released their treatment data for research purposes, approximately half of the participants (394/838, 47%) preferred a committee with experts and patient representatives over a committee with experts only or deciding for themselves. A suggestion to address this need is to involve patients in data access committees.

Low Concerns and High Expectations

Low Level of Concern in General and About Discrimination

In our study, the proportion of participants who were concerned about the use of clinical data (101/838, 12.1%) was considerably lower than the findings of 2 surveys conducted in Australia among citizens (24%-25%) [32] and patients (24%) [33]. A study conducted in the United States found that privacy concerns had the strongest influence on individuals' intentions to provide clinical data [34]. This discrepancy may be attributable to country-specific differences regarding trust in health care and government institutions [3] and the lack of experience with extensive data leaks or the misuse of clinical data in Germany. Participants' concerns about discrimination owing to their cancer were very low (34/838, 4.1%).

False Expectations of Personal Benefit

Most participants (486/838, 57.9%) incorrectly expected personal benefits from making their clinical data available for research purposes—even though the wording of the questionnaire had been adjusted during the pretest phase. Another study found that more than one-fourth of German patients hoped for personal benefit (28%) after being asked for consent for secondary use of clinical data and biomaterial collected during routine care [11]. Owing to the severity of the disease, patients with cancer may be particularly prone to this false expectation of personal benefit from research with their health data, which is comparable with therapeutic misconception [35] in clinical trials. The study showed that the proportion of those holding false expectation decreased considerably after the modification of consent information material (12%). To reduce the risk of false expectations, particularly in vulnerable groups such as patients with severe illnesses, careful education about the unlikelihood of direct benefits from making their clinical data available for research purposes is needed.

High Expectations of Other Patients and Physicians

Our results indicate a clear expectation toward fellow patients (696/838, 83.1%) to support medical research with clinical data, which is consistent with a study conducted in Germany among outpatients (80%-90%) [6]. Interestingly, more participants expected their physicians to share clinical data for research (754/838, 89.9%) than to protect their clinical data under all circumstances (570/838, 68%). This is the first study to investigate the expectations toward physicians.

Limitations

The recruited sample is largely representative of the population of patients with cancer in the federal state of Baden-Württemberg in age, gender, and cancer entity. However, we found that the educational level in our sample was higher than that of the corresponding age cohorts of the German population [36]. The educational level of the German population presumably applies to the group of patients with cancer and survivors of cancer. Owing to the topic of the survey, we suspect a self-selection bias correlating with high educational level. According to a study in the context of genetic research and biobanking, high educational level positively correlates with willingness to provide data [24]; consequently, our results may overestimate willingness to provide clinical data. In addition, false expectations of personal benefits from providing data for secondary use may have increased the participants' willingness to share clinical data.

A considerable proportion of participants who had previously agreed to hypothetically make their clinical data available *without restrictions*, favored restricted use of their clinical data when asked about specific requirements such as data user, duration, and data use in other countries (Multimedia Appendix 9). We assume that the participants have not yet formed a strong opinion about sharing their clinical data. Hence, the general willingness to provide clinical data seems to measure an overall attitude toward secondary use, rather than the actual willingness to provide clinical data without restrictions for research purposes.

Conclusions

Our study shows very high general willingness of patients with cancer to make their clinical data available for biomedical research purposes. However, the willingness to provide clinical data may be overstated owing to the above-average educational level of the respondents. For a considerable proportion of patients with cancer, willingness depends on certain requirements. In addition to the basic prerequisite of high level of data security and transparency in the use of the data, most patients shared the view that the data must not be used in countries with low data protection standards and that they should have the possibility to renew consent. In contrast to previous studies, the exclusion of use of data for private sector studies is not a requirement for most participants.

High willingness on the part of patients to accept loss of control over clinical data in favor of research benefits and request to maximize accessibility (and usability) of data for research were found. This is consistent with the acceptance of more research-friendly and low-control models, namely the broad consent model, followed by data use by default (with the option to opt out at any time). The striving for maximizing data use is also reflected by patients' expectations toward physicians and other patients to support secondary use.

Policy makers are well advised to account for patients' views when designing and implementing secondary use, with the aim to contribute to a socially legitimized culture of data sharing.

Acknowledgments

This paper was developed within the framework of the project, *Learning from Clinical Data*, funded by the Deutsche Forschungsgemeinschaft (German Research Foundation)—406103282. The project funding was awarded to ECW. The funders did not engage in the study design; collection, analysis, and interpretation of data; writing of the report; or decision to submit the paper for publication. No additional external funding was received for this study. The authors would like to thank the Cancer Registry of Baden-Württemberg for supporting data collection. The authors also thank their project partners, Kai Cornelius, Markus Spitz (University of Heidelberg, Germany), and Adrian Thorogood (University of Luxemburg), for conceptual counseling. The authors acknowledge Hellen Kachler and Niamh Sulzbach (both from the National Center for Tumor Diseases, Heidelberg University Hospital, Germany) for their assistance in researching the literature, data entry, and linguistic correction of the manuscript. The authors would also like to express their gratitude to Anne Müller, who assisted them in the recruitment of patients for the pretest phase, and to all the patients with cancer and survivors of cancer who participated in the study.

Data Availability

The data sets generated and analyzed in this study are available on the web [37].

Authors' Contributions

All the authors contributed to the conception and design of the study. AK and KM were involved in material preparation and data collection and analysis. ECW and KM supervised the study and supported data interpretation. AK wrote the first draft of the manuscript, and all the authors commented on the previous versions of the manuscript. All the authors read and approved the final manuscript.

Abstract

Background: Understanding how individuals think about a topic, known as the mental model, can significantly improve communication, especially in the medical domain where emotions and implications are high. Neurodevelopmental disorders (NDDs) represent a group of diagnoses, affecting up to 18% of the global population, involving differences in the development of cognitive or social functions. In this study, we focus on 2 NDDs, attention deficit hyperactivity disorder (ADHD) and autism spectrum disorder (ASD), which involve multiple symptoms and interventions requiring interactions between 2 important stakeholders: parents and health professionals. There is a gap in our understanding of differences between mental models for each stakeholder, making communication between stakeholders more difficult than it could be.

Objective: We aim to build knowledge graphs (KGs) from web-based information relevant to each stakeholder as proxies of mental models. These KGs will accelerate the identification of shared and divergent concerns between stakeholders. The developed KGs can help improve knowledge mobilization, communication, and care for individuals with ADHD and ASD.

Methods: We created 2 data sets by collecting the posts from web-based forums and PubMed abstracts related to ADHD and ASD. We utilized the Unified Medical Language System (UMLS) to detect biomedical concepts and applied Positive Pointwise Mutual Information followed by truncated Singular Value Decomposition to obtain corpus-based concept embeddings for each data set. Each data set is represented as a KG using a property graph model. Semantic relatedness between concepts is calculated to rank the relation strength of concepts and stored in the KG as relation weights. UMLS disorder-relevant semantic types are used to provide additional categorical information about each concept's domain.

Results: The developed KGs contain concepts from both data sets, with node sizes representing the co-occurrence frequency of concepts and edge sizes representing relevance between concepts. ADHD- and ASD-related concepts from different semantic types shows diverse areas of concerns and complex needs of the conditions. KG identifies converging and diverging concepts between health professionals literature (PubMed) and parental concerns (web-based forums), which may correspond to the differences between mental models for each stakeholder.

Conclusions: We show for the first time that generating KGs from web-based data can capture the complex needs of families dealing with ADHD or ASD. Moreover, we showed points of convergence between families and health professionals' KGs.

Natural language processing–based KG provides access to a large sample size, which is often a limiting factor for traditional in-person mental model mapping. Our work offers a high throughput access to mental model maps, which could be used for further in-person validation, knowledge mobilization projects, and basis for communication about potential blind spots from stakeholders in interactions about NDDs. Future research will be needed to identify how concepts could interact together differently for each stakeholder.

KEYWORDS

concept map; neurodevelopmental disorder; knowledge graph; text analysis; semantic relatedness; PubMed; forums; mental model

Introduction

Neurodevelopmental disorders (NDDs) are common and represent a group of diagnoses consisting of differences in the development of cognitive, motor, or social skills [1]. Attention deficit hyperactivity disorder (ADHD) is the most common cause of NDDs and affects the ability of children and adults to focus their attention and regulate their motor activity. Another condition is autism spectrum disorder (ASD), which is associated with differences in social interaction, language, and behavior. The prevalence of NDDs is up to 18% worldwide when considering its most common conditions (ADHD) [2,3], while some conditions like ASD will have prevalence closer to 1% [4]. Individuals with ASD and ADHD frequently experience, in addition to their core disorders symptoms, a variety of associated issues, including sleep difficulties, challenging behaviors, and mental health concerns, with repercussions not only on health but also on education and social needs. This creates a level of complexity for parents and a need for large care teams and challenges in communication for health professionals involved with families with NDDs.

Research in medical complexity has shown how communication and care can be improved by establishing each stakeholder's representation of a condition known as the mental model. Mental models are dynamic and are constantly evolving sets of beliefs and knowledge, which dictate parents' and professionals' decisions and behaviors [5,6]. When collaborating with others, having contradictory mental models can lead to conflicting expectations and impede communication [7,8]. Representing mental models visually as a map increases communication and collaboration in education [9] and health care [10]. Mental models have been mapped using various in-person techniques such as cognitive task analysis and concept mapping [11]. Nonetheless, those require trained professionals and access to stakeholders, thereby limiting their scalability.

Knowledge graphs (KGs), as a graph-based information representation format, have been widely applied in artificial intelligence and structural representation of information [12]. KG represents knowledge in a structured way—concepts are nodes connected to each other with edges denoting relationships similar to concept maps. Web-based information has been increasingly used to identify themes of interest to patients. For instance, analysis of web-based information for individuals with cancer has been used to compare patients' and family members' concerns [13], patients' concern and research questionnaires [14], or clinical trial topics [15]. In addition, natural language processing (NLP) techniques have been used to identify and compare the language used to describe different mental health disorders [16]. The word co-occurrence analysis has been used extensively to extract the meanings from text, including health [17], cancer [18], and COVID-19 information, from Twitter [19]. Semantic relatedness tasks play an important role in many NLP applications such as word sense disambiguation [20,21], aspect-based sentiment analysis [22], query expansion [23], and information retrieval from electronic health records [24]. Our study is the first, to our knowledge, to leverage KG building tools to represent mental models from different stakeholders. Moreover, it remains unclear how medical professional literature addresses the topics of most interest to families. Therefore, we propose an approach for comparing ASD-related or ADHD-related concepts that are important and frequently occurring in family forums and in the PubMed literature related to these conditions. Our proposed approach is different from that in the prior mentioned work as it utilizes the vector space model (VSM)–based semantic relatedness technique to construct the KG representation of ASD-related and ADHD-related unified medical language system (UMLS) concepts.

The developed KGs depict concept maps of information from 2 sources: online communities and PubMed abstracts. They help identify concepts with similar and dissimilar relevancy or priority and their frequency of occurrence for the case of both stakeholders. Such a methodology is essential, as obtaining such information directly from stakeholders requires extensive effort involving recruitment and conducting interviews or distributing surveys (with often limited response rate).

Methods

Data Collection

PubMed Abstracts

Search queries "neurodevelopmental disorders [MeSH]," "autism," "autism spectrum disorder [MeSH]," "autistic disorder," "attention deficit and disruptive behavior disorders [MeSH]," "attention deficit disorder with hyperactivity [MeSH]," and "ADHD" were performed in PubMed using Entrez Programming Utilities application programming interface by the National Center for Biotechnology Information. A unique list of 226,660 article identifiers was created, and abstracts were retrieved by making another PubMed application programming interface call, which returned 118,153 nonempty abstracts.

Forum Posts

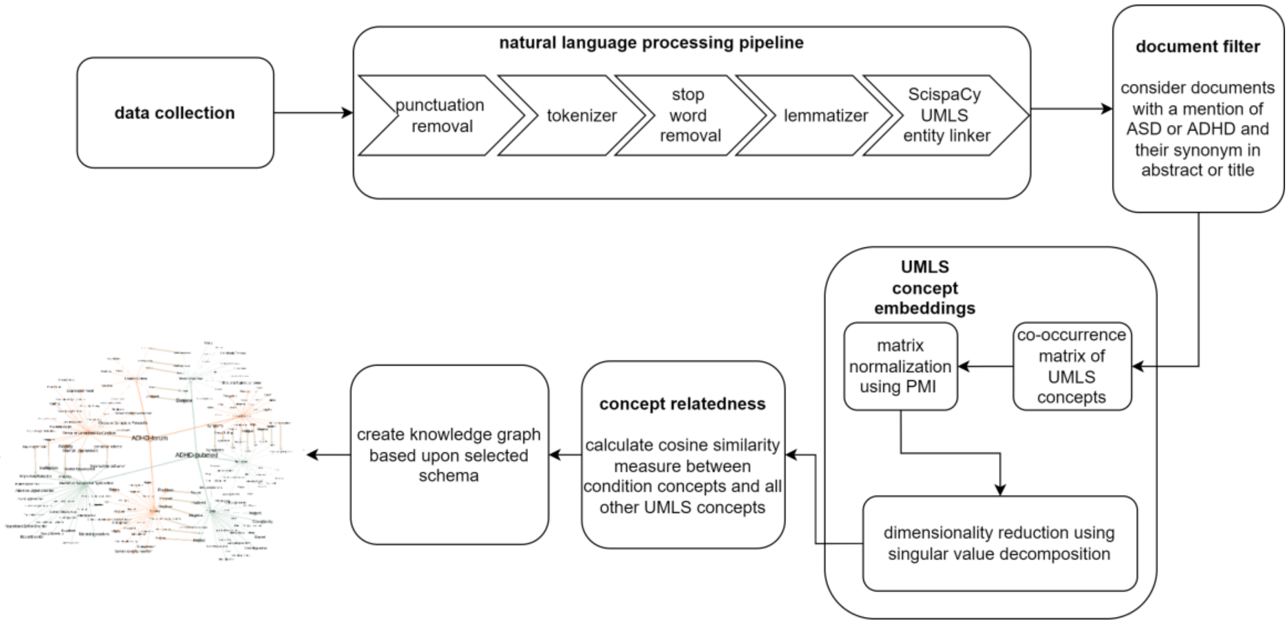
We manually googled publicly available web-based forums or communities and subreddits around the NDD topics to gather social media data and reviewed their privacy policies and terms of use. We selected 3 sources: healthboards.com [25], psychforums.com [26], and reddit [27], for which ethics approval for data collection and analysis was obtained from the University of Alberta. No HTML element containing identifiable personal information such as username was scraped, and only the one containing post was retrieved and stored locally. We did not contact any users for this research. As these online communities are not exclusively focused on NDD topics, we selected subforums about ASD and ADHD such as autism, Asperger syndrome, ADHD, and attention deficit disorder. We found various subreddits around ASD and ADHD, including askAutism, AutismBlogs, TeenAspies, ADD, adhd_anxiety, ADHD, and ParentingADHD. Python Scrapy framework [28] was used to scrape the posts from healthboards.com and psychforums.com, while Reddit application programming interface wrapper [29] was used to collect data from different subreddits. We only considered the main post of the thread and did not collect the list of replies to the thread. We assumed that the main thread consists of the concern posted by the forum user (which was our primary goal in building the KG). We did not include the replies as they would consist of the mention of the same concepts and would falsely boost the frequency of co-occurrence unless the text analysis pipeline has the ability to understand the complete sentence context such as relation extraction task. We did not filter the posts that were posted by parents only; therefore, these could be from any family member, caregiver, a friend of an individual with ASD or ADHD, or an individual with a condition itself.

NLP Pipeline

Data Preprocessing

All PubMed abstracts and forum posts (henceforth referred to as documents) were preprocessed using the Natural Language Toolkit Python library in order to remove punctuation, tokenize sentences into words, remove stop words, and lemmatize the words [30]. This process is illustrated in Figure 1. Stop words refer to the words that are not informative but occur a number of times such as is, am, are, and have. The default list of stop words provided by the Natural Language Toolkit was used as is.

Figure 1. Text processing and knowledge graph generation methodology. Data collection consists of forum scraping using Scrapy, Reddit wrapper application programming interface call, and PubMed application programming interface call. Collected documents are processed through the natural language processing pipeline. The knowledge graph is developed from top 25 concepts related to the condition concepts (autism spectrum disorder or attention deficit hyperactivity disorder) under selected semantic types. ADHD: attention deficit hyperactivity disorder; ASD: autism spectrum disorder; PMI: pointwise mutual information; UMLS: unified medical language system.



UMLS Entity Linker

The UMLS is a collection of over 100 controlled vocabularies, including but not limited to the International Classification of Diseases-10th classification, medical subject headings, and SNOMED Clinical Terms and contains over 4 million concepts [31]. UMLS facilitates biomedical entity detection by combining synonyms from different source vocabularies into canonical terms called concepts. UMLS also classifies all of its concepts into broader categories called semantic types; for instance, the ASD concept is classified as a mental or a behavioral dysfunction and the training programs concept as an educational activity. Semantic types provide the additional categorical information about the concept and are utilized in this project. An existing open-source Python library scispaCy is used to detect the UMLS concepts from documents [32]. The scispaCy UMLS entity linker provides the score for each detected concept, which ranges from 0 to 1. Low-scored terms would have higher chances of false positives, and we set the probability cutoff of 0.7 to reduce the chances of false positives. Therefore, only the concepts with scores greater than 0.7 along with their semantic type were considered in the final annotation.

In total, 124 UMLS semantic types from PubMed and 122 semantic types from the forum were detected, which could be applicable to all subfields of the medical domain. Peng et al [33] found that the precision of the UMLS entity linker tools could be low if the entities are not specific to ASD, and they used 13 semantic types in their analysis. Our preliminary analysis of all the semantic types was performed by comparing the frequencies of occurrence of each semantic type, which were calculated using all detected concepts from the documents corpus in each source. It showed that the most frequent semantic types such as qualitative concept, functional concept, and idea or concept in the database were not related to ASD and ADHD. Multimedia Appendix 1 shows the top frequent semantic types in each source. Considering the absence of established NDD-related semantic types, we prioritized a set of 26 types by reviewing associated concepts in collaboration with the NDD expert. The selected 26 semantic types are "activity," "age group," "behavior," "congenital abnormality," "diagnostic procedure," "daily or recreational activity," "disease or syndrome," "educational activity," "family group," "finding," "health care–related organization," "health care activity," "individual behavior," "injury or poisoning," "mental process," "mental or behavioral dysfunction," "occupational activity," "occupation or discipline," "organization," "patient or disabled group," "professional or occupational group," "professional society," "self-help or relief organization," "social behavior," "sign or symptom," and "therapeutic or preventive procedure." We excluded the frequent semantic types such as qualitative concept, functional concept, and idea or concept from the KG developed for this analysis. However, we are aiming to use those in future works.

If a concept is associated with more than one semantic type, then the scispaCy entity linker returns the list of all semantic types and does not consider the context of the sentences to select the semantic type being discussed. As it returns a list of all semantic types, we considered only the first returned semantic type. Concepts that occur in at least 10 documents in the corpus were considered for further analysis. Thus, we had 4494 unique concepts in PubMed documents and 3627 unique concepts in the forum.

Document Filter

All documents annotated with UMLS concepts passed through a filter that removed documents without mentioning ASD-related and ADHD-related concepts in the text. In UMLS, ASD, Asperger syndrome, and autistic disorder are different concepts; all the documents that mention any of these in either the abstract or the title are considered under ASD. Further, Asperger syndrome and autistic disorder concepts were replaced with ASD. As a result, we obtained a final data set of 55,461 PubMed abstracts in which 37,728 mentioned ASD, 20,805 mentioned ADHD, and 3072 mentioned both conditions. For the forum, the final data set contained 153,098 posts, in which 72,669 posts were about ASD, 90,372 were about ADHD, and 9943 had statements related to both conditions. Table 1 lists the number of posts collected from 3 web-based forums.

Table 1. Number of documents collected from different data sources.

Source	Autism spectrum disorder documents	Attention deficit hyperactivity disorder documents	Both autism spectrum disorder and attention deficit hyperactivity disorder documents
Reddit	66,552	87,022	9302
Psych forums	5029	1966	395
Health boards	1088	1384	246
Total documents from the 3 forums	72,669	90,372	9943
PubMed	37,728	20,805	3072

UMLS Concept Embeddings

Corpus-based numerical representation of concepts in the VSM represents the meaning of a concept based upon its context. It assumes that concepts that occur together in an environment (either document level, sentence level, or a neighborhood window of a particular size) would be related or similar to each other. The size of the context frames affects the representation of the concepts in the VSM, and many of the word embedding models such as the Skip-gram model and Continuous-bag-of-words model use window-context–based approaches called a local context. Document-level co-occurrence, referred to as a global context, provides more topical information around the concept, as many topic modeling approaches use the global context to detect the latent topics from a document [34]. As we want to detect topically most related concepts to ASD and ADHD, a global context-based co-occurrence matrix of size n × n is created where n refers to the total number of unique UMLS concepts in a source. The co-occurrence matrix is computed separately for PubMed and forum, as contextual information around a concept could be different depending upon the text corpus, which will eventually affect the relatedness scores.

Positive Pointwise Mutual information

Positive pointwise mutual information (PPMI) followed by truncated singular value decomposition (SVD) is used to embed the concepts, which provide comparative performance to neural network–based embedding models such as Word2Vec [35]. SVD PPMI usually produces consistent/stable results, where stability refers to the change in a word's neighborhood in the VSM, whereas neural network–based approaches (Word2vec, Glove) could lead to different results in different runs, as the weight of the hidden layers representing the word embeddings differs in multiple runs. SVD-based embeddings are not affected by this problem [36,37]. Pointwise mutual information (PMI) is a probabilistic approach to quantify the likelihood of co-occurrence and tells whether the co-occurrence is informative or by chance. It is defined as follows:

$$\text{PMI}(c_i, c_j) = \log [p(c_i, c_j) / (p(c_i) \times p(c_j))] \quad \textbf{(1)}$$

where c_i = i^{th} concept or the row

c_j = j^{th} context concept or the column

$p(c_i)$ = marginal probability of c_i

$p(c_j)$ = marginal probability of c_j

$p(c_i, c_j)$ = marginal probability of c_i and c_j

PMI varies from –1 to 1. If PMI is 0, co-occurrence of 2 concepts does not provide any information and is just by chance. When the joint probability is much higher than marginal probabilities, the co-occurrence is not by chance. If PMI is less than 0, then the independent occurrences of the concepts c_i and c_j are more informative as compared to co-occurrence. PPMI sets the PMI to 0 if it is less than 0.

$$\text{PPMI}(c_i, c_j) = \max(\text{PMI}(c_i, c_j), 0) \quad \textbf{(2)}$$

PPMI provides a square matrix M of size n × n. For the PubMed, n=4494 and for the forum, n=3627, which leads to high dimensionality of the VSM.

Truncated SVD

SVD is a dimensionality reduction technique used to obtain a low-rank approximation of a dense matrix M. SVD factorizes the matrix M as a product of 3 matrices:

$$M = USV^T \textbf{(3)}$$

where U and V are orthogonal matrices of size $n \times n$ and S is a $n \times n$ diagonal matrix with diagonal values sorted from high to low. The rank k (k<n) approximation of matrix M can be obtained from equation (3) as follows:

$$M_k = U_k S_k V_k^T \textbf{(4)}$$

Where U_k is a $n \times k$ matrix, S_k is a $k \times k$ diagonal matrix and V_k^T is a $k \times n$ matrix. U_kS_k is the matrix of size $n \times k$, which represents the n concepts in k dimensions. We set k=300 and used Python scikit-learn library to implement truncated SVD and obtain the 300D concept embedding [38]. Different low embedding sizes (usually 300-500) are shown to be used without specific mention of its effect on the final results and 300 dimensions of one of the commonly used sizes [39-41]. PPMI followed by SVD, once applied on forum and PubMed corpus separately, provides 2 VSMs, which represent the concepts depending upon their contextual information in each source.

Concept Relatedness

Semantic relatedness approaches detect the most related concepts for a given concept based upon the context in which it is used. Semantic similarity and relatedness tasks appear the same, but similarity refers to the concepts that are synonymous and can be used interchangeably, and relatedness refers to concepts that are related because of their usage in the same context. For example, ASD and aggressive behavior are related but not similar. The concept relatedness between 2 concepts c_i and c_j is measured using cosine similarity as the normalized dot product of the context vectors C_i and C_j:

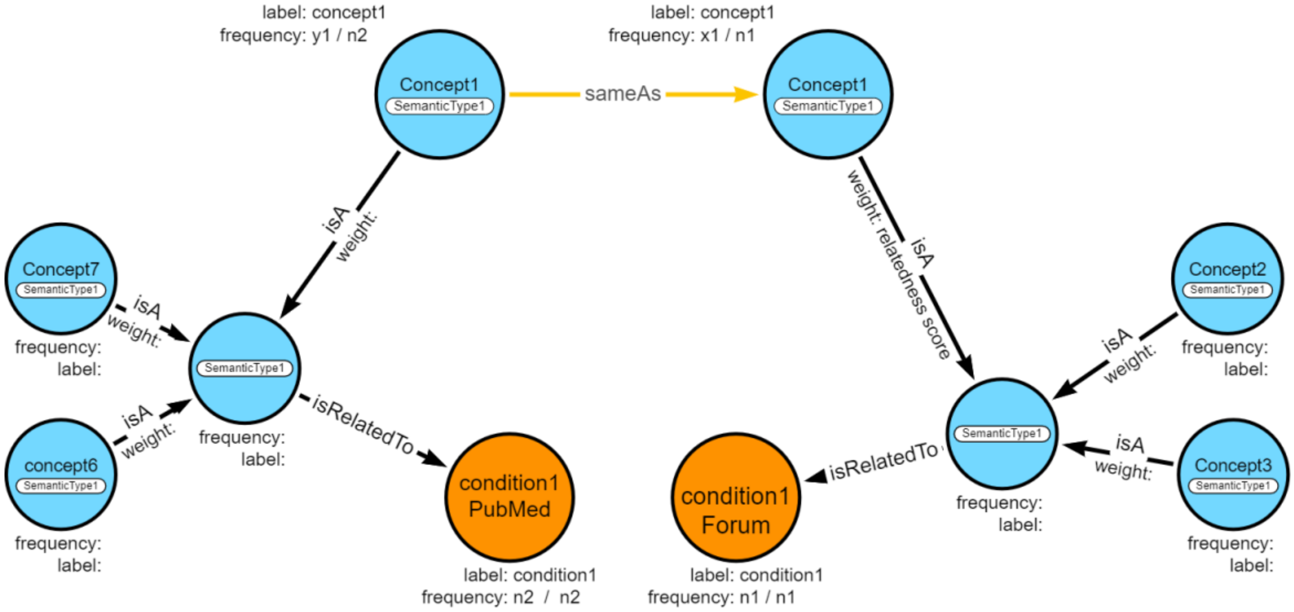
$$\text{relatedness}_{ij} = \text{cosineSim}(C_i, C_j) = C_i \cdot C_j \, / \, \| C_i \| \, \| C_j \|$$

relatedness_{ij} varies from (–1,1), where a value close to 1 means c_i and c_j are closely related to each other and both vectors have the same orientation in the VSM; a value close to 0 means c_i and c_j are dissimilar and both vectors are orthogonal in the VSM; and relatedness_{ij} of –1 indicates that c_i and c_j are in the opposite direction in multidimensional space.

KG Representation

The property graph schema, Figure 2, represents concepts associated with different UMLS semantic terms. There are nodes representing the condition (ASD or ADHD), related UMLS semantic types, and related concepts. Based upon relatedness scores between the condition and the concepts, the top 25 related concepts associated with each UMLS semantic type are used for creating the graph. An edge “isRelatedTo” links a semantic type node to a condition node, and each related concept is connected to its semantic type using the “isA” relationship. A set of property value pairs are stored on nodes as well as edges. All nodes have a label, which refers to the concept name, and the frequency, which is the proportion of documents in which a given concept co-occurred with the condition (ASD or ADHD), in each source data set. The frequency of a semantic type node refers to the average frequency of its top 25 concepts. The weight of the “isA” relationship indicates the relatedness score between the concept and the condition in a source data set, and no weight is assigned to “sameAs” and “isRelatedTo” relations. The Neo4j graph database is used to store the constructed KG [42].

Figure 2. Knowledge graph schema. The co-occurrence frequency of the concept (blue circle) and the condition (orange circle) is stored as the frequency of concept. The relatedness score of the concept to the condition is stored as the weight of isA relationship between the concept and the semantic type (also blue circle). The direction of the sameAs relationship can be either way.



Results

Diverse Areas of Concerns Around ADHD and ASD

The developed KG representation of PubMed and forums depict the mental models of both the stakeholders. We found a number of UMLS concepts associated with different semantic types in ADHD-related and ASD-related PubMed and forum data sets. All the detected concepts along with their semantic relatedness score are listed in Multimedia Appendix 2. In order to analyze the different areas of concerns, we assessed health care (PubMed abstracts) and family (forum posts) concepts associated with ADHD by visualizing the KGs from PubMed abstracts and family forums by using the Gephi network visualization tool [43]. In the KG visualizations, the thickness and color darkness of the relationship is proportional to cosine-based relatedness score of the concept to the condition (ADHD or ASD), and the size of the node/label is proportional to the co-occurrence frequency. We detected a few insignificant concepts in some of the semantic type groups. These concepts were then checked against the original text in the PubMed and forum documents, which showed that these concepts were false positives and therefore were removed from all of the analyses. Multimedia Appendix 3 shows the removed concepts along with the frequency of words linked to these concepts. Table 2 summarizes some of the most relevant terms for PubMed and forum documents on ADHD under different UMLS semantic types, which shows the different areas of concern for ADHD.

ADHD KGs generated from PubMed abstracts (see Multimedia Appendix 4) and forums (see Multimedia Appendix 5) show other areas of concerns such as “diagnostic procedure,” “individual behavior,” “health care activity,” and “professional or occupational group.” Similar to ADHD, ASD was found to be linked to diverse concepts in different domains represented by UMLS semantic types as shown in Table 3.

The KG representation of ASD PubMed abstracts (see Multimedia Appendix 6) and forums (see Multimedia Appendix 7) shows concepts under other semantic types, indicating other areas of concerns around ASD.

Table 2. Attention deficit hyperactivity disorder–related concepts in PubMed and forums for specific unified medical language system semantic types.

Unified medical language system semantic type	PubMed	Forum
Mental or behavioral dysfunction	• Inattention • Impulsive behavior • Hyperactive behavior • Attention deficit disorder • Substance abuse problem • Conduct disorder	• Executive dysfunction • Psychiatric problem • Anxiety • Hyperactive behavior • Inattention • Mental depression
Age group	• Adolescent • Adult • Young adult	• Adult • Adolescent • Child
Daily or recreational activity	• Sports • Youth sports • Recreational activity	• Reading activity • Speaking activity • Exercise
Educational activity	• Psychoeducation • Training programs • Socialization	• Homework • Home schooling • Training programs
Social behavior	• Parenting behavior • Social skills • Parent-child relationship	• Lifestyle • Conversation • Social behavior

Table 3. Autism spectrum disorder–related concepts in PubMed and forums under specific unified medical language system semantic types.

Unified medical language system semantic type	PubMed	Forum
Mental or behavioral dysfunction	• Developmental disabilities • Social communication disorder • Schizophrenia • Mental retardation	• Bullying • Aphasia • Social anxiety • Stereotypic movement disorder
Age group	• Child • Adult • Infant	• Child • Adult • Adolescent
Social behavior	• Communication • Social skills • Social cognition	• Social skills • Social situation • Eye contact
Mental process	• Perception • Cognition	• Stereotyping • Intelligence
Daily or recreational activity	• Physical activity • Youth sports • Speaking and reading activity	• Sports • Game • Speaking and reading activity
Educational activity	• Socialization • Training programs • Computer-assisted instruction • Special education • Parent training	• Socialization • Training programs • Special education • Toilet training • Home schooling

Comparing PubMed and Forum KG

KG helps identify concepts of similar and different relevance/priority between families and health professionals. Knowing that shared understanding (shared mental model) has been shown as a key factor in effective collaboration and quality communication in health care [44], we aimed at identifying potential concepts of similar and different relevance between forums and medical literature. For comparing concepts, we considered the top 25 concepts under selected UMLS semantic types, which were the most related to each condition (ASD and ADHD) based upon the relatedness scores, and visualized them using Gephi. As shown in Figure 3, KGs—one for PubMed and one for forum—are connected via the concepts that are of concern for both health professionals and online communities using "*sameAs*" relationship (orange arrow). The direction of this relationship can be either way. For the *“isA”* relationship (purple arrow), its thickness refers to the relatedness score of the concept to the condition (ADHD), which indicates the level of relevance or priority. Different node sizes of concepts connected with *“sameAs”* relationships show differences between the frequency of the concept in respective sources, such as mental depression and anxiety being more commonly discussed in ADHD forums as compared to ADHD PubMed abstracts, while hyperactive behavior, inattention, and impulsive behavior are more discussed in PubMed comparatively.

To summarize the concepts of similar and dissimilar relevance/priority, we compared the relatedness score of all the concepts in forum (FR) and PubMed (PR) and computed the score difference (score difference = FR – PR). The concept is of similar priority if its relatedness score is similar to both stakeholders and score difference of the concept is within $\mu \pm 2\sigma$, where μ is mean and σ is standard deviation of score difference. If score difference $> \mu + 2\sigma$, then the concept is more relevant for families (forum) and considered as a priority for them because of the substantial score difference. If score difference $< \mu - 2\sigma$, then the concept is considered as more relevant or as a priority for health professionals (PubMed). Interestingly, as shown in Table 4, we found several concepts of similar and dissimilar relevance to ADHD between PubMed and forum (see Multimedia Appendix 8 for KG visualization). The detailed relevance scores of all these concepts can be found in Tables S1-S3 in Multimedia Appendix 9.

Similarly, comparing the ASD-related concepts in both sources using relatedness score difference and KG representation provided various concepts of similar and dissimilar relevance, as shown in Table 5 (Multimedia Appendix 10 for KG visualization). Detailed relevance scores for all these concepts are listed in Tables S4-S6 in Multimedia Appendix 9.

Figure 3. Knowledge graph representation of forums and PubMed around attention deficit hyperactivity disorder for mental or behavioral dysfunction semantic type (green arrow). Concept label font size is proportional to the frequency of the concept in the source. The “sameAs” relationship (orange arrow) connects the overlapping concepts. The thickness of the edge “isA” (purple arrow) refers to the relatedness score of the concept to the condition (attention deficit hyperactivity disorder). ADHD: attention deficit hyperactivity disorder.

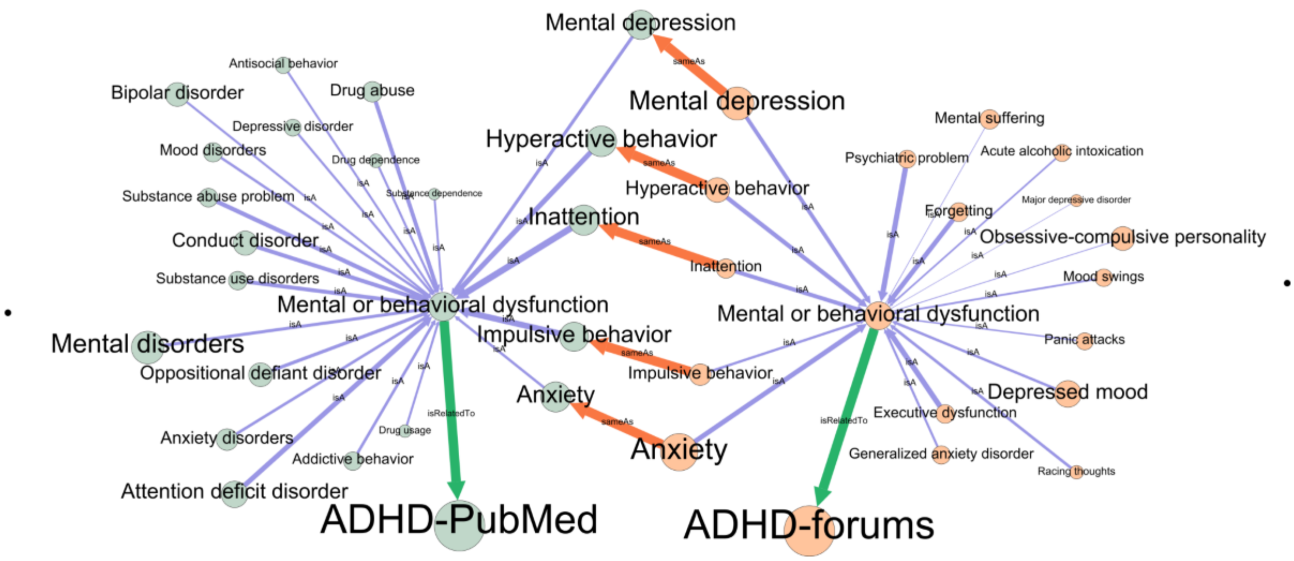


Table 4. Converging and diverging priority level for concepts in attention deficit hyperactivity disorders in PubMed and forum data.

	List of concepts
Concepts with similar relevance for both attention deficit hyperactivity disorder sources	• Impulsive behavior • Inattention • Anxiety • Mental depression • Hyperactive behavior • Sleeplessness • Emotional regulation • Attention • Training programs • Socialization
Concepts with high relevance to attention deficit hyperactivity disorder forums	• Executive dysfunction • Forgetting • Racing thoughts • Psychiatric problem • Nervousness • Exhaustion • Oversleep • Sluggishness • Study habits • Procrastination
Concepts with high relevance to attention deficit hyperactivity disorder in PubMed	• Substance abuse problem • Substance dependence • Conduct disorder • Antisocial behavior • Addictive behavior • Sleep phase delay • Amotivation • Anxiety symptoms • Oppositional behavior • Regulation of behavior

Table 5. Converging and diverging priority levels for concepts in autism spectrum disorder in PubMed and forum data sets.

	List of concepts
Concepts with similar relevance for both autism spectrum disorder sources	• Social communication disorder • Developmental disabilities • Aphasia • Autistic behavior • Intellectual disability • Mental disorders • Pervasive development disorder • Cerebral palsy • Seizures • Repetitive behavior • Social interaction • Nonverbal • Communication • Social behavior • Eye contact • Social skills • Aggressive behavior • Self-injurious behavior • Stereotyped behavior • Behavioral tic
Concepts with high relevance to autism spectrum disorder forums	• Bullying • Obsessions • Social phobia • Social anxiety • Temper tantrum • Mutism • Nervousness • Social problems • Introvert • Social life • Crowding
Concepts with high relevance to autism spectrum disorder in PubMed	• Immune dysregulation • Social cognition • Behavior adaptive

Discussion

Principal Findings

Understanding the needs and concerns of patients and their families is recently being recognized as a key factor for better communication between health professionals and families. This has led to emerging research into the role of mental models in medical practice [45-48] and their mapping [49]. Current approaches include interviews with patients, families, or experts and the identification of main concepts. Crandall et al [6] identified cognitive task analysis as one approach to building mental models. These rich interviews take place over a period of 60-90 minutes with approximately 10 participants. Although the information is rich and in depth, the process is both time-consuming and limited in participant numbers and diversity potentially.

From a theoretical perspective, our work shows how KG building techniques and NLP could help create mental models by using large-scale data sets and avoid bottlenecks such as limited access to experts and privacy/availability for families. Although the NLP methods used are well-established, the use of NLP to generate KGs to derive mental models and to compare them between families and health care professionals' perspective is completely novel to our knowledge. We show that web-based data from forums capture the diversity of concerns of parents of individuals with 2 important NDDs: ASD and ADHD. Publicly available web-based data could reflect the data obtained from more traditional approaches such as consultations or surveys as published in the literature. We show how using web-based data allows us to identify information about not only diagnostic criteria, medication, symptoms, or comorbidities of a condition but also other areas of concerns such as educational activities, recreational activities, and social issues around a condition, which were usually thought to be accessible mostly by interviews. We also show that the topics are not only related to controversies or unproven therapies, which has often been the rationale for not using web-based information in the medical domain. Similarly, interviews with medical experts are often a bottleneck in understanding concerns in the medical domain.

We also illustrate how web-based data can be used to identify points of convergence in priorities between the different stakeholders involved in complex medical conditions such as ADHD and ASD. Identification of converging points, that is, concepts of similar interest to health professionals and families could help clinicians and extension policy makers to identify "conversation starters" or shared interest. Identifying the diverging concepts or even blind spots for each stakeholder plays an important role for both clinicians and families. For instance, concepts that are highly relevant to families could be used by clinicians to frame continual medication education or training enhancement. For families, they could be the focus of knowledge mobilization, public education campaigns, or further studies aimed at enhancing literacy about their disorder and related conditions.

From a practical point of view, we present a framework that allows us to identify and rank relevant concepts for different sources by using corpus-based embeddings and semantic relatedness approaches as compared to simple co-occurrence frequency to rank related concepts. Developing a KG of the related concepts to represent the mental model visualizations could further assist in comparing converging and diverging concepts between both sources. To our knowledge, as there is no gold standard data set to evaluate the relatedness of concepts in NDDs, our framework proposes to use graph analysis tools such as Gephi to analyze and explore the KG visualizations manually, which could help validate the results by experts. Involving experts (expert in the middle) to review results of NLP approaches facilitates detection of incorrect concepts, which are the result of wrong mapping of abbreviations to concepts. Together, our research provides a proof-of-principle that will generate awareness about KGs as mental model maps and be of use to multidisciplinary researchers in a wide range of medical domains.

Comparison of KG-Based and Traditional Sources of Information

We compared our findings with previous literature or reports, which are the result of studies using traditional approaches such as interviews or surveys and involving participants (parents or health professionals) from the ASD and ADHD community. For ADHD, for instance, we found that priorities for individuals using the forum (parents, friends, caregivers) were related to prescription of medication and physician types. This reflected what has been discussed in the literature where participating parents were concerned about medication and nonpharmacological interventions (preferred behavior interventions) [50,51]. Another aspect of the topic of health professionals is around the source of information, which was noted previously as a major source of knowledge along with the internet [52]. Focus groups–based study, with caregivers included, showed that the major concern for the parents is about their child becoming a successful adult and improving school behavior [53,54] as well as improving their social situation and emotional state [55], which were identified as a priority before. We found the "behavioral habits" concept with relevancy score of 0.51 as the second most related to ADHD forums in UMLS semantic type "individual behavior." However, our current approach is based upon UMLS concept recognition and lacks the ability to understand the location as well as age context from the sentences that whether the "behavioral habits" is being discussed for school or home and child or teen. The NLP forum analysis also did not pick on an important trend for parents (and health professionals) to use multimodal interventions [56]. Similarly, our analysis of PubMed papers on ADHD identified topics previously identified by health experts as priorities. We found that the highest ranking topics were discussion of core symptoms of ADHD as well as comorbidities, conduct disorders, and substance use. This mirrors the health experts' consensus reports highlighting the importance of treatment efficacy for symptoms and raising the point of emotional aspects, academic performance, and work performance [57] as well as comorbidities such as mental illness and substance abuse [58-60]. Overall, we found that the perspectives in family ADHD forums and PubMed papers ranked at similar priority to the core symptoms of ADHD, comorbid conditions such as anxiety and depression, and the educational concerns of training programs and socialization.

With regard to ASD, our other NDD use case in this study, we found that the most overlapping topics had a similar priority level for the different stakeholders reflected by PubMed abstracts and ASD forums. These topics included classification of the condition, symptoms and behaviors that accompany ASD, and topics related to social interaction. Indeed, we found that priorities for people using ASD forums included concerns about social interaction such as social skills, communication, and friendship, as well as daily activities like speaking. This is similar to the findings of a survey distributed by Lai and Weiss [61] investigating service needs for ASD, which found that caregivers prioritized social skills and life-skills programs. Another study also found that the parents' main concern was social interaction [62], but that study found that the next most prevalent concerns were problem behavior and academics, which we did not see in our analysis of forums. A Serbian study similarly supported communication, social interaction, and daily activities as being caregiver priorities [63]. In addition, our analysis of PubMed abstracts revealed frequent discussion of classification of ASD and its relation to fetal alcohol spectrum and NDDs, concerns about social interaction and communication, and a focus on children with ASD. These priorities are supported by physicians' approach to ASD, which takes advantage of a diverse team of professionals to focus on improving social interaction and communication [64,65]. This is not to say that parents and research priorities are always aligned as shown in a recent survey in the United Kingdom, illustrating how research tends to be focused on biomedical aspects rather than services and supports [66].

We show that the KG derived from PubMed papers recapitulated the findings of position papers on the topic of ADHD and ASD as mentioned above. However, some of the differences in our findings and the participant-based study results could result from the differences in sample sizes or selection bias (age of caregivers and thus, children could be younger than school or adulthood ages). The collected web-based forum data are considerably larger than the number of participants in interview-based studies and therefore could include points of views not identified before. Alternatively, we could speculate that families may be more inclined to share personal concerns online than in an interview, although we did not find published studies looking into this topic. Further, we have included all the PubMed papers and web-based forums regardless of their publication or posting time (PubMed may include older concepts, which are no longer contemporary concerns), as opposed to the abovementioned expert opinions that were from the last 5 years or less.

Advantages of Our Approach

Although representing priorities and conceptions of individuals involved in a relation has already been shown to be beneficial to communication and efficacy, using web-based data offers the ability to include a larger number of individuals as shown here from the forum. This would allow for better coverage of the diverse opinion and reflect differences in experience. We also found that forum posts and PubMed papers presented with equivalent density of coverage for all domains examined, suggesting that they present a richness in perspectives and not only trends for instance. Moreover, in the future, our approach could be used to compare concerns of individuals in different countries, in city versus rural settings, or for newcomers to a country, for example. Obtaining the related concepts from the corpus-based VSM and representing those as connected nodes in a property graph model–based KG helps identify convergent and divergent concepts by using different dimensions of interpretability. Node size, which is the frequency of concepts in documents about a condition, tells how widely the concept is discussed in a source. Edge thickness, which is proportional to semantic relatedness score, tells how related a concept is to the condition (ASD or ADHD) depending upon the context in which it is used. This is important as it can help focus attention for knowledge translation and medical education and policy and research development.

Limitations of Our Approach

Some of the limitations relate to the nature of the data used to construct the graph. Forum posts present some challenges. The forums do not precisely define if the users are parents, caregivers, or potentially family members of individuals with ASD and ADHD. This may influence the type of information requested. In addition, the users are by definition selected on the basis of them using technology to gather information. This could represent a bias based on access to technology, which would be influenced by social determinants of health and therefore could have an incomplete representation of the concerns of parents. In addition, owing to concerns about confidentiality, parents may not share all the concerns they have about their family member with ADHD or ASD. Another important point is that health care is represented by PubMed literature here. Although it is true that PubMed represents a high-quality corpus of medical literature, it may not reflect completely what would be discussed by health care providers, say using web-based forums if they were present. In addition, from a technical standpoint, our proposed semantic relatedness–based KG representation utilizes only the categorical information about the UMLS concepts, which is indicated by the "isA" relationship in KG. However, UMLS provides a semantic network, which shows several meaningful relationships between different semantic types in the form of triples, that is, type1, relation, type2, etc: for instance, ("Mental or Behavioral Dysfunction," "associated_with," "Daily or Recreational Activity") and ("Disease or Syndrome," "co-occurs_with," "Mental or behavioral dysfunction"). Utilizing this information could provide more meaningful and direct relations between the concepts of different semantic types. We aim to apply the distantly supervised relation extraction approach on each document corpus, which utilizes the UMLS semantic network to obtain diverse relations between different concepts [67,68]. The output of this approach can also be used as training data for deep learning algorithms to train relation extraction models, which would allow us to create KG by processing text corpus not only for the NDD domain but also for any other condition.

Conclusion

Our study shows the benefits of using KGs developed based on the results of NLP analysis of a text. The graphs representing the mental models of key concerns from parents of individuals with ASD and ADHD are compared to those built on medical expert knowledge in the same field. The comparison allows identifying points of overlapping and diverging interest. We showed that there are several points of convergence and an extensive list of concerns in both types of stakeholders. This is important, as obtaining such information directly from stakeholders requires extensive effort for recruitment and conducting of interviews or distribution of surveys (with often limited response rate). Furthermore, we found that published reports of polling or interviews with ADHD or ASD families or medical experts identified similar concerns to what we identified through NLP and the comparison of graphs. Future field work would complement our work, which could help understand how different concepts present with complex interactions or how specific populations may differ from one another based on different factors such as social determinants of health.

Acknowledgments

We would like to thank Dr Osmar Zaiane and colleagues at the University of Alberta for helpful discussions. This work is funded by the Canadian Institute of Health Research and Natural Science and Engineering Research Council operating grant to FVB. PubMed data are collected by courtesy of the US National Library of Medicine and are shared in Multimedia Appendix 11 under National Center for Biotechnology Information's terms and conditions [69]. This data set will not reflect the most current/accurate data available from the National Library of Medicine in future.

Authors' Contributions

FVB conceptualized the project. MZR and MK designed the methodology. MK implemented the text analysis pipeline and contributed to the analysis of the results. FVB and EW analyzed the results. MK, EW, JC, KK, MZR, and FVB wrote the manuscript. FVB and MZR supervised the project.

Abstract

Background: During the COVID-19 pandemic, there have been increased reports of racial biases against Asian American and Native Hawaiian and Pacific Islander individuals. However, the extent to which different Asian American and Native Hawaiian and Pacific Islander groups perceive and experience (firsthand or as a witness to such experiences) how COVID-19 has negatively affected people of their race has not received much attention.

Objective: This study used data from the COVID-19 Effects on the Mental and Physical Health of Asian Americans and Pacific Islanders Survey Study (COMPASS), a nationwide, multilingual survey, to empirically examine COVID-19–related racial bias beliefs among Asian American and Native Hawaiian and Pacific Islander individuals and the factors associated with these beliefs.

Methods: COMPASS participants were Asian American and Native Hawaiian and Pacific Islander adults who were able to speak English, Chinese (Cantonese or Mandarin), Korean, Samoan, or Vietnamese and who resided in the United States during the time of the survey (October 2020 to May 2021). Participants completed the survey on the web, via phone, or in person. The Coronavirus Racial Bias Scale (CRBS) was used to assess COVID-19–related racial bias beliefs toward Asian American and Native Hawaiian and Pacific Islander individuals. Participants were asked to rate the degree to which they agreed with 9 statements on a 5-point Likert scale (ie, *1=strongly disagree* to *5=strongly agree*). Multivariable linear regression was used to examine the associations between demographic, health, and COVID-19–related characteristics and perceived racial bias.

Results: A total of 5068 participants completed the survey (mean age 45.4, SD 16.4 years; range 18-97 years). Overall, 73.97% (3749/5068) agreed or strongly agreed with ≥1 COVID-19–related racial bias belief in the past 6 months (during the COVID-19 pandemic). Across the 9 racial bias beliefs, participants scored an average of 2.59 (SD 0.96, range 1-5). Adjusted analyses revealed that compared with Asian Indians, those who were ethnic Chinese, Filipino, Hmong, Japanese, Korean, Vietnamese, and other or multicultural had significantly higher mean CRBS scores, whereas no significant differences were found among Native Hawaiian and Pacific Islander individuals. Nonheterosexual participants had statistically significant and higher mean CRBS scores than heterosexual participants. Compared with participants aged ≥60 years, those who were younger (aged <30, 30-39, 40-49, and 50-59 years) had significantly higher mean CRBS scores. US-born participants had significantly higher mean CRBS scores than foreign-born participants, whereas those with limited English proficiency (relative to those reporting no limitation) had lower mean CRBS scores.

Conclusions: Many COMPASS participants reported racial bias beliefs because of the COVID-19 pandemic. Relevant sociodemographic contexts and pre-existing and COVID-19–specific factors across individual, community, and society levels were associated with the perceived racial bias of *being Asian* during the pandemic. The findings underscore the importance of addressing the burden of racial bias on Asian American and Native Hawaiian and Pacific Islander communities among other COVID-19–related sequelae.

Introduction

Background

Over the past 2 years, Asian American individuals have been facing a dual pandemic—COVID-19, as well as increased experiences and fear of racial bias, discrimination, and hate. This has been fueled by racist rhetoric (eg, linking the COVID-19 pandemic with China) rather than a neutral framing of the virus in public health messaging as part of the pandemic response [1,2]. A recent review highlighted the increased anxiety associated with being Asian American during the COVID-19 pandemic among Asian American individuals overall and individuals of Chinese or East Asian descent in particular [3].

Although it is not new, reports of discrimination and hate incidents have been on the rise since the start of the pandemic. An April 2020 survey of 1001 adults found that 32% reported witnessing someone blaming Asians for the COVID-19 pandemic, whereas 60% of the Asian respondents had witnessed the same [4]. In a later public poll, Asian American respondents were most likely (than White, Hispanic, and Black adults) to report that they had experienced people acting as if they were uncomfortable around them (39%), been subject to slurs or jokes (31%), and feared that someone might threaten or physically attack them (26%) because of their race since the COVID-19 outbreak [5]. According to Stop AAPI Hate, >10,000 reports of anti-Asian hate incidents were reported on this site between March 2020 and September 2021 [6]. Compared with reports of anti-Asian hate incidents made in 2020, of the total number of hate incidents, physical assaults rose from 10.8% to 16.6%, and web-based hate incidents increased from 6.1% to 10.6% in 2021; furthermore, these hate incidents occurred more often in public streets, schools, and places of worship [6]. Few studies collected data on discrimination experiences or incidents broken down by Asian American and Native Hawaiian and Pacific Islander ethnic groups. A large survey (N=4971) of Asian American and Pacific Islander participants found that 60.7% experienced discrimination during the COVID-19 pandemic, and reports of these experiences were particularly high for Hmong (80%), ethnic Chinese (64.7%), Korean (64.2%), Filipino (61.3%), Japanese (57.7%), Vietnamese (55.7%), Asian Indian (41.5%), and Native Hawaiian and Pacific Islander (40.5%) participants [7]. In another survey of >2400 Asian American and Pacific Islander women during January and February of 2022, Native Hawaiian and Pacific Islander women reported the highest percentage (80%) of reporting racism or discrimination incidents or harassment, followed by similar levels reported by East Asian (72%), South Asian (73%), and Southeast Asian (75%) women [8].

There has been substantial coverage of anti-Asian incidents and hate crimes via popular news media, reports from Stop AAPI Hate, and findings from multiple surveys [4,5,8,9]. However, there is limited understanding of the extent to which Asian American and Native Hawaiian and Pacific Islander individuals' perceptions and experiences (firsthand or as a witness) relate to how COVID-19 has negatively affected people of their race, particularly about perceived racial bias sentiments by diverse Asian American and Native Hawaiian and Pacific Islander populations. Racial bias is defined as a personal or unreasonable belief or judgment of a person based on their race and is rooted in stereotypes and prejudices [10]. Prior research has shown a multitude of impacts of racial bias on one's lived experiences in the form of legal decisions regarding disparities in education and economic opportunities [11], as well as health care and health status [12,13].

Objectives

Social determinants of health and contextual models suggest that race and ethnicity, socioeconomic status, and social environment are important factors related to experiences of discrimination and racial bias [14,15]. Research on discrimination and Asian American individuals has shown that perceived discrimination varies by age, gender, and other demographic characteristics [7,16,17]. Drawing on these frameworks and previous research, we used data from the COVID-19 Effects on the Mental and Physical Health of Asian Americans and Pacific Islanders Survey Study (COMPASS), a nationwide, multilingual, community-based survey conducted in the United States to empirically examine racial bias beliefs on Asian American and Native Hawaiian and Pacific Islander individuals, as related to the COVID-19 pandemic, and a cross-sectional analysis of the factors associated with these beliefs. Uniquely, we also examined COVID-19–related racial bias beliefs in different Asian American and Native Hawaiian and Pacific Islander ethnic subgroups. Data disaggregation is important and pivotal for identifying the distinct challenges and needs of diverse Asian American and Native Hawaiian and Pacific Islander communities.

Methods

Data Source

Between October 2020 and February 2021, a total of 5218 Asian American and Native Hawaiian and Pacific Islander adults completed the COMPASS survey. COMPASS is a multilingual community-based nationwide survey that assesses the effects of COVID-19 on Asian Americans and Native Hawaiian and Pacific Islanders. The eligibility criteria for participating in the COMPASS included (1) self-identifying as Asian American or Native Hawaiian and Pacific Islander alone or in combination with other races and ethnicities; (2) being aged at least 18 years; (3) residing in the United States; and (4) able to speak or read English, Chinese (traditional or simplified), Korean, Samoan, or Vietnamese. These languages were selected as they represent some of the commonly spoken languages among Asian American and Pacific Islander individuals with limited English proficiency (LEP) [18], and this was the language capacity supported by the parent award for COMPASS at the time of the study [19]. Participants completed the survey on the web via the study's website [19], via phone, or in person in the abovementioned languages. We used the World Health Organization's process of translating and adapting instruments [20] to guide translations of study materials not readily available in the targeted Asian American and Native Hawaiian and Pacific Islander languages. REDCap (Research Electronic Data Capture; Vanderbilt University) [21,22] was used to capture and store data securely.

Participants could have heard about COMPASS through community partners who serve Asian American and Native Hawaiian and Pacific Islander individuals, personal or professional networks, social media, emails or listservs, flyers, and ethnic media. COMPASS also recruited from the Collaborative Approach for Asian Americans and Pacific Islanders Research and Education (CARE) registry [19], which is the first and only research recruitment registry that purposively engages Asian American and Native Hawaiian and Pacific Islander participants in multiple languages via strong community partnerships. Of the 2600 CARE registry participants who received an email invitation to participate in COMPASS, 526 (20.23%) completed the COMPASS survey. Approximately 86.64% (4521/5218) of participants completed the survey by themselves, and 11.33% (591/5218) of participants received help from family, friends, or research staff. The participants had the option to receive a US $10 electronic gift card upon survey completion. All participants provided informed consent for inclusion before participating in the study.

Measures

Overview

The measurement framework for this study was guided by the previously discussed literature on social determinants of health and contextual models suggesting that sociodemographic contexts and social environments are important factors related to experiences of racial bias [14,15]. We posit that there are multiple influences on COVID-19–related racial bias beliefs that operate within the sociodemographic contexts of Asian American and Native Hawaiian and Pacific Islander individuals (eg, cultural group, age, sex, sexual orientation, education, income, employment, marital status, English proficiency, nativity, percentage of life spent in the United States, geographic regions, and survey completion month), which intersect with individuals' experiences of COVID-19–specific impacts. These included individuals' COVID-19 status; perceived severity of COVID-19 in one's neighborhood or community compared with others; length of shelter-in-place (SIP); and COVID-19 effect on family income or employment, social support, and medical and mental health care access.

COVID-19–Related Racial Bias Beliefs

The 9-item Coronavirus Racial Bias Scale (CRBS) [23], accessed via the PhenX Toolkit [24], was used to assess beliefs about how the COVID-19 pandemic affected public attitudes (eg, the country becoming more dangerous), racial or ethnic biases affecting employment and access to health services, and racially charged social media and cyberbullying toward Asian American and Native Hawaiian and Pacific Islander individuals in the United States. Participants were asked to rate the degree to which they agreed with 9 statements on a 5-point Likert scale: 1=strongly disagree, 2=somewhat disagree, 3=neutral, 4=somewhat agree, and 5=strongly agree. Cronbach α for this study sample was .90; the α of CRBS ranged from .85 to .92 across the 5 survey languages. For participants who responded to all the 9 items (5068/5218, 97.12%), the total score was computed by averaging all the items (scores ranged from 1 to 5). A higher score indicated a greater degree of agreement with COVID-19–related racial bias beliefs.

Sociodemographic Characteristics

Participants' demographic characteristics included cultural group (Asian Indian, Ethnic Chinese, Filipino, Hmong, Japanese, Korean, Native Hawaiian and Pacific Islander, Vietnamese, and other or multicultural), age (<30, 30-39, 40-49, 50-59, and ≥60 years), sex (male, female, and other or decline to state), sexual orientation (heterosexual, not heterosexual, and decline to state), education level (high school or less, some college or technical school, bachelor's degree, and master's degree or higher), annual household income (≤US $25,000, >US $25,000 to US $75,000, >US $75,000 to US $150,000, >150,000, and decline to state), employment status (full-time, part-time, homemaker, unemployed, retired, and other), and marital status (single, married or living with partner, separated or divorced, and widowed). Self-rated English proficiency was assessed using "How well can you speak, read, and/or write English?" with responses of *a little bit* or *not at all* categorized as having LEP. Nativity was assessed using yes or no or whether the participant was born in the United States. For US-born participants, the percentage of life spent in the United States was 100%, and for non–US-born participants, this was calculated by subtracting the age of entry into the United States from the current age and dividing the current age. The US region (Midwest, Northeast, South, and West) was determined by converting the zip code or IP address in cases of missing zip codes (143/5068, 2.82%) per the Census Bureau definition [25]. The survey completion date was classified by month and year.

COVID-19–Related Experiences and Impacts

Individuals' *COVID-19 status* was measured by asking participants, "Have you been diagnosed with COVID-19 by a doctor or other health care provider?" The responses were recorded as yes, no, or unsure. This item was taken from the questionnaire for assessing the impact of the COVID-19 pandemic and accompanying mitigation efforts on older adults [26].

Perceived severity of COVID-19 was a single item developed by the COMPASS study team. Participants were asked, "How would you rate the severity of COVID-19 outbreak at where you live in comparison to other locations in the US?" The response options were 1 (much less severe than most other places in the United States), 2 (somewhat less severe), 3 (about the same), 4 (somewhat more severe), and 5 (much more severe).

The length of the SIP item was also developed by COMPASS. Participants were asked, "How long was the SIP (or stay-at-home) order at where you live?" The response options were 0 (no order), 1 (<1 month), 2 (1-2 months), and 3 (≥2 months).

Four items from the Coronavirus Impact Scale [27] were used to measure the impact of COVID-19 on four areas: family income or employment, social support, and access to medical and mental health care. Participants were asked to rate the extent to which COVID-19 changed their lives in each of the four areas using response options: 0 (no change), 1 (mild change), 2 (moderate), or 3 (severe). For medical health care access and mental health treatment access, participants were provided *not applicable* as a response option in addition to the 0 to 3 options.

Statistical Analyses

Descriptive statistics were computed to describe the study sample. Given that this study was among the first to use the CRBS with a large diverse sample of Asian American and Native Hawaiian and Pacific Islander individuals in multiple languages, we reported the percentages endorsed for each CRBS item. For descriptive purposes only, to provide an overall description of participants' endorsement of any of the COVID-19–related racial bias beliefs measured by the CRBS, we created a dichotomous variable—*any racial bias belief*—from the CRBS items. Participants who responded *strongly agree* or *agree* to any of the 9 CRBS items were classified as having COVID-19–related racial bias beliefs, and those who did not respond *strongly agree* or *agree* to any of the statements were classified as not having these beliefs. Chi-square tests were used to examine associations between sample characteristics and the presence of racial bias beliefs.

To examine the associations among demographic, health, and COVID-19–related characteristics and COVID-19–related racial bias beliefs, we fit unadjusted and fully adjusted multivariable linear regression models using the CRBS score as a continuous outcome. To ensure that all the important variables were included, this study selected a P value of <.10 a priori to include candidate variables in the final model. To avoid potential collinearity in the final model, as well as to capture the effect of both language proficiency and nativity, these variables were included in the final model, whereas the percentage of life in the United States was not. The model with LEP and nativity and the model with the percentage of life in the United States both performed similarly with respect to the model R^2 (0.33 vs 0.34, respectively). In addition, because of the rapidly evolving landscape of the COVID-19 pandemic, we included the survey completion month as a covariate in the final multivariable regression model. Finally, the selection of reference groups in the linear regression models was based on the group that was least likely to report experiences of racial bias. For example, for cultural group comparisons, Asian Indians were selected as the reference group as they reported the lowest proportion of racial bias perceptions among all the Asian American and Native Hawaiian and Pacific Islander subgroups. All statistical tests were 2-sided.

Ethics Approval

The study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the University of California San Francisco Institutional Review Board (protocol 20-31925).

Results

Participant Characteristics

A total of 5068 participants contributed to the final study sample. As shown in Table 1, 73.97% (3749/5068) of the participants reported having ≥1 of the 9 COVID-19 racial bias beliefs in the past 6 months (during the COVID-19 pandemic). The mean CRBS score was 2.59 (SD 0.96, range 1-5). The participants primarily identified as ethnic Chinese (including individuals from China, Hong Kong, and Taiwan; 1786/5068, 35.24%), Korean (1132/5068, 22.34%), and Vietnamese (953/5068, 18.8%). The participants had a mean age of 45.4 (SD 16.4, range 18-97) years. Most participants were male (3237/5068, 63.87%), identified as heterosexual (4618/5068, 91.12%), and were married or living with a partner (3288/5068, 64.88%). Approximately 22.99% (1165/5068) of participants had LEP, and approximately two-thirds were foreign born and resided in the Western United States region (3288/5068, 64.88%).

Only 3.39% (172/5068) of the study sample reported testing positive for COVID-19. In bivariate analyses, except for COVID-19 positivity, all demographic characteristics, other

COVID-19–related measures (eg, length of SIP, perceived severity of COVID-19, and changes because of COVID-19), and month of survey completion were significantly associated with having COVID-19–related racial bias beliefs.

Table 1. COVID-19 Effects on the Mental and Physical Health of Asian Americans and Pacific Islanders Survey Study participant characteristics (N=5068).

[a] For descriptive purposes only, we dichotomized responses to the CRBS items and categorized participants who responded *strongly agree* or *agree* to any of the 9 items as having COVID-19–related racial bias beliefs and those who did not as not having the perceptions.

[b] CRBS: Coronavirus Racial Bias Scale.

[c] N/A: not applicable.

[d] Ethnic Chinese includes mainland Chinese, Hongkonger, Taiwanese, and Huaren individuals.

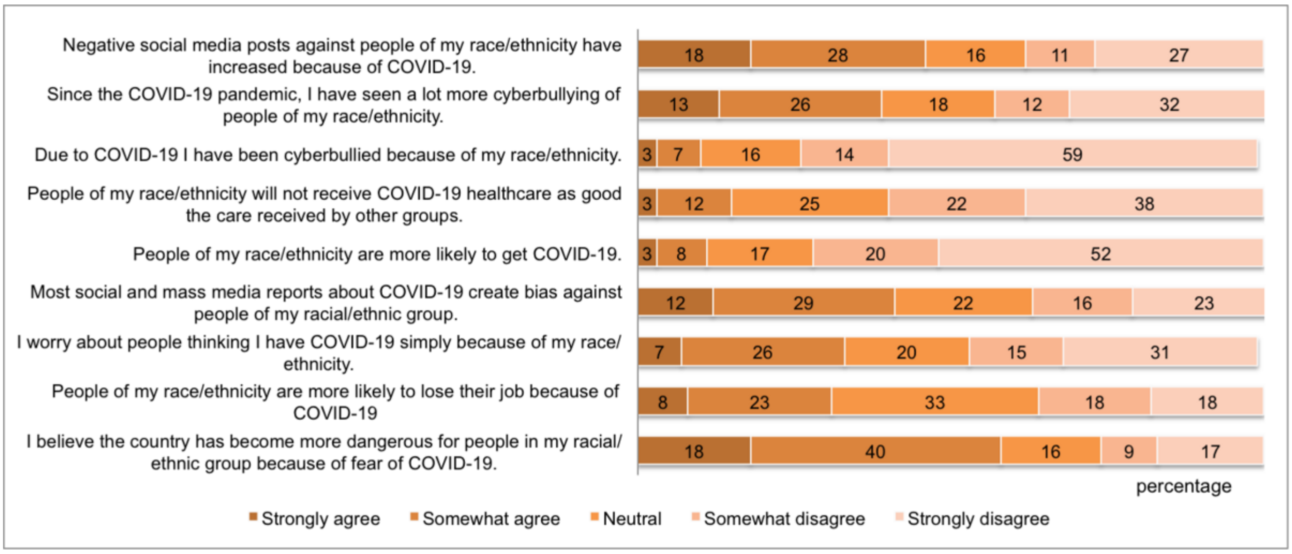
[e] LEP: limited English proficiency. Categorized as limited (yes) if speaking, reading or writing English were indicated as *some*, *a little*, or *not at all*.

[f] SIP: shelter-in-place.

COVID-19 Racial Bias Beliefs

Figure 1 shows the proportions of agreement or disagreement by CRBS item, which ranged from 10% of those who responded *agree* or *strongly agree* to the item "Due to COVID-19, I have been cyberbullied because of my race/ethnicity" to 58% of those who said they *agree* or *strongly agree* to the item "I believe the country has become more dangerous for my ethnic group."

Figure 1. Participants' beliefs of racial bias against Asian American, Native Hawaiian, and Pacific Islander individuals because of the COVID-19 pandemic, by proportion.



Correlates of Racial Bias Beliefs Against Asian Americans, Native Hawaiians, and Pacific Islanders

Multimedia Appendix 1 shows the unadjusted and adjusted associations between each correlate and the mean CRBS score. In the fully adjusted models, the associations remained significant for all variables in the model, except for some sociodemographic variables (marital status, employment status, and education) and perceived severity of COVID-19.

Many sociodemographic characteristics were independent correlates of the CRBS scores. In the fully adjusted model, compared with Asian Indians, ethnic Chinese (β=.79, 95% CI 0.69-0.89), Filipinos (β=.63, 95% CI 0.48-0.78), Hmong (β=.86, 95% CI 0.66-1.06), Japanese (β=.66, 95% CI 0.51-0.81), Korean (β=.15, 95% CI 0.04-0.26), Vietnamese (β=.37, 95% CI 0.26-0.49), and participants who identified as *other/more than one cultural group* (β=.71, 95% CI 0.57-0.85) had significantly higher mean CRBS scores. The mean difference in the CRBS score was not significantly different for Native Hawaiian and Pacific Islander individuals compared with Asian Indians. Compared with participants who were aged ≥60 years, those who were aged <30 years (β=.34, 95% CI 0.2-0.45), 30 to 39 years (β=.23, 95% CI 0.14-0.32), 40 to 49 years (β=.17, 95% CI 0.09-0.26), and 50 to 59 years (β=.10, 95% CI 0.02-018) had significantly higher mean CRBS scores. Women had higher mean CRBS scores than men (β=.05, 95% CI 0.01-0.10), and nonheterosexual individuals had higher mean CRBS scores than heterosexual individuals (β=.23, 95% CI 0.11-0.34). US-born participants had significantly higher mean CRBS scores than those who were foreign born (β=.19, 95% CI 0.13-0.25; β=.19, 95% CI 0.13-0.25), and those with LEP had higher mean CRBS scores than those with no LEP (β=.23, 95% CI 0.16-0.30). There were significant differences by region, with participants from the Midwestern (β=.21, 95% CI 0.12-0.31), Northeastern (β=.25, 95% CI 0.18-0.33), and Southern (β=.11, 95% CI 0.04-0.18) regions having significantly higher mean CRBS scores than the Western region. Compared with those who completed the survey in October 2020, those who completed the survey after that had significantly lower CRBS scores.

Most of the COVID-19–specific experiences were associated with the mean CRBS score, except for COVID-19 positivity (not significant in the unadjusted model and therefore not included in the full model) and perceived severity of COVID-19 where participants resided (became nonsignificant in the adjusted model). In the fully adjusted model, compared with participants without an SIP order, individuals who lived in places with <1 month (β=.09, 95% CI –0.04 to 0.22), 1 to <2 months (β=.24, 95% CI 0.13-0.35), 2 to <3 months (β=.27, 95% CI 0.16-0.38), and >3 months (β=.23, 95% CI 0.14-0.33) of SIP order had significantly higher mean CRBS scores. Higher mean CRBS scores were also observed for those who reported mild to severe changes in their family income, employment, medical health care access, mental health treatment access, and social support related to COVID-19 than for those who reported no change.

Discussion

Principal Findings

COMPASS was among the first nationwide surveys conducted in English and multiple other languages with >5000 Asian American and Native Hawaiian and Pacific Islander individuals and examined racial bias beliefs specifically related to the COVID-19 pandemic. Our findings revealed that 73.97% (3749/5068) of the survey respondents perceived racial bias within the past 6 months because of being *Asian American, Native Hawaiian, and Pacific Islander* during the COVID-19 pandemic. The unique contribution of this study is the documentation of disaggregated data of Asian groups in racial bias experiences reported during a 5-month period from October 2020 to February 2021, approximately 7-11 months after the start of the COVID-19 pandemic in the United States. Importantly, this study also identified multilevel factors associated with racial bias beliefs. These findings allow a comprehensive understanding of the sociodemographic contexts of being Asian American or Native Hawaiian and Pacific Islander and relevant COVID-19–related experiences that may have made Asian American and Native Hawaiian and Pacific Islander individuals vulnerable to perceived negative social attitudes, as exacerbated by the COVID-19 pandemic.

During the COVID-19 pandemic, our nationwide sample of Asian American and Native Hawaiian and Pacific Islander respondents shared that racial bias occurred in various forms. Among the most shared beliefs were perceiving that the United States had become more dangerous for individuals who identified with their ethnic group and observing negative social media posts against people of one's own ethnic group, which was reported by more than half of the respondents. Other racial bias experiences spanned across employment, perceived stigma of having COVID-19, exposure to social and mass media platforms, and observed or directly experienced cyberbullying. Consistent with the noticeable increase of anti-Asian hate incidents [6] and anxiety associated with being *Asian American*, particularly among individuals of Chinese or East Asian descent [3], these findings highlight the disproportionate burdens experienced by Asian American individuals during the pandemic, and such beliefs were shared across social contexts, physical environment, and cyberspace. When racial bias is perceived across multiple everyday contexts, such cumulative stressors and induced fears may have long-term psychological and physiological consequences [12,28,29], which warrants further studies on the long-term health and mental health consequences of COVID-19–related racial bias.

Our results showed that racial bias beliefs were particularly pronounced among some Asian American and Native Hawaiian and Pacific Islander groups and among those who were younger, a sexual minority, had higher income, were United States born, and were English proficient. Racial bias was perceived by many Asian American groups during the pandemic, ranging from 44.3% (132/298) among Asian Indian individuals to 94.5% (104/110) among Hmong. High levels of racial bias beliefs were also reported by ethnic Chinese, Filipino, and Japanese (>80%) individuals and those of multiple Asian descents (>90%). Although Asian Indians and Native Hawaiian and Pacific Islander individuals reported less racial bias beliefs compared with all other groups, perceiving racial bias was still reported by a large portion of individuals from these cultural groups: 44.3% (132/298) and 46.3% (63/136) for Asian Indian and Native Hawaiian and Pacific Islander individuals, respectively. These findings are consistent with the hate incidents reported by Asian American and Native Hawaiian and Pacific Islander individuals during the pandemic [3]. Although the observed cultural group differences persisted even after adjusting for other sociodemographic correlates, it should be noted that all Asian Indian participants and most Native Hawaiian and Pacific Islander participants completed the survey in English. Thus, these findings may not be generalizable to Asian Indian and Native Hawaiian and Pacific Islander participants with LEP. Nonetheless, a recent survey of Asian American, Native Hawaiian, and Pacific Islander women revealed similar levels of racism or discrimination incidents or harassment experienced across East Asian, Southeast Asian, South Asian, and Native Hawaiian and Pacific Islander individuals at a similarly high level (72% among East Asian individuals, to 80% among Native Hawaiian and Pacific Islander individuals) during the pandemic [8]. These findings underscore the urgency of addressing racial bias beliefs, discrimination, or related experiences among Asian American, Native Hawaiian, and Pacific Islander, particularly exacerbated during the pandemic.

Among those traditionally marginalized, Asian American or Native Hawaiian and Pacific Islander individuals who were nonheterosexual overwhelmingly (214/228, 93.8%) reported having racial bias beliefs during the pandemic. Those who had higher incomes, who were English proficient, and those who were United States born reported more racial bias beliefs. The reasons for this were unclear from the study data; a speculation could be related to increased access to and awareness of racial bias reports via media platforms in English [2,30-32]. Other studies have similarly shown that younger Asian American individuals and those with higher education perceived greater racism during the pandemic than older Asian American individuals and those with less education, respectively [5]. Finally, Asian American and Native Hawaiian and Pacific Islander respondents from all regions experienced more racial bias than those in the West, which had the highest population density of Asian American and Native Hawaiian and Pacific Islander individuals. This is in contrast to other data indicating that Asian American individuals on the west coast have reported high rates of discrimination [33]. However, locations such as New York reported an 833% change in anti-Asian crimes from 2019 to 2020 [34].

Although COVID-19 positivity and perceived severity of COVID-19 where respondents live were not relevant factors in racial bias beliefs with other factors adjusted, experiences of COVID-19–specific impacts were associated with COVID-19–related racial bias beliefs. In particular, respondents who had SIP orders for ≥1 month reported higher racial bias beliefs. COVID-19–specific sequelae with negative impacts on family income or employment, family and social support access, medical health care, and mental health care access were found to have contributed to Asian American and Native Hawaiian and Pacific Islander individuals' experiences and perceptions of racial bias. Income, social support, and health care access are all social determinants of health [35]. These findings also suggest a pathway through which COVID-19 affects higher racial bias beliefs and, thereby, health consequences. In addition, these findings revealed that the experience of COVID-19–specific impacts across each area was uniquely associated with and additive in contributing to COVID-19–related racial bias beliefs. These observed associations reflected the differential impacts of COVID-19–specific sequelae that have significant policy implications. Our findings may also reflect a consequence of pre-existing systemic and structural racism that was further exacerbated differentially at multiple levels during the pandemic [36-38].

Although the findings suggested COVID-19–related racial bias beliefs appeared to reduce after October 2020 over the 5-month data collection period of COMPASS, the list of sociodemographic correlates and COVID-19–specific experiences remain significant contributors to racial bias beliefs with the time of data collection adjusted. The findings from this study further underscore the importance of addressing these needs in our respective communities in a timely manner, with attention to cultural contexts and language needs. Moreover, 58% of Asian American individuals said that from March 2020 to March 2021, reports about discrimination and violence against Asian American individuals affected their own mental health [39], although the sequelae have not been well studied, which is a significant concern, given that Asian American individuals underuse mental health care [40,41]. Moving forward, racially motivated hate requires interventions at the structural (eg, hate crime laws, public awareness campaigns, and public health surveillance), interpersonal (eg, hate crime–specific training such as a semester-long college course and intergroup contact programs such as contact and skill-based prejudice reduction programs), and individual levels (eg, self-reflection exercises) [42]. This multilevel intervention was proposed by Cramer et al [42], given the rise of racially motivated hate against several populations, including Asian American individuals, and is based on a socioecological summary of hate-motivated behavior impacts and causes, risk factors for commission, and potential solutions. Cramer et al [42] offered the proposed solutions found in the literature.

Strengths and Limitations

COMPASS is one of the few nationwide surveys focused on the impact of COVID-19 on Asian American and Native Hawaiian and Pacific Islander populations and conducted in multiple Asian languages, which included a large, diverse sample of participants from multiple cultural groups. Data disaggregation is crucial in studies with Asian American and Native Hawaiian and Pacific Islander individuals and yet is rarely performed [43]. The survey was made accessible by smartphones, tablets, or computers, as well as by phone (and in person, if available), with the assistance of a staff member to remove barriers to participation. The study survey had a major focus on inclusion and was available in 5 languages; however, individuals with LEP may have been excluded by not offering the survey in other languages that were not supported.

Owing to the cross-sectional nature of this analysis, our study was limited to reporting experiences at one point in time and did not allow us to assess changes over time during the pandemic. It is possible that the participants experienced racial bias after completing the survey, which would not be reflected in our results. There may also be variation in participants' interpretations of racial bias based on acculturation, which was not assessed as part of the survey. Future research should consider assessing acculturation and the social desirability bias scale [44] to account for potential biases. The responses may have been affected by varying SIP and social distancing policies across regions and states in this nationwide survey.

Conclusions

Our study revealed that most Asian American and Native Hawaiian and Pacific Islander individuals reported racial bias beliefs due to being Asian American and Native Hawaiian and Pacific Islander during the COVID-19 pandemic. In the context of the sharp rise in anti-Asian incidents and hate crimes reported during the pandemic [4,5,9], the findings of this study further underscore the devastating impact of COVID-19 among Asian American, Native Hawaiian, and Pacific Islander individuals. Relevant sociodemographic contexts and pre-existing and COVID-specific impacts were associated with perceived racial bias of *being Asian American, Native Hawaiian, and Pacific Islander* during the pandemic. Racial biases have significant impacts on one's lived experiences, spanning across various everyday contexts that contribute to disparities in access to or opportunities for education, work, and health care [11-13]. Identifying, creating, and allocating culturally and linguistically appropriate resources dedicated to addressing such burdens on Asian American, Native Hawaiian, and Pacific Islander communities because of racial bias among other COVID-19–related sequelae are priorities of urgency. Future interventions such as those proposed earlier require significant resources (eg, academic-community partnerships and state-wide task forces) and funding, as well as comprehensive evaluations of each antihate intervention [42], all of which are necessary to combat this serious public health issue of racially motivated hate.

Acknowledgments

This study was supported by the National Institute on Aging, National Institutes of Health (3R24AG063718-02S1, R24AG063718, and R56AG069130). The authors wish to express their sincere gratitude to the National Pacific Center on Aging, International Children Assistance Network, and other community partners and members of the Community Advisory Board for assistance with the outreach and administration of the COVID-19 Effects on the Mental and Physical Health of Asian Americans and Pacific Islanders Survey Study (COMPASS).

The funder of the study had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; or the decision to submit the manuscript for publication.

Abstract

Background: A computer application called the National Death Information System (SINADEF) was implemented in Peru so that physicians can prepare death certificates in electronic format and the information is available online. In 2018, only half of the estimated deaths in Peru were certified using SINADEF. When a death is certified in paper format, the probability being entered in the mortality database decreases. It is important to know, from the user's perspective, the factors that can influence the successful implementation of SINADEF. SINADEF can only be successfully implemented if it is known whether physicians believe that it is useful and easy to operate.

Objective: The aim of this study was to identify the perceptions of physicians and other factors as predictors of their behavioral intention to use SINADEF to certify a death.

Methods: This study had an observational, cross-sectional design. A survey was provided to physicians working in Peru, who used SINADEF to certify a death for a period of 12 months, starting in November 2019. A questionnaire was adapted based on the Technology Acceptance Model. The questions measured the dimensions of subjective norm, image, job relevance, output quality, demonstrability of results, perceived usefulness, perceived ease of use, and behavioral intention to use. Chi-square and logistic regression tests were used in the analysis, and a confidence level of 95% was chosen to support a significant association.

Results: In this study, 272 physicians responded to the survey; 184 (67.6%) were men and the average age was 45.3 (SD 10.1) years. The age range was 24 to 73 years. In the bivariate analysis, the intention to use SINADEF was found to be associated with (1) perceived usefulness, expressed as "using SINADEF avoids falsifying a death certificate" (P<.001), "using SINADEF reduces the risk of errors" (P<.001), and "using SINADEF allows for filling out a certificate in less time" (P<.001); and (2) perceived ease of use, expressed as "I think SINADEF is easy to use" (P<.001). In the logistic regression, perceived usefulness (odds ratio [OR] 8.5, 95% CI 2.2-32.3; P=.002), perceived ease of use (OR 10.1, 95% CI 2.4-41.8; P=.001), and training in filling out death certificates (OR 8.3, 95% CI 1.6-42.8; P=.01) were found to be predictors of the behavioral intention to use SINADEF.

Conclusions: The behavioral intention to use SINADEF was related to the perception that it is an easy-to-use system, the belief that it improves the performance of physicians in carrying out the task at hand, and with training in filling out death certificates.

Introduction

Medical death certification is the main source of information on causes of death in a population [1]. Various studies worldwide report that there is low coverage of deaths that have medical certification of death [2,3], and those deaths that have certification of the causes of death do not have the desired quality [4,5]. In 2016, the coverage of deaths with medical certification of the causes of death in Peru was 56% [6] and the quality, measured as the proportion of codes of causes of death in the International Classification of Diseases classified as "garbage code," was among the highest in the world [7]. In 2017, a computer application called the National Death Information System (SINADEF) [8] was implemented in Peru, which is used by physicians to prepare death certificates online. This system was the result of coordinated work between the National Institute of Statistics and Informatics, the National Registry of Identification and Civil Status, and the Ministry of Health, supported by the Bloomberg "Data for Health" initiative. Before implementing SINADEF, physicians performed death certification on paper forms, which were entered into computer applications installed on computers with local databases, which were then sent through email messages at the regional and national levels. In addition to the lack of opportunity for data availability, this system has many other problems: it does not verify the identity of the deceased by consulting a database, it does not identify the hospital where the person died, it does not unequivocally locate the district where the death occurred, and often, the cause of death written by the doctor is illegible.

With SINADEF, physicians can certify a death online, verify the identity of the deceased and the hospital where the death occurred, consult online databases, and more accurately record the place of death. Further, the problem of the lack of legibility of the doctor's handwriting, which is very important in the registry of causes of death, disappears. From the perspective of electronic government, information and communication technology (ICT) can facilitate the services provided to citizens. It allows health authorities at all levels of government to monitor mortality indicators in a timely manner and improve prevention and control actions, as is happening now with the monitoring of the COVID-19 pandemic. Likewise, it allows other state agencies to be more efficient in public policy management processes. These aspects justify taking the greatest precautions to guarantee its successful implementation.

A paper [6] that reported the first results of the implementation of SINADEF showed that in July 2018, only half of the estimated deaths were certified using that system, and it identified some gaps and barriers that could limit the achievement of adequate coverage and quality of the registry of causes of death. One of them is the modality used by the doctor to certify a death [6]. When a doctor certifies a death on paper forms, the data may not enter the system. The paper forms can remain with the relative of the deceased or in a drawer of a hospital office, in funeral agencies, in the civil registry, etc. In July 2018, half of the estimated deaths were not entered in SINADEF. Some studies about the map of death registration processes carried out in Peru indicate that deaths registered in paper format are less likely to enter the mortality database [9], which highlights the importance of identifying factors linked with physicians, thereby improving the use of SINADEF to certify a death. Furthermore, SINADEF has played a fundamental role in documenting the excess mortality that occurred during the COVID-19 pandemic in Peru. Several studies [10-12] used SINADEF to warn, from the beginning of the first wave of transmission of COVID-19 in Peru, a significant difference in deaths that the physicians who used SINADEF attributed to COVID-19 and that were not reported by the system of epidemiological surveillance. In addition, they coincide in pointing out the importance of the quality of the data provided by SINADEF and the need to strengthen the entire death registration process so that it is useful for containing the health emergency. Recent studies using SINADEF reported that excess mortality from all causes in 2020 was more than 100,000 deaths and that more realistic figures have been obtained owing to coordination initiatives between those responsible for epidemiological surveillance, recording of vital events, and diagnosis [13]. However, they did not notice that a significant proportion of deaths, especially those that occur in the community, are not reported through SINADEF; therefore, it is important to evaluate the factors that could limit its real use.

Intuitively, it may seem that the information production process supported by paper format, when replaced by an electronic registry, as is the case with SINADEF, will immediately produce obvious improvements such as the reduction of errors due to data transcription. However, there are also bad experiences in the implementation of ICT projects in health services, which in theory were very robust, probably because the user experience was not considered in the design of the applications [14]. Therefore, it is necessary to know the determinants of the future use of a technology.

All innovation in health requires the intensive participation of the people who will be affected by the processes in which it will intervene. To expand the use of online death certification, it is important to know what the physicians think about the system. Some barriers related to the system itself are dependence on internet connectivity, limited availability of computers and printers in hospitals, and failures in technical support and application maintenance. Although the advantages include their use even from mobile devices, physicians may not be willing to use them. To understand why users accept or use new technologies, a predictive evaluation methodology of technology use known as the Technology Acceptance Model (TAM) has been proposed, which has been tested and validated in different contexts and studies [15,16]. The TAM has been used in the evaluation and implementation of ICT in the health field [17-20]. The TAM is based on user perceptions. If people believe that an ICT application helps them to do their job better ("perceived usefulness") and, at the same time, that it does not require additional effort ("perceived easy to use"), they will end up adopting that technology [15].

Rahimi et al [21] conducted a systematic review of 134 studies published between 1999 and 2017 that used TAM to evaluate ICT applications in the health field after their initial introduction. The areas of ICT studied were general information technologies, health information systems, electronic health records or electronic medical records, electronic prescription systems (e-prescription), pocket computers, telemedicine, mobile health, and personal health records. An online system for medical certification of death can be considered an electronic medical record component, but in this review, no study specifically evaluated an information system like SINADEF. The studies evaluated are widely distributed throughout the world, but they are scarce in Latin America, and none were reported in Peru. The main findings were that the application of TAM was quite heterogeneous. Most studies used extensions of the original TAM, which suggests that there is no optimal version of TAM to use in the field of health. Holden and Karsh [16] also carried out a review of TAM and highlight the importance of developing "the left part of the model," that is, the determinants with specific, contextualized, and actionable constructs.

In Peru, we have not identified previous research that describes the use of TAM to evaluate ICT in health; only 1 study evaluated the intended use of mobile banking services [22]. Our study aims to identify the perceptions of physicians about the usefulness and ease of use of SINADEF and other factors such as predictors of the behavioral intention to use SINADEF, contextualizing the predictor variables with specific propositions about the use of SINADEF to certify deaths.

Methods

Design

An observational, cross-sectional study was carried out that consisted of the application of a survey directed to physicians who used the national computer system of deaths (SINADEF) to produce a death certificate. The study population was made up of physicians with a professional practice in Peru and who, as of 2017, had the chance to carry out, at least once, the death certification process online through SINADEF.

Recruitment

Between November 24, 2019, and November 18, 2020, an electronic form was sent to 26,185 physicians who were registered as SINADEF users until December 31, 2017. Of them, 505 physicians opened the electronic form and 424 agreed to participate in the study; 111 physicians were excluded because they reported that they had no experience in the use of SINADEF, and 41 physicians were excluded because they had contradictory answers about their degree of agreement with the use of SINADEF to certify a death. Therefore, the sample consisted of 272 physicians.

TAM

Questionnaire

The questions in the questionnaire were based on TAM. TAM proposes that the behaviors of individuals depend on their beliefs and subjective norms and that the use of a new technology depends on 2 variables in particular: the perceived ease of use of the technology and the perceived usefulness. In turn, these 2 variables will directly influence the attitude of the individual toward the actual use of technology [15]. In a simpler way, if an individual has the belief that a technology is easy to use and at the same time, it is useful for the work that it has to fulfill, he or she will have a favorable attitude to use the technology effectively. In this study, the TAM2 model proposed by Venkatesh and Davis [23] was used, which incorporates the following variables: subjective norm, image, job relevance, output quality, and results demonstrability. The measurement scale used was based on the original proposals of Venkatesh and Davis [23] for the evaluation of information technology in general but adapted to the context of its use in the medical certification of deaths in Peru, following the recommendations of Holden and Karsh [16] on adapting the model specifically to the health context by using belief induction methods. In the propositions of beliefs, reference is made to the regulatory provisions of the Ministry of Health in Peru or the comparison of the use of SINADEF with the traditional way of using paper forms. The following operational definitions were used for each of the explanatory variables proposed in the model used (Textbox 1).

In addition, variables external to the model are included that can be explanatory or that intervene in the attitude or behavior of intention to use the technology of physicians, such as age, sex, medical specialty, workplace, time spent in service, and training in the filling of death certificates.

Textbox 1. Operational definitions of the Technology Acceptance Model used.

Subjective norm: Subjective perception of the individual on social pressures, which includes the perception of the beliefs of relevant people, for the adoption of the behavior of use of the National Death Information System (SINADEF), through their opinion of agreement or disagreement on a Likert scale of the following propositions:

- "I have to use SINADEF to certify deaths because it's already established that way."
- "The authorities of my hospital and the Ministry of Health could sanction me if I do not use SINADEF to certify deaths."
- "I have to use SINADEF because everyone already uses it to certify deaths."

Image: Refers to the user's self-perception, visual, or mental representation produced by the use of SINADEF. It was measured by their opinion of agreement or disagreement on a Likert scale of the following propositions:

- "I feel comfortable with information and communication technologies."
- "I consider myself a person open to change."
- "I have good adaptability."

Job relevance: Refers to the perceived attribution of the user that SINADEF is important for the performance of work tasks. It was measured by their opinion of agreement or disagreement on a Likert scale of the following propositions:

- "When SINADEF is implemented, the causes of death of the population will be known in a timelier manner."
- "The use of SINADEF will help the directors or managers of health organizations make decisions."
- "If SINADEF is consolidated, it will be possible to quickly consult the data of the deceased."

Output quality: Refers to the real or perceived attribution of the SINADEF user of the quality of the report provided by the technology. It was measured by their opinion of agreement or disagreement on a Likert scale of the following proposition:

- "The SINADEF death certificate is of higher quality than the paper format."

Perceived usefulness: Refers to an individual's perception that the use of SINADEF will improve job performance. It was measured by their opinion of agreement or disagreement on a Likert scale of the following propositions:

- "Using SINADEF avoids falsifying a death certificate."
- "Using SINADEF reduces the risk of errors in death certificates."
- "Using SINADEF allows me to produce a death certificate in less time than doing it in paper format."

Perceived ease of use: Refers to an individual's perception that using SINADEF does not require effort, through their opinion of agreement or disagreement on a Likert scale of the following propositions:

- "I think SINADEF is easy to use."
- "It's easy to get a password to use SINADEF."
- "It's easy to recover the SINADEF password when you forget it or it's blocked."
- "It's easy to get technical support from SINADEF when you need it."

Behavioral intention to use: Refers to the motivation or willingness of an individual to make the effort to use SINADEF to certify a death, through their opinion of agreement or disagreement on a Likert scale of the following proposition:

- "When I need to certify a death, I will use the SINADEF."
- "In any circumstance, if I need to certify a death, I will not use SINADEF."

Results demonstrability: Thinking that SINADEF allows you to demonstrate the results, through their opinion of agreement or disagreement on a Likert scale of the following proposition:

- "I can easily communicate the results of my experience using SINADEF."
- "For me, the results of using SINADEF will be visible."

Instrument Validation

The content of the proposed instrument was validated through an expert judgment process [24]. Six expert researchers were selected—2 of them experts in measurement and evaluation. The index of agreement of the judges on the propositions of the TAM variables was 84.9%, with a κ index of 0.7304. All elements with a κ index less than 0.6 were removed and replaced. Items with a κ index of 0.6571 were reviewed and their formulation was paraphrased or modified based on the judges' recommendations. The reliability of the 20-item measurement scale for the 8 variables that were included in the study was evaluated with the Cronbach α coefficient. The value obtained for the Cronbach α coefficient was .874.

Statistical Analysis

Overview

The data collected through the electronic forms were analyzed using the SPSS statistics package (IBM Corp). A description of the variables was made, presenting arithmetic means and standard deviations of the quantitative variables, such as age and years of medical work, and frequency tables of qualitative variables such as sex, workplace, and medical specialty. A bivariate analysis was performed between the independent variables such as perceived usefulness or perceived ease of use and the dependent variable behavioral intention to use. Subsequently, a multivariate analysis was performed using binary logistic regression with the Wald successive steps method with a likelihood ratio, evaluating models that included both descriptive and explanatory variables as independent variables, with the dependent variable behavioral intention to use. To carry out the bivariate analysis and binary logistic regression analysis, the responses to the propositions of each of the variables on a Likert scale were transformed into 2 alternatives: “agree” and “disagree.” In the initial model, all the variables of TAM that were found associated with the behavioral intention to use in the bivariate analysis were considered as independent or predictive variables. Additionally, the variables sex, age, main work center, and training in filling out death certificates were entered into the model. Following the TAM2 model, the variables subjective norm, image, job relevance, output quality, demonstrability of results, and perceived ease of use were crossed with perceived usefulness. In the successive steps, the variables with a Wald value less than 1 and with statistical significance less than .05 were eliminated.

Power

In the bivariate analysis, the chi-square test was used to establish the existence of an association between the variables, choosing a confidence level of 95%, a level of statistical significance of (α) equal to or less than .05, and a power of 80% (1-β) equal to or less than .20. To identify the variables associated with behavioral intention to use in the multivariate analysis, the logistic regression with Wald method (backward) of successive steps with the likelihood ratio was used. A confidence level of 95% and a significance level (α) equal to or less than .05 were chosen.

Ethics Approval

The research protocol and the informed consent signed by the participants were approved by the Research Ethics Committee of the San Marcos University School of Medicine (#19-0027).

Results

Sample

In this study, 272 physicians, who were SINADEF users since 2017, were studied. Most (184/272, 67.6%) were male. The average age was 45.3 (SD 10.1) years. The minimum age was 24 years and the maximum age was 73 years. Most of the respondents (100/272, 36.8%) were in the age group of 40 to 49 years. Only among young physicians between the ages of 24 and 30 years did women predominate (10/17, 58.8%), while in the rest of the age groups, there was a predominance of male physicians.

Description of the Population Studied

The most frequent participants in this study were general practitioners (70/272, 25.7%), pediatricians or neonatologists (30/272, 11%), internists (25/272, 9.2%), and obstetrician-gynecologists (15/272, 5.5%). Forensic physicians constituted 4.4% (12/272) of the participants. The study included graduates of all universities that have a faculty of medicine in Peru. Approximately 5.1% (14/272) of the participants studied abroad. Most of the study participants worked in hospitals as their main workplace, followed by those who worked in private clinics and health centers. Most of the participants (221/272, 81.3%) had worked for 10 or more years. Approximately 71% (193/272) stated that they had received some type of training in filling death certificates and among these, the majority did so through conferences given at the same hospital, through health services networks, or through a combination of training modalities (see Table 1).

Figure 1 shows the perceptions classified by their level of agreement among the respondents, and those with the highest agreement were perceived as people open to change, who considered the usefulness of the system to quickly consult information about the deceased, and the ability to adapt to innovative methods. Those who had less agreement corresponded to the ease of obtaining passwords or technical support and the possible sanctions that their nonuse would cause.

Table 1. Description of the main characteristics of the studied population (N=272).

Characteristics	Values, n (%)
Sex	
Male	184 (67.6)
Female	88 (32.4)
Age group (years)	
24-30	17 (6.3)
30-39	60 (22.1)
40-49	100 (36.8)
50-59	70 (25.7)
>59	25 (9.2)
Main workplace	
Hospital	190 (69.9)
Health center/post	32 (11.8)
Private clinic/physician's office	29 (1.7)
Medical-legal division	16 (5.9)
Other	5 (1.8)
Years of medical work	
Less than 10	51 (18.8)
10-19	99 (36.4)
20-29	83 (3.5)
More than 29	39 (14.3)
Training in filling death certificate	
Yes	193 (71)
No	79 (29)
Training modality (n=193)	
A conference at the health center or through a health services network	58 (3.1)
During undergraduate studies	28 (14.5)
During postgraduate studies	20 (1.4)
A virtual course	14 (7.3)
Combined (more than one of the above)	73 (37.8)

Figure 1. Level of agreement (%) in the physicians' perceptions about the use of the National Death Information System. MINSA: Ministry of Health; SINADEF: National Death Information System.

Bivariate Analysis

Physicians' perceptions that were found to be associated with behavioral intention to use ($P<.05$) were perceived usefulness as shown by "using SINADEF avoids falsifying a death certificate," "using SINADEF reduces the risk of errors," and "using SINADEF allows for filling out a certificate in less time," and perceived ease of use as shown by "I think SINADEF is easy to use," as well as other perceptions related to image, job relevance, output quality, and results demonstrability. As a subjective norm, no proposition was found associated with behavioral intention to use (see Table 2). There was also no significant association between age, sex, occupation characteristics, or training in filling out death certificates with behavioral intention to use.

Table 2. Behavioral intention to use according to the perceptions of the respondents.

Behavioral intention to use	Agree (n=256)		Disagree (n=16)		*P* value[a]
	Agree, n (%)	Disagree, n (%)	Agree, n (%)	Disagree, n (%)	
Perceived usefulness					
Using SINADEF[b] avoids falsifying a death certificate	220 (97.3)	36 (78.3)	6 (2.7)	10 (21.7)	<.001
Using SINADEF reduces the risk of errors in death certificates	221 (97.8)	35 (76.1)	5 (2.2)	11 (23.9)	<.001
Using SINADEF allows me to produce a death certificate in less time than doing it in paper format	207 (97.6)	49 (81.7)	5 (2.4)	11 (18.3)	<.001
Perceived ease of use					
I think SINADEF is easy to use.	236 (97.1)	20 (68.9)	7 (2.9)	9 (31)	<.001
It's easy to get a password to use SINADEF.	148 (96.1)	108 (91.5)	6 (3.9)	10 (8.5)	.11
It's easy to get technical support from SINADEF when you need it	93 (95.9)	163 (93.1)	4 (4.1)	12 (6.9)	.36
It's easy to recover the SINADEF password when you forget it or it's blocked	129 (95.6)	127 (92.7)	6 (4.4)	10 (7.3)	.25
Subjective norm					
I have to use SINADEF to certify deaths because it's already established that way	208 (94.5)	48 (92.3)	12 (5.5)	4 (7.7)	.54
The authorities of my hospital and the Ministry of Health could sanction me if I do not use SINADEF to certify deaths	81 (93.1)	175 (94.6)	6 (6.9)	10 (5.4)	.63
I have to use SINADEF because everyone already uses it to certify deaths	195 (95.6)	61 (89.7)	9 (4.4)	7 (10.3)	.07
Image					
I feel comfortable with information and communication technologies	233 (95.5)	23 (82.1)	11 (4.5)	5 (17.9)	.004
I consider myself a person open to change	254 (94.8)	2 (50)	14 (5.2)	2 (50)	.02[c]
I have good adaptability	245 (94.6)	11 (84.6)	14 (5.4)	2 (15.4)	.14
Job relevance					
When SINADEF is implemented, the causes of death of the population will be known in a timelier manner	237 (95.9)	19 (76)	10 (4.1)	6 (24)	<.001
The use of SINADEF will help the directors or managers of health organizations make decisions	203 (96.7)	53 (85.5)	7 (3.3)	9 (14.5)	.001
If SINADEF is consolidated, it will be possible to quickly consult the data of the deceased	250 (96.2)	6 (50)	10 (3.8)	6 (50)	<.001
Output quality					
The SINADEF death certificate is of higher quality than the paper format	224 (87.5)	7 (43.8)	32 (12.5)	9 (56.3)	<.001
Results demonstrability					
I can easily communicate the results of my experience using SINADEF	224 (87.5)	7 (43.8)	32 (12.5)	9 (56.3)	<.001
For me, the results of using SINADEF will be visible	217 (84.8)	7 (43.8)	39 (15.2)	9 (56.3)	<.001

[a] Chi-square test was performed.

[b] SINADEF: National Death Information System.

[c] Fisher exact test was performed.

Multivariate Analysis

Three models were tested that had perceived usefulness as a dependent variable, corresponding to the 3 perceptions that evaluated perceived usefulness: (1) SINADEF avoids death certificate forgery, (2) SINADEF reduces the possibility of errors, and (3) SINADEF is faster than filling out paper forms. We use as perceived usefulness predictors the perceptions of the variables proposed in the TAM2 model: subjective norm, image, job relevance, output quality, and results demonstrability. The first model reached an overall percentage of correctly classified cases of 84.2% and found subjective norm, image, job relevance, and results demonstrability as predictors significantly associated with perceived usefulness but did not find perceived ease of use as a variable significantly related to perceived usefulness. The second model reached a global percentage of correctly classified cases of 88.2% and found perceived ease of use, subjective norm, image, and job relevance as predictors of perceived usefulness. The third model reached a global percentage of correctly classified cases of 82.7% and, in addition to perceived ease of use, only found job relevance and results demonstrability as perceived usefulness predictors. The second model was chosen because it showed the highest percentage of prediction and included 3 of the 5 variables proposed in the TAM2 model as significant predictors of perceived usefulness. The second model was based on the perception that SINADEF reduces the possibility of making errors when making a death certificate as an indicator of perceived usefulness. It was found that they were significantly associated with perceived usefulness: subjective norms such as the belief that SINADEF should be used because everyone already uses it to certify deaths (odds ratio [OR] 2.407, 95% CI 1.008-5.75; *P*=.048); image, the perception of being comfortable with ICT (OR 5.363, 95% CI 1.886-15.255; *P*=.002); job relevance such as the perception that the use of SINADEF will help health directors to make decisions (OR 4.49, 95% CI 1.978-10.2; *P*<.001); and perceived ease of use as the perception that SINADEF is easy to use (OR 18.95, 95% CI 6.634-54.156; *P*<.001). The model reached a predictive ability of 88.2% (see Table 3).

The final model found the following statistically associated predictors with behavioral intention to use: perceived usefulness, measured by the belief that SINADEF reduces the risk of error in death certificate (OR 8.515, 95% CI 2.242-32.3; *P*=.002) and perceived ease of use, due to the belief that SINADEF is easy to use (OR 10.116, 95% CI 2.443-41.883; *P*=.001). Also included in this model was the variable training in the filling of death certificates, a variable external to the TAM2 model but which had a very important contribution (OR 8.324, 95% CI 1.615-42.895; *P*=.01). The final model reached a predictive ability of 95.6% (see Table 4 and Figure 2).

Table 3. Logistic regression of perceived usefulness predictors.

Predictor	β	Odds ratio (95% CI)	*P* value
Subjective norm: I have to use SINADEF[a] because everyone already uses it to certify deaths	.879	2.407 (1.008-5.75)	.048
Image: I feel comfortable with information and communication technologies	1.502	5.363 (1.886-10.2)	.002
Job relevance: The use of SINADEF will help the directors or managers of health organizations make better decisions	1.045	4.491 (1.978- 5.931)	<.001
Perceived ease of use: I think SINADEF is easy to use	2.942	18.955 (6.634-54.156)	<.001
Constant	–10.153	0.000	<.001

Discussion

Principal Results

Although it may seem that the implementation of an ICT project will be successful, this is not always the case. Projects can be successful, considering their management (scope, costs, and deadlines) from their gestation to their implementation [25]. However, in the case of ICT projects in health, their final adoption will also depend on the beliefs of health personnel, in which the real barriers and facilitators for their use can be identified [16]. SINADEF has contributed to improving the coverage [6] and the quality of information on causes of death [5]. However, until the end of 2017, its use rate was only 50%; therefore, it was pertinent to evaluate the intention of system use.

Most of the physicians interviewed considered themselves open to change. They believed that SINADEF would allow them to quickly consult the data of deceased people or that they could adopt innovative methods (95% or more). However, more than half of them did not agree with the idea that if they do not use the SINADEF, they should be sanctioned (68%) or that it is easy to obtain technical help when they have problems with the system (64%). Bivariate analysis revealed that perceived ease of use, measured by the belief that SINADEF is easy to use, was significantly associated with behavioral intention to use (*P*<.001). Perceived ease of use was measured on 4 propositions: the system is easy to use, it is easy to get a password, it is easy to get technical support, and it is easy to recover a password. Only the belief that the system is easy to use had a degree of agreement of 89.3%, while the other proposals had an agreement of less than 60%. Furthermore, in the bivariate analysis, only the perception that the system is easy to use was associated with behavioral intention to use; therefore, it was also part of the final logistic regression model to predict behavioral intention to use. In turn, perceived usefulness was measured with any of 3 ideas—SINADEF avoids falsifying a death certificate, fewer errors are made with SINADEF when creating a death certificate, or a death certificate is produced faster with SINADEF—and it was found to be associated with behavioral intention to use (*P*<.001). In addition, most or all the image, job relevance, output quality, and results demonstrability proposals were significantly associated with behavioral intention to use (*P*<.05).

In the multivariate analysis, among the 3 propositions that measured perceived usefulness, the proposition "using SINADEF reduces the risk of errors in death certificates" had the highest predictive capacity (88.2%). Subjective norm measured as "I have to use the SINADEF because everyone already uses it to certify deaths" (OR 2.4, 95% CI 1.0-5.8; *P*=.048), image measured as "I feel comfortable with technology" (OR 5.4, 95% CI 1.9-10.2; *P*=.002), job relevance measured as "the use of SINADEF will help directors or managers of health organizations to make decisions" (OR 4.5, 95% CI 2.0-5.9; *P*<.001), and perceived ease of use measured as "I believe that SINADEF is easy to use" (OR 19, 95% CI 6.6-54.2; *P*<.001) were significantly associated with perceived usefulness. In the final model, we found a significant association between perceived usefulness measured as "using SINADEF reduces the risk of errors in death certificates" (OR 8.5, 95% CI 2.2-32.3; *P*=.002), perceived ease of use measured as "I think that SINADEF is easy to use" (OR 10.1, 95% CI 2.4-41.9; *P*=.001), and training to fill out the death certificate (OR 8.3, 95% CI 1.9-42-9; *P*=.01), with behavioral intention to use. The correct classification of cases by the final model was 95.6%.

Limitations of This Study

A limitation of this study is the selection of the participating physicians. The sample was made up of physicians who responded to an invitation sent to the email registered in SINADEF, and the response rate was less than 2%. This is because most physicians did not read the messages because they have an email account assigned by the institution where they work, which they usually do not use, or because the message went to the "spam" folder. Regarding the participants, there is a probability that they have incurred a social desirability bias. Despite this, we believe the sample to be representative of physicians in terms of graduation from universities in the country, specialties, sex, and age. In addition, the sample size was adequate for carrying out the proposed statistical models. Another aspect to consider is that a significant proportion of the surveys was completed in 2020, the initial year of the COVID-19 pandemic in Peru, in which SINADEF played an important role in monitoring mortality in Peru, and it is possible that this factor, not measured in this study, influenced the favorable opinion of physicians toward intention to use. It is also possible that the proposals to be accepted or rejected by the participants do not represent all the factors that may be linked to the process of the medical certification of deaths in Peru. It should also be considered that, as in all observational studies, it should not be inferred that there is a causal relationship between perceived usefulness and perceived ease of use and training with behavioral intention to use but only an association between them. This study also did not evaluate the performance or the real and objective effectiveness of the technology, but only the beliefs of the users about its usefulness that will motivate its future use and its final adoption.

Comparison With Prior Work

There is a need to institutionalize SINADEF to intensify the process of improving the coverage and quality of information on causes of death. The use of paper forms, from the logistics of their supply to the procedures that ensure their entry into a database, can be a barrier to improving death certification [6]. This situation was verified during the COVID-19 pandemic by observing that the use of paper forms to certify a death decreased the probability that the data would enter the mortality database [9]. In addition, considering that there are 18 mortality information subsystems in Peru, most of which use paper forms and none of which have complete information [26], the consolidation of SINADEF as the main information system would reduce the fragmentation of currently existing data.

The usefulness that SINADEF has shown for mortality surveillance during the COVID-19 pandemic is another aspect that highlights the importance of contributing to its institutionalization. During the COVID-19 pandemic, SINADEF was used in several studies [10-12,27] as an important source of information to document excess mortality from all causes in Peru and was recognized as the most reliable way to measure the severity and the impact of COVID-19 on the population. With the support of SINADEF, an excess mortality of 371.9 per 100,000 inhabitants in 2020 was documented in Peru [28], and in general, all the researchers agreed in highlighting the importance of strengthening the mortality documentation system in Peru.

We have not identified studies of the application of TAM to evaluate acceptability, specifically in mortality information systems, but there are several publications that have studied the technological acceptance of health information systems that include electronic medical records or electronic health records. As in other studies, we found that perceived usefulness and perceived ease of use are powerful predictors of the intention to use SINADEF. These findings are consistent with most of the previous research synthesized in systematic reviews. Gagnon et al [29] carried out a systematic review of the factors that influence the adoption of ICT in health and found that the most common direct determinants of adoption were usefulness and ease of use. Later, Rahimi et al [21] reviewed 134 publications on the use of TAM to find out the perceptions of users of health information systems as predictors of the use of technology. Although the reference framework used or the methods for analyzing the results may differ, most of the studies reviewed agree in confirming that the perceived usefulness and the perceived ease of use are important predictors of the intention to use the technology.

In our study, the direct predictors of behavioral intention to use were perceived usefulness, perceived ease of use, and training in filling out death certificates, and the predictors of perceived usefulness were subjective norm, image, and job relevance. When reviewing the predictor variables of behavioral intention to use, in the cases under study, considerable heterogeneity was observed. Some studies found only 1 primary variable from TAM, such as perceived usefulness or perceived ease of use, associated with intention to use [30,31], and other studies reported subjective norm or job relevance directly related to behavioral intention to use, without being intermediated by perceived usefulness [30-32]. There are also studies that describe predictors of perceived ease of use, such as job relevance, management support, and training or computational self-efficacy [33,34], and some others found that age, sex, or clinical specialty were predictors of both perceived usefulness and perceived ease of use [31]. This variability supports the idea of contextualizing the results of each study not only referring to the type of technology used but also to the organizational culture in which the technology will work.

In our study, subjective norm (“I use SINADEF because everyone already uses it”), image (“I feel comfortable with technology”), and job relevance (“SINADEF helps managers to make decisions”) were predictors of perceived usefulness. This is partially consistent with studies reporting peer influence [35] or computational self-efficacy as perceived usefulness predictors [32,34]. Perceived usefulness measured by the idea that the system helps reduce errors is a performance indicator. In this regard, a study [36] found that improvements in performance are related to the intentions of health professionals to use electronic medical record systems.

In our perceived ease-of-use study, measured in its simplest and most direct way, “SINADEF is easy to use” was a strong and significant determinant of physicians’ intention to use SINADEF and influenced their perceived usefulness. However, the physicians did not agree with the perceived ease of use propositions that “it’s easy to obtain a username and password” or that “it’s easy to obtain technical support,” and indeed, these were not significantly related to the intention to use. In this regard, Boonstra and Broekhuis [37] reported that the lack of technical support to address problems that arise during system operation is a barrier to the adoption of the electronic medical record.

Training in filling out death certificates had a significant direct influence on behavioral intention to use. In this regard, the implementation of SINADEF was accompanied by a training process both in the competence to identify the cause of death and the technical management of the computer application. It is recognized that training to improve physicians’ knowledge regarding the proper filling of death certificates will improve the usability of mortality statistics. This study demonstrated that this activity is a direct predictor of the use of SINADEF in Peru [38]. This is consistent with the identification of the lack of technical knowledge and insufficient skills for the management of ICTs as a barrier to the adoption of technologies by becoming a source of resistance that hinders their adoption [37].

Conclusions

According to our study, it seems that the intention to use SINADEF is related to the perception that it is an easy-to-use system, it is widely accepted, it improves the performance of the physicians who use it, and it helps to manage health services. Additionally, training in the filling of death certificates plays an important role in the intention to use the system. It also informs ICT decision-makers of, for example, opportunities for improvement to address possible barriers that may limit the sustainability of the system, such as deficiencies in technical support and in the timely resolution of emerging problems. This study provides important knowledge based on the opinion of physicians on the intention to use SINADEF, which should effectively contribute to its institutionalization in the country.

Acknowledgments

We thank Vital Strategies and the Bloomberg “Data for Health” initiative for the opportunity to explore this topic. We thank the professors of San Marcos University who participated as reviewers of the manuscript drafts. We thank Carolina Tarqui, Javier Silva, and Diana Kumar for their contributions and comments.

Abstract

Background: HIV and sexually transmitted infections (STIs) are major global public health concerns. Over 1 million curable STIs occur every day among people aged 15 years to 49 years worldwide. Insufficient testing or screening substantially impedes the elimination of HIV and STI transmission.

Objective: The aim of our study was to develop an HIV and STI risk prediction tool using machine learning algorithms.

Methods: We used clinic consultations that tested for HIV and STIs at the Melbourne Sexual Health Centre between March 2, 2015, and December 31, 2018, as the development data set (training and testing data set). We also used 2 external validation data sets, including data from 2019 as external "validation data 1" and data from January 2020 and January 2021 as external "validation data 2." We developed 34 machine learning models to assess the risk of acquiring HIV, syphilis, gonorrhea, and chlamydia. We created an online tool to generate an individual's risk of HIV or an STI.

Results: The important predictors for HIV and STI risk were gender, age, men who reported having sex with men, number of casual sexual partners, and condom use. Our machine learning–based risk prediction tool, named MySTIRisk, performed at an acceptable or excellent level on testing data sets (area under the curve [AUC] for HIV=0.78; AUC for syphilis=0.84; AUC for gonorrhea=0.78; AUC for chlamydia=0.70) and had stable performance on both external validation data from 2019 (AUC for HIV=0.79; AUC for syphilis=0.85; AUC for gonorrhea=0.81; AUC for chlamydia=0.69) and data from 2020-2021 (AUC for HIV=0.71; AUC for syphilis=0.84; AUC for gonorrhea=0.79; AUC for chlamydia=0.69).

Conclusions: Our web-based risk prediction tool could accurately predict the risk of HIV and STIs for clinic attendees using simple self-reported questions. MySTIRisk could serve as an HIV and STI screening tool on clinic websites or digital health platforms to encourage individuals at risk of HIV or an STI to be tested or start HIV pre-exposure prophylaxis. The public can use this tool to assess their risk and then decide if they would attend a clinic for testing. Clinicians or public health workers can use this tool to identify high-risk individuals for further interventions.

Introduction

HIV and sexually transmitted infections (STIs) are major global public health concerns [1,2]. The World Health Organization (WHO) estimated that over 1 million curable STIs occur every day among people aged 15 years to 49 years worldwide [3]. An estimated 29,090 people have been infected with HIV in Australia as of the end of 2020, with an HIV prevalence rate of 0.14% among people over 15 years old [4]. The estimated undiagnosed HIV infection rate among all people living with HIV in Australia was about 9% in 2020 [4]. Gonorrhea, chlamydia, and early syphilis can be asymptomatic. There were large increases in STIs in Australia between 2013 and 2017. The notification rates of STIs for chlamydia increased from 302.2/100,000 to 394.9/100,000 in men and from 430.7/100,000 to 441.8/100,000 in women, gonorrhea increased from 91.1/100,000 to 174.2/100,000 in men and from 39.6/100,000 to 61.8/100,000 in women, and syphilis increased from 12.3/100,000 to 31.1/100,000 in men and from 1.4/100,000 to 5.5/100,000 in women [5]. In addition, STIs account for a large health and economic burden in limited-income countries [6].

In response to the rising rates of STIs, the WHO proposed the “Global health sector strategy on Sexually Transmitted Infections, 2016-2021,” which aimed to end STI epidemics as public health concerns by 2030. This specifically includes a 90% reduction in gonorrhea incidence globally from the 2018 global baseline and achieving a rate of ≤50 congenital syphilis cases per 100,000 live births in 80% of countries [7]. In 2018, the United Nations proposed “The 2030 Agenda for Sustainable Development,” which called for an end to the AIDS epidemic by 2030 [8]. Key to the effective control of these infections is accessible health care and, in particular, frequent testing because treated infections rapidly become noninfectious [2]. Screening of asymptomatic individuals is important for diagnosis, treatment, prevention, and control of HIV and STIs [9]. Barriers to testing include misjudgment of an individual's HIV and STI risk, limited availability of testing, and high cost of testing [10]. Therefore, developing innovative tools will help individuals accurately judge their risk of HIV and STIs, hence increasing screening in high-risk individuals.

An easily accessible and user-friendly tool that accurately identifies an individual's risk of infection could form part of a web-based risk prediction program and play a role in risk prediction and personalized risk management [11]. Providing the public with risk prediction tools to assist them in estimating the risk of HIV and STIs may encourage those individuals at high risk to test more regularly. A previous study showed that increased risk perceptions were associated with greater STI health care use (eg, testing) [12]. An HIV and STI risk prediction tool may increase risk perceptions and motivate individuals to seek HIV and STI testing or treatment. Another review study suggested that web-based screening apps can effectively increase the uptake of health screening in the general population [13]. However, there is no web-based tool we could identify that provides users with an individual’s current quantitative risk of HIV and STIs (gonorrhea, chlamydia, and syphilis) using self-reported questions.

A number of mathematical techniques can be used to generate an individual’s risk of HIV and STIs. Logistic regression has limitations in predictive analysis that uses complex and big data. Logistic regression methods require strong assumptions and cannot easily deal with nonlinear relationships, interactions, and multicollinearity [14,15]. In contrast, nonlinear machine learning approaches can address these limitations and have numerous advantages (eg, capturing nonlinear relationships and interactions) in predictive analysis using big data [16]. Machine learning also can identify rare health outcomes with high accuracy [17]. Ensemble learning is also a machine learning approach that combines multiple machine learning algorithms to improve the model's performance [18].

Despite the advantages of machine learning approaches, there is an absence of individual risk prediction tools for HIV and STI risk using machine learning models. Existing studies using machine learning algorithms to predict HIV and STI acquisition mainly focus on HIV [19-30], and few focus on STIs [19,21,31]. Of these HIV prediction studies, 4 studies focused on high-risk individuals (such as men who have sex with men [MSM] [20,21,24,29]), 2 studies used imaging or clinical text data [22,30], 4 studies used more than 40 predictors [23,26-28], and 2 studies assessed future but not current HIV prediction [19,25]. Of the STI prediction studies, 1 study was conducted with MSM [21], and the other 2 studies focused on future STI prediction [19,31]. These studies also found that nonlinear machine learning models (eg, random forest [RF], gradient boosting machine [GBM], and neural networks) performed better than logistic regression in HIV and STI prediction [19,21,24,31]. These published studies highlight a lack of machine learning models that use simple self-reported questions, predict both the risk of HIV and STIs, and can be used by both men and women. Therefore, to address the current lack of studies that predict the risk of both STIs and HIV, particularly in lower-risk heterosexual individuals, we aimed to use a stacking ensemble learning framework and self-reported questions to predict HIV and 3 common STIs (gonorrhea, chlamydia, and syphilis) in both men and women and a subsequent web-based HIV and STI risk prediction tool.

Methods

Study Population

The Melbourne Sexual Health Centre (MSHC) is the largest public sexual health center in Victoria, Australia and offers free HIV and STI testing and management [32]. At the MSHC, individuals' demographic information and sexual practices are recorded using a computer-assisted self-interview (CASI) at each visit, at least 3 months apart [33]. We used clinical consultation data from the electronic health record (EHR) at MSHC to develop and validate the risk prediction model. We chose March 2, 2015, as the commencement date because this date was when we adopted a new testing platform for gonorrhea and chlamydia (Aptima Combo, Hologic, Marlborough, MA). Our study data included men and women aged 18 years and older who was tested for HIV or an STI at the MSHC between March 2, 2015, and January 29, 2021. We excluded transgender people and individuals aged younger than 18 years.

We used data from March 2, 2015, to December 31, 2018, as the development data set (training and testing data set). The HIV study data set included training and testing data (88,642 consultations). The syphilis, gonorrhea, and chlamydia study data sets had 92,291, 97,473, and 115,845 consultations, respectively.

We used temporal validation as the external validation to evaluate the transportability and generalizability of our risk prediction models. The COVID-19 epidemic may potentially have changed the demographics of those who attend the MSHC [34]. We performed 2 temporal validations to validate our models further and reduce the possible bias caused by COVID-19. The 2 external validation data sets included data from 2019 as external "validation data 1" and data from January 2020 and January 2021 as external "validation data 2." For HIV, the first external validation data set contained 28,875 consultations, and the second external validation data set contained 18,052 consultations. For syphilis, the first external validation data set contained 30,302 consultations, and the second external validation data set contained 19,150 consultations. For gonorrhea, the first external validation data set contained 36,805 consultations, and the second external validation data set contained 22,886 consultations. For chlamydia, the first external validation data set contained 36,393 consultations, and the second external validation data set contained 22,615 consultations.

Ethical Approval

Ethical approval was granted by the Alfred Hospital Ethics Committee, Melbourne, Australia (project number: 124/18). All methods were carried out following relevant guidelines and regulations of the Alfred Hospital Ethics Committee. As this was a retrospective study involving minimal risk to the privacy of the study participants, the need for informed consent was waived by the Alfred Hospital Ethics Committee. All identifying details of the study participants were removed before any computational analysis.

Predictors

The data fields we selected for inclusion as predictors were informed by literature review, expert opinion, and prior work [21]. The predictors were self-reported questions from the EHR, including demographics, sexual practices, STI history, and STI contact history (summarized in Table 1 and Tables S1-S5 in Multimedia Appendix 1).

Table 1. Characteristics of clinic consultations in the training and testing data set.

Variables	HIV (n=88,642 consultations)	Syphilis (n=92,291 consultations)	Gonorrhea (n=97,473 consultations)	Chlamydia (n=115,845 consultations)
Gender, n (%)				
Female	26,651 (30.1)	27,134 (29.4)	31,282 (32.1)	38,548 (33.3)
Male	61,991 (69.9)	65,157 (70.6)	66,191 (67.9)	77,297 (66.7)
Age at consultation (years), median (IQR)	29.0 (24.0-35.0)	29.0 (25.0-35.0)	28.0 (24.0-35.0)	28.0 (24.0-34.0)
Country of birth, n (%)				
Australia	39,148 (44.2)	40,990 (44.4)	43,881 (45.0)	51,162 (44.2)
Overseas	46,003 (51.9)	47,670 (51.7)	49,835 (51.1)	60,272 (52.0)
Missing	3491 (3.9)	3631 (3.9)	3757 (3.9)	4411 (3.8)
STI[a] symptoms, n (%)				
No	56,175 (63.4)	57,413 (62.2)	54,595 (56.0)	68,584 (59.2)
Yes	25,067 (28.3)	27,150 (29.4)	34,751 (35.7)	38,930 (33.6)

[a] STI: sexually transmitted infection.

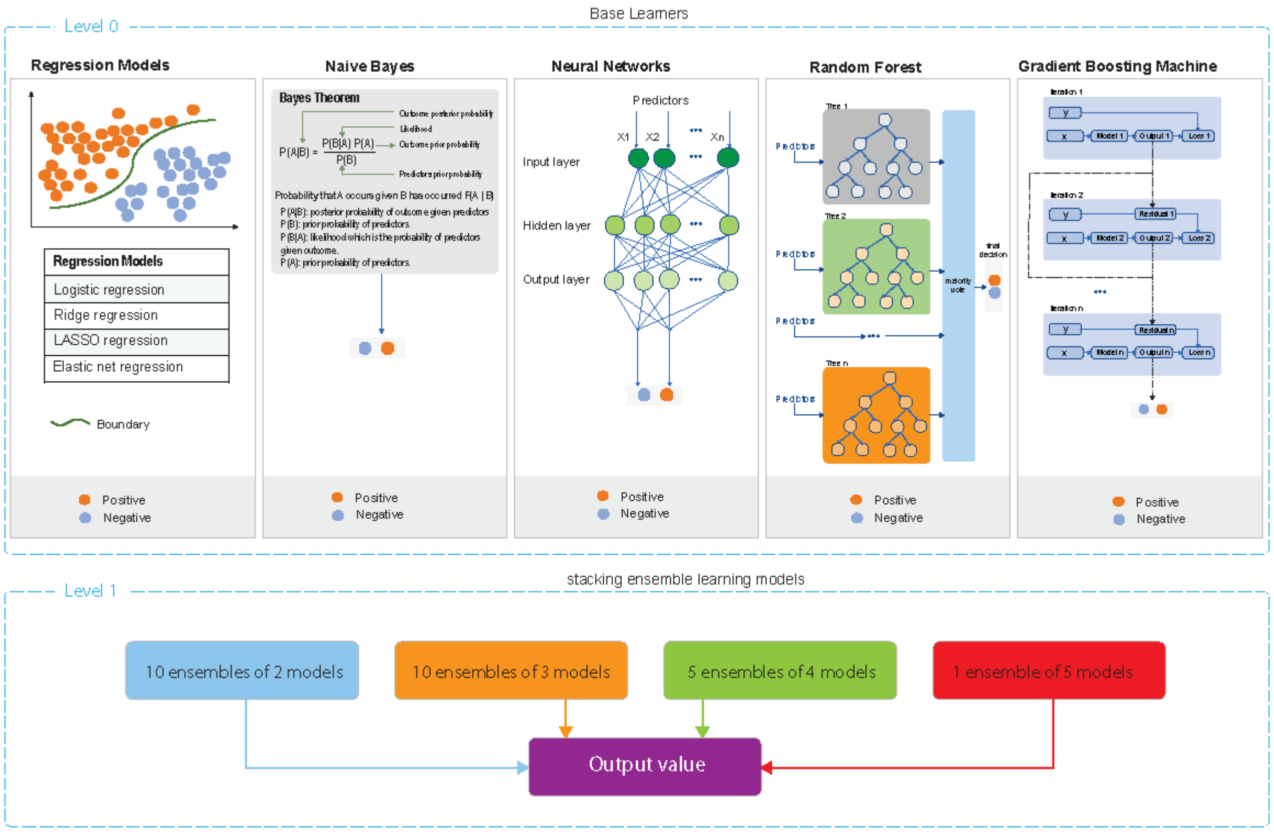
Measurement of Outcomes

HIV infection was defined as a new diagnosis of HIV based on serology. Syphilis infection was defined as a new diagnosis of early syphilis (primary, secondary, and early latent [<2 years]) using a blood test or nucleic amplification test (NAAT). Gonorrhea infection was defined as a new diagnosis of gonorrhea using culture or NAAT at any anatomical site. In the clinic, gonorrhea testing initially occurs with NAAT, and culture is mostly used after a positive NAAT. Chlamydia infection was defined as a new diagnosis using NAAT at any anatomical site. Our previous publications report the diagnostic methods in detail [19,21].

Risk Assessment Model Development

We developed 34 machine learning models to assess the risk of acquiring HIV, syphilis, gonorrhea, and chlamydia (details in Figure 1).

Figure 1. Development of machine learning algorithms. The architecture of the gradient boosting machine was adapted from Feng et al [35]. LASSO: least absolute shrinkage and selection operator.



Base Learner

Logistic regression has been widely used to predict the risk of incident STIs and HIV [36,37]. GBM uses boosting based on decision trees by adjusting the parameters to minimize a loss function and determine the optimal point with the smallest error [38]. RF comprises an ensemble of decision trees using bootstrap aggregation and randomization of predictors to achieve a high degree of predictive accuracy [39]. Naive Bayes (NB) is simple, has high accuracy and speed in large databases, and has been widely used for disease classification [40]. Deep learning (DL) has effectively solved many medical problems and utilizes a hierarchical level of an artificial neural network to perform the classification process [41].

We first established 4 regression models, including logistic regression, ridge regression, least absolute shrinkage and selection operator (LASSO) regression, and elastic net regression (ENR). Based on the preliminary results of the 4 regression analyses, we found that ENR was better than the other 3 regression analyses (details in Multimedia Appendix 1). Considering our previous machine learning study among MSM [21] and the advantages of NB (eg, high accuracy and speed in large databases), we developed 5 base models, including the aforementioned ENR, NB, DL (neural networks), RF, and GBM.

Stacking Ensemble Learning

Stacking ensemble learning is an ensemble learning method that trains a new model based on the combined predictions of 2 (or more) previous machine learning models. Stacking ensemble learning often performs better than individual machine learning techniques [42]. We systematically established 26 ensemble learning models by combining the aforementioned 5 base models to improve the performance of predicting HIV and STIs. Details are in Multimedia Appendix 1 (summarized in Table S6).

Machine Learning Training Techniques

Our models used a one-hot encoding scheme for data classification. We did not impute missing data but created a binary feature vector indicating missing values. The data were considered “imbalanced” given that each of the 4 infections was <10%. Imbalanced data may cause either overfitted or underperformed predictive results [43]. We used 5 x 10 (5 outer folds, 10 inner folds) nested cross-validation (CV) for model selection and training [21,44]. The outer 5-fold CV was used to address the selection bias caused by using a single data set. The inner 10-fold CV was used on the training data set to perform the hyperparameter tuning of machine learning models. We used the area under the curve (AUC) to select the best model. An AUC of 0.7 to 0.8 is considered acceptable, 0.8 to 0.9 is considered excellent, and >0.9 is considered outstanding [45]. Machine learning models were built using the *h2o* package (version 3.32.1.2) in R software (3.6.1 and R studio 1.2.5019).

Estimating the Risk of HIV and STIs

Our machine learning models predicted the probability of HIV or an STI with a normalized distribution between values 0 and 1. The model-predicted probability was calibrated to the actual prevalence level of HIV and STIs. We used a logistic function to provide a fitting curve for each model-predicted probability and infection prevalence. We regarded the estimated infection prevalence as the “calibrated risk” of infection and presented it in the risk report. We used MATLAB R2019a (MathWorks, Natick, MA) to calibrate the model-predicted probability to the actual prevalence level. The method is described in detail in our previous paper [19]. We classified the calibrated risk of HIV or an STI into 3 risk levels: HIV (low, <0.1%; medium, 0.1%-1.0%; and high, >1.0%), syphilis (low, <0.2%; medium, 0.2%-5.0%; and high, >5.0%), gonorrhea (low, <0.1%; medium, 0.1%-1.0%; and high, ≥1.0%), and chlamydia (low, <2.0%; medium, 2.0%-15.0%; and high, >15.0%).

Establishment of a HIV and STI Risk Prediction Tool

To investigate the effect of predictors, we used the best base machine learning model to calculate the variable importance for HIV, syphilis, gonorrhea, and chlamydia infection. We identified and selected predictors that accounted for more than 80.0% of the overall model performance for each infection. We retrained, retested, and revalidated the best performing model based on these predictors. We compared the AUC, sensitivity, and specificity to re-evaluate the model performance with the shortlisted predictors. We also used the AUC to evaluate the change in performance in the best machine learning model before and after predictor shortlisting (details in Multimedia Appendix 1). We formed a new questionnaire by pooling the important predictors to develop a web-based tool for HIV and STI risk prediction.

Results

Characteristics of the Study Data

Our training and testing data included 216 (0.2% of 88,642 consultations) HIV infections, 787 (1.9% of 92,291 consultations) syphilis infections, 7581 (7.8% of 97,473 consultations) gonorrhea infections, and 10,217 (8.8% of 115,845 consultations) chlamydia infections. The proportion of each of the 4 infection data sets that was men was between 66.7% (77,297/115,845) and 70.6% (65,157/92,291). Further details are provided in Table 1 and Table S1 in Multimedia Appendix 1. The characteristics of the external validation data are shown in Tables S2-S5 in Multimedia Appendix 1.

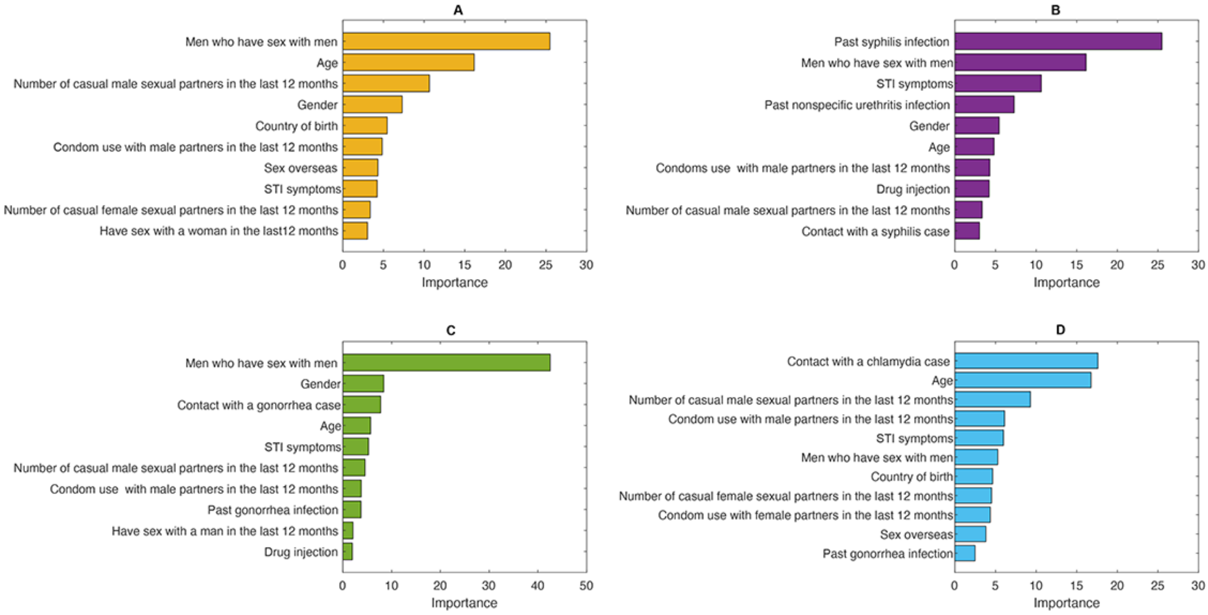
Selecting the Best ML Model for the HIV and STI Risk Prediction Tool

Our results demonstrated that the ensemble learning models performed better than individual machine learning models. Of all 34 models, our best model (ensemble ENR+GBM+RF) provided acceptable or excellent performance on testing data for predicting HIV (AUC=0.78), syphilis (AUC=0.84), gonorrhea (AUC=0.78), and chlamydia (AUC=0.70; Figures S1-S3 in Multimedia Appendix 1). Details on the testing data analysis are provided in Tables S7-S22 in Multimedia Appendix 1. Our external validation results showed very comparable AUCs (0.69-0.85) to the testing data analysis. Details on the external validation analysis are provided in Tables S7-S22 in Multimedia Appendix 1.

Selecting the Most Important Predictors for the HIV and STI Risk Prediction Tool

The top 10 predictors for each of the 4 infections accounted for >80.0% of the overall HIV and STI model performance. These predictors included gender, presence of STI symptoms, MSM, age, country of birth, having sex with a man in the last 12 months, the number of casual male sexual partners in the last 12 months, condom use with male partners in the last 12 months, the number of casual female sexual partners in the last 12 months, drug injection in the last 12 months, sex overseas in the last 12 months, past gonorrhea infection, past nonspecific urethritis infection, past syphilis infection, contact with a gonorrhea case, contact with a chlamydia case, and contact with a syphilis case (Figure 2). We formed the final HIV and STI risk prediction questionnaire with the top 10 predictors for each infection.

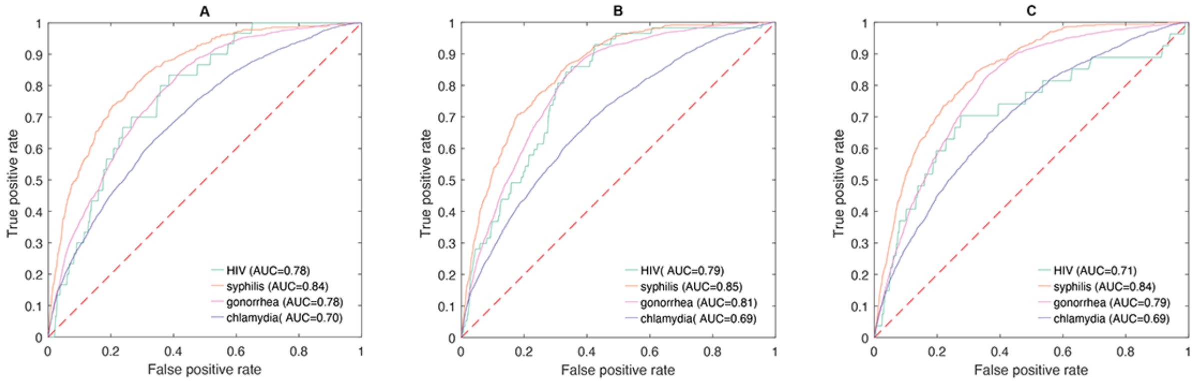
Figure 2. Importance of the top 10 predictors in the prediction of HIV or sexually transmission infections (STIs) using a gradient boosting machine, for detecting (A) HIV, (B) syphilis, (C) gonorrhea, and (D) chlamydia.



Establishment and Evaluation of the HIV and STI Risk Prediction Tool, MySTIRisk

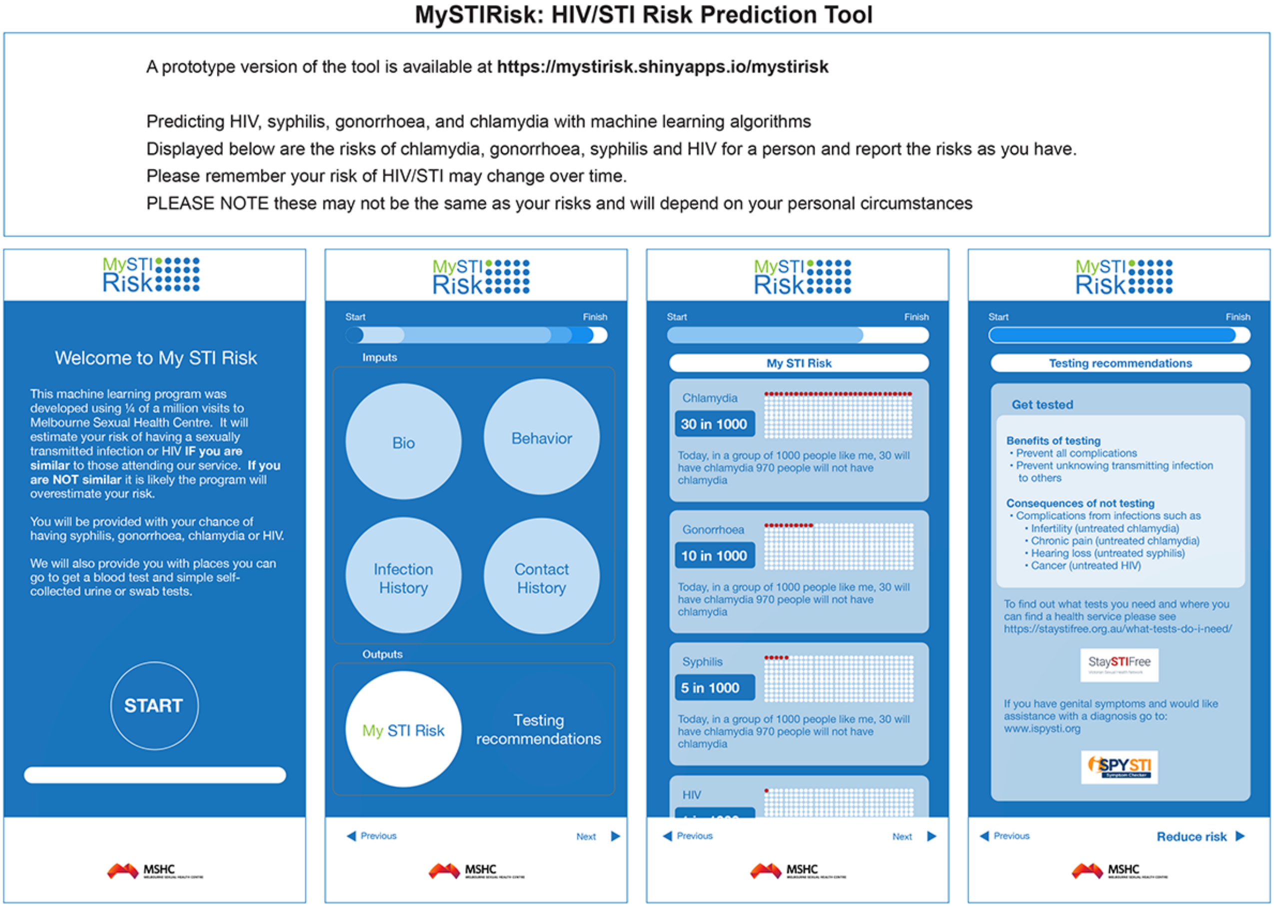
Based on the selected most important predictors and the best model (ensemble ENR+GBM+RF), we built a HIV and STI risk prediction tool, named *MySTIRisk*. We examined *MySTIRisk* and demonstrated its performance on testing to be acceptable or excellent (AUC for HIV=0.78; AUC for syphilis=0.84; AUC for gonorrhea=0.78; AUC for chlamydia=0.70), similar to its original model based on predictors. Our risk prediction tool obtained stable performance on external validation data from 2019 (AUC for HIV=0.79; AUC for syphilis=0.85; AUC for gonorrhea=0.81; AUC for chlamydia=0.69). Our risk prediction tool also achieved stable performance on external validation data from 2020-2021 (AUC for HIV=0.71; AUC for syphilis=0.84; AUC for gonorrhea=0.79; AUC for chlamydia=0.69; Figure 3 and Tables S23-S26 in Multimedia Appendix 1). Using the selected predictors, our risk prediction tool showed comparable AUCs to the best machine learning model using all predictors (Table S27 in Multimedia Appendix 1).

Figure 3. Receiver operating characteristic curve performance of the HIV and sexually transmitted infection (STI) risk prediction tool on (A) testing data analysis from 2015-2018, (B) external data validation analysis from 2019, and (C) external data validation analysis from 2020-2021. AUC: area under the curve.



To estimate the risk of HIV or an STI, we fitted the data using a logistic function to provide a fitting curve for each model-predicted probability and infection prevalence (Figures S4-S7 in Multimedia Appendix 1). Then, a prototype version of the tool was created with R Shiny [46,47] to allow for individual input and HIV and STI risk computation. A prototype version of the tool is available online [48]. The graphical user interface elements of the tool are summarized in Figure 4. The web application collects individual characteristics, processes the collected characteristics, loads the trained machine learning models, calculates a quantitative HIV and STI risk, and displays the results of the risk and recommendations. The web application's input was designed using previous successful websites or internal CASI questionnaires (60,000 entries a year) that operate at MSHC and used individual characteristic data, including demographics, sexual practices, STI history, and STI contact history. The web application's output includes HIV and STI risk prediction results and recommendations that were developed in consultation with Professor Jon Emery at the University of Melbourne, who is an expert in the communication of risk (see the Acknowledgments section). We acknowledge that this is a prototype and that further development will take place in optimizing this output for accurate risk communication.

Figure 4. Graphical user interface elements of the HIV and sexually transmitted infection (STI) risk prediction tool, called MySTIRisk. A prototype version of the tool is available at [48]. Machine learning algorithms are used to predict a person’s risk of chlamydia, gonorrhea, syphilis, and HIV.



MySTIRisk: HIV/STI Risk Prediction Tool

A prototype version of the tool is available at **https://mystirisk.shinyapps.io/mystirisk**

Predicting HIV, syphilis, gonorrhoea, and chlamydia with machine learning algorithms
Displayed below are the risks of chlamydia, gonorrhoea, syphilis and HIV for a person and report the risks as you have.
Please remember your risk of HIV/STI may change over time.
PLEASE NOTE these may not be the same as your risks and will depend on your personal circumstances

Welcome to My STI Risk

This machine learning program was developed using ¼ of a million visits to Melbourne Sexual Health Centre. It will estimate your risk of having a sexually transmitted infection or HIV **IF you are similar** to those attending our service. **If you are NOT similar** it is likely the program will overestimate your risk.

You will be provided with your chance of having syphilis, gonorrhoea, chlamydia or HIV.

We will also provide you with places you can go to get a blood test and simple self-collected urine or swab tests.

Chlamydia: 30 in 1000. Today, in a group of 1000 people like me, 30 will have chlamydia 970 people will not have chlamydia

Gonorrhoea: 10 in 1000. Today, in a group of 1000 people like me, 30 will have chlamydia 970 people will not have chlamydia

Syphilis: 5 in 1000. Today, in a group of 1000 people like me, 30 will have chlamydia 970 people will not have chlamydia

Get tested

Benefits of testing
- Prevent all complications
- Prevent unknowing transmitting infection to others

Consequences of not testing
- Complications from infections such as
  - Infertility (untreated chlamydia)
  - Chronic pain (untreated chlamydia)
  - Hearing loss (untreated syphilis)
  - Cancer (untreated HIV)

To find out what tests you need and where you can find a health service please see https://staystifree.org.au/what-tests-do-i-need/

If you have genital symptoms and would like assistance with a diagnosis go to: www.ispysti.org

These are examples of the HIV and STI risk prediction results:

> *Your HIV risk is about 2/1000. In a group of 1000 people like me, 2 will have HIV. 998 people will not have HIV.*
>
> *Your syphilis risk is about 10/1000. In a group of 1000 people like me, 10 will have syphilis. 990 people will not have syphilis.*
>
> *Your gonorrhea risk is about 30/1000. In a group of 1000 people like me, 30 will have gonorrhea. 970 people will not have gonorrhea.*
>
> *Your chlamydia risk is about 50/1000. In a group of 1000 people like me, 50 will have chlamydia. 950 people will not have chlamydia.*

The following examples describe testing recommendations:

- Benefits of testing: Prevent all complications and prevent unknowingly transmitting infection to others.
- Consequences of not testing: Complications from infections such as infertility (untreated chlamydia), chronic pain (untreated chlamydia), hearing loss (untreated syphilis), and cancer (untreated HIV).

Discussion

Principal Findings

This is the first web-based risk prediction tool based on machine learning algorithms and self-reported data to accurately identify HIV and syphilis, gonorrhea, and chlamydia infection in men and women and was stable on external validation. Our findings showed that machine learning algorithms could predict HIV and STIs in clinic attendees. Our results also showed that stacking ensemble learning algorithms perform better than individual machine learning models to predict HIV and STIs. We then developed a web-based application to provide an immediate and individualized assessment for the risk of a positive diagnosis of HIV and 3 STIs. Our application could be a part of clinic websites or digital health platforms to identify individuals with a higher risk of HIV and STIs or potential candidates for HIV pre-exposure prophylaxis (PrEP). Further validation studies in other countries can assess the usefulness of this risk prediction tool, which helps reduce HIV and STI incidence and the cost of HIV and STI screening, which requires expensive equipment and specialized expertise.

Comparison With Prior Work

Our results showed that nonlinear machine learning algorithms provided better performance than the conventional logistic regression for predicting HIV and STIs in men and women. Our findings are consistent with the results of previous machine learning predictive models for HIV and STIs [19,21,24,31]. Bao et al [21] showed that a GBM model performed better than logistic regression in MSM. Our study suggests that nonlinear machine learning models (eg, GBM, RF) could provide better performance than conventional logistic regression even without ensemble learning.

Our results showed that the stacking ensemble machine learning techniques outperform individual machine learning models. We systematically developed and tested 34 machine learning models and found that stacking ensemble learning technology outperformed individual machine learning models [18]. Previous studies have used ensemble learning models to predict an individual's HIV risk [19,25]; however, no study has looked at the risk of gonorrhea, chlamydia, or syphilis using ensemble learning models. The only study we could identify was one that had predicted the risk of a repeat STI with ensemble learning. Elder et al [31] showed that an ensemble of models could perform better for 2 or more repeat STIs within 730 days of follow-up than the individual classifiers (AUC=0.76). Our results found that stacking ensemble techniques could also be applied to enhance the performance of HIV prediction. The AUC of our ensemble HIV model (AUC=0.78, 95% CI 0.74-0.83) was higher than that in a similar study in Kenya and Uganda for HIV risk prediction (AUC=0.73, 95% CI 0.71-0.76) [25]. We also found that the combinations of more individual machine learning models do not necessarily lead to a better stacking ensemble model. For example, in our study, the stacking ensemble learning of 4 models for syphilis was not higher than a stacking ensemble learning of 3 models. We also found that a better performing stacking ensemble model always included GBM. The findings of our stacking ensemble learning strategies may have implications for future stacking ensemble learning frameworks.

Our models have several strengths compared with previous machine learning models for predicting HIV and STIs. First, our predictive models were not limited to high-risk groups (such as MSM). HIV and STI risk prediction models have been published previously but mainly for high-risk individuals, such as MSM [20,21,24,29]. Our models could predict HIV and STI acquisition in both men and women, including homosexual and heterosexual individuals. Second, our predictive models only used self-reported and simple questions to develop models. Previously published studies used numerous predictors for their models [23,26-28]. Third, we systematically developed 26 ensemble models. In our study, we tested all possible combinations of 5 base models. The final strength of our research is that we performed 2 external validation analyses of each model.

We were unable to locate any web-based, publicly available tool to quantify STI risk. We identified some available web-based HIV prediction tools, such as the “HIV risk prediction tool” [49], “HIV/AIDS Risk Calculator” [50], and “Online Risk Assessment” [51]. We also identified some available web-based STI prediction tools, such as “Find out if you need to get tested for an STD” [52], “Online STI Testing” [53], and “Take a free test” [54]. These HIV and STI prediction tools provide only subjective terms such as “high” risk or “You are advised to take an HIV/STI test.” Our risk prediction tool could quantify the risk of HIV and STIs. In addition, our artificial intelligence (AI)–based risk prediction tool can simultaneously provide risk scores for HIV and 3 common STIs (gonorrhea, chlamydia, and syphilis) for men and women aged 18 years and older.

Implications

Our web-based HIV and STI risk prediction tool can be used as a screening tool to potentially increase HIV and STI testing and encourage access to testing and health care (Figure S8 in Multimedia Appendix 1). The tool could be used on clinic websites so the public could assess their risk and then decide if they would attend a clinic for testing. It may also be used within a clinic to identify and triage those at higher risk of HIV and STIs if the demand in the clinic is too great to see everyone who attended. However, an AI-based risk prediction tool cannot replace formal HIV and STI testing and treatment in clinical settings, but it would allow individuals to understand their own risks and increase testing uptake. Our tool could increase risk perception and concern about infection, thus increasing HIV and STI testing. A study in the British population showed that increased risk perceptions are associated with greater STI health care use [12]. Further external validation of our AI-based risk prediction tool in other countries or regions, such as low- and middle-income countries, may provide an opportunity to reduce the cost of HIV and STI screening by better focusing testing on those at highest risk [55].

There are many possible ways that our web-based risk prediction tool could be potentially used, including as part of a behavioral intervention to control HIV and STIs or to help clinicians or public health workers identify high-risk individuals for risk management or further interventions. An example of this exists in adolescent health risk behaviors. Researchers used an individual’s risk behavior scores and personalized feedback as part of an intervention for health behaviors, including nutritional behaviors, physical activity, and sleep [56]. In this randomized clinical trial, the youths in the intervention group significantly reduced their risk behavior scores at 3 months compared with the control group [56]. Our web-based risk prediction tool could serve as a behavioral intervention tool in the same way.

Future work will investigate the effectiveness of this web-based HIV and STI risk prediction tool for behavioral change (ie, uptake of PrEP or condom promotion) and STI service utilization behaviors (timely clinic attendance and HIV and STI testing uptake) after receiving risk prediction results and testing recommendations. Implementing this web-based HIV and STI prediction tool may encourage individuals with STI symptoms or those at high risk without symptoms to attend health services for timely testing and regular testing. Since February 2009, the MSHC has offered MSM regular SMS reminders for STI screening [57]. For example, providing an estimated risk of HIV and STIs and risk reduction advice (ie, uptake of PrEP or condom promotion) among high-risk populations (eg, MSM) in an SMS reminder message may encourage testing and behavioral changes.

Limitations

This study has some limitations. First, the predictive factors depend on self-reported information from the CASI system, which is subject to the participants' recall, nonresponse, and social desirability bias. For example, MSM who declined to report the number of male partners were at a higher risk of chlamydia [58]. There has been substantial work undertaken on the CASI system's validity and accuracy [59]. Second, machine learning models may suffer from overfitting. We used repeated CV to tackle the overfitting problem. We also used ensemble learning methods to enhance the model's generalizability. Third, the generalizability of our models to those not attending the clinic or to other countries or regions is limited because it was derived from a single sexual health service. Thus, if it is used in other countries and regions, further validation is required. Finally, the risks of HIV have changed rapidly over this time by introducing PrEP, so future models will need to include this question, given how the potency of this single preventive strategy.

Conclusions

This is the first web-based risk assessment tool using machine learning algorithms and self-reported data to identify HIV, syphilis, gonorrhea, and chlamydia in men and women. Our online risk prediction tool could accurately predict the risk of HIV and STIs in clinic attendees with a simple self-administered questionnaire. Our risk prediction tool could be part of clinic websites or digital health platforms. The public can use this risk prediction tool to assess their HIV and STI risk to inform testing. Clinicians or public health workers can use this risk prediction tool to identify high-risk individuals for further interventions.

Abstract

Background: Emergency department (ED) crowding is a global health care issue. eHealth systems have the potential to reduce crowding; however, the true benefits are seldom realized because the systems are not integrated into clinicians' work. We sought a deep understanding of how an eHealth system implementation can be structured to truly integrate the system into the workflow.

Objective: The specific objectives of this study were to examine whether work system theory (WST) is a good approach to structure the implementation of an eHealth system by incorporating the entire work system, and not just the eHealth system, in the implementation framework; identify the role that specific elements of WST's static framework and dynamic work system life cycle model play in the implementation; and demonstrate how WST can be applied in the health care setting to guide the implementation of an eHealth system.

Methods: Through a case study of an ED in a rural hospital, we used a mixed methods approach to examine the implementation of a surge management system through the lens of WST. We conducted 14 hours of observation in the ED; 20 interviews with clinicians, management, and members of the implementation team; and a survey of 23 clinicians; reviewed related documentation; and analyzed ED data to measure wait times. We used template analysis based on WST to structure our analysis of qualitative data and descriptive statistics for quantitative data.

Results: The surge management system helped to reduce crowding in the ED, staff was satisfied with the implementation, and wait time improvements have been maintained for several years. Although study participants indicated changes to their workflow, 72% (13/18) of survey participants were satisfied with their use of the system, and 82% (14/17) indicated that it was integrated with their workflow. Examining the implementation through the lens of WST enabled us to identify the aspects of the implementation that made it so successful. By applying the WST static framework, we saw how the implementation team incorporated the elements of the ED work system, assessed their alignment, and designed interventions to address areas of misalignment. The dynamic work system life cycle model captured how planned and unplanned changes were managed throughout the iterative implementation cycle—83% (15/18) of participants indicated that there was sufficient management support for the changes and 80% (16/20) indicated the change served an important purpose.

Conclusions: The broad scope and holistic approach of WST is well suited to guide eHealth system implementations as it focuses efforts on the entire work system and not just the IT artifact. We broaden the focus of WST by applying it to the implementation of an ED surge management system. These findings will guide further studies and implementations of eHealth systems using WST.

Introduction

Background

Emergency department (ED) crowding is a major global health care issue [1]. The negative consequences are well established and include adverse patient outcomes and increased mortality [1,2]. ED crowding describes a situation in which the demand for emergency services exceeds the ability to provide care in a reasonable amount of time. When an ED has reached the point of overcapacity, the hospital implements a process, called surge, to allow for decompression. The use of eHealth systems, including systems to manage surge, has the potential to offer numerous benefits for EDs; however, the benefits have often been less than anticipated in many cases owing to implementation difficulties [2]. In particular, the difficulty of integrating the system into clinicians' work is cited as a key barrier to the successful implementation of ED [3] and other eHealth systems [4,5]. Several systematic reviews of eHealth interventions found that workflow was one of the most common barriers to successful implementations [6-8]. Granja et al [6] recommended that there is a critical need to perform in-depth studies of the workflow when implementing eHealth interventions to identify facilitators and barriers at the earliest possible stage of the implementation to ensure that they are defined in the implementation strategy. This highlights the need for those undertaking such projects to understand the factors that affect the staff's work and workflow, so that they can modify and improve the implementation to align with the organization's and staff's requirements. However, we lack a thorough understanding of how the implementation of such systems can be structured to incorporate the broad work system.

Objectives

We propose that using work system theory (WST) [9,10] to guide the implementation of eHealth systems may help to attain desired outcomes by incorporating the entire work system into the implementation framework. To evaluate whether WST will be a good approach, we examined the implementation of a surge management system in an ED of a rural, Canadian, 80-bed hospital through the lens of WST.

The surge management system was designed to track patient demand and capacity in the ED, calculate surge levels, and prescribe volume-based staffing. One of the most important eHealth systems in the health care domain is the ED information system to manage information and workflow and support patient care in the emergency room, and there are numerous studies supporting the advantages of its use [2]. However, although surge management is often a component of many ED information systems and there are a plethora of studies examining many processes to manage surge (ie, lean management [11], small cycles of process changes [12], and implementation of fast-tracking [13]), there are few studies examining eHealth systems specifically for the management of surge in the ED.

WST is a well-established theory for understanding relationships between technology and work systems. A work system is "a system in which human participants and/or machines perform work (processes and activities) using information, technology, and other resources to produce specific products/services for specific internal and/or external customers" (p75) [9]. WST is based on the premise that systems, and the work processes they affect must be properly managed to fit with practice. The adoptive entity is not only the system but also the entire IT-enabled work system. WST views the work system from two perspectives: (1) a static framework, with (2) a dynamic life cycle. The static framework presents a view of the work system at a particular time interval through 9 elements constituting the work system's form, function, and environment. According to WST, the 6 internal elements of the static framework—processes and activities, participants, information, technologies, customers, products, and services—should be balanced. The remaining 3 external elements—environment, infrastructure, and strategies—provide the context in which the work system operates. The dynamic work system life cycle (WSLC) model, presents how the work system changes over time through planned and emergent (unplanned) changes. In this study, we used a mixed methods approach to examine the implementation of the surge management system from a WST perspective and conceptualize the eHealth system as only a component within a broad ecosystem. We propose that WST can be useful for structuring the implementation of such eHealth systems.

Methods

Overview

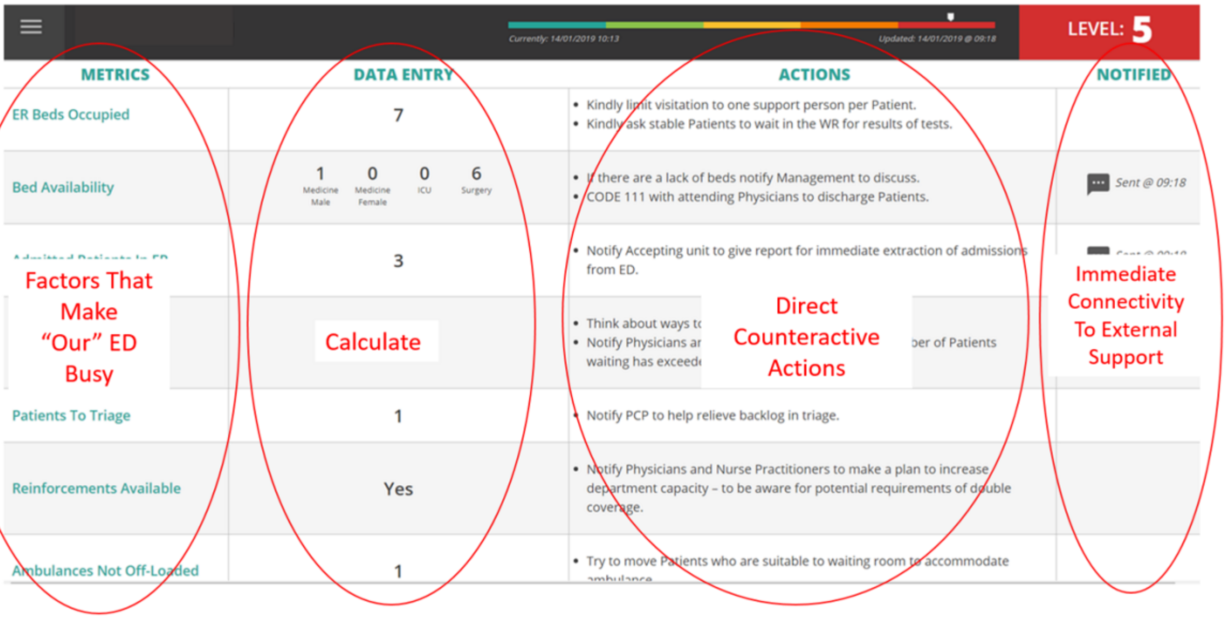
We followed a longitudinal case study methodology over approximately 2 years using a mixed methods approach to collect data during and after the implementation of the surge management system. The ED is located in a rural hospital that provides emergency and inpatient services to a catchment population of approximately 40,000. At any point of time, the ED has 8 stretchers, 3 high-turnover examination beds, and average daily volume of approximately 80 patient visits. The ED team is made up of 1 primary family physician who practices emergency medicine, 1 secondary coverage physician, 1 nurse practitioner, and up to 4 registered nurses per shift. In total, the ED has approximately 50 staff and management directly involved in surge management.

Surge Management System—Background

The surge management system is composed of the eHealth system and related interventions to manage surge levels in the ED (ie, new surge management processes and procedures and new personnel). When we refer to the surge management system in this study, we are not only referring to the eHealth system portion but also to the other components of the new surge management process. This reflects the view of WST that technology is only an element of the work system. The surge management system was implemented iteratively over approximately 5 years, and our study examines the last 2 years of the implementation, and in particular, the implementation of the eHealth system portion of the surge management system. The implementation team did not follow a formal implementation framework; instead, there was a unique situation in which the surge management system was developed by 2 ED clinicians, and they led the implementation.

The eHealth system portion of the surge management system is installed in the ED nursing station, and staff receives notifications of surge levels through a smartphone app via email and SMS text messages (Figure 1). Patient demand and capacity are entered at least every 2 hours for identified metrics that influence waiting times in the ED. Data are entered more frequently if the staff perceives the patient demand to be increasing. A surge level score is calculated in real time using algorithms. Each score has a corresponding set of prescribed volume-based staffing, management, and overcapacity protocols. For example, a total score of 40 triggers the highest level (level 5) and is associated with actions such as sending a text to frontline management and staff, calling 'Surge Level 5,' sending all patients with low acuity to the waiting room, and contacting physicians with potential discharges.

Figure 1. Screenshot of the surge management system.



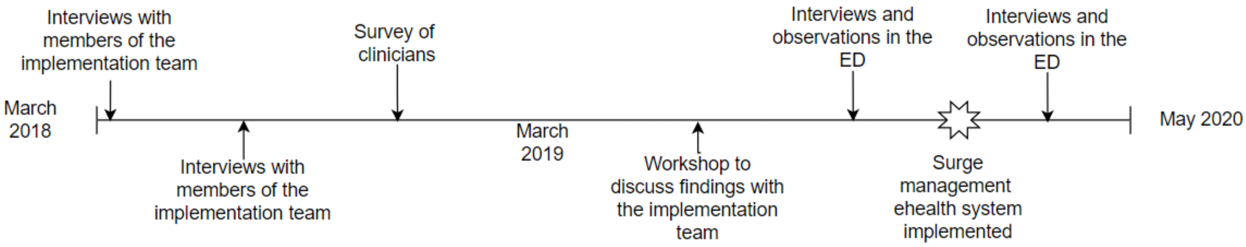
METRICS	DATA ENTRY	ACTIONS	NOTIFIED
ER Beds Occupied	7	• Kindly limit visitation to one support person per Patient. • Kindly ask stable Patients to wait in the WR for results of tests.	
Bed Availability	1 Medicine Male 0 Medicine Female 0 ICU 6 Surgery	• If there are a lack of beds notify Management to discuss. • CODE 111 with attending Physicians to discharge Patients.	Sent @ 09:18
	3	• Notify Accepting unit to give report for immediate extraction of admissions from ED.	
		• Think about ways t • Notify Physicians ar ber of Patients waiting has exceed	
Patients To Triage	1	• Notify PCP to help relieve backlog in triage.	
Reinforcements Available	Yes	• Notify Physicians and Nurse Practitioners to make a plan to increase department capacity – to be aware for potential requirements of double coverage.	
Ambulances Not Off-Loaded	1	• Try to move Patients who are suitable to waiting room to accommodate	

Data Collection and Analysis

We started our primary data collection several months after most of the manual changes to the surge management process were in place and as the team was beginning the implementation of the eHealth system portion. At this time, the clinicians used a manual version of the surge management system, in which they calculated surge levels by hand and manually reported the surge levels. Figure 2 shows a time line of our data collection.

We started by conducting open-ended interviews with 2 key members of the implementation team over a period of several months. These interviewees also worked in the ED and were key participants in the surge management process. This gave us background information about the decision to implement the surge management system, overview of the hospital and ED functioning, and insight into the ongoing and planned implementation processes.

Figure 2. Time line of data collection. ED: emergency department.



After 4 months, we distributed a web-based survey to the clinical staff in the ED to determine their satisfaction with the surge management system, the perceived benefits to the hospital, and the nature of their job level change. We also asked about their perceptions of fairness of the change, management support for the change, and their commitment to the change. Validated measures were used and adapted for our setting where necessary [14-18]. The survey was completed by 23 clinicians who play a direct role in surge management at the hospital. Though the sample size for the surveys appears small (n=23), it represents approximately 50% of the population of potential users. Refer to Multimedia Appendix 1 for the survey questions. To cope with the statistical limitations of the small survey sample size, we confined our quantitative analyses to descriptive statistics. We conducted a workshop with members of the implementation team to discuss the initial observations and to receive feedback, thereby increasing internal validity [19].

Then, we used the findings from the initial interviews and survey to inform our observations in the ED and to probe areas further through additional interviews approximately 9 months later and again after 4 months once all aspects of the eHealth system implementation were complete. We conducted 14 hours of observation over 2 days (1 day during the implementation process and 1 day after the eHealth portion of the surge management system, and all related changes were implemented). Each day included several clinical shifts so that we could see how the process functioned at various times throughout the day and at various surge levels. We had full access to the ED and our observations involved observing the environment, staff interactions and events, activities, and processes occurring in the hospital, which are associated with the use of the surge management system. We took notes on what was observed and asked questions to understand what was happening. Refer to Multimedia Appendix 1 for the observation protocol. During this time, we also conducted 16 interviews with frontline clinicians and management, and members of the implementation team were included in this group. Refer to Multimedia Appendix 1 for the interview guide. We stopped our phases of observations and interviews when data saturation was reached. All notes and recordings of interviews and observations were transcribed, and all sources were anonymized. We reviewed documentation on the system and the implementation, including documentation on the surge management system and the surge protocol, implementation plans, business case for the surge management system, and specification of outcome measures. Table 1 provides an overview of the data collection.

Table 1. Data collection overview.

Data source	Details	Respondent characteristics
Surveys	A total of 23 respondents	• A total of 13 internal support (n=4, 31% primary RNs[a]; n=1, 8% triage RN; n=5, 38% primary care paramedics; and n=3, 23% ED[b] physicians) and 10 external support (n=1, 10% admitting physician; n=3, 30% RN on inpatient unit; and n=6, 60% other)
Observations	A total of 14 hours of observation	• Observed the ED over 2 days and several clinical shifts—1 day during the system implementation and 1 day after the implementation. • Observed clinicians using and interacting with the system and managing flow in the ED. Full access was available wherever required.
Interviews	A total of 20 interviews	• Of the 20 interviews, 4 (20%) were with ED physicians, 11 (55%) were with ED RNs, 2 (10%) were with nurse practitioners, 1 (5%) was with primary care paramedic, 1 (5%) was with ED manager, and 1 (5%) was with patient care facilitator (inpatient beds)
Document review	Surge management system documentation, surge protocol documentation, implementation plans, business case for the surge management system, and specification of outcome measures	N/A[c]
ED wait time data	Patient ED wait times from point of registration to patient departure from the ED, from April 1, 2017, to March 31, 2021	N/A

[a] RN: registered nurse.

[b] ED: emergency department.

[c] N/A: not applicable.

We used template analysis [20] based on the elements of WST to structure the qualitative data analysis. Template analysis forced us to take a well-structured approach to handle the data [20] and allowed us to examine the data according to the elements of WST. We started by coding the data according to the static framework. The 9 elements of the static framework adapted to the implementation of the surge management system in the ED are shown in Figure 3 [9]. The figure shows that the *participants* use *information* and *technologies* in various *activities and processes* to create *products and services* to serve their *customers* (ie, *the 6 internal elements*). The *environment, strategies*, and available *infrastructure (ie, the 3 external elements)* also influence the work system. The arrows indicate that the specific elements in the work system must be in alignment.

We started by producing a list of codes (ie, the template) for each of the 9 elements of the WST and their interactions (ie, a code for participants, a code for activities and processes, and a code for the interaction between these elements). This enabled us to identify conceptual themes and then cluster them into broader groupings. Then, we created a hierarchical organization of codes, with groups of similar codes clustered together to produce more general high-order codes. For example, separate codes relating to different groups of *activities and processes* were incorporated into high-order activities and processes code. Then, this was further subdivided into codes to capture different activities and processes, and these were further divided into factors influencing when and how different activities and processes were followed, codes capturing the challenges with performing the different activities and processes, and codes capturing the interventions that the hospital implementation team conducted to deal with the challenges that arose (ie, changing the triage process in the ED, initiating training, or adding an extra physician). As we coded the transcripts and marked them with the appropriate code, we revised the template as needed. For example, as we identified an issue that was not covered by an existing code, we added a new code; we also deleted codes if we found that there was no need to use it. This was an iterative process of reading the transcripts, assigning codes, and reviewing the coding template until we were confident that the template was sufficiently clear and comprehensive.

Next, we used template analysis to code the WSLC model to capture the iterative process through which the system was implemented from initiation to operation and maintenance to identify planned and unplanned changes and the resulting interventions. Figure 4 [9] shows the WSLC model, adapted to the implementation of the surge management system. We coded the data according to the 4 phases of the WSLC model (ie, initiation, development, implementation, and operation and maintenance), interactions between the phases, planned and emergent changes, and outcomes. Similar to the coding of the static framework, this was an iterative process involving coding and further refinement of the template until we reached a state that enabled us to capture the WSLC model. Once all the transcripts were coded according to the final templates for the static framework and the WSLC model, we reviewed the coded text to identify themes and relationships between them.

Finally, we obtained data from the ED to measure wait times before, during, and after our study period. The data contained the patient ED wait times from patient registration to patient departure from the ED. We analyzed the data from approximately 1 year before our study started to 1 year after our study was completed (April 1, 2017, to March 31, 2021). We collected data for total patient visits, time to provider initial assessment (PIA), length of stay for departed patients (LOSDep), and patients who left without being seen. Time to PIA is the elapsed time from the point a patient first registers at the ED until the designated provider (ie, physician or nurse practitioner) makes contact. LOSDep is the time interval between a patient's arrival to the ED to the time the patient physically leaves the ED. The number of patients who left without being seen is the percentage of patients who have registered at the ED and have been triaged but leave before being seen by a designated provider.

Figure 3. Static framework for the surge management system (adapted from the publication by Alter [9]). ED: emergency department; RN: registered nurse.

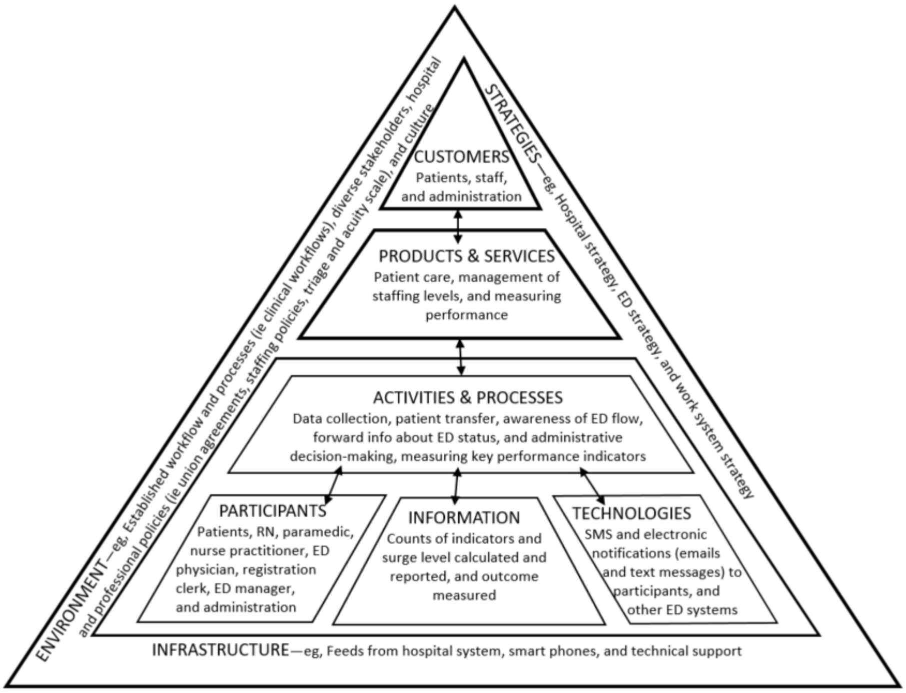


Figure 4. Work system life cycle model for the surge management system (adapted from the publication by Alter [9]). ED: emergency department; PIA: provider initial assessment.

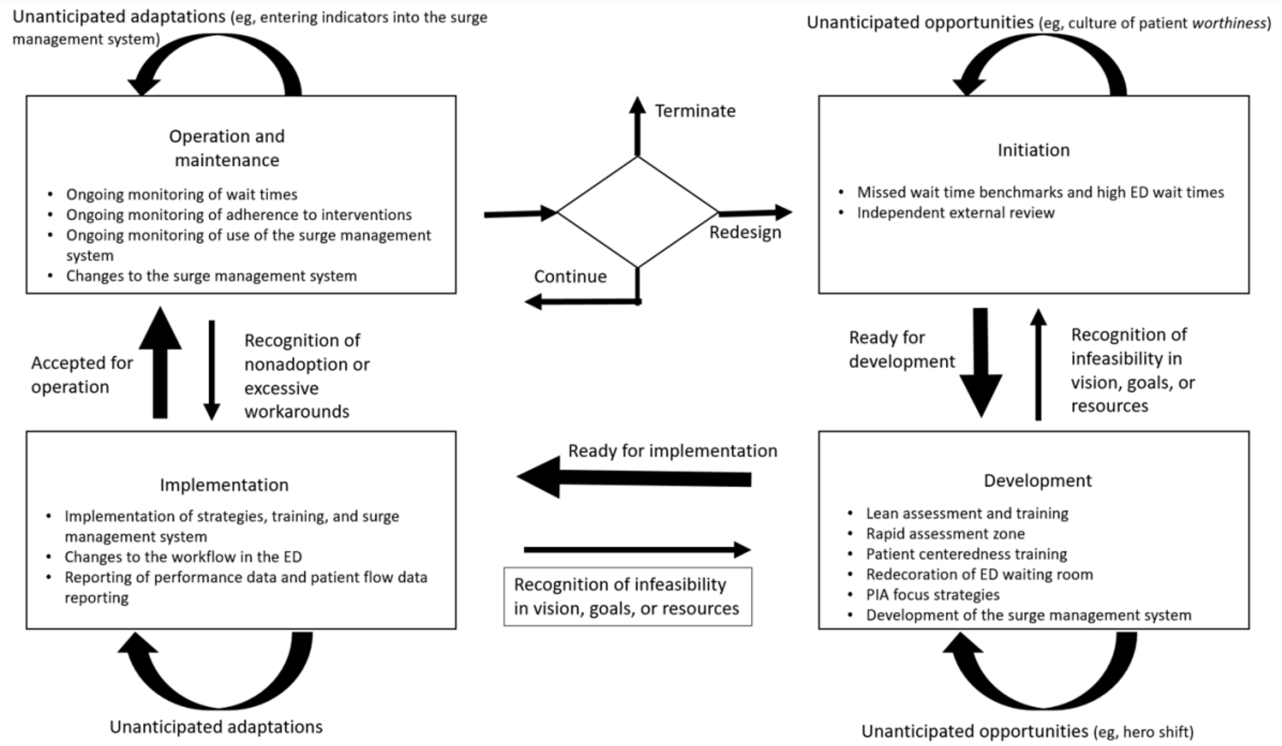


Ethics Approval

Participants provided informed consent, and the Memorial University's Interdisciplinary Committee on Ethics in Human Research approved the study (20190669-BA).

Results

Summary

The results indicate that WST is a useful approach to structure the implementation of an eHealth system because it incorporates the entire work system, and not just the eHealth system, in the implementation framework. In this section, we identify the role that specific elements of WST's static framework and dynamic WSLC model played in the implementation and demonstrate how WST can be applied in the health care setting to guide the implementation of an eHealth system. Although the implementation team did not follow WST specifically, they included many of its elements in their approach.

Static Framework

Overview

We found that the hospital implementation team began the project with an independent external review to assess the organization and function (ie, the elements) of the ED work system. Then, they designed interventions to address the issues that were found. They did not just examine the eHealth system portion of the surge management process, rather, they recognized the radical change that they were trying to implement in the ED and examined the entire work system. A member of the implementation team commented the following during the implementation of the surge management system:

> *I guess the electronic piece [of the surge management system] is one thing, but there's also the strategy that goes along with it and we're examining that in the broader sense. And the strategy is controversial, a little bit. So if you don't have supportive buy-in from some of the frontline staff, and if it's not presented in a way that would be well explained, it could be definitely seen as something that people wouldn't want to do.*

Internal Environment

The implementation team recognized the need to focus their efforts on meeting the needs of their *customers* (ie, the staff, hospital administration, and patients). They involved the staff in the implementation. A staff member commenting on the implementation of the surge management system said the following:

> *Management driven, it's frontline driven from us. And we're like, what can we change about this process.*

The implementation team designed strategies to address their customers' (ie, staff and patient) issues. For example, time to PIA is strongly correlated with patient satisfaction; thus, they developed strategies (ie, briefly assessed patients even when formal assessment space was not immediately available or emergency physicians could triage with nursing staff in the triage room without waiting and discharge if applicable) to reduce time to PIA. As can be seen in Figure 3 [9], this is a basic component of the WST static framework, which places customers at the top of the triangle. An aspect of the implementation that could have been improved in the beginning was staff training on the overall new surge management process. As we describe in the following sections, the implementation team realized that more training was needed during the implementation for staff entering data into the surge management system; however, their approach to training focused primarily on learning the job and did not always seem to provide the staff an understanding of the overall purpose of the surge management changes or their role in the process. There were comments that the way the surge management process functioned depended on who was on shift that day, and that, in particular, physicians can have a big impact on the process. In situations such as the ED, where teamwork is so important, and as one staff member commented, "You're making decisions on the fly and you can't really plan ahead," a shared purpose and approach to surge management is needed. Furthermore, most survey respondents (11/18, 61%) indicated (agreed or strongly agreed) that they thought that the surge management system had improved their productivity and ability to coordinate continuity of care (11/18, 61%) and improved the hospital's patient care delivery, productivity, and clinical outcomes (Table 2—user satisfaction and benefits to hospital); however, in the interviews, most staff indicated that they were not aware of the real impact on patients or efficiency in the ED. They had not seen the time to PIA, LOSDep, number of patients who left without being seen, or surge levels over time; thus, they were not sure what benefits were realized. A staff member commented the following:

> *It'd be nice to see the stats and if [the surge management system] was actually related in respect to getting patients to the floor. Like door-to-doctor, or triage-to-doctor, that kind of stuff...or what's decreasing over time. That would be nice to see.*

The implementation team did not include patients, and the project did not measure patient satisfaction. Following a WST approach may have helped to ensure that they had designed the implementation with a focus on customers (ie, staff and patients), and some of these issues may have been addressed at the onset of the project.

Despite some issues with implementation, many elements of the static framework were applied. We found that rather than just implementing the eHealth system portion of the surge management system (ie, the *technology*), the implementation team recognized that there was a need to change *activities and processes*, adjust *participant* perceptions of how the ED should function, and track and share various *information* such as performance indicators (Figure 3) [9]. The implementation team was redesigning the ED's work system to address areas of misalignment identified between elements of the static framework. For example, when the implementation team recognized that waiting for beds for patient assessment, blood tests, electrocardiograms, and other minor procedures were contributing to overcrowding in the ED, they created a rapid assessment fast-track zone. When they recognized the need to decrease time to PIA, they designed changes in the workflow to reduce the time to PIA. These changes to the work processes helped to address the misalignment between the *activities and processes* and *products and services* elements and focus the work system on providing patient care and decreasing wait times. Interventions to address the misalignment between *participants* and *activitiesand processes* were addressed through lean training for frontline ED staff to encourage them to become active participants in the improvement process and redecoration of the waiting and examination rooms to have a more inviting environment for patients. Regular performance reporting facilitated alignment between *information* and *activities and processes*. The implementation team also used the information obtained from the external review and through the various interventions to design and develop a surge management system that was aligned with the activities and processes in the ED. The team recognized that the eHealth portion of the surge management system was only a component of the ED work system. They understood the impact and importance of the changes on other elements of the work system. A staff commented the following:

> *All of these different things, super track, nurse practitioner, the hero shift...some days we'd sink if we never had it.*

Table 2. Staff perceptions of the surge management system as indicated in the survey.

	Value, mean (SD; range)
User satisfaction[a]	
How satisfied are you with the surge management system?[b]	3.52 (1.08; 1-5)
The surge management system improves my productivity.	3.71 (1.10; 2-5)
The surge management system enhances my ability to coordinate continuity of care.	3.76 (1.18; 2-5)
The surge management system makes my job easier.	3.48 (1.12; 1-5)
The surge management system improves the quality of care that I can provide.	3.52 (1.12; 2-5)
The surge management system improves the quality of my decision-making.	3.48 (1.12; 1-5)
Benefits to hospital[a]	
Using the surge management system has improved patient care delivery.	3.94 (0.97; 1-5)
Using the surge management system has improved clinical outcomes.	3.82 (0.95; 2-5)
The surge management system improves our productivity.	4.12 (0.99; 1-5)
Job level change[a,c]	
I am expected to do more work than I used to.	2.78 (0.85; 2-5)
The nature of my work has changed.	3 (0.90; 2-5)
My job responsibilities have changed.	2.91 (1; 2-5)
I find greater demands placed on me at work because of this change.	2.91 (1; 2-5)
I am experiencing more pressure at work because of this change.	2.74 (1.01; 1-5)
The work processes and procedures I use have changed.	2.96 (0.88; 2-5)
My use of the surge management system is integrated with my workflow.	4.06 (0.83; 2-5)
Change fairness[a]	
Sufficient advanced notice was given to employees affected by the change.	3.96 (1.40; 1-5)
Those affected by the change had ample opportunities for input.	3.78 (1.35; 1-5)
The hospital kept everyone fully informed during the change.	3.65 (1.27; 2-5)
People affected negatively by this change were treated fairly.	3.78 (1; 2-5)
Management support for the change[a]	
Sufficient resources were available to support this change.	4 (0.85; 2-5)
All levels of management were committed to this change.	3.95 (0.84; 2-5)
Management dealt quickly and effectively with surprises during the change.	3.59 (0.91; 2-5)
There was sufficient management support for this change.	3.82 (0.96; 2-5)
Management was supportive of this change.	4.05 (0.67; 3-5)
People in this hospital find their work more interesting.	3.32 (1.13; 1-5)
Most people in this hospital are better off.	3.35 (1.19; 1-5)
People’s quality of life at work has improved.	3.36 (1.14; 2-5)
Commitment to change[a]	
This change serves an important purpose.	4.04 (0.82; 2-5)
I believe in the value of this change.	4 (0.90; 2-5)
This change is a good strategy for this organization.	4.09 (0.73; 3-5)
I think management is making a mistake by introducing this change.[c]	1.91 (0.79; 1-4)
Things would be better without this change.[c]	1.83 (0.72; 1-3)
This change is not necessary.[c]	1.78 (0.74; 1-3)

[a] Scoring: 1=strongly disagree, 2=disagree, 3=neutral, 4=agree, and 5=strongly agree.

[b] Scoring: 1=extremely dissatisfied, 2=dissatisfied, 3=neither satisfied nor dissatisfied, 4=satisfied, and 5=extremely satisfied.

[c] Reverse score.

External Environment

According to WST, the 6 elements of the static framework are influenced by the 3 elements of the external environment of the hospital that affect the work system (Figure 3 [9])—the *environment*, *strategies*, and *infrastructure*. First, within the environment, the culture had a major impact on the implementation of the system. The ED staff had a history of resistance to change and certain beliefs about who should be in the ED. Commenting on staff acceptance of the changes related to the surge management system, a staff member said, "I think it was really hard to go from being very rule oriented to being more flexible." The implementation team created patient-centeredness training to address the belief system that patients with low acuity should not seek care in the ED. One of the members of the implementation team commented, "We changed a complex system of beliefs." Other factors such as established processes and professional practices also created some resistance to the new approach. A member of the implementation team commented the following:

> *We have been, since 1998 in Canada, seeing patients based on Canadian triage acuity scale. [The surge management system] kind of meddles with that a little bit.*

These initiatives appeared to bring staff on board and create a culture that was more accepting of change. In addition, a change committee was established to help communicate and identify needs for change on an ongoing basis. Second, the *strategies* at the hospital, ED, and work system were in alignment. The health authority, hospital, and ED were focused on improving patient care in the ED and supportive of innovative approaches. A manager commented the following:

> *[The health authority] has tried to put a more innovative angle in healthcare and [this hospital] been chosen as there are innovative kind of people in the frontline doing some things that can help get innovation into healthcare. Another strategy is probably improving patient satisfaction...We know that usually what happens in the ED is often reflected in how well your hospital works and how well patients are satisfied. If you don't have a good ED, you're not going to be reflected as having a good hospital. So the more that we get things improved in the ED, it tends to transform and cross over to other hospitals or areas.*

The hospital management and ED management were in support of this initiative and devoted staff and funds to support the project, and their strategies were aligned and focused on reducing ED wait times. Third, there were some issues with the infrastructure as they were not able to connect the eHealth portion of the surge management system with the hospital's other systems; therefore, staff had to continue to input the values for the indicators into the surge management system. There appeared to be some confusion regarding the responsibility for this task, and we observed that sometimes, the indicators were not entered regularly. This impaired the use of and possible benefits from the system.

Outcomes of the Implementation

The strength of this whole system approach to structuring the implementation is reflected in the success of the surge management system. The new approach to surge management changed the work system in the ED (Table 2—job level change), with comments from staff such as, "It's a whole new way of thinking." Despite these changes in workflow in the ED, we observed a strong commitment to the system (Table 2—user satisfaction). In total, 72% (13/18) of the survey participants were satisfied or extremely satisfied with their use of the system, 82% (14/17) would like to increase or significantly increase their use of the system in the future, and 82% (14/17) agreed or strongly agreed that it was integrated with their workflow.

We observed that most staff accepted the new collaborative approach to surge management (eg, "People are willing to work together and help"), and many commented that the patients seemed happy (eg, "A lot of people seem happier"). Furthermore, participants indicated that they agreed or strongly agreed that the system has improved patient care delivery (14/17, 82%), clinical outcomes (10/17, 59%), and productivity (15/17, 88%; Table 2—benefits to hospital).

The ED wait time data indicated an improvement in ED wait times at the beginning of the implementation from October 1, 2014, to March 31, 2017. Despite approximately 26% increase in patient volume, the time to PIA decreased by 62.1 minutes, LOSDep decreased by 65 minutes, and patients who left without being seen decreased from 12.1% to 4.6% [21]. Our study began approximately 1 year later when the eHealth system portion of the surge management system was being implemented. Our analysis shows that the wait times have plateaued, but stayed consistent since the time of initial implementation and through the implementation of the eHealth system portion of the surge management system, despite the increase in patient volume. Table 3 shows the characteristics of patient visits to the ED from April 1, 2017, to March 31, 2021. The dramatic decrease in ED wait times after the initial implementation of the surge management system and the ability of the ED to maintain these wait times in the 4 years after the implementation and through the implementation of the eHealth system portion of the surge management system can be seen in Figure 5. Slight variations in the time to PIA and LOSDep and large increase in the number of patients who left without being seen can be seen around the beginning of the COVID-19 pandemic in March 2020; however, since this time, the wait times have returned to their prepandemic values.

Table 3. Characteristics of patient visits to the emergency department (2013-2021).

Characteristics	July 1, 2013, to September 30, 2014[a]	January 1, 2016, to March 31, 2017[a]	April 1, 2017, to March 31, 2018	April 1, 2018, to March 31, 2019	April 1, 2019, to March 31, 2020	April 1, 2020, to March 31, 2021
Total visits, n	23,898	30,031	26,966	29,321	29,014	22,931
Number of daily visits, mean (SD)	52[b]	66[b]	74 (6.54)	80 (6.25)	79 (8.03)	63 (10.05)
Time to PIA[c] (minutes), mean (SD)	104.3 (0.9)	42.2 (8.1)	49.6 (5.5)	48.5 (4)	51.9 (5.7)	41.3 (5.5)
LOSDep[d] (minutes), mean (SD)	199.4 (16.8)	134.4 (14.5)	158.2 (7.3)	139.7 (8.3)	147.8 (10)	145.6 (11.5)
Patients who left without being seen (%), mean (SD)	12.1 (2.2)	4.6 (1.7)	4.1 (0.3)	3.7 (0.2)	3.8 (0.4)	5.0 (1.1)

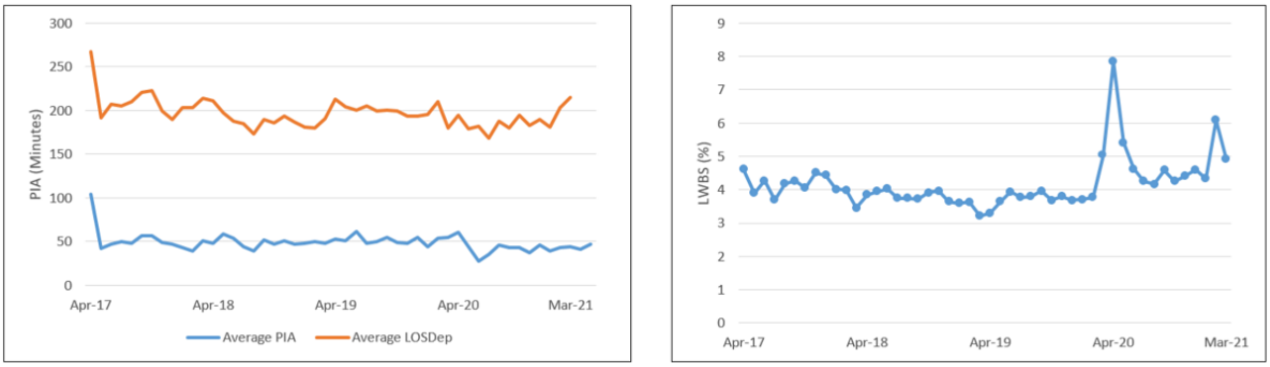
[a] These data were obtained from the publication by Patey et al [21].

[b] SD value is unavailable.

[c] PIA: provider initial assessment.

[d] LOSDep: length of stay for departed patients.

Figure 5. Average time to provider initial assessment (PIA), length of stay for departed patients (LOSDep), and patients who left without being seen.



WSLC Model

In contrast to the static framework that we used to examine the work system at one point in time, we applied the WSLC model to examine the changes to the work system over time through planned and unplanned changes as part of the system's natural evolution. We found that the surge management system project followed the 4 phases of the WSLC: initiation, development, implementation, and operation and maintenance (Figure 4) [9]. The project was initiated to address missed wait time benchmarks and high ED wait times, and it was initiated with the independent external review. As we discussed, this review identified areas for improvement, and interventions for a new surge management system were created in the development phase, planned strategies were implemented in the ED, and surge management system process and outcomes were continuously monitored. Initially, continuous monitoring was performed informally; however, as we mentioned previously, a change committee was created to take a more systematic approach to monitor the surge management system and make the necessary changes over time.

The planned changes included the eHealth system portion of the surge management system itself, along with the interventions described previously; however, in addition, we found that unanticipated opportunities and challenges emerged through the development cycle. For example, during initiation, the implementation team found that in addition to the changes in workflow, training, and creation of the surge management system that the team thought they would have to make, they discovered that they also needed to create a culture of patient *worthiness*, and an intervention to address this change was developed. Throughout the phases of the project, we found that the implementation team followed an iterative approach. When they recognized that changes were necessary in the static framework elements, they had the authority to make those changes. An implementation team member commented the following:

> *It's interim improvements as we go...where we're going to fix what we see is wrong before we go anywhere else.*

During the implementation phase, the team found that during the busy times, despite following the new surge management policies and procedures, staff were still often unable to manage the wait times sufficiently. Therefore, the team went back to the development phase and created a new *hero* shift to provide added ED physician and nursing support during these times. This was an unanticipated opportunity and proved to have beneficial results. In addition, during the operation and maintenance phase, the team saw unanticipated adaptations in the frequency with which staff entered the surge measures in the surge management system, and additional staff training was conducted. The implementation team also saw issues with accessing information for some indicators, and the surge management system was modified accordingly.

We found that the iterative approach helped the team to address issues as they arose. However, the changes required by the new ED surge management process were not easily made, and the implementation team faced some resistance. Staff commented the following:

> *Some people understand the process of flow better than others.*
>
> *And then you've got some doctors, it's like pulling teeth...they're just associated with the old way of doing things.*
>
> *I think it was really hard to go from being very rule-oriented to being more flexible.*

The implementation team recognized the challenges with the new system:

> *The strategy is controversial...it could be definitely seen as something that people wouldn't want to do.*

For example, the changes included broadening the scope of work for the primary care paramedics to include transporting patients to an admitting floor. This could have been perceived as negative, but survey participants indicated a high degree of change fairness (Table 2):

> *People affected negatively by this change were treated fairly.*

The implementation team commented that the challenges to incorporating the surge management system into the daily workflow were exacerbated by the fact that they could not make the use of the system mandatory:

> *It's really tough to do mandatory things. It's not like a factory...most people got practices that are guided by professional bodies...probably the biggest challenge here is that.*

However, we found that, overall, the staff indicated that the changes were managed well, as demonstrated by agreement levels (Table 2—change fairness, management support for the change, and commitment to change). Sufficient resources were available to support the change (14/20, 70% agreed or strongly agreed), there was sufficient management support for the changes (15/19, 79%), and the change served an important purpose (16/20, 80%).

The need for an iterative approach was also reflected in the fact that the ED work system itself was not stable. We saw that there were changes to the surge management system, new staff, new activities and process, and other new systems. An ED staff member commented the following:

> *...Change is now part of regular work...and here it seems to just be part of what you do now. It's actually become just regular work.*

This reflects the need for continuous monitoring of the surge management process and illustrates how the WSLC model can be used to manage the implementation to recognize unanticipated opportunities and adaptations over time.

Discussion

Principal Findings

The broad scope and holistic approach of WST is well suited to guide eHealth system implementations in the ED as it has the potential to address a key barrier to successful implementations—integrating the system into clinicians' work. EDs are complex systems that involve a variety of groups responsible for guiding patients through different organizational and clinical processes during their care. System implementation in such a complex setting requires focus on the work system, and not just the IT artifact. The surge management system is an example of a successful implementation, as the surge management system and related interventions improved key ED wait times. In our study, we demonstrate what made this implementation a success, through a WST analysis lens. It is important to understand what aspects of the implementation made it a success because if we understand what works, other implementation teams also can use this approach. We found that the key success factors were the incorporation of the entire work system into the implementation framework and the iterative approach.

Although the implementation team did not follow WST, we propose that it can be applied in the implementation of eHealth systems in such environments. The WST's static framework can help to broaden the focus of implementation from just the eHealth system to a view that considers the eHealth system as a part of a large work system, in which human and technological components work together to manage patient care. The emphasis on the services produced and the value of those services to the staff and patients is particularly beneficial in the health care setting. This will ensure that the implementation is focused on the end user and the ultimate goal of the system, rather than a narrow focus such as system's use. We saw that the external review helped to identify all the elements of the ED work system and not only the eHealth system portion of the surge management system that can affect the success of the system implementation. The resulting interventions helped to ensure alignment among elements in the WST's static framework and to focus the attention throughout implementation on the ultimate goal of reducing ED wait times.

We saw how taking a more holistic approach for the implementation helped to alleviate some of the common barriers to eHealth system success. For example, rather than focusing on the technical components of the surge management system, something that is a significant contributor to the gap between prospect and reality [22,23] and which is only a component of the WST static framework, the implementation team also focused on the other elements of the static framework. Furthermore, they addressed resistance to change, which is another barrier to eHealth interventions [24,25], by involving staff in the implementation, through training and creation of a change committee. We saw how they considered the different perspectives of different staff and management involved in the surge management process by involving them in the implementation process, something, which if not done can be another barrier [26,27]. There is a widespread perception in human-computer interaction that recognizes the importance of user-centered design and participatory design approaches. This has also been shown to be important in the design of workflow associated with eHealth system implementations. On the basis of their review of the factors influencing the outcome of eHealth interventions, Granja et al [6] proposed that user involvement in the design of the workflow is the most important factor for the success of eHealth systems. Using the WST lens helped us to identify the different elements of the work system and discover how the interventions addressed any misalignment between the elements. We propose that applying the static framework will help implementation teams to ensure that they are including the essential elements of the work system and provide them with a systematic way to assess the alignment between the elements.

Viewing the implementation of the surge management system through the WSLC model created an approach that differs fundamentally from the traditional systems development life cycle. In the systems development life cycle methodology, the system is the technical artifact that is created, and it does not necessarily incorporate iterations. We found that viewing the surge management system as part of dynamic work processes with a series of changes that emerged through planned and unplanned events, and their interactions, highlighted the importance of continuously identifying the changes or areas of misalignment in the work system. It also helped to clarify what interventions were needed and how to manage such changes, while recognizing that changes to the work system can occur through planned initiatives or emerge over time. We propose that implementation teams can use the WSLC model to follow an iterative approach that will allow them to be open to unanticipated opportunities and recognize unanticipated adaptations during the implementation and give them a structured way of dealing with the planned and emergent changes.

Researchers have adapted and used WST in different areas over several decades [9,10]; however, it has had limited application in health care [28,29]. To the best of our knowledge, it has not yet been applied in the ED, nor has it focused on how it can be used during the implementation of an eHealth system. Therefore, we broaden the focus of WST by applying it in the health care field (specifically ED) and to its use in the implementation of eHealth systems. We propose that the static framework can be used by non-IT and IT professionals to analyze the work system to incorporate the sociotechnical aspects of implementing an eHealth system as part of a large work system. Then, the WSLC model can be used to structure the implementation and monitor and manage the system over time. Future studies can examine the implementation of an eHealth system with a team that is following the WST approach, to uncover any problems that may arise and identify opportunities for overcoming them.

Limitations

This study was conducted in 1 rural hospital ED. Experiences regarding the implementation of the same or other ED systems may be different in other types of ED settings, thus limiting generalizability. However, the practices of WST have been shown to improve implementation success in other complex settings. Another limitation is the small sample size of the survey; however, approximately half of the ED staff responded. Moreover, the observations were conducted only for 2 days; however, during observation, we asked if the shifts represented a typical day, and they indicated that they did. They also indicated that after 10 PM, the ED is generally not busy, and thus, surge management during nights is similar to a nonbusy time during the day. The ED wait time data before, during, and after implementation of the surge management system support the success of this implementation. The use of the mixed methods approach with surveys, interviews, observations, document review, and ED wait time data analysis should have helped to combat potential limitations.

Conclusions

This conceptualization of the surge management system implementation through the lens of WST gives us insight into how to structure the implementation of a surge management system to incorporate the broad work system. We captured how the static framework can be a useful tool to assess the elements of the broad work system that need to be changed and managed to successfully implement an ED surge management system, and we propose that the WSLC model can provide a structured way to manage the implementation of such changes. This study addresses the need for more studies on surge management systems and methodologies to implement eHealth systems that incorporate the broad work system. These findings can guide further studies and implementations of eHealth systems.

Abstract

Background: Depression is a common comorbid condition in individuals with chronic back pain (CBP), leading to poorer treatment outcomes and increased medical complications. Digital interventions have demonstrated efficacy in the prevention and treatment of depression; however, high dropout rates are a major challenge, particularly in clinical settings.

Objective: This study aims to identify the predictors of dropout in a digital intervention for the treatment and prevention of depression in patients with comorbid CBP. We assessed which participant characteristics may be associated with dropout and whether intervention usage data could help improve the identification of individuals at risk of dropout early on in treatment.

Methods: Data were collected from 2 large-scale randomized controlled trials in which 253 patients with a diagnosis of CBP and major depressive disorder or subclinical depressive symptoms received a digital intervention for depression. In the first analysis, participants' baseline characteristics were examined as potential predictors of dropout. In the second analysis, we assessed the extent to which dropout could be predicted from a combination of participants' baseline characteristics and intervention usage variables following the completion of the first module. Dropout was defined as completing <6 modules. Analyses were conducted using logistic regression.

Results: From participants' baseline characteristics, lower level of education (odds ratio [OR] 3.33, 95% CI 1.51-7.32) and both lower and higher age (a quadratic effect; age: OR 0.62, 95% CI 0.47-0.82, and age^2: OR 1.55, 95% CI 1.18-2.04) were significantly associated with a higher risk of dropout. In the analysis that aimed to predict dropout following completion of the first module, lower and higher age (age: OR 0.60, 95% CI 0.42-0.85; age^2: OR 1.59, 95% CI 1.13-2.23), medium versus high social support (OR 3.03, 95% CI 1.25-7.33), and a higher number of days to module completion (OR 1.05, 95% CI 1.02-1.08) predicted a higher risk of dropout, whereas a self-reported negative event in the previous week was associated with a lower risk of dropout (OR 0.24, 95% CI 0.08-0.69). A model that combined baseline characteristics and intervention usage data generated the most accurate predictions (area under the receiver operating curve [AUC]=0.72) and was significantly more accurate than models based on baseline characteristics only (AUC=0.70) or intervention usage data only (AUC=0.61). We found no significant influence of pain, disability, or depression severity on dropout.

Conclusions: Dropout can be predicted by participant baseline variables, and the inclusion of intervention usage variables may improve the prediction of dropout early on in treatment. Being able to identify individuals at high risk of dropout from digital health interventions could provide intervention developers and supporting clinicians with the ability to intervene early and prevent dropout from occurring.

Introduction

Background

Chronic back pain (CBP) is a major global health concern with lifetime prevalence rates of 60%-70% [1]. CBP is the leading cause of activity limitation and work absenteeism and accounts for the highest number of disability-adjusted life years worldwide [2]. Approximately 1 in 5 adults with CBP are diagnosed with major depression and many more experience subclinical symptoms [3]. In patients with CBP, comorbid depression is often associated with lower treatment adherence, poorer treatment outcomes, increased medical complications, and higher health care use [4-6].

Psychological interventions have been demonstrated to be effective in the treatment of depression for individuals with CBP [7]. Accordingly, cognitive behavioral therapy is now recommended as the first-line treatment in most international guidelines, for example, the National Institute for Health and Care Excellence [8]. However, the ability to access psychotherapy is a significant barrier to treatment. On average, less than 1 in 5 people in high-income countries and less than 1 in 27 people in low- and middle-income countries receive appropriate treatment [9], giving rise to a *treatment gap* in mental health care [10].

Digital interventions, which deliver psychotherapeutic components via a web browser or smartphone app, have been proposed as a scalable, cost-effective way to meet the growing demand for psychological treatment and address many of the challenges associated with accessing traditional face-to-face therapy [11-15]. There is now a large body of evidence supporting the efficacy of digital interventions for the prevention and treatment of depression [16-20], with recent studies providing promising evidence for the treatment of depression in patients with comorbid physical conditions [21-25].

Despite the demonstrated efficacy, adherence to digital interventions remains a major challenge. A recent meta-analysis on digital interventions for depression identified that, on average, little more than half of the participants completed the full intervention and only 25% of the participants completed the full intervention when the intervention was delivered within routine health care settings [16]. The same meta-analysis also identified that completing the full intervention was the strongest predictor of outcomes, underscoring the importance of treatment adherence [26]. Similar rates of intervention dropout have been reported in other studies on digital health interventions [27-30], giving rise to what Eysenbach [31] has referred to as the “law of attrition,” the observation that a substantial proportion of users in eHealth apps will stop using the intervention before completing the full treatment protocol.

Several studies have assessed predictors of dropout in digital mental health interventions [27,32-34]. In a systematic review of internet-based interventions for anxiety and depression, Christensen et al [34] found that higher baseline depression severity and older age were associated with higher rates of intervention dropout. In a meta-analysis of individual patient data, Karyotaki et al [33] found that being male, having a lower education level, younger age, and comorbid anxiety symptoms significantly increased the risk of dropout from self-guided digital interventions for depression.

However, to the best of our knowledge, no research has been published to date that assesses which factors may predict dropout in a digital intervention for depression in patients with comorbid somatic illness. This question may be particularly pertinent for these individuals as chronic pain and depression are often associated with reduced motivation to initiate or complete goal-directed tasks [35,36]. As the treatment schedules of patients with multimorbidities can already be quite demanding [37,38], higher levels of pain disability—or lower confidence in performing activities while in pain (pain self-efficacy)—may therefore influence an individual’s ability to adhere to a digital intervention and thus experience the benefits [39].

Knowing which patient characteristics predict a higher likelihood of dropout may be valuable for identifying individuals in advance of treatment that might benefit from alternative care pathways [33,40]. However, it is unclear how useful the baseline predictors may be once a patient has already started treatment. In most digital health interventions, there is a steady attrition over time, with most users dropping out after completing the first 1 or 2 modules—the “attrition-phase” [31,41,42]. The ability to identify which individuals are at high risk of dropout early on in treatment could be valuable for supporting clinicians, especially within stepped-care models where rapid identification of nonresponders and the speed of providing alternative treatment can have a significant influence on outcomes [43,44].

Although the field is still nascent, there is a wealth of data generated from digital interventions that may aid the prediction of dropout once a patient has started treatment. In the same way that many digital apps outside of health care use *churn-prediction models* to identify if a user is likely to churn (ie, stop using the app as intended), similar models and principles of human-computer interaction may be valuable to predict dropout and maximize adherence within the field of digital health. For example, in a digital intervention for a chronic lifestyle disease, Pedersen et al [45] were able to predict dropout with 89% precision using a model that included the number of messages received from the health coach, 2 weeks of inactivity, and the provider of the intervention as the most significant predictors. In a study of a self-help digital intervention for the treatment of insomnia, Bremer et al [46] identified individuals at risk of dropout with an area under the receiver operating curve (AUC) of 0.719 using a combination of baseline characteristics (eg, self-reported stress levels) and intervention usage data (eg, number of days to complete each module). One of the most significant findings of the study was that the prediction of user dropout was possible early on in the intervention (after completion of the introductory module).

Objectives

As digital mental health interventions are being increasingly adopted by health care systems worldwide [13,47], the ability to identify patients at risk of dropout may provide valuable information to improve the adherence, and thus effectiveness, of digital interventions. This study aimed to identify the factors that may predict dropout in a digital intervention for depression in individuals with CBP. In particular, we sought to assess which participant characteristics may be associated with a higher risk of dropout and whether intervention usage data could help improve the identification of individuals at risk of dropout early on in treatment.

Drawing from 2 recent studies on a guided digital intervention for the treatment and prevention of depression in individuals with comorbid CBP, we asked the following research questions:

1. Can we predict intervention dropout from participant baseline characteristics? If so, which participant characteristics predict a higher likelihood of dropout?
2. Can we develop an “early warning system” that identifies participants at risk of dropout early on in the intervention? Specifically, how accurately can we predict which participants will drop out after completion of the first module and what is the most accurate model for classifying at-risk individuals?
3. Do predictors of dropout differ between patients clinically diagnosed with major depressive disorder (where the intervention is targeting treatment) and patients with subclinical depressive symptoms (where the intervention is targeting prevention)?

Methods

Study Design

This study was a secondary analysis of data from 2 trials that assessed the efficacy of a therapist-guided internet-based intervention for the treatment [48] and prevention [21] of depressive symptoms in patients with comorbid CBP. Both trials were observer-masked, multicenter, pragmatic, and randomized controlled trials with a parallel design. The trials were conducted simultaneously using the same intervention, procedures, and research setting but targeted individuals with different levels of depressive symptomatology (diagnosed depressive disorder of mild to moderate severity in the study by Baumeister et al [48] and subclinical but at least mild levels of depressive symptoms in the study by Sander et al [21]). For the purpose of this study, the trial data were combined. All the participants provided written informed consent.

Participants

All participants (N=253) assigned to the intervention arms of the primary studies were included in this analysis. The inclusion criteria of the primary studies were as follows: (1) age ≥18 years; (2) presence of depressive symptoms, either reported persistent subthreshold depressive symptoms in the past 3 months or meeting the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, criteria for a mild to moderate depressive episode or persistent depressive disorder; (3) diagnosed back pain chronicity of at least 6 months; (4) have German language skills; and (5) access to internet and PC. The exclusion criteria were as follows: (1) having ongoing or planned psychotherapy within the forthcoming 3 months, (2) being currently suicidal or having had suicidal attempts within the past 5 years, or (3) having had a severe depressive episode within the past 6 months. In the primary studies, participants were recruited during or following discharge from 1 of the 82 orthopedic clinics across Germany. They were recruited personally by a clinician or on the web using a flyer and information letters distributed by the clinic.

Intervention

The intervention is a guided internet- and mobile-based intervention for the treatment (eSano BackCare-D [49]) or prevention (eSano BackCare-DP [50]) of depression in patients with comorbid CBP. The content of the intervention is based on cognitive behavioral therapy for depression and includes elements of psychoeducation, social skills, problem-solving, behavioral activation, relaxation, motivation for physical exercises, and psychological pain intervention elements. Modules consist of information provided by text, video, audio, and interactive exercises and include a homework assignment. At the start of each module, participants reported their perceived stress level at the time and whether they had experienced any negative events in the previous 7 days. There are 6 regular modules and 3 optional modules focusing on sleep, partnership and sexuality, and work. Participants were advised to complete 1 session per week. During the intervention, participants were guided by trained and supervised psychologists (e-coaches) who provided written feedback within 48 hours of each completed module and by answering any queries.

Measures

Baseline Measures

In this study, 8 baseline characteristic variables were assessed as potential predictors of dropout. Variables were chosen on the basis of previous research pointing to demonstrated or hypothetical relationships between the predictor variables and intervention adherence or dropout [32-34,45,46,51]. Demographic characteristics included age, sex (male or female), education level (based on the International Standard Classification of Education by UNESCO [52], low: level 1-2, medium: level 3-4, and high: level 5+), marital status (single, in a relationship, or divorced or widowed), and social support (low, medium, or high). Clinical characteristics included depression, as measured by the Hamilton Depression Rating Scale (HAM-D; [53]); pain disability, as measured by the Oswestry Disability Index (ODI; [54]); and pain self-efficacy, as measured by the Pain Self-Efficacy Questionnaire (PSEQ). The process variables included internet affinity, as measured by the Internet Affinity Scale. Further details on all measurements are provided in the original study protocols [49,50].

Intervention Usage Measures

Intervention usage measures included both active and passive measures. The active measures were the stress level reported by the participant at the start of each module ("Burden") and the occurrence of any negative events experienced in the past 7 days, self-reported by the participant at the start of each module ("Negative Events"). Burden was assessed using a Likert scale from 0 to 10, where 0="not burdened at all" and 10="extremely burdened." Negative events were dummy coded as 0="no negative event in the past week" and 1="at least one negative event in the past week." For passive measures, we included the number of days taken to complete each module ("N Days to complete module") and the number of minutes spent on the web completing each module ("Time spent online completing module").

Dropout

Dropout was defined as completing <6 intervention modules, in accordance with the intervention developers [49,50]. It was operationalized as a binary outcome (dropped out or did not drop out).

Analytic Strategy

Predicting Dropout From Participant Baseline Characteristics

To assess whether participants' baseline characteristics could predict dropout, analyses were conducted using logistic regression in 3 steps. First, we conducted a series of bivariate analyses to assess the odds ratios (ORs) of each baseline variable (bivariate "bivariate model"). Second, we repeated the analyses with all baseline variables simultaneously entered into the binomial model (the "complete model"). Finally, we built a "parsimonious model" in which we excluded nonsignificant predictors with no incremental predictive power from the complete model in a stepwise procedure.

Akaike information criterion (AIC) and Bayesian information criterion (BIC) were used as measures of model fit and for model comparison. For nested models, likelihood ratio tests were used to directly compare whether 2 models were significantly different from one another [55]. Collinearity was assessed using variance inflation factors and tolerance (1/variance inflation factors). The assumption of linearity of the logit (a linear relationship between the predictors and dropout) was assessed for all continuous predictor variables, and any variables found violating the assumption were transformed based on a visual inspection of the plot.

As this was an exploratory study, we did not adjust for multiple testing. The study was not powered for confirmatory analysis of the predictors, and alpha adjustment may have increased the likelihood of type II errors.

Predicting Dropout Early on in the Intervention

To assess whether we could identify people at risk of dropout early on in the intervention, we first created a subset of the data available up until the point of module 1 completion (ie, baseline assessment data and intervention data captured until participants had completed the first module). We then compared the performance of three separate logistic regression models using the constrained data set: (1) a model based on participant baseline characteristics only—the "baseline characteristics model," (2) a model based on intervention usage variables only—the "intervention usage model," and (3) a model combining all baseline characteristics and intervention usage variables—the "combined model." The quality of the models was assessed using the area under the receiver operating characteristic curve (AUROC) and related measures of sensitivity and specificity [55]. The optimal threshold for AUROC was determined using Youden J statistic [56].

Sensitivity analyses were conducted to assess whether predictors differed in the prevention and treatment studies. Here, study was included as a dummy-coded variable (0=PROD-BP for the prevention study and 1=WARD-BP for the treatment study) in all parsimonious models, first as an additional predictor to assess for a main effect of study type on dropout and then as an interaction term with other predictors in the model to assess whether the effect of a predictor differed across studies.

To assess whether the number of modules completed influenced the relative risk of dropout, we conducted sensitivity analyses using Cox proportional hazards regression [57]. In this study, we assessed whether significant predictors of dropout differed between the 2 methods. Analyses were conducted according to the procedures outlined by Eysenbach [31]. The number of completed modules was used as a proxy for time. Models were built using the same 3-step procedure outlined above for logistic regression.

Missingness occurred in 111 out of 3084 (3.6%) data points and was assumed to be missing at random, indicating that missingness depended on observed data [58]. To avoid bias introduced by missingness, missing data were imputed using multiple imputation by chained equations [59,60]. Predictors for missing values were selected based on (1) model-induced predictors, (2) predictors based on bivariate correlation, and (3) bivariate correlation with missingness according to the procedures outlined by van Buuren and Groothuis-Oudshoorn [60]. Predictive mean matching was used as the imputation method. The number of imputed data sets was set to 20, and the number of iterations was set to 10. Convergence was visually assessed and confirmed. Regression analysis was performed on each imputed data set, and the results were pooled according to the rules by Rubin [61]. Sensitivity analyses were conducted using observed (nonimputed) data to compare with the results of the complete models using imputed data.

All analyses were conducted in R using R Studio (RStudio, PBC; [62]). The pROC package was used to calculate the AUROC [63]. The Caret package (R Foundation for Statistical

Computing) was used to calculate the sensitivity and specificity [64]. The multiple imputation by chained equations (MICE) package was used for multiple imputation and likelihood ratio tests [60].

Ethics Approval

This study was a secondary of analysis of data from two RCTs—Sander et al [21] and Baumeister et al [48]. In the original studies, all the participants provided written informed consent. The trial in Sander et al [21] was registered at German Clinical Trials Register (DRKS00007960). The trial in Baumeister et al [48] was registered at the World Health Organization International Clinical Trials Registry (DRKS00009272). All procedures were approved by the ethics committee of the Albert Ludwigs University of Freiburg, Germany (REC No. 8022-6-BW-H-2015; No. 297/14_150513 for the WARD-BP trial, EK-297/14_150513 for the PROD-BP study).

Results

Descriptive Statistics

Among the 253 participants, 149 (58.9%) were female and 104 (41.1%) were male. The age of participants ranged from 24 to 78 years, with a mean age of 51.1 (SD 8.88) years. Of the 253 participants, 171 (67.6%) reported having a low level of education. Of the 253 participants, 34 (13.4%) were single, 180 (71.1%) were in a relationship or married, and 39 (15.4%) were divorced or separated. The mean depression severity at baseline was 10.3 (SD 5.93), as measured by the HAM-D, and 9.94 (SD 4.41), as measured by the Patient Health Questionnaire-9. The mean level of pain disability was 31.3 (SD 14.7), as measured by the ODI, and the mean level of pain self-efficacy was 34.9 (SD 13.0), as measured by the PSEQ. Table 1 provides a detailed summary of the demographic and clinical characteristics of the participants.

On average, the participants completed 4.65 out of the 6 regular and 3 optional modules (SD 3.48). The participants took an average of 17.64 (SD 19.55) days to complete each module, and the mean time on the web taken to complete a module was 80.26 (SD 136.96) minutes. The mean self-reported burden was 4.55 (SD 1.97), and the mean number of self-reported negative events across the intervention was 0.80 (SD 1.33). Table 2 shows that 45.1% (114/253) of the participants dropped out of the intervention before completing at least six modules. The table also shows that the number of participants completing the modules decreased steadily as the intervention progressed.

Negative events, mean (SD)	0.81 (1.33)
Dropout, n (%)	114 (45.1)

Predicting Dropout Using Participant Baseline Characteristics

Table 3 displays the performance of the models used to predict dropout based on the participant baseline characteristics. As the Patient Health Questionnaire-9 and PSEQ scores were highly correlated with HAM-D and ODI (r=0.63 and r=−0.73, respectively) and were not significant in the bivariate analyses, they were not included in the multivariate predictor models to prevent collinearity. The results of the bivariate analysis indicated that a lower level of education was significantly associated with a higher risk of dropout (OR 2.43, 95% CI 1.19-4.97; P=.01, whereas higher age predicted a lower risk of dropout (OR 0.97, 95% CI 0.94-0.99; P=.02). None of the other potential predictors (sex, social support, internet affinity, baseline depression severity, and baseline pain intensity) were statistically significant at the level of P<.05 in the bivariate analysis.

In the complete model, being single was found to be an additional significant predictor of dropout (OR 2.54, 95% CI 1.09-5.90; P=.03). When age was added as a quadratic term (age^2) to the model to account for the nonlinear relationship between age and dropout, we found that both age (OR 0.63, 95% CI 0.47-0.84; P<.001) and age^2 (OR 1.55, 95% CI 1.17 to –2.05; P<.001) were significant predictors, such that both lower and higher age were associated with increased risk of dropout.

In the parsimonious model, where predictors were reduced stepwise to relevant predictors only, low education (OR 3.33, 95% CI 1.51-7.32; P<.001) and age (OR 0.62, 95% CI 0.47-0.82; P<.001 and age^2: OR 1.55, 95% CI 1.18-2.04; P<.001) remained significant predictors of dropout. Marital status, internet affinity, baseline depression severity, and baseline pain intensity were found to be nonsignificant after controlling for the other predictors.

Predicting Dropout Early on in the Intervention

Tables 4-6 provide a comparison of the models used to predict dropout following the completion of the first module. In the parsimonious model using only participant baseline characteristics, higher and lower age (OR 0.57, 95% CI 0.41-0.79; *P*=.001 and age^2: OR 1.68, 95% CI 1.22-2.31; *P*=.001) and low education (OR 2.98, 95% CI 1.04-8.56; *P*=.04) were significant predictors of dropout. The AUROC for the model was 0.70, the sensitivity was 68%, and the specificity was 62%.

In the parsimonious model using only intervention usage data, a higher number of days to module completion predicted a higher risk of dropout (OR 1.04, 95% CI 1.01-1.07; *P*=.005), whereas a self-reported negative event in the previous week was associated with a lower risk of dropout (OR 0.30, 95% CI 0.11-0.81; *P*=.02). The AUROC for the model was 0.61, the sensitivity was 56%, and the specificity was 54%.

In the parsimonious model that combined participant baseline characteristics and intervention usage variables as predictors, higher and lower age (OR 0.60, 95% CI 0.42-0.85; *P*=.004 and age^2: OR 1.59, 95% CI 1.13-2.23; *P*=.008), medium versus high social support (OR 3.03, 95% CI 1.25-7.33; *P*=.02), and a higher number of days to module completion (OR 1.05, 95% CI 1.02-1.08; *P*=.002) all predicted a higher risk of dropout, whereas a self-reported negative event in the previous week was associated with a lower risk of dropout (OR 0.24, 95% CI 0.08-0.69; *P*=.008). The AUROC for the model was 0.72, the sensitivity was 76%, and the specificity was 59%.

As shown in Table 7, a comparison of the parsimonious models based on participant baseline characteristics and intervention usage variables revealed that the model that combined baseline and intervention usage variables was the most accurate in predicting dropout (AIC=198.9; BIC=253.9) and significantly more accurate than the model using participant baseline characteristics only (AIC=212.6; BIC=254.7; χ^2_{181}=5.3; *P*=.006).

[b] BIC: Bayesian information criterion.

[c] AUROC: area under the receiver operating characteristic curve.

Sensitivity Analyses

Sensitivity analyses assessing whether findings differed between the treatment (WARD-BP) and prevention (PROD-BP) studies found no significant difference between the two, either in terms of main effect or interaction effects with other predictors. Sensitivity analyses assessing whether findings differed when using Cox proportional hazards regression versus logistic regression found no difference in the significant predictors. Multimedia Appendix 1 presents the results from the Cox regression analyses. Sensitivity analyses assessing whether the results differed between the models using observed data and those using imputed data revealed no difference in the predictors found to be significant. Results from the models using observed data are presented in Multimedia Appendix 2.

Discussion

Principal Findings

This study aimed to identify the predictors of treatment dropout in a digital intervention for the treatment and prevention of depression in patients with comorbid CBP. From the participants' baseline characteristics, we found that a lower education level and lower and higher age (a quadratic effect) predicted a higher risk of dropout. From the intervention usage variables, we found that a higher number of days to module completion predicted a higher risk of dropout, whereas the occurrence of a negative event in the previous week predicted a lower risk of dropout.

Participants with lower education levels were more likely to drop out of treatment, which is consistent with a large body of research on adherence to both digital interventions and face-to-face psychotherapy [33,51,65-67]. This may reflect the fact that these individuals find it harder to comprehend the intervention material or the digital format, and thus, they lose the motivation to continue [30,51]. It is worth noting that 67.5% (171/253) of the participants in this study were classified as having low levels of education. Lower levels of education have also been associated with longer duration or higher occurrence of back pain [68], underscoring the need for additional research on digital interventions for this particular patient group. The finding that both younger and older age predicted higher risk of dropout suggests that the relationship between age and dropout may be more complex than has been previously identified, either owing to the nonlinear relationship between the two or a possible interaction between age and other factors such as computer literacy [33,69]. More pertinently, it points to the challenges of predicting which individuals are likely to drop out of a digital intervention based on baseline characteristics alone [70]. Finally, the finding that neither pain disability nor depression severity levels were associated with an increased risk of dropout is important as it suggests that digital interventions targeting comorbid depression are acceptable for patients with varying levels of pain intensity and depression symptom severity. This is further supported by the fact that we found no significant difference in predictors when the intervention was aimed at prevention and when it was aimed at treatment. Taken together, these findings provide promising evidence that digital interventions may provide a scalable approach for integrating psychological treatment within pain management routines in health care settings.

This study also demonstrated the feasibility of predicting dropout early on in the intervention based on data restricted to the first module and participant baseline characteristics. Our finding that the number of days taken to complete the first module significantly predicted dropout is consistent with the study by Bremer et al [46] that identified the average number of days taken to complete each module as one of the strongest predictors of dropout in a digital intervention for insomnia. This may reflect a number of underlying causes, including challenges interacting with the intervention, low motivation, lack of time, or low perceived value [40]. The finding that a self-reported negative event in the previous week predicted a lower risk of dropout may be because of the fact that experiencing a negative event (or being asked to report on one) provided greater intrinsic motivation to complete the module and is consistent with research demonstrating that some people drop out from an intervention because they no longer feel they need it [30,31,40]. However, it is worth highlighting that the CIs for the predictor were wide, so the results should be interpreted with caution and examined in future studies using larger sample sizes to determine whether the findings replicate. Notwithstanding, this is the first study to identify that a simple 1-item self-report questionnaire may be used to aid the prediction of dropout during a digital intervention, thus highlighting the potential of incorporating such assessments within digital interventions in the future. Interestingly, the relationship between participant education level and dropout was no longer significant in the models that combined baseline characteristics and intervention usage variables (Table 6). This suggests that a patient's education level may be less important at predicting dropout when including variables that reflect how the patient interacts with the intervention, such as how long it takes them to complete a specific module.

Indeed, a comparison of models using baseline characteristics and intervention usage variables revealed that a model that combined baseline characteristics and intervention usage data generated the most accurate predictions and was significantly more accurate than models based on baseline characteristics only or intervention usage data only. Moreover, in terms of clinical utility, the AUROC of 0.72 and sensitivity of 76% exceeded the accuracy threshold of 65%-70%, at which clinicians reportedly become willing to act on predictions [71]. Implemented within an intervention, dropout risk models such as this could be used to alert supporting clinicians and health care workers when an individual is at high risk of dropout, so that they are able to intervene early and ideally prevent it.

Notwithstanding the above, there is still significant room for improving model performance. In particular, the development of models that are able to predict dropout *before* completion of the first module would be especially valuable as a significant proportion of individuals drop out before then [65,69]. Developing more accurate models will require intervention developers to capture more granular data related to engagement with the intervention, for example, the number and timing of log-ins, interaction with specific components of the modules (eg, homework; [72]), data specifically related to the intervention target (eg, sleep data for an insomnia intervention; [46]), and additional self-report data such as early measures of therapeutic alliance with the coach [40,73]. Armed with comprehensive intervention usage data such as this, researchers will be better positioned to engineer both handcrafted (theory-driven) and automated features and assess their impact on predictive accuracy. Exploring the role of nonlinear machine learning models in improving model performance is also an area that holds potential, as has been demonstrated in several studies comparing the classification performance of machine learning algorithms with logistic regression in the prediction of dropout [45,46].

Finally, as the findings of this study were specific to one intervention, future research would also benefit from assessing whether the predictors found herein are valuable for predicting dropout in other digital interventions, alternative disorders, and different populations. If it is consistently found that there are a set of variables such as "number of days to module completion" that are associated with higher risk of dropout, these predictors may then be used to inform the basis of models for other interventions in the future. In the same way that outcome feedback technology that identifies individuals at risk of deterioration during treatment has been shown to improve eventual treatment outcomes [43,44], dropout warning systems could be used to alert the supporting clinician, guide care pathways (eg, in stepped-care models), or personalize the intervention itself in the case of self-help interventions. Given the high dropout rates found in real-world settings [16], this will become increasingly important as interventions are implemented within public and private health care systems to meet the growing demand for psychotherapy [47].

Strengths and Limitations

To the best of our knowledge, this is the first study to examine the predictors of dropout in a digital intervention for depression in individuals with a comorbid somatic illness. This is also the first study to compare whether predictors of dropout differ when the intervention is aimed at prevention (in a subclinical population) versus treatment (in a clinically diagnosed population) and using study samples with clinically verified diagnoses at baseline. Finally, in contrast to most studies conducted to date, which have been based on efficacy trials with small sample sizes and convenient samples [33], this analysis was based on data from 2 large-scale effectiveness trials. These trials were conducted within routine health care settings, where dropout rates are typically significantly higher [16], thereby providing high ecological validity.

Despite these strengths, we acknowledge several limitations of this study. First, the analyses were based on data specific to a prevention and treatment version of one intervention and one population, namely, individuals with depressive symptoms and CBP. As such, the predictors we found to be significant and the subsequent accuracy of the classification models may not generalize to other interventions or other populations. For example, dropout has been found to be significantly greater in unguided interventions than in guided interventions, and the mechanisms underlying dropout may differ between the two [33,51]. Future research would, therefore, benefit from assessing whether the predictors found to be significant in this study generalize to other interventions, populations, and settings. Second, as this was an exploratory study, we did not just adjust for multiple testing as alpha adjustment may have increased the likelihood of type II errors. Future research aimed at replicating the current findings in studies that are sufficiently powered for a confirmatory analysis would be valuable. Third, we had only a limited set of data from the intervention available for analysis. Several studies have demonstrated that a number of other variables derived from intervention usage are valuable in the prediction of both adherence and outcomes, including in-depth measures of engagement such as the frequency of log-ins [45] and interactions with specific content formats [72]. Accordingly, there may be other variables with further explanatory power that were not included in our models. The same applies to baseline characteristics, where studies have shown that data obtained from electronic medical records may be used to identify those at risk of dropout during face-to-face therapy [74,75]. Finally, although dropout in this study was operationalized according to the usage intended by the clinicians who developed the intervention [76], it is important to highlight that it is not always necessary for patients to complete the full per-protocol treatment to benefit clinically [30]. In other words, dropout is not always representative of a negative experience [31,40].

Conclusions

The high dropout rates associated with digital health interventions remain one of the biggest challenges to their successful implementation in real-world health care settings. Being able to identify individuals at high risk of dropout early on in treatment may provide clinicians and intervention developers with a valuable opportunity to intervene early and prevent dropout from occurring. Using a combined set of predictors from patient baseline characteristics and intervention usage data, we were able to identify individuals at risk of dropout early on in a digital intervention for depression in patients with comorbid CBP. Future research should explore ways of improving model accuracy and investigate the feasibility and efficacy of using these models directly within the interventions themselves to improve adherence.

Authors' Contributions

IM, YT, HB, LBS, and DDE contributed to the study conception and design. IM, YT, HB, and DDE contributed to the methods and analysis. IM prepared the original draft. YT, SP, SS, LPR, HB, LBS, and DDE critically reviewed and edited the manuscript. All authors read and approved the final manuscript and account for all aspects of this work.

Conflicts of Interest

SS has received fees for lectures or workshops from training institutes for psychotherapists in the context of digital health research. HB has received consultancy fees, fees for lectures or workshops from chambers of psychotherapists and training institutes for psychotherapists in the context of digital health research and license fees for an Internet-intervention. LBS has received consultancy fees, fees for lectures and workshops from chambers of psychotherapists and training institutes for psychotherapists in the context of digital health research. DDE has received consultancy fees/served in the scientific advisory board from several companies such as Minddistrict, Lantern, Novartis, Sanofi, Schoen Kliniken, Ideamed, German health insurance companies (BARMER, Techniker Krankenkasse) and a number of federal chambers for psychotherapy. He is a stakeholder of the Institute for health training online (GET.ON), which aims to implement scientific findings related to digital health interventions into routine care. The authors have no further conflicts to declare.

Abstract

Background: Sickle cell disease (SCD) is characterized by severe acute pain episodes as well as risk for chronic pain. Digital delivery of SCD pain self-management support may enhance pain self-management skills and accessibility for youth. However, little is known about how youth with SCD and their caregivers engage with digital health programs. iCanCope with pain is a digital pain self-management platform adapted for youth with SCD and caregivers through a user-centered design approach. The program was delivered via a website (separate versions for youth and caregiver) and mobile app (youth only).

Objective: We aimed to characterize patterns of user engagement with the iCanCope with SCD program among youth with SCD and their caregivers.

Methods: A randomized controlled trial was completed across multiple North American SCD clinics. Eligible youth were aged 12-18 years, diagnosed with SCD, English-speaking, and experiencing moderate-to-severe pain interference. Eligible caregivers were English-speaking with a child enrolled in the study. Dyads were randomized to receive the iCanCope intervention or attention-control education for 8-12 weeks. This report focused on engagement among dyads who received the intervention. User-level analytics were captured. Individual interviews were conducted with 20% of dyads. Descriptive statistics characterized quantitative engagement. Content analysis summarized qualitative interview data. Exploratory analysis tested the hypothesis that caregiver engagement would be positively associated with child engagement.

Results: The cohort included primarily female (60% [34/57] of youth; 91% [49/56] of caregivers) and Black (>90% of youth [53/57] and caregivers [50/56]) participants. Among 56 dyads given program access, differential usage patterns were observed: both the youth and caregiver engaged (16/56, 29%), only the youth engaged (24/56, 43%), only the caregiver engaged (1/56, 2%), and neither individual engaged (16/56, 29%). While most youth engaged with the program (40/57, 70%), most caregivers did not (39/56, 70%). Youth were more likely to engage with the app than the website (85% [34/57] versus 68% [23/57]), and the most popular content categories were goal setting, program introduction, and symptom history. Among caregivers, program introduction, behavioral plans, and goal setting were the most popular content areas. As hypothesized, there was a moderate positive association between caregiver and child engagement (χ^2_1=6.6; P=.01; φ=0.34). Interviews revealed that most dyads would continue to use the program (11/12, 92%) and recommend it to others (10/12, 83%). The reasons for app versus website preference among youth were ease of use, acceptable time commitment, and interactivity. Barriers to caregiver engagement included high time burden and limited perceived relevance of content.

Conclusions: This is one of the first studies to apply digital health analytics to characterize patterns of engagement with SCD self-management among youth and caregivers. The findings will be used to optimize the iCanCope with SCD program prior to release.

Introduction

Sickle cell disease (SCD) is the most common genetic blood condition in North America and primarily affects people of African descent [1]. The hallmark feature of SCD is recurrent episodes of acute severe pain due to vaso-occlusive crisis [2]. Vaso-occlusive crisis occurs when sickled red blood cells block blood flow, resulting in tissues becoming deprived of oxygen and causing pain. SCD pain is reportedly worse than postoperative pain and as intense as terminal cancer pain, and it can negatively impact all aspects of health-related quality of life [3-5]. Youth tend to experience increased SCD pain burden as they age into adolescence and young adulthood, with increased health care utilization [4-7]. In addition to acute pain from vaso-occlusive crisis, many youth with SCD also experience daily chronic pain [8,9]. The negative consequences of acute and chronic SCD pain can include depression and anxiety, academic underachievement related to missing school, limited opportunities for social interaction with peers, impaired physical activity, poor sleep, and high stress [9]. The vast majority of SCD pain episodes are treated in the home setting [10]. Unfortunately, many of these episodes may not be optimally managed with pharmacological approaches alone [11-13].

Self-management has been defined as “the individual’s ability to manage the symptoms, treatment, physical and psychological consequences, and lifestyle changes inherent to living with a chronic illness” [14]. The most successful self-management interventions are rooted in the principles of cognitive behavioral therapy [15-18]. Cognitive behavioral therapy involves normalization of the patient’s experience through education, training in strategies for managing disease-related symptoms and other stressors, enhancing self-efficacy, and guidance on developing and maintaining a long-term self-management plan. Gaining skills in monitoring and managing SCD symptoms independently is particularly critical to achieve early in the disease trajectory, as many youth experience worsened pain and disability in adulthood [19].

Barriers to implementing cognitive behavioral therapy in SCD populations include the challenge of delivering pain self-management interventions in traditional office-based visits, costly resources required to provide such support, and maintaining patient engagement [12,20]. Ubiquitous consumer technologies (eg, smartphones) offer opportunities to enhance the accessibility and interactivity of self-management support for youth with SCD [21,22].

iCanCope with pain is a digital pain self-management platform originally developed for youth with chronic pain [23-25]. The platform was adapted for youth with SCD through a user-centered design approach, including a qualitative needs assessment and design sessions [12,26]. The iCanCope with SCD program is currently undergoing efficacy evaluation through a multi-centered randomized clinical trial (NCT03201874) [26]. In the present report, we explore engagement with the digital intervention during the course of this trial.

Little is known about how youth with SCD and their caregivers engage with digital health interventions, and research to date has focused mostly on internet-delivered programs [27]. A scoping review focusing on user engagement with mobile health apps did not identify any studies specific to SCD [28]. Moreover, there is little standardization of engagement metrics due to the heterogeneity of available digital health programs. To add to this body of knowledge, our goal was to operationally define user engagement (tied to program content) with the iCanCope with SCD pain self-management program, to characterize patterns of user engagement among youth with SCD and their caregivers, and to identify individual youth and caregiver perspectives about the digital intervention. Lastly, in an exploratory fashion, we tested the *a priori* hypothesis that caregiver engagement would be positively associated with child engagement.

Methods

Study Design

A 2-arm randomized trial design was used. Dyads were randomized to 1 of 2 possible study conditions: (1) iCanCope with SCD intervention or (2) attention-control education. Details on the trial methodology are available in an open-access protocol paper [26], and the trial has been registered on ClinicalTrials.gov (NCT03201874). This paper will focus on program engagement data from dyads who received the intervention condition. Comparative efficacy results from the broader trial will be reported separately in a future paper.

Ethics Approval

The study was approved by the locally responsible institutional ethics boards (Seattle Children's Institutional Review Board, STUDY00001578; Emory University Institutional Review Board, 00092216; Connecticut Children's Institutional Review Board, 17-115-CCMC; and The Hospital for Sick Children Research Ethics Board, 1000053724).

Participants

The main recruitment sites were Connecticut Children's Medical Center, Children's Healthcare of Atlanta/Emory University, Seattle Children's Hospital, and The Hospital for Sick Children in Toronto. In addition, study referrals were accepted from University of Mississippi Medical Center, Boston Medical Center, and Northwestern University/Lurie Children's Hospital. The study was centrally managed at Seattle Children's Research Institute.

Youth were eligible if they (1) were aged between 12 and 18 years, (2) were diagnosed with any SCD genotype, (3) were able to speak and read English, (4) scored at least 4 (indicating moderate-to-severe pain interference over the past month) on the Sickle Cell Pain Burden Interview [6], and (5) were willing and able to complete online measures. Youth were excluded if they had significant cognitive limitations that would impair their ability to use and understand the iCanCope program, as per their health care provider or caregiver. Youth were also excluded if they had received more than 4 sessions of outpatient psychological therapy for pain management in the 6 months prior to the time of screening.

Caregivers were eligible if (1) they were able to speak and read English, (2) they were willing and able to complete online measures, and (3) their child was a study participant. Youth were permitted to enroll in the study even if their caregiver chose not to participate.

Procedure

Dyads assigned to the intervention condition were given user-authenticated access to the iCanCope with SCD program for a period of 8-12 weeks. The program content, based on the principles of cognitive behavioral therapy, was delivered via a modular website and complementary smartphone app as summarized in Tables 1 and 2. Standardized orientation materials were used to guide participants on how to login and independently use the program. Separate websites with unique content were provided for youth and caregiver participants, while a smartphone app (iOS/Android) was provided for youth participants only. Website navigation can be found in Figures S1 and S2 in Multimedia Appendix 1. The youth and caregiver websites were each organized into 6 core modules in addition to 2 optional youth modules on insomnia and negative mood. Features of the smartphone app included a daily symptom tracker (ie, pain intensity, pain impact, mood, and sleep quality), a calendar to view historical symptom data, goal setting in relevant domains (eg, sleep and mood), a library of SCD education and pain coping strategies, and a community forum to interact with other users (Figure S3 in Multimedia Appendix 1).

Table 1. iCanCope with sickle cell disease program content and delivery for youth.

iCanCope with SCD[a] program		Content delivery	
Content category	Example content	Website	App
Introduction to the program	General information about the iCanCope with SCD program and what to expect	Yes	Yes
About pain management	3Ps of pain management (psychological, physical, and pharmacological strategies)	Yes	Yes
About SCD and treatment	Genetics, potential impact of SCD on daily life, and treatment options	Yes	Yes
Goal setting	Guidance on how to formulate specific, measurable, achievable, relevant, and time-bound goals; a feature within the smartphone app where users could set and track personalized goals to improve activity, mood, and sleep	Yes	Yes
Symptom tracking	A feature within the smartphone app where users could report daily pain intensity, pain impact, mood, and sleep quality and view their symptom trends	N/A[b]	Yes
History	A feature within the smartphone app where users could view previously reported symptoms	N/A	Yes
Community support	A forum feature within the smartphone app where users could post responses to community questions and "favorite" the posts of other app users	N/A	Yes
Stress, relaxation, and negative emotions	Reducing negative thoughts, thought stopping, deep breathing exercises, muscle relaxation, imagery, scheduling pleasant activities, and finding the positives	Yes	Yes
Sleep and insomnia	Pain and sleep, healthy sleep habits, ways to fall and stay asleep, and how to think differently about sleep	Yes	Yes
Communication and self-advocacy	Communication skills, talking with the health care team, and talking with the school	Yes	Yes
Healthy lifestyle and looking ahead	Pacing, graded activity, hydration, considerations for the future, and transition to adult health care	Yes	Yes

[a] SCD: sickle cell disease.

[b] N/A: not applicable.

Table 2. iCanCope with sickle cell disease program content and delivery for caregivers.

iCanCope with SCD[a] program		Content delivery	
Content category	Example content	Website	App
Introduction to the program	What teens are learning in the program; specific, measurable, achievable, relevant, and timebound goals to support teens	Yes	N/A[b]
Behavioral plans	How to create behavioral plans to increase teen adaptive behaviors	Yes	N/A
Problem solving	Learn how to approach problems positively, identify problems effectively, and generate and implement solutions	Yes	N/A
Communication	Strategies to help communicate with teens, health care providers, and school staff	Yes	N/A
Wrap-up	Review of key concepts	Yes	N/A

[a] SCD: sickle cell disease.

[b] N/A: not applicable.

Outcome Measurement

Baseline Characteristics

At baseline, caregivers completed a background questionnaire to capture sociodemographic data (eg, age, race, and ethnicity), and both caregivers and youth completed information about their technology access and usage. Youth were screened into the study using the Sickle Cell Pain Burden Interview to assess SCD pain burden in the past month. The Sickle Cell Pain Burden Interview yielded a total score ranging from 0 (no pain burden) to 28 (severe pain burden). Dyads additionally completed several other clinical effectiveness outcomes detailed in an open-access protocol paper [26].

Primary Outcome

Quantitative

User-level analytics were captured for the app and website components of the iCanCope with SCD program. App engagement was characterized using APEEE (Analytics Platform to Evaluate Effective Engagement) [29], while website engagement data were captured using Google Analytics.

Qualitative

To gather perceptions of the treatment program from youth and caregivers, individual semistructured interviews were conducted with a convenience subset of dyads representing approximately 20% of the intervention group. All dyads were invited to complete an interview following their posttreatment assessment and prior to their 6-month follow-up assessment. Recruitment for the interview continued until 12 caregivers and youth completed the interviews. Separate interviews were conducted with youth and caregivers. The interview guide was designed to capture perspectives on the experience of using the iCanCope with SCD program, including likes, dislikes, value, and areas for improvement. Interviews were 15-20 minutes in duration, conducted over the telephone, and audio recorded for later transcription.

Data Analysis

Quantitative data were analyzed using STATA version 15.1 (Stata Statistical Software). Descriptive statistics were used to summarize background characteristics of the sample and program engagement data. An engagement interaction with the website was defined as a unique content page view. For the app, the following engagement interactions were captured: symptom check-in completed; goal created; library article viewed; and interaction within the community forum. For the youth-specific intervention, program content was distributed across the website and app such that an individual user might access topic-specific information (eg, “healthy sleep habits”) by viewing a website page or reading an app library article. Given this overlap in program content delivery, engagement data for youth participants were also mapped by content category (Table 1).

To address our exploratory aim regarding the relationship between parent engagement and child engagement, we conducted a chi-square test (significance was set at $\alpha<.05$) and assessed the strength of the association using the phi correlation. The phi correlation can range from 0 to 1 and was interpreted as follows: no correlation or very weak correlation (0-0.19), weak correlation (0.20-0.29), moderate correlation (0.30-0.49), strong correlation (0.50-0.69), and very strong correlation (0.70-1.00) [30].

Audio recordings from the qualitative interviews were transcribed verbatim and analyzed by 2 team members (CL and FN) using Dedoose Version 9.0.17 (SocioCultural Research Consultants, LLC). Simple content analysis, a dynamic process that summarizes the informational content of data, was used [31,32]. Specifically, data for all participants were coded and organized into categories that reflected the emerging themes. The raw data were revisited on a regular basis throughout the analytic process to ensure that the codes were grounded in the data. Any disagreements were resolved through consensus.

Participant recruitment spanned periods before and after onset of the COVID-19 pandemic. For analysis purposes, March 2020 was used to differentiate between *prepandemic* and *pandemic* recruitment periods in North America.

Results

Baseline Characteristics

Recruitment was carried out between January 1, 2018, and September 30, 2021. A total of 57 youth and 56 caregivers (56 dyads and 1 youth-only participant) were randomized to the iCanCope with SCD intervention condition and received instructions on how to access the program. The sample included dyads who enrolled in the study before (43/56, 75%) and after (14/56, 25%) pandemic onset. Demographic characteristics of the sample are provided in Tables 3 and 4.

Nearly all youth participants (55/57, 96%) were in middle school or high school. Most youth (47/57, 82%) reported using a smartphone multiple times per day. Caregiver participants (n=56) reported their highest completed education level as high school or less (11/56, 20%), vocational or trade school or some college/university (15/56, 27%), college or university (18/56, 32%), or graduate degree or professional school (11/56, 20%). Most dyad households (30/56, 54%) included 1 or 2 children under 18 years of age (range of 1 to 6 children). With regard to the total annual household income before taxes, participants reported less than US $24,999 (11/56, 20%), US $25,000-49,999 (16/56, 29%), US $50,000-74,999 (9/56, 16%), US $75,000-99,999 (9/56, 16%), and US $100,000 or more (5/56, 9%).

Table 3. Characteristics of youth participants.

Characteristic	Youth value (N=57)
Age (years), mean (SD)	14.8 (2.0)
Sex, n (%)	
Female	34 (60)
Male	23 (40)
Gender identity[a], n (%)	
Female	34 (60)

Quantitative Results

Dyad-Level Program Engagement

Of the 56 dyads who were given access to the iCanCope with SCD program, differential usage patterns were found. Engagement by both the youth and caregiver occurred for 29% (16/56) of the dyads, whereas it was more likely for only youth to engage in the program (24/56, 43%). In 1 dyad out of 56 (2%), only the caregiver engaged with the intervention, and neither individual engaged for 29% (16/56) of dyads. The 1 youth participant who joined the study without a corresponding caregiver did not engage with the program.

Differential engagement of youth and caregivers with components of the iCanCope with SCD intervention is visualized in Figure 1. Content-specific engagement among youth and caregivers is summarized in Figure 2 and Figure 3, respectively. Among the content categories, the most popular for youth were goal setting, introduction to the program, and history. For caregivers, the most popular content categories were introduction to the program, behavioral plans, and goal setting.

Figure 1. Engagement of youth and caregivers with components of the iCanCope with sickle cell disease (SCD) intervention.

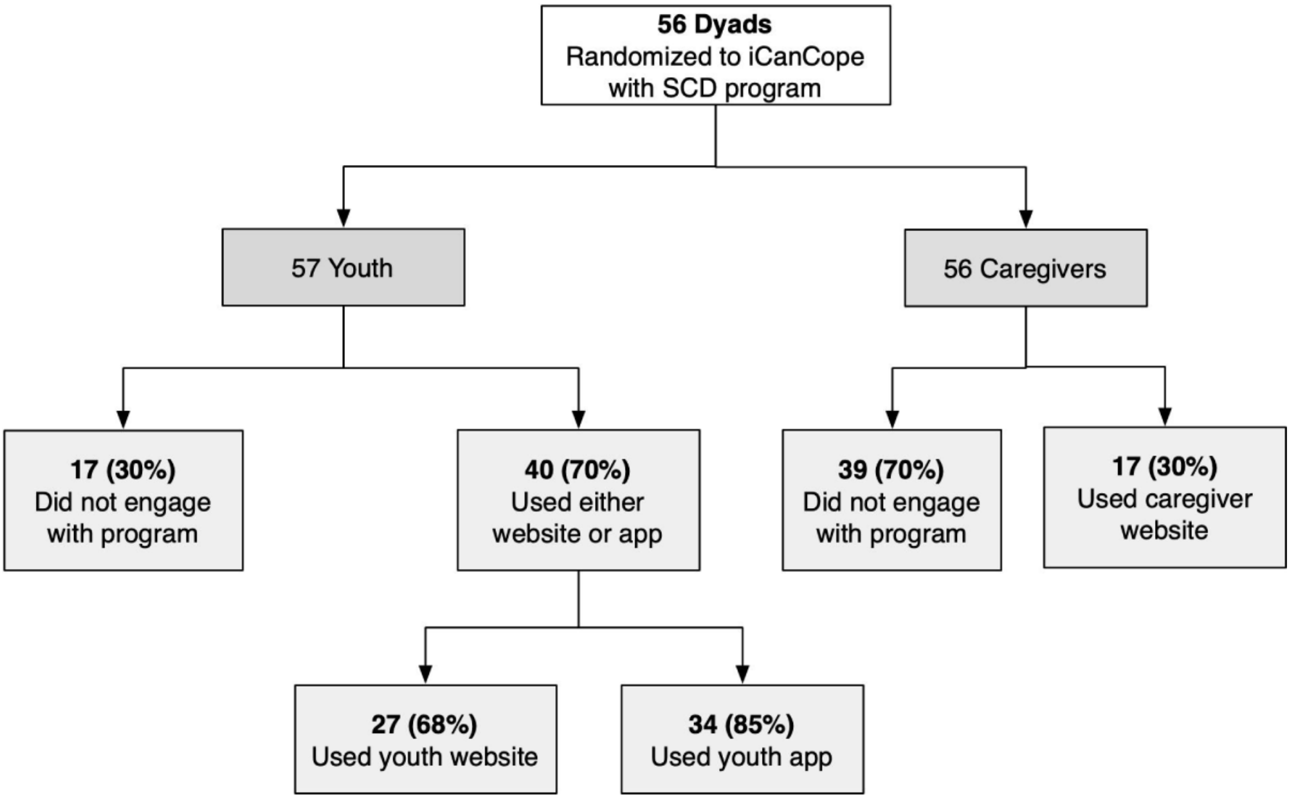

Figure 2. Differential content engagement among youth who used the iCanCope with sickle cell disease program (N=40). SCD: sickle cell disease.

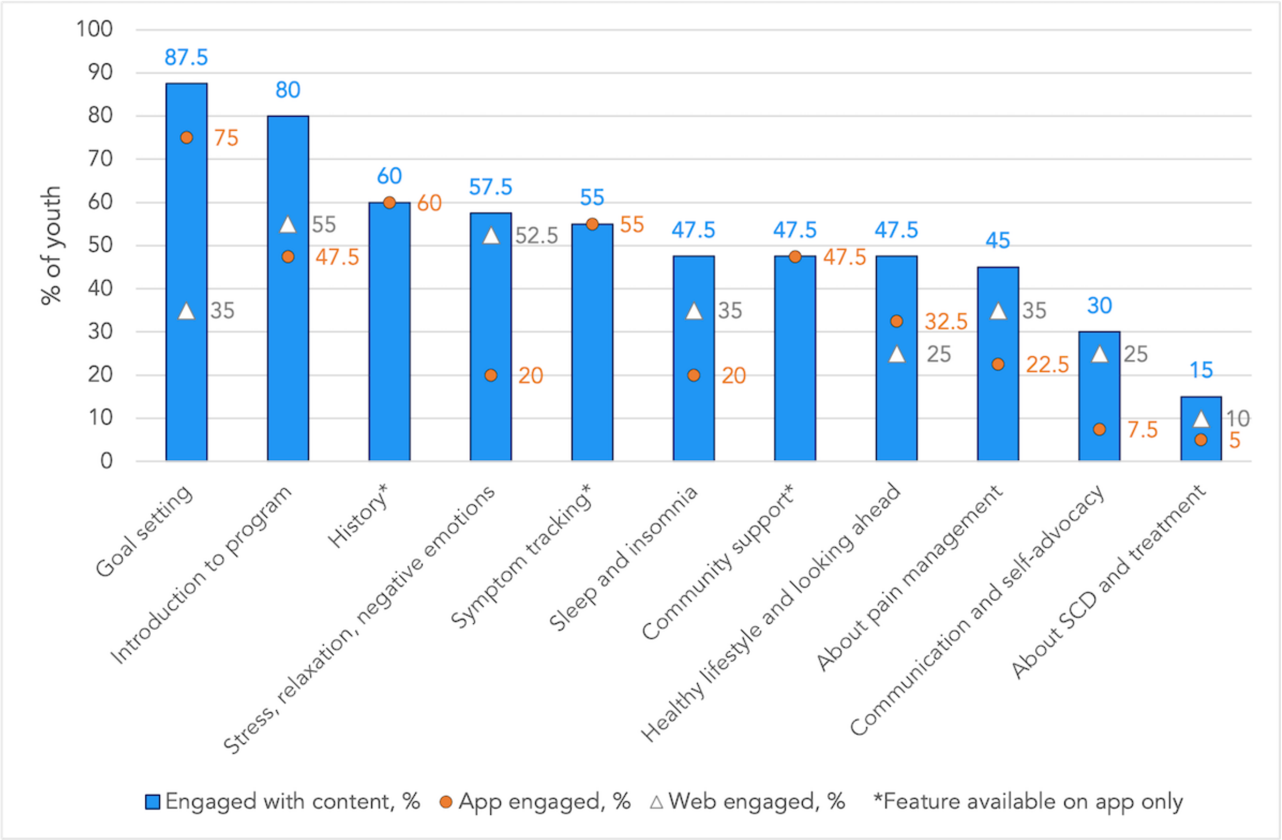

Figure 3. Differential content engagement among caregivers who used the iCanCope with sickle cell disease program (N=17). SCD: sickle cell disease.

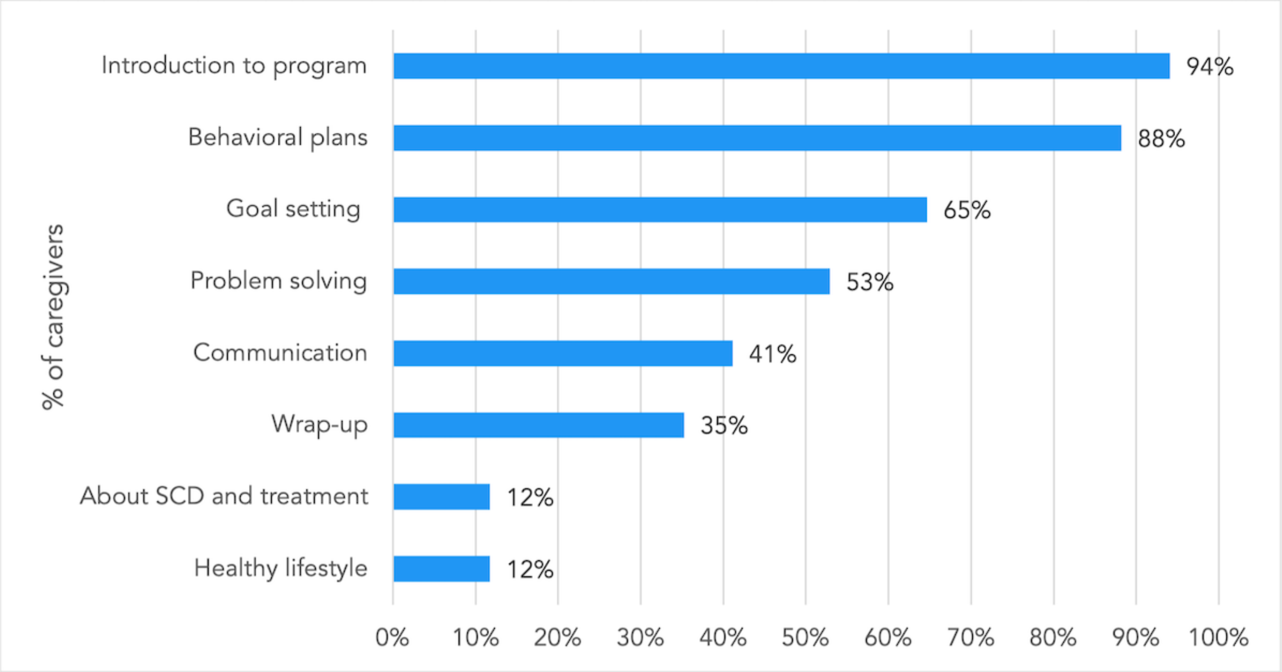


Exploratory Predictor of Treatment Engagement

As hypothesized, there was a moderate positive association between caregiver engagement and child engagement with the intervention (χ^2_1=6.6; *P*=.01; φ=0.34).

Qualitative Results

Interview Participants

Individual interviews were completed with 12 dyads between September 2019 and October 2021, representing participants who completed the study either before (5/12, 42%) or after (7/12, 58%) onset of the COVID-19 pandemic. Youth interviewees ranged in age from 12 to 18 years, and most were female (10/12, 83%). All interviewed caregivers were mothers. The interview sample included dyads where both the youth and caregiver engaged with the program (5/12, 42%), only the youth engaged (6/12, 50%), and only the caregiver engaged (1/12, 8%). Among youth interviewees, 11 of 12 (92%) used either the website or app, 7 of 12 (58%) used the website, and 10 of 12 (83%) used the app. Among caregiver interviewees, 6 of 12 (50%) viewed the website content during the study period and the remainder did not engage with the program.

Motivation for Program Use Among Youth

Nearly all youth interviewees (11/12, 92%) indicated that they intended to continue using the iCanCope with SCD program in the future. Moreover, youth who used the app were asked how they would hypothetically rate it on the iOS or Android mobile store between 0 and 5 stars. Among the 10 youth who used the app, 6 (60%) gave a rating of 5 stars and 4 (40%) gave a rating of 4 stars. As rationale for their ratings, 1 participant shared,

> *…I think this is the first app I've heard about sickle cell and I think it's really informative and I like it.* [Youth #126]

Cited motivating factors for wishing to use the program after study completion are summarized in Figure 4.

Figure 4. Motivation for continued use of the iCanCope with sickle cell disease program among youth interviewees.

Tailoring for age group

"…[it] made me feel like it was **made for people my age** because of the **animations** and then you had the **informational side** and you could comment on stuff which was **really fun**… it made me **really comfortable**… it didn't make me feel like I had to do too much. Every time I go on the app, it would be **really calming.**" [Youth 538; age 13; female]

Resource in moments of pain

"…especially if I need it…**if I'm in pain**, I'll probably look at it and see if there's anything **I could refer to**." [Youth 511; age 12; female]

Caregiver encouragement

"The thing that is motivating me to continue using this program is **my mom**." [Youth 337; age 13; female]

Motivating factors for continued program use

Appealing design

"It's really just like a **peaceful** app." [Youth 538; age 13; female]

"I like that I got to make a little character – that was **fun**." [Youth 336; age 16; female]

"They can **heart your posts** [in the community]…it was fun." [Youth 124; age 12; male]

Ease of finding information

"…[the website] had different sections and it had different columns. For example, if I were looking for one specific article, I could go to that specific column, and **I can find it**, so I really like [that]." [Youth 126; age 14; female]

Ability to track symptoms over time

"…when I would set my pain to like a zero, it would either tell me **I'm on track or I'm not** and I really like that about the app." [Youth 126; age 14; female]

Rationale for Program Recommendation Among Caregivers

Most caregiver interviewees (10/12, 83%) indicated that they would recommend the program to a friend or family member living with SCD. One caregiver shared,

> *I have a host of family members that deal with sickle cell, so I would also like to be able to visit the website and provide them with different coping mechanisms or different kind of information that I have found useful.* [Caregiver #337]

Acknowledging the ups and downs of SCD, another caregiver stated,

> *…let me help you cope with this craziness that's going on in your life every day.* [Caregiver #336]

Several caregivers noted that they would be more likely to recommend the program to youth who are newly diagnosed with SCD or have frequent pain crises. For instance, 1 caregiver commented as follows:

> *…for someone that doesn't have a lot of crises, that wouldn't be helpful...for someone that [has] a lot of crises, this would be very helpful.* [Caregiver #537]

Similarly, a caregiver who characterized the program as a good refresher made the following statement:

> *I like the way it's laid out in terms of the content being very layman terms. You know, there's not a lot of – you're not overwhelmed with a lot of medical things that people are saying 'oh, well what's this, and what's that, and what's this?'. So, in terms of that content, I think it's fantastic. So, I would recommend it.* [Caregiver #119]

Exploring Reasons for Low Engagement

Among the 6 of 12 (50%) caregiver interviewees who did not use the program during the study period, the reasons for low engagement included a perceived lack of relevance to their circumstances.

> *…I found that some of the questions on it, things they would ask me - the exercises the [program] would ask me to do was sort of not relevant to me…I felt like it didn't really apply to [my child] or to me.* [Caregiver #127]

This caregiver also noted that another reason for lack of engagement was the large amount of content.

> *…there's so many sections within one unit itself. So, when I thought I was almost done, I still had more to do. I'm able to do only one section at a time or not even able to finish the whole unit because of timing.*
>
> *…when I get home, I'm exhausted. I'm a nurse and I work in ICU so we're very busy at work especially with the COVID…I live really far from work, so I leave home early, I get home really late, and it's just busy that's all but nothing else.*

Among caregivers who did not use the program themselves, some noted that it was helpful for their children.

> *I think it made her more aware and more focused and…process…how she can cope with it and mostly like she's not alone in this… that there are people out there that care. I think it really helped.* [Caregiver #126]

Others noted that the program helped them understand how to better support their children.

> *…it actually shed a lot of light into a couple of things especially when it gets to her mood swings and why she does certain things and also helping her manage her pain.* [Caregiver #112]

One youth interviewee who did not engage with the program did not provide a specific reason why but did indicate interest in using it after the study was complete.

> *…because I feel like it's a good…way to…learn more about it and I could learn and study more myself.* [Youth #520]

Differential Engagement With Program Components

As shown in Figure 1, youth who engaged with the program were more likely to use the app (34/40, 85%) compared with the website (27/40, 68%). Reasons for this preference described by interviewees included perceived ease of use and acceptable time commitment.

> *I liked the app more because it was easier to use than the website…the app was simple, and it only took a couple of minutes.* [Youth #537]

The interactivity of the app feature set was also cited as a reason for use.

> *I like the app more than I like the website because of the daily diaries and connecting to others…and there [is] a library inside the app where you can read and how you can set goals.* [Youth #126]

This user continued with the following statement:

> *I think I have some downsides with the website because the website you only have to read, but the app – it's fun.*

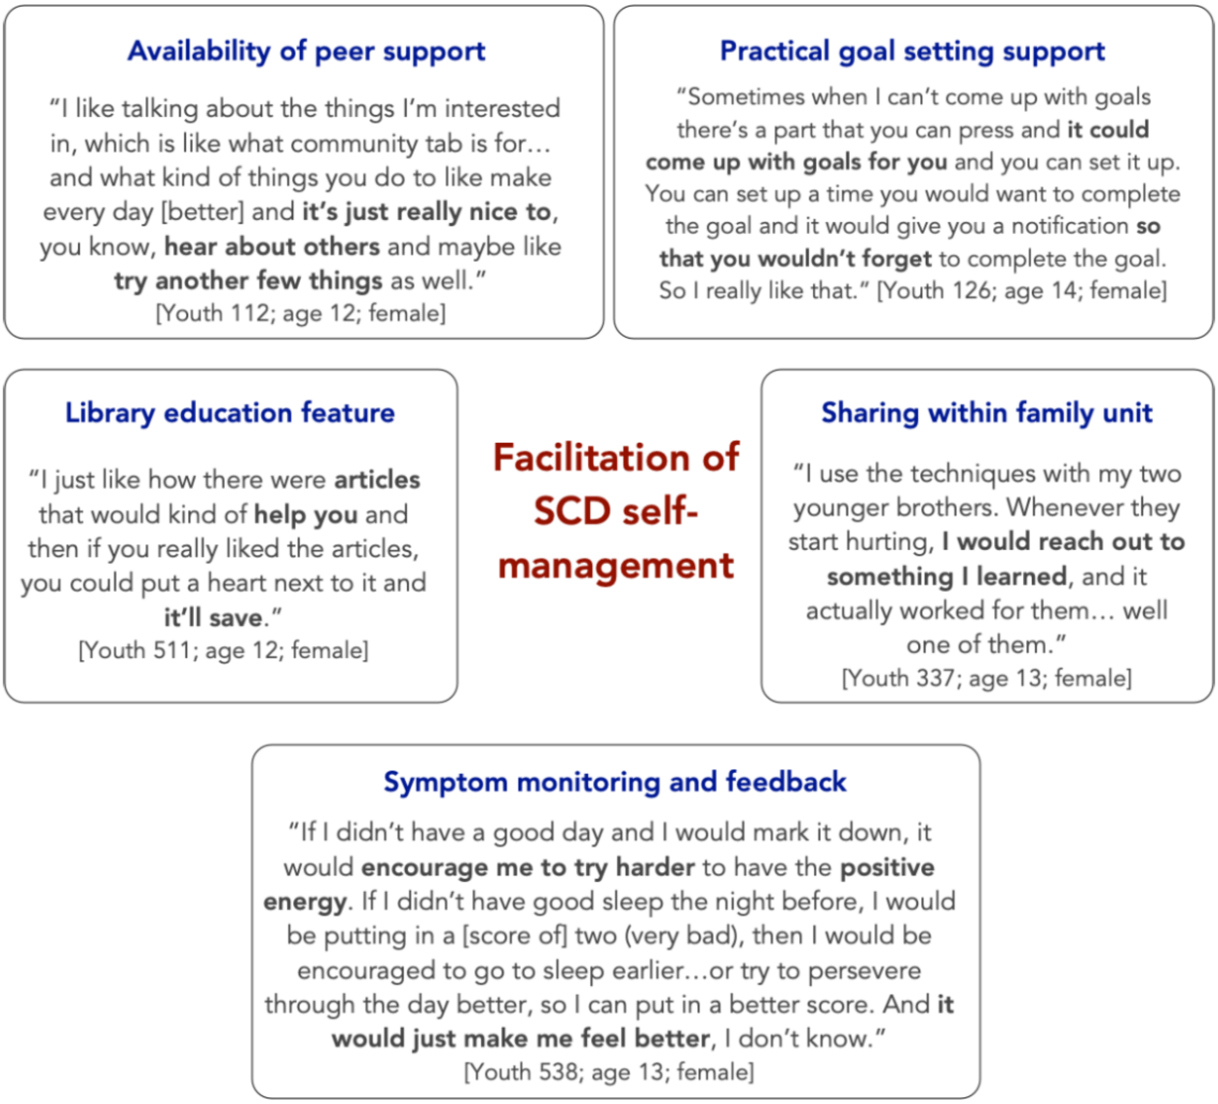
While technical bugs were rare and minimally disruptive (eg, broken external resource link within the youth website and temporary app diary error), technical limitations of the website caused frustration among some participants and may have impacted engagement with that program component. For instance, a caregiver who had low program engagement noted the following:

> *…the website can't save what you write, so every time you come back it does get deleted.* [Caregiver #537]

Promotion of Disease Self-management Behaviors

When asked about how they used the program in their day-to-day life, youth interviewees described several concrete ways that the program supported them to engage in SCD self-management, as summarized in Figure 5.

Figure 5. Examples of how the program facilitated disease self-management. SCD: sickle cell disease.



Availability of peer support

"I like talking about the things I'm interested in, which is like what community tab is for… and what kind of things you do to like make every day [better] and **it's just really nice to**, you know, **hear about others** and maybe like **try another few things** as well." [Youth 112; age 12; female]

Practical goal setting support

"Sometimes when I can't come up with goals there's a part that you can press and **it could come up with goals for you** and you can set it up. You can set up a time you would want to complete the goal and it would give you a notification **so that you wouldn't forget** to complete the goal. So I really like that." [Youth 126; age 14; female]

Library education feature

"I just like how there were **articles** that would kind of **help you** and then if you really liked the articles, you could put a heart next to it and **it'll save**." [Youth 511; age 12; female]

Facilitation of SCD self-management

Sharing within family unit

"I use the techniques with my two younger brothers. Whenever they start hurting, **I would reach out to something I learned**, and it actually worked for them… well one of them." [Youth 337; age 13; female]

Symptom monitoring and feedback

"If I didn't have a good day and I would mark it down, it would **encourage me to try harder** to have the **positive energy**. If I didn't have good sleep the night before, I would be putting in a [score of] two (very bad), then I would be encouraged to go to sleep earlier…or try to persevere through the day better, so I can put in a better score. And **it would just make me feel better**, I don't know." [Youth 538; age 13; female]

Influence of the Pandemic on Self-management

Youth who completed the study during the pandemic described that the program helped to mitigate some disruptions to their self-management routines.

> *I found the app very helpful because for me it can be very hard especially because I'm in high school…now that we're online…I like do my work and…I just stay in my room and I don't do the stuff that I'm supposed to do to ensure that I'm preventing crises. So, having the app, especially the goal chapter, was very helpful because I was able to put what goals I wanted. For example, if I wanted to drink more water or I wanted to get more sleep that week then I was able to do that. That motivated me to want to achieve the goal.* [Youth #127]

Discussion

Principal Findings

This is one of the first studies to characterize patterns of engagement with a web- and app-based pain self-management program among youth with SCD and their caregivers. The data demonstrate that most youth with SCD engaged with the program (40/57, 70%) while most caregivers did not (39/56, 70%). The youth program was delivered via a mobile app and a website. Youth were more likely to engage with the app than the website, and the most popular content categories were goal setting, introduction to the program, and symptom history. Among caregivers who engaged with the website, introduction to the program, behavioral plans, and goal setting were the most popular content areas. Exploratory analysis revealed a significant moderate association between caregiver and youth engagement with the intervention. The key insights from qualitative interviews were as follows: (1) nearly all youth intended to continue using the program; (2) caregivers would recommend the program to others living with SCD who were newly diagnosed or who frequently experienced pain crises; (3) caregivers cited the large amount of content and low relevance to their specific circumstance as reasons for low engagement; (4) youth preferred the app over the website because of perceived greater ease of use, acceptable time commitment, and interactivity; and (5) use of the youth program helped to facilitate SCD self-management behaviors such as goal setting, applying strategies for pain management, symptom trend monitoring, and learning through peer support.

Comparison With Prior Work

There are several app- and web-based interventions designed for children and youth with SCD [33-36] that focus on enhancing SCD knowledge, medication adherence, quality of life, transition to adult care, and pain management. However, engagement or adherence metrics for these interventions were reported in only a few studies. Among 4 recent studies [34-36] that reported some engagement data, operational definitions varied, making direct comparisons difficult. First, Palermo et al reported high engagement with web-based management of adolescent pain (WebMAP), an internet-delivered cognitive-behavioral therapy intervention tailored for SCD [27]. Engagement was defined as participants completing at least one module in the WebMAP program. They found that 14 of 15 (93%) participants met this threshold, which was higher than the proportion of youth (40/57, 70%) who engaged with any iCanCope content. Second, Phillips et al reported engagement with an app-based program called Voice Crisis Alert V2 over a 12-week intervention period [35]. They characterized engagement based on the use of individual app components, similar to the content categorization approach used in our study. Among 60 dyads, symptom tracking and history were the most popular features (used by 90% of dyads), while a clinician messaging feature was least popular (total of 5 message threads generated during the study). In our study, we similarly found that symptom tracking and history were among the most popular content areas. Third, Saulsberry et al offered the Sickle Cell Transition E-Learning Program to 183 youth, of whom, 53 (29%) completed at least one of the 6 available modules [36]. In our study, a higher proportion of youth (70%) who were offered the iCanCope program engaged with the content. Fourth, Leonard et al reported engagement with a medication adherence app as percentage of days that each participant logged medication administration [34]. In a pilot sample of 11 patients, average engagement was 80%. Our study found a wide range of youth engagement with various program components, with the most popular feature being goal setting (35/40, 88%) and the least popular being education about SCD and treatment (6/40, 15%).

The iCanCope program has also been assessed in youth with juvenile idiopathic arthritis and chronic pain [24,25]. Usage levels were similar in the SCD population, although engagement was higher with the symptom history function in the juvenile idiopathic arthritis population [25] at 80% versus 60% among SCD users. A systematic review focusing on engagement and adherence to mHealth interventions in children and youth in clinical and nonclinical populations reported average adherence of 78% [37].

Several contextual factors may explain the differences in engagement patterns seen across studies in the SCD population, among users of other iterations of the iCanCope program, and generally among the pediatric population. These factors include differences in the intervention scope (eg, pain management versus transition readiness), distinct definitions of engagement, different study designs and clinical populations, and technology variation (eg, wearable technology vs app based) [38]. The literature suggests that treatment adherence among youth with SCD may be impacted by forgetfulness, side effects of pharmacological interventions (eg, nausea, heart racing, and taste aversion), questioning efficacy of treatment, and a desire to be “normal,” and some of these factors may similarly impact adherence to digital health interventions [39]. Previous literature also suggests that sociodemographic factors can impact engagement with digital interventions, highlighting lower rates of engagement among racial or ethnic minorities, and those with low socioeconomic status [40-42].

There is limited research on caregiver engagement with digital health interventions for SCD. Many interventions designed for youth do not have a caregiver component. However, 3 recent digital health studies have reported parent engagement in pediatric SCD, chronic pain, and cancer populations, respectively [43,44]. The WebMAP program was designed for pediatric chronic pain patients and adapted for the SCD population. In the chronic pain population, caregiver engagement was higher compared with youth (82% vs 74% completed at least one module) [43]. Similarly, caregiver engagement was also higher (100% vs 93% completed at least one module) than youth engagement in the SCD population [27]. In contrast, the Teens Taking Charge Cancer web-based self-management program [44] reported lower caregiver engagement compared with youth (8% vs 28% completed at least one module), which is consistent with our results. One study on the psychology of eHealth use among caregivers with children having complex health conditions found that factors, such as poor caregiver psychosocial health, high eHealth literacy, and high acceptability of eHealth, were associated with increased engagement [45]. Furthermore, caregiver engagement with nondigital or analog health interventions that report high levels of engagement tend to include methods, such as motivational interviewing and teaching-learning processes (eg, role play and interactive problem solving) [46]. Our program was self-guided, which may have contributed to lower levels of engagement from caregivers.

Strengths and Limitations

Our study had several strengths. First, a phased evidence-based approach was used to develop the iCanCope with SCD program. A qualitative needs assessment involving youth with SCD, caregivers, and health care providers was completed to determine essential components of the program [12]. Next, design sessions were completed with patient partners with SCD to adapt the platform and content for a population with SCD [26]. The changes that were implemented (eg, content tailoring and app design) were cited by participants and their caregivers as positive aspects of the iCanCope program. Second, this study used both qualitative and quantitative methods, which enhanced our ability to understand and contextualize the diverse set of engagement experiences. Furthermore, by including youth and caregiver perspectives, we were able to distinguish their unique experiences and understand how the family unit engaged with the program. Third, this study was a multi-center randomized controlled trial, and this increases the generalizability of the findings to SCD patients in North America. Moreover, the study sample was inclusive of families from a variety of socioeconomic backgrounds.

These findings should be considered in the context of a few limitations. First, caregivers were not heavily included in the design of the iCanCope program, which may partially explain their reduced engagement with the content. As per the user design approach, the creation of iCanCope was focused on meeting the needs of youth, as the primary users were envisioned to be youth, rather than caregivers. However, our study findings indicate that parent engagement with SCD program content is important as it is positively associated with child engagement. Unfortunately, poststudy interviews with caregivers revealed that the program was too content heavy and time-consuming. One strategy to improve caregiver engagement would be to account for the individual need for cognition, which refers to the enjoyment of deep thinking [47]. For those with a low need for cognition, information could be provided in short easily accessible excerpts, such as videos or infographics. In contrast, long-form content would be more suited for individuals with a high need for cognition. Notably, once the program is publicly released, caregivers will be able to review content at their own pace rather than within the time constraints of a research study. In addition, consultations with parents may be completed to fine tune the program to meet their needs prior to public release. Second, differential use of the app versus website among youth suggests a need for changes to the website to increase engagement with the overall program. A specific technical limitation of the website was that it was unable to store the responses of participants, making it difficult for them to gauge their progress. Finally, we were only able to interview 1 youth participant who did not engage with the program at all.

Future Directions

Prior to public release of the program, there are opportunities for refinement using the elements of persuasive design [48]. Wen et al found that more frequent prompts were associated with higher engagement in studies with clinical pediatric populations [37]. Although the iCanCope app did incorporate reminders to prompt participants to engage (eg, push notifications to complete check-ins or set a goal), the frequency and timing of the reminders could be customized. However, it is important to balance the number of reminders while minimizing interruptions to the user. As such, identifying ideal opportunities to use the iCanCope program individualized to each participant is important. A novel approach includes using algorithms to determine these opportunities, which have been developed for adult populations [45,49]. In tandem, providing praise (eg, congratulatory messaging) and rewards when participants complete a check-in, read an article from the library, or complete a goal may influence engagement positively [48]. Rewards can include elements of gamification where participants gain points or virtual rewards for completing certain tasks, which they can use to promote engagement with self-management content. Finally, real-world use of the iCanCope program can also be studied in the future, after public release.

In terms of program dissemination, using strategies to target the family unit, rather than individual members, may increase engagement as SCD typically impacts multiple members of a family. This approach is supported by youth participants who reported *ad hoc* sharing of program content with their siblings and the finding that parent and child engagement was positively associated. Furthermore, by partnering with SCD clinics, the program could be introduced to youth and families when the SCD pain becomes more frequent to help cope with the corresponding increase in pain burden.

Conclusions

This is one of the first studies to apply digital health analytics to characterize patterns of engagement with SCD self-management among youth and caregivers. Differential engagement patterns were found, with more youth engaging in the program than their caregivers; however, youth were more likely to engage with the app than the website. These findings will be used to optimize the iCanCope with SCD program prior to release, with the potential to improve the accessibility and acceptability of pain self-management support for families affected by SCD.

Abstract

Background: In health care, the benefits of digitalization need to outweigh the risks, but there is limited knowledge about the factors affecting this balance in the work environment of physicians. To achieve the benefits of digitalization, a more comprehensive understanding of this complex phenomenon related to the digitalization of physicians' work is needed.

Objective: The aim of this study was to examine physicians' perceptions of the effects of health care digitalization on their work and to analyze how these perceptions are associated with multiple factors related to work and digital health usage.

Methods: A representative sample of 4630 (response rate 24.46%) Finnish physicians (2960/4617, 64.11% women) was used. Statements measuring the perceived effects of digitalization on work included the patients' active role, preventive work, interprofessional cooperation, decision support, access to patient information, and faster consultations. Network analysis of the perceived effects of digitalization and factors related to work and digital health usage was conducted using mixed graphical modeling. Adjusted and standardized regression coefficients are denoted by b. Centrality statistics were examined to evaluate the relative influence of each variable in terms of node strength.

Results: Nearly half of physicians considered that digitalization has promoted an active role for patients in their own care (2104/4537, 46.37%) and easier access to patient information (1986/4551, 43.64%), but only 1 in 10 (445/4529, 9.82%) felt that the impact has been positive on consultation times with patients. Almost half of the respondents estimated that digitalization has neither increased nor decreased the possibilities for preventive work (2036/4506, 45.18%) and supportiveness of clinical decision support systems (1941/4458, 43.54%). When all variables were integrated into the network, the most influential variables were purpose of using health information systems, employment sector, and specialization status. However, the grade given to the electronic health record (EHR) system that was primarily used had the strongest direct links to faster consultations (b=0.32) and facilitated access to patient information (b=0.28). At least 6 months of use of the main EHR was associated with facilitated access to patient information (b=0.18).

Conclusions: The results highlight the complex interdependence of multiple factors associated with the perceived effects of digitalization on physicians' work. It seems that a high-quality EHR system is critical for promoting smooth clinical practice. In addition, work-related factors may influence other factors that affect digital health success. These factors should be considered when developing and implementing new digital health technologies or services for physicians' work. The adoption of digital health is not just a technological project but a project that changes existing work practices.

Introduction

Background

Digital transformation is rapidly changing the health care sector, and the COVID-19 pandemic has accelerated this transition to digital solutions [1]. The digital transformation of health care is expected to enhance health outcomes by improving person-centered care and self-management, data-driven treatment decisions, and medical diagnoses as well as creating more evidence-based knowledge, skills, and competencies for professionals to support health care delivery [2]. Physicians are one of the most important stakeholders in health care, and they have the potential to shape this change for the benefit of clinical care [3].

The digital transformation of workplace can be defined as a phenomenon in which new technologies significantly change the way employees perform tasks and processes, their social relationships, and subsequently their overall workplace experience [4]. Indeed, physicians have seen digital health as a dynamic facet of new ways of working [5]. Digital health is the field of knowledge and practice related to the development and use of digital technologies to improve health [2]. The broad scope of digital health includes categories such as health information systems (HISs; including, eg, electronic health record [EHR] systems and clinical decision support systems [CDSSs]) as well as telemedicine, wearable devices, mobile health, and personalized medicine [6].

Digital health can provide additional work processes next to existing ones or completely replace current processes [7]. It also changes the culture toward shared decision-making and the democratization of care [8]. Patients are suggested to no longer be just customers but active participants in their own care processes [5,8]. Digital health can empower patients to advocate for themselves, take control of their care, and make better-informed decisions about their health [9-11]. In a variety of settings, digital interventions can be effective in both preventing and treating disease [12-17]. In addition, digital health appears to impact interprofessional cooperation [18-23]. EHRs influence cooperation by facilitating access to patient information and data sharing between different stakeholders and hospitals [21,24,25]. There is also a need for effective cooperation between information technology professionals and physicians to improve the quality and implementation of HISs [26]. Participation in development may also increase one's sense of control over work [27]. Technology such as CDSSs can support physicians by minimizing errors [28], improving the accuracy of physician diagnoses [29] and outcomes [28,30,31], and increasing efficiency [29,32]. Physicians have described the greatest benefits of digitalization in terms of care quality, readability, and ease of access to patient data [33,34]. In addition, digitalization has been shown to support collaboration, decision-making, and continuous learning [5], and it has been associated with improved job satisfaction and work-life balance [35].

However, the digital transformation of health care is a highly multifaceted issue [7]. Physicians have expressed concerns about the impact of digitalization on information overload and ambiguity, interaction with patients, privacy issues, disruptions to workflows, and increasing workloads [5,34,36-39]. The digitalization of work has also been found to be associated with the stress levels of physicians [40,41]. Dissatisfaction has been particularly associated with the implementation of new EHRs [42-45] and the subsequent transition period [46].

Reports on the impact of digitalization on work performance have been inconclusive [34]. Digitalization potentially affects and is affected not only by the characteristics of the digital health used but also by the physical and psychosocial work environment. It is well known that work characteristics have an important impact on employee attitudes toward the digital workplace transformation [4]. Moreover, the various effects of digitalization are likely to be interconnected. Although physicians' perceived benefits of digitalization appear to outweigh the risks [5], there is limited knowledge about the factors affecting this balance. To achieve the benefits of digitalization, a more comprehensive understanding of this complex phenomenon related to the digitalization of physicians' work is required.

To date, conceptual and statistical tools to analyze and illustrate such complexities have been lacking. However, the recently introduced psychological network approach offers a promising methodology to address the interplay between multiple factors in multiple areas [47]. To understand complex phenomena, it is often insufficient to only focus on how the individual components of a system function. Instead, one must also study the organization of the system's components, which can be represented in a network. In this field of research, psychosocial, organizational, and behavioral entities are conceptualized as an interplay of social, psychological, and other components that interact in a network consisting of nodes representing observed variables and connected by edges representing statistical relationships [47-51].

Goal of This Study

The aim of this study was to examine physicians' perceptions of the effects of health care digitalization on their work and to analyze how these perceptions are associated with multiple factors related to work and digital health usage. With this information, it is possible to further develop digital health to meet the needs of clinical practice. In addition, the information can be used to improve the understanding of the changing nature of clinicians' work and enable organizations to develop physicians' orientation, promote staff empowerment and well-being, and improve the quality of care services. The research questions (RQs) were as follows:

- RQ1: How has the digitalization of health care affected the work of physicians from their perspective?
- RQ2: How are (1) the effects of digitalization (patients' active role, preventive work, interprofessional cooperation, decision support, access to patient information, and faster consultations), (2) factors related to work (purpose of using the HIS, employment sector, and specialization status), and (3) factors related to digital health usage (EHR experience, EHR grade, participation in HIS development, and telemedicine) connected in the network structure?

Methods

Study Sample

The nationwide survey *EHR systems as a tool for physicians 2021* was conducted in Finland as part of the national STePS 3.0 project [52,53]. The survey method and questionnaire have been described in detail elsewhere [54]. The data were collected between January and March 2021. An invitation to participate in the web-based survey was sent by email to all physicians of working age (<65 years) who had provided their email addresses to the Finnish Medical Association (n=19,142). The register represents 90.51% (19,142/21,148 of all working age physicians who live in Finland [55]. We received responses from 4683 physicians (response rate 4683/19,142, 24.46%). A total of 53 responses were removed from the data because the respondents reported that they did not use health care information systems at all (n=43) or they did not respond to this question (n=10). The final sample included 4630 physicians (2960/4617, 64.11% women) who worked directly with patients, in administration, or both. Information on the status of clinical work was no longer included in the registry, so the number of clinically active physicians is an estimate based on several data sources and the expertise of researchers at the Finnish Medical Association. According to their analyses, the respondents were representative of the population. However, older physicians responded slightly more often than younger physicians, as did specialists. The hospital sector was also slightly overrepresented [56].

Ethics Approval

According to Finnish legislation, a statement from the ethics committee is not required to conduct surveys on respondents' opinions [57]. Participation in the survey on the EHR systems as a tool for physicians in 2021 was voluntary. All participants provided informed consent by choosing to participate actively in the study by answering the questionnaire.

Context

Finland is one of the leading countries in digitalization, ranking first in a comparison of digitalization levels across European Union member states [58]. The public sector has the primary responsibility for health services, which are complemented by private sector services [59]. Private service providers deliver a quarter of all social and health services [60]. Almost half (49%) of Finnish physicians work in hospitals, a quarter (25%) in health centers, and 16% in the public sector [55].

EHRs are widely deployed across Finland [61]. As early as 2007, EHR coverage in the public sector in Finland reached 100%, and in 2017, all hospital districts achieved 100% usage intensity in conservative, operative, and psychiatric care. In 2020, 91% of private actors reported usage intensities above 90% [61]. All EHRs are integrated with national health information exchange services (Kanta services), which comprise My Kanta Pages, Prescription service, Pharmaceutical database, Patient Data Repository, and archiving of old patient data [62]. Participation in Kanta services is mandatory for all public health care providers. Private providers are also required to join Kanta services if the organization archives its clients and medical records in an electronic form [62]. In addition, there are several ancillary systems, for example, radiology and laboratory information systems, and HISs for operating rooms, intensive care units, labor and delivery, and emergency departments [63,64]. However, due to suboptimal integration solutions within the organizations, insufficient data structures in Kanta services, and barriers set by legislation, patient information is not always readily usable across different sectors, organizations, or facilities [61]. Comprehensive digital services are also made available to patients by solutions such as patient portals, access to their own data in the Kanta eArchive via My Kanta Pages, digital symptom checkers, and digital self-management guides [65]. Telemedicine with patients via video visits or chat messages, as well as self-recorded health data and monitoring services, already increased before the COVID-19 pandemic [61].

Measurements

The Effects of Digitalization on Work

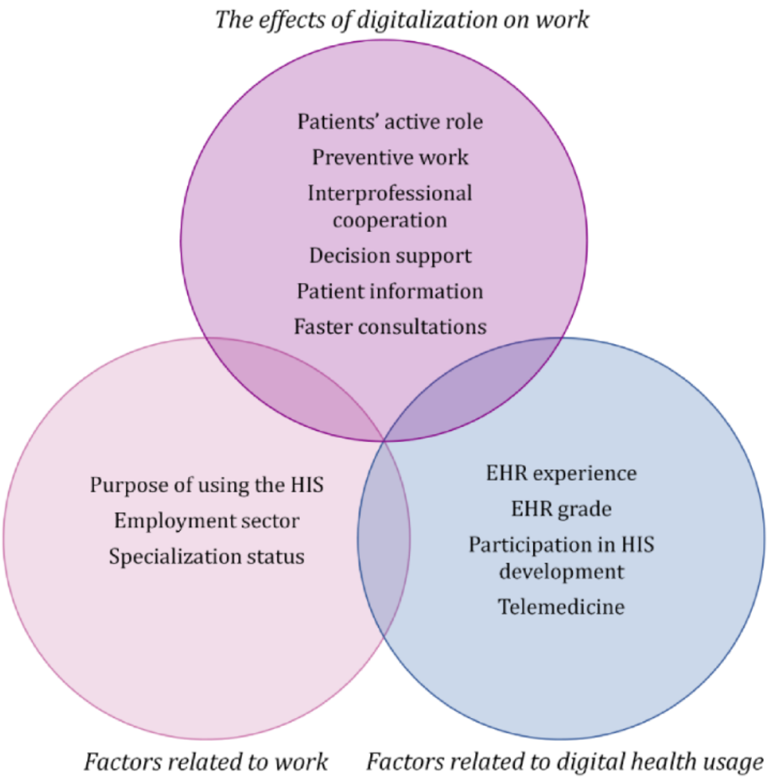
All variables used are presented in Figure 1 and Multimedia Appendix 1. The measurement of the perceived effects of digitalization on work was based on the strategic focus areas of the Finnish eHealth and eSocial Strategy 2020 [66]. The survey questionnaire included 6 statements related to physicians' experiences with digitalization. Respondents were asked how the digitalization of health care has affected their work and asked to assess the change during the last 3 years.

The 6 statements were as follows:

1. Patients have assumed a more active role in their treatment (patients' active role).
2. Possibilities for preventive work have improved (*preventive work*).
3. Interprofessional cooperation has progressed (*interprofessional cooperation*).
4. Intelligent decision support systems support a physician's work (*decision support*).
5. It has become easier to obtain information on patients (*patient information*).
6. Consultations with patients have become faster (*faster consultations*).

Response options were rated on a 5-point Likert scale ranging from 1 (fully agree) to 5 (fully disagree). For the analysis, the responses were reversed from 1 (fully disagree) to 5 (fully agree). Variables were recoded for the descriptive results, as (1) somewhat or fully disagree (response options 1-2), (2) neither agree nor disagree (response option 3), and (3) somewhat or fully agree (response options 4-5). In the network analysis, each statement was used separately as a continuous variable.

Figure 1. Variables used in this study. EHR: electronic health record; HIS: health information system.



Work-Related Factors

Work-related factors included purpose of using the HIS, employment sector, and specialization status.

Purpose of using the HIS was assessed by asking whether respondents used the HIS (1) for patient work, (2) for administrative work, (3) for both, or (4) not at all. The variable was coded as a dichotomous variable: 0=uses not only for work with patients (response options 2-3) and 1=uses only for work with patients (response option 1). Response option 4 was coded as missing.

Employment sector was assessed with the following response options: (1) municipality, (2) state, (3) private (including The Social Insurance Institution of Finland [Kela]), (4) university, and (5) I am not employed. The variable was coded as a dichotomous variable: 0=public (response options 1-2) and 1=private (response options 3-4).

Specialization status was assessed using response options (1) not specialized, (2) in specialist training, and (3) specialized and coded as a dichotomous variable: 0=not specialized (response options 1 and 2) and 1=specialized.

Factors Related to Digital Health Usage

The factors related to digital health usage included EHR experience, EHR grade, participation in HIS development, and telemedicine.

EHR experience was assessed by asking respondents how long they had used the EHR system that they mainly use in their employment. The response options were (1) less than 6 months, (2) 6 months—less than a year, (3) 1 to 3 years, (4) 4 to 6 years, and (5) more than 6 years. The variable was coded as a dichotomous variable: 0=less than 6 months and 1=6 months or more.

The EHR grade was assessed by asking, "On a scale of 4 to 10 (with 4 being the lowest score and 10 being the highest score), how would you rate the EHR you mainly use?" Response options ranged from 4 to 10, including a response option of "I am not able to give a grade, or I do not wish to answer." The variable was coded as a dichotomous variable: 0=4 to 7 (low grade) and 1=8 to 10 (high grade). The response option "I am not able to give a grade, or I do not wish to answer" was coded as missing.

Participation in HIS development was assessed by asking whether the respondent had participated in HIS development activities. The response options were (1) yes, some of my working time has been allocated for such development work; (2) yes, in addition to my work; and (3) no. The variable was recoded as a dichotomous variable: 0=no and 1=yes (response options 1-2).

Telemedicine was assessed by asking whether the respondent's main employment involved telemedicine with patients (remote treatment by phone, chat, video contact, and other electronic contact). The response options were (1) very much, (2) much, (3) some, (4) a little, and (5) not at all. The variable was recoded as a dichotomous variable: 0=little or not at all (response options 4-5) and 1=somewhat to very much (response options 1-3).

Statistical Analysis

Descriptive analyses were performed using SPSS (IBM SPSS Statistics 27) to characterize the sample characteristics and the variables used. Owing to nonresponse in some items, the number of observations varied in the descriptive analyses. Subsequently, network analysis was performed using mixed graphical models [67] in R Statistical Software (version 4.1.1; R Foundation for Statistical Computing 2020) to estimate the associations between the perceived effects of digitalization, work-related factors, and factors related to digital health usage. The scale-based effects of digitalization were modeled as continuous variables: patients' active role, preventive work, interprofessional cooperation, decision support, patient information, and faster consultations. The skewed distributions of these variables were normalized using the nonparanormal transformation (huge.npn function) [68]. The following binary work-related factors were modeled as 2-level categorical variables: purpose of using the HIS, employment sector, and specialization status. The following binary digital health usage–related factors were also modeled as 2-level categorical variables: EHR experience, EHR grade, participation in HIS development, and telemedicine.

As the data contained both continuous and binary variables, we estimated the main network with mixed graphical models using the mgm package (version 1.2.12) [67]. The package estimates a network model by running regularized generalized regressions on each variable and estimating the edges associated with that variable. We provided the data, removed the missing values, and specified the type and number of levels for each variable. The regularization parameter λ was selected by 10-fold cross-validation, and the parameter k was set to 2 only to estimate the pairwise relationships. The computed relationships were represented in undirected graphical models [69] and visualized using the qgraph package [70]. Each variable was represented as a node in the network and pairwise connections between variables were represented as edges. The adjusted and standardized regression coefficients are denoted by b in the text. We added the strength of the dependencies by the width of the edges and information about the sign of the edges: green and blue edges indicate positive relationships and red edges indicate negative relationships. Two different colors indicating positive edges (green and blue) were used for illustration purposes.

Centrality statistics for the networks were examined to assess the relative influence of each factor in the network in terms of standardized node strength (the sum of edge weights associated with a given node) [47,71]. The predict function in mgm was used to obtain estimates of predictability for each factor. Predictability refers to the extent to which the variable can be explained by other variables included in the network [72]. Estimates are reported on a scale from 0 to 1, with 1 reflecting complete predictability. To evaluate the stability and accuracy test of the main network, the bootnet package [71] with the mgm specification was used to compute nonparametric bootstrap intervals around the estimated network edges and significance tests for edge differences using 1000 bootstrap samples.

Results

Characteristics of the Study Population

The characteristics of the sample are shown in Table 1. The majority (3668/4630, 79.22%) used HISs exclusively to work with patients. Most participants (3676/4614, 79.67%) worked in the public sector, and more than two-third (3134/4630, 67.69%) were specialists. For nearly half of the respondents (2177/4625, 47.07%), their work involved at least some telemedicine with patients. In total, 15.77% (727/4611) of the respondents had less than 6 months of experience with their current EHR. Nearly two-third (2974/4610, 64.51%) gave the EHR they primarily used a low rating.

Table 1. Characteristics of the study sample of Finnish physicians (N=4630).

Characteristic	Participants, n (%)
Age group (years) (n=4591)	
<35	948 (20.65)
35-44	1211 (26.38)
45-54	1148 (25)
55-64	1284 (27.97)
Gender (n=4617)	
Women	2960 (64.11)
Men	1626 (35.22)
Other or did not want to respond	31 (0.67)
Purpose of using the HIS[a] (n=4630)	
Not only for work with patients	962 (20.78)
Only for work with patients	3668 (79.22)
Employment sector (n=4614)	
Public	3676 (79.67)
Private	938 (20.33)
Specialization status (n=4630)	
Not specialized	1496 (32.31)
Specialized	3134 (67.69)
EHR[b]experience (months) (n=4611)	
<6	727 (15.77)
≥6	3884 (84.23)
EHR grade (4-10) (n=4610)	
Low grade	2974 (64.51)
High grade	1636 (35.49)
Participation in HIS development (n=4601)	
No	3495 (75.96)
Yes	1106 (24.04)
Telemedicine with patients (n=4625)	
Little or not at all	2448 (52.93)
Somewhat to very much	2177 (47.07)

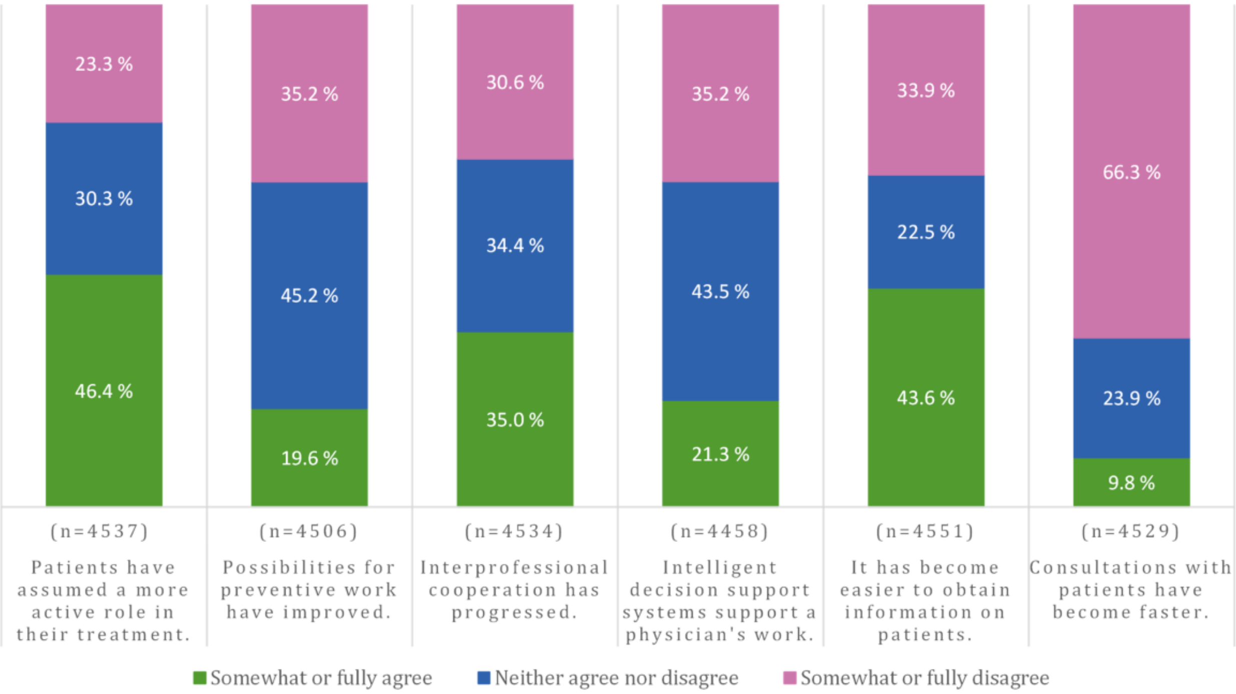
[a] HIS: health information system.

[b] EHR: electronic health record.

Perceived Effects of Digitalization on Work

The descriptive statistics of the perceived effects of digitalization are shown in Figure 2. Nearly half (2104/4537, 46.37%) of the respondents agreed that digitalization of health care has had a positive effect by giving patients a more active role in their treatment (mean 3.24, SD 0.99). This statement was rated as the most positive of all the estimated effects of digitalization on work. In addition, nearly half (1986/4551, 43.64%) of the respondents indicated that obtaining information about patients has become easier (mean 3.06, SD 1.18). The weakest positive effect of digitalization was found in consultation times (mean 2.12, SD 1.03). Only one-tenth (445/4529, 9.82%) found that consultations with patients have become faster. Almost half (2036/4506, 45.18%) of the respondents estimated that digitalization has neither increased nor decreased the possibilities for preventive work (mean 2.78, SD 0.91). Almost half (1941/4458, 43.54%) of the respondents could not state whether the CDSSs have supported their work (mean 2.77, SD 0.99). Assessments of the progress of interprofessional cooperation were evenly distributed (mean 3.01, SD 1.01).

Figure 2. Physicians' perceptions about the effects of digitalization on work. The scale ranged from 1 (fully disagree) to 5 (fully agree). Somewhat or fully disagree included response options 1 to 2, and somewhat or fully agree included response options 4 to 5.



Network Analyses

The resulting network (Figure 3) shows the interconnections between the perceived effects of digitalization on work. In the estimated network, each node was connected to 3, 4, or 5 other nodes. The strongest associations were between the patients' active role and preventive work (b=0.36), patient information and faster consultations (b=0.32), interprofessional cooperation and preventive work (b=0.29), interprofessional cooperation and patient information (b=0.23), and decision support and patient information (b=0.19). The other associations ranged from 0.07 to 0.16, indicating weaker interconnections.

According to the centrality statistics (Figure 4), the most central perceived effect of digitalization in terms of strength (ie, how strongly a variable was connected to all other nodes) was preventive work, followed by interprofessional cooperation. Patients' active role had the lowest cumulative strength of connections to other variables.

Figure 3. A visualized network (n=4339) of the perceived effects of digitalization on the physicians' work. The strength of the dependency is reflected in the weight of the pairwise edge. Positive edges are shown in green.

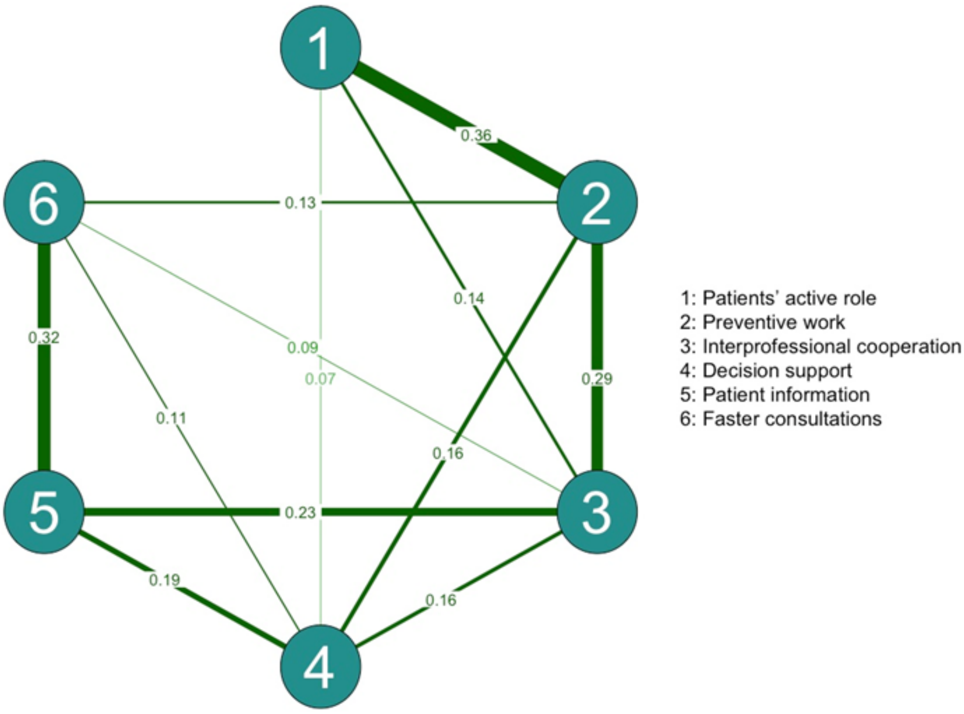


Figure 4. Standardized (ie, *z* scores) centrality indexes denoting node strength for perceived effects of digitalization.

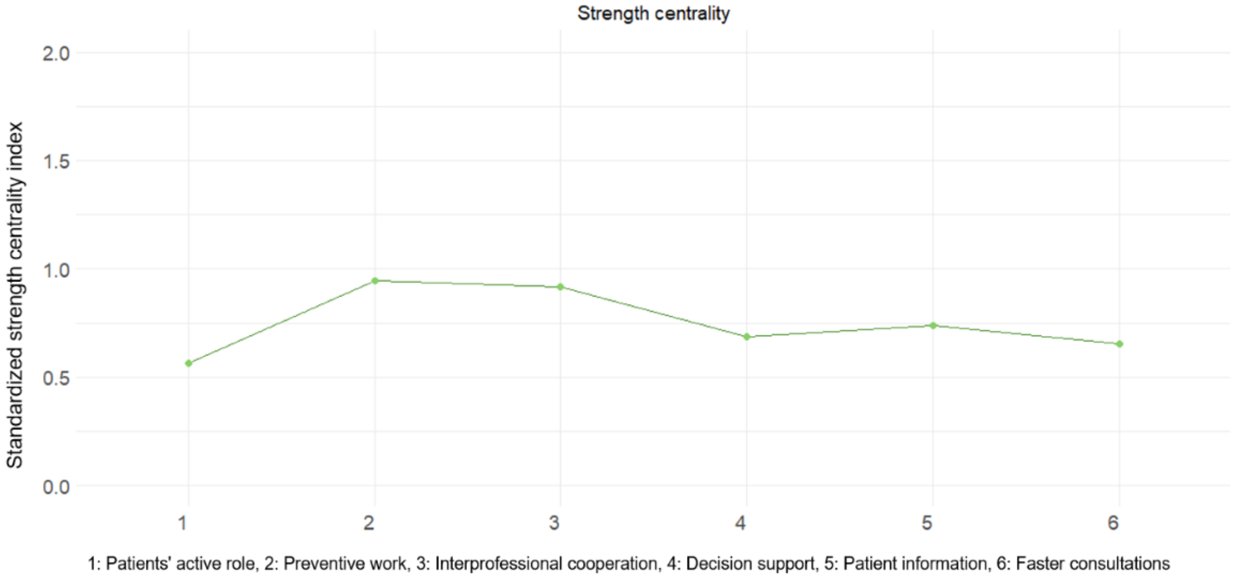
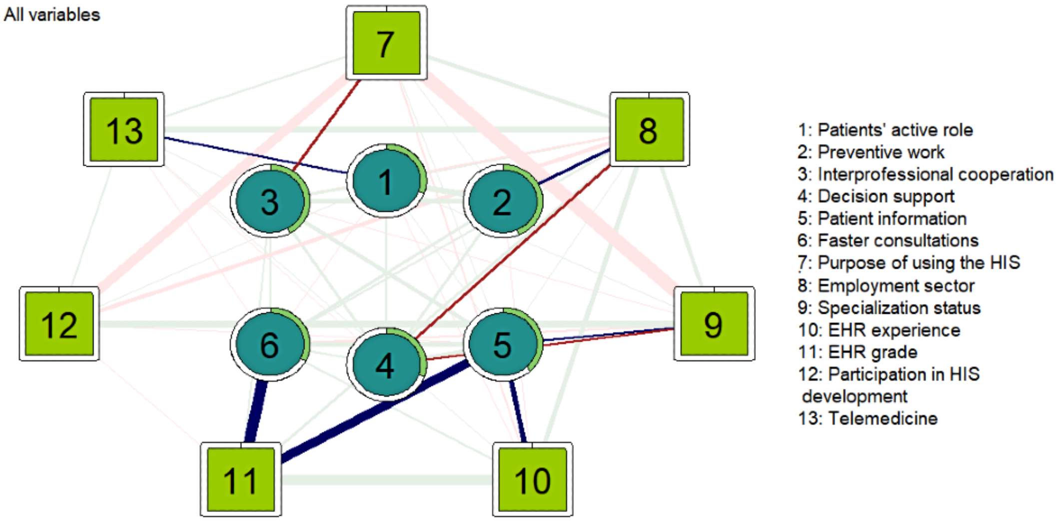


The resulting main network (Figure 5) shows the connections between all 13 factors: perceived effects of digitalization on work (1-6) and factors related to work (7-9) and digital health usage (10-13). In the estimated network, the nodes were connected to 5 to 10 other nodes. The strongest direct links to effects of digitalization were with EHR grade. A higher EHR grade was associated with faster consultations (b=0.32) and facilitated access to patient information (b=0.28). At least 6 months of experience with the main EHR was associated with facilitated access to patient information (b=0.18). Using the HIS only for working with patients was negatively associated with progressed interprofessional cooperation (b=−0.16). The private sector was positively associated with improved possibilities for preventive work (b=0.16) and negatively associated with the supportiveness of CDSSs (b=−0.15). Specialization was negatively associated with the supportiveness of CDSSs (b=−0.13) and positively associated with facilitated access to patient information (b=0.13). A greater amount of telemedicine with patients was associated with a more active role of patients (b=0.12).

Pairwise connections for all visualized variables that reach a value above 0.20 are reported. There was a strong negative association between specialization status and the purpose of using the HIS (b=−0.85). A strong positive association was found between a longer experience with the main EHR and a higher EHR grade (b=0.67). There was also a strong negative association between the purpose of using the HIS and participation in HIS development (b=−0.59). In addition, being specialized was associated with participation in HIS development (b=0.38). The private sector was associated with a greater number of telemedicine services (b=0.34), longer experience with the main EHR (b=0.27), and using the HIS only for patient work (b=0.21). The predictability of each node (perceived effects of digitalization) ranged from 30.2% (decision support) to 43.6% (preventive work) of the explained variance in the continuous variables.

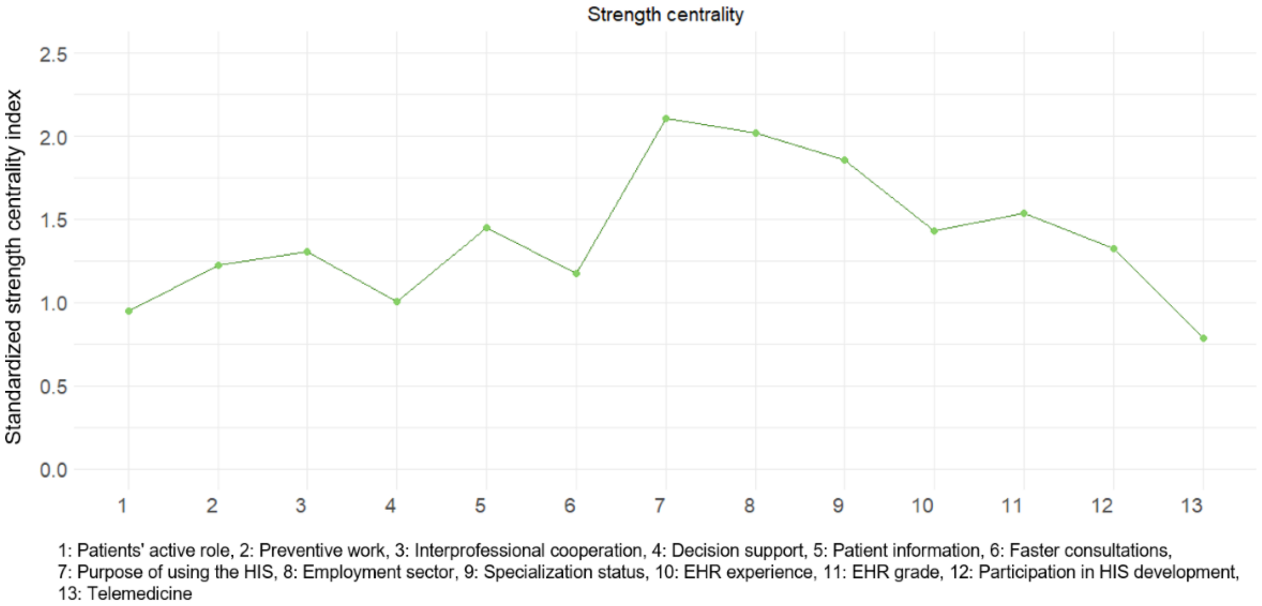
Figure 5. A visualized main network (n=4339) of the perceived effects of digitalization on the work and factors related to work and digital health usage. The strength of the dependency is reflected in the weight of the pairwise edge. Positive edges are shown in green and blue, and negative edges are shown in red. The green ring around each node represents its predictability. EHR: electronic health record; HIS: health information system.



The work-related factors were the most central in the main network (Figure 6). In terms of strength, reflecting the overall influence in the network, purpose of using the HIS had the highest cumulative strength of connections to other variables, followed by employment sector and specialization status. Among the factors related to digital health usage, EHR grade had the highest cumulative strength, while the level of telemedicine had the lowest. Of the perceived effects of digitalization, obtaining information had the highest strength and patients' role had the lowest.

Network stability analysis provided some large and overlapping bootstrapped CIs around the edge weights (Figure S1 in Multimedia Appendix 2). The generally large, bootstrapped CIs urge caution in interpreting the relative sizes of edges. However, correlation stability for strength centrality was 0.517, meaning that 51.7% of cases could be dropped to maintain a correlation with the original centrality greater than 0.7 with a 95% confidence. Values greater than 0.5 were considered stable. Figure S2 in Multimedia Appendix 2 shows the resulting strength-stability plot. Testing for significant differences revealed that all edges differed significantly from several other edges (Figure S3 in Multimedia Appendix 2). In addition, all node strengths differed significantly from those of at least half of the other nodes (Figure S4 in Multimedia Appendix 2).

Figure 6. Standardized (ie, *z* scores) centrality indexes denoting node strength for each factor. EHR: electronic health record; HIS: health information system.



Discussion

Principal Findings

On the basis of our results, nearly half of the physicians assessed that digitalization has promoted an active role for patients in their own care and easier access to patient information. However, only 1 in 10 participants felt that digitalization has had a positive impact on consultation times with patients. The network analysis highlighted the complex interdependence of several factors related to the perceived effects of digitalization on physicians' work. The most central factors in the main network were work related: purpose of using the HIS, employment sector, and specialization status. However, the strongest direct links to the perceived effects of digitalization was with how highly physicians rated the EHR they primarily used. A higher EHR grade was associated with perceptions of faster consultations and easier access to patient information. Overall, purpose of using the HIS, employment sector, specialization status, and EHR grade seemed to be key factors that influenced how positively the effects of digitalization on work were perceived.

The Perceived Effects of Digitalization on Work

Our results showed that nearly half of the respondents agreed that digitalization has helped patients take a more active role in their care. This finding supports the idea that digital health empowers patients to be active participants [9-11]. However, the changing role of patients may have required physicians to more actively encourage their patients to engage in digital health [73]. Patients also need a variety of skills, such as digital health literacy, to play an independent role [74]. Simultaneously, physicians are increasingly expected to assess whether patients have properly understood health information in relation to their own situation [75].

While our results show that the role of patients in their own care was seen as more active and it was associated with improved possibilities for preventive work, nearly half of the physicians estimated that digitalization had neither increased nor decreased opportunities for prevention. Although there is extensive research on the effectiveness of digital health interventions [12-17], not all digital health interventions are created equal and many lack evidence, and achieving outcomes depends on providing the right type of intervention to the right population [12]. From the point of view of the changing work of physicians, digital health prevention work may require a new kind of support for patients, which should be properly and differently targeted.

Almost half of the respondents agreed that digitalization had facilitated access to patient information. Similarly, previous studies have shown that EHRs support the bidirectional flow of patient information and facilitate information sharing among stakeholders [21]. Physicians have perceived obtaining real-time patient data as one of the benefits of EHRs [25]. Patient data sharing between hospitals has also increased [24]. According to our results, easier access to patient information was associated with faster consultation times. However, a significant majority (3003/4529, 66.31%) of the respondents disagreed that consultations with patients have become faster due to digitalization. This was clearly the lowest-rated area and indicates that the time advantage gained in obtaining the information may be lost elsewhere. Previous studies have reported, for example, increased documentation time and time spent on the computer during short-term follow-ups [18,76,77]. The initial transition to the new EHR appears to increase documentation time, but the workflow seems to improve as staff members become more familiar with the system [18]. Most physicians in this study had been using the same system for at least 6 months; thus, recent implementations were unlikely to significantly explain respondents' time use.

Interprofessional cooperation was also connected to improved possibilities for preventive work and for more easily obtaining information on patients. The connection to improved possibilities for preventive work was presumable as interprofessional context had previously been argued to help expand a narrow interpretation of one field and promote the contribution of each member of the team [78]. Health promotion generally involves professionals with different disciplinary backgrounds, who typically also work in different sectors [79]. In this study, over one-third of the respondents estimated that interprofessional cooperation has improved. However, almost as many felt that digitalization has not influenced cooperation. Multiple studies have suggested that the implementation of EHRs [18,19] and electronic prescribing systems [20] can have negative effects on interprofessional communication. However, Chao [21] showed an increased frequency of interprofessional communication while maintaining intraprofessional communication patterns after EHR implementation. Digital health use is also shown to support interdisciplinary cooperation [22], and there are encouraging results for the use of specialists in nonspecialist telemedicine [23]. We cannot draw direct conclusions about the efficiency of collaboration, but our results suggest that digitalization is clearly changing the way professionals interact.

Nearly half of the respondents felt that digitalization had neither increased nor decreased the support physicians received from the CDSSs. However, better support from CDSSs and easier access to patient information were associated. Documenting patient information in a structured, uniform, and simple manner has been previously described as essential for electronic decision support [80]. Previous research suggests that CDSSs can support physicians [28,29,32] and improve outcomes [28,30,31], but they continue to fall short of their full potential [31]. Ford et al [81] pointed out that many previous CDSSs were not developed with the end user, practice context, or clinical workflow in mind. In addition, previous studies show that user attitudes [82] and acceptance are central to the success of CDSSs [83,84].

The Main Network

In the estimated main network, the strongest direct links to the perceived effects of digitalization were with EHR ratings. Higher EHR grades were associated with the perceptions of faster consultations and easier access to patient information. This finding largely supports the work of other studies in this area that link EHR to accessible patient information [21,24,25]. Our network analysis also showed that longer experience with the EHR that was primarily used was associated with perceptions of facilitated access to patient information.

The network also revealed other factors directly associated with the perceived effects of digitalization on work, but these were all relatively weaker. Physicians who used the HIS only to work with patients perceived less progression of interprofessional cooperation than physicians who also used the HIS for other purposes. Physicians with administrative roles may use digital technologies and also collaborate in diverse ways. Leadership in digital health services is thought to require interprofessional and intersectoral collaboration [85]. It is also suggested that leaders in health care may generally view the effects of digitalization differently and more positively than professionals (Kaihlanen, unpublished data, June 2022).

Specialists experienced less support from CDSSs but better access to patient information compared with nonspecialists. Previous research has shown that specialists have also used CDSSs less frequently than general practitioners [86]. This could be related not only to expertise but also to the clinical work itself. General practitioners are known to find electronic medical records more useful than specialists because they are faced with a wider range of symptoms to diagnose, treat, or refer [87].

Physicians who worked in the private sector perceived better opportunities for preventive work but less support from CDSSs than physicians in the public sector. These associations may indicate the different natures of medical work in the private and public sectors. For example, specialized medical care and emergency care are provided in hospitals, and most hospitals in Finland are public sector hospitals [59]. Moreover, employers are responsible for the preventive health care of their employees, most of which is provided by the private sector [60]. The perceived lower level of support from the CDSSs may also be because the CDSSs in Finland are used less in the private sector than in the public sector [61].

Physicians who used more telemedicine with patients felt that digitalization has promoted the active role of patients more than those who barely used telemedicine or did not use it at all. Previous studies have also shown that telemedicine requires patient engagement but also encourages patients to take more responsibility for their own care [88,89]. In addition, physicians who have used telemedicine are more likely known to perceive the potential benefits of telemedicine than physicians who do not use telemedicine with patients [90].

Work-related factors (purpose of using the HIS, employment sector, and specialization status) were found to be the most central factors in the network. Our results suggest that physicians who use HISs primarily for patient work participate less in development work than physicians who also have administrative responsibilities. Participation is known to provide an important sense of control over one's work [27], and physician-initiated improvements to EHR systems have also been found to be useful [91]. The estimated network also showed that specialized physicians were more likely to participate in development work than physicians who were not specialized or were still in training. One possible explanation for this is that those with specialization are in demand for development work because their expertise is in a narrow area of medicine and they receive recognition for their esoteric skills and knowledge [92].

Working in the private sector was associated with a greater amount of telemedicine, longer experience with the main EHR, and the use of HISs only for patient work. An earlier study also found differences among practices, hospitals, and academic medical centers in the use of telemedicine with patients [93], and private hospitals have been more successful than public hospitals in adopting telemedicine [94]. Physicians in the private sector also had more experience with the primary EHR brand used than those in the public sector. Longer experience with the EHR was associated with higher EHR ratings. Shorter experience may indicate new staff members or recent EHR implementation. Several previous studies have shown that physicians are less satisfied after implementing a new EHR [43,44] primarily because of increased workflow disruptions [45]. Significantly more disruptions are noted during the transition period of approximately 6 months, after which the situation recovers [46]. Overall, the results suggest that the employer sector plays an important role in indirectly influencing how physicians view the effects of digitalization through factors related to telemedicine, experience with using EHRs, and the purpose of using HISs.

Limitations

This study has several limitations. First, the psychometric properties of the measure of the perceived effects of digitalization on physicians' work have not been tested previously. However, the statements are based on the Finnish eHealth and eSocial Strategy 2020 and describe the effects of digitalization on the work of physicians from the perspective of the focus areas included in the strategy. Moreover, the items were planned by a large team of experts who have been working on the digitalization of physicians' work for a long time. The content and wording of the measures were pilot tested and evaluated by 2 physicians. On the basis of their feedback, minor revisions were made before the survey was disseminated. Contrary to many previous studies that have focused on the negative ramifications of digitalization on physicians' work [40,95], our questions focused on aspects that can be considered to be positive in nature. Thus, the results may have been different if we would have focused on the negative ramifications of digitalization on the work of physicians.

Second, we used the Likert scale variables as continuous variables in the network, but this has been successfully practiced in other studies of mgm network modeling [eg, 96]. Third, as our data were cross-sectional, the directionality of the observed relationships was not established. Some factors may precede others but some may both contribute to and be influenced by other factors in the network. The network analyses suggest that incorporating factors measured over time, or studies that rely on longitudinal structural model tests, could provide the confirmatory evidence needed [47]. In addition, the response rate was relatively low (24.46%), indicating a higher likelihood of nonresponse bias. However, the sample size was large, and it was well representative of the target population [56]. Finally, Finland is one of the pioneers of the digitalization of health care, and tax-funded universal health care is available to all residents [97]. Therefore, caution should be exercised when generalizing our findings to countries with other types of health care systems or information communication technology infrastructure. However, digitalization is advancing at a rapid pace, and all physicians and health care organizations should be prepared for future changes.

Conclusions

Our results suggest that, from the physicians' perspective, digitalization has improved the active role of patients and the patient information flow, while consultation times with patients have not become faster. Further studies are needed to examine where the potential time benefit of accessible patient information is lost and how the potentially increased documentation time affects the quality of care. Physicians' work should be organized so that the time spent on the computer is not out of the time spent with patients during appointments.

The network highlights that several factors have a complex relationship with the perceived effects of digitalization on physicians' work. The EHR system used appears to be critical for easier access to patient information and faster consultations. Therefore, it seems that a high-quality EHR system is important for the promotion of smooth clinical practice. Thus, organizations could benefit by investing in a well-functioning EHR and the factors that influence its successful use.

In addition, the physician's work (patient or administrative), employer sector, and career stage may play an important background role and influence many other factors that affect the success of digital interventions and their implementation. Thus, it would be advisable for organizations to involve specialists and nonspecialists equally when developing new digital tools or processes in their work. Moreover, some benefits of digitalization seem to be sector specific. Therefore, the specific context and intended use should be considered when developing and implementing digital health. Sectors can also learn from each other; for example, when and how to use telemedicine with patients, how to use digital health in health promotion, and how to benefit from CDSSs in practice. Thus, the information flow and exchange between sectors should be improved.

Overall, a more comprehensive view is needed when assessing the impact of digitalization on specific work environments and work processes. Digitalization of work and related factors should also be considered when orienting physicians. When new digital health is introduced, training on changing work processes should be provided. This would be a priority in addition to technical training. The introduction of digital health is not only a technological project but also a project that changes existing work practices and the professionals' work environment.

Acknowledgments

This study was supported by the Strategic Research Council of the Academy of Finland (project 327145) and the Ministry of Social Affairs and Health (project 414919001). ME was supported by the Academy of Finland (project 339 390). The authors would like to express their gratitude to all physicians who responded to the questionnaire as well as the Finnish Medical Association for collaboration.

Abstract

Background: Electronic health records (EHRs) with large sample sizes and rich information offer great potential for dementia research, but current methods of phenotyping cognitive status are not scalable.

Objective: The aim of this study was to evaluate whether natural language processing (NLP)–powered semiautomated annotation can improve the speed and interrater reliability of chart reviews for phenotyping cognitive status.

Methods: In this diagnostic study, we developed and evaluated a semiautomated NLP-powered annotation tool (NAT) to facilitate phenotyping of cognitive status. Clinical experts adjudicated the cognitive status of 627 patients at Mass General Brigham (MGB) health care, using NAT or traditional chart reviews. Patient charts contained EHR data from two data sets: (1) records from January 1, 2017, to December 31, 2018, for 100 Medicare beneficiaries from the MGB Accountable Care Organization and (2) records from 2 years prior to COVID-19 diagnosis to the date of COVID-19 diagnosis for 527 MGB patients. All EHR data from the relevant period were extracted; diagnosis codes, medications, and laboratory test values were processed and summarized; clinical notes were processed through an NLP pipeline; and a web tool was developed to present an integrated view of all data. Cognitive status was rated as cognitively normal, cognitively impaired, or undetermined. Assessment time and interrater agreement of NAT compared to manual chart reviews for cognitive status phenotyping was evaluated.

Results: NAT adjudication provided higher interrater agreement (Cohen κ=0.89 vs κ=0.80) and significant speed up (time difference mean 1.4, SD 1.3 minutes; P<.001; ratio median 2.2, min-max 0.4-20) over manual chart reviews. There was moderate agreement with manual chart reviews (Cohen κ=0.67). In the cases that exhibited disagreement with manual chart reviews, NAT adjudication was able to produce assessments that had broader clinical consensus due to its integrated view of highlighted relevant information and semiautomated NLP features.

Conclusions: NAT adjudication improves the speed and interrater reliability for phenotyping cognitive status compared to manual chart reviews. This study underscores the potential of an NLP-based clinically adjudicated method to build large-scale dementia research cohorts from EHRs.

Introduction

In recent years, electronic health records (EHRs) have become increasingly common in US health care facilities; they provide a wealth of information on patient demographics, medical history, clinical data, and health system interactions. EHRs offer an unprecedented opportunity to improve clinical care and examine a broad variety of scientific, health care utilization, and heath policy questions [1-3]. An important first step in conducting EHR research is accurately identifying patients with a certain health condition, event, or disease, which is known as phenotyping [1,4]. The identified patient sample is subsequently leveraged for a wide range of purposes, such as providing clinical decision support for health care delivery [5], conducting epidemiological research [4,6], and for the practice of precision medicine [7].

Phenotyping cognitive status (ie, distinguishing between normal cognition and any stage of cognitive impairment) in EHR is a major challenge since dementia is underrecognized, underdiagnosed, and underreported in claims data [8-12], leading to inaccurate identification of dementia cases in many studies based on claims or EHR data [13-15]. Informative missingness, errors, and biases in EHR may further exacerbate the challenges of defining dementia outcomes [16]. Yet another challenge of phenotyping arises from complex, subjective, loosely-defined diagnostic criteria as well as the format—that is, structured (eg, diagnosis codes and medications) versus unstructured (eg, clinical notes and images)—in which the information is stored [4]. Previous studies have demonstrated that information on cognitive status is often found only in free text [17-19]. Clinicians may chart symptoms of cognitive problems in clinical notes but may not make a formal diagnosis, refer to a specialist, or prescribe medication for multiple reasons including clinical role, lack of time or expertise, patient resistance, or limited treatment options [20-22]. Thus, accurately phenotyping cognitive status requires the combined use of both structured data, such as diagnosis codes, medications, and laboratory test results, as well as unstructured clinical notes.

Several algorithms have been developed for phenotyping cognitive status; some studies used structured data, such as diagnosis codes, missed appointments, or health care utilization patterns [15,23], whereas others have applied natural language processing (NLP) to unstructured notes [18,19,24]. None of these prior efforts combined both structured and unstructured input modalities, and manual annotation by clinical experts is limited by the lack of available tools to facilitate efficient chart review [25]. Thus, we hypothesized that the best approach for phenotyping cognitive status is a semiautomated one in which automated NLP is applied to clinical notes and presented in an integrated view to the clinical expert for final manual adjudication of cognitive status.

We developed NAT, a semiautomated NLP-powered annotation tool, to facilitate adjudication of cognitive status. The tool extracts and processes data from EHRs and then ranks clinical notes based on a deep learning NLP algorithm (Macro F_1=0.92) that classifies whether a note indicates normal cognition, cognitive impairment, or has no pertinent information [26]. It highlights key information and presents a summarized view to the annotator. We evaluated NAT in two EHR data sets: (1) Medicare beneficiaries from the Mass General Brigham (MGB) Accountable Care Organization (ACO) who were labeled in another study using manual chart reviews [15] and (2) MGB patients with laboratory confirmed SARS-CoV-2 (a case-control study to investigate the effects of COVID-19 on people with and without HIV was used as an exemplar of a research cohort that requires labeling of cognitive status). We evaluated interrater agreement in the first data set and compared it to interrater agreement in Epic—the EHR system used at MGB since 2015. The second data set was used to compare timings of manual to NAT adjudication, as the timing of manual adjudication was not available in the first data set.

By addressing the gaps in current chart review methods and leveraging existing NLP methods, we demonstrate that NAT increases both the efficiency and the interrater reliability of phenotyping cognitive status in EHR (relative to manual chart reviews) to build future research cohorts.

Methods

Clinical Settings and Data Sources

This diagnostic study was conducted at MGB—formerly Partners Healthcare—a private nonprofit organization comprising two major academic hospitals, community hospitals, and community health centers in the Boston metropolitan area. Data were sourced from the MGB Enterprise Data Warehouse that stores data from Epic. We evaluated NAT adjudication for phenotyping cognitive status on two distinct data sets. The first one included EHR data from January 1, 2017, to December 31, 2018, of 100 patients randomly selected from a larger data set that was expert-annotated via manual Epic chart reviews and reported elsewhere [15]. Specifically, this manually expert-annotated data set contained 1002 Medicare beneficiaries from the MGB ACO who were classified into (1) normal cognition, (2) borderline of normal cognition and mild cognitive impairment (MCI), (3) MCI, (4) borderline of MCI and dementia, or (5) dementia [15]. The experts graded their confidence in the adjudication as low, medium, moderate, or high. The 100 patients were randomly sampled from these 5 classes with 20 from each class, ensuring that each class had a similar distribution of confidence scores. The second data set included 527 MGB patients with a laboratory confirmed SARS-CoV-2 infection based on polymerase chain reaction testing between March 1 and December 31, 2020. The data set was created for a case-control study to investigate the effects of COVID-19 on people with and without HIV; EHR data up to 2 years prior to and any time after the index positive polymerase chain reaction test were used to investigate the performance of NAT adjudication.

Ethics Approval

This study was approved by the MGB Institutional Review Board (2015P001915).

Definition of Cognitive Impairment

In this study, to phenotype cognitive status, patients were annotated with three labels: (1) cognitively normal (CN), (2) cognitively impaired (CI), and (3) undetermined. Patients were labeled as CI if there was any documented suspicion or concern of memory or cognitive decline, whether based on symptoms, observations, or objective testing. This ranged from any dementia-related International Classification of Diseases (ICD) codes or medicines in the patients' charts to cognitive concerns—relayed by patients, family members or friends, or providers in the notes and phone logs—as these concerns often reflect an underlying change in cognition even if a cognitive evaluation is normal (in which case they prompt a diagnosis of subjective cognitive decline [27]). Conversely, to be annotated as CN, at least implicit evidence of no cognitive concerns was required (eg, the patient continued to work, clearly managed their own care or hobbies, and followed complicated instructions, or they had annual wellness or specialist notes with multisystem assessment and no mention of a cognitive concern). The strongest evidence for a CN annotation was a cognition test performed with an explicit note of intact cognition. If there was conflicting evidence of both cognitive impairment and evidence of no cognitive impairment in a patient's chart, the latest evidence or specialist notes (if any were available) informed the adjudication. Finally, patients were marked as "undetermined" if the EHR did not have sufficient information.

Data Preparation

Data query, preparation, and preprocessing steps are described in Multimedia Appendix 1. For each patient, the following EHR data from the relevant time period were extracted from the Enterprise Data Warehouse: (1) patient demographic information, including name, medical record number, birth date, sex, ethnic group, marital status, and educational level; (2) all clinical notes, including reason for visit, history, note text, encounter type, and MGB provider (including provider department, specialty, and qualifications); (3) current primary care provider; (4) patient care coordination note; (5) medication history and current medications; (6) magnetic resonance imaging and computerized tomography orders; (7) laboratory orders and results; (8) problem list, including ICD diagnoses and diagnosis codes; and (9) visit cancellations.

Several features were engineered from the EHR to facilitate assessment of cognitive status. Dementia-related medications and ICD codes (medications: galantamine, donepezil, rivastigmine, and memantine; ICD-9 codes: 290.X, 294.X, 331.X, and 780.93; ICD-10 codes: G30.X and G31.X) and laboratory tests (eg, vitamin B12, folate, and thyroid-stimulating hormone) related to assessment of cognitive status were identified and highlighted. The numbers of cancellations, no-shows, and refill requests, relative to the total number of encounters, were computed.

Finally, NLP was applied to the clinical notes. We curated two lists of regular expressions or keywords related to the presence or absence of both (1) cognitive impairment and (2) the functional impairment of activities of daily living (ADLs) or independent ADLs, respectively (Multimedia Appendices 2 and 3). We identified regular expression matches and highlighted these within the text of the notes with different colors for each category (eg, cognition vs ADLs) to facilitate their identification by the clinician. We applied a previously developed NLP model [26] to generate classification probabilities of the following classes for each note: CI, no CI, or neither. The notes were ranked based on these classification probabilities, and notes that the model predicted as indicative of CI were displayed at the top.

Development of an Annotation Tool

We designed and developed a web-based chart review and annotation tool, using the Python-based open-source Django web development framework with a SQLite database. We established data models for patient-level demographic and clinical data, encounter-level clinician notes, user account creation and authentication, and patient assignment to individual or multiple annotators (Multimedia Appendix 4). We created several user interfaces (ie, pages) to present the various data modalities in an integrated fashion for annotation.

Statistical Analysis

We evaluated NAT adjudication using three metrics: agreement with manual Epic chart reviews, assessment time, and interrater agreement. We evaluated agreement between manual Epic chart reviews and NAT adjudication as well as interrater agreement for NAT adjudication using Cohen κ, whereas assessment time in minutes was compared using a paired samples Wilcoxon test (also known as the Wilcoxon signed-rank test). There were no missing data for these variables. All analyses were conducted using the R statistical software (version 4.1.2; R Core Team).

Results

Patient Characteristics

The patient characteristics of the two data sets are shown in Table 1. The ACO data set comprised 100 patients (63/100, 63.0% were women; mean age 78.8, SD 7.4 years; 7/100, 7% racial or ethnic minorities, 1 missing; 51/100, 51.0% with a college degree or more, 3 missing; and 50/100, 50.0% were married). The COVID-19 data set comprised 527 patients (226/527, 42.9% women; mean age 52.6, SD 15.0 years; 318/527, 60.35% racial or ethnic minorities, 21 missing;

160/527, 30.4% college education or more, 62 missing; and 195/527, 37.0% married, 16 missing).

Table 1. Characteristics of Accountable Care Organization (ACO) and COVID-19 data sets used for NLP[a] annotation tool (NAT) evaluation.

Characteristics	Patients (N=627)	
	ACO data set (n=100)	COVID-19 data set (n=527)
Sex, n (%)		
Male	37 (37)	301 (57.1)

[a] NLP: natural language processing.

[b] PCP: primary care provider.

[c] ICD: International Classification of Diseases.

Features of NAT

Upon logging in to our annotation tool, an authenticated user is presented with a dashboard listing the patient IDs, ages, and sexes of their assigned patients (Figure 1). In addition, the total number of notes, the sequences within the notes that match a cognition or ADL keyword (Multimedia Appendices 1 and 2), and the number of notes for each predicted class (ie, cognition and ADL) are also presented. After annotation, the patient's label (CN, CI, or undetermined) is displayed with background colors reflecting the patient's annotated cognitive status.

Selecting a patient navigates the user to an annotation view summarizing the patient's demographic and clinical information (Figure 2A). Engineered features, including the total number of notes, encounters, no shows, cancellations, and refill requests, along with the patient care coordination note (if any), diagnosis ICD codes, and medications, are displayed (Figure 2B). Brain imaging and relevant laboratory tests, such as thyroid-stimulating hormone or vitamin B12, allow annotators to consider systemic causes of cognitive changes (Figure 2C). Finally, notes sorted by the predicted probability and with highlighted keywords are presented to expedite the review of the entire chart history during the relevant period for the clinical adjudication of cognitive status. Examples of the three predicted classes of notes (CN, CI, and undetermined) are shown in Figure 2D.

Figure 1. NAT dashboard: screenshot of the NAT dashboard displaying the current workload and assigned patients. A summary of patient information is displayed in each row, and the background reflects the cognitive status assigned to the patient. NAT: NLP annotation tool; NLP: natural language processing.

Evaluation of NAT

Two teams of expert clinicians were randomly assigned patients and adjudicated the ACO data set, using NAT (team 1: LB, GKR, SSM; team 2: MBW and HA). We compared the phenotyping of cognitive status using NAT to manual chart reviews using Epic (labels were obtained from Moura et al [15]; patients who were not CN were grouped into the CI class). We removed patients annotated as “undetermined” in the set adjudicated using NAT, as they had little information in EHR to assess cognitive status and could not be directly compared to the labels obtained from Moura et al [15]. The agreement between NAT and manual Epic chart reviews was moderate for both team 1 (Cohen κ=0.68) and team 2 (Cohen κ=0.65) with a mean Cohen κ=0.67; the breakdown is shown in Figure 3A. Surprisingly, patients whose NAT label disagreed with the manual Epic chart reviews were annotated as CI using Epic and as CN using NAT. We manually reviewed the patients where the diagnostic labels disagreed; we found that NAT was able to highlight certain passages of text, such as “language, attention, and memory function are intact with good fund of knowledge”; the highlighted text facilitated the labeling of the patient as CN, whereas such phrases were easily missed in manual chart reviews. Moreover, if a patient had a transient cognitive deficit and was later evaluated as CN, for example, NAT presented all notes with highlighted evidence along with their dates in one view, making it easier to follow the sequence of events. The disagreements were mostly among patients annotated with a low confidence score in the Epic manually annotated data set [15] (Figure 3B). The interrater agreement of NAT adjudication between team 1 and team 2 was higher (Cohen κ=0.89) than the interrater agreement (Cohen κ=0.80) with manual Epic chart reviews reported in Moura et al [15].

Next, we compared the time required for phenotyping of cognitive status via NAT adjudication versus manual chart reviews in Epic. Four of the authors (DW, ER, HA, and SSM) adjudicated the full COVID-19 data set using NAT and recorded the annotation time for 129 patients. Two of the authors (HA and SSM) timed manual chart reviews in Epic for 32 randomly sampled patients. To ensure that a patient was not adjudicated using both methods by the same person, HA used Epic to perform chart reviews of patients adjudicated by SSM using NAT and vice versa. For most of the patients, the annotation time was substantially shorter with NAT as compared to manual chart reviews in Epic (Figure 3C). Adjudications using NAT provided substantial speed-up of annotations compared to manual chart reviews in Epic (time difference mean 1.4, SD 1.3 minutes; *P*<.001; ratio median 2.2, min-max 0.4-20). Additionally, we observed that clinicians spent more time using NAT on the first half of patients compared to the second half. This “learning effect” was not observed with manual Epic chart reviews. The breakdown of the cognitive status for the COVID-19 data set is shown in Figure 4. Notably, the cognitive status for 21.1% (n=111) of patients was undetermined, suggesting that there was little information in EHR to determine their cognitive status.

Figure 3. Comparison of adjudication with natural language processing (NLP)–powered annotation tool (NAT) and manual Epic chart reviews: (A) contingency table displaying adjudication with NAT versus Epic by team 1 (top row) and team 2 (bottom row); (B) distribution of confidence scores assigned in Epic manual chart reviews (Moura et al [15]) for agreements and disagreements between the two methods; (C) annotation time comparisons between NAT versus Epic.

Discussion

Principal Findings

In this study, we developed and evaluated a novel semiautomated NLP-powered annotation tool, NAT, to facilitate phenotyping of cognitive status. Clinical experts adjudicated the cognitive status of 627 patients at MGB health care using NAT or traditional chart reviews. NAT improves the efficiency and interrater reliability of chart review as compared to manual adjudication.

Strengths

Phenotyping methods have been applied to EHR to successfully identify patients with autism [28], diabetes [29], immunological diseases [30], and several chronic diseases [16]. EHR has been extensively used for dementia research, but the outcomes are typically defined by diagnosis codes or specialist diagnoses. Although phenotyping tools using NLP have been developed to detect cognitive impairment [18,19,24], they have been limited by their performance. In this study, we propose a novel semiautomated approach that combines NLP outputs with manual adjudication.

We selected this approach as it combines the automation of an NLP tool and the expert review required for phenotyping cognitive status. Phenotyping cognitive status requires the input from both structured (eg, diagnosis codes and medications) and unstructured (eg, clinical notes and images) data, and currently, there are no machine learning tools that integrate multiple data modalities. The approach has several advantages over manual chart reviews. Cognitive concerns are often subjective, and a significant amount of information is required to confidently ascertain the correct diagnosis. Since diagnoses are staged across months or years, individual notes across time must be evaluated together—NAT filters data for the period of interest and thus facilitates the adjudication process. Next, the absence of cognitive deficits is often difficult to adjudicate with confidence. In these cases, the annotator needs to review all notes to ensure there were no signs of cognitive impairment. NAT improves the efficiency of such tasks, as it automatically flags notes with signs of cognitive impairment as well as those with information on normal cognition and ranks them in order of importance. In addition, clinicians often use a wide variety of terms and phrases in clinical notes that can easily be missed in manual reviews. NAT, on the other hand, highlights all cognition-related patterns and phrases, decreasing the likelihood that the annotator might miss any information relevant to the decision-making task. Finally, NAT streamlines an established adjudication protocol and thus improves interrater agreement. NAT can, in principle, be extended to local hospitals and clinics that have digitized data but not an EHR system.

Limitations

This study has several limitations. First, NAT does not link to brain images, which may contain information relevant to brain function. Second, although NAT improves the efficiency of adjudicating cognitive status compared to manual chart reviews, it is not scalable to large data sets of thousands of patients. To scale to such sample sizes, fully automated machine learning algorithms that replicate the adjudication process are required. In the future, we plan to use NAT to create gold-standard data sets for training and validation of such machine learning algorithms for phenotyping cognitive status. Third, NAT adjudication was evaluated on data from a single health care system. Whether the cognition and ADL-related keywords apply to other health care settings is yet to be confirmed. The performance of the NLP tool [26] also needs to be evaluated with external data. Fourth, adjudicators were not blinded to identifiable information in EHR, which may have introduced biases in their labels. Tools, such as Philter, could be used in the future to remove protected health information in NAT [31]. Finally, research studies using EHR-based data sets are limited by the information available within the health care system and miss records of care outside the system. Such patients with missing information were labeled as "undetermined" in this study, but studies that use diagnosis codes for phenotyping of cognitive status may incorrectly label such patients as CN instead of distinguishing them as patients with insufficient information. Our study highlights the issue of missing information when phenotyping cognitive status in EHR, and consequently, the need for future work to minimize biases if such patients are excluded in a research study.

Conclusions

Although there is no substitute for a longitudinal cohort with formal cognitive evaluations to study Alzheimer disease and related dementias, leveraging EHR data with NLP holds promise. In this diagnostic study, we developed and evaluated a semiautomated NLP-powered annotation tool, NAT, to facilitate the phenotyping of cognitive status in EHRs. Expert clinicians adjudicated cognitive status of 627 patients from two distinct data sets; NAT had a high interrater agreement and improved the speed of annotations compared to manual chart reviews. Using NAT to adjudicate cognitive status would likely increase the feasibility and scalability of building gold-standard data sets for machine learning algorithms and research cohorts to study cognitive decline.

Acknowledgments

This study was supported by funding from National Institute on Aging awards (K08AG053380, R01AG073410, and P30AG062421), a National Institute of Mental Health award (K23MH115812), the James S McDonnell Foundation, and the Rappaport Fellowship. Abstract

Background: The increasing prevalence of smartphone apps to help people find different services raises the question of whether apps to help people find physical activity (PA) locations would help better prevent and control having overweight or obesity.

Objective: The aim of this paper is to determine and quantify the potential impact of a digital health intervention for African American women prior to allocating financial resources toward implementation.

Methods: We developed our Virtual Population Obesity Prevention, agent-based model of Washington, DC, to simulate the impact of a place-tailored digital health app that provides information about free recreation center classes on PA, BMI, and overweight and obesity prevalence among African American women.

Results: When the app is introduced at the beginning of the simulation, with app engagement at 25% (eg, 25% [41,839/167,356] of women aware of the app; 25% [10,460/41,839] of those aware downloading the app; and 25% [2615/10,460] of those who download it receiving regular push notifications), and a 25% (25/100) baseline probability to exercise (eg, without the app), there are no statistically significant increases in PA levels or decreases in BMI or obesity prevalence over 5 years across the population. When 50% (83,678/167,356) of women are aware of the app; 58.23% (48,725/83,678) of those who are aware download it; and 55% (26,799/48,725) of those who download it receive regular push notifications, in line with existing studies on app usage, introducing the app on average increases PA and decreases weight or obesity prevalence, though the changes are not statistically significant. When app engagement increased to 75% (125,517/167,356) of women who were aware, 75% (94,138/125,517) of those who were aware downloading it, and 75% (70,603/94,138) of those who downloaded it opting into the app's push notifications, there were statistically significant changes in PA participation, minutes of PA and obesity prevalence.

Conclusions: Our study shows that a digital health app that helps identify recreation center classes does not result in substantive population-wide health effects at lower levels of app engagement. For the app to result in statistically significant increases in PA and reductions in obesity prevalence over 5 years, there needs to be at least 75% (125,517/167,356) of women aware of the app, 75% (94,138/125,517) of those aware of the app download it, and 75% (70,603/94,138) of those who download it opt into push notifications. Nevertheless, the app cannot fully overcome lack of access to recreation centers; therefore, public health administrators as well as parks and recreation agencies might consider incorporating this type of technology into multilevel interventions that also target the built environment and other social determinants of health.

Introduction

The increasing prevalence of smartphone apps to help people find different services (eg, Yelp and OpenTable to find restaurants, Fandango to find movie theaters, AllTrails to find hikes, GasBuddy to find gas stations, Expedia to find hotels, and Zillow to find homes and apartments) raises the question of whether apps to help people find physical activity (PA) locations (eg, ClassPass [1] and Fit Reserve [2]) would help to better prevent and control having overweight and obesity. Such place-tailored apps can help assemble, collate, and present information that may be available on different websites so that an individual can quickly find the closest location of interest. These place-tailored apps can be particularly helpful for PA locations and opportunities since they may exist in different and less obvious forms (eg, irregular timing of classes, walking and bike paths, outdoor tracks, and tennis or basketball courts). Such an app can also offer crowdsourced ratings of each location, details about specific services (eg, time, availability, costs, promotions, and deals), and even social connections with people who have the same interests or are in the same area. Previous studies have shown that people may not be aware of or have difficulty finding locations to engage in PA [3-5]. This may be the case in underresourced and otherwise disadvantaged communities where parks, affordable gyms, and other opportunities may be more difficult to find if they are in less-frequented or obscure locations, or if they are not regularly advertised or promoted [6]. African American women who live disproportionately in underresourced communities spend at least as much time as any other racial or ethnic group using apps and the internet (approximately 19 hours and 27 minutes each week versus 17 hours and 8 minutes each week), and approximately 80% of African American women own a smartphone [7], raising the possibility that this could be an effective means to help these women find PA opportunities. However, before such an app is rolled out in the "real world," it can be helpful to use simulation modeling to guide the design and test the potential impact of such an app. Such an approach is used in other fields (eg, aeronautical engineering and manufacturing) since running simulation models can take much less time and can be significantly less costly than conducting a real-world trial (which can take months to set up, recruit for, and implement). Moreover, once a trial is completed, one cannot go back and change the circumstances as they can in a simulation model. Therefore, we further developed our agent-based simulation model of Washington, DC to test the impact of such a place-tailored digital health app.

Methods

Ethics Approval

All authors' institutions were included in the institutional review board approval (IRB #00004203) at Johns Hopkins as the study began while certain members of the research team (MCF, KJO, YA, MM, SMB, PTW, SS, SR, MSG, MD, KR, DH, RS, and BYL) were based at Johns Hopkins.

Model of Washington, DC

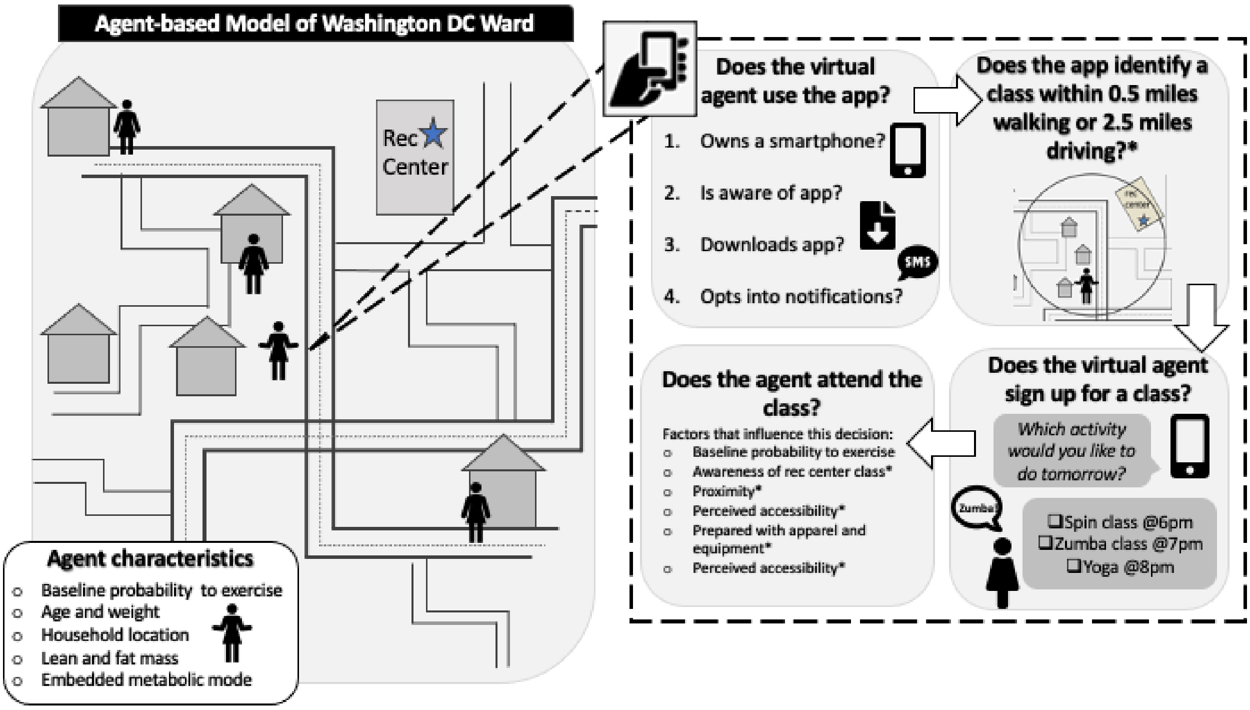
We used and further developed a Virtual Population Obesity Prevention, agent-based model of Washington, DC in 2020-2021 [8,9], which includes computer model–based representations of households, workplaces, and recreation centers throughout all 8 wards (similar to districts in other cities) in Washington, DC.

Agents Representing People

We represented each of the 167,356 African American women (aged 18-65 years) living in Washington, DC with a computer model–based agent. Each agent (ie, each African American woman in Washington, DC) has attributes for age, height, lean or fat mass, household location, work location, and income based on representative data for the region and population. Each agent also has an embedded metabolic model, which converts daily caloric intake and expenditure to corresponding lean or fat mass [10,11]. Caloric expenditure from exercise is determined by exercise intensity, duration, and the agent's current body weight [10,11]. Since individuals may vary in their inclination to exercise, each agent had a baseline probability of wanting to exercise each day. This accounts for an agent's past experiences and existing tendencies to exercise and includes factors such as household financial status, family responsibilities, chronic health conditions, and social influences. Different scenarios ranged this baseline probability from 10% (10/100) to 50% (50/100) to explore how this probability might affect the results.

In each simulated day, women may participate in a recreation center class, depending on a number of factors (Figure 1; Multimedia Appendix 1, Table S1 [8, 9, 12-23]), including the following: (1) her baseline probability to exercise (this accounts for an agent's past experience and existing tendencies to participate in recreation center classes), which we vary between simulation experiments; (2) objective accessibility to locations, based on the geographic locations of recreation centers [12], the distance individuals need to travel to reach these locations, and access to the types of transportation (eg, cars) that might be required to reach locations further away [24,25]; (3) perceived accessibility of locations [15], based on the individual's understanding and knowledge of nearby recreation centers; (4) awareness of classes at recreation centers; and (5) preparedness to exercise (whether or not she remembers her apparel and equipment).

Figure 1. A digital health app that helps locate and send reminders about recreation (rec) center classes. *Factors influenced by phone app.



Representations of Recreation Centers

Multimedia Appendix 1, Table S2 shows key characteristics (eg, number of recreation centers) for each ward. If an agent ultimately participates in a recreation center class, she is active for 50 minutes [12] at an intensity of approximately 6.5 metabolic equivalents [16].

Representations of Digital Health App

In the model, we represent a digital health app that helps locate and send reminders about in-person recreation center classes to increase the agents' likelihood of participation (Figure 1). This mobile app uses a database of public locations that have been previously identified as locations for PA, such as recreation centers in the case of this paper. Once this registry is verified, a geofence—a geographic boundary—can be created within the mobile app with a set distance surrounding the chosen location; in this case, our simulated app searched for recreation centers within 0.5 miles of the user. When the simulated mobile app detects that the user is within this defined boundary, it will generate a notification that will alert the user of the available resources in the area. Unlike existing fitness apps, this digital health app considers the geographic location of the user and the recreation centers to connect agents with recreation center classes that align with their neighborhood environment and schedules; prompts users to remind them about upcoming classes and what equipment they will need; and provides individually tailored information about class time, location, and necessary equipment to maximize user engagement (Figure 1). If an agent has a smartphone, downloads the app, and opts into notifications (Multimedia Appendix 1, Table S1), the app will send a question each evening asking the user which activity or class she would like to participate in the following day, thereby increasing an agent's knowledge of class schedules. After selecting the class, agents will receive a notification with a reminder of the class's time, location, and activity, as well as a reminder to bring clothes or equipment, thereby increasing an agent's probability of being prepared for and attending class. When representing the digital health app, we introduced it at the beginning of the 5-year simulation, but not all participants continued to use the app for the entire simulation duration (eg, we represented attrition, people discontinuing app use, during the 3 months following the introduction of the app; Multimedia Appendix 1, Table S1).

Representations of Engagement With the Digital Health App

Since only a certain percentage of the population may be aware that the app is available, we varied the proportion of women across the population who, in a given scenario, were aware of the app, subsequently downloaded the app, and then opted into push notifications (25%-75%). This means, 25% (41,839/167,356) of women are aware of the app, 25%

(10,460/41,841) of those who are aware download it, and 25% (2615/10,460) of those who download it receive regular push notifications from the app. We ranged this to 75% (125,517/167,356) of women aware of the app, 75% (94,138/125,517) of those who are aware download it, and 75% (70,603/94,138) of those who download it opt into the app's push notifications. Varying the level of user engagement across a range can help identify the thresholds of app engagement that result in observable and statistically significant impacts on PA and weight.

Simulation Experiments

We used the model of Washington, DC to simulate the impact of a digital health app on in-person recreation center class participation, recreation center class PA (minutes per week), subsequent changes in BMI, as well as the prevalence of obesity and the state of having overweight. Each simulation experiment consisted of running the model of Washington, DC and all 167,356 computer model–based agents, 10 times over 5 simulated years.

Validation

Validation consisted of comparing different model-generated metrics to observed values to determine if the model was representing what was occurring. For example, when we ran simulation runs, we saw that, on average, 2.1% (3514/167,356) of women were participating in recreation center classes daily compared to the observed 3.8% from the 2017 American Time Use Survey [17]. Since the people who exercised on one day will not necessarily be the same people who exercised on a different day, there will be a certain proportion of the population that exercised at least once over the course of the month. Thus, we also simulated the average percentage of women participating in recreation center classes at least once on a monthly basis (19.1% [31,965/176,356]) and compared this to the observed proportion of women participating in workout class activity on a monthly basis (16.1%), as reported by the Behavioral Risk Factors Surveillance System [18]. The model-generated data generally matched the observed data, and the differences are likely due to differences between populations and the classes available to that population. Further model validation details are available in Multimedia Appendix 1.

Results

No Mobile App

Table 1 shows PA from recreation center classes and weight-related outcomes after 5 years with no mobile app for different baseline probabilities to exercise. Figure 2 shows how the percent of women who exercised at least once in the simulation when there was no app varied by the Washington, DC ward. For example, Ward 6 had the highest percent of the population who exercised at least once (69.1% [4331/20,739], 95% CI 68.9%-69.2%), while Ward 7 had the lowest (48% [15,710/32,729], 95% CI 47.9%-48.0%) when there was no mobile app (25% [25/100] baseline probability to exercise). This trend in ward-level variation was consistent across all baseline exercise probabilities.

Table 1. Physical activity, overweight, obesity, BMI outcomes by baseline probability to exercise for different scenarios (eg, with and without digital health app).

Simulation scenarios at each baseline probability to exercise	Percent of population exercising at recreation centers, mean (95% CI)	Average number of physical activity min/week, mean (95% CI)	Overweight prevalence, mean (95% CI)	Obesity prevalence, mean (95% CI)	Average BMI, mean (95% CI)	Average BMI among women with obesity, mean (95% CI)
10% (10/100) baseline probability to exercise

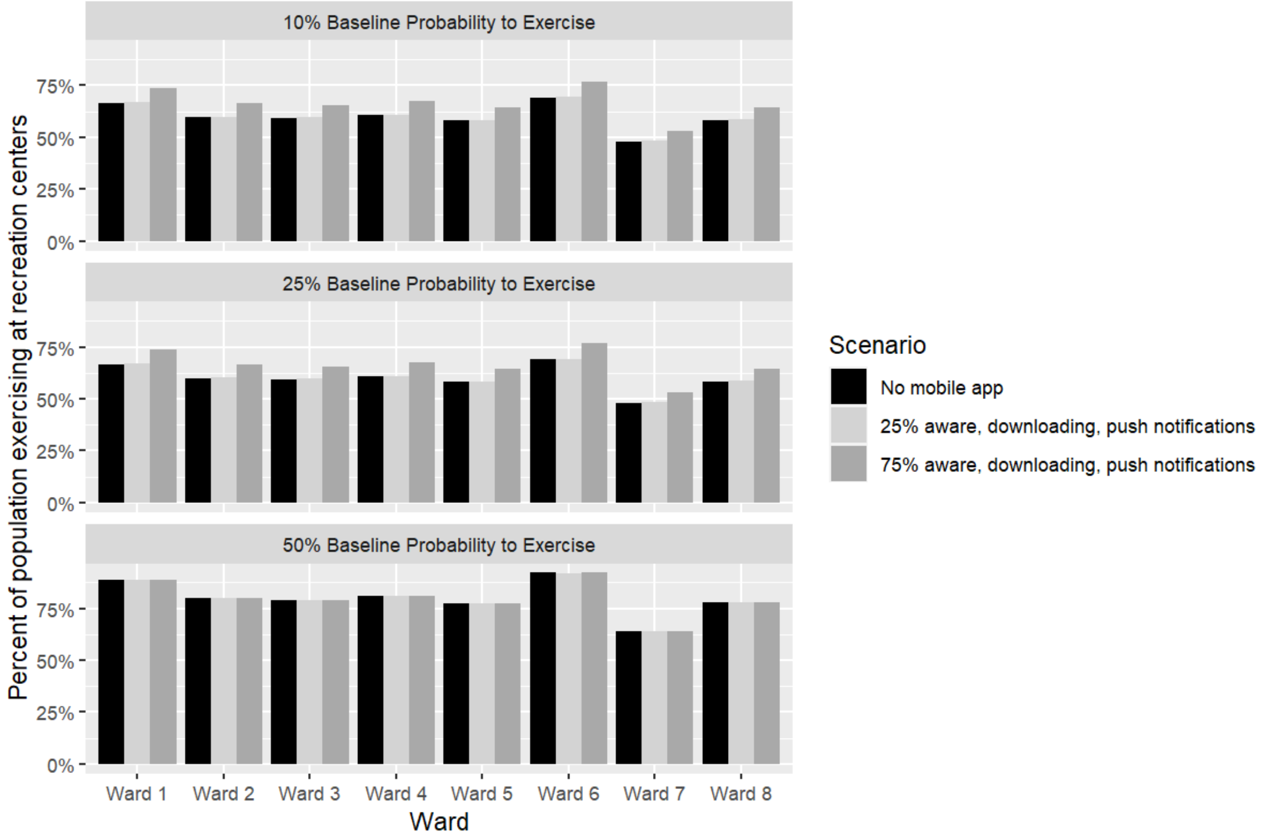
[a] 25% (41,839/167,356) aware of the app, 25% (10,460/41,839) of those who are aware download the app, and 25% (2615/10,460) of those who download it receive notifications.

[b] 50% (83,678/167,356) aware of the app, 50% (48,725/83,678) of those who are aware download the app, and 50% (26,799/48,725) of those who download it receive notifications.

[c] 75% (125,517/167,356) aware of the app, 75% (94,138/125,517) of those who are aware download app, and 75% (70,603/94,138) of those who download it receive app notifications.

Figure 2. Percent of women exercising with and without the mobile app within each ward in Washington, DC.



Impact of Introducing a Place-Tailored Mobile App That Connects Users to Recreation Center Classes

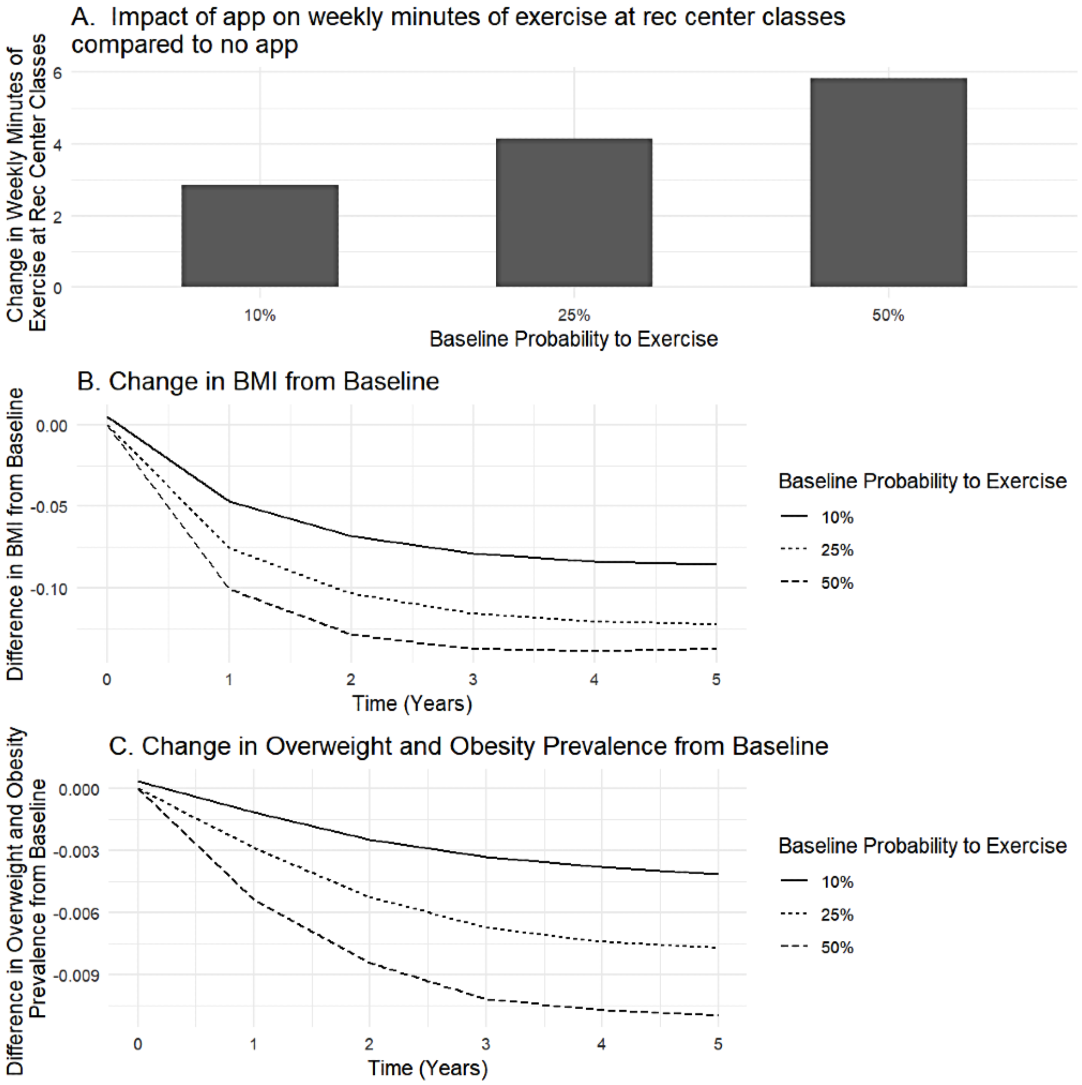
With lower levels of user engagement with the mobile phone app, that is 25% aware of app (41,839/167,356), 25% of those aware download app (10,460/41,839), and 25% (2615/10,460) of those who download it receive app notifications, the app had a negligible and nonsignificant impact on the additional minutes of PA (<1 minute), on the additional percent of women who ever exercise (0.2% [335/167,356]; Figure 2), and on reductions in obesity prevalence (0.1% [167/167,356]). Thus, even lower levels of app engagement (eg, below 25% [25/100]) would have no effect on physical activity and weight.

Increasing user engagement to approximately 50% (eg, 50% aware [83,678/167,356], 58.23% [48,725/83,678] of those who are aware download the app [19], and 55% [26,799/48,725] of those who download it receive regular push notifications [20]) resulted in moderate improvements to PA from recreation center classes and weight-related outcomes across the population. Figure 3 shows these observable changes to PA (panel A), BMI (panel B), and overweight and obesity prevalence (panel C). With a 10% (10/100) baseline probability of exercise, the PA minutes per week increase by 2.9 minutes (95% CI –1.4 to 17.9), BMI decreases by 0.09 kg/m^2 (95% CI –0.56 to 0.39), and obesity prevalence decreases by an absolute 0.43% (720/167,356; 95% CI –2.7% to 2.93%) at the end of the 5-year simulation. When baseline probability increases to 50% (50/100), there are larger increases in weekly PA minutes (5.4 minutes, 95% CI –4.1 to 15.8), and larger reductions in BMI (0.14 kg/m^2, 95% CI –0.67 to –0.4) and obesity prevalence (1.8% [3012/167,356]; 95% CI –2.6% to 6.2%).

The percent of women attending at least one recreation center class over the course of the simulation shows additional gains between when the baseline probability to exercise is between 10% (10/100; 2.43% [4067/167,356], 95% CI –4.24% to 9.1%) and 25% (25/100; 2.5% [4184/167,356]; 95% CI –4.2% to 9.2%). When the baseline probability to exercise is 50% (50/100), the percent of women exercising at least once hits a ceiling of 78% (130,538/167,356) (increase of 0.05% [84/167,356]; 95% CI –8.68% to 8.77%), due to the location and accessibility of recreation centers for some women. Thus, at lower probabilities to exercise (eg, 10%-25%), the app is more effective at increasing the number of women participating in at least one recreation center class (Figure 2). However, additional PA minutes per week from recreation center classes increase with baseline probability to exercise (eg, 4.14, 95% CI –1.9 to 10.2 vs 5.9, 95% CI –4.1 to 15.7 minutes per week at 25% [25/100] and 50% [50/100] baseline probabilities to exercise, respectively; Figure 3). Figure 3 also shows how reductions in BMI and overweight and obesity prevalence due to app use accrue over time during the 5-year simulation.

Further increasing app engagement to 75%, with 75% (125,517/167,356) of women aware of the app, 75% (94,138/125,517) of those who are aware downloading the app, and 75% (70,603/94,138) of those who download it opting into the app's push notifications resulted in statistically significant gains to PA and reductions in obesity prevalence. For example, weekly PA increased by 10.7 (95% CI 4.2-17.2) minutes per week, and obesity prevalence decreased by an absolute 4.09% (6,845/167,356; 95% CI 1.2%-7.0%) with 25% baseline exercise probability (Table 1).

Figure 3. Impact of mobile app on physical activity, BMI, as well as overweight and obesity prevalence at each baseline probability to exercise. Rec: recreation.



Ward-Level Impact of Place-Tailored Mobile App

The results varied substantially by ward. For example, at 25% (25/100) baseline probability to exercise (assuming 50% [83,678/167,356] aware, 50% [48,725/83,678] of those who are aware downloading the app, and 50% [26,799/48,725] of those who download it receiving app notifications), Ward 6 had the highest absolute increase in average PA minutes per week (4.85, 95% CI 4.58-5.11), and the greatest reduction in average BMI (–0.15 kg/m^2, 95% CI –0.19 to –0.11). However, Ward 7 had the lowest (3.39, 95% CI 3.24-3.53) increase in PA minutes per week and the smallest reduction in BMI (–0.09 kg/m^2; 95% CI –0.12 to –0.06). Changes in overweight and obesity prevalence also varied between wards and decreased by as much as 2.6% (539/20,739; 95% CI 2.3%-2.9%) in Ward 6, where participation in recreation center classes was highest and as little as 1.9% (622/32,729; 95% CI 1.7%-2.1%) in Ward 7 (25% baseline exercise probability).

Discussion

Principal Findings

Our simulation model of African American women in Washington, DC, and their use of a place-tailored digital health app to help identify recreation center classes shows that the app does not result in substantive population-wide health effects at lower levels of app engagement (eg, 25% of women are aware of the app, 25% of those aware of the app download it, and 25% of those who download it receive regular push notifications from the app). When 50% of women are aware of the app, 58.23% of those who are aware download the app, and 55% of those who download it receive regular push notifications from the app, there are observable changes in PA and weight across the population, but the impact is not statistically significant. For the app to result in statistically significant increases in PA and reductions to obesity prevalence over 5 years, there needs to be at least 75% of women who are aware of the app, 75% of those aware of the app downloading it, and 75% of those who download it opting into the app's push notifications. Thus, we demonstrated the minimum levels of engagement needed at the outset of a mobile phone app campaign (approximately 50% aware of the app, 50% of those who are aware download the app, and 50% of those who download it receive app notifications, assuming reductions in use over the first 3 months) to observe a change in PA and weight across the population. Studies have shown how perceived usefulness of an app, user-friendliness, backing from health care professionals, and continued engagement impact app usage [26,27] could be addressed through a structured marketing and communications strategy. Thus, future interventions should prioritize efforts to increase marketing for the place-tailored app to increase the percent of women who are aware of and use the app to reach the impactful threshold of engagement and obtain further benefits.

Further, our results show that a place-tailored app is more likely to be successful in increasing PA in those who already have a higher likelihood to exercise. While the results showed that the app was successful at encouraging individuals who have a low baseline probability (eg, 10% [10/100] and 25% [25/100]) to exercise to attend at least one new class over the course of the simulated period, this alone was not enough to drive a sustained change in regular exercise. The app did a better job at increasing the average duration of PA each week as baseline probability to exercise increased. This indicates that improving knowledge of recreation center classes, while important, should be coupled with interventions to help overcome personal and social barriers (eg, limited social support for PA or time constraints) that determine baseline exercise probability [28,29]. Place-tailored digital health apps could potentially address some of these barriers through the release of new features and functionality such as a social networking component [30,31].

Regardless of user engagement with the app, place-tailored digital health apps need to be combined with increasing physical access to recreation centers to see greater than additive effects in PA and subsequent health outcomes. There is a limit to a place-tailored app's impact because some individuals cannot access recreation centers due to the distance and lack of transportation (eg, access to car) from their home location. As shown in our results, there are clear disparities in the success of the app in improving health outcomes in neighborhoods with greater access to recreation centers (with nearly a 1.4-fold increase in the use of recreation center classes in these neighborhoods [eg, Ward 6]) compared to neighborhoods with less accessible recreation centers (eg, Ward 7), even with 75% of women who are aware of the app, 75% of those aware of the app download it, and 75% of those who download it opt into the app's push notifications. Past studies have shown that lower-income neighborhoods in many cities around the United States have less accessible PA locations and recreation centers [32]. Therefore, it is important for public health administrators and park and recreation agencies to consider pairing this type of digital health technology with improvements to recreation center access such as changes to the built environment, perceived safety, or transportation.

Our results also show that it takes time for the effect of the place-tailored mobile app to fully manifest (>2 years). In general, 1 year is not enough time to see an impact on BMI and overweight and obesity prevalence, as population-level effects on weight and subsequent health benefits accrue over years. This shows the need to continuously measure the value of intervention programs over a period of several years, since reductions in overweight and obesity prevalence may not be demonstrated immediately, and effective interventions may wrongly be deemed unsuccessful if evaluated too early. Accounting for this ramp-up period is important, as it can also take time for a new technology to be adopted and used. Our results show that the speed of the reduction in overweight and obesity prevalence in the population increases year after year as adoption rates increase, revealing a potential opportunity to increase momentum as more users adopt similar place-tailored digital health technology.

In addition to being able to simulate extended periods of time, another benefit of simulation modeling is that it can be adapted and refined over time. For example, simulation modeling can be used in conjunction with clinical trials [33,34] so that the model can continuously inform digital health phone app design and multipronged PA interventions. The simulation model can be run first, to help determine the impact of an app, which can then inform the implementation of a trial. Data and information from the trial can then further update the model. This iterative process can continue until the app or intervention is optimally designed.

Limitations

All models are simplifications of reality and cannot account for all possible factors that may affect PA decision-making. Our model included a few simplifying assumptions. For example, we did not account for objective accessibility to a recreation center near a woman's workplace and used the objective accessibility near the home as a proxy. In addition, since we wanted to demonstrate how to design an app that harnesses geographic location and the value of such an app, our study focused on the app locating and reminding individuals about in-person classes, rather than web-based classes. However, such an app may offer similar benefits for web-based classes such as reminding individuals about when classes are scheduled and what equipment is needed, while reducing potential geographic barriers to exercise. We also assumed that in-person classes are available (eg, not during a public health emergency such as the COVID-19 pandemic). When determining body weight changes for each woman, we assumed that compensatory eating did not occur. Our model simulated behavior of and used data specific to Washington, DC African American women, which may limit generalizability to other populations or geographic areas.

Conclusions

Our study shows that a digital health app that helps identify recreation center classes does not result in substantive population-wide health effects at lower levels of app engagement (eg, 25% of women who are aware of the app, 25% of those who are aware of the app download it, and 25% of those who download it receive regular push notifications from the app). For the app to result in statistically significant increases in PA and reductions to obesity prevalence over 5 years, there needs to be at least 75% of women aware of the app, 75% of those aware of the app download it, and 75% of those who download it opt into the app's push notifications. Even so, the app cannot fully overcome lack of access to recreation centers, and therefore, public health administrators as well as parks and recreation agencies might consider incorporating this type of technology into multilevel interventions that also target the built environment and other social determinants of health.

Abstract

Background: Questionnaires have been used in the past 2 decades to predict the diagnosis of vertigo and assist clinical decision-making. A questionnaire-based machine learning model is expected to improve the efficiency of diagnosis of vestibular disorders.

Objective: This study aims to develop and validate a questionnaire-based machine learning model that predicts the diagnosis of vertigo.

Methods: In this multicenter prospective study, patients presenting with vertigo entered a consecutive cohort at their first visit to the ENT and vertigo clinics of 7 tertiary referral centers from August 2019 to March 2021, with a follow-up period of 2 months. All participants completed a diagnostic questionnaire after eligibility screening. Patients who received only 1 final diagnosis by their treating specialists for their primary complaint were included in model development and validation. The data of patients enrolled before February 1, 2021 were used for modeling and cross-validation, while patients enrolled afterward entered external validation.

Results: A total of 1693 patients were enrolled, with a response rate of 96.2% (1693/1760). The median age was 51 (IQR 38-61) years, with 991 (58.5%) females; 1041 (61.5%) patients received the final diagnosis during the study period. Among them, 928

(54.8%) patients were included in model development and validation, and 113 (6.7%) patients who enrolled later were used as a test set for external validation. They were classified into 5 diagnostic categories. We compared 9 candidate machine learning methods, and the recalibrated model of light gradient boosting machine achieved the best performance, with an area under the curve of 0.937 (95% CI 0.917-0.962) in cross-validation and 0.954 (95% CI 0.944-0.967) in external validation.

Conclusions: The questionnaire-based light gradient boosting machine was able to predict common vestibular disorders and assist decision-making in ENT and vertigo clinics. Further studies with a larger sample size and the participation of neurologists will help assess the generalization and robustness of this machine learning method.

vestibular disorders; machine learning; diagnostic model; vertigo; ENT; questionnaire

Introduction

Dizziness and vertigo are the major complaints of patients with vestibular disorders, with an estimated lifetime prevalence of dizziness (including vertigo) of 15%-35% [1]. Dizziness and vertigo are incapacitating and considerably impact patients' quality of life. These conditions often lead to activity restriction and are closely associated with psychiatric disorders such as anxiety, phobic, and somatoform disorders [1-3]. Patients with dizziness and vertigo are also at a higher risk of falls and fall-related injuries, especially older people [4]. However, the diagnosis of vestibular disorders is challenging and time-consuming. It involves a variety of vestibular and neurological causes and complex pathological processes, leading to misdiagnosis and potentially widespread overuse of imaging among vertiginous patients [5-8]. Consequent delays in diagnosis can worsen the functional and psychological consequences of the disease.

The application of artificial intelligence in diagnosing dizziness and vertigo dates back more than 30 years. Expert systems such as *Vertigo* [9], *Carrusel* [10], and *One* [11] consist of knowledge bases with fixed diagnostic rules. They infer through nonadaptive algorithms that were unable to learn from patients' data. Different machine learning algorithms, including genetic algorithms, neural networks, Bayesian methods, k-nearest neighbors, and support vector machines, have also been employed to analyze patient data from *One* [12-16]. The predictive accuracy was 90%-97% for 6 common otoneurologic diagnoses and 76.8%-82.4% for 9 diagnostic categories. *EMBalance* is a comprehensive platform that was launched in 2015 to assist the diagnosis, treatment, and evolution of balance disorders by using ensemble learning methods based on decision trees (Adaptive Boosting) [17,18]. There has been a shift from pure knowledge-driven to data-driven methodology in computer-aided diagnosis of vestibular disorders.

Except *Vertigo*, all of the models mentioned above are based on patients' medical history and examinations combined with necessary tests, while in practice, patient history alone provides important clues to possible diagnosis and further evaluation [19]. Numerous questionnaires for dizziness and vertigo have emerged during the past 2 decades to assist the clinical diagnosis of vestibular disorders [20-27]. Most of these studies used simple statistical models, typically logistic regression, validated with the same data as modeling [26-28]. Few studies have tried to apply machine learning algorithms. However, the accuracy of these models was not as good as that of simple statistical models owing to small data sets or inappropriate choice of modeling data [29,30].

This study is part of the Otogenic Vertigo Artificial Intelligence Research (OVerAIR) study, in which the overarching purpose is to build a comprehensive platform that integrates diagnosis, treatment, rehabilitation, and follow-up in a cohort of patients with otogenic vertigo by using artificial intelligence. The specific aims of this study include developing and verifying a diagnostic platform for vertigo and assisting clinical decision-making by using machine learning techniques and further exploring the effectiveness and clinical utility of the proposed platform.

Methods

Study Design

Patients presenting with a new complaint of vertigo or dizziness according to the classification of vestibular symptoms by the Barany Society [31] were enrolled consecutively from the ENT and vertigo clinics of Eye & ENT Hospital of Fudan University, The Second Hospital of Anhui Medical University, The First Affiliated Hospital of Xiamen University, Shengjing Hospital of China Medical University, Shanghai Pudong Hospital, Shenzhen Second People's Hospital, and The First Affiliated Hospital of Chongqing Medical University from August 2019 through March 2021. At their first interview with an ENT specialist, patients completed the electronic version of the questionnaire via a tablet or smartphone after giving informed consent. Those who were unable to read and complete the questionnaire by themselves answered the questions read by the researchers. We did not interfere with the normal medical procedures of the patients. Patients were scheduled for a next visit as the specialist considered necessary; therefore, they did not stick to a fixed follow-up time.

Ethics Approval

This study was approved by the Institutional Review Boards of all participating centers (approval 2019091). This study followed the Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis reporting guidelines [32].

Outcomes

Each patient went through routine history collection followed by complete otoneurological examinations, and further workup (ie, pure tone audiometry, vestibular testing, computed tomography, and magnetic resonance imaging) was prescribed when necessary. The clinical diagnosis given by ENT specialists with more than 5 years of clinical experience who were blinded to questionnaire responses was used as the reference diagnosis. The reference diagnostic standards include practice guidelines for benign paroxysmal positional vertigo (BPPV) by the American Academy of Otolaryngology-Head and Neck Surgery [33] and diagnostic criteria for vestibular disorders (including vestibular migraine [34], Meniere disease [35], persistent postural-perceptual dizziness [36], vestibular paroxysmia [37], and bilateral vestibulopathy [38]) by the Barany society. Patients with typical clinical features who did not meet the criteria of definite diagnosis were given probable diagnosis. Patients without a specific diagnosis within 2 months or who stopped coming for visits before reaching a final diagnosis were labeled undetermined.

Questionnaire Development

The diagnostic questionnaire was developed through an iterative process that mainly consisted of the following 3 stages.

1. Focus group and panel meeting: First, a focus group discussion and 3 follow-up panel meetings were convened to identify the commonly seen peripheral vestibular disorders in ENT clinics. In this process, 16 disorders were identified and the featured manifestations of each disorder were listed. The literature of diagnostic or practice guidelines for each disorder was searched and the pertinent ones were carefully reviewed. After that, the initial questionnaire composed of 43 items was drafted.
2. Patient interview: Fifteen patients who presented with vertigo in our ENT clinic were interviewed for the understandability and easiness of filling out the questionnaire. Two patients reported that it was too long and time-consuming. Another 3 complained of being asked too many questions such as heart disease and medication taken, which seemed unrelated to their vertigo condition. At this stage, the wording of the questionnaire was thoroughly simplified and 6 questions were deleted.
3. Expert group meeting: At a national conference, 12 experts (from ENT, neurology, vestibular examination, and rehabilitation) were invited to evaluate the suitability and clarity of the questionnaire, and they put forward suggestions for further revision. During this process, the items were reordered and some were combined or omitted.

Statistical Analysis

We compared 9 candidate machine learning methods to screen for the one with the best performance. Five non–ensemble learning algorithms were considered, namely, decision tree [39], ridge regression [40], logistic regression (with L2-regularization) [41], support vector classification [42], and support vector classification with stochastic gradient descent [43]. Ensemble learning refers to a general meta approach that strategically improves predictive performance by combining the predictions from multiple models. Four of the ensemble learning methods were implemented, namely, random forest [44], Adaptive Boosting [45], gradient boosting decision tree [46], and light gradient boosting machine (LGBM) [47]. We took bootstrapped cross-validation that randomly sampled data into train and validation sets by 7:3, which were repeated 100 times with replacement [48]. Models were trained on the training set and evaluated based on the prediction performance on the validation set. The best model was selected and tuned based on the average prediction performance over the 100 validation set. The area under the curve (AUC) was used to evaluate the performance of the models. In multiclass prediction, sensitivity, specificity, likelihood ratio, and AUC were calculated through a one-vs-rest scheme (microaverage). Then, recalibration was performed using calibration curves [49] and Brier scores [50] to adjust the difference between the predicted probability and observed proportion of each diagnostic category. External validation was performed using the data of the newest patients in the cohort (enrolled during the last 2 months), which constituted the test set. The 95% CIs of all the metrics were calculated through bootstrapping.

The missing values of Boolean variables were imputed with False in the main results, and sensitivity analysis was conducted by comparing different imputation strategies (ie, without imputation or imputation with True). All machine learning algorithms were implemented in Python, and the code is available in online resources. Hyperparameters are set to default according to the state-of-art machine learning package: sklearn.

Robustness and Sample Size Analysis

As a data-driven prediction approach for boosting clinical diagnosis, it is necessary to verify that the number of samples is enough for model development and validation. Following Riley [51] and Riley et al [52], we quantified the sufficiency of sample size in terms of the global shrinkage factor and the minimal number of samples. The criterion of enough sample size is to ensure a shrinkage factor >0.9. Further, given the acceptable shrinkage factor (eg, 0.9), the necessary size of the samples to develop a prediction model can be estimated based on the Cox-Snell ratio of explained variance.

Further, the increased flexibility of modern techniques implies that larger sample sizes may be required for reliable estimation compared with classical methods such as logistic regression. Thus, we followed the approach of van der Ploeg et al [53] to evaluate our best model LGBM’s sensitivity on sample size. The training set is of different sizes and subsampled from the development set. Each training set size is repeated 30 times to eliminate randomness, while the average AUC measures the performance on the test set.

Important Variables

To measure the importance of variables, we first evaluated multivariate feature importance according to information gains in cross-validation and selected the top 20 important variables. Then, to figure out feature importance in individual diagnostic categories, each selected variable was used to predict the 5 diagnostic categories independently, and univariate variable importance was measured in terms of AUC.

Results

Overview of the Diagnostic Questionnaire

The final questionnaire consists of 23 items that incorporated branching logic. The full version of the questionnaire is available in Multimedia Appendix 1. The contents of the items are shown in Textbox 1.

Textbox 1. Items in the diagnostic questionnaire.

- One question on the characteristic of the symptom: was the head spinning or not? If not, then the kind of dizziness needs to be specified (heavy/muddled head, staggering, or other)
- Three questions on the frequency, duration, and duration it has been since the first vertigo attack
- One question on the condition of hearing loss, that is, which side and how it changes
- Three questions on the condition of tinnitus, aural fullness, and earache, that is, which side and whether it changes before and after the attack should be specified (aggravate before/during the attack, relieve after the attack)
- One question on the presence of headache, specifically the time of headache attack and relevant family history
- One question on accompanied photophobia or phonophobia
- One question on unsteadiness during, after, or without vertigo attacks
- One question on whether symptoms worsen when standing or walking
- Two questions on the condition of fall, consciousness state, and whether there was incontinence during the attack
- Five questions on the triggering factors of vertigo, that is, lying down, turning over, getting up quickly, holding breath, loud stimulation, in some special scenes, special foods or smells, fatigue, insomnia, and getting angry
- One question on whether it is cervical vertigo, that is, upper limb numbness and pain or neck pain
- One question on prodrome, that is, cold, fever, and diarrhea before onset
- One question on the medical history of otological disorders, that is, otorrhea, otitis media, ear surgery
- One question on head and neck trauma and surgery history

Demographic Characteristics of the Participants

A prospective cohort of 1693 patients was enrolled from the ENT and vertigo clinics of 7 participating centers (Table 1). The response rate was 96.2% (1693/1760, 67 declined participation). Of the 1693 enrolled patients, 1041 (61.5%) received 1 final diagnosis by the treating specialists, 14 (0.8%) had more than one diagnosis, 145 (8.6%) had a probable diagnosis, while the other 493 (29.1%) did not receive the final diagnosis within 2 months. The final diagnoses were found to be unevenly distributed. The most common diagnoses were BPPV, vestibular migraine, sudden sensorineural hearing loss with vestibular dysfunction (SSNHL-V), and Meniere disease. Since only patients with 1 final diagnosis were included in the model development and validation, 1041 patients (median age 50 [IQR 38-61] years, 608 [58.4%] females) in the 5 diagnostic categories were included in the model development and validation. Less frequent diagnoses with no more than 20 cases were labeled as “others” for the moment because there were not sufficient cases for them to form separate categories.

Of the 1041 patients, 928 were classified into the training set (for modeling and cross-validation) and 113 were included in the test set (Table 2). Figure 1 shows the study flowchart. The details of the training set and test set are described in Table 2.

Table 1. Demographic characteristics of the participants (N=1693).

Characteristic	Value
Age (years), median (IQR)	51 (38-61)
Sex, n (%)	
Female	991 (58.5)
Male	702 (41.6)
Diagnoses, n (%)	
Benign paroxysmal positional vertigo	398 (23.5)
Vestibular migraine	203 (12)
Meniere disease	194 (11.5)
Sudden sensorineural hearing loss with vestibular dysfunction	173 (10.2)
Others[a]	73 (4.3)
Multiple diagnosis	14 (0.8)
Probable diagnosis	145 (8.6)
Undetermined	493 (29.1)

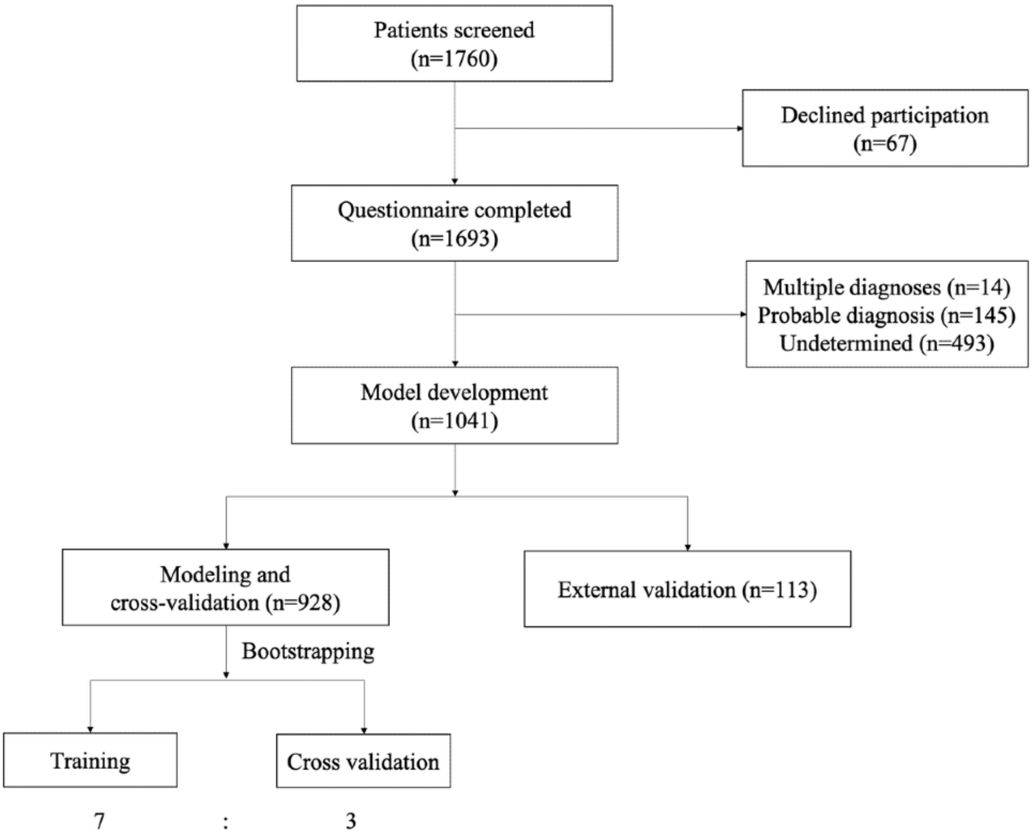
[a] This category included vestibular neuritis, persistent postural-perceptual dizziness, psychogenic dizziness, delayed endolymphatic hydrops, vestibular paroxysmia, cervicogenic vertigo, acoustic neuroma, presbyvestibulopathy, light cupula, Ramsay-Hunt syndrome, labyrinthine fistula, and superior semicircular canal dehiscence syndrome.

Table 2. Characteristics of the training data set and test set.

Characteristic	Training set (n=928)	Test set (n=113)
Age (years), median (IQR)	50 (37-60)	53 (41-63)
Sex, n (%)		
Female	536 (57.8)	72 (63.7)
Male	392 (42.2)	41 (36.3)
Diagnoses, n (%)		
Benign paroxysmal positional vertigo	348 (37.5)	50 (44.2)
Vestibular migraine	182 (19.6)	21 (18.6)
Meniere disease	168 (18.1)	26 (23)
Sudden sensorineural hearing loss with vestibular dysfunction	164 (17.6)	9 (8)
Others[a]	66 (7.1)	7 (6.2)

[a] This category included vestibular neuritis, persistent postural-perceptual dizziness, psychogenic dizziness, delayed endolymphatic hydrops, vestibular paroxysmia, cervicogenic vertigo, acoustic neuroma, presbyvestibulopathy, light cupula, Ramsay-Hunt syndrome, labyrinthine fistula, and superior semicircular canal dehiscence syndrome.

Figure 1. Patients with a new vertigo or dizziness complaint were screened between August 2019 and March 2021. Diagnoses were recorded within 2 months of follow-up.



Development and Validation of the Model

The LGBM model had the highest AUC of 0.937 (95% CI 0.917-0.962) and the lowest Brier score of 0.057 (95% CI 0.049-0.068) among the 9 models in cross-validation (Table 3). Therefore, it was recalibrated and used as the final predictive model.

For sensitivity analysis, when imputing the missing value with mode (the most frequent label), the AUC and Brier score of all 9 methods dropped (Table 4). Note that LGBM does not rely on imputation methods; therefore, it can directly utilize the information from *missing* to achieve a better prediction performance. LGBM without imputation performs as well as the recalibrated LGBM (imputed with 0), which verifies the robustness of our method. Ensemble learning methods performed better than non–ensemble learning methods except logistic regression with LASSO in cross-validation, indicating that the introduction of ensemble learning in vertigo diagnosis is effective across specific ensemble approaches. Further, LGBM performs better than other methods in AUC and Brier scores.

The receiver operating characteristic curves of the recalibrated LGBM model in cross-validation are shown in Figure 2. Table 5 presents the AUC, sensitivity, specificity, likelihood ratios, and accuracy in different diagnostic categories in both cross and external validation. The model made highly accurate prediction for SSNHL-V (AUC>0.98, positive likelihood ratio [+LR]>20, negative likelihood ratio [–LR]<0.05), accurate prediction for BPPV and Meniere disease (AUC>0.95, sensitivity>0.8, specificity>0.9, accuracy>0.9, +LR>10, –LR<0.2), and showed fair discriminative ability for vestibular migraine (AUC 0.9, 95% CI 0.87-0.92). The prediction of other diagnoses was unstable owing to the limited sample size and great heterogeneity in this category, with an AUC ranging from 0.771 to 0.929 in cross-validation and 0.879 to 0.957 in external validation.

Calibration curves in cross-validation (Figure 3) properly estimated the probability of Meniere disease and vestibular migraine and slightly underestimated the probability of SSNHL-V and BPPV. The predictions for other diagnoses were relatively conservative, as it was less likely to give probabilities close to 0 or 1. The Brier score was 0.058 (95% CI 0.049-0.068) in cross-validation, which suggested that the predicted probabilities fitted well with the actual proportions of the diagnoses. We also applied our methods to the external data set. The results indicated that the selected best model, LGBM, was of generalization ability in predicting vertigo diagnosis, achieving an AUC of 0.958 (95% CI 0.951-0.969). Meanwhile, LGBM also performed better than the second-best method, logistic regression, which achieved an AUC of 0.939 (95% CI 0.925-0.956) in external validation. The multivariable feature importance in terms of information gain is shown in Table 6.

The analysis of the global shrinkage factor of each diagnostic category and sensitivity analysis results indicated that the sample size of this study is sufficient for model development. See Multimedia Appendix 2 for more details of sample size analysis. Then, to figure out feature importance in individual diagnostic categories, each of the top 20 contributing variables in Table 6 was used to predict the 5 diagnostic categories independently, and univariate variable importance was measured in terms of AUC (Figure 4).

Table 3. The prediction performance of candidate algorithms.

Method	Area under the curve (95% CI)	Brier score (95% CI)
Non–ensemble learning		
Decision tree	0.765 (0.726-0.798)	0.125 (0.104-0.146)

Figure 3. Calibration curves (blue solid lines) with pointwise 95% confidence limits (grey ribbon) on the validation data based on recalibrated light gradient boosting machine model. BPPV: benign paroxysmal positional vertigo; SSNHL-V: sudden sensorineural hearing loss with vertigo.

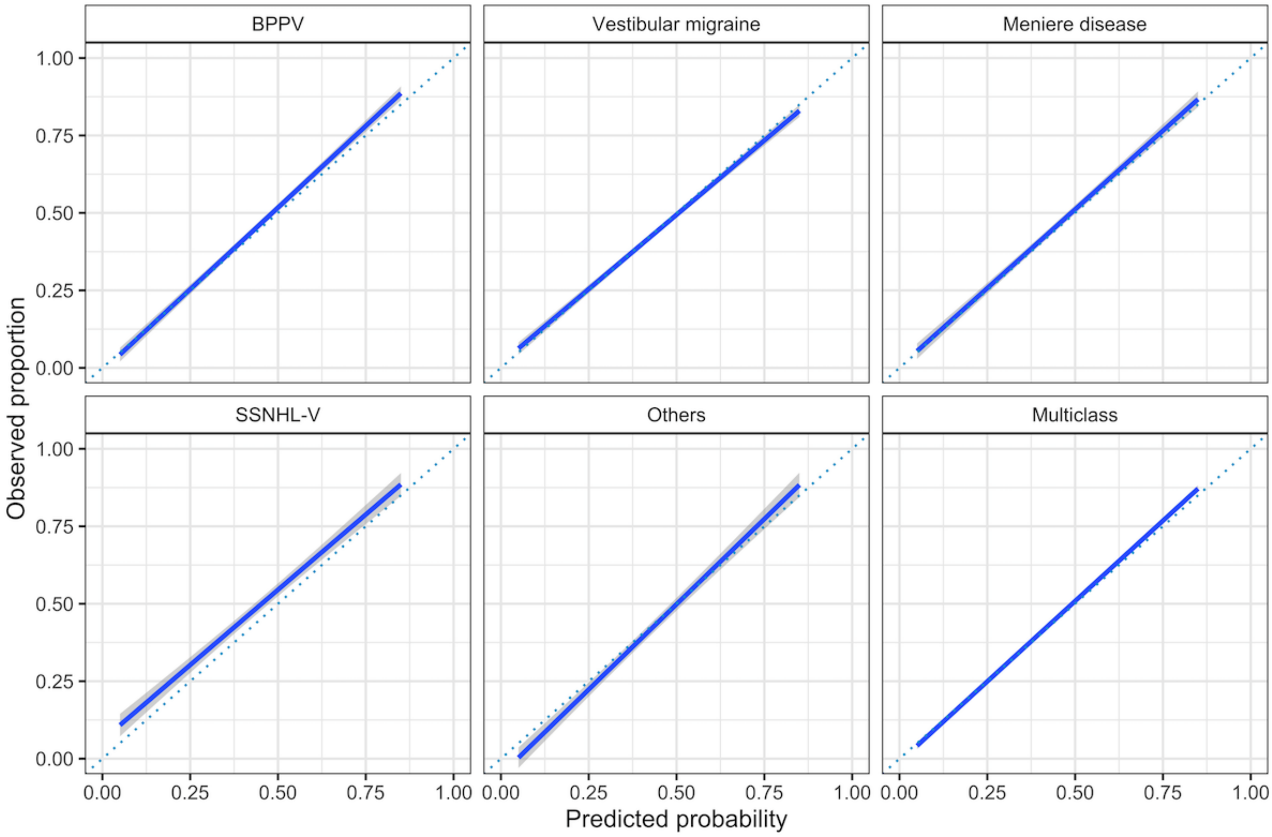

Table 6. Multivariable feature importance in light gradient boosting machine model.

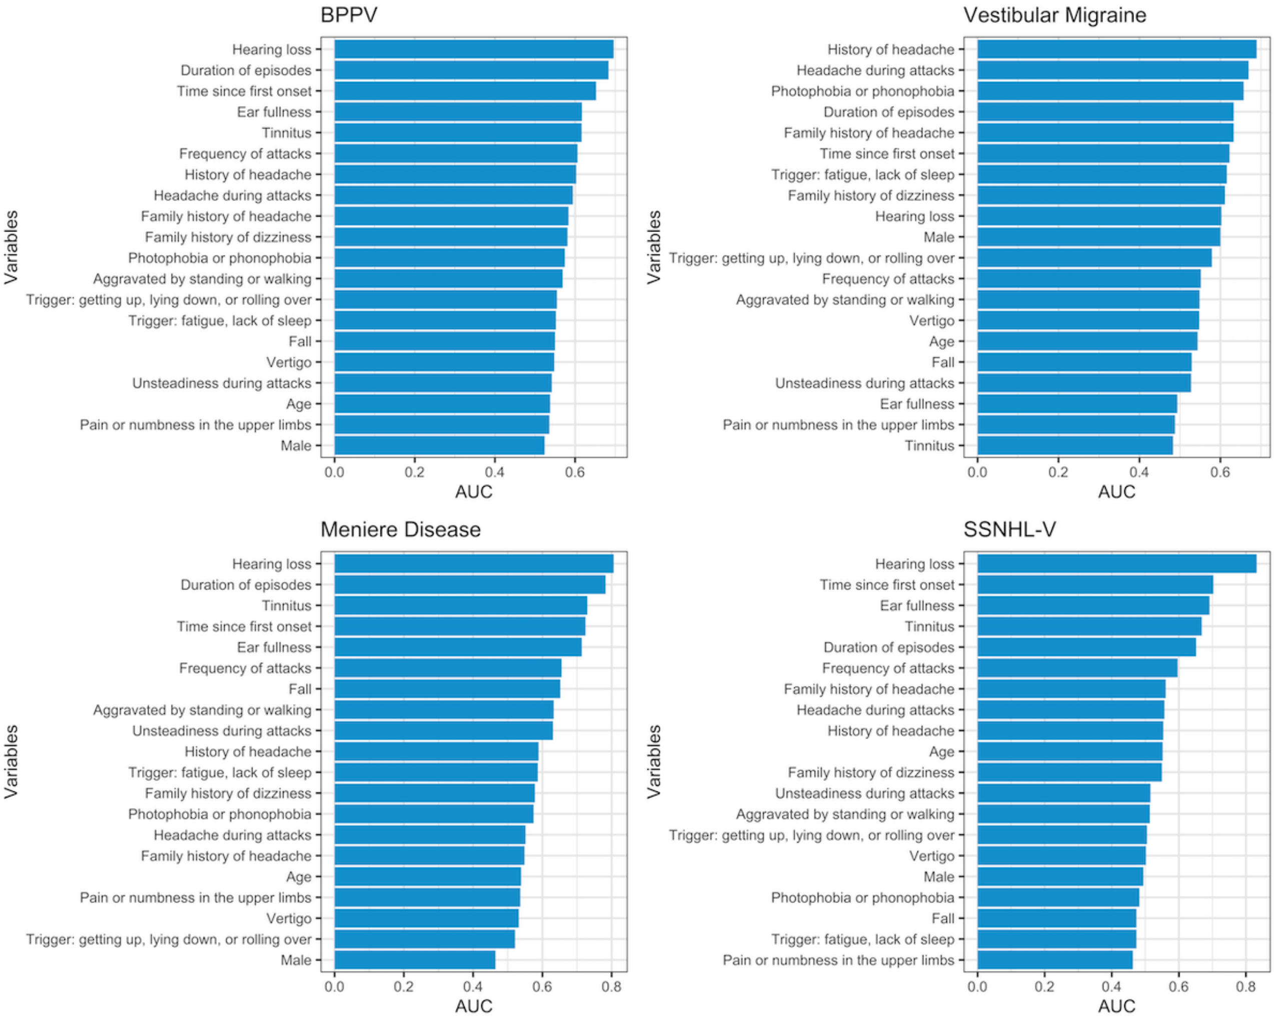
Variable	Feature importance
Sudden hearing loss	1039.8
Duration of episodes	912.3
Hearing loss	694.8
Time since first onset	468.1
Trigger: getting up, lying down, or rolling over	358.0
Age	255.6
History of headache	250.6
Frequency of attacks	221.4
Fluctuating hearing loss	186.3
Photophobia or phonophobia	185.7
Time since first hearing loss	183.7
Recurring symptoms	155.9
Tinnitus	135.5
Ear fullness	135.4
Headache during attacks	117.7
Aggravated by standing or walking	80.4
Trigger: fatigue, lack of sleep	69.7
Vertigo	65.0
Pain or numbness in the upper limbs	62.4
Unsteadiness during attacks	59.5
Family history of headache	54.2
Male	54.1
Fall	47.3
Loss of consciousness, incontinence	44.6
Tinnitus: aggravated before an attack, alleviated after an attack	36.7
Trigger: visual stimuli	31.0
Trigger: sound and pressure	23.0
Unsteadiness: after first onset	22.4
Prodrome: cold, fever, vomiting, or diarrhea	22.0
Family history of dizziness	17.4
Trigger: certain foods	15.9
Otalgia	11.6
Conscious when falling	9.8
History of otitis media or ear surgery	7.2
Tinnitus: worsen during vertigo	4.5
Fluctuating: gradually worsen	0.0
Unsteadiness between attackss	0.0
Recent history of head and neck trauma or surgery	0.0

Figure 4. Area under the curve in univariate prediction was used as the estimate of variable importance. AUC: area under the curve; BPPV: benign paroxysmal positional vertigo; SSNHL-V: sudden sensorineural hearing loss with vertigo.



Discussion

Principal Findings

In this multicenter prospective cohort study, a questionnaire was developed to diagnose vertigo, and an LGBM model was developed using patients' historical data collected through the questionnaire. This is, to our knowledge, the first questionnaire-based machine learning model to predict multiple diagnoses of vertigo. Because all the patients in this study were from ENT and vertigo clinics, the distribution of diagnoses differs from that in previous studies conducted in neurology and balance clinics [19-21,26]. There was a much higher prevalence of SSNHL-V (173/1693, 10.2%) and a lower prevalence of vestibular neuritis (22/1693, 1.3%) in our study.

Our model outperformed previously reported questionnaire-based statistical models in predicting common vestibular diagnoses [20,21,26]. A possible explanation is that machine learning methods are better at dealing with potentially nonlinear relationships and overfitting. Additionally, given the subjectivity of patient-reported historical information, data-driven models are better fits in questionnaire-based prediction than knowledge-driven models [9,11,54,55]. Compared with previous machine learning diagnostic systems that used comprehensive patient history data, physical examination, and laboratory tests, our questionnaire-based diagnostic model has its merits [13-17]. First, medical history provides important clues to the cause of vertigo, based on which the doctor will try to confirm or exclude a presumptive diagnosis. Therefore, a questionnaire-based diagnostic tool can provide early decision support according to patient history and help reduce unnecessary workup. Further, since questionnaire data come directly from patients, the model's performance does not rely on the accurate interpretation of patient history by professionals. Besides, considering the limited accessibility of specific tests (eg, pure tone audiometry, caloric test, video head impulse test), a questionnaire requiring no special equipment is suitable across different clinical settings. However, a questionnaire-based diagnostic model also has intrinsic limitations. Patient-reported medical history can be imprecise because it can be easily affected by recall bias, misinterpretation, emotional state of the patients, and other subjective factors. Meanwhile, for patients with only nonspecific symptoms, physical examination and laboratory testing are more important diagnostic tools. Patient history should always be combined with objective evidence to make a more reliable diagnosis. Therefore, it is necessary to introduce physical examination and laboratory test results into the system in the future to make a comprehensive stepwise diagnostic prediction.

Limitations

This study had the following limitations. The uneven distribution of diagnoses made it difficult for the model to give accurate predictions of rare diagnoses. In order to reduce potential noise, we included only patients with 1 final diagnosis in modeling. The exclusion of patients with undetermined diagnosis was a potential source of bias. There were several reasons that these patients did not receive a specific diagnosis. In some cases, patients with BPPV might experience spontaneous remission while waiting for the scheduled positional test and treatment (1-2 weeks later), which also explains the relatively low prevalence of BPPV in our cohort than that in other ENT clinics [56]. The exclusion of these patients could reduce noise and improve model performance. Besides, some patients only experienced transient symptoms without observable structural, functional, or psychological changes; therefore, no specific diagnosis was given. Moreover, while a majority of patients completed all the necessary examinations within the follow-up, it was also possible that some rare causes were not determined within 2 months, possibly adding to the imbalance of data. Nevertheless, as the cohort expands, more patients with rare diagnoses will be included, which will enable the model to predict rare diagnoses with higher accuracy. We can also manage the influence of imbalanced data during modeling. Meanwhile, the observed AUC in external validation was higher than that in cross-validation, which could be accounted for by the relatively small sample size of the test set. More participants with definite diagnosis are needed for providing further validation. Finally, since this study was conducted in the ENT and vertigo clinic of tertiary centers, the predictive power of the model is yet to be verified in different clinical settings.

Conclusion

This study presents the first questionnaire-based machine learning model for the prediction of common vestibular disorders. The model achieved strong predictive ability for BPPV, vestibular migraine, Meniere disease, and SSNHL-V by using an ensemble learning method LGBM. As part of the OVerAIR platform, it can be used to assist clinical decision-making in ENT clinics and help with the remote diagnosis of BPPV. We have also been working on a smartphone app that integrates the questionnaire with referral, follow-up, treatment, and rehabilitation to improve the health outcomes of patients with vertigo. The next phase of the OVerAIR study will involve the participation of neurologists, which is expected to improve the model's predictive ability for central vertigo and help assess its generalization and robustness.

Acknowledgments

This study was supported by the Capacity Building Project for interdisciplinary diagnosis and treatment of major diseases (otogenic vertigo), Shanghai Municipal Health Commission, Shanghai Municipal Key Clinical Specialty (shslczdzk00801), General Project of Scientific Research Fund of Shanghai Health Committee (grant 202040286), and the National Natural Science Foundation of China (91846302 and 72033003). The funding sources played no part in the design and conduct of this study; collection, management, analysis, and interpretation of data; writing of the report; or the decision to submit the manuscript for publication.

Authors' Contributions

FY and HD had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. FY, PW, HD, CZ, and HL were responsible for the concept and design of this study. All authors contributed to the acquisition, analysis, or interpretation of data and critical revision of the manuscript for important intellectual content. FY, PW, and HD drafted the manuscript. FY and HD performed the statistical analysis. HL and CZ obtained the funding for this study. FY, PW, HD, JW, HY, CZ, and HL provided administrative, technical, or material support. HL and CZ supervised the study.

Abstract

Background: Heart failure (HF) is a common disease and a major public health problem. HF mortality prediction is critical for developing individualized prevention and treatment plans. However, due to their lack of interpretability, most HF mortality prediction models have not yet reached clinical practice.

Objective: We aimed to develop an interpretable model to predict the mortality risk for patients with HF in intensive care units (ICUs) and used the SHapley Additive exPlanation (SHAP) method to explain the extreme gradient boosting (XGBoost) model and explore prognostic factors for HF.

Methods: In this retrospective cohort study, we achieved model development and performance comparison on the eICU Collaborative Research Database (eICU-CRD). We extracted data during the first 24 hours of each ICU admission, and the data set was randomly divided, with 70% used for model training and 30% used for model validation. The prediction performance of the XGBoost model was compared with three other machine learning models by the area under the curve. We used the SHAP method to explain the XGBoost model.

Results: A total of 2798 eligible patients with HF were included in the final cohort for this study. The observed in-hospital mortality of patients with HF was 9.97%. Comparatively, the XGBoost model had the highest predictive performance among four models with an area under the curve (AUC) of 0.824 (95% CI 0.7766-0.8708), whereas support vector machine had the poorest generalization ability (AUC=0.701, 95% CI 0.6433-0.7582). The decision curve showed that the net benefit of the XGBoost model surpassed those of other machine learning models at 10%~28% threshold probabilities. The SHAP method reveals the top 20 predictors of HF according to the importance ranking, and the average of the blood urea nitrogen was recognized as the most important predictor variable.

Conclusions: The interpretable predictive model helps physicians more accurately predict the mortality risk in ICU patients with HF, and therefore, provides better treatment plans and optimal resource allocation for their patients. In addition, the interpretable framework can increase the transparency of the model and facilitate understanding the reliability of the predictive model for the physicians.

Introduction

Heart failure (HF), the terminal phase of many cardiovascular disorders, is a major health care issue with an approximate prevalence of 26 million worldwide and more than 1 million hospital admissions annually in both the United States and Europe [1]. Projections show that by 2030 over 8 million Americans will have HF, leading to an increase of 46% from 2012 [2]. Each year, HF costs an estimated US $108 billion, constituting 2% of the health care budget globally, and it is predicted to continue to rise, yet half of it is possibly avoidable [3]. As COVID-19 continues to spread across the world, HF, a severe complication, is associated with poor outcome and death from COVID-19 [4,5].

The critically ill patients in intensive care units (ICUs) demand intensive care services and highly qualified multidisciplinary assistance [6]. Although ICU plays an integral role in maintaining patients' life, this also implies the workforce shortage, limited medical resources, and heavy economic burden [7]. Therefore, early hospital mortality detection for patients is necessary and may assist in delivering proper care and providing clinical decision support [8].

In recent years, artificial intelligence has been widely used to explore the early warning predictors of many diseases. Given the inherent powerful feature of capturing the nonlinear relationships with machine learning algorithms, more researchers advocate the use of new prediction models based on machine learning to support appropriate treatment for patients rather than traditional illness severity classification systems such as SOFA, APACHE II, or SAPS II [9-11]. Although a large number of predictive models have shown promising performance in research, the evidence for their application in clinical setting and interpretable risk prediction models to aid disease prognosis are still limited [12-15].

The purpose of our study is to develop an interpretable model to predict the risk mortality for patients with HF in the ICU, using the free and open critical care database—the eICU Collaborative Research Database (eICU-CRD). In addition, the SHapley Additive exPlanations (SHAP) method is used to explain the extreme gradient boosting (ie, XGBoost) model and explore prognostic factors for HF.

Methods

Data Source

The eICU-CRD (version 2.0) is a publicly available multicenter database [16], containing deidentified data associated with over 200,000 admissions to ICUs at 208 hospitals of the United States between 2014-2015. It records all patients, demographics, vital sign measurements, diagnosis information, and treatment information in detail [17].

Ethical Considerations

Ethical approval and individual patient consent was not necessary because all the protected health information was anonymized.

Study Population

All patients in the eICU-CRD database were considered. The inclusion criteria were as follows: (1) patients were diagnosed with HF according to the International Classification of Diseases, ninth and tenth Revision codes (Multimedia Appendix 1); (2) the diagnosis priority label was "primary" when admitted to the ICU in 24 hours; (3) the ICU stay was more than 1 day; and (4) patients were aged 18 years or older. Patients who had more than 30% missing values were excluded [18].

Predictor Variables

The prediction outcome of the study is the probability of in-hospital mortality, defined as patient's condition upon leaving the hospital. Based on previous studies [19-22] and experts' opinion (a total of 6 independent medical professionals and cardiologists in West China Hospital of Sichuan University), demographics, comorbidities, vital signs, and laboratory findings (Multimedia Appendix 2) were extracted from the eICU-CRD, using Structured Query Language (MySQL) queries (version 5.7.33; Oracle Corporation). The following tables from eICU-CRD were used: "diagnosis," "intakeoutput," "lab," "patient," and "nursecharting." Except for the demographic characteristics, other variables were collected during the first 24 hours of each ICU admission. Furthermore, to avoid overfitting, Least Absolute Shrinkage and Selection Operator (LASSO) is used to select and filter the variables [23,24].

Missing Data Handling

Variables with missing data are a common occurrence in eICU-CRD. However, analyses that ignore missing data have the potential to produce biased results. Therefore, we used multiple imputation for missing data [25]. All selected variables contained <30% missing values. Data were assumed missing at random and were imputed using fully conditional specification with the "mice" package (version 3.13.0) for R (version 4.1.0; R Core Team).

Machine Learning Explainable Tool

The interpretation of the prediction model is performed by SHAP, which is a unified approach to calculate the contribution and influence of each feature toward the final predictions precisely [26]. The SHAP values can show how much each predictor contributes, either positively or negatively, to the target variable. Besides, each observation in the data set could be interpreted by the particular set of SHAP values.

Statistical Analysis

All statistical analysis and calculations were performed using R software and Python (version 3.8.0; Python Software Foundation). The categorical variables are expressed as total numbers and percentages, and the χ^2 test or Fisher exact test (expected frequency <10) is used to compare the differences between groups. The continuous variables are expressed as median and IQR, and the Wilcoxon rank sum test is used when comparing the two groups.

Four machine learning models—XGBoost, logistic regression (LR), random forest (RF), and support vector machine (SVM)—were used to develop the predictive models. The prediction performance of each model was evaluated by the area under the receiver operating characteristic curve. Moreover, we calculated the accuracy, sensitivity, positive predictive values, negative predictive values, and F_1 score when the prediction specificity was fixed at 85%. Additionally, to assess the utility of models for decision-making by quantifying the net benefit at different threshold probabilities, decision curve analysis (DCA) was conducted [27].

Results

Patient Characteristics

Among 17,029 patients with HF in eICU-CRD, a total of 2798 adult patients diagnosed with primary HF were included in the final cohort for this study. The patient screening process is shown in Figure 1. The data set was randomly divided into 2 parts: 70% (n=1958) of the data were used for model training, and 30% (n=840) of the data were used for model validation. The LASSO regularization process resulted in 24 potential predictors on the basis of 1958 patients in the training data set, which were used for model developing. Patients in the nonsurvivor group were older than the ones in the survivor group (*P*<.001). The hospital mortality rate was 9.96% (195/1958) in the training data set and 10% (84/840) in the testing data set (Multimedia Appendix 3). Table 1 shows the comparisons of predictor variables between survivors and nonsurvivors during hospitalization.

[e] SpO_2: O_2 saturation.
[f] RDW: red blood cell distribution width.

Model Building and Evaluation

Within the training data set, the XGBoost, LR, RF, and SVM models were established, and the testing data set obtained AUCs of 0.824, 0.800, 0.779, and 0.701, respectively (Table 2 and Figure 2). Comparatively, XGBoost had the highest predictive performance among the four models (AUC=0.824, 95% CI 0.7766-0.8708), whereas SVM had the poorest generalization ability (AUC=0.701, 95% CI 0.6433-0.7582). DCA was performed for four machine learning models in the testing data set to compare the net benefit of the best model and alternative approaches for clinical decision-making. Clinical net benefit is defined as the minimum probability of disease, when further intervention would be warranted [28]. The plot measures the net benefit at different threshold probabilities. The orange line in Figure 3 represents the assumption that all patients received intervention, whereas the yellow line represents that none of the patients received intervention. Due to the heterogeneous profile of the study population, treatment strategies informed by any of the four machine learning–based models are superior to the default strategies of treating all or no patient. The net benefit of the XGBoost model surpassed those of the other machine learning models at 10%~28% threshold probabilities (Figure 3).

Table 2. Performance of each model for prediction.

Model	AUC[a] (%)	Sensitivity (%)	F_1 score	Accuracy (%)	PPV[b]	NPV[c]
XGBoost	0.824	0.595	0.407	0.826	0.307	0.950
LR[d]	0.800	0.607	0.413	0.827	0.311	0.951
RF[e]	0.779	0.571	0.392	0.823	0.298	0.947
SVM[f]	0.701	0.345	0.258	0.801	0.204	0.921

Explanation of XGBoost Model With the SHAP Method

The SHAP algorithm was used to obtain the importance of each predictor variable to the outcome predicted by the XGBoost model. The variable importance plot lists the most significant variables in a descending order (Figure 4). The average of blood urea nitrogen (BUN) had the strongest predictive value for all prediction horizons, followed quite closely by the age factor, the average of noninvasive systolic blood pressure, urine output, and the maximum of respiratory rate. Furthermore, to detect the positive and negative relationships of the predictors with the target result, SHAP values were applied to uncover the mortality risk factors. As presented in Figure 5, the horizontal location shows whether the effect of that value is associated with a higher or lower prediction and the color shows whether that variable is high (in red) or low (in blue) for that observation; we can see that increases in the average BUN has a positive impact and push the prediction toward mortality, whereas increases in urine output has a negative impact and push the prediction toward survival.

Figure 4. The weights of variables importance. Avg: average; BUN: blood urea nitrogen; max: maximum; min: minimum; NIBP: noninvasive blood pressure; RDW: red blood cell distribution width; SHAP: SHapley Additive exPlanation; SpO_2: O_2 saturation; WBC: white blood cell.

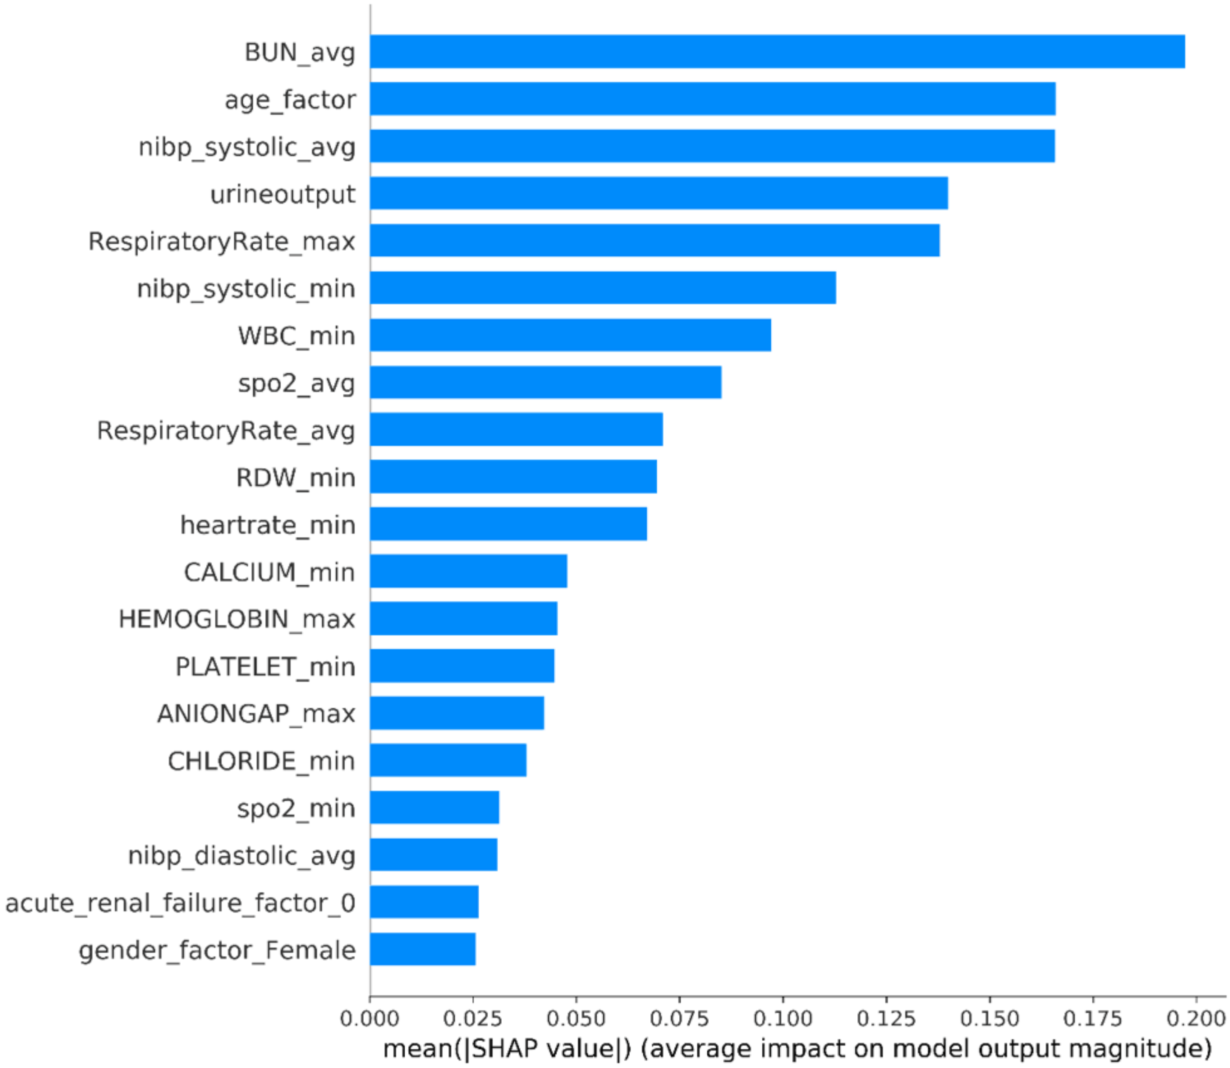

Figure 5. The SHapley Additive exPlanation (SHAP) values. Avg: average; BUN: blood urea nitrogen; max: maximum; min: minimum; NIBP: noninvasive blood pressure; RDW: red blood cell distribution width; SpO_2: O_2 saturation; WBC: white blood cell.

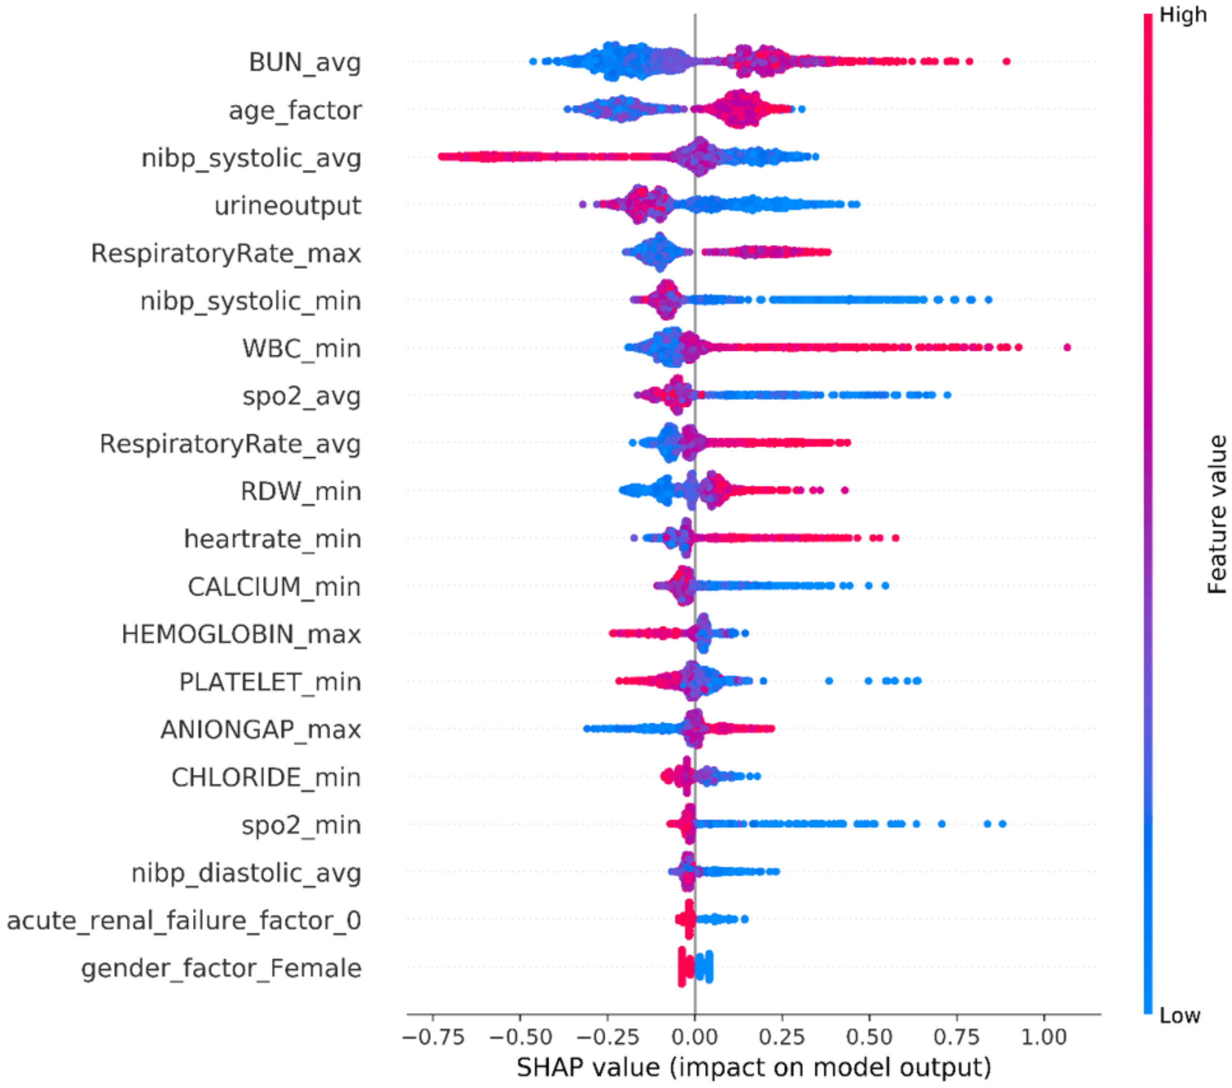

SHAP Individual Force Plots

Figure 6 shows the individual force plots for patients who (A) did not survive and (B) survived. The SHAP values indicate the prediction-related feature of individual patients and the contribution of each feature to the mortality prediction. The bold-faced numbers are the probabilistic predicted values (f(x)), whereas the base values are the values predicted without giving input to the model. The f(x) is the log odds ratio of each observation. The red features (on the left) indicate features that increase the mortality risk, and the blue features indicate features that decrease the mortality risk. The length of the arrows helps visualize the magnitude of the effect on the prediction. The longer the arrow, the larger the effect.

B. survivor

Discussion

Principal Findings

In this retrospective cohort study of a large-scale public ICU database, we developed and validated four machine learning algorithms to predict the mortality of patients with HF. The XGBoost model outperforms the performance of LR, RF, and SVM. The SHAP method is used to explain the XGBoost model, which ensures the model performance and clinical interpretability. This will help physicians better understand the decision-making process of the model and facilitates the use of prediction results. Besides, to avoid ineffective clinical interventions, the relevant threshold probability range of DCA that we focused on was between 15% and 25%, during which XGBoost performed better. In critical care research, XGBoost has been widely used to predict the in-hospital mortality of patients and may assist clinicians in decision-making [29-31]. However, the mortality of patients with HF included in the final cohort is just 9.97%. Although DCA shows that the XGBoost model is better than the two default strategies, the positive predictive value is just 0.307 when the prediction specificity is fixed at 85%. Therefore, the XGBoost model may not be fully acceptable to provide decision-making support for clinicians. Evaluation of the benefits of earlier prediction of mortality and its additional cost is necessary in clinical practice.

Using SHAP to explain the XGBoost model, we identified some important variables associated with in-hospital mortality of patients with HF. In this study, the average BUN was recognized as the most important predictor variable. As a renal function marker to measure the amount of nitrogen in blood that comes from protein metabolism, previous studies also showed that BUN was the key predictor of HF mortality prediction with machine learning algorithms [32,33]. Kazory [34] concludes that BUN may be a biomarker of neurohormonal activation in patients with HF. From the perspective of pathophysiology, the activity of sympathetic nervous systems and the renin-angiotensin-aldosterone system increases with the aggravation of HF, which causes the vasoconstriction of the afferent arterioles. A reduction in renal perfusion further leads to water and sodium retention and promotes urea reabsorption, ultimately resulting in an increased BUN. However, further research is needed to explore the applicability of this SHAP method, due to the lack of an external validation cohort.

Limitations

This study had some limitations. First, our data were extracted from a publicly available database, and some variables were missing. For example, we intended to include more predictor variables that may affect in-hospital mortality such as prothrombin time as well as brain natriuretic peptide and lactate; however, the missing values were over 70%. Second, all data were derived from the ICU patients from the United States, so the applicability of our model remained unclear in other populations. Third, our mortality prediction models were based on data available within 24 hours of each ICU admission, which may neglect the subsequent events that change the prognosis and cause confounders to some extent. Fourth, due to lack of an external validation cohort, the applicability of the developed XGBoost model may not be very efficient in clinical practice. Currently, we are trying to collect data of patients with HF in ICUs from West China Hospital of Sichuan University. Although we have obtained some preliminary data, it is not feasible for the external prospective validation because of the limited sample size.

Conclusions

We developed the interpretable XGBoost prediction model that has the best performance in estimating the mortality risk in patients with HF. In addition, the interpretable machine learning approach can be applied to accurately explore the risk factors of patients with HF and enhance physicians' trust in prediction models. This will help physicians identify patients with HF who have a high mortality risk so as to timely apply appropriate treatments for them.

Abstract

Background: Artificial intelligence (AI) for use in health care and social services is rapidly developing, but this has significant ethical, legal, and social implications. Theoretical and conceptual research in AI ethics needs to be complemented with empirical research to understand the values and judgments of members of the public, who will be the ultimate recipients of AI-enabled services.

Objective: The aim of the Australian Values and Attitudes on AI (AVA-AI) study was to assess and compare Australians' general and particular judgments regarding the use of AI, compare Australians' judgments regarding different health care and social service applications of AI, and determine the attributes of health care and social service AI systems that Australians consider most important.

Methods: We conducted a survey of the Australian population using an innovative sampling and weighting methodology involving 2 sample components: one from an omnibus survey using a sample selected using scientific probability sampling methods and one from a nonprobability-sampled web-based panel. The web-based panel sample was calibrated to the omnibus survey sample using behavioral, lifestyle, and sociodemographic variables. Univariate and bivariate analyses were performed.

Results: We included weighted responses from 1950 Australians in the web-based panel along with a further 2498 responses from the omnibus survey for a subset of questions. Both weighted samples were sociodemographically well spread. An estimated 60% of Australians support the development of AI in general but, in specific health care scenarios, this diminishes to between 27% and 43% and, for social service scenarios, between 31% and 39%. Although all ethical and social dimensions of AI presented were rated as important, accuracy was consistently the most important and reducing costs the least important. Speed was also consistently lower in importance. In total, 4 in 5 Australians valued continued human contact and discretion in service provision more than any speed, accuracy, or convenience that AI systems might provide.

Conclusions: The ethical and social dimensions of AI systems matter to Australians. Most think AI systems should augment rather than replace humans in the provision of both health care and social services. Although expressing broad support for AI, people made finely tuned judgments about the acceptability of particular AI applications with different potential benefits and downsides. Further qualitative research is needed to understand the reasons underpinning these judgments. The participation of ethicists, social scientists, and the public can help guide AI development and implementation, particularly in sensitive and value-laden domains such as health care and social services.

Introduction

Background

Artificial intelligence (AI) and automation are accelerating in many fields driven by an increase in the availability of massive linked data sets, cloud computing, more powerful processors, and the development of new types of algorithms, particularly in the field of machine learning. In this paper, AI will be broadly conceptualized, consistent with the Australian Council of Learned Academies definition, as "a collection of interrelated technologies used to solve problems and perform tasks that, when humans do them, requires thinking" [1]. These technologies are being applied in social services, including to automate eligibility verification, target and personalize welfare services, and aid in the detection of fraud and debt liability [2,3]. Health care, initially slow to adopt AI, is also seeing rapid development for applications including health service planning and resource allocation, triage, screening and diagnosis, prognostication, robotics in applications such as aged care, and health advice chatbots [4-6]. These areas of practice—social services and health care—have traditionally been provided via extensive human-to-human contact by staff with professional autonomy and the capacity to exercise discretion in handling the problems of service users or patients.

Ethical, Legal, and Social Implications of AI

A growing body of literature acknowledges the complex ethical, legal, and social implications (ELSI) of AI deployment [1,7,8]. In the 2010s, many intergovernmental, academic, and industry groups examined the ELSI of AI in a general sense, producing lists of high-level principles for AI ethics [1,7,9,10] often reminiscent of existing frameworks in bioethics [11]. In parallel, a set of approaches that foreground the significance of power, oppression, discrimination, and injustice has been developed, contextualized in the sociotechnical systems in which AI is embedded [12]. Other work critiques the corporate AI sector for establishing AI ethics boards and documents while persisting with unethical practices and points to the difficulties faced by AI ethics researchers when working inside corporations producing AI systems [13]. The abstract principles and frameworks that have proliferated in AI ethics offer accessible ways in to ethical debates, but they cannot be sufficient to address ethical issues in practice [14]. There are now calls to complement ethical frameworks with other forms of knowledge, including analysis of detailed use cases and investigation of what members of the public think and value regarding the use of AI [15]. Two linked cases are the focus of this study: the use of AI in health services and in social services, which are an important social determinant of health especially for marginalized and disadvantaged populations.

For the first case, health care AI, research on ELSI has been rapidly expanding since 2019. In a 2020 review, Morley et al [16] highlighted 3 groups of ELSI issues for health care AI: epistemic concerns (that the evidence on which health care AI is based is inconclusive, inscrutable, or misguided), normative concerns (highlighting unfairness and the potential for transformative unintended consequences), and concerns about the ability to either identify algorithmic harm or ascribe responsibility for it. Another 2020 review focused on health care emphasized the potential to worsen outcomes or cost-effectiveness, the problem of transportability (that algorithms may not work equally well in different populations), automation bias (that humans tend to be too willing to accept that algorithmic systems are correct), the potential to intensify inequities, the risk of clinical deskilling, increased threats to data protection and privacy, lack of contestability of algorithmic decisions, the need to preserve clinician and patient autonomy, and the potential to undermine trust in health care systems [17]. A 2021 scoping review on health care AI ELSI highlighted data privacy and security, trust in AI, accountability and responsibility, and bias as key ethical issues for health care AI [18]. Also in 2021, Goirand et al [19] identified 84 AI-specific ethics frameworks relevant to health and >11 principles recurring across these while noting that few frameworks had been implemented in practice. In parallel, empirical evidence demonstrates a continuing need to address the ELSI of health care AI. A well-known example is an AI system used to allocate health care in many US health services that allocated more care to White patients than to Black patients, even when the Black patients had greater need, because the AI learned from historical underservicing that Black patients had lower care requirements [20].

Regarding our second case, AI in the social services, ELSI research is also gaining momentum, particularly as part of broader inquiries into the digital welfare state or in relation to high-profile examples of technology failure [2,21,22]. This research highlights the potential of AI to improve the consistency and accuracy of welfare decision-making and increase cost-efficiency. However, it also raises grave concerns regarding the social costs associated with implementing AI in the social services, particularly for vulnerable populations. For example, the pioneering ethnographic study by Eubanks [21] of AI and automation technologies in the United States in 2018 illustrates how new technologies can disempower poor citizens, intensify existing patterns of discrimination, and *automate inequality*. Similar concerns have been raised in Australia in relation to the Online Compliance Intervention known as *robodebt*. The scheme automated the calculation of welfare debts based on an income-averaging algorithm. The legality of the algorithm was successfully challenged before a domestic court in 2019, culminating in an Aus $1.8 billion (US $1.25

billion) class action lawsuit against the Australian government and prompting significant public and scholarly criticism of the scheme [23].

AI applications in the welfare sector pose novel challenges to legal and regulatory compliance. Many AI systems, including robodebt, have been designed and implemented in the absence of proper legal frameworks or in contravention of prevailing laws and administrative principles [2,24]. Other high-profile examples include the System Risk Indication system of the Dutch government, which was used to predict an individual's risk of welfare fraud. System Risk Indication was successfully challenged based on the fact that the system breached the right to privacy contained in the European Convention on Human Rights [2]. Such cases have prompted a growing body of literature concentrated on the legal and human rights implications of AI in the social services. The recent report by the United Nations Special Rapporteur on Extreme Poverty [2] calls for a human rights–based approach to digital regulation in social protection systems, which has prompted further research on AI and human rights principles [25].

Existing Research on Perceptions of the ELSI of Using AI, Including in Health Care and Social Services

An approach to thinking about the ELSI of AI is to examine public attitudes and judgments toward these technologies. In areas such as health care and social services, this includes the attitudes and judgments of patients and service users. A small body of literature exists on general attitudes toward AI. In 2018, Zhang and Dafoe [26] surveyed 2000 American adults and found mixed support for developing AI and strong support for the idea that AI should be carefully managed. In April 2020, the Monash Data Futures Institute surveyed 2019 Australians on their attitudes toward AI, adapting some questions from Zhang and Dafoe [27]. They found that Australians did not consider themselves knowledgeable about AI, but 62.4% expressed support for the development of AI. When asked whether they supported the use of AI in particular fields, respondents were most supportive of AI use in health (44.1% strong support) and medicine (43% strong support) and less supportive of AI use in *equality and inclusion* (21.5% strong support) and public and social sector management (20.2% strong support). Respondents tended to agree that AI would do more social good than harm overall [27].

Research on the attitudes of patients and service users is developing; most research to date—such as this study—has been speculative, asking informants about their views or intentions rather than their direct experience of AI. Studies asking patients to imagine the use of AI in their care generally report broad acceptance [28-30] in areas including skin cancer screening and neurosurgery. Promises of greater diagnostic accuracy are well received [30], and sharing deidentified health data for the development of medical AI may be acceptable to most [28]. A study reported experiences with a diabetic retinopathy screening AI—96% of patients were satisfied or very satisfied [31]. However, respondents in most studies also express concerns. Regarding skin cancer screening, concerns included inaccurate or limited training sets; lack of context; lack of physical examination; operator dependence; data protection; and potential errors, including false negatives and false positives [28,30]. In the context of neurosurgery, respondents wanted a human neurosurgeon to remain in control [29]. Finally, a study of patients with cancer in China suggested that despite reporting that they *believed in* both diagnoses and therapeutic advice given by an AI (90% and 85%, respectively), when this differed from the advice given by a human clinician, most patients would prefer to take the human clinician's recommendation (88% and 91%, respectively) [32].

Research examining public and professional attitudes toward AI in the welfare sector is very limited. To the authors' knowledge, research is yet to explore citizens' general attitudes toward AI in the domain of welfare provision. However, there is a small body of research documenting service users' experiences of specific AI applications in the social services, particularly users' negative experiences of exclusion and discrimination [21,33], providing context-specific insights into system users' experiences of AI and illustrating the high-stakes nature of implementing AI in this domain. This work, together with some small-scale, mostly qualitative studies involving frontline social service staff [34-38], illustrates the complex and dynamic relationship between AI and the routines of social welfare professionals and indicates mixed reactions to these systems among staff. For example, the study by Zejnilović et al [36] of counselors in a Portuguese employment service in 2020 found high levels of distrust and generally negative perceptions of an AI system used to score clients' risk of long-term unemployment. However, the survey data also indicated that workers would continue to rely on the system even if it became optional, suggesting that respondents harbor mixed feelings about the system.

The Australian Values and Attitudes on Artificial Intelligence (AVA-AI) study set out to understand Australians' values and attitudes regarding the use of AI in health care and social services. Australia has been relatively slow to approve and adopt medical AI compared, for example, with the United Kingdom and the United States. The adoption of AI and automation technologies in the social services is comparatively advanced in Australia, although its development has been uneven and marked by controversy, including the case of robodebt. Multiple stakeholders are now confronting the opportunities and risks of these technologies. Policy makers need high-quality evidence of what Australians consider acceptable or unacceptable to ensure that their decision-making is legitimate. This study used an innovative methodology to survey Australians regarding these questions. Our aims were to understand Australians' front-of-mind normative judgments about the use of AI, especially in the underresearched fields of social services and health care, and what attributes of AIs they would consider to be most important if those AIs were to be deployed in health care and social services. Although parallel literature seeks to model the characteristics of AI that predict acceptance [39], this work has the complementary aim of seeking to understand the prevalence and patterning of different normative judgments about AI.

The research questions answered in this study are as follows: (1) How do Australians' general judgments regarding the use of AI compare with their judgments regarding the particular uses of AI in health care and social services? (2) Do Australians make different judgments about different health care and social service applications of AI? (3) What attributes of health care and social service AI systems do Australians consider most important?

Methods

Aims

The *AVA-AI study* was conducted to (1) provide information on Australians' attitudes and values regarding AI, especially in health care and social services, and (2) allow for analysis of how these vary across different subpopulations and are associated with people's sociodemographic characteristics and familiarity with technology. This study focuses on attitudes and values, how they differ for different scenarios, and the relative importance of different attributes of health care and social service AI. A selection of concepts from AI ethics relevant to understanding this study is outlined in Textbox 1. Analyses across different subpopulations will be reported in future papers.

Textbox 1. Concepts from artificial intelligence (AI) ethics used in the Australian Values and Attitudes on Artificial Intelligence (AVA-AI) study.

Concept and meaning in the context of AI ethics

- Accuracy: the degree to which an AI can perform tasks without errors. In the context of screening or targeting, for example, this would include the ability of the AI to detect a condition or identify a person without false positives (where a case is identified as having a condition or being a target when they do not fit the criteria). It also includes the ability of the AI to avoid false negatives (where a case is identified as not having a condition or not being a target when they do fit the criteria).
- Algorithmic targeting: the use of AI to find people with a certain profile, often predictively (eg, to identify people likely to be unable to find work or people likely to commit a crime).
- Autonomous machine decision-making: situations in which an AI makes a decision that would previously have been made only by a person, for example, whether a person has a condition or whether a person is eligible for a social security payment.
- Contestability: whether machine decision-making can be effectively challenged. Contestability is to some extent dependent on explainability but is also dependent on policy settings.
- Explainability: whether it is possible to explain how an AI makes a decision. For some forms of AI, especially deep learning algorithms, humans do not explicitly instruct the AI on what basis it should make decisions. This makes explainability potentially more challenging, leading such algorithms to be labeled as *black box* algorithms.
- Deskilling: when tasks previously undertaken by humans are delegated to AI, humans lose their ability to complete those tasks; that is, they deskill in relation to those tasks.
- Fair treatment: AI systems tend to reflect human bias; this relates to the concept of justice, which is complex and multidimensional. Doing justice is unlikely to entail treating everyone identically as different people have different needs and opportunities. In the AVA-AI study, we asked respondents how important it was to "know that the system treats everyone fairly" to capture an intuitive judgment of a system's capacity to deal justly or unjustly with different individuals and populations.
- Personal tailoring: the ability of an AI, by comparing the data of an individual with large, linked data sets, to recommend services or interventions that respond to the particularity of an individual's situation.
- Privacy: freedom from intrusion into personal matters, including the ability to control personal information about oneself.
- Responsibility: a complex and multidimensional concept, which attributes moral or legal duties and moral or legal blame, including for errors or harms.

Instrument Development

When designing the study, there were no existing instruments we could adopt. We used a question from the 2018 survey by Zhang and Dafoe [26] and developed other questions based on a review of the AI ethics literature. Before the study commenced, the instrument underwent multiple rounds of input from investigators and expert colleagues, as well as cognitive testing.

Final Instrument Design

In addition to sociodemographic variables, the survey asked about the use of AI in health care and welfare. Questions were of 2 types. The first type, in the form of *How muchdo you support or oppose*, presented a 5-point scale. Questions of this type asked about the development of AI in general (B01, taken from Zhang and Dafoe [26], running from *strongly support* to *strongly oppose*) and the use of AI in 6 particular health care and welfare AI scenarios for which potential advantages and disadvantages were presented in a balanced way (C03-C05 and D03-D05, for which the 5-point scale ran from *I support this use of AI* to *I oppose this use of AI*; Multimedia Appendix 1). A final question of this type (E01) asked respondents to indicate what they valued more on a 5-point scale: *Quicker, more convenient, more accurate health and social services* or *More human contact and discretion in health and social services.* This trade-off asked respondents to evaluate a bundle of benefits commonly attributed to AI-enabled services against a bundle of benefits commonly attributed to services provided by human professionals.

The second type of question presented a scenario involving AI use and then asked respondents to consider 7 ELSI dimensions or values (eg, *getting an answer quickly* and *getting an accurate answer*) and rate how important each dimension was to them personally on a scale from *extremely important* to *not at all* *important*. There were 4 questions of this type: 2 with health care scenarios (C01-C02) and 2 with welfare scenarios (D01-D02). Module C presented health care questions and module D presented welfare questions; respondents were randomly allocated to receive module C or D first, and the order of presentation of the values was also randomized. Table 1 summarizes the variables presented as well as the concepts each question was designed to assess. Note that the dimensions or values were identical for module C and D questions except that the health care questions had an item about responsibility, including mistakes (reflecting the status quo of medical professional autonomy), whereas the social service questions had an item about personal tailoring (reflecting a promised potential benefit of AI in social services).

The final survey instrument is provided in Multimedia Appendix 1.

Table 1. Summary of the variables collected in the Australian Values and Attitudes on Artificial Intelligence (AI) study.

Type of variable	Question number and variable	Concepts tested
General support or opposition	• B01—how much do you support or oppose the development of AI in general (with multiple examples given)?[a]	• Broad support for or opposition to AI

Importance of different attributes of AI in health care scenarios	• C01—machine reads medical test, diagnoses, and recommends treatment
	• C02—machine triages when you are unwell
		• In relation to:
		  • C01—delegation of clinical decisions to an autonomous machine
		  • C02—automating decisions about need for health care services (time-sensitive)
		• Importance of:
		  • Explanation
		  • Speed
		  • Accuracy
		  • Human contact
		  • Reducing system costs
		  • Fair treatment
		  • Responsibility

Importance of different attributes of AI in welfare scenarios	• D01—machine processes application for unemployment benefits (data sharing required)
	• D02—chatbot advises about carer payments
		• In relation to:
		  • D01—foregoing privacy as a barrier to access services
		  • D02—automation of information services
		• Importance of:
		  • Explanation
		  • Speed
		  • Accuracy
		  • Human contact
		  • Reducing system costs
		  • Fair treatment
		  • Personal tailoring

Support for or opposition to AI in specific health care scenarios	• C03—nonexplainable hospital algorithms • C04—data sharing for quality care • C05—deskilling physicians	• C03—importance of explainable machine recommendations • C04—importance of privacy (balanced against quality of care) • C05—importance of retaining human clinical skills
Support for or opposition to AI in specific welfare scenarios	• D03—targeted compliance checking • D04—nonexplainable job services • D05—automated assignment of parent support with limited contestability	• D03—algorithmic targeting of punitive policy • D04—importance of explainable machine recommendations • D05—importance of contestability (balanced against accuracy)
Speed—human contact	• E01—trade-off between quicker, more convenient, more accurate health care and social services and more human contact and discretion in health care and social services	• E01—speed and convenience and accuracy vs human contact and discretion
Sociodemographic	• Age, gender, concession card type, and employment status; household income, education, household type, language other than English spoken at home, and general health • Centrelink payment, employment field, relevant experience, relevant degree, life satisfaction, and disability	• Descriptive variables collected using standard sociodemographic questions
Geographic	• State or territory, capital city or rest of state, and SEIFA[b] (geographic measure of disadvantage)	• Descriptive variables collected using standard questions about location of residence

Type of variable	Question number and variable	Concepts tested
Lifestyle	- How often they check the internet, how often they post comments or images to social media, how often they post on blogs, forums, or interest groups, early adopter by type, and television viewing by type of viewing	- Variables collected for weighting purposes

[a] Variables in italics were collected from both the Life in Australia and web-based panel samples; all others were collected from the web-based panel alone.

[b] SEIFA: Socio-Economic Indexes for Areas.

Data Collection Processes and Weighting

Data collection occurred between March 16, 2020, and March 29, 2020, with respondents mainly completing the questionnaire on the web.

The AVA-AI study comprises 2 sample components: one obtained from the Life in Australia (LIA) survey [40] with a responding sample size of 2448 and a web-based panel sample with a responding sample size of 2000. Thus, the combined responding sample size was 4448.

The full set of questions was used for the web-based panel sample. For the LIA sample, a subset of sociodemographic variables and all the geographic and lifestyle questions were used. The LIA sample also answered the general support question (B01) and the importance of AI attributes for scenario C01. In Table 1, the variables in italics were collected from both the LIA and web-based panel samples, and all others were collected from the web-based panel alone.

The LIA sample was selected using scientific probability sampling methods, whereas the web-based panel sample was a nonprobability sample. Weights for the LIA sample were calculated using standard methods for a probability sample using generalized regression estimation [41] to adjust for differences in selection probabilities and nonresponse and calibrate to population benchmarks obtained from the population census, current demographic statistics, and the 2017 to 2018 National Health Survey obtained from the Australian Bureau of Statistics. The variables used in the calibration were age by highest education level, country of birth by state, smoking status by state, gender by state, household structure by state, part of state, and state or territory.

A web-based panel allowed us to generate a relatively large sample, enabling a good level of disaggregation into subpopulations, comparisons between groups, and analysis of associations. Such panels can be subject to self-selection biases and coverage issues, reducing the accuracy of population prevalence estimates [42], but may enable the examination of associations and, with adjustments to reduce biases, improve the estimation of population characteristics [43]. The calibration to population benchmarks for major sociodemographic variables may not eliminate these issues. To enhance our adjustment of the web-based panel data in the AVA-AI study, we included 2 substantive questions, a set of behavioral and lifestyle questions, and major sociodemographic variables in both the web-based panel survey and the probability sample–based LIA survey, as indicated in Table 1. This approach was similar to that used in the study by Zhang and Dafoe [26], although our approach for the AVA-AI study went further by adjusting for behavioral and lifestyle variables and 2 substantive variables. The use of behavioral and lifestyle variables in adjusting web surveys, also known as webographic variables, is discussed in the study by Schonlau et al [44], for example.

In the AVA-AI study, questions common to the LIA and web-based panel samples were used to calibrate the web-based panel to the LIA sample, producing weights designed to reduce potential biases owing to the web-based panel sample being nonrandom; the LIA served as a reference survey [35]. The probability of inclusion for the web-based panel respondents was estimated using a propensity score model. This involved combining the LIA and web-based panel samples and fitting a logistic regression model, with the response variable being membership of the web-based panel. In fitting this model, the original LIA weights were used for respondents in that sample, and a weight of 1 was used for the web-based panel respondents. The variables used in the logistic regression were selected using Akaike Information Criterion–based stepwise regression and consisted of age by education, gender, household structure, language spoken at home, self-rated health, early adopter status, and television streaming watching. In a final calibration step, the weights were further adjusted to agree with the population benchmarks for these variables. This approach is described, for example, in the study by Valliant and Dever [45,46] and by Elliot and Valliant [47]. The weighting led to a weighted sample of 1950 for the web-based panel and 2498 for the LIA sample.

Statistical Analysis Methods

Overview

All estimates and analyses were based on a weighted analysis using the largest sample possible. Each respondent had a weight determined by the sample they came from. The weights were scaled so that the sum of the weights for the combined sample was 4448. Two substantive questions (B01 [general support or opposition] and C01 [support or opposition for autonomous machine decision-making in medical testing]) were asked to the combined LIA+web-based panel sample. The remainder of the attitude and value questions was asked only to the web-based panel sample. Any analysis involving questions included in the LIA and web-based panel sample was based on the combined sample and the associated weights. Any analysis involving questions that were only collected from the web-based panel sample was based on the web-based panel sample and the associated weights.

The analyses focused on determining and comparing the distribution of responses to the attitude and value questions. The methods used accounted for the use of weights in calculating estimates and associated 95% CIs and allowed for the testing of statistical significance, assessed when the *P* value of the relevant statistical test was <.05.

Statistical Analysis of Each Question Using Univariate Analyses

All variables concerning attitudes and values had 5 substantive response categories reflecting *support* or *importance.* Univariate analysis calculated the estimated percentage in each response category for each question, with 95% CIs for each estimated percentage. For questions asking for degree of support or opposition, we examined whether there was a majority support and compared across scenarios and between health care and welfare contexts; for questions asking for the importance attached to different attributes or values, we examined whether attributes or values mattered more in some contexts than others.

Weights must be accounted for in the calculation of estimates and in the statistical inference, such as estimates of SEs and the associated CIs obtained from them and *P* values for any statistical tests used. The CIs and *P* values were obtained using *Complex Samples* in SPSS (version 26; IBM Corp), which accounts for the use of weights in producing the estimates. Although the use of weights can reduce bias, there is an associated increase in variances and SEs of the estimates. This is reflected in the design effect, the variance of an estimate accounting for the weights (and complex design if used), compared with the use of simple random sampling and no weighting. The effect is variable specific, but a broad indication can be obtained considering the design effect because of weighting or unequal weighting effect [48,49]. This is 1+*Cw2*, where *Cw* is the coefficient of variation of the weights, which is the SD of the weights divided by their mean. For the combined sample, the design effect because of weighting was 1.83; for the LIA, it was 1.99; and, for the web-based panel, it was 1.61. For any specific estimates or analysis in this study, the SEs estimated from the survey data accounting for the weights were used. The effect on the SE is the square root of the design effect (ie, the design factor [50]) and is the factor by which the CIs are larger than if weights did not have to be used. A design effect of 1.83 implies a design factor of 1.35. In this analysis, the design effects were almost all between 1.50 and 2.00.

For questions using ordinal scales from 1 to 5, we also calculated an overall mean response to each question and the associated 95% CI. These included variables assessing the degree of support (ie, B01, C03-C05, and D03-D05), importance attached to attributes of AI (ie, C01-C02 and D01-D02), and the final question (E01) on trading off machine versus human traits. Mean scores close to the midpoint of the scale (3.00) indicated an overall neutral or balanced response to the question, that is, an equal or symmetric distribution of respondents on the respective scale. For support-or-oppose questions, lower scores indicated support and higher scores indicated opposition; for importance questions, lower scores indicated greater importance and higher scores indicated less importance; for E01, lower scores favored machine traits and higher scores favored human traits. For all questions, we tested the null hypothesis that the mean was 3.00 (ie, a distribution centered at the midpoint of the scale, or a balanced distribution of responses) using a 2-tailed *t* test allowing for weighting.

Statistical Analysis Comparing Responses to Questions Using Bivariate Analyses

To assess differences in the responses to pairs of questions—for example, is the support for the use of AI different when respondents are presented with different scenarios?—we compared the distributions of the responses. This was not to assess whether the responses to the 2 questions were independent, which is unlikely, but whether the percentages in their marginal distributions were the same.

Our goal was to determine what percentage of people changed their response between 2 questions and whether this change was net positive or negative. To examine this issue for any 2 questions, we created a *shift variable* to represent the difference between two variables (variables A and B): (1) if the response to variable A was in a category greater than the response to variable B, the *shift variable* was +1, which corresponded to a more positive attitude toward AI for variable B and, equivalently, a more negative attitude for variable A; (2) if the response to variable B was in a category greater than the response to variable A, the *shift variable* was −1, which corresponded to a more positive attitude toward AI for variable A and, equivalently, a more negative attitude for variable B; and (3) if the responses to variables A and B were identical, the *shift variable* was 0.

We estimated the percentage of respondents where the *shift variable* was 0, indicating no change. For those that changed, we estimated the percentage with a shift variable of −1, corresponding to a more positive attitude for the first variable and a more negative attitude for the second variable, and tested for equal percentages of positive and negative changes. The adjusted Pearson chi-square test in SPSS *Complex Samples* was used, which is a variant of the second-order adjustment proposed by Rao and Scott [51]. These tests allowed us to assess the statistical significance of the differences in responses under different scenarios.

We also tested for equal marginal distributions using the ordinal scores. SPSS uses a paired *t* test using these scores, which is similar to the test for marginal homogeneity described in the study by Agresti [52]. This test was implemented accounting for the weights using *Complex Samples* in SPSS by creating a variable for each person equal to the difference between the scores of the 2 questions and testing that the mean difference was 0. We tested answers to our research questions, that is, to determine whether respondents answered differently when questions tested the same ELSI concept in different settings or when questions tested different ELSI concepts in comparable settings. The estimated mean difference and associated 95% CI and the *P* value for the test that the mean difference was 0 were produced.

Ethical Considerations

This study was approved by the University of Wollongong Social Sciences Human Research Ethics Committee (protocol number 2019/458).

Results

Sample Composition

Table 2 provides a summary of the weighted combined sample and web-based panel sample for the key variables. A full composition of the overall combined sample and the web-based panel, including unweighted and weighted frequencies and proportions for key sociodemographic variables, is provided in Multimedia Appendix 2. The use of weights improved the representation of the combined sample for capital cities, age groups <35 years, men, employed status, nonuniversity as the highest level of education, language other than English spoken at home, those with excellent or very good health, and people who look for information over the internet several times a day. The sample was well spread and had respondents across many different sociodemographic groups.

The web-based panel sample was also well spread across many different sociodemographic groups. The effect of weighting was similar to that in the overall sample, although there was very little effect for age and capital cities. Comparing the weighted percentages between the combined sample and the web-based panel sample, the only appreciable difference is for those employed (2709/4448, 60.9% vs 1061/1950, 54.41%, respectively).

Support for AI in General and in Specific Scenarios

Background

We first discuss questions focused on support for or opposition to AI. The CIs for questions B01 and C01 tended to be narrower as they were based on the combined sample. However, for all questions, estimates of percentages had margins of error (ie, twice the SE) of <3 percentage points, reflecting the relatively large sample size and the reliability of all estimates.

Respondents Expressed General Support for AI

Figure 1 and Table 3 show the level of support for the development of AI in general—an estimated 60.3% in the *strongly support* or *somewhat support* categories.

Although the estimate for the *support* categories was 60.3%, it was only 13.4% for the *opposed* categories and 26.3% for the *neutral* or *don't know* responses. The on-balance support mean score of 2.35 was statistically significant when tested against the midpoint of 3.00 (*P*<.001). The design effects are consistent with the design effect that was due to a weighting of 1.83.

Table 4 shows the percentage that selected a *support* category after *don't know* responses were excluded and also after don't know and neutral responses were excluded. This allowed for direct comparison of support and opposition and examination of whether there was majority support. We tested whether the resulting percentages were >50% using the adjusted Pearson F test for equal percentages in SPSS, where an estimate of 50% would indicate equal levels of support and opposition. Table 4 clearly demonstrates majority support among those taking a positive or negative position—63.1% when *don't know* responses were excluded and 81.8% when neutral and don't know responses were excluded, with *P* values indicating that both estimates were statistically significantly different from 50%.

For each question in the remaining analyses, the very small proportion of refused and *don't know* responses were not included and were no more than 8 cases for any of these questions.

Figure 1. Responses to question B01: How much do you support or oppose the development of artificial intelligence?

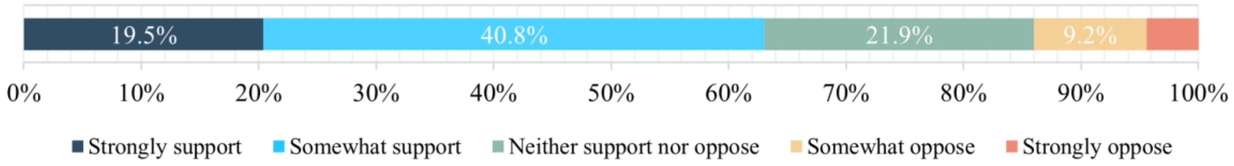

Table 3. Estimated percentages, mean, and 95% CIs for responses to question B01: How much do you support or oppose the development of artificial intelligence?[a,b]

	Estimated percentage (95% CI)	Design effect
Strongly support	19.5 (17.9-21.1)	1.87
Somewhat support	40.8 (38.9-42.8)	1.84
Neither support nor oppose	21.9 (20.3-23.5)	1.74
Somewhat oppose	9.2 (8.1-10.4)	1.87
Strongly oppose	4.2 (3.5-5.1)	1.76
I don't know	4.4 (3.6-5.3)	1.96

[a] Percentages and CIs adjusted for weighting.

[b] The mean score was 2.35 (95% CI 2.31-2.39) with a design effect of 1.83.

[b] *P* value for adjusted Pearson *F* test for equal proportions in *support* and *oppose* categories.

Respondents Showed Less Support for Specific AI Use Scenarios and Supported Some Scenarios More Than Others

Figure 2 shows the estimates of the level of support for AI in specific health care and welfare scenarios, with scenarios presented in increasing order of level of support. Multimedia Appendix 3 shows the related estimates and 95% CIs. Table 5 presents estimates of support in categories 1 and 2 combined for specific scenarios, associated 95% CIs, and *P* values for the test against 50%. For all these specific scenarios, less support was expressed than in the question about AI in general (Figure 1).

Figure 2 shows that the strongest support was expressed for a learning health care system making diagnostic and treatment recommendations, where *over time, patients get different care depending on whether they do, or do not, share their health record with the AI system* (ie, people receive health benefits only at the expense of health data privacy). Overall, the support for this item was 42.3% (Table 5). Regarding social services, the highest level of support was for targeted compliance checking for welfare debt (38.9%). In this scenario, a government department used an algorithm to check groups deemed *high-risk* for welfare overpayment twice as often, which found more welfare debts, saved money, and reduced the number of checks on other people but meant people in high-risk groups were checked more even if they had not done anything wrong. The next highest support was for automated systems to identify parents who required assistance to return to work with limited contestability (34.9%) and employment support recommendation systems that were nonexplainable to employment service workers (31.2%). The least support overall was expressed for AI systems that led to physician deskilling (27% support and 48.3% opposition) and those that made diagnostic and treatment recommendations but were not explainable to physicians (29.1% support and 41.6% opposition).

For the estimates in Table 5, the neutral middle category with a score of 3 was included in the denominator. To directly compare the level of support and opposition and assess whether there was majority support or opposition, we removed the neutral category and recalculated the estimates and tests (Table 6). With the neutral score included, the level of support never reached a majority and ranged from 27% (deskilling physicians) to 42.3% (data sharing for quality care). Once the middle category was excluded, Table 6 shows that, for the nonneutral respondents, there were majorities supporting data sharing and targeted compliance checking; a balance on automated parent support without contestability; and a majority opposed to nonexplainable hospital algorithms, nonexplainable job services, and especially deskilling physicians.

Table 7 uses mean scores to indicate on-balance opposition or support—a score >3.00 indicates on-balance opposition, and a score <3.00 indicates on-balance support, along with *P* values for testing that the mean score was 3 (neither supportive nor opposed on balance). The means of general support for the development of AI were included for comparison. Marginal on-balance support was demonstrated for data sharing for quality care only (this should not be overinterpreted as the mean score was so close to neutral). For targeted compliance checking and noncontestable automated parent support, views were balanced. For both explainability scenarios and clinical deskilling, respondents expressed on-balance opposition at a statistically significant level.

Figure 2. Responses to questions C03 to C05 and D03 to D05: support for or opposition to specific scenarios. AI: artificial intelligence.

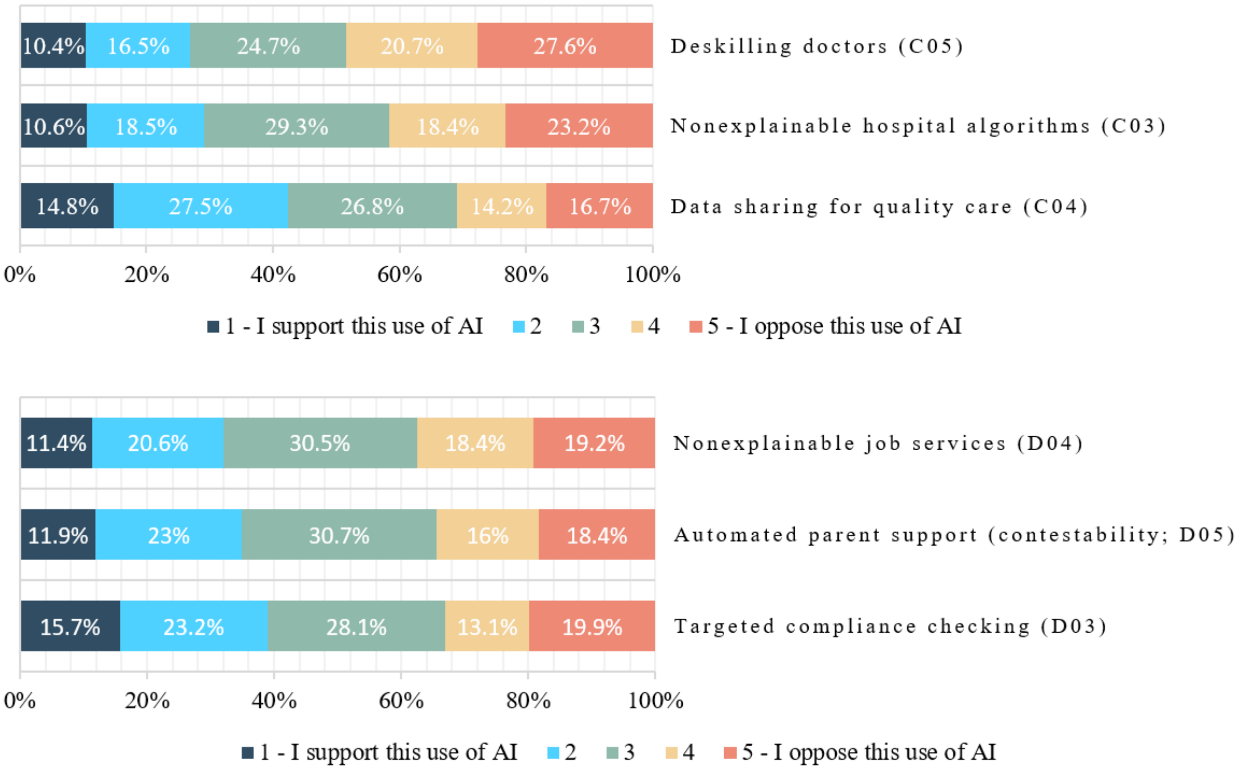

Table 5. Percentage of those supporting artificial intelligence in specific scenarios, 95% CIs, and *P* values for testing against 50%[a].

Domain and scenario	Estimated percentage in "support" or "strongly support" categories (95% CI)	*P* value[b]	Design effect
Health			
Data sharing for quality care (C04[c])	42.3 (39.6-45.1)	<.001	1.62
Nonexplainable hospital algorithms (C03)	29.1 (26.7-31.6)	<.001	1.57
Deskilling physicians (C05)	27 (24.6-29.5)	<.001	1.57
Welfare			
Targeted compliance checking (D03)	38.9 (36.2-41.7)	<.001	1.61
Automated parent support (contestability; D05)	34.9 (32.3-37.6)	<.001	1.59
Nonexplainable job services (D04)	31.2 (28.7-33.8)	<.001	1.56

Table 6. Proportion of respondents supporting artificial intelligence in specific scenarios, associated 95% CIs, and *P* values for testing against 50%; neutral responses deleted[a].

Domain and scenario	Estimated percentage in "support" or "strongly support" categories	*P* value[b]	Design effect
Health			
Data sharing for quality care (C04[c])	57.8 (54.5-61.1)	<.001	1.63
Nonexplainable hospital algorithms (C03)	41.1 (38-44.4)	<.001	1.58
Deskilling physicians (C05)	35.8 (32.8-38.9)	<.001	1.58
Welfare			
Targeted compliance checking (D03)	54.1 (50.9-57.4)	.01	1.58
Automated parent support (contestability; D05)	50.4 (47-53.7)	.82	1.62
Nonexplainable job services (D04)	44.1 (40.8-47.4)	<.001	1.59

[a] Percentages and CIs adjusted for weighting.

[b] *P* value for adjusted Pearson *F* test for 50% proportions in categories 1 and 2 combined.

[c] Code in parentheses (eg, C04) indicates question number in instrument.

Table 7. Analysis of mean support for use of artificial intelligence (AI) in specific scenarios, 95% CIs, and *P* values for testing against a mean of 3. A score <3 represents support, and a score of >3 represents opposition[a].

Domain and scenario	Estimated mean (95% CI)	*P* value[b]	Design effect
General—support for the development of AI (B01[c])	2.35 (2.31-2.39)	<.001	1.83
Health			
Data sharing for quality care (C04)	2.90 (2.83-2.98)	.01	1.65
Nonexplainable hospital algorithms (C03)	3.25 (3.18-3.32)	<.001	1.57
Deskilling physicians (C05)	3.39 (3.31-3.46)	<.001	1.62
Welfare			
Targeted compliance checking (D03)	2.98 (2.91-3.06)	.64	1.62
Automated parent support (contestability; D05)	3.06 (2.99-3.13)	.10	1.60
Nonexplainable job services (D04)	3.19 (3.12-3.26)	<.001	1.59

[a] Means and CIs adjusted for weighting.

[b] *P* value for *t* test that the mean score was 3.0 using complex samples.

[c] Code in parentheses (eg, B01) indicates question number in instrument.

Statistical Significance of Differences Between Support in General and in Specific Scenarios

To further investigate these results, we statistically tested changes in responses between the general question (B01) and the more specific scenario questions (C03-C05 and D03-D05). Table 8 shows the percentage of those who changed between question B01 and each of the more specific scenarios and, of those who changed, what percentage changed to a more negative attitude. The change was tested against 50%, which corresponded to an equal change in a positive and negative direction.

Table 8 shows that the estimated percentage that answered differently between the general and the more specific questions was between 60.2% and 70.6%. Of those who changed, between 70.8% and 83% changed to a more negative response, and all of these changes were statistically significant. There was also a slight increase of 3% to 9% in neutral responses across specific scenarios compared with the general question.

Table 8. Estimated percentage of those who changed their response between the general question on the development of artificial intelligence and the specific scenarios and, of those who changed, the percentage that had a more negative attitude in the specific scenarios, with 95% CIs and the *P* value for the test of equal change in each direction[a].

Domain and scenario	Percentage of those who changed	Percentage of those who changed becoming more negative (95% CI)	*P* value[b]	Design effect
Health				
Data sharing for quality care (C04[c])	60.2	70.8 (67.3-74)	<.001	1.59
Nonexplainable hospital algorithms (C03)	65.6	81.4 (78.6-83.9)	<.001	1.53
Deskilling physicians (C05)	70.6	83 (80.3-85.3)	<.001	1.56
Welfare				
Targeted compliance checking (D03)	63.8	71.9 (68.5-75)	<.001	1.65
Automated parent support (contestability; D05)	65	76.1 (73-78.9)	<.001	1.56
Nonexplainable job services (D04)	66.6	80.3 (77.5-82.9)	<.001	1.50

[a] Percentages and CIs adjusted for weighting.

[b] Adjusted Pearson *F* test for equal proportions changing in each direction.

[c] Code in parentheses (eg, C04) indicates question number in instrument.

Statistical Significance of Differences in Support Between Scenarios

To assess the statistical significance of differences in support for different detailed scenarios, Table 9 shows estimates of the percentage of those who changed in response to pairs of questions and, of those who changed, the percentage expressing a more negative attitude on the second question and the associated test against 50%. Although most comparisons were within the health care or welfare domain, we asked about explainability in both the health care and welfare contexts, allowing us to make direct comparisons between this pair of questions.

As noted, the health care and welfare question blocks were randomized per participant, and the questions were randomized within blocks. As shown in Table 9, respondents did make different judgments in specific scenarios—there were statistically significant changes within all pairs except between the questions regarding explainability in health care and in welfare. Despite 45.7% of people changing their responses between these 2 questions, people changed their minds in both directions in approximately equal proportions. This suggests divided views on the importance of explainability in different scenarios. The differences between all health care scenarios were statistically significant. Answers on nonexplainability and deskilling were significantly different, and most were more negative than those on data sharing; answers on deskilling were significantly different, and most were more negative than those on nonexplainability. In addition, most changed their responses between these questions in the same direction. A similar pattern was seen in the welfare scenarios—a significant proportion of respondents changed their response among targeted compliance checking, automated parent support without contestability, and nonexplainable job services, in all cases to a more negative response. Again, most tended to change their responses among these questions in the same direction.

Comparisons of the general support and support in specific scenarios and between the scenarios were also analyzed using differences in the means, with similar conclusions.

Table 9. Estimated proportion of those who changed their response between 2 scenarios and, of those who changed, the percentage that expressed a more negative attitude in the second question, with 95% CIs and the *P* value for the test of equal change in each direction[a].

Domain and scenarios compared	Percentage of those who changed	Percentage of those who changed becoming more negative (95% CI)	*P* value[b]	Design effect
Health				
C03[c] (explainability) vs C04[d] (data sharing)	38.1	26.7 (22.7-31.1)	<.001	1.77
C03 (explainability) vs C05[e] (deskilling)	43.6	59.2 (55-63.3)	<.001	1.62
C04 (data sharing) vs C05 (deskilling)	45.7	77.9 (74.2-81.2)	<.001	1.69
Welfare				
D03[f] (compliance checking) vs D04[g] (explainability)	41.7	64.2 (60-68.2)	<.001	1.60
D03 (compliance checking) vs D05[h] (contestability)	45.1	55.6 (51.4-59.6)	.008	1.59
D04 (explainability) vs D05 (contestability)	42.3	41.7 (37.6-45.9)	<.001	1.59
Explainability in health vs in welfare—C03 vs D04	45.7	46.1 (42-50.2)	.06	1.64

Which Attributes of Health Care and Social Service AIs Were Most Important?

We provided 2 health care scenarios (C01 [machine diagnosis and treatment recommendations] and C02 [machine triage]) and 2 social service scenarios (D01 [automation of unemployment benefit decision-making] and D02 [chatbot advice about carer payments]). We asked respondents to rate the importance of different attributes of the AI system in each one, where the attributes reflected a key ethical, legal, or social dimension of the AI or its use. For health care scenarios, these attributes included responsibility for decision-making as this is central to medicolegal frameworks and professional autonomy. For welfare scenarios, they included personal tailoring as this is a key promise of automation and machine decision-making in welfare contexts.

Figure 3 shows these responses to the health care and welfare scenarios to allow comparisons to be made between the distributions of the responses to any 2 questions assessing the same ethical or social dimension of AI. Multimedia Appendix 4 provides the detailed estimates of the proportions and the associated estimates of 95% CIs on estimated proportions for Figure 3.

Table 10 provides a summary of the importance that respondents ascribed to different attributes using mean scores, 95% CIs, and design effects. The response categories were scored from 1 for *extremely important* to 5 for *not at all important*; thus, lower scores indicate more importance. All means were <3, the midpoint of the scale; t tests against a mean of 3 were statistically significant with *P*<.001, indicating that more of the distribution of responses was in the extremely or very important categories. The attributes in Table 10 are in ascending order of means, that is, from most to least important (where the most important value is presented first).

As shown in Figure 3 and Table 10, there were distinctions between attributes. In all 4 scenarios, accuracy was rated as most important on average (1.49-1.61), and the ability of an AI system to reduce system costs was rated as least important (2.30-2.60), especially in health care. After accuracy, fairness was the second most important attribute in both social service scenarios (1.80 and 1.81) but, in the health care scenarios, it placed lower relative to other attributes (1.87 and 1.94). After accuracy, responsibility and human contact were the next most important in both health care scenarios. Speed was slightly more important in a health care triage scenario (1.90) than in a medical testing scenario (2.08).

Table 11 compares the mean responses to the attribute questions for the 2 health care scenarios (C01 vs C02) and the 2 welfare scenarios (D01 vs D02) to assess whether there were differences in importance in specific scenarios. In these comparisons, a negative estimate of the difference implies more importance for the first listed question, and a positive difference implies more importance for the second listed question. Table 12 provides further analysis, including statistical significance testing, of shifts in responses to the questions. Taken together, these tables show that, among the health care scenarios, the only statistically significant differences were in relation to speed (more important in triage) and reducing costs (more important in decision support). In the social service scenarios, more statistically significant differences were found, with explanation and cost reduction being more important in automating unemployment benefits and human contact, speed, and personal tailoring being more important in receiving automated carer support advice.

Figure 3. Responses to questions C01 to C02 versus D01 to D02: summary and comparison of health (C) and welfare (D) scenarios. Numerical estimates <10% are not given.

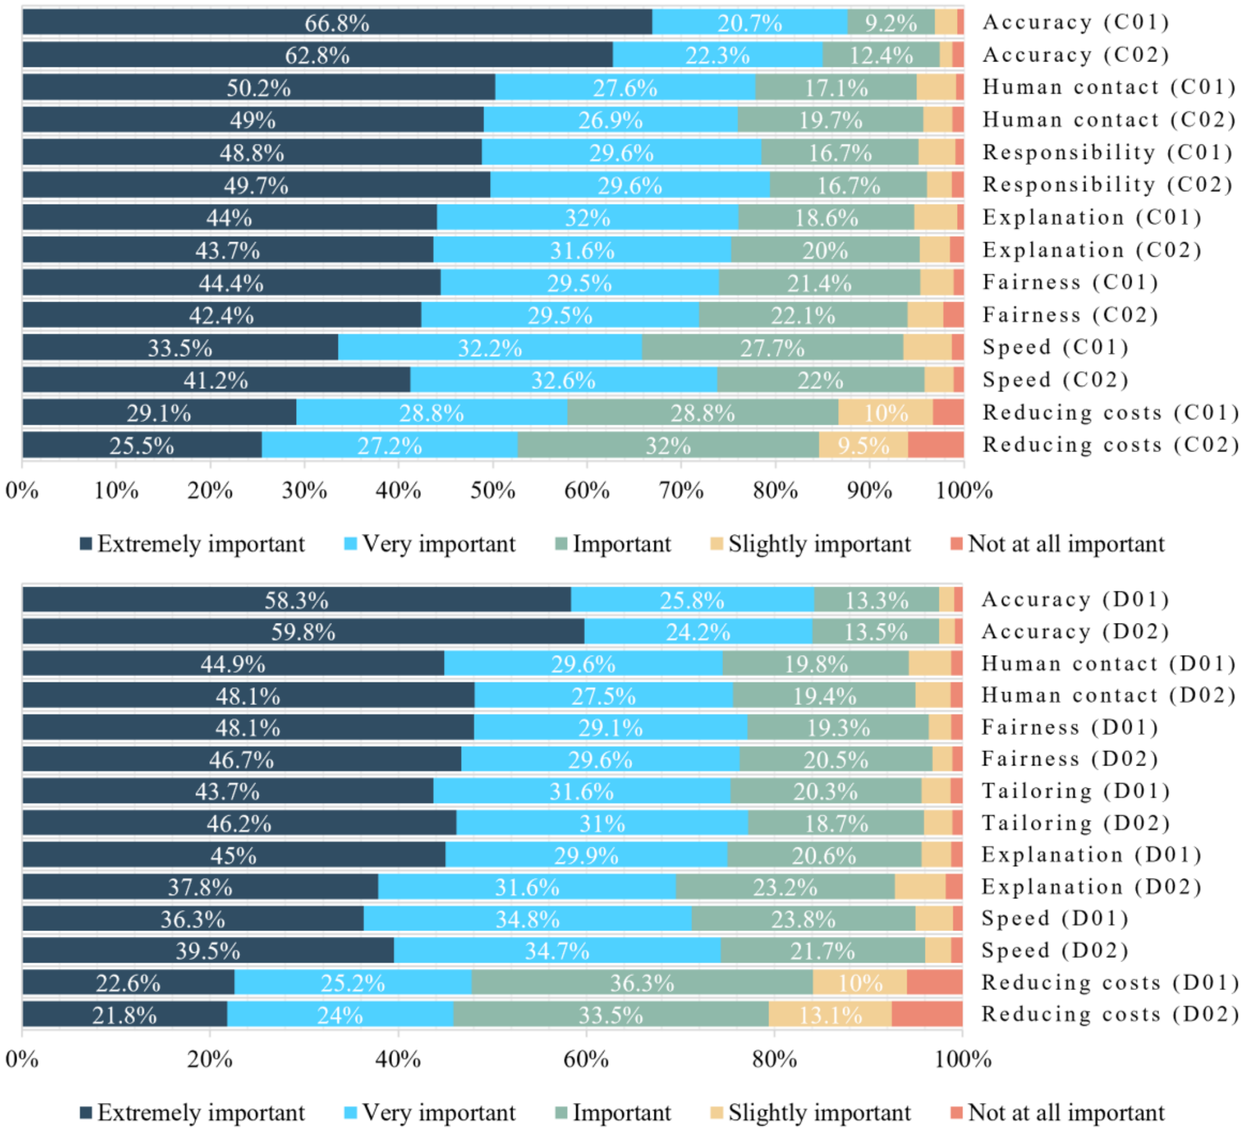

Table 10. Means, 95% CIs, and design effects for importance of values.

	Estimate of the mean[a] (95% CI)	Design effect
C01[b] —machine reads medical test, diagnoses, and recommends treatment		
Accuracy	1.49 (1.46-1.53)	1.98
Human contact	1.78 (1.74-1.81)	1.95
Responsibility	1.78 (1.75-1.82)	1.98
Explanation	1.86 (1.82-1.90)	1.96

Final Bundled Attribute Trade-off of AI and Human Attributes

Figure 4 shows the estimated percentages for the final bundled trade-off question (E01), where respondents were asked to weigh speed, convenience, and accuracy against human contact and discretion. Table 13 provides the estimated percentages, mean scores, and 95% CIs. These results show that human attributes were generally valued more, as indicated by a mean score >3. The estimated proportion of those who preferred the machine attributes (categories 1 or 2) was 20.3%, whereas, for human attributes (categories 4 or 5), it was 52%; 27.7% selected a middle position.

Figure 4. Responses to question E01: speed, accuracy, and convenience versus human contact and discretion.

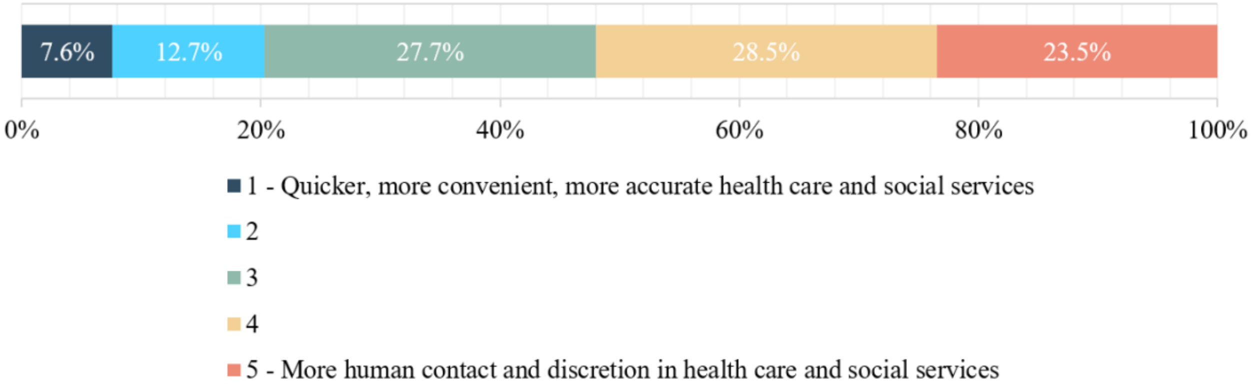

Table 13. Speed, accuracy, and convenience versus human contact and discretion; estimated percentages; and 95% CIs for responses to question E01[a].

	Estimate (95% CI)
1: speed, convenience, and accuracy	7.6 (6.2-9.1)
2	12.7 (11-14.7)
3	27.7 (25.3-30.3)
4	28.5 (26.1-31.1)
5: human contact and discretion	23.5 (21.2-26)
Mean score[b]	3.38 (3.41-3.54)

[b] *P*<.001 for testing that the mean score was 3; design effect=1.602.

Discussion

Principal Findings

Overview

The AVA-AI study has created one of the first large, robust data sets reflecting public views on the potential use of AI in health care and social services, with particular attention to the ELSI of those technologies. Future studies will provide a greater breakdown of the variation in responses among different population subgroups. This analysis focused on answering 3 key questions: how judgments in general compare with judgments in particular, how judgments about use in health care compare with judgments about use in social services, and whether judgments differ when ELSI differ.

General Versus Particular Judgments About AI

Our first general question about support for or opposition to AI was taken from the 2018 survey of the American public by Zhang and Dafoe [26], which included 2000 respondents and used a similar weighting methodology; the Monash Data Futures survey [27] also included this question and surveyed 2019 respondents. Owing to our methodology, we asked this question to 4448 respondents. Table 14 compares these results—as the Monash survey reports combined *all support* and *all oppose* categories only, we have done the same. Both the AVA-AI study and the Monash survey suggest more positive general views in Australia than in the United States, although the results of the AVA-AI study are less positive than those of the Monash survey. Speculative reasons for this difference could include more prominent public discourse regarding harms from AI deployment in the US context (eg, in policing, justice, warfare, and the retail sector) or, more tentatively, that, in the 2 years between the surveys (mid-2018 for the study by Zhang and Dafoe [26] vs March 2020-April 2020 for both the AVA-AI study and the Monash survey), Australians may have had additional positive experiences of the everyday AI described in that question (eg, language translation, spam filters, and streaming content suggestions).

As a minority of AVA-AI study respondents began the survey with negative general views on AI and >60% expressed support, any negative judgments expressed seem likely to be a response to the details of the scenarios presented rather than reflect prejudice against or fear of AI in general. When asked about specific scenarios for AI use, respondents were consistently more negative—the reduction in support between the general question and all 6 specific scenarios was statistically significant, and support expressed in the specific scenarios dropped between 17 and 33 percentage points. The simple opening *support-or-oppose* question presented familiar, helpful everyday examples of AI in use and did not demonstrate any downsides of AI. In contrast, the detailed scenario questions were designed for balance. Each question emphasized that AI could both improve services (eg, make them quicker, more convenient, and more accurate) and have downsides (eg, reduced explainability, contestability, and privacy; unfair burdens on minorities; or human deskilling). On the basis of our findings, we hypothesize that members of the general public may remain broadly unaware of the potential downsides of AI in use and that some of these downsides (eg, deskilling) matter more to them than others (eg, privacy). We did not test the level of awareness of ELSI problems with AI—this is a potential direction for future research. Participants' more negative judgments in the case-specific questions also empirically reinforce what has already been argued in the literature: that the ELSI of AI applications need to be considered in the context of detailed cases.

Table 14. Comparison of findings from the studies by Zhang and Dafoe [26] and the Monash Data Futures Institute [27] and from the Australian Values and Attitudes on Artificial Intelligence (AVA-AI): How much do you support or oppose the development of artificial intelligence?

	Zhang and Dafoe [26] (2018), weighted %	Monash Data Futures Institute [27] (2020), weighted % by age only	AVA-AI (2020), weighted %
Strongly or somewhat support	40.94	62.4	60.3
Neither support nor oppose	27.84	23	21.9
Strongly or somewhat oppose	21.69	10.5	13.4
I don't know	9.54	4.1	4.4

Judgments About Health Care Versus Judgments About Social Services

Respondents had slightly stronger, more diverse, and more negative views on using AI in health care as opposed to in social services. This may be because they themselves have more direct experience of using health care or consider health care more relevant to them; alternatively, respondents may consider health care to be a higher-stakes service for which they are less tolerant of social or ethical wrongs or harms. Again, respondents in the AVA-AI study were less strongly supportive than respondents in the Monash survey, expressing 27% to 43% support for health care scenarios and 31% to 39% support for social service scenarios. In the Monash survey, respondents were asked to rate their support or opposition to *the application of artificial intelligence to social, humanitarian and environmental challenges*. The areas that received the most support—>75% of respondents—were *health* and *medicine*, whereas the areas that received the least support (although still >60%) included *equality and inclusion* and *public and social sector management*.

The differing responses to the 2 surveys may arise from the framing of the questions. The Monash questions were framed optimistically and presented no downsides; the AVA-AI questions presented both benefits and downsides or burdens. In health care, we held effectiveness and health benefits against requirements to share data, nonexplainability, and clinical deskilling. In social services, we held the accuracy and consistency of predictions and decisions against the potential for overtargeting, poor contestability, and nonexplainability. The differences in responses between the 2 surveys may show that the ethical and social risks of AI matter to people and will make a difference in their evaluations.

Do Judgments Differ When ELSI Differ?

The respondents clearly made judgments about the ELSI of AI. Although all ELSI were considered important, this was by degree. Respondents made quite finely graded judgments that intuitively aligned with the characteristics of the scenarios, suggesting both that they took the questions seriously and that different attributes will be differently important in different cases. For example, speed was more important in triage, where time is critical, than in diagnosis. Explanation was more important in automating unemployment benefits than in an information chatbot, which would be consistent with the view that people deserve to know why they do or do not receive payments. Human contact, personal tailoring, and speed were more important for the chatbot than for the benefits system, possibly reflecting that chatbot interactions are short and information-heavy and that people want a human to talk to if the automated system fails.

Two things were consistent: accuracy was always the most highly valued, and reducing costs was always the least highly valued across health care and social services. The lack of any significant difference in the importance of accuracy across scenarios suggests that this is an entry-level requirement for the use of AI (although defining *accuracy* in different contexts is not straightforward). The lower importance given to cost reduction may reflect a general rejection of instrumental decision-making in policy and of cost-based arguments in public services. Contextual factors include Australia's publicly funded health care system being *popular and entrenched* [53] and that, despite holding negative views on welfare recipients, the Australian public remains similarly supportive of the welfare system as a whole [54].

Fairness was more important in social services than in health care. This may reflect the centrality of the concept of procedural fairness—that is, the fairness of the decision-making process—in social service administration, particularly within Australia's bureaucratic and rule-bound welfare system [55]. It may also reflect heightened concern for issues of fairness in light of the public controversy surrounding the robodebt program, which centered on the legality, accuracy, and fairness of the program's debt calculations [23]. Perhaps the most deliverable promise of AI is increased speed, but this was not highly valued by respondents in any of the scenarios presented.

Knowing who is responsible for decisions, especially any mistakes made, was consistently important in health care, suggesting that the regulatory and ethical governance challenges in health care AI will matter to the public. Human contact was also important in health care. Prominent health care AI advocates have suggested that the core benefit of health care AI is its ability to release clinicians from mundane duties, freeing them to engage more deeply in care work [56]. However, the digitization of health care in some contexts has had the opposite effect, overburdening clinicians with data management and system requirements that alienate them from patient care [57]. This will be a key challenge to manage if health care AI is to deliver on its promises. Relatedly, respondents rejected medical deskilling most strongly among our 3 health care scenarios. This resonates with empirical research suggesting that people strongly value the preservation of human oversight for AI decision-making but also suggests the need for more work on what kinds of deskilling matter most as deskilling is highly likely to occur as automation increases. As in other research, participants were weakly supportive of sharing their health data with a learning health system if it delivered better quality care [58], although qualitative and deliberative research suggests that this support is likely to be conditional [59]. Respondents were also weakly supportive of algorithmic targeting of welfare compliance checking to high-risk groups if this saved money and reduced the number of checks on other people, which may reflect an on-balance judgment about proportionality or may simply reflect the aforementioned negative views on welfare recipients.

We asked about explainability in both health care and welfare scenarios and contestability in welfare scenarios. Respondents expressed an on-balance opposition to both health care and welfare AIs that were not explainable to relevant professionals. However, different respondents valued explainability differently in health care and welfare scenarios, suggesting that there may be some divergence in people's views on the domains in which explanation is more important. There was also an on-balance opposition to noncontestability in welfare scenarios, which reinforces support for processes of review and appeal when welfare decision-making is automated.

When asked to make an on-balance judgment about the *bundle* of attributes most commonly associated with machines versus with humans, respondents strongly preferred human attributes. Although they considered attributes such as accuracy to be important if an AI system was to be implemented, they still highly valued human support and connection and were not prepared to give them up in exchange for accuracy (despite the accuracy of AI being highly valued in itself). This suggests the importance of pursuing an augmentation rather than a replacement role for AI in both health care and social services. For all of these findings, further qualitative research is needed to better understand the reasons underpinning people's judgments.

Limitations

To the best of the authors' knowledge, this study is one of the largest and most robust surveys of public attitudes toward health care and welfare AI to date. The methodological approach taken allowed for the collection of detailed information on attitudes for a substantial sample using a relatively low-cost web-based panel while compensating for the potential biases in the creation of such a panel. Although the results suggest that respondents were able to engage with the details of the questions, the relatively low level of knowledge of AI in the community and the speculative nature of the questions mean that people's responses to a direct experience of AI may differ from their responses in this survey. A strength of our design was the use of questions that were deliberately structured to present both the potential benefits and the potential burdens or harms of AI while attempting to maintain neutral sentiment and avoid normative valence in the language used. The survey was conducted before the onset of the COVID-19 pandemic, which initiated the rapid digitization of many health care and social services; it is possible that responses would be different if the survey were repeated today.

Conclusions

Australians support the idea of AI in a general sense, but their support diminishes when considering the details of particular scenarios and the potential harms or burdens that may accompany any promised benefits. Respondents consistently rated the accuracy of performance as the most important attribute in an AI system, but only 1 in 5 valued the speed, accuracy, and convenience of AI systems more than continued human contact and discretion in service provision. Overall, this study suggests that the ethical and social dimensions of AI systems matter to Australians and that Australians want AI systems to augment rather than replace humans in the provision of both health care and social services and to reflect human values. Meaningful engagement and participation of ethicists, social scientists, and the public can highlight what harms and wrongs are most important to avoid in all stages of the development and implementation of AI, including in sensitive and value-laden domains such as health care and social services.

Acknowledgments

This research was funded by the University of Wollongong Global Challenges Program. The authors acknowledge Andrew Ward at the Social Research Centre for weighting the data and Kathleen Prokopovich, who assisted with project management and cognitive testing.

Abstract

Background: Clinical practice guidelines recommend antiplatelet and statin therapies as well as blood pressure control and tobacco cessation for secondary prevention in patients with established atherosclerotic cardiovascular diseases (ASCVDs). However, these strategies for risk modification are underused, especially in rural communities. Moreover, resources to support the delivery of preventive care to rural patients are fewer than those for their urban counterparts. Transformative interventions for the delivery of tailored preventive cardiovascular care to rural patients are needed.

Objective: A multidisciplinary team developed a rural-specific, team-based model of care intervention assisted by clinical decision support (CDS) technology using participatory design in a sociotechnical conceptual framework. The model of care intervention included redesigned workflows and a novel CDS technology for the coordination and delivery of guideline recommendations by primary care teams in a rural clinic.

Methods: The design of the model of care intervention comprised 3 phases: problem identification, experimentation, and testing. Input from team members (n=35) required 150 hours, including observations of clinical encounters, provider workshops, and interviews with patients and health care professionals. The intervention was prototyped, iteratively refined, and tested with user feedback. In a 3-month pilot trial, 369 patients with ASCVDs were randomized into the control or intervention arm.

Results: New workflows and a novel CDS tool were created to identify patients with ASCVDs who had gaps in preventive care and assign the right care team member for delivery of tailored recommendations. During the pilot, the intervention prototype was iteratively refined and tested. The pilot demonstrated feasibility for successful implementation of the sociotechnical intervention as the proportion of patients who had encounters with advanced practice providers (nurse practitioners and physician assistants), pharmacists, or tobacco cessation coaches for the delivery of guideline recommendations in the intervention arm was greater than that in the control arm.

Conclusions: Participatory design and a sociotechnical conceptual framework enabled the development of a rural-specific, team-based model of care intervention assisted by CDS technology for the transformation of preventive health care delivery for ASCVDs.

Introduction

Background

Atherosclerotic cardiovascular diseases (ASCVDs) are the leading cause of morbidity and mortality in the United States and exemplify the national urban-rural health disparity [1,2]. Rural populations, which comprise 20% of the US population, have a 40% higher absolute prevalence of ASCVDs than urban dwellers [2]. According to the American Heart Association (AHA), rural residents also have higher rates of uncontrolled cardiovascular risk factors than their urban counterparts [2]. These risk factors include tobacco use, hypertension, and high cholesterol [3-6]. For patients with established ASCVDs, adherence to risk modification strategies prevents adverse events, improves survival, reduces the need for revascularization procedures, and enhances life quality [7]. However, strategies for risk modification are underused by patients with ASCVDs, especially in rural communities [2,8].

Clinical practice guidelines from the AHA and the American College of Cardiology for patients with ASCVDs recommend risk modification strategies, including antiplatelet and statin therapies, blood pressure control, and cessation of the use of tobacco products for secondary prevention in patients with established ASCVDs [7,9-11]. These recommendations are collectively referred to as cardiovascular guideline recommendations *(V4)* and are also endorsed by the “Million Hearts” initiative from the Centers for Disease Control and Prevention [12]. The *V4* recommendations have been designated as Class I, which indicates that the supporting data are strong and treatment is useful and effective and should be administered to most patients under most circumstances [9,13]. The level of evidence that supports these guideline-endorsed recommendations is also considered to be of the highest quality (level of evidence designation “A”) as it is derived from multiple randomized controlled trials [9,14,15].

Objectives

Multiple health care system factors affect the appropriate delivery of cardiovascular risk modification strategies to rural residents [2]. One factor is the inadequate number of physician providers in rural communities, as documented by the World Health Organization, the AHA, and the American Stroke Association [2,16]. A presidential advisory document from the AHA and the American Stroke Association has suggested that new and sustainable rural-specific and team-based care models assisted by technology may be a solution to improve the delivery of care in rural communities [2]. The question of this study was what are the characteristics of a rural-specific, team-based model for the delivery of care assisted by technology that is feasible in “real-world” rural clinics? The study goal was to develop and evaluate the feasibility of a new team-based model for rural practices with the following 2 components: a care model (the socio component) and a technological component (the clinical decision support [CDS] system).

It has been proposed that team-based care involves collaboration between physicians and nonphysician health professionals for the delivery of care instead of the traditional model in which care is delivered by physicians only [17]. A previous study showed that pharmacists working in collaboration with other health professionals in a team-based model improved cardiovascular health [18]. A second study demonstrated that a team-based delivery model using both physicians and advanced practice providers delivered outpatient cardiovascular care of a similar quality compared with a physician-only model [17,19].

For the sustainable adoption of new models for care delivery, it is fundamental that intended users are involved in the design process to ensure integration within redesigned user workflows [20,21]. Previous studies have demonstrated that well-executed participatory design processes support the implementation of health interventions [22-29]. According to Carrol and Rosson [30], participatory design advocates that users be included in the design process, and their input will increase the likelihood of successful design. According to Clemensen et al [31], the main feature of this design approach is the participation of users who work with researchers to produce new technology systems that can be understood and managed in practice.

Previously, in underserved rural settings, participatory design has informed strategies for the development of scalable systems such as mobile technology to disseminate health information for reproductive and child health services [32] and electronic, tablet-based community assessment tools for food and physical activity assessment [33]. When conducted under the sociotechnical theory framework, participatory design promotes the adoption of health care IT systems, including CDS [21,34]. The sociotechnical systems theory encourages the joint design of both the social and technical elements of a system [35]. A purely technocentric approach to system design may be unable to address the complex relationships between human and social factors and technology within the organizational context [36]. Therefore, in this study, participatory design under the sociotechnical system theory framework was used to design a new rural-specific and team-based care model for the coordination and delivery of secondary prevention to patients with ASCVDs assisted by CDS technology.

Methods

Setting and Context

The Office of Management and Budget defines rural counties as those with an urban core of ≥10,000 to <50,000 people [2]. By this definition, Austin, an urban core of 25,000 residents located in Mower County, Minnesota (MN), was identified as the site for the development of the rural-based model of care. Austin is the only urban core area in Mower County. The outpatient primary care clinic located in Austin where this study was conducted is part of the Mayo Clinic Health System (MCHS). The MCHS is a network of community-based health care professionals in primary care clinics located in >60 communities in MN, Iowa, and Wisconsin. Within this care network, patients receive primary care in their own communities. These clinics use the Mayo electronic health record (EHR) with digital medical data stored in a common centralized data warehouse that enables the deployment of CDS populated by EHR data for use in the rural clinics of the MCHS. Austin is located within driving distance (42 miles) of Rochester, MN.

The research team drove to Austin or connected remotely with Austin providers and patients during this study. The design, IT, and clinical informatics teams were from Rochester, whereas the rural primary care teams that participated in the study worked in the MCHS Austin. Primary care providers in the primary care teams included physicians and advanced practice providers such as nurse practitioners (NPs) and physician assistants. Primary care nursing supported the day-to-day work of primary care providers within a team and included registered nurses (RNs) and licensed practical nurses (LPNs). The expanded primary care team supported multiple primary care teams and included pharmacists, tobacco cessation coaches, and other teams of nurses such as care coordinators and complex disease coordinators. Importantly, all teams collaborated in the design of a rural-specific and team-based model for the delivery of care from June 2019 to December 2020.

Ethics Approval

This project was approved by the Mayo Clinic Institutional Review Board (approval numbers 19-011925 and 20-001192).

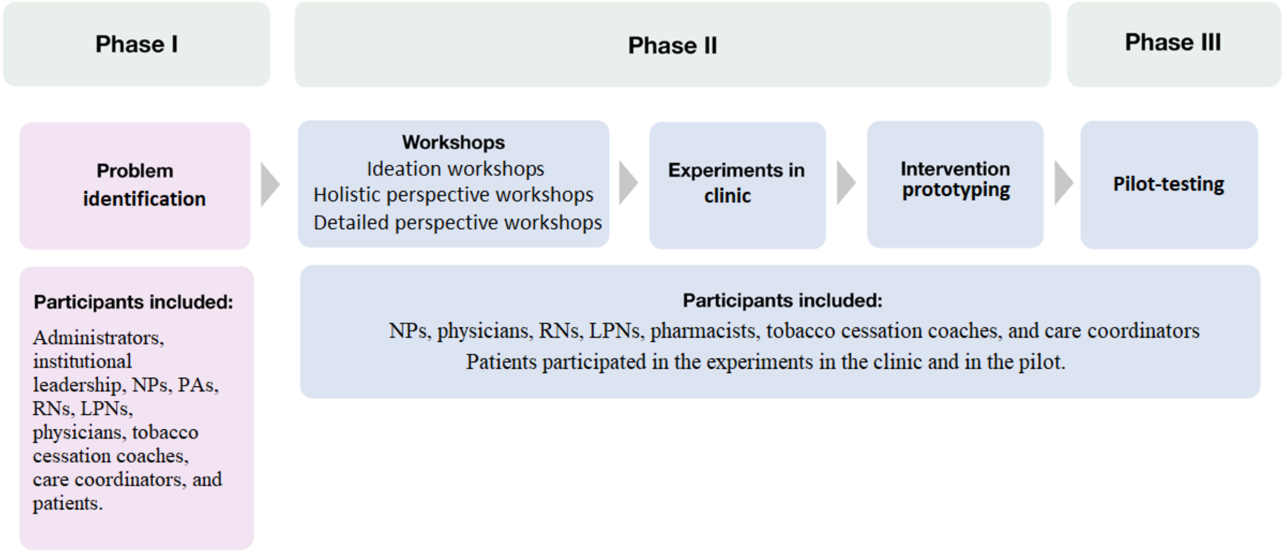
Project Phases

Overview

The project had three distinct phases: (1) problem identification, (2) experimentation, and (3) testing (Figure 1). The first aim of the activities in phase I was to gather information about the current status of ASCVD secondary prevention management. The second aim of this phase was to discuss ways of improving delivery of care to these patients. A cohesive group of participants was established representing different stakeholders (Figure 1). In phase II, the aim was to gain insights into possible solutions for the identified problems, creating and testing prototypes in experiments conducted in clinical practice. In phase III, the intervention prototype was tested and iteratively refined with user feedback in a 3-month pilot trial.

In this study, the participatory design activities of telling, making, and acting were conducted in iterative plan-action-observe-reflect cycles [31,37]. The provider workflows and CDS technology components of the sociotechnical model were developed using design activities and plan-action-observe-reflect cycles. The MCHS Austin leadership identified and recruited a team of local health care professionals to participate in this study. Patients who underwent medical visits in the MCHS Austin were recruited for interviews and observations. For the pilot trial, the patient cohort was identified electronically via a Cohort Knowledge Solution platform, and the patients were randomized into the control or intervention arm.

Figure 1. Project phased-design approach. LPN: licensed practical nurse; NP: nurse practitioner; PA: physician assistant; RN: registered nurse.



Phase I—Problem Identification

Phase I had 2 components: problem identification and ideation workshops.

Problem Identification

- Overview: The purpose of this phase was to gather data about the intervention context, including the setting, barriers, and facilitators of integration of the proposed technology solution into the rural clinic [31,37,38]. This phase focused on telling design activities. Applied ethnographic methods of participant observation and interviews comprised the telling activities [31,37], conducted during 75 hours of workflow observation in the clinic and 18 semistructured interviews with patients and health care professionals. Purposive sampling was used to identify interview participants with relevant roles and expertise, including administrators; institutional leadership; and various clinical health care professionals, including pharmacists, RNs, NPs, tobacco cessation coaches, and physicians. In this phase, 8 patients (mean age 77, SD 10 years; n=6, 75% women and n=2, 25% men) were also interviewed after primary care visits. Research team members (MEK, MP, and NP) performed rapid content analysis on observation field notes and verbatim interview transcriptions to identify key concepts and themes related to user needs for a sociotechnical-driven integration of the

CDS technology [39]. The results of the analysis were synthesized to inform making and prototyping activities.

- Output from problem identification: The insights from problem identification that informed the design of the ideation workshops are outlined in Textbox 1.

Textbox 1. Insights from the problem identification component.

Insights from patients and providers

- For many patients, especially those not meeting cardiovascular guideline (*V4*) recommendations, cardiovascular care was a low priority and, consequently, not addressed during office visits. Patients cited frequent provider turnover as a barrier, expressing uncertainty about who was responsible for managing cardiovascular health. The following are examples from patients:
  - “It is hard to get an appointment.”
  - “It isn’t like you can call in and see your doctor when you don’t feel right.”
  - “I find it extremely difficult to see anyone.”
  - “Our one thing here is, getting a doctor and keeping a doctor.”
- The cost of medications was not considered a barrier, but the cost of visits was a frequent concern. The following are examples from patients:
  - “I have always had really good medical insurance that help cover the cost, it’s never been a problem.”
  - “The cost of all this is just astronomical.”
- Patients who had previous intolerance for medications prescribed for cardiovascular prevention were reluctant to try another medication, especially in the absence of a relationship with a trusted provider. The following are examples from providers:
  - “Patients with elevated LFTs so a barrier to statin therapies and using it comfortably in those types of patients.”
  - “People who are not on statin who are have a cardiovascular event usually have problems with tolerating statins before so then it’s just sort of going down the statin.”
- Rural social networks are tightly knit, indicating that health care would ideally be delivered by local professionals. The following are examples from providers and patients:
  - “You form that connection and they look to you, a familiar face” (provider).
  - “People feel like they can trust us, that it’s a well-established practice” (provider).
  - “After we meet them for the first time, we develop relationships, they can see we can help” (provider).
  - “They become like family” (provider).
  - “They rely on you” (provider).
  - “Just knowing that you are going to be with them on their journey. They feel better about that” (provider).
  - “It depends on how I feel about the person. If I trust them” (patient).
  - “Feeling like you have someone’s undivided attention” (patient).
  - “I think they want to work with us” (patient).

Ideation Workshops

The ideation workshop structure was as follows:

- Overview: The purpose of the ideation workshops was to discuss future ways of organizing the delivery of care for patients with ASCVDs. In total, 2 ideation workshops were conducted. Each workshop drew health care professionals from various roles, including 5 RNs, 4 NPs, 3 LPNs, 2 pharmacists, 3 physicians, 1 tobacco cessation coach, and 1 care coordinator.
- Output from the ideation workshops: The insights from the ideation workshops that informed the design of the phase II experimentation workshops are outlined in Textbox 2.

Textbox 2. Insights from the ideation workshops.

Insights from providers

- Nonphysician care team members were motivated to collaboratively deliver preventive cardiovascular care to patients. However, there were no dedicated workflows and tools to support such initiatives. The following are examples from providers:
    - "I don't know sorting it out by their blood pressures, whether they're elevated, just being on medication or not, obviously smokers, are they on medications? What meds?"
    - "Being able to distinguish the groups like that might be helpful for us in determining where our resources should go."
- Preventive cardiovascular care should be proactively and intentionally delivered. The following are examples from providers:
    - "We don't get referrals like we used to."
    - "They probably need a visit with the provider."
    - "Some of them definitely should have been seen by a provider just because of the length of time they've been seen."
    - "They're not able to take that medication is there something else we can find for them."
- Improving the delivery of preventive cardiovascular care on a systematic level cannot be regarded as a low priority. The following are examples from providers:
    - "They just get through if they've been in the hospital."
    - "Identifying those patients that need more care and making sure that they are getting scheduled every so often, just for checking in, so that its keeping them out of the ED and out of the hospital."
- Existing personnel should be dedicated to the intentional delivery of preventive cardiovascular health care. The following are examples from providers:
    - "Regular appointments rather than waiting for something to happen...and they're probably going to need more time then we can give in fifteen to thirty minute appointments."
    - "Get back into that role of relationship building and connecting with people and then from there we can then take the next step."

Phase II—Experimentation

This phase had 3 components: prototyping workshops (including holistic and detailed perspective workshops), experiments in the clinic, and intervention prototyping.

Prototyping Workshops

The prototyping workshop structure was as follows:

- Overview: The purpose of the prototyping workshops was to design components of the novel model for the delivery of preventive cardiovascular health care for rural communities. The prototyping workshops involved making design activities. In making activities, user workshops were conducted to generate ideas to address issues identified during the telling activities and tailor the intervention to the needs of users and the context of the rural clinic. The multidisciplinary workshop methodology proposed by Scandurra et al [28] was used for the workshops. Prototyping workshops covered holistic and detailed perspectives from the different types of professionals on the care team [28].
- Holistic perspective workshops: There were 2 multidisciplinary interprofessional prototyping workshops in phase II. These workshops covered strategies for co-operation between different professionals [28] and included 4 RNs, 4 NPs, 3 LPNs, 2 pharmacists, 1 tobacco cessation coach, 1 RN care coordinator, and 3 physicians. In the first of these workshops, the staff suggested possible experiments. In the second workshop, participants selected the experiments and built on the proposed experiments in an iterative process. In these workshops, pamphlets summarizing insights and ideas were the discussion-inducing artifacts to facilitate collaborative and iterative idea generation [40].
- Detailed perspective workshops: These workshops included 1 health care professional work category each and focused on details of current and future professional workflows with discussion, feedback, and usability tests. There were workshops for nurses (4 NPs, 3 LPNs, 4 RNs, and 1 RN care coordinator), pharmacists (n=2), and tobacco cessation coaches (n=1). Artifacts for these workshops included system workflow diagrams, CDS user screenshots, deidentified patient information, drafts of templates for clinical notes summarizing encounters, and handouts summarizing insights from experiments.
- Output from prototyping workshops: Health care professionals participating in the prototyping workshops designed the "rooming reminder" and "reaching out" prototypes. Both prototypes were evaluated during experiments in the clinic.

Experiments in the Clinic

The experiments in the clinic were carried out as follows:

- Overview: The purpose of the experiments in the clinic was to explore how designs affect and change practice. This phase focused on acting design activities. For acting, activities were conducted as prototype intervention experiments. The experiments enabled quick testing of the prototypes and evaluation of new ideas through iterative cycles [31,37]. During >37 hours of experimentation, 2 prototypes were evaluated. The experiments evaluated the "rooming reminder" and "reaching out" prototypes.

- Rooming reminder experiment:
  - Overview: Insights from patients and health care professionals indicated that, often during routine medical encounters, other complex medical issues are prioritized, and cardiovascular prevention is not addressed. These insights led to the decision to design a rooming reminder experiment. The purpose of the rooming reminder was to remind clinicians to address cardiovascular prevention during upcoming encounters using handouts that summarize the gaps in preventive cardiovascular care for each patient. Handouts were created and named the "Cardiovascular-Patient Appointment Note" (Figure 2). During the experiment, hard copies of these handouts were given to primary care providers by a desk attendant for rapid review before the encounter. The design team observed the Cardiovascular-Patient Appointment Note impact on provider-patient interactions and the content of the medical visits. After 5 days, the team concluded that the Cardiovascular-Patient Appointment Notes had minimal impact. The notes affected only 21% (3/14) of the visits from patients with ASCVDs from a total of 196 visits during this time frame. Providers were interviewed before starting the experiment and asked follow-up questions after experiment completion. In addition, providers were observed during the rooming reminder experiment.
  - Output from the rooming reminder experiment: In total, 3 main insights were gained from the rooming reminder experiment. First, not all the information in the EHR was up to date. Second, only a small number of patients not meeting V4 metrics came to the clinic weekly, suggesting that focusing on current in-visit care will not have the greatest impact. Third, the experiment made clear that the visit context was a major influence on whether cardiovascular health was evaluated. Clinicians used their judgment to determine whether the visit context was appropriate to discuss individual patient cardiovascular metrics. The Cardiovascular-Patient Appointment Note successfully prompted cardiovascular health conversations when all variables identified in Textbox 3 were met, which was rare. Although prompting discussions on cardiovascular prevention during routine outpatient visits can affect care, there is more opportunity to optimize community health through intentional encounters focused on cardiovascular prevention.

- Reaching out experiment:
  - Overview: Insights that guided the "reaching out" experiment were that cardiovascular prevention is often not addressed during routine medical encounters and that rooming reminders had minimal impact. The purpose of the reaching out experiment was to actively contact patients for intentional delivery of preventive cardiovascular care. This experiment had three phases: (1) verification, (2) care coordination and sorting algorithm, and (3) care output (Figure 3). In the reaching out experiment, a total of 8 workflows and 48 processes were developed and tested. A detailed description of these 3 phases is provided in the following sections.
  - Verification phase: Overview: We learned that clinicians must trust the information used for patient management. However, EHR information is often outdated and should be verified with patients before making decisions. The purpose of the verification phase was to gather updated information on the use of guideline-recommended strategies directly from the patients. Output from the verification phase: The initial verification had 2 stages. First, messages were sent through the Mayo Clinic portal app containing a survey asking patients about their cardiovascular prevention status. A team member called patients who did not reply to portal messages and conducted a scripted telephone interview with the same questions used in the survey sent via the portal app. Textbox 4 shows the patient survey questions. As an initial proof of concept, 89 web-based surveys were sent to patients active on the Mayo Clinic portal app. The response rate was 40% (36/89).

- Care coordination and sorting algorithm phase:
  - Overview: The purpose of this phase was to define criteria to assign the right patient to the right provider. The insight that informed this step was the need to assign the right patient to the right provider. Provider skill sets had to match patient gaps in preventive care such that health care professionals with the appropriate skill set would be assigned to evaluate patients with specific gaps in preventive cardiovascular care. Examples from providers are shown in Textbox 5.
  - Output from the care coordination and sorting algorithm phase: Initially, health care professionals (2 pharmacists, 2 RNs, and 1 advanced practice provider) reviewed the charts of 10 patients with ASCVDs and recommended which care team role should be assigned to each patient. Subsequently, the design team worked with health care professionals to articulate criteria for an automated sorting algorithm assigning patients to the most appropriate team member (both in terms of licensure and specialty) to deliver care plans to each patient tailored to care gaps.

- Care output phase:
  - Overview: The purpose of "care output" was to use patient preference for the selection of the type of encounter for the delivery of cardiovascular prevention by rural providers. The insight that informed the "care output" was that patient preference defined the type of encounter for the delivery of preventive cardiovascular care. The options for encounter types were phone call conversation, telemedicine, or in-person visit. For example, patients with limited access to transportation may prefer either phone call conversations or

telemedicine visits. By contrast, those with access to transportation may prefer an in-person visit. Examples from providers and patients are shown in Textbox 6.

- Output from the care output phase: This experiment created and tested workflows to assign encounter types based on patient preference and 10 templates for clinical notes documenting encounters.

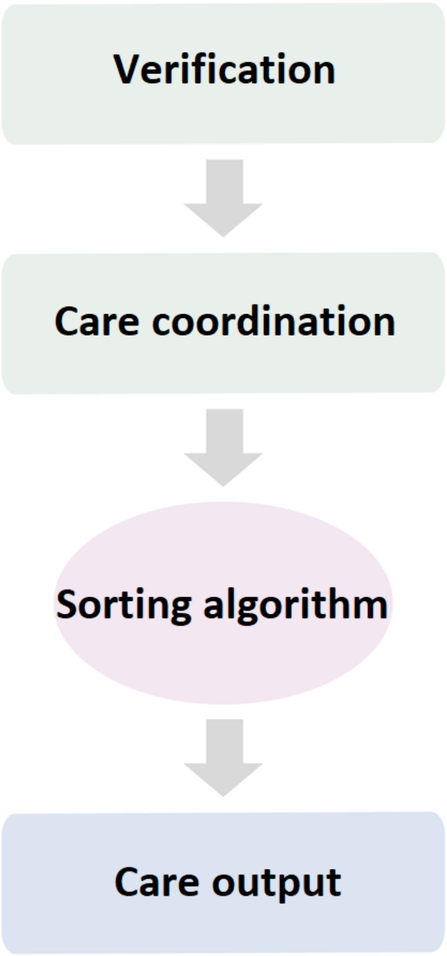
Textbox 3. Factors needed before initiating a cardiovascular preventive health conversation with patients.

Factors necessary for starting cardiovascular prevention evaluation

- Visit appropriateness: visits regarding well-managed chronic care more readily transitioned to a conversation on cardiovascular metrics. By contrast, complex or uncontrolled comorbidities became top visit priority and left little time for other discussion.
- Patient appropriateness: provider perception of patient workload to capacity determined whether the provider would address cardiovascular metrics.
- Provider priorities: providers addressed what they viewed as patients' health priorities. Providers needed to believe cardiovascular guideline (*V4*) recommendations were important for patient health for them to address them. Trust between patient and clinician further enabled dialogue and negotiation related to cardiovascular care.
- Trust in information: providers needed to believe that the recommendations were tailored to each patient case and not based on generic guidelines.
- Actionability of information: actionable recommendations reduced the time required for providers to match up information with next steps for patients.

Figure 3. Design of the reaching out experiment.



Textbox 4. Questions in the patient verification survey.

Questions

- Do you currently take a daily aspirin?
- Do you know the dose of aspirin you take daily?
- Do you know another antiplatelet medication you take? Which dose?
- Do you know which statin you take? Which dose?
- Have you tried a statin in the past? Did you experience any adverse reactions because of the statin you took previously?
- Would you be open to our team’s medication expert connecting with you to discuss medication strategies for reducing your risk of future cardiovascular episodes?
- Are you taking daily blood pressure (BP) medications?
- Would you be open to a care team member (a pharmacist or nurses) working with you on custom strategies to lower your BP?
- Do you have a BP monitoring device at home?
- If known, what was your last BP reading from your home BP monitor? What date was it taken?
- Are you currently using tobacco products?
- Would you be open to our tobacco cessation coach calling you to offer information or see if you have questions?
- If your care team wishes to recommend next steps, what would be the best means to contact you? Messages via the Mayo app, phone call, or both?

Textbox 5. Example quotes from providers for the care coordination and sorting algorithm phase.

Example quotes

- “The only thing about blood pressure vs statin and aspirin, statin and aspirin are you, you’re on it or you’re not on it, that’s it, blood pressure we’re adjusting and fine tuning.”
- “Smoking is definitely its own thing.”
- “A lot of different medications, there are certain ones that need lab work, how often am I going to need to monitor you.”
- “Statin and aspirin at a certain level you’re prescribing it now in a perfect world they are taking it as well. But you’re prescribing it whereas smoking and blood pressure are contingent on patient behavior.”
- “They need different tracks.”
- “Different providers own different groups.”

Textbox 6. Example quotes from providers and patients for the care output phase.

Example quotes from providers

- “Assisted living or at home, are they home bound?”
- “Can they get out?”
- “Barriers to even getting here (at the clinic) in the first place.”
- “Where people live and how they get here (at the clinic).”

Example quotes from patients

- “See somebody [health care provider] personally, I prefer that.”
- “I like the good old phone call.”
- “Coming to the clinic, oh it’s nice to be out.”

Results

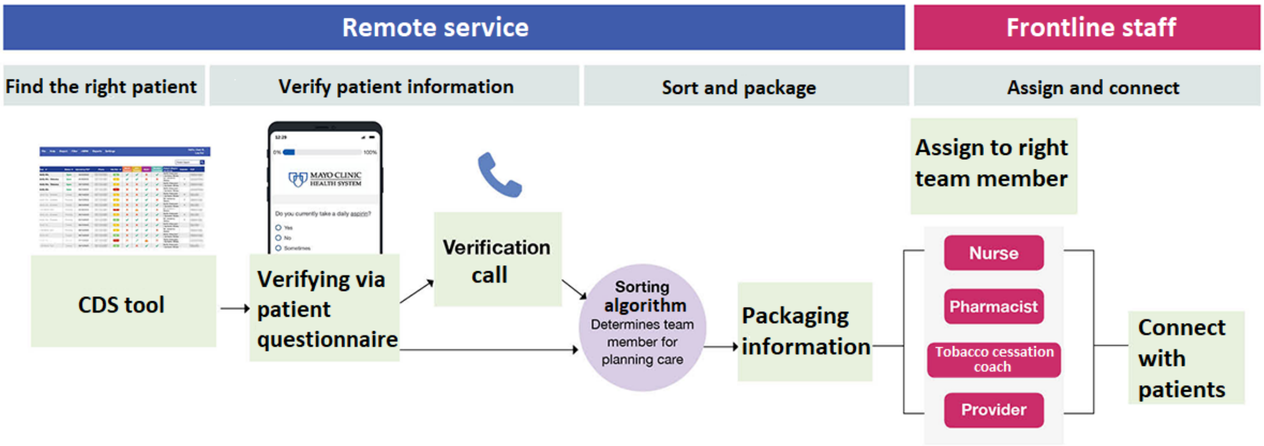
Intervention Prototyping

Overview

The purpose of this phase was to iteratively design an intervention prototype with health care professionals based on the insights from the experimentation phase. The design team delivered handouts for health care professionals during detailed perspective workshops summarizing insights from phase II experiments to facilitate collaborative and iterative idea generation [40].

This process resulted in the design of a sociotechnical intervention prototype with the following components: (1) finding the right patient, (2) verifying patient information, (3) sorting and packaging patient information, and (4) assigning the right provider and connecting with patients (Figure 4). Each component of this intervention is described separately in the following sections.

Figure 4. The final resulting intervention design is a sociotechnical system—a combination of roles, processes, and technology—to enable primary care teams to improve the delivery of cardiovascular prevention strategies. CDS: clinical decision support.



Finding the Right Patient

On the basis of stakeholder feedback, rapid prototyping of the CDS tool was conducted in the testing environment of the web-based technology platform, termed Cohort Knowledge Solution, using the Agile Scrum methodology for software development [41]. The Cohort Knowledge Solution platform is populated by EHR data that are computationally extracted from the institutional data warehouse. Computational phenotyping algorithms were installed in the Cohort Knowledge Solution to automatically identify patients with ASCVDs and identify individual gaps in adherence to *V4* recommendations [42].

ASCVDs include coronary artery disease, peripheral artery disease (PAD), and ischemic stroke [43]. Rule-based billing code algorithms for identification of patients with these conditions were deployed via the Cohort Knowledge Solution platform. Random samples of the retrieved data were manually reviewed by a trained abstractor following the written criteria for standardization to create a reference standard. The processes to support accurate data collection were developed using iterative validation cycles and used Boolean combinations of billing codes [44]. The rule for retrieval of coronary artery disease was a diagnostic code for myocardial infarction or angina pectoris or a procedural code for coronary revascularization procedure (percutaneous or surgical); for ischemic stroke, it required the presence of an International Classification of Diseases, 10th Revision, diagnostic code for ischemic stroke or transient ischemic attack; and, for PAD, a diagnostic code and International Classification of Diseases, 10th Revision, procedural code for lower extremity limb revascularization (endovascular or surgical) was required. Performance metrics were generated by comparison with the reference standards (Table 1).

Given the inferior performance of billing codes for PAD cohort identification, a natural language processing algorithm for the extraction of PAD from clinical narratives was also created and validated with a sensitivity of 91% and a positive predictive value of 92% [45]. This previously validated natural language processing PAD algorithm was also deployed to the Cohort Knowledge Solution to identify cases.

Wireframe usability tests were conducted with care team members to identify which data were most relevant for planning and delivering preventive cardiovascular care. The technology developed also enabled these data to be retrieved from the EHR data and displayed on the same screen with a single mouse click (Figure 5).

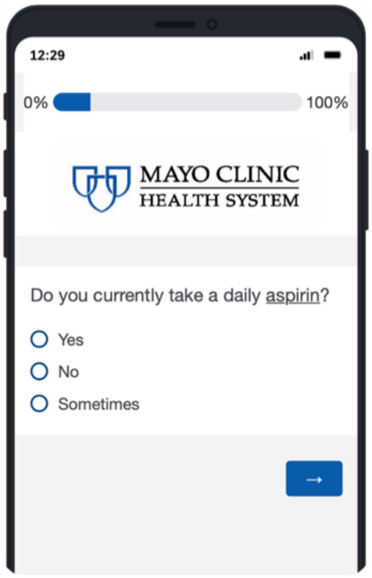
Verifying Patient Information

Health care professionals need the right information to deliver medical care efficiently and effectively. Messages were delivered to patients through the Mayo Clinic portal app with survey questions regarding adherence to *V4* recommendations (Textbox 4 and Figure 6). Patients who did not complete the portal survey, did not answer 3 phone calls from the study team, or declined to participate in this project continued to receive care through the usual model of care. Patients who opted to participate in the intervention were connected with health care professionals with expertise tailored to patient gaps for cardiovascular prevention management. Survey responses were used to update the EHR of each patient, and workflows were designed to support the verification process.

Figure 6. Screenshot of the verification survey sent via the Mayo Clinic patient portal app.



Do you currently take a daily aspirin?

○ Yes
○ No
○ Sometimes

Sorting Algorithm

The design team adapted the sorting algorithm into criteria that the informatics team translated into a sorting computational algorithm for the Cohort Knowledge Solution. Examples of criteria included "if patients were missing statin or anti-platelet, send to pharmacist" or "if a patient reported taking an undocumented anti-platelet, message nurses to update the medical record." The workflows were redesigned by incorporating the new CDS technology.

Packaging Patient Information

The design team originally assumed that the local care team members (eg, pharmacists and nurses) would use the platform. However, during usability testing, the participant health care professionals expressed dissatisfaction with the thought of using another tool for clinical practice. Accordingly, the workflow was redesigned to have a dedicated remote user—analogous to the role of an "air traffic controller." This dedicated remote user took responsibility for care coordination using the Cohort Knowledge Solution in a central hub model. Once patients had filled the verification questionnaire, the dedicated user aggregated relevant patient information within the Cohort Knowledge Solution and electronically assigned it to the right provider.

Assigning the Right Provider

The dedicated user leveraged the Cohort Knowledge Solution sorting algorithm to identify the right providers and sent an in-basket message with the aggregated medical information. The care team members, often nonphysician health care professionals, used the packaged medical information to plan care and "connect with patients" following workflows specifically designed for this phase.

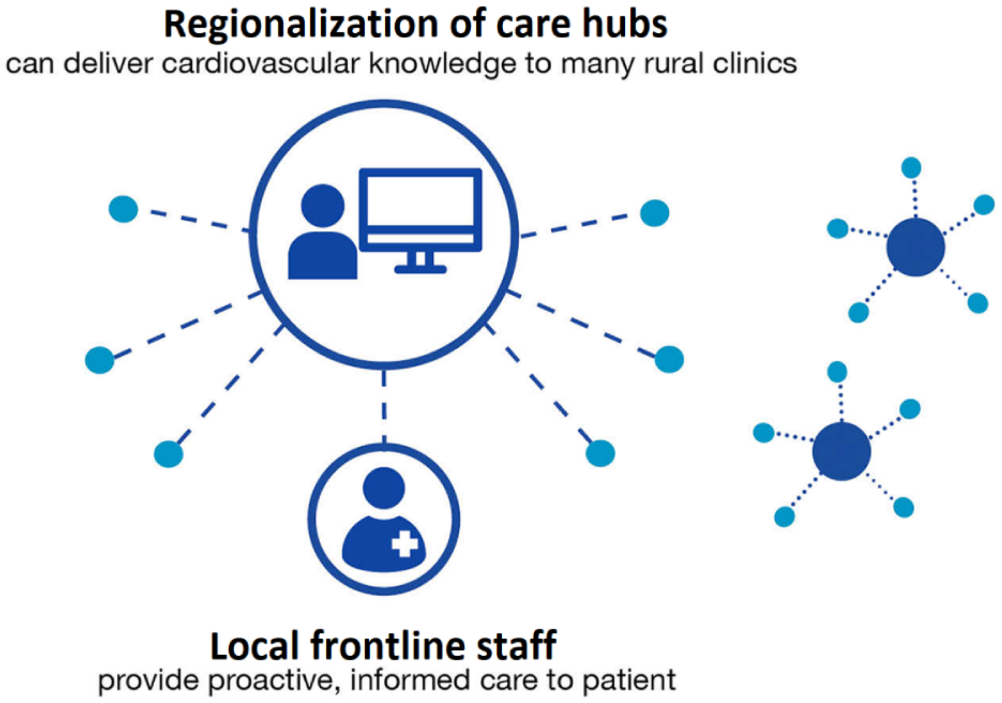
Connecting With Patients

Rather than developing new cardiovascular visits, we focused on routing patients to the existing visit types. Therefore, the redesigned workflows assigned the right patient to the right provider. The provider reviewed the packaged medical information and initiated communication, such as phone calls, video telemedicine, or face-to-face encounters, based on patient preferences and needs.

Centralized Hub Model

To address obstacles stemming from the rural provider shortage, a regionalization of the care hub model was designed (Figure 7). Verifying and packaging patient information took place in a central rural hub with dedicated resources assisted by technology to gather and summarize the patient-specific gaps in preventive care. The information gathered at the central hub was shared with the right rural provider for delivery of care locally. The central hub gathered all the information necessary for the delivery of care, reducing the need for manual chart review by health care professionals and enabling them to focus on delivering tailored care.

Figure 7. The regionalization of the care hub model.



Phase III—Testing

A 3-month prospective randomized pilot trial was conducted in the outpatient primary care clinic in Austin, MN. The goal of this pilot was to test and iteratively refine the sociotechnical intervention prototype with all the components, as shown in Figure 4. Patients with ASCVDs were assigned to the intervention or control arm by stratified randomization with strata based on the number and types of *V4* cardiovascular recommendations in use. The intervention was a rural-specific and sociotechnical model prototype that was proactive and delivered preventive cardiovascular care specific to each patient. The care delivery model for the control arm was usual care, which is a symptom-based and reactive model. In the usual care model, health care professionals rely on patients to contact the system for evaluation of symptoms [46,47]. Patients assigned to the control and intervention arms were evaluated during the same period. A Cohort Knowledge Solution ASCVD registry was used to identify patients with ASCVDs. A total of 369 patients with ASCVDs on ≤3 *V4* guideline recommendations were randomly assigned to the control (n=182, 49.3%) or intervention (n=187, 50.7%) arm. Baseline clinical characteristics were similar in patients assigned to the 2 study arms (Table 2).

Subsequently, the medical records of all patients were reviewed by a trained abstractor before surveying to find extenuating circumstances that would justify not reaching out to a given patient during the pilot. These circumstances included dementia or cognitive impairment, end-stage medical conditions on hospice care, active cancer treatment, hospitalization during the pilot, patient relocation to a different county and no longer receiving medical care from MCHS Austin, upcoming cardiology appointment within 3 months of the pilot, or other medical conditions that did not require the use of *V4* (Figure 8). These reasons were discussed with health care professionals in the detailed perspective workshops and subsequently incorporated into the workflows.

A total of 33 patients crossed over to the usual model of care arm for analysis after this review. After crossing over, 82.4% (154/187) of eligible patients remained in the intervention arm and were surveyed. The patient survey (depicted in Textbox 4) was a component of the intervention and was delivered via portal messages or addressed during scripted telephone interviews. Patients in the intervention arm completed the verification survey and answered the following question: “If your care team wishes to recommend next steps, what would be the best means to contact you? Messages via the Mayo app, phone call, or both?” The patients were contacted using their preferred strategy. Those who did not respond to this question were not contacted. Of the 154 contacted patients, 86 (55.8%) responded to the patient survey via electronic messages or scripted telephone interviews in <3 months. These patients were subsequently assigned to nonphysician health care professionals for the proactive delivery of patient-specific V4 strategies for secondary prevention. There were no differences in the proportion of patients implementing guideline recommendations between those who answered the survey via the patient portal and those who answered the survey by phone call.

The primary outcome of the pilot trial was the proportion of *V4* recommendations delivered, as measured by encounters with nonphysician health care professionals. Encounters with nonphysician health care professionals (nurses, pharmacists, or tobacco cessation coaches) included consults (in person or via telemedicine) or phone conversations. During the pilot, the proportion of patients who had encounters with nonphysician health care professionals for delivery of V4 recommendations in the intervention arm was greater for all types of professionals than in the control arm (Table 3). After exclusion of the 33 patients who crossed over from the intervention arm to the control arm, similar results were observed. In subsequent analysis removing all participants in the control arm who met the criteria for exclusion from the intervention arm (73/369, 19.8%), the results remained unchanged.

During and after the pilot, health care professionals were interviewed, and the information gathered was used to further refine the intervention. The pilot trial demonstrated that this model (1) connected the right health care professional with the right patient, (2) saved time by reducing the need for manual chart review, (3) enabled health care professionals to work to the top of licensure, (4) has potential for expansion to other conditions, and (5) promoted interdisciplinary collaboration to optimize care.

Table 2. Characteristics of patients assigned to the control and intervention arms (N=369).

Clinical variables[a]	Control arm (n=182)	Intervention arm (n=187)
Age (years), mean (SD)	71 (13)	71 (14)
Sex (male), n (%)	92 (50.5)	95 (50.8)
Race (White), n (%)	167 (91.8)	174 (93)
Ethnicity (“not Hispanic or Latino”), n (%)	171 (94)	178 (95.2)
Married, n (%)	94 (51.6)	103 (55.1)
Taking antiplatelet medications, n (%)	120 (65.9)	121 (64.7)
Taking statin medications, n (%)	111 (61)	112 (59.9)
Nonsmokers, n (%)	132 (72.5)	135 (72.2)
Blood pressure at goal, n (%)	87 (47.8)	89 (47.6)

[a] Two-sample 2-tailed *t* tests were used to compare means, and chi-square tests were used for comparison of percentages; all *P* values comparing the control and intervention arms were not significant (*P*>.05).

Figure 8. Pilot trial design. V4: cardiovascular guideline recommendations. *Extenuating circumstances included dementia or cognitive impairment, end-stage medical conditions on hospice care, active cancer treatment, hospitalization during the pilot, patient relocation to a different county and no longer receiving medical care from the Mayo Clinic Health System Austin, upcoming cardiology appointment within 3 months of the pilot, or other medical conditions that did not require the use of V4.

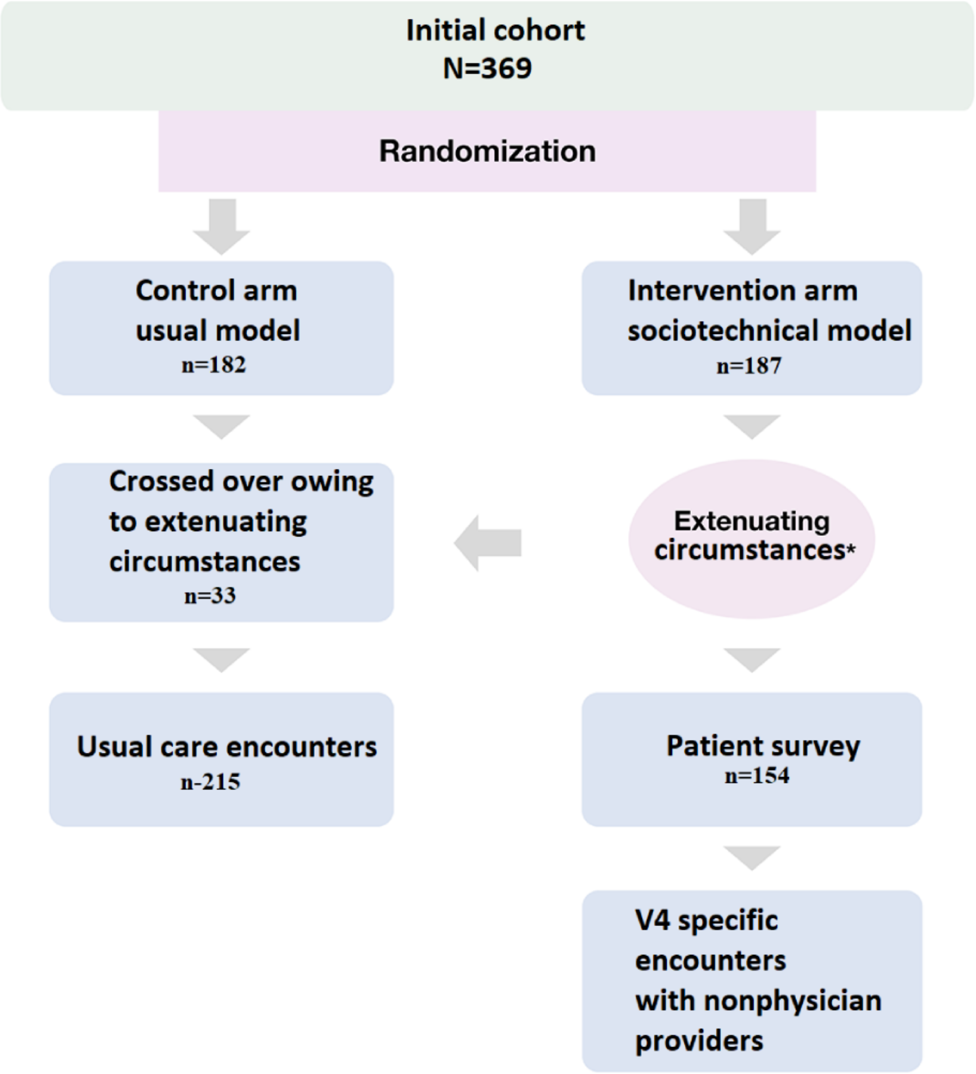


Table 3. Number of encounters for the delivery of cardiovascular guideline recommendations (V4) by nonphysician health care professionals during the pilot (after crossover; N=369).

	Control arm (n=215)[a], n (%)	Intervention arm (n=154)[a], n (%)	*P* value[b]
Nursing encounters for the delivery of *V4* recommendations	48 (22.3)	51 (33.1)	.02
Pharmacist encounters for the delivery of *V4* recommendations	1 (0.5)	31 (20.1)	<.001
Tobacco cessation coach encounters for the delivery of tobacco discontinuation strategies	3 (1.4)	30 (19.5)	<.001

[a] Total number of patients in each arm after crossing over.

[b] Two-sample 2-tailed *t* tests were used to compare means, and chi-square tests were used for comparison of percentages; for all analyses, *P*<.05 was considered significant.

Discussion

Principal Findings

This study used participatory design and the sociotechnical theory framework to create a team-based care model for the coordination and delivery of secondary prevention to rural patients with ASCVDs by nonphysician health care professionals. The new model of care redesigned workflows, integrated health care professional roles, and deployed a novel CDS technology. The subsequent pilot trial demonstrated the feasibility for effective implementation of this new model of care in a rural outpatient clinic. For the next phase of this project, a scalable intervention is planned to be implemented in other rural sites of the MCHS and evaluated in a multisite trial.

The requirements for successful practice transformation include changes in both workflows and technology [48]. Importantly, the optimal use of technology is dependent on the interrelation of the system with skilled and pragmatic work by health care professionals [49]. The design of systems focusing only on technological factors has been a major contributor to their underuse [36,50]. A previous study showed that, for most patients (80% of 5568 patients), providers disregarded the recommendations of a CDS to improve the use of ASCVD secondary prevention at hospital discharge [51]. In that study, the CDS was not part of a sociotechnical system and was not integrated with provider workflows [51]. The low use rate of an EHR-based CDS for cardiovascular risk reduction in community health centers was also reported in a cluster randomized clinical trial that focused on CDS technology [52,53].

This study reported a practical application of the sociotechnical system theory framework to design an intervention to improve the delivery of cardiovascular prevention. The sociotechnical design approach considers both technological and social factors to inform system design [50,54,55]. The use of a sociotechnical theory approach for system design leads to systems that are more acceptable to users and have long-term sustainability [36,56,57]. For these reasons, the sociotechnical design approach was used to design an intervention that will be likely sustainable when implemented in the rural sites of a large medical enterprise.

A previous study in India developed a CDS tool for cardiovascular risk screening used for single-visit encounters [58]. In that study, the CDS was not linked to information from EHRs, and it was not possible to follow patients longitudinally, which is a fundamental requirement for the workflow of providers managing secondary prevention strategies for patients with ASCVDs. By contrast, the CDS of this study was populated with data automatically extracted from EHRs, enabled the delivery of longitudinal care for patients with ASCVDs, and was integrated with provider workflows. A second study reported a CDS linked to the EHR for the primary prevention of patients without established ASCVDs in an urban setting, and a printed copy of the CDS summary screen containing the patient-specific status of use of guideline recommendations was placed on the exam door for rapid review by providers before the encounter [59]. In this study, the rooming reminder experiment used a similar approach. However, this strategy had minimal impact as not all the information in the EHR was up to date, only a small number of patients not meeting V4 metrics came to the clinic weekly, and the visit context had a major influence on whether cardiovascular health was evaluated. On the basis of these insights, the subsequent experiment (reaching out) aimed to actively contact patients for the intentional delivery of preventive cardiovascular care. Insights from the reaching out experiment became a core component of the new model for the intentional delivery of care designed for this study.

Health care professionals work in teams and are commonly assisted by computerized information systems. These systems display the information that different health care professionals need to complete their work. Scandurra et al [28,60] proposed multidisciplinary thematic workshops based on participatory design and computer-supported participatory work theories. This method uses a collaborative design and enables the translation of health care professionals' needs into technical requirements. This study applied this methodology for the development of a team-based model of care, enabling multidisciplinary co-operation among team members for the delivery of preventive care for rural patients with ASCVDs.

A systematic review of the literature by Hardy et al [61] showed that access to the internet, digital literacy, and computer skills are important characteristics for the design of sustainable technology tools for residents of rural areas. This pilot recruited older adult patients from rural communities. Patient recruitment was first conducted using patient portal messages. We observed a low response rate to portal messages and, in the intervention group, 39.6% (61/154) did not have active portal accounts. Other studies have also demonstrated that access to and ability to use technology and the internet are barriers to the use of portals by older adult patients [62-64]. To overcome these barriers, in this study, patients who did not have active portal accounts or did not respond to portal messages were contacted by phone. The same survey questions sent via portal messages were used for scripted telephone conversations. The survey questions were simple and focused on patient-specific gaps in preventive cardiovascular care. The survey response rate of 55.8% (86/154) was superior to the 43.9% response rate of a previous survey of community-dwelling older adults in rural areas [14].

On the basis of our observations, rural providers need to consider patient preference for visit type to mitigate barriers to transportation and limited mobility, which often occur in rural residents, especially older adults, who were a major target group for this intervention. Compared with their urban counterparts, rural citizens are more prone to mobility and transportation barriers that make access to health care difficult [61]. In mitigation, phone conversations and telemedicine became options of visit types connecting patients and providers for the delivery of secondary prevention strategies for patients with ASCVDs. In addition, it is important to underscore that rural society values "neighborliness," which manifests as trust in community members and potential distrust of outsiders [61]. The intervention developed in this study leveraged neighborliness and supported a rural place-based identity. Consequently, the hub model was maintained regionally rather than centrally in Rochester, MN (Mayo Clinic headquarters). The regionalization of the care model promoted the delivery of care by rural providers. During the implementation of this intervention, staff resources will be distributed to serve small rural clinics located in the area covered by a hub. In other rural health care settings, a similar process for the allocation of rural providers may be used.

The novel model of care described in this study assigns the right patient to the right professional for the delivery of preventive care. In addition, the selection of the encounter type was based on patient preference for in-person visits at the clinic, phone conversations, or video encounters via telemedicine. This flexibility facilitated access to health care professionals for patients with limited transportation resources. Furthermore, this model also enabled a patient-centered health connection that goes beyond traditional symptom-based visits. The primary outcome of the pilot trial was the proportion of *V4* recommendations delivered, as measured by encounters with nonphysician health care professionals. These metrics were set a priori following good practice. During the pilot, the proportion of patients who had encounters with nonphysician health care professionals for the delivery of *V4* recommendations in the intervention arm was greater for all types of professionals than in the control arm. Therefore, the pilot trial showed that this model connected the right health care professional with the right patient for the delivery of guideline-recommended strategies for patients with ASCVDs, demonstrating the feasibility of the intervention.

Limitations

The pilot study was not powered to evaluate the differences in the use of specific guideline-recommended strategies. However, we are planning a subsequent prospective randomized implementation trial in the Midwest sites of the MCHS with central hubs spanning multiple rural clinics. This trial will be powered to evaluate the impact of the intervention on the proportion of patients using specific guideline-recommended strategies. In preparation for this implementation, the informatics and IT teams have been building the additional Cohort Knowledge Solution functionalities designed in this study, which are aligned with the new workflows. These functionalities include automation of the sorting algorithm and automated retrieval of extenuating circumstances.

The reason for not including patients in the workshops was that the Cardiovascular-Patient Appointment Note experiment showed that a major obstacle for the delivery of preventive cardiovascular care was the difficulty in reaching out to patients. Strategies for health care professionals to reach out to patients were developed to overcome this barrier. The cost of visits was a concern for patients. However, during this study, there was no additional cost for the patients. Further analysis of the cost of health care and strategies for billing will be performed during the implementation phase. During the pilot trial, health care professionals were asked questions about their experience with the intervention. However, patients were not asked similar questions. During the planned implementation trial, patients will be asked to identify barriers to and facilitators of the implementation of this sociotechnical intervention.

This novel team-based model of care was specifically designed to enable the delivery of care in resource-constrained clinics located in rural communities and promotes teamwork with shared responsibilities among team members. For clinics that do not have certain types of health care professionals (eg, pharmacists), we propose to use the resources of the regional hubs, in which health care professionals from other rural clinics could remotely support the teams where this specific expertise is not available. In addition, during the process of implementation, further information will be gathered about the characteristics of the intervention that are necessary for adaptation to other enterprises. Other implementation studies are needed to evaluate the reproducibility and scalability of this model of care to other enterprises that deliver health care to patients in rural communities.

Conclusions

Participatory design within the sociotechnical theory framework enabled the development of a rural-specific, team-based care intervention assisted by CDS technology for the transformation of preventive health care delivery in rural clinics for patients with ASCVDs. By systematically promoting preventive care, this intervention has the potential to strengthen longitudinal relationships between clinics and their communities—the underlying requirement for secondary prevention for patients with ASCVDs in rural settings.

Acknowledgments

This research project was funded by the Mayo Clinic Practice Transformation Award. The authors thank the pharmacists, tobacco cessation specialists, nurse managers, registered nurses, licensed practical nurses, nurse practitioners, care coordinators, and informatics nurses for their invaluable contribution in developing the intervention. The authors also thank the IT and informatics teams for their work on the Cohort Knowledge Solution tool; the study coordinators for conducting the scripted telephone conversations; the project managers for management of the project; Tessa Flies for secretarial support; Jor Arcila for the picture posted on the Journal's website; and Jill Smith, Jennifer Walter, and Dr Robert C Albright Jr for their invaluable support.

Conflicts of Interest

None declared.

Abstract

Background: Historic constraints on research dollars and reliable information have limited firearm research. At the same time, interest in the power and potential of social media analytics, particularly in health contexts, has surged.

Objective: The aim of this study is to contribute toward the goal of establishing a foundation for how social media data may best be used, alone or in conjunction with other data resources, to improve the information base for firearm research.

Methods: We examined the value of social media data for estimating a firearm outcome for which robust benchmark data exist—specifically, firearm mortality, which is captured in the National Vital Statistics System (NVSS). We hand curated tweet data from the Twitter application programming interface spanning January 1, 2017, to December 31, 2018. We developed machine learning classifiers to identify tweets that pertain to firearm deaths and develop estimates of the volume of Twitter firearm discussion by month. We compared within-state variation over time in the volume of tweets pertaining to firearm deaths with within-state trends in NVSS-based estimates of firearm fatalities using Pearson linear correlations.

Results: The correlation between the monthly number of firearm fatalities measured by the NVSS and the monthly volume of tweets pertaining to firearm deaths was weak (median 0.081) and highly dispersed across states (range –0.31 to 0.535). The median correlation between month-to-month changes in firearm fatalities in the NVSS and firearm deaths discussed in tweets was moderate (median 0.30) and exhibited less dispersion among states (range –0.06 to 0.69).

Conclusions: Our findings suggest that Twitter data may hold value for tracking dynamics in firearm-related outcomes, particularly for relatively populous cities that are identifiable through location mentions in tweet content. The data are likely to be particularly valuable for understanding firearm outcomes not currently measured, not measured well, or not measurable through other available means. This research provides an important building block for future work that continues to develop the usefulness of social media data for firearm research.

Introduction

Motivation

Firearm violence is a major and costly public health burden in the United States [1-3], and constraints on the availability of research dollars and reliable information to support firearm research have imposed limits on the ability to gather scientific evidence on effective gun policy [4-7]. At the same time, interest in the power and potential of social media analytics in public health contexts has surged. Several aspects of social media data have heightened their promise as a resource, including the fact that the data are inexpensive to obtain compared with survey data; provide access to continuous, automated, and near–real-time monitoring; and are passively collected in a naturalistic setting as part of an individual's day-to-day life, eliminating biases inherent to sampling procedures, questionnaires, and recall [8-13]. Such data are, of course, not without their own methodological challenges and limitations, and practices for their ethical and meaningful use are evolving [14-16].

To date, such data have been deployed in firearm-related research in several ways, including to record narratives, sentiment, and emotion around shooting events [17-20]; characterize gun advertisements on social media [21]; and reflect opinions on gun policies and gun control [22,23]. In this paper, we take up the question of how social media data may contribute to understanding firearm-related outcomes. We identify methodological approaches, challenges, and limitations associated with using social media data for understanding a specific firearm outcome—firearm mortality—for which a benchmark measure for comparison is available from a traditional data source. The analysis of firearm mortality is intended to serve as a test of the potential utility of social media data for understanding firearm outcomes not currently measured, not measured well, or not measurable through other available means.

Assessing the Usefulness of Twitter Data

Specifically, we assessed the usefulness of Twitter data for understanding firearm mortality. Twitter is an online microblogging platform that has >206 million daily active users worldwide and >77 million daily active users in the United States [24]. A key feature of Twitter is its short format: members can only post messages, known as *tweets*, of up to 280 characters. We developed machine learning (ML) classifiers for identifying tweets that pertain to firearm fatalities and compared measures of firearm-fatality discussion volume to firearm-fatality estimates by state from the National Vital Statistics System (NVSS). The NVSS represents one of the few sources of US health-related data with consistently collected and reliable information on a specific gun outcome measured by geographic area. Our goal was to begin to establish a foundation for how social media data may be used by itself or in conjunction with other data resources, such as through data-blending techniques, to improve the information base on which firearm research relies.

Methods

Ethics Approval

The institutional review board of Georgetown University reviewed our submission, STUDY00002288, and determined the study to be exempt.

Overview

Our overarching approach was to compare—within state over time (by month)—measures of firearm-fatality tweet discussion volume with NVSS estimates of firearm fatalities using Pearson linear correlations. Methodologically, with respect to Twitter data, we used a multistage process as described in detail in the following subsections. We first describe our benchmark data and then describe in detail our approach to analyzing Twitter data.

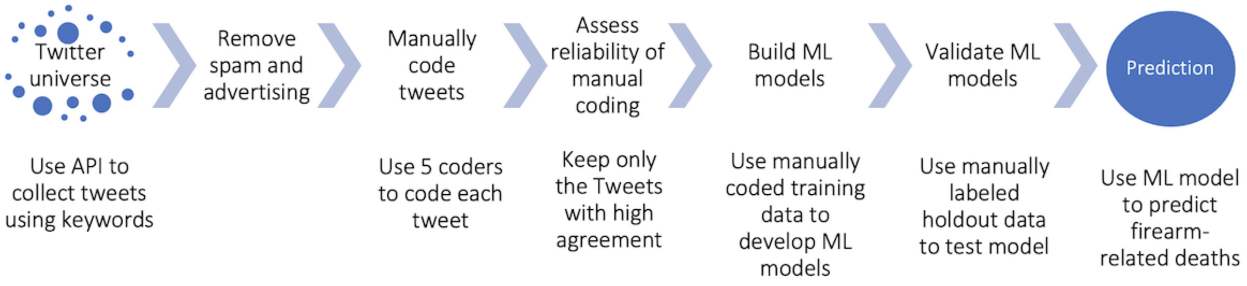
Benchmark Data

Our benchmark data are NVSS estimates of overall firearm fatalities by state and month for 2017 and 2018. Diagnostic (International Classification of Diseases, Tenth Revision) codes in the NVSS identify mortality from accidental firearm discharges, assaults (homicides) by discharge of firearms, and intentional self-harm (suicides) by firearms. Data are collected nationwide using standardized forms and a set of common procedures to ensure comparability of data across locations.

Twitter Data

We developed a Twitter-based gun-related analytic platform based on content culled from the Twitter Enterprise application programming interface (API) for the 2017-2018 time period through the multistage process depicted in Figure 1. The process consists of 4 stages to prepare the data for ML and 3 stages associated with ML analysis.

Figure 1. Construction of the Twitter-based gun-related analytic platform. API: application programming interface; ML: machine learning.



The API allows permitted users to access publicly available Twitter content—including tweets; tweet IDs (a unique identification number generated for each tweet); and Twitter profile information such as display name, username, user bio, and publicly stated location—under a developer agreement. The developer agreement requires that the data are used in ways consistent with people's reasonable expectation of privacy and are not used for developing, creating, or offering commercial services in ways that violate Twitter's policies. To identify relevant tweets, we hand curated a selected set of keywords and hashtags relating to firearms by looking at a random sample of actual tweets and using keywords identified in previous literature. The query we used to collect data from the API included >200 keywords and hashtags (Multimedia Appendix

1). The data retrospectively collected through the API adds a language label to each tweet. In this study, we used tweets labeled as being written in English.

The initial database we derived from the Twitter API using our curated set of firearm-related keywords and hashtags included >2.3 million tweets for 2017 and 2018. More specifically, we obtained 651,466 tweets from 2017 and 1,675,083 tweets from 2018 (with the increase in the number of tweets over time reflecting larger trends in Twitter discussion on the topic). Given that billions of tweets are posted each year in English on Twitter, the discussion of firearms constitutes a relatively modest size.

Next, in *stage 2*, because social media data are subject to the influence of robots, advertisers, and marketers, the data must be classified and filtered to exclude irrelevant data. We used a multistage process to identify and remove spam (advertising, dead links, pornography, etc). We began by detecting spam using a content-based algorithm because spam can be generated by both humans and bots. The content-based algorithm first looks for website URLs related to known advertising, phishing scheme, malware, gambling, and pornography sites. Our spam blacklist contains >2 million website URLs. The second part of the spam classifier looks for content that maps to standard spam content or differs significantly from other content on the tweet stream being collected [25].

In *stage 3*, we randomly sampled tweets from the resulting data for manual labeling—a process of assigning each tweet a set of characteristics, or features, relevant to the study question. We labeled three firearm-related features of tweets: whether the tweet pertains to (1) firearms (2) fatality or fatalities, or (3) a mass shooting. Our analyses focused on firearm fatality (a combination of characteristics 1 and 2) and mass shooting. We also labeled tweets as an advertisement or irrelevant, spam, or noise and used these labels to further improve our spam classifier and remove identified spam tweets from further analysis.

The manual labeling process relied on crowdsourced, distributed labor through Amazon Mechanical Turk (MTurk) [26-28]. We recognize that varying and evolving views exist regarding the use of this platform [29-31] and were attentive to these considerations in our study design, which was vetted and approved by our institutional review board. We applied best practices, creating as clear and streamlined a task as possible and training MTurk coders through a written instruction guide and with labeling examples (Multimedia Appendix 2) [32]. Recent research confirms that MTurk can be a useful resource for quickly gathering reliable data labels for training ML models when best practices are used [33].

We required each tweet to be labeled by 5 different coders, and we calculated the interrater reliability of labeling across coders. The manual labeling process continued until we reached a threshold number (minimum of 400) of tweets that were labeled as positively identifying a particular characteristic. We found that at least 400 tweets for each class in our ML model was reasonable for building a reliable classifier for our learning tasks. The total number of tweets labeled for each characteristic varied because coders may label one or more characteristics for each tweet, rather than all characteristics for each tweet.

As a means of assessing the manual labeling process, we calculated 2 scores for the set of tweets labeled for each characteristic. The first measured task agreement. For each tweet, we assigned the value of the characteristic being measured according to the majority vote (eg, if, of 5 labelers, 3 chose *yes* for firearm-related and 2 chose *no*, we assigned the value of *yes*) and then calculated the percentage of coders who agreed on this value (in this case, 3/5 = 60%). The task agreement is the average across all tweets for a given characteristic of this score. Second, we calculated a worker performance score for each coder in which the denominator was the total number of characteristics a coder labeled, and the numerator was the number of characteristics labeled for which the coder's assigned label aligned with the majority vote. We then calculated the average worker performance score for the set of coders who labeled the set of tweets used for measuring each of the characteristics.

Table 1 summarizes the number of tweets that were manually labeled along with task agreement and worker performance score metrics.

As shown in Table 1, we found high rates of task agreement and worker performance for identifying firearm fatalities (97.14% and 97.19% for task agreement and worker performance, respectively) and mass shooting events (95.42% and 94.96% for task agreement and worker performance, respectively). We noted that 50 tweets that were labeled as being firearm-related were not labeled with a mass shooting characteristic. This occurred in our initial experiment of the labeling task. In this experiment, we labeled tweets as being about a mass shooting, homicide, or suicide. If a tweet was labeled as being about a homicide or suicide, we did not ask the labeler to determine whether the tweet was about a mass shooting. In subsequent experiments, we only focused on capturing firearm-related deaths more broadly and mass shootings explicitly to allow for count adjustments. Therefore, for subsequent experiments (we collected a few hundred labels at a time), we always asked labelers to determine whether a tweet about firearm-related fatality was discussing a mass shooting event.

In *stage 4*, we defined *reliably labeled* tweets as those for which there was manual labeling agreement among ≥3 coders. We dropped tweets that had a reliable label of uncertain or were not reliably labeled from further analysis. This means that our training data did not include ambiguous tweets and, therefore, may undercount our characteristics.

The next three stages (*stages 5*, *6*, and *7*) of the process involved firearm-related ML. In *stage 5*, we divided the subset of reliably labeled tweets into training data—on which we built ML classifiers—and holdout data, which were used to validate the classifiers. We randomly selected 80% of reliably labeled tweets for the training data and 20% for the holdout. When building the ML classifiers, we used 5-fold cross-validation on the training data to measure the reliability of the classifiers. Cross-validation is a resampling procedure that allows researchers to determine whether their ML models are generalizable [34-36]. In 5-fold cross-validation, the data set is partitioned into 5 equal subparts (or *folds*). Of the 5 folds, 4

(80% of the data) are used for training, and 1 (20% of the data) is used for testing. This is repeated 5 times so that each fold is part of the training set 4 times and part of the testing set 1 time, and the final accuracy of the model is determined by taking the mean accuracy of all the created models on the testing set.

We began building ML classifiers to identify tweets pertaining to a firearm fatality and to a mass shooting. We minimally preprocessed the data: lowercased text, removed punctuation and URLs, and removed stopwords. We generated a number of features for the ML classifiers: frequent n-grams, words and phrases, and sentiment. The classifiers we compared were random forest, support vector machine, logistic regression, decision tree, and naïve Bayes. In *stage 6*, we validated the classifiers we developed for firearm fatalities and mass shootings in *stage 5* by further testing them on holdout data. We calculated the sensitivity and specificity of the ML model predictions against those of the manually coded firearm-fatality label.

Table 2 summarizes the best-performing ML classifier for each classification task along with the training and holdout data set sizes and a measure of reliability based on the testing data, using our cross-validation approach, and the holdout data. The F_1-score is a weighted average of sensitivity and specificity (precision and recall) that considers both false positives and false negatives. For firearm-related fatality, we had 6045 labeled tweets. For mass shooting, we had 5842 labeled tweets. Because of heavy skews (imbalance) in the training data, we randomly undersampled from the labeled data of the majority label to balance the training and holdout data sets. Table 2 shows the training and holdout data set sizes after this procedure.

We selected random forest classifiers for both firearm fatalities and mass shooting characteristics. The F_1-scores, as shown in Table 2, are high and comparable for the testing and holdout data, indicating a clear ability of the classifiers to generalize beyond the training data set.

Stage 7 completed the development of our Twitter-based gun-related analytic platform with the third and final piece of the ML analysis. In *stage 7*, we applied the validated classifier to identify firearm-fatality tweets.

Table 1. Manually labeled tweet characteristics.

Tweet label	Firearm-related fatality	Mass shooting
Total number of tweets labeled (yes, no, unsure)	5868 (5528, 330, 10)	5478 (419, 5056, 3)
Task agreement, %	97.14	95.42
Worker performance score, %	97.19	94.96

Table 2. Machine learning (ML) classifier type and reliability.

Prediction task	Firearm-related fatality	Mass shooting
Training data size, n	1142	1038
Holdout data size, n	286	256
Best ML classifier	Random forest	Random forest
F_1-score: cross-validation, test data, mean (SD)	0.91 (0.017)	0.88 (0.012)
F_1-score: holdout data	0.90	0.88

Geographic Area Estimation of Twitter Firearm-Fatality Discussion Volume

The NVSS classifies fatalities according to the geographic jurisdiction in which the fatality occurred. Thus, for comparison with the state-level NVSS estimates, the *location of the fatality* being discussed on Twitter is the location of interest (vs the location of the individual who is tweeting). We relied on the tweet content to identify the location of the fatality because location information from either profile information or tweet geocoding (which some users permit) identifies the location of the user (as opposed to location of the fatality).

Importantly, location mentions in tweets primarily refer to city names. In some cases, state name is also mentioned, whereas in other cases, state can be inferred from the city name. To obtain a reasonably sufficient number of tweets per location for estimating area-level fatality discussion volume, we focused on identifying the larger cities mentioned in tweets. Specifically, we identified tweets in our sample that mentioned any of the 250 most populous cities in 2018 (based on US Census data [35]). A limitation of this approach is that it focuses on fatalities in urban areas rather than in rural areas.

We augmented the list of 250 city names with alternative city names commonly used on social media, such as *nyc*, and with city names that contain no spaces between multiple words, such as *sanfrancisco*. We standardized posts—converting the text to lowercase and removing URLs, user mentions (words prefixed with @), and common phrases that may look as though they are city mentions when they are not. An example of a common phrase we removed is *drag queens* because it may be accidently mapped to Queens, New York City, New York. After standardization, we searched the text for city names that matched our location ontology. The majority of city names among the 250 are associated with, and can thus be reliably mapped to, a single state. For our specific set of tweets, there were no cities mentioned that mapped to multiple states.

We summed tweet discussion volume across the most populous cities within a state to create a state-level measure. We constructed state-level estimates for Arizona, California, Colorado, Florida, Georgia, Illinois, Indiana, Kentucky, Louisiana, Maryland, Massachusetts, Michigan, Missouri, Nevada, New Jersey, New York, North Carolina, Ohio, Pennsylvania, Tennessee, Texas, Virginia, Washington, and Wisconsin. We excluded from further analysis those states for which the sample size of tweets was <200 tweets after the mass shooting adjustments (described in the next paragraph) because they are home to only one or only a few of the more populous cities (eg, Idaho, Iowa, Nebraska, and Oregon), and the populous cities in the state are relatively small (eg, Kansas, Alabama, and Arkansas).

The resulting data set, after applying the best ML classifier to identify firearm-fatality tweets and identifying the state of the fatality using location mentions, included 31,747 tweets from 2017 and 44,779 from 2018. We summarized firearm-fatality discussion volume for each state using these data. We then adjusted the state-level estimates of firearm-fatality discussion volume in 3 ways. First, mass shooting events tend to generate disproportionately high levels of discussion, that is, levels of discussion that are far higher than for other less high-profile fatalities. We accounted for the potential distorting influence of mass shooting events on the relationship between a gun fatality and tweet discussion volume by excluding tweets from the location of mass shooting events for a period of 1 week after the event. We based the 1-week exclusion period on observed trends in mass shooting discussion volume. We identified mass shooting events during the time frame of our data using information from the Gun Violence Archive [37], Everytown Research [38], and The Violence Project [39]. Finally, we adjusted our estimates of state-level discussion volume by the percentage of the state-level population that uses Twitter [40].

We tested for serial correlation and found that the NVSS data contained 10 states in our final data set with some moderate serial correlation, and the Twitter data contained 5 states with moderate serial correlation. For this reason, we made each time series stationary by differencing monthly estimates [41]; we refer to this as the *Change* result. For the level correlation, we removed states in which both time series had higher levels of serial correlation because the correlation is valid if one of the time series exhibits serial correlation and the other does not [42]. This issue arose with four states: Georgia, Indiana, Michigan, and North Carolina.

Results

Correlation Analysis

Table 3 shows results from our correlation analysis. We estimated the correlation within state by month between the *level* of firearm-fatality discussion volume and the *level* of NVSS-reported fatalities, as well as the correlation within each state in the monthly *change* in discussion volume versus the monthly *change* in the NVSS fatality rate.

Table 3. Results of correlation analysisa.

	Discussion volume	Discussion volume adjusted for average state-level Twitter use
LEVEL: Correlation, range	–0.293 to 0.535	–0.289 to 0.537
LEVEL: Correlation, mean; median	0.085; 0.091	0.087; 0.093
CHANGE: Correlation, range	–0.057 to 0.682	–0.059 to 0.688
CHANGE: Correlation, mean; median	0.313; 0.303	0.312; 0.301

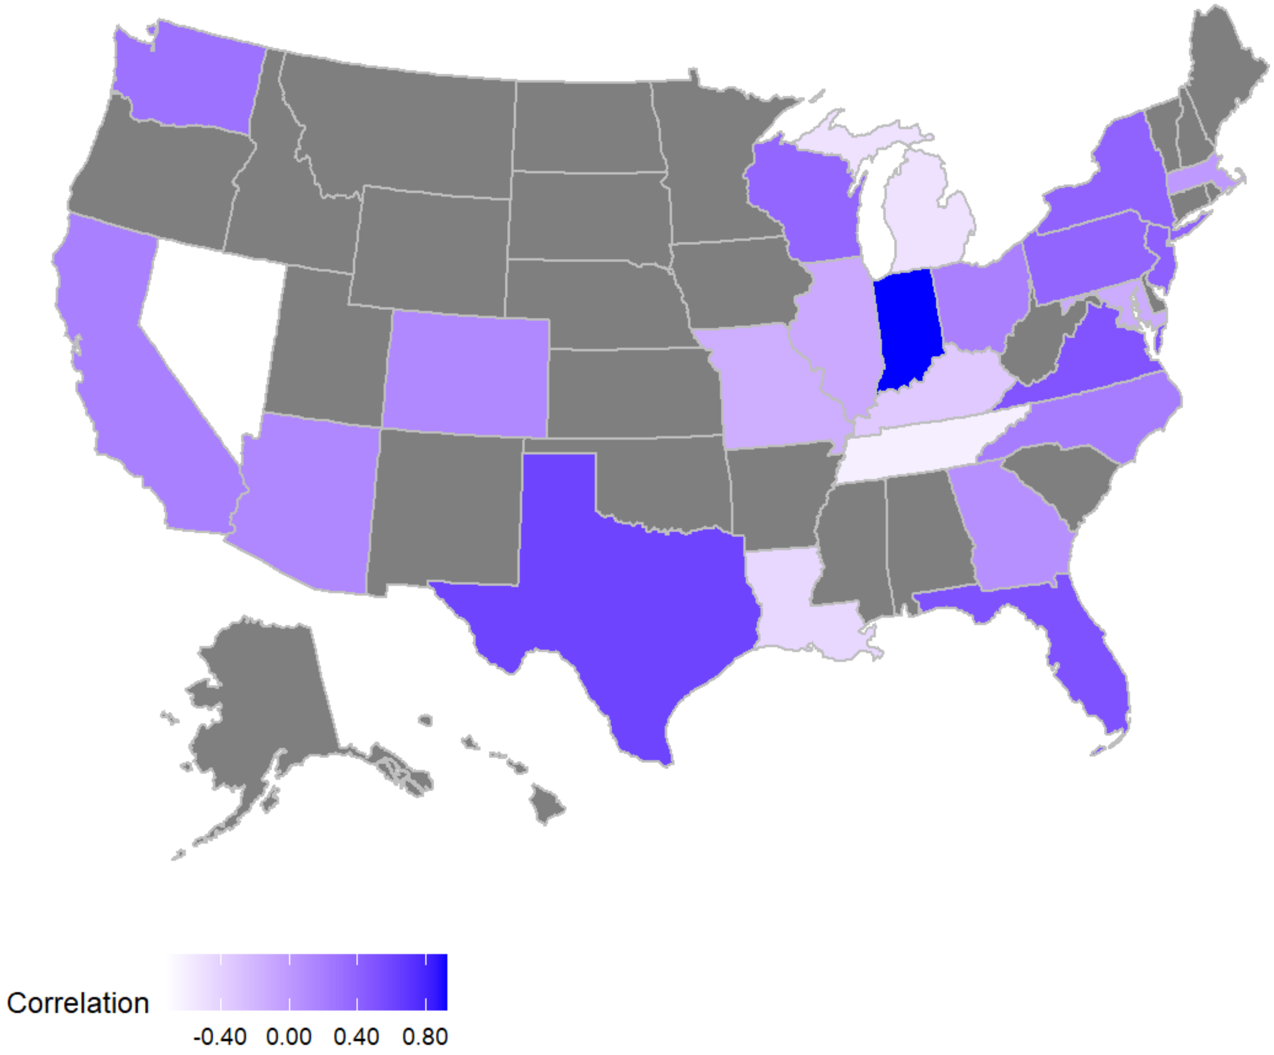
[a] Pearson linear correlations are reported.

The correlation between the monthly level of firearm-fatality tweets and the monthly number of fatalities measured by the NVSS is weak (median 0.081) and widely dispersed across states (range –0.31 to 0.54). The correlation between month-to-month changes in firearm fatalities discussed in tweets versus those estimated in the NVSS is moderate (median 0.30) and exhibited less dispersion among states than the monthly level correlations (range –0.057 to 0.68). For the correlation among month-to-month changes in firearm fatalities, almost half (11/24, 46%) of the states have correlations ranging from 0.1 to 0.4. More than a quarter (7/24, 29%) of the states have correlations below this range, and a quarter (6/24, 25%) have correlations above this range. The results for the adjusted discussion volume (second row of Table 3, discussion volume adjusted for Twitter use in the state) are very similar to the unadjusted results, with negligible differences observed in estimated correlation rates.

Figure 2 provides additional details for the correlation in monthly changes in fatality discussion volume and NVSS-estimated fatalities, with a depiction of state-by-state (adjusted) correlation rates for 2017. White-shaded states have no correlation. The darker the purple shade of a state, the higher the correlation. The gray-shaded states are those for which we were not able to estimate a Twitter fatality discussion rate (refer to the Twitter Data subsection under Methods). Not unexpectedly, the strength of the correlation seems to be related to the percentage of the state's population living in one of the most populous cities that we use in our location ontology; for example, one-third or more of the state population in Texas, New York, and Arizona reside in one of the top 100 most populated cities in the state (34%, 44%, and 51%, respectively). These states exhibit some of the highest correlation rates between monthly fluctuation in firearm-fatality discussion volume and NVSS-based fatality estimates. Likewise, Georgia, Michigan, and Maryland are among the states with both the lowest percentage of their population living in more populous cities (5%, 7% and 10%, respectively) and have some of the lowest rates of correlation among the states studied.

By contrast, 47% of Nevada residents live in one of the most populous cities, but the correlation rate in Nevada falls into a lower tier than the correlation rates in Texas, New York, and Arizona. Although we adjusted for mass shooting discussion volume by removing tweets from the week after such an event, the lower correlation observed in Nevada suggests that the adjustment may have been insufficient for capturing the extent of discussion volume distortion in the wake of the mass shooting event in Las Vegas, given the magnitude of the event. Analyzing the data in more detail shows that discussion of this shooting returns at anniversaries (1 year) and when other larger mass shootings occur in other parts of the country, identifying a need for a more extensive adjustment for historically large mass shootings.

Figure 2. Correlation by state between change in firearm–fatality tweets and change in National Vital Statistics System–estimated firearm fatalities in 2017.



Comparison of Correlations

Furthermore, a comparison of correlations for each state in 2017 versus 2018 shows that states with the largest cities tend to have the most stable correlations; for example, Texas, New York, California, Florida, and Ohio; whereas states with fewer large cities and fewer tweets tend to have higher variation in their correlation estimates; for example, Missouri, Tennessee, South Carolina, and Maryland. An additional factor that is likely to affect the correlation rate is the location within the state of firearm fatalities. To the extent that fatalities within a state are more concentrated in the most populated cities, the correlation between NVSS-estimated fatalities and Twitter discussion volume is expected to be higher.

Discussion

Principal Findings

Among the subset of states studied, we found weak-to-moderate correlation between our measure of the level of firearm-fatality tweets and the NVSS-based estimates of the level of firearm fatalities and higher moderate correlation in measures of the month-to-month changes in firearm-fatality tweets and estimated fatalities. As our ontology for Twitter location mentions relies on identification of the 250 most populous cities, our correlation is higher in states in which more of the state’s population was living in one of these cities. We further expected the correlation to be higher in areas where firearm fatalities were concentrated in the most populated cities and found suggestive evidence regarding this point.

A key limitation of this analysis is that we relied on tweets from more populated cities to develop a state-level estimate of discussion volume. Our approach reflected, dually, the limited availability of firearm-fatality data at the city level and the limited availability of location identifiers for tweets. An important feature of this analysis was the need to identify the location of the event being discussed versus the location of the user. In the case of the latter, geocoding of the user profile is advantageous and can provide a state-level identifier, but the former relies only on location mentions within the tweet.

Even with these limitations, the correlation capturing fluctuation in firearm mortality is moderate. We view this as a promising signal for the potential of social media data to provide meaningful information on gun-related outcomes in the future. More specifically, our findings suggest that Twitter data may hold particular value for tracking dynamics in gun-related outcomes. In addition, for location-specific firearm-related outcomes, the data are most valuable for understanding dynamics in relatively populous cities that are identifiable through location mentions in tweet content. Finally, the data are likely to be particularly valuable for understanding firearm outcomes not currently measured, not measured well, or not measurable through other available means. A key advantage of Twitter data is the continuous, automated, and near–real-time monitoring they provide [13]. Once big data infrastructure has been invested in, the data can be relatively easily processed. The initial cost of big data infrastructure can be high if researchers want to stream data for large periods of time. However, for a single study, researchers who can access a server should be able to conduct the analysis at a low cost. Because of this potentially higher investment, we have developed a text analytic portal that allows researchers to construct variables from our social media data [43], thereby enabling future research with these data without the cost of setting up big data infrastructure.

We recognize the need for additional analyses to continue to adapt and extend upon the approach developed and applied in this research, including, for example, work that assesses the reliability of associations over longer time periods. We also note that, unlike survey data that are sampled to be representative of the underlying population, social media data emanate from those who use a particular platform. Although the use of Twitter in the United States is significant (in 2021, nearly a quarter of adults reported using Twitter, and among those who reported using the platform, nearly half said that they use it once a day or more) [44], it is nonetheless also true that rates of social media use are correlated with age and to some extent with other demographic characteristics [44]. Much of the existing analytic work with social media data does not directly deal with this issue. In our approach, we adjusted our estimates for the percentage of Twitter users in each state. Additional statistical adjustments that more completely account for engagement with the platform are important for future work. Furthermore, social media data include limited sociodemographic information about users. Additional methodological strides toward developing robust methods for demographic imputations represent an important dimension of future efforts.

Usefulness of Social Media Data

The Centers for Disease Control and Prevention [45] describes its public health approach to prevention of violence, including firearm violence, as encompassing four steps: defining and monitoring the problem, identifying risk and protective factors, developing and testing prevention strategies, and assuring widespread adoption [46]. For firearm violence, the first step—building a foundation of information for describing the epidemiology of such violence—requires focused resources and development. In addition to recent developments in survey, administrative, and other data, such as the important efforts by news media and other organizations to track gun violence incidents in significant detail and the advent of data scraping from obituaries [37,47,48], social media data are a promising future source. This research provides an important building block for future work that continues to develop the usefulness of social media data, alone or in conjunction with other data resources, to strengthen the information base on which firearm research relies, and, more generally, contributes to the process of integrating emerging big data algorithms and traditional data sources for behavioral understanding, decision support, and evidence-based public policy.

As we build out the power of social media data for informing public health problems such as firearm violence, several important dimensions need to be kept in mind. The role that social media may play in exacerbating gun violence or spreading trauma related to gun violence cannot be ignored. However, these data can also be used to help target and improve our understanding of those who use guns and allow for new approaches to gun violence–prevention interventions [49]. To use these data to improve public health outcomes and our understanding of human beliefs and behaviors, we must spearhead establishing best practices for using social media data in ethical ways [50-52], as well as understanding representativeness, methodological limitations, and algorithmic biases.

Acknowledgments

This project was conducted at the Massive Data Institute (MDI) at Georgetown University, thanks to funding by the National Collaborative on Gun Violence Research and the MDI. The authors also thank Rebecca Vanarsdall and the MDI technical team for their support.

Authors' Contributions

LS and CRG conceptualized the project, led the team, and wrote the paper. YW and SH conducted the main analysis.

Abstract

Background: Health care utilization after coronary artery bypass graft (CABG) surgery is high and is partly of an unplanned nature. eHealth applications have been proposed to reduce care consumption, which involve and assist patients in their recovery. In this way, health care expenses could be reduced and quality of care could be improved.

Objective: The aim of this study was to evaluate if an eHealth program can reduce unplanned health care utilization and improve mental and physical health in the first 6 weeks after CABG surgery.

Methods: A single-blind randomized controlled trial was performed, in which patients scheduled for nonacute CABG surgery were included from a single center in the Netherlands between February 2020 and October 2021. Participants in the intervention group had, alongside standard care, access to an eHealth program consisting of online education videos and video consultations developed in conjunction with the Dutch Heart Foundation. The control group received standard care. The primary outcome was the volume and costs of a composite of unplanned health care utilization, including emergency department visits, outpatient clinic visits, rehospitalization, patient-initiated telephone consultations, and visits to a general practitioner, measured using the Medical Technology Assessment Medical Consumption Questionnaire. Patient-reported anxiety and recovery were also assessed. Intention-to-treat and "users-only" analyses were used.

Results: During the study period, 280 patients were enrolled and randomly allocated at a 1:1 ratio to the intervention or control group. The intention-to-treat analysis consisted of 136 and 135 patients in the intervention and control group, respectively. At 6 weeks, the primary endpoint had occurred in 43 of 136 (31.6%) patients in the intervention group and in 61 of 135 (45.2%) patients in the control group (hazard ratio 0.56, 95% CI 0.34-0.92). Recovery was faster in the intervention group, whereas anxiety was similar between study groups. "Users-only" analysis yielded similar results.

Conclusions: An eHealth strategy comprising educational videos and video consultations can reduce unplanned health care utilization and can aid in faster patient-reported recovery in patients following CABG surgery.

Introduction

Coronary artery bypass graft (CABG) surgery is one of the most frequently performed cardiac surgeries in the world, which is generally performed with good outcomes and relatively low 30-day mortality (~1.5%) [1]. In more recent years, the care chain for patients undergoing CABG surgery has been demonstrated to increase efficiency and reduce costs. As a result, the duration of hospitalization has decreased substantially, with patients discharged on the 7th postoperative day (mean). These efficiency-driven early discharge protocols require more self-management skills among patients. Early discharge reduces the time physicians can spend with their patients in the direct postoperative phase in spite of the well-known benefit of patient counseling and guidance through recovery [2,3].

After discharge, patients commonly experience anxiety or uncertainty about symptoms or appropriate physical exercise [4]. These issues are typically addressed during hospitalization; however, after discharge, patients' recall of information is often incomplete and they do not always know who to address with questions [4]. The advantages of a shortened hospital stay might therefore be counterbalanced by preventable unplanned health care utilization, especially since planned care is not initiated until several weeks after discharge. At present, nearly 1 in 7 patients are readmitted in the first 30 days after discharge for noncardiac causes and roughly 15% of patients visit the emergency department within 1 month after CABG surgery [5-8]. It was estimated that potentially preventable readmissions following CABG surgery cost Medicare US $151 million in 2005, placing a significant burden on society [7]. With the expected increase in the number of future patients undergoing CABG surgery, this is a pressing issue urging evaluation and a potential redesign of postoperative follow-up.

eHealth is defined by the World Health Organization as "the cost-effective and secure use of information and communication technologies in support of health and health-related fields," which encompasses multiple digital interventions that can aid in the delivery of patient-centered care and postoperative patient guidance, thereby potentially reducing unplanned health care utilization [9]. eHealth strategies have been successfully applied in postoperative follow-up in various forms, which have been shown to improve patient outcomes, speed recovery, and reduce health care utilization in various surgical populations [10]. In addition, eHealth has proven to be of value for patients to enhance their self-management through better understanding of their disease, increased independence, and improved acceptance to adhere to lifestyle advice [3,11]. However, experience with eHealth in patients following CABG surgery is limited, and it remains unclear if eHealth strategies would be effective in this population.

The objective of this trial was to fill this knowledge and experience gap. We hypothesized that restructuring the postoperative period with an eHealth strategy will reduce unplanned health care utilization through improved mental and physical health and faster recovery.

Methods

Trial Design

The IMPROV-ED trial was a randomized controlled trial (RCT) performed between February 2020 and December 2021 at Catharina Hospital in the Netherlands. A detailed study protocol was published prior to enrollment of the first study participant [11]. No changes were made to the study protocol between publication and initiation of the trial. The trial is reported using the CONSORT (Consolidated Standards of Reporting Trials) checklist for RCTs [12].

Ethics Considerations

The study was approved by the medical ethics committee (R19.100) and was registered in the Netherlands Trial Registry (NL8510). Written informed consent was obtained from all patients who met the inclusion criteria and were willing to participate.

Participants

To minimize selection bias, all patients on the waiting list for isolated CABG surgery over 18 years of age were contacted by telephone and informed about the study by one of the investigators. Patients were eligible for participation if they had access to a computer/tablet/smartphone with internet connection and a webcam/built-in camera; had sufficient knowledge of the use of internet and email (assistance was allowed); and were able to speak, read, and interpret the Dutch language. The eHealth strategy would not be applicable to patients who did not comply with these inclusion criteria and they were therefore not eligible for participation. At inclusion, patients were randomized 1:1 to the intervention or control group using a block size of 4. A certified program was used for sequence generation and randomization (Research Manager). When a patient was randomized but no longer qualified for the inclusion criteria or was lost to follow-up, the patient was excluded from further follow-up and analysis.

Interventions

Patients randomized to the control group received standard postoperative care, comprising planned outpatient follow-up by their cardiothoracic surgeon at 6-8 weeks after discharge and a cardiac rehabilitation program supervised by cardiologists with outpatient follow-up starting between 4 and 8 weeks after surgery. As a result of the COVID-19 health crisis and the measures taken by the government, most of these contacts were telephone consultations (TCs) rather than physical consultations.

Patients randomized to the intervention group had access to the eHealth strategy in addition to standard care. The eHealth strategy comprised web-based educational videos developed by the Dutch Heart Foundation and two postoperative video consultations (VCs) with a physician from the department of cardiothoracic surgery at 1 and 3 weeks after discharge.

Upon randomization, patients in the intervention group received access to the educational videos via a link sent by email. The same link was sent via email again at discharge. By clicking the link, patients were referred to a hidden (for nonparticipants and the control group) part of the website from the Dutch Heart Foundation that contained the educational videos. The content of the educational videos was constructed and validated by physicians and patient representatives prior to the trial. Based on these evaluations and a scoping review of the literature on delivery of information to patients with varying degrees of health literacy, the full content was delivered to patients at inclusion instead of by fragmentized access to videos applicable to the patient's situation [13]. Nevertheless, to prevent cognitive overload in patients with low health literacy, educational videos were categorized in three categories: treatment (10 videos with information on the surgery and how to prepare for admission), recovery (6 videos about what to expect in the postoperative course and when to contact a physician), and healthy living (2 videos on cardiovascular risk management, including smoking cessation, weight reduction, cholesterol management, and exercise). The videos were delivered in spoken text supported by animations for optimal health communication to patients with low and adequate health literacy [13]. Usage data were extracted from the web log for evaluation purposes. Educational videos were available to patients in the intervention group throughout the trial (ie, not only when the link was sent). See the published study protocol for an illustrative overview of the educational videos [11].

VCs were conducted by a nurse practitioner or junior doctor using Microsoft Teams. The dates for VCs were sent to patients by email at discharge. On the day of the VC, patients received an email with a link providing access to the VC. The VC was not scheduled on the same day as routine outpatient follow-up. During the VCs, patients were questioned about their recovery and physical and mental complaints. The sternotomy wound was visually inspected. Patients who required physical examination or diagnostic tests based on the VC were instructed to visit the general practitioner or emergency department, or were scheduled for early outpatient follow-up (within 1 week) at discretion of the physician. The nurse practitioner/junior doctor who conducted the VCs was blinded to the study's objectives and outcomes. Study participants were not blinded. If a VC was unexpectedly not possible (eg, due to unforeseen connection errors, problems with hardware, technical issues), the VC was replaced by a TC. Reasons for replaced VC were reported.

Outcomes

The primary outcomes of the IMPROV-ED trial were the volume and costs of unplanned health care utilization defined by a composite of all emergency department visits, outpatient clinic visits, rehospitalization, patient-initiated TCs, and visits to a general practitioner, as measured by the Institute for Medical Technology Assessment Medical Consumption Questionnaire (iMCQ) at the 6-week follow-up [14]. Cross-validation with the patients' reported health care utilization was performed by contacting their health care providers. The secondary outcomes were the individual unplanned health care activities, and a composite of planned and unplanned in-hospital care (emergency department visits, outpatient clinic visits, rehospitalization, and patient-initiated TCs) and planned and unplanned primary care (consultations with a general practitioner, allied health professionals, psychologists) at 6 weeks. The other secondary outcomes were the patients' self-reported physical and mental health, as measured with the Hospital Anxiety and Depression Scale (HADS) and Recovery Index-10 (RI-10) questionnaires [15,16].

Data Collection

All patients received questionnaires at inclusion (anxiety subscale of the HADS), at discharge (HADS and RI-10), 1 week after discharge (HADS and RI-10), 2 weeks after discharge (HADS and RI-10), and 6 weeks after discharge (HADS, RI-10, and iMCQ). Only the anxiety subscale from the HADS was used. A higher score indicated more symptoms of anxiety (HADS maximum score 21) or favorable progress of recovery (RI-10 maximum score 50). The iMCQ resulted in absolute frequencies of visits for the questioned care activities. Patients in the intervention group also received a self-made questionnaire to evaluate the eHealth strategy and to question them about the use of the education videos (see Figures S1 and S2 in Multimedia Appendix 1). If patients had not returned the iMCQ by 8 weeks postdischarge, the questionnaire was conducted over the telephone. If patients had not returned 2 subsequent questionnaires, a research nurse called patients with a reminder. Questionnaires that were not returned or collected otherwise were considered missing.

Statistical Analysis

We calculated the sample size needed for the study based on the expected effect of the intervention on the primary outcome. Previous studies using a comparable eHealth strategy in CABG patients with health care utilization measured with the iMCQ were not available. In a study with abdominal surgery patients, total health care utilization was estimated at a mean of 0.88 (SD 0.15) per patient [17]. In a systematic review by van der Meij et al [10], the effect of an eHealth strategy in surgical patients was not consistent. Therefore, a small to medium effect (d=0.35) was expected from our intervention. Combined with an α of .05 and a power of 0.80, a total sample size of 260 patients was required. We aimed for 280 participants to account for loss to follow-up and nonadherence to the intervention and return of questionnaires (attrition rate 5%, rounded up to a whole number). Demographic data of randomized patients were collected using definitions in line with the Netherlands Heart Registration [18]. Education was grouped into three levels (low, medium, and high) according to the general definition by Statistics Netherlands (see Multimedia Appendix 1 for the full definition).

The main analysis was performed according to the intention-to-treat (ITT) principle. Because patients in the intervention group were not obliged to use the educational videos and VCs might not be possible due to technical errors, per-protocol analysis was also performed, which included only patients who used the intervention strategy as intended (defined as having at least one VC or TC and accessed the educational videos at least once).

Planned subgroup analyses of the primary outcome were performed according to age (<65 years vs ≥65 years), sex, recent myocardial infarction, left ventricular function, diabetes, type of CABG (on-pump vs off-pump), log EuroScore, and highest level of education.

Continuous variables and outcomes are expressed as mean (SD) in cases of a normal distribution and as median (IQR) in cases of a nonnormal distribution. The Kolmogorov-Smirnov test and Q-Q plots were used to test for normality of the data distribution. Categorical data are summarized as absolute and relative frequencies. The updated Dutch Manual for Cost Analysis in Health Care Research was used as the source for cost prices per health care activity if available [19]. Other tariffs were calculated using top-down microcosting as described by Tan and Hakkaart-van Roijen et al [20, 21] (see Multimedia Appendix 1 for details). Each consumed health care activity was multiplied by the cost price and total costs were calculated by summing these multiplications. The HADS and RI-10 questionnaire scores at each interval were compared between study groups. *P*<.05 was considered significant. Primary and secondary outcomes are presented with effect-size estimates and 95% CIs using the Cox proportional hazards model. The proportional hazard assumption was assessed by log (–log) plots. Analyses were performed using SPSS 25 and RStudio.

Results

Study Population

In total, 280 patients were included in the study between February 2020 and December 2021, and subsequently randomized yielding 140 patients in each study group. One patient in the intervention group and two patients in the control group were excluded after randomization because they underwent percutaneous coronary intervention instead of CABG surgery. In the intervention group, three patients were lost to follow-up (1 withdrew consent, 1 had an early readmission due to a complication, and 1 died). In the control group, three patients were lost to follow-up (1 withdrew consent and 2 died). The ITT analysis therefore consisted of 136 and 135 patients in the intervention and control group, respectively. Weblog and planning data revealed that 8 patients did not use the intervention as intended, whereby 128 patients were included in the intervention group in the per-protocol analysis (Figure 1).

Baseline characteristics of patients were similar in the two groups (Table 1), with a median age of 67.9 and 69.6 years for the intervention and control group, respectively. The majority of patients were male in both groups. At the time of surgery, 25% of patients had an urgent indication and the remainder underwent surgery in the elective setting. In the majority of patients, on-pump CABG was performed using 3 distal anastomoses. The left or right internal mammary artery was used in >98% of patients. Duration of admission was also similar in the two groups (Table 1).

Figure 1. Enrollment overview. CABG: coronary artery bypass graft; PCI: percutaneous coronary intervention.

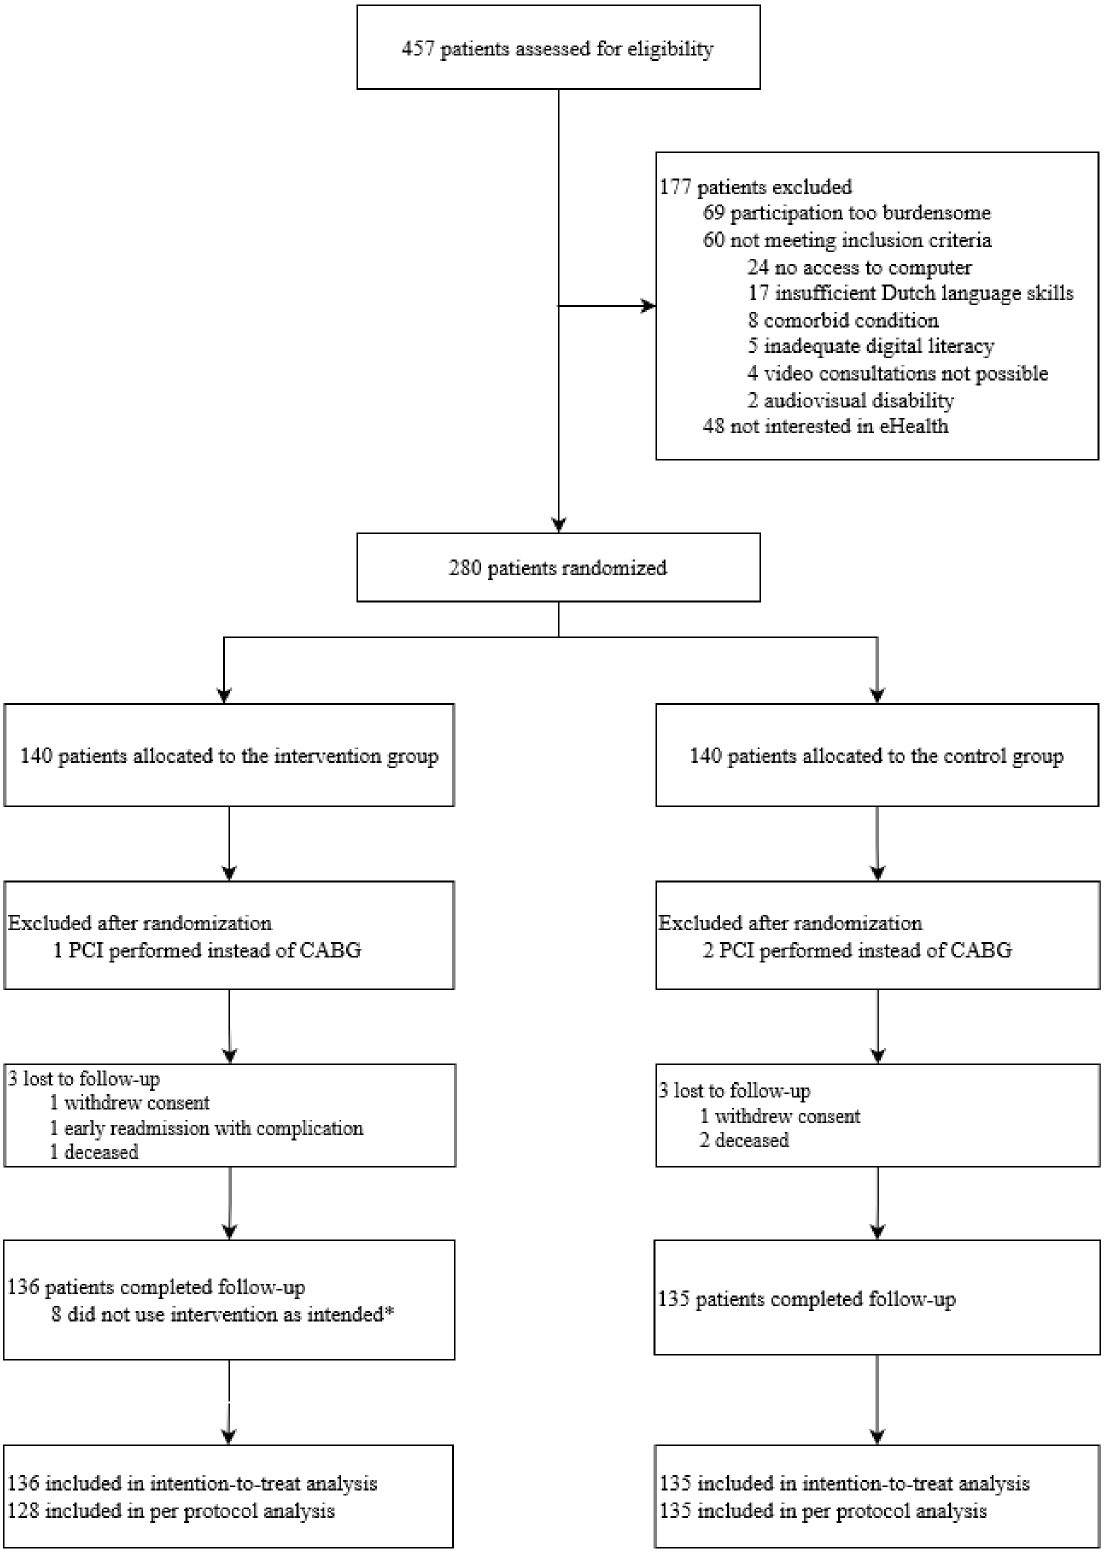

Table 1. Baseline characteristics and procedural data (intention-to-treat analysis).

Characteristics	eHealth group (n=136)	Standard care (n=135)
Age (years), median (IQR)	67.9 (61.5-73.3)	69.6 (65.2-74.1)
Male, n (%)	121 (89.6)	113 (83.1)
BMI, median (IQR)	27.7 (25.1-30.6)	27.2 (25.2-30.3)
Medical history, n (%)		
Diabetes mellitus	45 (33.3)	33 (24.3)

[a] MDRD: Modification of Diet in Renal Disease.

[b] MI: myocardial infarction.

[c] PCI: percutaneous coronary intervention.

[d] NYHA: New York Heart Association.

[e] SF-36: Short Item-36.

[f] HADS: Hospital Anxiety and Depression Scale.

[g] ECC: extracorporeal circulation.

Outcomes

At 6 weeks, care was consumed by less patients in the intervention group than in the control group (Table 2). The benefit of the eHealth strategy was most noticeable in patients over 65 years of age, those of male sex, those with recent myocardial infarction, or with a EuroScore>2 (see Figure S3 in Multimedia Appendix 1). Reduction in individual care activities was significantly different between groups for TCs and was borderline significant for general practitioner visits (Table 2).

Costs related to the primary outcome were significantly higher in the standard care group compared with those in the eHealth group (*P*<.001, Table 2), which was attributed to the higher volume of care consumption in the control group (see Table S1 in Multimedia Appendix 1).

A composite of unplanned in-hospital care, a composite of planned and unplanned in-hospital care after discharge, and use of planned and unplanned primary care were all higher in the control group than the intervention group (Table 2). The volume of consumed care was also higher in the control group (Table S1 of Multimedia Appendix 1).

The RI-10 score, indicating patient-reported recovery, was significantly higher in the intervention group in the 3rd and 6th weeks after discharge (Figure 2). Anxiety was not significantly different between study groups (Figure 2). Per-protocol analysis revealed similar findings (see Tables S2 and S3 in Multimedia Appendix 1).

Table 2. Outcomes at 6 weeks.

Outcomes	eHealth group (n=136)	Standard care (n=135)	Hazard ratio (95% CI)	*P* value
Primary outcomes				
Composite outcome[a], n (%)	43 (31.6)	61 (45.2)	0.56 (0.34-0.92)	.02
Cost (Euro[b]), Median (IQR)	0 (0-95)	66 (0-215)	N/A[c]	<.001
Cost (Euro), mean (SD)	183 (515)	285 (777)	N/A	<.001
Secondary outcomes, n (%)				
Composite unplanned in-hospital care	36 (26.5)	53 (39.3)	0.56 (0.33-0.93)	.03
Emergency department visits	14 (10.3)	23 (17.0)	0.56 (0.27-1.14)	.11
Readmissions	7 (5.1)	9 (6.7)	0.76 (0.28-2.10)	.59
Outpatient clinic visits	11 (8.1)	10 (7.4)	1.10 (0.45-2.68)	.83
Telephone consultations	29 (21.3)	47 (34.8)	0.51 (0.29-0.87)	.01
General practitioner visits (unplanned)	28 (20.6)	41 (30.4)	0.59 (0.34-1.04)	.07
Composite of all in-hospital care[d]	69 (50.7)	97 (71.9)	0.40 (0.24-0.67)	<.001
Composite of all primary care[e]	82 (60.3)	101 (74.8)	0.58 (0.36-0.97)	.04

[a] Composite of unplanned health care utilization (ie, emergency department visits, readmissions, outpatient clinic visits, telephone consultations, or general practitioner visits).

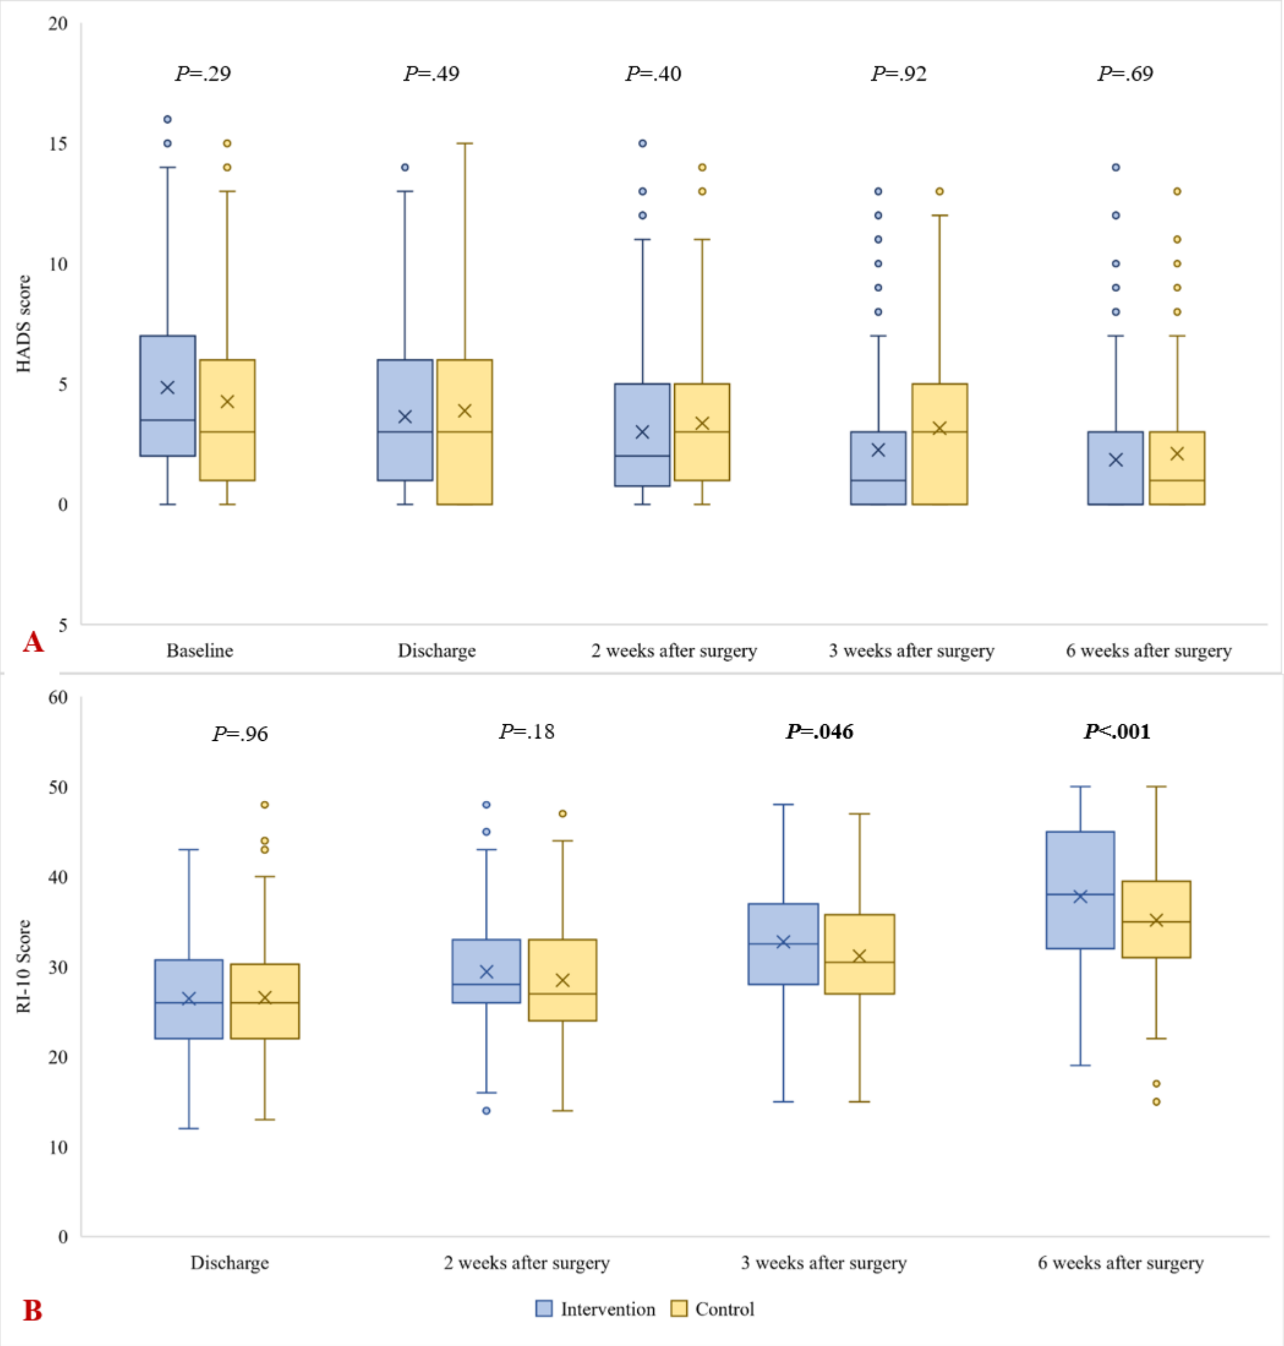
[b] 1 Euro=US $1.13.

[c] N/A: not applicable.

[d] Composite of in-hospital care comprising planned and unplanned emergency department visits, readmissions, outpatient clinic visits, and telephone consultations.

[e] Composite of primary care comprising planned and unplanned visits to the general practitioner, visits to allied health professionals (physical therapists, dieticians, speech therapists, exercise therapy, social workers), and psychologist visits.

Figure 2. Anxiety level measured with the Hospital Anxiety and Depression Scale (HADS) anxiety subscale (A) and progress of recovery measured using the recovery index-10 (RI-10) questionnaire (B).



Process Evaluation

Among patients who were provided access to the educational videos, 95% accessed the videos at least once. A total of 248 of the 272 planned VCs were conducted. Eight patients did not use the intervention as intended and did not receive VCs (n=16 VCs). The other VCs that did not take place were substituted with a TC due to technical errors (n=8). The median duration of VCs was 10 minutes (IQR 8-11) for the first VC and was 8 minutes (IQR 7-9) for the second VC. Patients reported positive attitudes toward the education videos and the VC (Figures S1 and S2 in Multimedia Appendix 1). Most notably, patients reported a fairly positive attitude toward substitution of a face-to-face contact with a VC, but patients also reported that the VC with a physician (not the surgeon) or nurse practitioner should not substitute the consultation with the surgeon.

Discussion

Principal Findings

The principal finding of the IMPROV-ED trial is that an eHealth strategy comprising educational videos and VCs results in a reduction of unplanned care and costs. In addition, the eHealth strategy is associated with faster patient-reported recovery. These findings are of medical and societal importance given the increasing interest in digital health and the need for value-based alongside evidence-based care. Our study is the first to provide robust evidence that an eHealth intervention can aid in reduction of health care utilization and associated costs. This effect appears applicable to both in-hospital care as well as primary care. One of the most pressing concerns from health care insurance companies and decision-makers toward eHealth is the great investment that is required for development of content and the necessary infrastructure and issues that arise after implementation due to lack of reimbursement options [22]. Our findings refute these concerns by showing positive effects on costs. Furthermore, the eHealth strategy did not only contribute to less patients consuming care (Table 2) but also reduced the care consumed per patient (Table S1 of Multimedia Appendix 1), which underlines the high potential of eHealth strategies for this patient population to also positively influence the burden on health care personnel. With an aging population, a vast increase in health care consumption is expected in the near future. Based on the results of our study, an eHealth program is proven to aid in the sustainment of health care systems.

The findings of our study shine new light on previous studies comparing an eHealth program with standard care because it is the first study to use health care utilization as a primary outcome [10]. Very limited studies are available that use health care utilization as an outcome, and those that have considered care consumption as a secondary or tertiary outcome. Previous studies were also not adequately powered to draw reliable conclusions on the use of eHealth in reduction of care consumption and, consequently, these studies reported mixed outcomes. For example, Keeping-Burke et al [23] incorporated health care use as a tertiary outcome in an RCT of patients after CABG surgery using postoperative VCs, and concluded that patients in the telehealth group had fewer physician contacts. Zahlmann et al [24] used telecommunication in the postoperative period after cataract surgery (n=62) and also concluded that care in the intervention group was lower than that in the control group. Conversely, Barnason et al [25,26] conducted two RCTs in 232 and 50 CABG patients, respectively, using a supportive telehealth program and concluded that both groups had similar health care use at 6-month follow-up. Barnason et al [25] and Keeping-Burke et al [23] both reported no differences in emergency department visits and readmissions between study groups. Readmission was also similar in a study by Gandsas et al [27] after laparoscopic gastric bypass using robotic telerounding during admission.

Another major strength of the current eHealth program is that it provides patients of various degrees of socioeconomic status and health literacy with information on the procedure and their medical condition from a reliable source that is endorsed by their surgeon. The Dutch Heart Foundation is a respected organization that is dedicated to providing information on cardiovascular health, advocating patient interests, and conducting research [28]. The educational videos are developed in conjunction with patient representatives and physicians. In the VCs, additional questions are answered and uncertainties are addressed. The impact of educational videos and VCs is presumably in improvement of self-management skills and reduction of fear and anxiety. Recall of information on information provided preoperatively or at discharge is often incomplete, and patients might not know what physical activity is allowed after discharge or who to contact in case of complaints. Patients can turn to the internet for information; however, this information is uncontrolled, sometimes inaccurate, and is not tailored to the care processes of their provider. Because planned care is not initiated until 6 weeks after surgery (and sometimes later in practice), conflicting advice can induce insecurity, which will lead to use of care and will hamper recovery. The results of our study are consistent with this hypothesis. Nevertheless, the anxiety symptoms measured with the HADS questionnaire relate to anxiety in a narrow sense, whereas the anxiety experienced by patients after CABG surgery is likely to be more subtle in nature, which may have contributed to the nonsignificant difference in measured anxiety found in this study.

However, health care utilization is the resultant of a multifactorial behavioral model that attributes a combination of predisposing factors (eg, patient characteristics such as age, sex, sociodemographic parameters, or health literacy and attitude toward health), enabling factors (eg, income, health insurance status, health care organization), and need factors (eg, experience with health care) to health care utilization [29]. The eHealth strategy used in the IMPROV-ED trial has a positive influence on some of these attributes but not all. Interestingly, subgroup analysis showed that the eHealth program had a greater benefit in more vulnerable patients (EuroScore≥2) and revealed a trend toward more benefit in patients with a low level of education. By contrast, a small group of patients who provided informed consent did not use the educational videos or VCs that were part of the eHealth strategy. These patients reported to have received sufficient information from their physician, nurse, or paramedic during admission, or that they found the relevant information online themselves. It might therefore be reasonable to consider adding different modes of digital health delivery to the currently used eHealth strategy (eg, mobile apps, live chat, home monitoring, telerehabilitation) to manage more attributes of health utilization and to offer a more individualized approach tailored to the patients' needs. Combining different modes of digital care might thereby further reduce health care utilization and potentially also improve clinical outcomes [22].

Learning Points and Limitations

Even though the IMPROV-ED study yielded positive results toward the primary outcome (Table 2) and patients were generally positive about the eHealth strategy (Figures S2 and S3 in Multimedia Appendix 1), several learning points and limitations should be taken into account for future eHealth programs.

First, the IMPROVE-ED trial is designed for patients who consume care as a result of insecurity, anxiety, lack of medical knowledge, and/or inadequate discharge counseling. As can be concluded from Figure 1, a relevant number of patients who were invited to participate in the trial did not provide informed consent due to the general burden of having to undergo cardiac surgery (patients used terms such as "stressful," "anxiety," and "insecurity") in conjunction with study obligations. The effect of the eHealth strategy may be underestimated because this group of patients might have been part of the target population in which the eHealth strategy would have incremental value.

Due to ethical constraints (patients did not provide informed consent for participation and thus for data collection), these patients were not further analyzed for the study outcomes.

In this study, standard care was not replaced by digital alternatives, and yet the costs of the intervention group were still lower than those of the control group receiving only standard care. Because VCs were used as an add-on to standard care, there are potentially more opportunities to reduce costs further. The fact that eHealth is being implemented *on top* of current health care services is, in addition to cost concerns, one of the challenges identified by the European Society of Cardiology as hampering the introduction of eHealth into everyday clinical practice [22]. Future endeavors should focus on investigating the potential of substitution of standard physical care with digital alternatives, especially since the patients' attitude was generally positive toward the (hypothetical) substitution of a physical contact with a VC in this study (Figure S1 of Multimedia Appendix 1). Previous studies also stated that it is feasible to obtain the same effective communication and interaction with VCs as with face-to-face care [30].

The majority of patients included in the IMPROV-ED trial were included during the COVID-19 pandemic. The results of the study might therefore be an underrepresentation of care consumption because patients feared transmission in the hospital setting [31]. Nevertheless, the randomized design balances this influence between the study groups.

Conclusion

An eHealth strategy comprising educational videos and VCs can reduce unplanned in-hospital and primary health care utilization and costs, and can aid in faster patient-reported recovery following CABG surgery.

Abstract

Background: The ever-growing amount of health information available on the web is increasing the demand for tools providing personalized and actionable health information. Such tools include symptom checkers that provide users with a potential diagnosis after responding to a set of probes about their symptoms. Although the potential for their utility is great, little is known about such tools' actual use and effects.

Objective: We aimed to understand who uses a web-based artificial intelligence–powered symptom checker and its purposes, how they evaluate the experience of the web-based interview and quality of the information, what they intend to do with the recommendation, and predictors of future use.

Methods: Cross-sectional survey of web-based health information seekers following the completion of a symptom checker visit (N=2437). Measures of comprehensibility, confidence, usefulness, health-related anxiety, empowerment, and intention to use in the future were assessed. ANOVAs and the Wilcoxon rank sum test examined mean outcome differences in racial, ethnic, and sex groups. The relationship between perceptions of the symptom checker and intention to follow recommended actions was assessed using multilevel logistic regression.

Results: Buoy users were well-educated (1384/1704, 81.22% college or higher), primarily White (1227/1693, 72.47%), and female (2069/2437, 84.89%). Most had insurance (1449/1630, 88.89%), a regular health care provider (1307/1709, 76.48%), and reported good health (1000/1703, 58.72%). Three types of symptoms—pain (855/2437, 35.08%), gynecological issues (293/2437, 12.02%), and masses or lumps (204/2437, 8.37%)—accounted for almost half (1352/2437, 55.48%) of site visits. Buoy's top three primary recommendations split across less-serious triage categories: primary care physician in 2 weeks (754/2141, 35.22%), self-treatment (452/2141, 21.11%), and primary care in 1 to 2 days (373/2141, 17.42%). Common diagnoses were musculoskeletal (303/2437, 12.43%), gynecological (304/2437, 12.47%) and skin conditions (297/2437, 12.19%), and infectious diseases (300/2437, 12.31%). Users generally reported high confidence in Buoy, found it useful and easy to understand, and said that Buoy made them feel less anxious and more empowered to seek medical help. Users for whom Buoy recommended "Waiting/Watching" or "Self-Treatment" had strongest intentions to comply, whereas those advised to seek primary care had weaker intentions. Compared with White users, Latino and Black users had significantly more confidence in Buoy ($P<.05$), and the former also found it significantly more useful ($P<.05$). Latino (odds ratio 1.96, 95% CI 1.22-3.25) and Black (odds ratio 2.37, 95% CI 1.57-3.66) users also had stronger intentions to discuss recommendations with a provider than White users.

Conclusions: Results demonstrate the potential utility of a web-based health information tool to empower people to seek care and reduce health-related anxiety. However, despite encouraging results suggesting the tool may fulfill unmet health information needs among women and Black and Latino adults, analyses of the user base illustrate persistent second-level digital divide effects.

Introduction

Background

The ever-growing amount of health information available on the web is increasing the demand for tools that provide personalized and actionable health information. In addition, patients avidly seek information to inform their own health care decisions, either directly or by verifying information discussed during professional consultations. The broad scope of web-based health information includes generic information obtained through web-based searches and decision aids and tools that deliver personalized advice based on information specific to users. Such tools include symptom checkers that provide users with a potential diagnosis after responding to a set of probes about their symptoms.

Web-based symptom checkers are becoming increasingly popular, and the emergence of the COVID-19 pandemic has increased interest in these tools [1]. However, only a few studies have examined how and why they are used [2-4]. The limited research on symptom checkers has found generally positive effects of their use; technologically sophisticated web-based triage systems may help reduce unnecessary visits to emergency rooms and overuse of antibiotics [4], make health care accessible in low-resource settings [5], and increase patient engagement [6]. However, although the potential for their utility is great, more research is needed on the actual use and effects of such tools.

Some studies have raised concerns about the potential of web-based health information systems to spread disinformation and inaccurate diagnostic information [2,7,8]. For example, a study evaluating the diagnostic and triage accuracy of 23 web-based symptom checkers found that physicians performed better than the symptom checker algorithms [4]. However, physicians made incorrect diagnoses in 15% of the cases. Although research suggests that symptom checkers may be less effective than physicians in terms of diagnostic accuracy, it might be more critical that symptom checkers provide recommended actions (eg, whether symptoms warrant a trip to the hospital). Therefore, it is important to understand the impact of symptom checkers on how patients seek care and respond to health care advice.

A significant potential contribution of web-based symptom checkers as triage systems may be to reduce the negative effects of the current overwhelming health information environment, such as the health information overload experienced by web-based health information seekers and their struggle to discern reliable information from misinformation. A web-based medical information system that addresses the abovementioned problems can help people better understand the potential causes of the symptoms they are experiencing, empower them to seek the right kind of help, and potentially reduce anxiety caused by the symptoms they are experiencing.

Users must be able to trust and follow their recommendations for web-based symptom checkers to make meaningful contributions. If web-based symptom checkers are not trusted, they are less likely to be adopted by users, thereby limiting their potential [9]. Moreover, users may be unclear about the technology behind web-based symptom checkers. Research suggests that web-based symptom checkers' artificial intelligence (AI) systems are neither transparent nor comprehensible to users, which may undermine trust in such tools [10]. Nevertheless, despite hesitancy and concerns regarding the accuracy, AI-powered symptom checkers have been perceived as useful for diagnosis by users [11].

A large body of research on information seeking grounded in the uses and gratification frameworks [12] has examined how people use different media to fulfill or gratify various needs. Research in this tradition has characterized health information–seeking behaviors by sources (ie, web-based vs offline seeking [13,14]) or objective (ie, seeking for themselves vs others [15-17]). Multiple studies have confirmed that active information seekers from nonclinical sources, including the internet, are more likely to be White, female, and have relatively high levels of education and income [18-22]. Racial differences in health information–seeking, as well as confidence in information and trust in various sources, have been well documented. There may be different levels of trust and use of sources by racial groups, which can lead to disparities if inaccurate sources are used [23].

Research based on self-reported media use has established that deliberate information seeking from media, including the internet, has been associated with better health outcomes [24], increased engagement in prevention behaviors [25], and more positive patient-clinician interactions [26-28] and has also assisted individuals in coping with uncertainty [20]. Web-based health information–seeking before presenting to an emergency physician also has the potential to improve patient-provider interaction without negatively affecting adherence to treatment [29].

Despite this extensive body of research on information seeking and the importance of the internet and other "new" media as sources of medical information, the quality of the evidence for the effects has been limited. Most previous studies examining information seeking from nonclinical sources, including nearly all internet-based health information–seeking studies, are limited by their reliance on self-reports of individuals' information-seeking behaviors and behavioral or psychosocial outcomes. Furthermore, most studies rely on generalized, non–time-bound health information–seeking behaviors (ie, "Have you ever looked for information about [a topic] from [a source]”), or ask about information seeking within a specific timeframe, but do not examine the content of the information retrieved or the recommendation provided. Thus, the next frontier in this line of research is one that links objective measures of information seeking—both sources and content—with clinical and psychosocial outcomes to understand how people use the information they seek and find from nontraditional sources.

Objectives

This study aimed to address the methodological limitations of prior information-seeking research and examine who seeks information from an intelligent web-based symptom checker and for what purpose, how users experience the tool, what they intend to do with the information, and predictors of intentions to follow the tool recommendations. The following research questions (RQs) guided this study:

1. RQ1: Who uses a web-based symptom checker?
2. RQ2: What drives users to use a web-based symptom checker?
3. RQ3: What were the web-based symptom checker’s recommendations?
4. RQ4: How do users perceive the web-based symptom checker?
5. RQ5: What is the relationship between perceptions of a web-based symptom checker and intention to follow recommended actions?

Methods

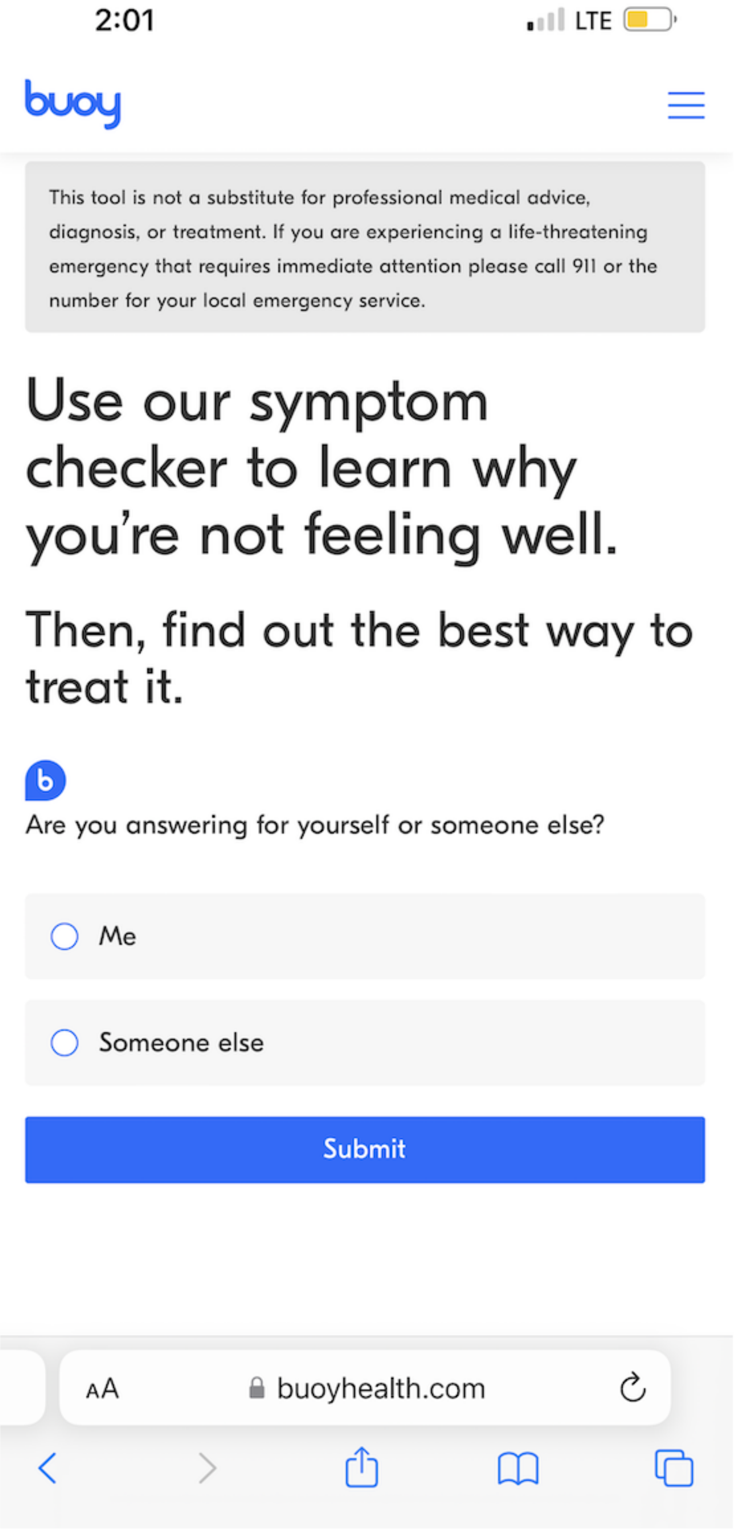
We conducted a cross-sectional survey of web-based health information seekers immediately following the completion of a visit to a web-based intelligent symptom checker, Buoy Health (Buoy Health, Inc [30]; N=2437).

Buoy Health: an AI-Powered Web-Based Symptom Checker

This cross-sectional study used data from patient encounters using Buoy Health, an AI-powered web-based symptom checker, between January 14, 2019, and February 28, 2019. Founded in 2014 by a team of physicians and researchers, the tool is based on conversational medical interviewing, mirroring a conversation with a provider. At the time of writing, Buoy’s symptom checker remains accessible for free on the web or through an app to any internet-connected person. The AI-powered tool uses a progressive series of health questions communicated via a chatbot to assess user symptoms (Figure 1). Buoy’s triage or diagnostic system by design offers health information customized for the user.

Buoy’s proprietary algorithm sources data from >18,000 clinical research studies [31]. Users receive 3 possible diagnoses and recommendations for appropriate levels of care (Figure 2). According to Buoy, the tool’s diagnostic accuracy is 90% [32]. Thus, tools such as Buoy—and other intelligent symptom checkers—have the potential to cut through the clutter of too much and contradictory information to provide personalized, science-based recommendations. A study examining how patients’ use of Buoy affected their plans for seeking care found that Buoy decreased uncertainty among users [33]. Buoy also lowered the level of urgency in patients associated with their condition. This study suggests tools such as Buoy are associated with users’ intended behavior when seeking care based on triage questions. Accordingly, our study adds to the growing literature that seeks to understand how patients use tools such as Buoy together with their providers to manage their health.

Figure 1. Screenshot of the patient-facing, artificial intelligence–assisted Buoy Health symptom checker.



This tool is not a substitute for professional medical advice, diagnosis, or treatment. If you are experiencing a life-threatening emergency that requires immediate attention please call 911 or the number for your local emergency service.

Use our symptom checker to learn why you’re not feeling well.

Then, find out the best way to treat it.

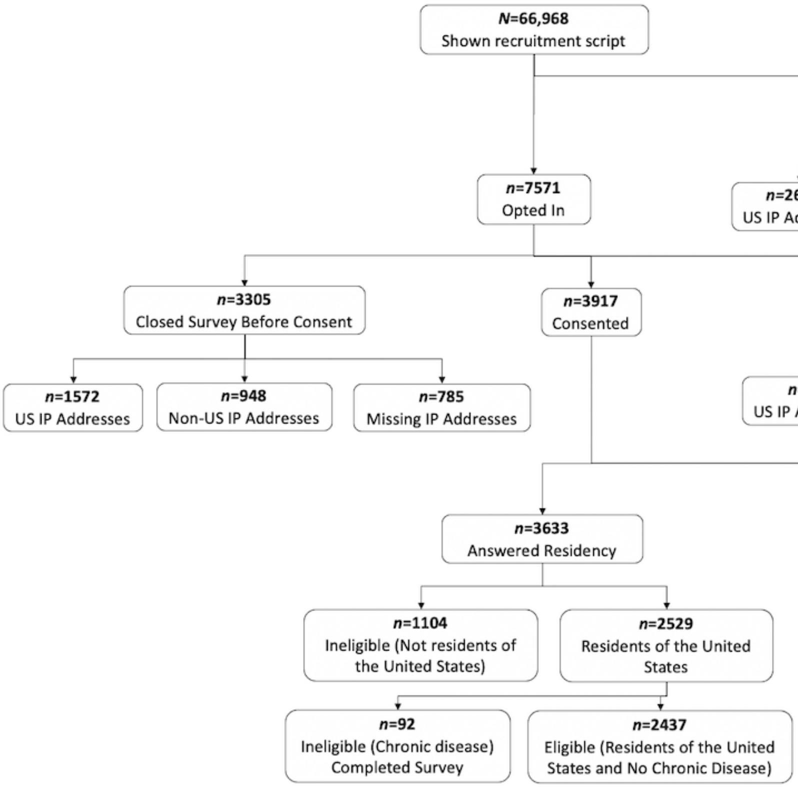
Sampling and Procedure

A recruitment script was shown to Buoy users, assumed to be web-based health information seekers, who met the inclusion criteria via a pop-up window immediately following their Buoy session. Inclusion criteria included completion of the Buoy interview to the recommendation stage in ≤10 minutes, being aged ≥18 years, and residency in the United States (although not necessarily physically in the United States at the time of seeking).

In addition, potential participants must have completed the Buoy interview for themselves; that is, they were seeking information about their symptoms. As 95% of Buoy users complete the diagnostic interview within 10 minutes, users who took longer were not representative of the typical user and thus were not invited to participate in our study to avoid other unanticipated ways in which they might differ from the typical user. Using similar logic, we excluded people who had a pre-existing serious or chronic condition [34] as they may not be representative of the typical Buoy user either. It is expected that their health information–seeking habits and use patterns of Buoy would be different from all other Buoy users. Finally, for ethical reasons, we excluded users who Buoy advised to seek immediate medical care from eligibility, including immediate medical care via 911 or in the emergency department. Figure 3 shows attrition at each stage.

Participants received a US $5 electronic gift card in appreciation of their time following completion of the survey, which had a mean time to completion of 8.61 (SD 6.78) minutes. The gift cards were delivered to an email address that was also used for follow-up. Participants were informed that they would receive another incentive (US $10) following the completion of a second survey. A follow-up assessment was administered 2 weeks after the initial survey to those who chose to provide an email address; however, this study reports only the baseline data.

Figure 3. Flow diagram showing attrition of participants.



Constructs and Measures

Overview

This study followed the tradition of uses and gratifications research [12]. We sought to understand who uses Buoy, perceptions of the user experience, and what they intend to do with the information they obtain. The survey was guided by the integrative model of behavior change [35]. The key constructs and measures are described in the following sections, and the complete survey instrument is available upon request from the corresponding author.

Reasons for Using Buoy

Patients could select ≥1 of 5 reasons for using Buoy; the list was based on the review of internet use for appraisal of symptoms of physical illness by Mueller et al [3]. Options included not being confident that the health care provider provided the correct diagnosis, symptoms not serious, sensitive or embarrassing symptoms, new symptoms, and persistent symptoms. An open-ended response was also provided, and the results were interpreted by 2 coders to map to original close-ended or new codes (access, anxiety, curiosity, and triage).

Trust in Health Information Sources

Trust in a variety of health information sources was assessed using a single Likert item, with responses ranging from “Not at all” (1) to “A lot” (4), adapted from the National Cancer Institute’s Health Information National Trends Survey [36]. The question stem was “In general, how much would you trust information about health or medical topics from each of the following?” The list of sources was randomized: physician/family or friends/newspapers or magazines/radio/internet news/television/government health agencies/social media (such as Facebook or Twitter)/Google/blogs/Buoy.

Prior research has demonstrated that the usability of the health information website affects trust in and credibility of the health information found on the site [37]. Thus, we assessed confidence, comprehensibility, perceived utility, and the emotional effects of using Buoy.

Confidence in Smart Symptom Checkers

A total of 2 items with 5-point response values from “Not at all confident” to “Very Confident” were adapted from Sivakumar et al [38] and combined as a scale where higher values represented greater confidence.

Comprehensibility of Smart Symptom Checkers

We assessed the extent to which the language on the website was easy to understand and the website was understandable and easy to read using 3 response values of 5 points (strongly disagree to strongly agree). Items were based on a scale by van Weert et al [39], with higher values representing greater comprehensibility of Buoy.

Perceived Utility of Smart Symptom Checkers

A total of 3 items with 5-point response values (strongly disagree to strongly agree) and combined as a scale by Davis [40] were used to assess the extent to which the website made the diagnosis of symptoms quicker and easier and the website’s overall usefulness.

Emotional Effects of Using Smart Symptom Checkers

The emotional effect was informed by White and Horvitz [41] and was measured using a scale of 2 items of 5 points (strongly disagree to strongly agree). The items assessed anxiousness about a perceived medical condition and the extent to which the website encouraged help seeking. Higher values represented more positive emotional effects of using the website.

Recommended Action

At the conclusion of the Buoy diagnostic interview, users were given at least one and up to 3 of 8 possible recommendations for the next steps (triage level) that correspond to their cluster of symptoms and potential diagnosis: (1) wait and watch, (2) self-treatment, (3) phone call or in-person visit in the next 3 days, (4) primary care physician in 2 weeks, (5) primary care physician in 1 to 2 days, (6) in-person visit that day or as soon as possible, (7) hospital emergency room, and (8) emergency medical service. Buoy users who received the 2 most urgent recommended actions were not included in our study for ethical reasons. A complete description of the recommendations is available in Multimedia Appendix 1. Buoy provided the research team with the actual recommendations shown to all eligible users. In addition, we asked participants to indicate which of the 6 possible recommendations they had received from Buoy. We compared participants’ self-reports with the Buoy-reported recommendations as a manipulation check. The comparison matched survey responses with at least one of the Buoy recommendations. Most self-reported recommendations matched at least one recommendation, as reported by Buoy (1595/2141, 74.49%).

Intention to Follow Recommended Action

The reasoned action approach informed this measure [35]. Intention was measured for all 6 included recommended actions and intentions to discuss Buoy’s recommendation with a physician or other health professional. The response values ranged from 1 (strongly disagree) to 5 (strongly agree). Examples of the statement are as follows, “I intend to [follow Buoy’s recommendation]” and “I intend to discuss the information I got from Buoy with my doctor or other health care professional.” Higher values on the item represented a stronger intention to follow Buoy’s recommendations or discuss the same with the physician. The recommended action was assessed as a binary variable. Users who scored 4 or 5 on intention (high) were classified as having medical intention, whereas those who scored 1, 2, or 3 were classified as having no medical intention. Intention to follow “Wait and Watch” and “Self-Treatment” were combined on a “No Medical Intention” scale. The intentions “Phone Call or In-Person Visit in the next 3 Days,” “Primary Care Doctor in 1-2 days,” and “In-Person Visit Today or ASAP” were combined in a “Medical Intention” scale.

Coding of Symptoms and Diagnoses

Users’ self-reported symptoms resulting from the Buoy interview were coded into 13 categories using the Centers for Disease Control and Prevention National Ambulatory Medical Care Survey (NAMCS) coding protocol [42]. During the interview, the users were prompted to enter up to 5 presenting symptoms. We report only on the first as that was the primary issue driving the use of the web-based symptom checker. Using an iterative coding process, we generated a set of unique symptoms (N=2040) and unique diagnoses (N=938) from all Buoy data sets.

A total of 2 coders independently coded the first symptom. Coder 1 was part of the codebook development process. Coder 2 was introduced into the study once the codebook was finalized. Disagreements were resolved by discussion. The second author resolved disagreements when consensus was not possible. Cohen κ was run to determine interrater reliability between the 2 coders’ assignment of NAMCS codes for the 2040 unique symptoms; there was substantial agreement between the 2 coders (κ=0.73; [43]). We further categorized whether the first symptoms were serious and likely to require medical attention based on Shapiro et al [44] (chest pain that is heart related, bleeding, loss of consciousness, shortness of breath, and weight loss).

Users are provided with up to 3 possible diagnoses or display names at the completion of their interview, ranked and weighted according to Buoy’s proprietary algorithm, along with recommendations for subsequent actions. Diagnoses were coded into 25 categories comprising major systems, disorders, and conditions, in line with the NAMCS. We report the first diagnosis display name as the algorithm had the highest confidence in it. In addition, the first diagnosis display name had no missing data.

Analytic Approach

For this descriptive analysis, we computed frequencies and percentages to summarize participant characteristics and experiences, overall and by sex and ethnicity where relevant, and to assess intentions to comply with Buoy recommendations. ANOVAs with Bonferroni correction examined the mean outcome differences between racial or ethnic groups on user experience and recommendations. Nonparametric tests in the form of the Wilcoxon rank sum test were performed to test the mean differences between sexes in user experience and recommendations. The relationship between perceptions of the symptom checker and intention to follow recommended actions was assessed using logistic regression. Logistic regression models examined the factors affecting confidence in recommendations and intention to follow these. Analyses were conducted using R (version 4.0.3; R Foundation for Statistical Computing).

Ethics Approval

The University of California, Merced Institutional Review Board approved this study (approval number: UCM2018-124).

Results

Users of a Web-Based Symptom Checker

Consistent with prior studies on health information seekers, Buoy users were well-educated (1384/1704, 81.22% some college or more), mostly White (1227/1693, 72.47%), and female (2069/2437, 84.89%). The mean age of the users was 39.4 (SD 14.7) years. Users were similar to other users of web-based symptom tools, and a prior study of web-based symptom checkers found that users were predominantly female with a mean age of 40 years [33]. Findings from other studies further indicate an age, sex, and socioeconomic divide among adults' web-based health information–seeking behaviors [45]. The sampled users were also relatively privileged in terms of health care access; most had insurance (1449/1630, 89%) and a regular health care provider (1307/1709, 76%). They were generally in good health; 59% (1000/1703) reported their health as good, very good, or excellent. Table 1 shows the additional demographic details.

Table 1. Sample characteristics and comparison with all users of an intelligent web-based symptom checker.

Characteristics	Analytic sample[a] (N=2437)	Eligible opt-outs (N=27,816)

<20,000	304 (18.38)	
20,000-34,999	226 (13.66)	—
35,000-49,999	232 (14.03)	—
50,000-74,999	316 (19.11)	—
75,000-99,999	237 (14.33)	—
≥100,000	339 (20.50)	—
General health status (self-reported; N=1703), n (%)		
Excellent	63 (3.70)	—
Very good	288 (16.91)	—
Good	649 (38.11)	—
Fair	532 (31.24)	—
Poor	171 (10.04)	—
Have regular health care provider (N=1709), n (%)	1307 (76.48)	—
Have insurance (N=1630), n (%)	1449 (88.90)	—

[a] The number of Buoy users in the analytic sample was 2437; during the period of the study, there were a total of 27,816 potentially eligible users (aged ≥18 years, US IP address, those seeking for themselves, and who completed the Buoy interview in <10 minutes) who opted not to participate.

[b] Data not available.

Drivers for Users to Use a Web-Based Symptom Checker

Users selected ≥1 of the 5 stated reasons for using Buoy, as well as open-ended responses, which were coded into 5 new categories. Over one-third (839/2437, 34.43%) of the users indicated persistent symptoms as a reason for using Buoy, followed by new symptoms (767/2437, 31.47%), symptoms not serious (545/2437, 22.36%), sensitive or embarrassing symptoms (269/2437, 11.04%), and not confident that health care provider provided correct diagnosis (220/2437, 9.03%). Less common reasons included new categories/codes: curiosity (66/2437, 2.71%), access (36/2437, 1.48%), anxiety (16/2437, 0.66%), triage (29/2437, 1.19%), and other (30/2437, 1.23%; data not shown).

Recommendations of the Web-Based Symptom Checker

We report the patterns in symptoms and diagnoses in 2 ways. First, we report the frequencies of symptoms and diagnoses organized by the NAMCS Biological Systems associated with them (Multimedia Appendix 2 [42,44]). Second, we report the top 10 symptoms and diagnosis categories, overall and by sex and race/ethnicity (Table 2).

Table 2. Top 10 symptoms and diagnoses (sorted into major categories), overall and by sex and ethnicity (N=2437).

Symptoms and diagnoses	Overall	Female (n=2069)	Male (n=368)	White (n=1227)	Latino (n=139)	Black (n=189)	Asian or Pacific Islander (n=86)

Only 3 types of symptoms—pain (855/2437, 35.08%), gynecological issues (293/2437, 12.02%), and masses or lumps (204/2437, 8.37%)—accounted for almost half (1352/2437, 55.48%) of the site visits. The top 3 symptoms entered by men included pain (154/368, 41.8%), masses or lumps (49/368, 13.3%), and skin issues (33/368, 8.9%), whereas the top 3 symptoms in women included pain (701/2069, 33.88%), gynecological issues (293/2069, 14.16%), and masses or lumps (155/2069, 7.49%). Pain, gynecological issues, and masses or lumps were also reported as the top 3 symptoms for White, Black, and Asian or Pacific Islander users. The top 3 symptoms in Latino users were pain (43/139, 30.9%), gynecological issues (22/139, 15.8%), and gastrointestinal problems (14/139, 10.1%).

In comparison, Native Americans, who represented <1% of users, only entered five symptoms: pain (4/13, 31%), gynecological issues (4/13, 31%), skin issues (1/13, 8%), gastrointestinal problems (1/13, 8%), and impaired sensation (1/13, 8%).

Among the entire sample, major diagnoses were musculoskeletal (303/2437, 12.43%), gynecological (304/2437, 12.47%) and skin conditions (297/2437, 12.19%), and infectious diseases (300/2437, 12.31%). Comparably, the top 3 diagnoses reported by Buoy for men included musculoskeletal conditions (63/368, 17.1%) and skin conditions (62/368, 16.8%) and infectious diseases (37/368, 10%). The top 3 diagnoses for women included gynecological conditions (304/2069, 14.69%), infectious diseases (263/2069, 12.7%), and musculoskeletal conditions (240/2069, 11.59%). The diagnoses based on race or ethnicity followed a similar pattern. White users also reported musculoskeletal conditions (177/1227, 14.42%), infectious diseases (163/1227, 13.28%), and skin conditions (148/1227, 12.06%) as the top 3 diagnoses. Latino, Black, and Asian or Pacific Islander users reported gynecological conditions, skin conditions, and infectious diseases as the top 3 diagnoses. Gynecological conditions were reported as the top diagnosis category by Black (42/189, 22.2%) and Asian or Pacific Islander (17/86, 20%) users, whereas Latino users reported infectious diseases (26/139, 18.7%) as the top diagnosis category.

Buoy's primary recommendation was more evenly split across the less-serious triage categories. Users self-reported primary care physicians in 2 weeks (754/2141, 35.22%), self-treatment (452/2141, 21.11%), and primary care in 1 to 2 days (373/2141, 17.42%) as the top 3 recommendations provided by Buoy, followed by wait and watch (339/2141, 15.83%). Only 5.74% (123/2141) and 4.67% (100/2141) of users self-reported phone calls or in-person visits in the next 3 days and in-person visits that day or as soon as possible, respectively. The recommendations reported by Buoy closely matched primary care physicians in 2 weeks (924/2437, 37.91%), self-treatment (552/2437, 22.65%), and primary care in 1 to 2 days (456/2437, 18.71%). Most users (2098/2437, 86.09%) had 2 recommendations. Approximately 71.85% (1751/2437) had 3 recommendations, as reported by Buoy.

Users' Perceptions of the Web-Based Symptom Checking Experience

Users generally reported high levels of confidence in Buoy (mean 3.47, SD 0.97), found it useful (mean 4.18, SD 0.81) and easy to understand (mean 4.64, SD 0.53), and said that Buoy made them feel less anxious (mean 3.60, SD 1.05) and more empowered to seek medical help (mean 3.75, SD 0.96) Compared with White users, Latino and Black users had significantly more confidence in Buoy (*P*<.05), and the former also found it significantly more useful (*P*<.05; Table 3). Consistent with prior studies on trust in web-based health information sources [46-48], physicians were the most trusted source. However, Buoy was trusted more (mean 3.68, SD 0.61) than any other nonmedical source, including government agencies (mean 2.85, SD 0.95), family (mean 2.64, SD 0.76), and Google (mean 2.52, SD 0.79).

Table 3. Buoy user experience and recommendations (N=2437).

Item	Overall	Male (n=368)	Female (n=2069)	White (n=1227)	Latino (n=139)	Black (n=189)	Asian or Pacific Islander (n=86)
Comprehensibility of Buoy, mean (SD)	4.64 (0.53)	4.61 (0.49)	4.65 (0.53)	4.67 (0.50)	4.68 (0.55)	4.67 (0.53)	4.60 (0.45)

Relationship Between Perceptions of a Web-Based Symptom Checker and Intention to Follow Recommended Actions

Overall, most users reported intentions to follow Buoy's recommendations (1428/1886, 75.71%) and discuss Buoy's recommendations with a physician or health care professional (1198/1830, 65.44%; Table 4). Users reported the strongest intention to follow Buoy's wait and watch recommendation (mean 4.38, SD 0.90), followed by self-treatment (mean 4.33, SD 0.93), in-person visit that day or as soon as possible (mean 4.17, SD 1.01), phone call or in-person visit in the next 3 days (mean 4.05, SD 1.05), primary care physician in 2 weeks (mean 3.92, SD 1.19), and primary care physician in 1 to 2 days (mean 3.68, SD 1.26).

Intention to discuss Buoy's recommendations was positively associated with having a regular provider (odds ratio [OR] 1.37, 95% CI 1.04-1.82), and an income >US $50,000 was negatively associated (OR 0.75, 95% CI 0.57-0.98; OR 66, 95% CI 0.48-0.91; Table 5). Users aged between 35 and 44 years (OR 1.51, 95% CI 1.13-2.03) and 45 and 64 years (OR 1.57, 95% CI 1.18-2.10) had better intentions of discussing recommendations than younger users (aged 18-34 years). Compared with White users, Latino (OR 1.96, 95% CI 1.22-3.25) and Black (OR 2.37, 95% CI 1.57-3.66) users had stronger intentions to discuss recommendations with a provider, and Black users were twice as likely to intend to do so. Confidence in Buoy (OR 1.54, 95% CI 1.34-1.76), perceived utility (OR 1.32, 95% CI 1.10-1.58), and anxiety reduction because of using Buoy (OR 1.43, 95% CI 1.24-1.63) were associated with higher intention to discuss Buoy's recommendations.

Overall, users had strong intentions to follow Buoy's recommendations, and users who self-reported very good or excellent health had the strongest intention to wait or watch or self-treat (OR 1.92, 95% CI 1.04-3.65; Table 5). Those who reported Buoy as easy to read and understand were 2.2 times (95% CI 1.21-4.14) more likely to intend to wait or watch or self-treat than those who reported lower comprehensibility for Buoy. Users with health insurance (OR 2.21, 95% CI 1.36-3.57) and a regular provider (OR 1.59, 95% CI 1.11-2.28) had the strongest intentions to seek care. Confidence in Buoy (OR 1.87, 95% CI 1.56-2.25) and anxiety reduction because of Buoy (OR 1.54, 95% CI 1.29-1.83) were also associated with a higher intention to seek care.

Table 4. Intentions to follow and discuss Buoy recommendations (N=2437).

Item	Overall	Male (n=368)	Female (n=2069)	White (n=1227)	Latino (n=139)	Black (n=189)	Asian or Pacific Islander (n=86)
Intentions to follow Buoy's recommendations (n=1886), n (%)	1428 (75.71)	187 (9.91)	1241 (65.8)	908 (48.14)	116 (6.15)	149 (7.9)	62 (3.29)

Discussion

Principal Findings

This study sought to understand who uses web-based AI-powered symptom checkers and for what purposes. The demographic profile of Buoy users was similar to that described in other studies of web-based health information seekers, suggesting that older, marginalized groups continue to be digitally excluded. Consistent with data on internet-based health-seeking behaviors more generally [49], most Buoy users were middle-aged (or younger), female, and highly educated. More research is needed to better understand older adults' web-based health information–seeking behaviors and support their medical and health decisions [50]. Although a scoping review of articles examining AI-driven symptom checkers from various perspectives found that those who do not have access to health care services are more likely to use symptom checkers [51], Buoy users overwhelmingly reported having health insurance. This finding does not negate the possibility that users were motivated by financial considerations, as most contemporary health plans require an out-of-pocket copayment. Nevertheless, this suggests that other considerations such as convenience were also salient.

Along these lines, prior research has identified an association between stigmatizing conditions and the use of symptom checkers [51]. In this study, gynecological problems were among the top 3 symptom groups. Furthermore, across presenting symptoms or diagnoses, approximately 11.04% (269/2437) of the respondents were "too embarrassed" to seek in-person care. Taken together, these findings suggest that symptom checkers might be particularly useful for users affected by conditions considered personal, embarrassing, stigmatizing, not warranting the physician's attention, or requiring potentially uncomfortable or psychologically stressful physical examinations (such as pelvic examinations).

In examining the reasons for using the tool, approximately one-third of the respondents had persistent symptoms that failed to resolve spontaneously, another one-third had new symptoms, and the rest either thought they did not need professional attention or (as mentioned previously) were too embarrassed to seek care. Thus, some patients used the symptom checker because they had significant health-related concerns; some because they lacked sufficient concern to warrant in-person care; and some because they had issues with perceived quality, cost, or convenience of available care or simply wanted a second opinion. Symptoms that persist longer than expected have been identified as strong drivers of health-related anxiety and, thus, health care use [52]. At the same time, valuing convenience and lack of trust in the health care system (factors that may be particularly prominent among young people and racially and ethnically minoritized groups, respectively) have been associated with a lower propensity to use formal health care services [53].

Regarding the user experience, users had high levels of confidence in Buoy and found it useful. Moreover, users trusted Buoy more than any other nonmedical source. Perceived confidence, utility, and trust were associated with a stronger intention to discuss Buoy's recommendations with a physician. This finding is in line with a study examining patient perspectives on the usefulness of a symptom checker [11]. Most Buoy users found the tool useful for diagnosis, and most reported that they would use it again. Although the experiences of users who discussed recommendations with their physicians varied, most felt that physicians were open to discussing the results of the tool. This is an important finding, as users may not follow recommendations to seek care if they believe that acting on the advice of a symptom checker will be questioned or even belittled by their physician, regardless of their confidence in the tool.

This study ultimately advances the understanding of web-based health information–seeking behaviors and outcomes by linking objective measures of information seeking from a web-based AI-powered system with clinical and psychosocial outcomes. The results demonstrate the potential utility of an artificially powered web-based health information tool to improve outcomes for users. Symptom checkers have been described as a means of addressing the lack of access to physicians and reducing unnecessary office visits [4].

There is a lack of research on whether the use of symptom checkers translates into medical care–seeking behaviors [4,33]. Future research should examine the effects of such tools on medical care seeking, specifically how users interpret recommendations, whether the recommendations are followed, and how user responses vary among sociodemographic groups. For example, one might surmise that individuals with limited access to care or with prior negative health care experiences might be more likely to attend to, appreciate, and follow such recommendations than their more privileged counterparts. Although symptom checkers may empower users to make more informed decisions, they might paradoxically worsen health disparities if their use were less accessible to some groups. Currently, web-based symptom checkers are mostly available for free. As web-based symptom checker companies establish partnerships with employers and health insurance companies to ensure profits, not all users may be equally ready or able to pay for symptom checking.

Limitations and Strengths

We partnered with the Buoy technical and medical staff to sample the users. Owing to our partnership approach, we were able to obtain the specific symptoms reported by the participants as the primary reason for using Buoy, as well as the possible diagnoses identified by Buoy and Buoy's triage recommendation. This allowed for the comparison and validation of self-reported data. We also obtained from Buoy the symptoms, diagnoses, triage, and sex of eligible users who opted not to participate in our study. This allowed us to compare our sample to the population of users and assess potential bias. In addition, a benefit of a collaborative approach is the potential to overcome the self-report limitations of prior studies. Thus, we obtained from Buoy the paths that individuals took and Buoy's final recommendation. We were also able to match the initial reason for the consultation to the reason reported in the survey and assess the extent to which respondents understood the recommendation and intended to act upon it. By leveraging a public or private partnership, we were able to explore the use and effects of a web-based symptom checker, which has important implications for health equity and the health care system during and after the COVID-19 crisis.

The limitations of this study include the use of cross-sectional data, which limited the ability to make any causal inferences, and the potential lack of applicability to other web-based symptom checkers. In addition, we did not assess the actual search terms entered by users. Finally, our study used a limited definition of web-based health information. Searches for symptoms using a web-based symptom checker differ from other forms of health-related information communicated through the internet. For example, web-based health communities can also be a source of social support [54] and peer-to-peer medical advice [7].

Conclusions

The results of this study demonstrate the potential utility of a web-based health information tool to empower people to seek appropriate care and reduce health-related anxiety. An interactive symptom checker might provide more personalized and potentially reliable medical information than other forms of web-based health information–seeking. Despite encouraging results suggesting that the web-based tool may fulfill unmet health information needs among women and Black and Latino adults, analyses of the user base illustrate persistent second-level digital divide effects.

For web-based symptom checkers to make a meaningful contribution, they must not only be trusted by users but also meet their diverse needs, especially those concerning usability and comprehensibility. The inability to access web-based symptom checkers may also be associated with increased disparities in access to care, particularly among groups that have lagged historically in terms of digital access and literacy. Moreover, web-based symptom checker business models may further exacerbate these disparities. In contrast, AI technologies such as Buoy have the potential to alleviate disparities by allowing users to access accurate, actionable, and personalized advice within an evolving but often confusing web-based health information environment. Finally, there is a lack of evidence on whether web-based symptom checkers influence care-seeking behaviors. To address this gap, future research will use Buoy users' follow-up data to assess the extent to which users discuss their web-based findings with physicians, as well as barriers to the same and patient satisfaction.

Acknowledgments

This project was supported by a gift from Buoy Health to the University of California, Merced. Buoy Health staff provided access to participants and internal data used to validate self-reported data but had no role in data analysis or interpretation. The authors gratefully acknowledge Jovo Velasco, Stephanie Reyes, and Michael Vang for their data collection and coding support in this research. The contents are solely the responsibility of the authors and do not necessarily represent the official views of Buoy Health or the University of California.

Conflicts of Interest

The authors received funding and some technical assistance in recruiting from Buoy Health, although they were not involved in the research design, data analysis, or interpretation.

Abstract

Background: The development of COVID-19 vaccines has been crucial in fighting the pandemic. However, misinformation about the COVID-19 pandemic and vaccines is spread on social media platforms at a rate that has made the World Health Organization coin the phrase *infodemic*. False claims about adverse vaccine side effects, such as vaccines being the cause of autism, were already considered a threat to global health before the outbreak of COVID-19.

Objective: We aimed to synthesize the existing research on misinformation about COVID-19 vaccines spread on social media platforms and its effects. The secondary aim was to gain insight and gather knowledge about whether misinformation about autism and COVID-19 vaccines is being spread on social media platforms.

Methods: We performed a literature search on September 9, 2021, and searched PubMed, PsycINFO, ERIC, EMBASE, Cochrane Library, and the Cochrane COVID-19 Study Register. We included publications in peer-reviewed journals that fulfilled the following criteria: original empirical studies, studies that assessed social media and misinformation, and studies about COVID-19 vaccines. Thematic analysis was used to identify the patterns (themes) of misinformation. Narrative qualitative synthesis was undertaken with the guidance of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 Statement and the Synthesis Without Meta-analysis reporting guideline. The risk of bias was assessed using the Joanna Briggs Institute Critical Appraisal tool. Ratings of the certainty of evidence were based on recommendations from the Grading of Recommendations Assessment, Development and Evaluation Working Group.

Results: The search yielded 757 records, with 45 articles selected for this review. We identified 3 main themes of misinformation: medical misinformation, vaccine development, and conspiracies. Twitter was the most studied social media platform, followed by Facebook, YouTube, and Instagram. A vast majority of studies were from industrialized Western countries. We identified 19 studies in which the effect of social media misinformation on vaccine hesitancy was measured or discussed. These studies implied that the misinformation spread on social media had a negative effect on vaccine hesitancy and uptake. Only 1 study contained misinformation about autism as a side effect of COVID-19 vaccines.

Conclusions: To prevent these misconceptions from taking hold, health authorities should openly address and discuss these false claims with both cultural and religious awareness in mind. Our review showed that there is a need to examine the effect of social media misinformation on vaccine hesitancy with a more robust experimental design. Furthermore, this review also demonstrated that more studies are needed from the Global South and on social media platforms other than the major platforms such as Twitter and Facebook.

KEYWORDS

social media; misinformation; COVID-19 vaccines; vaccination hesitancy; autism spectrum disorder

Introduction

Background

An unprecedented global effort has been undertaken to develop vaccines that protect against COVID-19. However, there is a grave concern that vaccine hesitancy will be a major obstacle to reaching herd immunity. In 2019, the World Health Organization (WHO) had already named vaccine hesitancy as 1 of 10 threats to global health [1]. Global vaccine distribution equity is also a major challenge. Figures from February 2022 show that 61.9% of the world's population has received at least one dose of a COVID-19 vaccine, but only 10.6% of people in the Global South have received a dose [2]. Furthermore, the rate of people receiving a COVID-19 vaccine in some high-income countries where vaccines are available and free has dropped [3]. The WHO reiterates that COVID-19 vaccines remain critical and are considered effective against severe disease and death [4].

The reasons behind COVID-19 vaccine hesitancy are complex. Fear of side effects and concerns about the pace at which the vaccines were developed have been cited as primary reasons behind this hesitancy [5]. In addition, misinformation about COVID-19 and vaccines has spread on social media platforms at a rate that has made the WHO coin the phrase infodemic [6]. An infodemic is "too much information including false or misleading information in digital and physical environments during a disease outbreak" [7,8].

A well-known false claim is that the measles, mumps, and rubella (MMR) vaccine can cause autism [9]. The claim has since been empirically refuted many times but is still stated as a major concern for some parents [10]. Motta and Steccula [11] examined American public opinion data on MMR safety collected before and after a retracted 1998 study linking autism to MMR. The researchers detected a statistically significant increase in public concern about MMR safety following the retracted study and the media attention it received. This suggests that misleading vaccine information can impact public confidence in vaccines and cause skepticism about vaccines in general. Since the retracted 1998 study, groups of vaccine deniers or *antivaxxers* have grown, and claims that vaccines are harmful have spread to almost all vaccines [12]. Pullan and Dey [13] analyzed search patterns in Google Trends during the early stage of the pandemic in 2020 and found that search interest in COVID-19 vaccines had understandably increased, but also found that well-known antivaccine searches such as "autism" and "mercury" also had a growing presence and similar spikes as search patterns for COVID-19 vaccines. These results confirm that the false claim of associations between autism and MMR vaccines has become an argument for all types of vaccines and also possibly a concern when it comes to COVID-19 vaccines. Therefore, we examined whether misinformation on social media in recent times linked autism to COVID-19 vaccines.

Furthermore, vaccine hesitancy based on misinformation seems to be a worldwide phenomenon regardless of the uneven distribution of COVID-19 vaccines [4]. Social media plays a crucial role in disseminating both correct information and misinformation about infectious diseases and vaccines [14]. Wilson and Wiysonge [15] showed, in a global cross-national analysis of geographically coded tweets and vaccination rates from 166 countries, that there was a significant relationship between social media use and vaccine hesitancy. However, there has been a joint effort by several of the largest social media platforms and technology companies to combat the spread of misinformation about COVID-19 [16].

Objective

We aimed to synthesize the existing research on misinformation about COVID-19 vaccines spread on social media platforms and its effects. The secondary aim was to gain insight and gather knowledge about whether misinformation about autism and COVID-19 vaccines is being spread on social media platforms. The following questions guided our inquiry: What is known about misinformation regarding COVID-19 vaccines spread on social media platforms? What is known about the effects of misinformation about COVID-19 vaccines spread on social media platforms? What is known about social media misinformation on COVID-19 vaccines concerning autism spectrum disorder?

Methods

Design

We followed the guidance from Cochrane Rapid Reviews [17]. We chose a rapid review protocol in line with the recommendations by Cochrane; that is, the need "for timely evidence for decision-making purposes including to address urgent and emergent health issues and questions deemed to be of high priority” [17]. The need to address vaccine hesitancy toward COVID-19 vaccines is an emergent health issue. The narrative qualitative synthesis was undertaken with the guidance of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 Statement [18] and the Synthesis Without Meta-analysis reporting guideline [19].

Search Strategy and Selection Criteria

With the help and expertise of an information retrieval specialist, we used the following search string in this rapid review: (“misinformation” OR “disinformation” OR “information”) AND (“social media” OR “Facebook” OR “Twitter” OR “Instagram” OR “WhatsApp” OR “Telegram” OR “Tumblr” OR “Pinterest” OR “YouTube” OR “VKontakte” OR “Snapchat” OR “TikTok” OR “Weibo” OR “WeChat” OR “Reddit”) AND (“covid*” OR “corona*” OR “pandemic” OR “Sars-CoV-2” AND “vaccine*” OR “vaccination*”).

No date or language limitations were used. The full search strategy of the information retrieval specialist is available in Multimedia Appendix 1.

Publications were excluded if the studies were not original empirical research, if studies examined vaccines in general and not COVID-19 vaccines, if studies did not examine social media misinformation, and if data were gathered before the COVID-19 vaccine Pfizer-BioNTech phase 3 clinical trial [20].

Data Collection Process and Extraction

This review was registered with the PROSPERO international register of systematic reviews (CRD42021277524). Systematic searches in the PubMed, PsycINFO, ERIC, EMBASE, Cochrane Library, and Cochrane COVID-19 Study Register databases were conducted by an information retrieval specialist on September 9, 2021. Duplicates were identified and removed by IS and EG. We used Rayyan [21] as the screening tool. Rayyan is a web application and mobile app for systematic reviews. It eases the process of the initial screening of abstracts and titles and helps researchers save time when they share and compare include-exclude decisions. All titles and abstracts were screened by IS and ANH independently. In the initial search, no date restriction was set. However, during the piloting of the title and abstract screening, IS and ANH discussed the fact that there were studies that explored misinformation about COVID-19 vaccines at a very early stage in the pandemic, before any COVID-19 vaccines were a reality. We decided that we needed a threshold date as to when we believed we found misinformation about the actual COVID-19 vaccines to be relevant, as misinformation at a very early stage would be about a potential vaccine. Therefore, we decided to include studies that were conducted during and after the Pfizer-BioNTech phase 3 clinical trial, because then the news about an actual vaccine was starting to spread around the world and thus starting to become a reality. We chose the Pfizer-BioNTech vaccine because it was the first COVID-19 vaccine to be approved by the WHO [22].

Of the 319 titles and abstracts screened, IS and ANH disagreed on 35. The disagreements were resolved through discussions between the 2 reviewers and if an extra opinion was needed, EG was consulted. Of these articles, 1 article was in German, 2 were in Spanish, and the rest were in English. IS can understand German and EG speaks Spanish. IS and EG performed a further assessment of the eligibility of the full-text records and conducted a pilot exercise using the same 10 full-text articles to calibrate and test the review form. After the screening, both reviewers assessed the articles that the other had excluded. ANH assisted with conflicts and discussed doubts surrounding the included or excluded articles. The data extraction from the included articles involved 2 reviewers (IS and EG), where IS extracted data using a piloted form and EG checked for the correctness and completeness of the extracted data. Data from the included articles were extracted based on design and study population, type of misinformation, effect of misinformation, misinformation about autism, ethical considerations, and social media channels. The agreed evidence was then synthesized narratively.

To synthesize the knowledge gathered about the types of misinformation, a thematic analysis was performed [23]. After the data extraction, IS gathered the data on the content of the misinformation. The data extracts on misinformation were then coded by ANH. IS and ANH searched for themes based on the codes and agreed upon 3 final themes of misinformation: conspiracies, medical misinformation, and vaccine development. EG approved the themes. Multimedia Appendix 2 provides an overview of the thematic analysis that was undertaken.

Assessment of Risk of Bias

The risk of bias was graded according to the Joanna Briggs Institute (JBI) Critical Appraisal tool “Checklist for Analytical Cross-sectional Studies” [24] by 1 experienced reviewer (DSQ). The evaluation was based on answers to 8 questions (yes, no, or not applicable). The studies were classified as having low (>70%), moderate (40%-70%), or high (<40%) risk of bias. A complete overview of the assessment can be found in Multimedia Appendix 3 [25-69].

Assessment of the Quality of the Evidence

One experienced reviewer (RW) assigned certainty of evidence ratings based on recommendations by the Grading of Recommendations Assessment, Development and Evaluation (GRADE) working group [70]. The included studies that looked at associations were given a narrative GRADE score related to the outcome “Association between social media misinformation and vaccine hesitancy.” The level of quality of evidence was classified as very low, low, moderate, or high. A complete overview of the assessment can be found in Multimedia Appendix 4 [25-69].

Data Synthesis

Narrative synthesis was undertaken with the guidance of the PRISMA 2020 Statement [18] and Synthesis Without Meta-analysis reporting guideline [19]. In the synthesis, findings from our included studies were grouped according to study design, population, social media sample, types of social media, types of misinformation reported, misinformation about autism, the reported effect of the misinformation on vaccine hesitancy, and the assessments of risk of bias and quality of evidence. When synthesizing the findings narratively, studies with a low risk of bias or high quality of evidence will be highlighted on several occasions.

Results

Study Selection and Risk of Bias

We identified 45 relevant studies (Figure 1). The list of excluded articles during the full-text review and the reasons for exclusion are reported in Multimedia Appendix 5. The risk of bias in 53% (24/45) of the included studies was classified as low, according to the JBI Critical Appraisal tool [25-42,47-52]. In total, 18% (8/45) of the studies showed a moderate risk of bias [43-46,53-56]. Finally, 27% (12/45) of the included studies showed a high risk of bias [57-68]. Of the 45 studies, in 1 (2%) study [69], none of the questions in the JBI tool were applicable.

We grouped the studies into 2 major categories according to data sampling. One group gathered data through surveys, interviews, or focus groups (Table 1). The other group gathered data from social media platforms (Table 2). The largest total population sample in the first group of 22 studies (Table 1) came from Europe, with 27,975 respondents in total. All respondents were described as adults or >18 years, except for 2 studies in the United States where the participants were aged ≥65 years [28,34]. Another exception was 1 study from Slovenia, where participants aged ≥15 years were included [35]. Gender has not been a focal point in any of the 45 included studies.

Data were extracted from social media platforms in 23 of the included studies. These studies formed the second group (Table 2).

The 12 studies that were assessed to have a high risk of bias were found in the second group (Table 2), whereas the studies in Table 1 had a low or moderate risk of bias according to the JBI tool.

Many of the studies did not name social media platforms in the first group (Table 1) but rather discussed social media platforms in general. However, some studies did specify which social media platforms they were assessing. Figure 2 summarizes the types of social media platforms specified in the 45 included studies.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram for new systematic reviews.

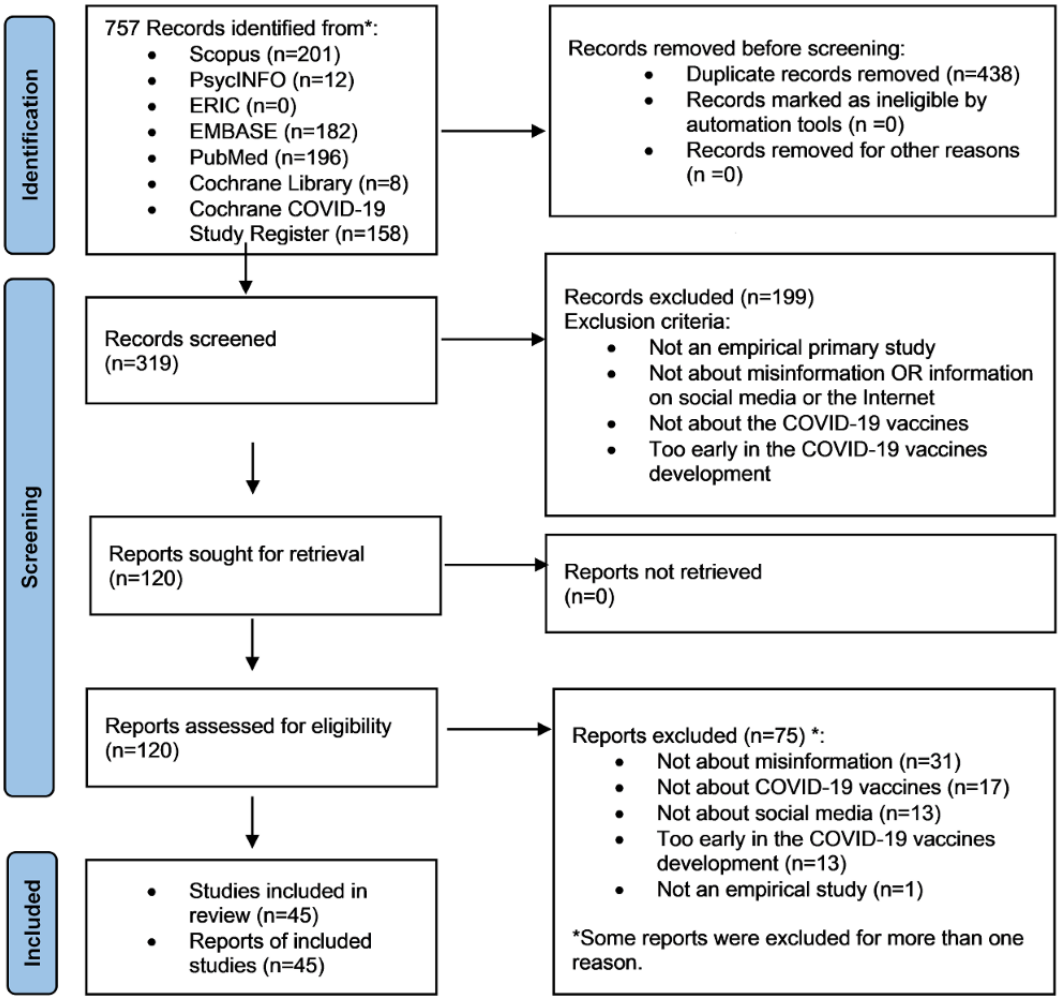

Table 1. Studies in which data were collected through surveys, observations, or interviews (n=22).

Study	Country	Study period	Study design	Type of social media	Social media or population sample	Type of misinformation reported	Risk of bias (JBI[a])
Alibrahim and Awad [25], 2021	Kuwait	March 26 to April 26, 2021	Cross-sectional study	Not specified	4147 adults, ≥18 years	COVID-19 is not a serious infection that requires vaccination	Low
Allington et al [26], 2021	United Kingdom	November 21 to December 21, 2020	Cross-sectional study	Not specified	4343 UK residents, aged 18-75 years	Conspiracy theories (not specified)	Low
Aloweidi et al [27], 2021	Jordan	January 22 to February 28, 2021	Cross-sectional study	Not specified	646 adults	The vaccines are unsafe; effect of the vaccines on a genetic level; causes chronic illnesses; may lead to infertility; can affect their offspring; contains toxic heavy metals and neurotoxic materials; it is a part of a secret research	Low
Bhagianadh and Arora [28], 2021	United States	October to November 2020	Longitudinal survey	Not specified	5784 Medicare enrollees, ≥65 years	Distrust of government narrative about vaccines; vaccine will cause COVID-19	Low
Brodziak et al [29], 2021	Poland	January 26 to February 28, 2021	Survey	Not specified	635 adult patients with cancer	The vaccine contains bodies of aborted children; COVID-19 does not exist	Low
Chadwick et al [30], 2021	United Kingdom	September 24 to October 17, 2020	Cross-sectional study	Not specified	5114 adults in the United Kingdom	Conspiracies (not specified)	Low
Ebrahimi et al [31], 2021	Norway	January 23 to February 2, 2021	Cross-sectional study	Not specified	4571 Norwegian adults	Not specified	Low
Kanyike et al [32], 2021	Uganda	Monday, March 15, and Sunday, March 21, 2021	Cross-sectional study	Not specified	600 medical students, ≥18 years	Negative information about COVID-19	Low
Karabela et al [33], 2021	Turkey	February 1, 2021, to February 28, 2021	Cross-sectional study	Social media, WhatsApp, and YouTube	1216 adults	Conspiracy theories (not specified)	Low
Park et al [34], 2021	United States	October to November 2020	Cross-sectional study	Not specified	6478 Medicare beneficiaries	The belief that COVID-19 is not that dangerous	Low
Petravić et al [35], 2021	Slovenia	December 17 to December 27, 2020	Cross-sectional study	Not specified	12,042 Slovenian residents, ≥15 years. Analysis of responses from the 2320 respondents (12%) who answered the open-ended question	The vaccines will cause a genocide; COVID-19 is the same as influenza	Low
Sallam et al [36], 2021	Jordan	January 19 to January 23, 2021	Cross-sectional study	Not specified	1106 university students	COVID-19 was man-made for enforcing vaccinations; COVID-19 vaccinations intends to implant microchips into people to control them; COVID-19 vaccination will lead to infertility	Low
Sallam et al [37], 2021	Jordan, Kuwait, and Saudi Arabia	December 4 to December 18, 2020	Cross-sectional study	Facebook, Instagram, Twitter, and WhatsApp	3414 respondents	An artificial origin of the virus; the disease was man-made to enforce vaccination; microchip implanting and infertility claims	Low

Study	Country	Study period	Study design	Type of social media	Social media or population sample	Type of misinformation reported	Risk of bias (JBI[a])
Sharevski and Gover [38], 2021	United States	January and February 2021	Cross-sectional quasi-experimental study	Twitter	304 respondents, ≥18 years	Exaggeration of rare side effects of COVID-19 vaccines	Low
Zhang et al [39], 2021	China	September 1 to September 7, 2020	Cross-sectional study	WeChat, WeChat moments, Weibo, TikTok	2053 Chinese factory workers (full-time employees) ≥18 years	Negative information about COVID-19 vaccines	Low
Zhang et al [40], 2021	China	September 1 to September 7, 2020	Cross-sectional study	WeChat, WeChat moments, Weibo, TikTok	2053 Chinese parents, ≥18 years	Negative information about COVID-19 vaccines	Low
Costantino et al [41], 2021	Italy	December 2020 to March 2021	Cross-sectional study	Not specified	363 adults	Unfavorable information about COVID-19 vaccines	Low
Jennings et al [42], 2021	United Kingdom	Survey: December 12 to December 18, 2020. Focus groups: November 30 to December 7, 2020	Cross-sectional qualitative and quantitative (mixed method) study	TikTok, Instagram, Snapchat, Twitter; Facebook, YouTube	1476 UK adults participated in the survey; 29 adults in the United Kingdom participated in the focus groups	Conspiracy theories (not specified)	Low
El-Far Cardo et al [43], 2021	Germany	August and November 2020	Cross-sectional study	Facebook, Twitter, Telegram	808 persons	COVID-19 is not a health threat	Moderate
Knights et al [44], 2021	United Kingdom	June 18 and November 30, 2020	Cross-sectional qualitative study	Not specified	64 primary care professionals and administrative staff and 17 recently arrived migrants	5G conspiracy theory	Moderate
Berry et al [45], 2021	United States	December 30, 2020, to January 15, 2021	Qualitative observational study	Not specified	193 skilled nursing facility workers	Vaccines cause COVID-19; microchip; the virus has been around for a long time and killed many people since 1918; fear of racist motives and the safety of the vaccines; the vaccines have fetal cells from abortions	Moderate
Choudhary et al [46], 2021	India	February 18 to February 28, 2021	Cross-sectional study	Not specified	272 Indian adults, ≥18 years	COVID-19 is a conspiracy	Moderate

[a] JBI: Joanna Briggs Institute.

Table 2. Studies in which data were collected from social media platforms (n=23).

Study	Country	Study period	Study design	Type of social media	Social Media or population sample	Type of misinformation reported	Risk of bias (JBI[a])
Chan et al [47], 2021	The United Kingdom	December 10, 2020	Cross-sectional study (social media data extraction)	YouTube	48 COVID-19 vaccine–related videos on YouTube	Misinformation about COVID-19 vaccines (not specified). Only 2 (4.2%) videos made nonfactual claims.	Low
Herrera-Peco et al [48], 2021	Spain	December 14 to December 28, 2020	Cross-sectional study (social media data extraction)	Twitter	5040 Twitter users participated, generating a total of 1,664,261 impressions	Messenger RNA vaccines will produce changes in human DNA; government and pharmaceutical industries are allies; adverse effects leading to genocide.	Low
Hughes et al [49], 2021	United States	October 2020 to November 2020	Cross-sectional study (social media data extraction and modeling)	Facebook, Twitter, YouTube, and Instagram	Using hashtag and keyword searchers, a team of subject matter experts identified 20 channels (ie, bounded sources of content, such as a social media account), which appeared to contain a high degree of antivaccine content or COVID denialism.	Corrupt elites; physical deformities; mental illness; microchips that violate your autonomy and privacy; the people who intentionally created the COVID vaccine are shadowy and suspicious.	Low
Larrondo-Ureta [50], 2021	Spanish-speaking countries	December 2020 and February 2021	Cross-sectional study (social media data extraction)	Twitter	62,045 tweets and 258,843 retweets	Antivaccine discourse (not specified)	Low
Liu and Liu [51], 2021	English-speaking countries	November 1 to November 22, 2020	Cross-sectional study (social media data extraction)	Twitter	5000 COVID-19 vaccine–related tweets, which were posted by 4796 unique users.	Microchips; alters DNA; women become sterile.	Low
Sobkowicz and Sobkowicz [52], 2021	United States and Poland	March 1, 2021	Cross-sectional study (social media data extraction)	Reddit and Interia	Reddit and Interia antivaccine groups	Antivaccination discussions about COVID-19 vaccines.	Low
Guntuku et al [53], 2021	United States	December 1, 2020, to February 28, 2021	Cross-sectional study (social media data extraction)	Twitter	78.1 million vaccine-related tweets	Evangelical hubs posted conspiracy theories about Bill Gates and China.	Moderate
Hernández-García et al [54], 2021	Spain	February 9 2021	Cross-sectional study (social media data extraction)	YouTube	118 YouTube videos	Hoaxes and conspiracy theories (not specified).	Moderate

Study	Country	Study period	Study design	Type of social media	Social Media or population sample	Type of misinformation reported	Risk of bias (JBI[a])
Islam et al [55], 2021	Australia	December 31, 2019, to November 30, 2020	Cross-sectional study (social media data extraction)	Facebook, YouTube, and Twitter	637 news articles, social media narratives, web-based reports, and blogs spread on social media	Daughter of the Russian president had died after receiving the second dose of COVID-19 vaccine; children and soldiers dying after receiving the vaccine in multiple countries; conspiracy theory about Bill Gates; COVID-19 vaccine can monitor the human population and take over the world; COVID-19 vaccines contain a microchip through which biometric data could be collected, and large businesses could send signals to the chips using 5G networks; crucial phases of the clinical trials were skipped; COVID-19 vaccine contains cells from aborted fetus or genes from pigs.	Moderate
Kwok et al [56], 2021	Australia	January 22 and October 20, 2020	Cross-sectional study (social media data extraction)	Twitter	31,100 COVID-19 vaccine–related tweets	Conspiracy theories such as the “mark of the beast” and microchips in vaccines.	Moderate
Alliheibi et al [5,8], 2021	Saudi Arabia	December 15, 2020, to May 25, 2021	Cross-sectional study (social media data extraction)	Twitter	37,467 Arabic tweets from 23,748 users	COVID-19 vaccination is a cover for a plan devised by Bill Gates to implant trackable microchips to control people.	High
Baines et al [58], 2021	United States	November 20, 2020, to January 6, 2021	Cross-sectional study (social media data extraction)	Parler	400 random parleys from a large sample of 7000 parleys	Sterilization possibilities for men and women; COVID-19 vaccine to control the population; Bill Gates and Anthony Fauci had instigated measures (ie, microchips and enzymes in the vaccine) to control the population through the administration of the COVID-19 vaccine; governments and certain powerful individuals “planned” this health crisis to vaccinate children without parental consent as part of the new world order to control future populations.	High
Basch et al [59], 2021	United States	December 2020	Cross-sectional study (social media data extraction)	TikTok	100 videos studied garnered 35,338,600 views	38 videos discouraged the vaccine; 3 videos claimed that the vaccine is a hoax.	High

Study	Country	Study period	Study design	Type of social media	Social Media or population sample	Type of misinformation reported	Risk of bias (JBI[a])
Boucher et al [60], 2021	Canada	November 19 and November 26, 2020	Cross-sectional study (social media data extraction)	Twitter	636,516 English and French tweets	COVID-19 vaccines are poison and the messenger RNA technology has not been tested yet and is harmful.	High
Criss et al [61], 2021	United States	October 2020 to January 2021	Cross-sectional study (social media data extraction)	Twitter	1110 tweets	Misleading information that countered scientific research about the vaccines; the government using vaccines to insert microchips and control the population; the immune system is stronger than the vaccines; race extermination conspiracy that claims that the vaccine was created to "kill off [people of color] POC."	High
Herrera-Peco et al [62], 2021	Spain	December 8 to December 23, 2020	Cross-sectional study (social media data extraction)	Twitter	6080 Twitter interactions (n=499 of those are single tweets)	Deny the existence of the virus; the vaccine will modify the DNA of human beings; industry lobbies to kill older adults and leave young adults with Bells syndrome.	High
Melton et al [63], 2021	United States	December 1, 2020, to May 15, 2021	Cross-sectional study (social media data extraction)	Reddit	13 Reddit communities	Misinformation about side effects.	High
Pascual-Ferrá et al [64], 2021	United States	December 29, 2019, to January 2, 2021	Cross-sectional study (social media data extraction)	Facebook, Instagram, Reddit, and YouTube	Peaks and interactions	Viral video of a nurse fainting after vaccine uptake. Misinformation about COVID-19 vaccines (not specified).	High
Rotolo et al [65], 2021	United States	March 19, 2020, and June 16, 2021	Cross-sectional study (social media data extraction)	Facebook, Twitter, and Instagram	Aim: share 49 infographics to counter vaccine hesitancy.	COVID-19 myths.	High
Savolainen [66], 2021	Finland	February 2021	Cross-sectional study (social media data extraction)	Reddit, from the subreddit VaxxHappened	40 threads contained in total 1877 messages	Misinformation about COVID-19 vaccines (not specified).	High
Thelwall et al [67], 2021	United Kingdom	March 10 to December 5, 2020	Cross-sectional study (social media data extraction)	Twitter	446 COVID-19 vaccine–hesitant tweets in English	Deep state conspiracy; depopulation; microchips; Bill Gates; fearing that people of color are at risk for experimentation—motivated by the infamous US federal government Tuskegee Syphilis study ending in 1972 that secretly experimented on poor African American men.	High

Study	Country	Study period	Study design	Type of social media	Social Media or population sample	Type of misinformation reported	Risk of bias (JBI[a])
Wawrzuta et al [68], 2021	Poland	November 1, 2020, to May 1, 2021	Cross-sectional study (social media data extraction)	Facebook	3414 Facebook comments	The vaccine was created only for the profit of pharmaceutical companies; conspiracy theories, hidden vaccine effects (eg, chips); the vaccine will be dangerous to health; the vaccine has existed before the COVID-19 pandemic.	High
Doyno et al [69], 2021	Unites States	January to April 2021	Quasi-experimental study	YouTube, Twitter, Facebook, and Instagram	Information campaign with 79 COVID-19 vaccine–related videos in English, Cantonese, Spanish, Mandarin, and Polish	Misinformation (not specified).	N/A[b]

Thematic Analysis

Figure 3 provides an overview of the 3 overarching themes of misinformation identified from the thematic analysis, and examples from the data extraction and codes that laid ground for the final 3 themes are seen in the inner circles of the figure.

Of the 45 included studies, 18 (40%) studies reported misinformation across all 3 categories [27-29,35-37,45,48,49,51,55,57, 58,60-62,67,68], 9 (20%) studies reported only on conspiracies [26,30,33,42,44,46,53,54,56], 6 (13%) studies were concerned specifically with medical misinformation [25,34,38,43,63,64], and 12 (27%) studies reported on COVID-19 vaccine misinformation or antivaccine discourse without going into further detail [31,35,39-41,47,52,59,65,66,69].

Figure 3. Types of misinformation about the COVID-19 vaccine on social media platforms.

Effects of Social Media Misinformation

We identified 19 studies that made assumptions regarding the effects of social media misinformation on vaccine hesitancy (Table 3). The evaluation of the certainty of evidence of these 19 studies that measured the “Association between social media misinformation and COVID-19 vaccine hesitancy” was classified as moderate or low to moderate according to GRADE in 2 cases [38,65]. For the rest of the studies, the certainty of evidence according to GRADE was considered low or very low.

The 2 studies with a higher certainty of evidence had an experimental design. Rotolo et al [65] aimed to develop and distribute infographics that addressed COVID-19 vaccine hesitancy and misinformation. Although their infographics reached thousands of people, they were unable to determine the impact on vaccine hesitancy. Sharevski and Gover [38] analyzed the perceived accuracy of COVID-19 vaccine–related tweets when they were moderated by smart device technology that Twitter applies to COVID-19 misinformation. The results from the 304 participants suggested that vaccine-hesitant users ignored warnings as long as the tweets aligned with their personal beliefs.

Table 3. Studies in which the effect of social media misinformation is measured or discussed (n=19).

Study	Reported effect of misinformation	Certainty of evidence (GRADE[a])
Sharevski and Gover [38], 2021	Amazon Alexa was not able to dispel any biases that were rooted in personal beliefs. One's hesitancy from COVID-19 vaccination sufficed for biased perception of the information from Alexa despite any labeling as long as the tweets echoed their skeptical outlook on the whole COVID-19 vaccination effort.	Moderate
Rotolo et al [65], 2021	Each infographic reached thousands to tens of thousands of people. We do not know whether those who viewed these infographics changed their perspective on vaccination, so we are unable to conclude their impact on vaccine hesitancy based on this study alone.	Low to moderate
Allington et al [26], 2021	Informational reliance on all social media platforms was positively correlated with vaccine hesitancy; this correlation was strongest concerning Facebook and YouTube (R_S[b]=0.15 and R_S=0.18, respectively). Coronavirus conspiracy suspicions and general vaccine attitudes appear uniquely predictive, jointly explaining 35% of variance.	Low
Bhagianadh and Arora [28], 2021	Those depending on social media as the main source of information on COVID-19 expressed higher negative vaccine intent (OR[c] 3.36, 95% CI 1.44-7.82). Among those who expressed a negative vaccine intent, 40% (n=298) expressed no trust in government, and 10% (n=74) said that the vaccines cause COVID-19.	Low
Boucher et al [60], 2021	The study showed 2 clusters opposite to these vaccine acceptant clusters exhibiting more vaccine-hesitant narratives. There were 23.4% (n=146,191) of conversations on Twitter during this period of observation that can be directly attributed to vaccine hesitancy.	Low
Chadwick et al [30], 2021	Combinations of news avoidance and high levels of the news-finds-me attitude and social media dependence and high levels of conspiracy mentality are most likely to be associated with web-based discouragement of vaccination.	Low
Jennings et al [42], 2021	Holding conspiracy beliefs is a significant predictor of vaccine hesitancy. In the bivariate analysis, there is some support for a relationship between social media use (Snapchat, TikTok, YouTube, and Instagram) and increased vaccine hesitancy. YouTube users were significantly less willing to be vaccinated, with a two-thirds likelihood of vaccine willingness compared with nonusers.	Low
Liu and Liu [51], 2021	279 tweets stated their behavioral intentions. A total of 97 tweets were labeled with positive behavioral intentions, while 182 tweets contained negative behavioral intentions.	Low
Park et al [34], 2021	The study found that social media dependence and high levels of conspiracy mentality were most likely to be associated with web-based discouragement of vaccination. The likelihood of COVID-19 vaccine uptake was significantly lower among those relying on social media (OR 0.40, 95% CI 0.25-0.65)	Low
Zhang et al [39], 2021	Regarding social media influence, higher frequency of exposure to positive information related to COVID-19 vaccination was associated with a higher intention to receive a COVID-19 vaccination at market rate (AOR[d] 1.53, 95% CI 1.39-1.70) or a free vaccination (AOR 1.52, 95% CI 1.35-1.71).	Low
Zhang et al [40], 2021	Higher exposure to positive information related to COVID-19 vaccination on social media was associated with higher parental acceptability of COVID-19 vaccination (AOR 1.35, 95% CI 1.17-1.56). Higher exposure to negative information related to COVID-19 vaccination was negatively associated with the dependent variable (AOR 0.85, 95% CI 0.74-0.99).	Low
Aloweidi et al [27], 2021	The effect of social media (OR 1.21, 95% CI 1.04-1.41; *P*=.01) was significantly associated with the willingness to take COVID-19 vaccine. Circulated information about COVID-19 vaccines on social media platforms that they believed in: it is unsafe (n=283, 43.8%); effect of the vaccines on a genetic level (n=87, 13.5%); causes chronic illnesses (n=60, 9.3%); may lead to infertility (n=43, 6.7%); can affect their offspring (n=56, 8.7%); toxic heavy metals and neurotoxic materials (n=47, 7.3%); it is a part of a secret research (n=101, 15.6%)	Very low to low
Brodziak et al [29], 2021	A total of 432 (68%) used social media every day. Unwilling to vaccinate against COVID-19: social media as a source of information about vaccinations (OR 1.42, 95% CI 0.72-2.80). Not a significant predictor; attitudes toward COVID-19 vaccines: afraid of the vaccine's side effects (n=284, 44.7%); afraid of the composition of the vaccine (n=239, 37.6%); contains bodies of aborted children (n=49, 7.7%); COVID-19 does not exist (n=42, 6.6%)	Very low to low
Ebrahimi et al [31], 2021	Individuals with a preference for social media platforms as compared with those preferring source-verified media platforms had a near 2-fold (ie, 1.64) odds of being hesitant toward vaccination. Belief in superiority of natural immunity: OR 2.663, 95% CI 2.350-3.028; *P*<.001	Very low to low
El-Far Cardo et al [43], 2020	Factors that were negatively associated to get vaccinated were using social media in general as an information source about COVID-19 (*P*=.01) and the use of Facebook (*P*=.05) or Telegram (*P*=.05). However, using Twitter was not significantly associated with adverse vaccination intentions (*P*=.56). Believing that COVID-19 is not dangerous was associated with unwillingness to get vaccinated.	Very low to low

Study	Reported effect of misinformation	Certainty of evidence (GRADE[a])
Petravić et al [35], 2021	Those who trusted alternative media sources (alternative explanations on social media) and had a distrust of the government were more vaccine hesitant.	Very low to low
Sallam et al [36], 2021	The lowest rate of intention to get the vaccine was among those who depended on social media platforms (19.8%) compared with dependence on medical doctors, scientists, and scientific journals (47.2%, $P<.001$). Conspiracy beliefs were evaluated using the validated VCBS[e], with higher scores implying embrace of conspiracies. A significantly higher VCBS score was correlated with reluctance to get the vaccine ($P<.001$).	Very low to low
Costantino et al [41], 2014	A total of 71.4% (n=60) responded that unfavorable information about COVID-19 vaccines obtained from the internet, social media, or media was associated with the decision to not take the vaccine.	Very low
Karabela et al [33], 2021	Although the correlation was not significant, of the participants, those who considered having vaccination mostly trusted YouTube as their source of information. In contrast, the participants who stated that they would have the COVID-19 vaccine did not trust social media sites such as Facebook, Twitter, and Instagram ($P<.005$). There was a positive and low-level relationship between attitudes toward COVID-19 vaccines and conspiracy theories ($r=0.214$).	Very low

[a] GRADE: Grading of Recommendations Assessment, Development and Evaluation.

[b] R_S: Spearman Rank Correlation Coefficient.

[c] OR: odds ratio.

[d] AOR: adjusted odds ratio.

[e] VCBS: Vaccine Conspiracy Belief Scale.

Allington et al [26] analyzed findings from a web-based survey conducted with a sample of 4343 adults in the United Kingdom. They found a positive correlation between trust in social media and vaccine hesitancy and the strongest link was found for YouTube and Facebook. Conspiracy suspicions about COVID-19 and general vaccine attitudes appeared to be uniquely predictive, jointly explaining 35% of the variance. Boucher et al [60] analyzed 636,516 English and French tweets. A total of 23.4% (n=146,191) of the conversations on Twitter during the study period could be directly attributed to vaccine hesitancy. A British study by Liu and Liu [30] of 5114 adults found that social media dependence and high levels of conspiracy mentality were most likely to be associated with web-based discouragement of vaccination. In a study of 4571 Norwegian adults, individuals who preferred social media platforms had nearly 2-fold (ie, 1.64) odds of being hesitant toward COVID-19 vaccination compared with those preferring source-verified media platforms [31]. In addition, those who held the belief of the superiority of natural immunity over vaccination were more vaccine hesitant (odds ratio 2.663, 95% CI 2.350-3.028; $P<.001$). Petravić et al [35] asked 12,042 Slovenian residents about their attitudes toward COVID-19 vaccines. Those who trusted alternative media sources and alternative explanations on social media were more vaccine hesitant. A total of 11 studies [27-29,33,34,36,39-43] discussed social media misinformation, vaccine uptake, and vaccine intentions.

Discussion

Principal Findings

The 45 included studies about misinformation on social media platforms about COVID-19 vaccines suggest that there should be great concern about the volume of misinformation being spread, and the association between COVID-19 vaccine misinformation and vaccine hesitancy. To our knowledge, this is the first review to analyze social media misinformation about COVID-19 vaccines. We identified 3 overall categories of misinformation, namely, medical misinformation, conspiracies, and distrust in vaccine development; however, the 3 categories are connected and sometimes overlapping, as distrust in vaccine development might be founded in conspiratorial beliefs about hidden power structures and corrupt elites. The included studies were predominantly from Europe and the United States, and therefore, there is a lack of information, especially from African and South American countries. Twitter was the most studied platform, with Facebook and YouTube being in the second and third place, respectively.

Fear of side effects is a major concern when it comes to vaccine hesitancy, and as this review shows, this concern can easily turn into medical misinformation and exaggerations of side effects. To synthesize what is known about social media misinformation about COVID-19 vaccines from the included studies, a thematic analysis was undertaken. The coded extract of data that made up the theme medical misinformation contained misinformation about side effects such as infertility, chronic illness, changes in DNA, physical deformities, and mental illness. Only one study mentioned autism as an adverse side effect of COVID-19 vaccines [63]. Knowing that the side effects of the vaccines are a major concern [5], medical misinformation has the potential to do a lot of harm.

When we examined the types of reported misinformation, we also found that a lot of misinformation is grounded in conspiracy theories. Some of these conspiracy theories have become infamous, such as the belief that there are secret societies and hidden power structures run by corrupt elites. These elites are believed to be networking with big pharmaceutical companies to make money or to depopulate the world. There are also conspiracy theories about racially motivated depopulation. For example, we found 3 studies from the United States that mentioned the fear of racist motives by official health authorities as a reason for vaccine hesitancy [45,61,67]. Some of this fear has historical roots in the United States, as one of these studies [67], for instance, brought up the Tuskegee Syphilis study. This was a clinical study (1932-1972) in which the United States Public Health Service used African Americans to observe untreated syphilis and therefore denied them treatment [71]. This exemplifies that a lack of trust in public health institutions might have deep historical roots in some countries and cultures. Other issues to be aware of are religious concerns and vaccine hesitancy. We found several studies that reported on misinformation about the content and development of vaccines and in some studies [29,45,55], we found very explicit language (eg, “pigs” and “cells from aborted children”). Such wording can cause worry in some religious communities.

The second objective of this review was to examine the effects of social media misinformation about COVID-19 vaccines. The 19 studies identified in Table 3 interpreted the results as associations among social media use, misinformation, and vaccine hesitancy. According to the JBI and GRADE evaluations, there is a need for more robust designs to become more certain regarding the actual effect of social media misinformation on vaccine hesitancy. Only 1 study, an intervention study regarding the impact of addressing misinformation on Twitter users, was assessed to have a low risk of bias and moderate quality of evidence [38]. In addition, 4 studies reported significance levels of associations, but the effect size was not reported [31,32,35,50]. Other studies in this review showed that social media platforms did not necessarily spread misinformation to a great extent, perhaps reflecting that the effort made by some social media platforms to halt misinformation has worked. Chan et al [47] examined 48 COVID-19 vaccine–related videos on YouTube in December 2020 and found only 2 videos (4.2%) that made nonfactual claims. Hernández-García et al [54] also examined YouTube videos during February 2021 and found that only 2 out of 110 videos contained COVID-19 vaccine hoaxes or conspiracy theories. Pascual-Ferrá et al [64] examined social media data from Facebook, Instagram, Reddit, and YouTube and did not find evidence of the dominance of misinformation. However, what is being spread and discussed in closed groups is another question that needs to be examined further. Another valid approach would also be to examine comment sections. Although antivaccine content has been prevented from surfacing in searches, this does not prevent people from commenting about their beliefs or posting other types of information in the comment section. It is controversial to deplatform people [72] and might even do harm, as these people might be seen as someone speaking against the establishment, which are, in essence, some of the core beliefs of some conspiracy theorists.

Surprisingly, there was a dearth of studies examining misinformation about autism and COVID-19 vaccines. Considering the history of misinformation about vaccines and autism over the past 2 decades, more research should focus on this topic. One could also speculate whether this would have played out differently if COVID-19 vaccines were more targeted toward younger children. Future research should also aim to examine social media platforms such as TikTok, which is a very popular platform worldwide, and is often used by people who are younger than, for instance, the average Twitter user [73]. The low inclusion of some social media platforms such as TikTok or Telegram is a limitation, as certain parts of the population and particular communities are not included.

When addressing vaccine hesitancy, one should be careful before labeling all vaccine-hesitant people as antivaxxers or misinformed people. The primary concerns from people who say that they are vaccine hesitant are the safety of the vaccines and the rapid pace of their development [7]. However, being hesitant and skeptical does not mean that these people are unwilling to take the vaccines but rather that they have some concerns that should be adequately addressed to convince them of the safety and efficacy of the vaccines. To understand a complex issue such as vaccine hesitancy, knowledge about sociodemographic conditions and cultural awareness is key. In addition, countries with a more undemocratic regime will suffer from a lack of trust in official authorities, which may damage an official vaccine campaign. People’s trust in the government varies between countries and cultures. Although some countries have a tradition for mandatory vaccination, this is less acceptable in other countries.

The issue of trust is also an important issue to be considered. “Fake news” became a buzzword in the last decade and the term was used not only to actually coin false news but also to spread distrust to news agencies and official actors, accusing them of spreading falsehoods. Vosoughi et al [74] aimed to understand how false news spread and examined a set of rumors (n=126,000) spread by 3 million people on Twitter from 2006 to 2017. The results showed that false news spread much faster and reached a larger audience than real news. Social media has contributed to a far more complex information landscape than before and has created new challenges when it comes to building trust in official actors. These are issues that need to be addressed and analyzed in future studies of misinformation about vaccines.

Limitations

We did not include gray literature or preprints in this review. The rapid pace at which the pandemic is moving makes preprint research particularly relevant. However, although peer review is not a guarantee of quality, we decided not to include gray literature or preprints and limited eligible articles to peer-reviewed manuscripts. We did not contact researchers with potential projects on this subject matter. Furthermore, the searched databases were selected based on the topic at hand. There will always be a chance that other, more specified or general databases would capture other studies.

A limitation of the evidence included in this review is that, in our assessment, all but one received a low score on the assessment of quality of evidence. However, it is a challenge in the process of assessing quality of evidence and risk of bias, that the included studies have a range of different designs, each with its strengths and weaknesses. We applied 2 tools in this regard: 1 from the JBI [24] and 1 from the GRADE Working Group [70]. Neither tool provides a complete picture of the included studies, but they may help the reader in obtaining a broader view of the included studies.

Furthermore, there is a poor correlation between self-reported social media use and actual use [75]. A high proportion of these studies extracted data from Twitter because Twitter has opened up access for researchers to extract data from its platform, making it more accessible compared with other social media platforms. The Twitter sample may not be representative of a random sample of the population, as its users tend to range in age from 25 to 34 years and are predominantly from the United States [76,77]. Furthermore, we did not assess the potential presence of social media bots (automated accounts) spreading incorrect information in these studies. We also did not discuss how social media algorithms partake in creating echo chambers [78]. These are well-known challenges in researching data gathered from social media [79]. Only 1 study included in this review was from an African country [32]. The study was from Uganda and included 600 participants. There were no studies from Middle or South American countries or Pacific Island countries and Australia. The studies included in this review focused mostly on high-income countries, thus making the conclusions and generalizations weaker in terms of applying them to Global South nations.

Conclusions

This review suggests that there should be great concern about the volume of misinformation being spread and the association between COVID-19 vaccine misinformation and vaccine hesitancy. Many studies have shown that there is a link between misinformation on social media and COVID-19 vaccine hesitancy. However, there is a need to examine this effect using a more robust experimental design to assess this effect. It is possible to conduct more experimental studies in an ethical manner in a laboratory setting; for instance, a study to see whether people are able to distinguish between false and true information and how they do so. Such a study would, of course, have to be based on informed consent and be approved by an ethics committee. It is also possible to improve observational studies that extract data from social media by gathering more representative data (eg, including data from several social media platforms, different audiences, several languages, and covering longer periods). There are many types of misinformation that are spread on social media platforms, and to prevent these myths from taking hold, health authorities should openly address and discuss these false claims with both cultural and religious awareness in mind. This review showed that a greater variation in studies is needed when it comes to both social media platforms and geographic location. We only found one study that mentioned misinformation about autism and COVID-19 vaccines, but taking the history of autism and the antivaxx community into account, we believe that this an issue that should be given attention in future research.

Although some major tech companies have taken steps to prevent misinformation, more action is needed to stop this infodemic. One valid approach proposed for infodemic management is first information monitoring (infoveillance); second, to enhance and build eHealth literacy and science literacy capacity; third, to encourage quality improvement processes such as fact-checking and peer review; and finally, to encourage accurate and timely knowledge translation [80].

Misinformation about COVID-19 vaccines is still thriving on social media platforms. However, this undertaking represents a balance between people’s right to speak their minds and strategies to counter the spread of misinformation.

Acknowledgments

The authors would like to thank senior librarian Kjell Erik Johnsen for his help and input in conducting the systematic searches.

Data Availability

All relevant data are available in this paper and its supplementary files. Correspondence and requests for additional material should be addressed to the corresponding author (IS).

Authors' Contributions

IS, EG, and ANH conceived the idea for this study. IS and ANH screened the titles and abstracts. IS and EG full-text screened the articles. IS performed data extraction with verification from EG. DSQ assessed the risk of bias, and RW evaluated the quality of evidence. IS took the lead in writing the manuscript. All authors discussed, revised, and contributed to the final manuscript. All authors have read and agreed to the final published version.

Abstract

Background: Social media has changed the way we live and communicate, as well as offering unprecedented opportunities to improve many aspects of our lives, including health promotion and disease prevention. However, there is also a darker side to social media that is not always as evident as its possible benefits. In fact, social media has also opened the door to new social and health risks that are linked to health misinformation.

Objective: This study aimed to study the role of social media bots during the COVID-19 outbreak.

Methods: The Twitter streaming API was used to collect tweets regarding COVID-19 during the early stages of the outbreak. The Botometer tool was then used to obtain the likelihood of whether each account is a bot or not. Bot classification and topic-modeling techniques were used to interpret the Twitter conversation. Finally, the sentiment associated with the tweets was compared depending on the source of the tweet.

Results: Regarding the conversation topics, there were notable differences between the different accounts. The content of nonbot accounts was associated with the evolution of the pandemic, support, and advice. On the other hand, in the case of self-declared bots, the content consisted mainly of news, such as the existence of diagnostic tests, the evolution of the pandemic, and scientific findings. Finally, in the case of bots, the content was mostly political. Above all, there was a general overriding tone of criticism and disagreement. In relation to the sentiment analysis, the main differences were associated with the tone of the conversation. In the case of self-declared bots, this tended to be neutral, whereas the conversation of normal users scored positively. In contrast, bots tended to score negatively.

Conclusions: By classifying the accounts according to their likelihood of being bots and performing topic modeling, we were able to segment the Twitter conversation regarding COVID-19. Bot accounts tended to criticize the measures imposed to curb the pandemic, express disagreement with politicians, or question the veracity of the information shared on social media.

Introduction

Social media has radically changed the way we live and communicate. These new communication platforms offer unprecedented opportunities to improve many aspects of our lives, including public health [1,2]. They are useful to improving our access to evidence-based health information that can be fundamental to promoting healthy habits and fostering risk prevention [2]. In addition, the progressive growth of web-based, health-related knowledge and content has been found to be useful for patients who need to acquire medical skills and enhance their self-efficacy for adherence to treatments or therapies as well as for disease prevention [3].

Nevertheless, social media has also opened the door to new social and health risks [4,5]. Policies to mitigate misinformation and false health rumors are becoming increasingly common. In fact, some of the most widespread social media platforms such as Facebook, Instagram, and Twitter have implemented policies to combat the spread of misinformation regarding the COVID-19 pandemic. However, the web-based ecosystem is still overrun with health myths, hoaxes, and fake news stories that—either consciously or unconsciously—are propagated by social media users for different purposes. These messages can lead to attitude and behavior changes that may result in inadequate health decisions [6,7]. The effect of health misinformation has also been found to be determinant in health decision-making during risky situations and outbreaks such as the H5N1, Ebola, and Zika [5] viruses and the more recent COVID-19 pandemic [8,9]. Misleading messages have even hampered public health actions taken to tackle outbreaks [10-12]. For instance, in the context of the COVID-19 pandemic, misleading information has been detected regarding the origin of the virus, the potential treatments and protective measures available, and the real impact of the disease [13]. In one sample of tweets relating to COVID-19, 24.8% of the tweets included misinformation and 17.4% included unverifiable information [13]. Recently, much of the misinformation during the pandemic has focused on the debate regarding the vaccination process and the subsequent doubts the new vaccines have raised among the population [14].

Therefore, the role of social media during the COVID-19 pandemic has been critical. Although these new platforms have been useful to keep the public informed during the most critical moments of the pandemic, the responses by health authorities to combat the outbreak have been followed by a massive "infodemic," recently defined as "an overabundance of information—some accurate and some not—that makes it hard for people to find trustworthy sources and reliable guidance when they need it" [15]. Information consumption, opinion formation, and social contagion processes relating to COVID-19 across the social media ecosystem have become a major challenge for researchers [16], since these processes can strongly affect people's behavior and reduce the effectiveness of the countermeasures implemented by governments and health organizations [17].

Recently, misinformation dynamics have increased their complexity due to the emergence of so-called "social bots" (ie, automated web-based accounts). The role of social bots in the spread of misinformation on social media platforms has been widely recognized during political campaigns and election periods [18] and in relation to health debates, especially during health crises [19]. Regarding health communication on social media platforms, some studies have found that social bots are used to promote certain products to increase company profits and favor certain ideological positions [20] or contradict health evidence [21,22]. Bots have certain behavioral characteristics that make them potential super-spreaders of misinformation (eg, excessive posting and frequent retweeting of emerging news and tagging and mentions of influential topics or relevant figures) [20,23,24]. These accounts often use amplification as a strategy for the dissemination of content that misinforms based on the interests of the creators of these automatic accounts [25], although they are also often used as a tool to generate disagreement and social polarization [22].

The activity of social bots has dramatically increased in the context of the COVID-19 infodemic [25] due to their participation in the debate on the health measures to control the pandemic and the vaccines that have emerged during this period [26]. To date, it has been established that the progressive proliferation of social bots (and particularly unverified accounts) in the complex social media ecosystem may contribute to the increased spread of COVID-19 misinformation and the subsequent evolution of the pandemic, either by amplifying messages of dubious quality or generating polarization in relation to controversial issues [25]. However, a better understanding is needed on the role of these bots in the COVID-19 infodemic [27]. In an attempt to fill this knowledge gap, this study aimed to explore the role of social bots during the early stages of the COVID-19 pandemic. Our objective was to answer 3 basic questions: (1) What were the main conversation topics during the outbreak of COVID-19 on Twitter? (2) How do these topics vary depending on the information source (nonbots, bots, or self-declared bots)? and (3) How does the general tone of the conversation vary depending on the source?

Methods

Data Collection

Data collection started on March 16 and ended on June 15, 2020, using the Twitter streaming API with the following hashtags: *covid_19*, *covid19*, *covid*, and *coronavirus*. These hashtags were used during this period to capture the conversation during the first wave of COVID-19. To simplify the subsequent analysis, only tweets written in the English language were selected. The resulting data sample contained approximately 14 million tweets from about 285,000 different Twitter accounts.

Bot Classification

We used *Botometer* (formerly *BotOrNot*; OSoMe project) [28] to obtain the likelihood of whether each account is a bot or not. *Botometer* is a publicly available service that leverages more than 1000 features to evaluate the extent to which a Twitter account exhibits similarity to the known characteristics of social bots. As in other studies [29,30], 0.8 is the score used to classify an account as a bot. In addition, the percentage of bot accounts in benchmark studies is between 9% to 15% of the total number of accounts on Twitter [31]. In our case, this score classified approximately 14% of the accounts as bots.

In addition to the overall likelihood of being a bot, *Botometer* also gives specific scores for 6 different bot types: echo chamber, fake follower, financial, self-declared, spammer, and other. Given the differing nature of social bots, it was considered necessary to draw a distinction between self-declared bots and other types of bots. Self-declared bots are extracted from Botwiki [28,32].

Topic Modeling

Finally, together with the bot classification, we also applied topic-modeling techniques. This unsupervised classification approach allows the classification of texts, using techniques such as clustering to find groups of texts with similar content. In this case, we used latent dirichlet allocation (LDA), a popular topic-modeling technique which considers each document as a random mixture of various topics and each topic as a mixture of words [33].

To correctly interpret the results, we considered the distribution of the topics within the corpus, the keywords of each of the topics, and the intertopic distance [34]. Based on this, the most common topics of the different documents in the corpus were extracted. For each topic, we obtained the most relevant words and the 50 most characteristic tweets according to the model. We then carried out an inductive qualitative process to characterize each topic, followed by a descriptive process to codify the information [35]. Discrepancies were shared and resolved by mutual agreement. We also analyzed the distribution of the different types of accounts in the topics. This approach allowed us to determine the main conversation topics [36] and the most common ones for each type of account.

In addition, we plotted an intertopic distance map [34] to visualize the topics in a 2D space. The area of the topic circles is proportional to the number of tokens (ie, single words) that belong to each topic across the dictionary. The circles were plotted using a multidimensional scaling algorithm based on the words they comprise, with the topics that are closer together having more words in common.

Sentiment Analysis

For each of the groups, we used sentiment analysis to examine the tone or sentiment associated with the content. Sentiment analysis is an area of knowledge in the field of natural language processing, text analysis, and computational linguistics used to identify and extract subjective information from resources. In the case of text mining, sentiment analysis involves automatically mass-classifying documents based on the positive or negative connotation of the language in the document [37].

For the sentiment extraction, we used Valence Aware Dictionary and Sentiment Reasoner (VADER), a rule-based tool specifically attuned to sentiments expressed on social media platforms [38]. VADER uses a combination of sentiments associated with lexicons that are generally labeled according to their semantic orientation as positive or negative. Unlike other text analysis tools, VADER works well on texts extracted from social media platforms, because it does not need as much text as other tools [39-41].

Another feature of this method is the output value. Most sentiment analyses classify texts as positive, negative, and neutral; for example, texts with a predominance of words, expressions, or ways of writing perceived as positive are classified as positive. However, the method used here returns a sentiment score between –1 and 1, allowing a higher level of comparison between the different types of accounts.

Results

Bot Classification

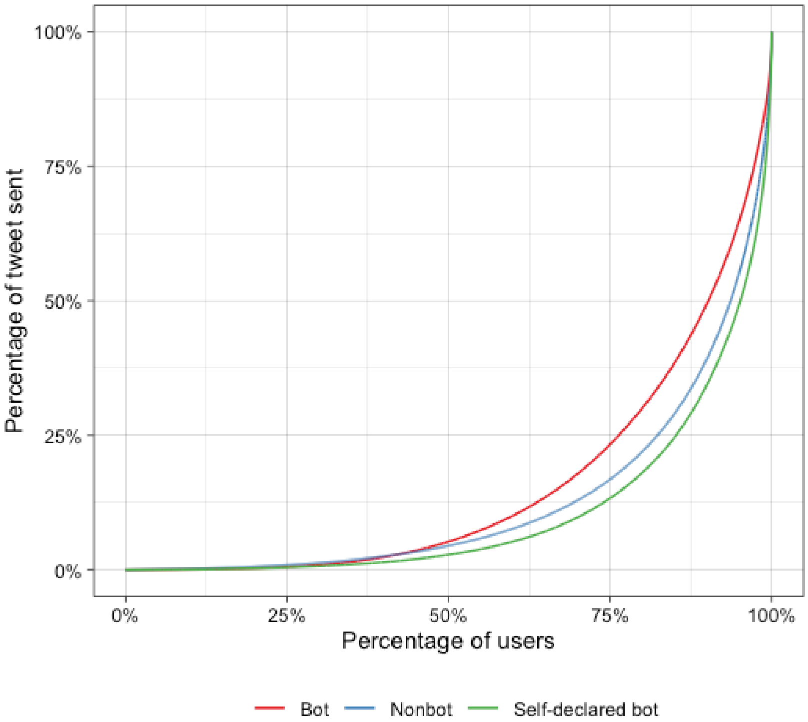
Table 1 shows the resulting classification. If the probability of an account being a bot is lower than 0.8, we considered it as a normal user (ie, nonbot). If the probability of an account being a self-declared bot is higher of 0.8, we classified it as a self-declared bot. Accounts with the probability of being a bot higher than 0.8 and the probability of being a self-declared bot lower than 0.8 were classified as bots. Of the 205,298 accounts, most (n=187,992, 91.6%) were normal users; 4.2% (n=8616) were classified with a high likelihood of being bot accounts; and 4.2% (n=8690) were classified as self-declared bots. Bot accounts posted an average of 123.3 tweets per user. During the 3-month time window, accounts classified as self-declared bots posted a slightly lower average of 121.1 tweets per user. However, accounts classified as having a low likelihood of being bots posted 42.5 tweets per user. These differences between the mean values were statistically significant ($F_{2,284,814}$=1056; P<.001). As also noted in Broniatowski et al [22], the most active accounts on average were those classified as bots.

Not all groups contributed to the same extent. Likewise, the contribution of the participants in the global discussion was highly unequal. The Gini index was used to measure this inequality. This index is a measure of the distribution, with a higher Gini index indicating greater inequality. Figure 1 shows these distributions, with a Gini index of 0.786 for self-declared bots, 0.744 for nonbots, and 0.686 for bots. Self-declared bots had the most unequal distribution: 75% (6517/8690) of self-declared bots posted 12.5% (131,559/1,052,471) of the total number of tweets. In contrast, 75% (6462/8616) of the bot accounts posted 25% (265,499/1,061,997) of the total tweets.

Table 1. Distribution of bot classification.

Source	Account (N=205,298), n (%)	Tweet (N=10,098,455)		
		n (%)	Mean	Median
Nonbot	187,992 (91.6)	7,983,987 (79.1)	42.5	9.0
Bot	8616 (4.2)	1,061,997 (10.5)	123.3	35.5
Self-declared bot	8690 (4.2)	1,052,471 (10.4)	121.1	15.0

Figure 1. Lorenz curve showing inequality in the number of tweets.



In the case of self-declared bots, the most active accounts spread official data (the number of COVID-19 cases and mortality, etc). Second, several of these accounts were digital magazines or independent news agencies. The descriptions of these accounts mentioned that they created messages to provide periodic reports on the situation and communicate the global evolution of COVID-19 or substantial changes in the evolution of the pandemic. Many of these accounts indicated that their purpose was informative. Given this situation, these profiles were separated from those classified as regular bots in the analysis.

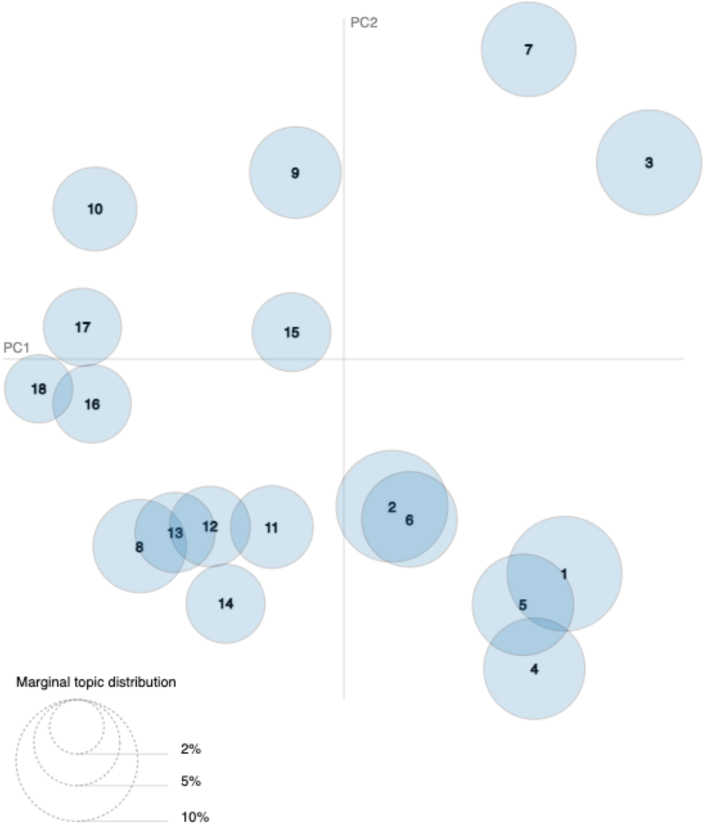
The descriptions of the accounts classified as bots were very different from each other. Many accounts identified themselves with technology companies. Others identified themselves as activists, either political, environmental, or even military. These accounts tweeted about the pandemic, the political measures taken, or complaints about the situation resulting from inaction.

Topic Modeling

After classifying the accounts, the topics were extracted using LDA. To select the correct number of topics, we relied on the coefficient of variation, which measures the coherence between the topics inferred by a model. In other words, the coefficient indicates which combination of topics is the most coherent. Higher values indicate that the topics are semantically interpretable. Topic coherence measures score a single topic by measuring the degree of semantic similarity between high-scoring words in the topic. This concept brings together several measures to assess the coherence between the topics. To choose the number of topics, the LDA model was reapplied with different outputs, and those with the highest coefficient of variation were selected (Multimedia Appendix 1). In total, 18 topics were extracted and plotted using the intertopic distance map.

In the intertopic distance map below (Figure 2), each bubble represents a topic. Each topic was assigned a number depending on the number of tweets inside it. Accordingly, Topic 1 had a higher percentage of tokens than Topic 2 and so on. The larger the bubble, the higher the number of tokens classified in this topic. The further the topics are away from each other, the more different they are. Therefore, there are not many differences between 2 nearby topics. On the contrary, there are greater differences if they are further apart.

Figure 2. Intertopic distance map. PC: principal component.



We also plotted the most common terms in a bar chart (Figure 3). The terms were sorted according to the number of times they appear. The colored bars show the estimated number of times a term is in each topic. The grey bars represent the overall frequency of each term in the corpus. When interpreting the results, it is not only necessary to consider the most common terms but also the most salient terms. Saliency is the product of weighting the probability of a word, *P*(w), by its distinctiveness, a measure of how informative the specific term is to determine the generative topic. Saliency is therefore a measure of the degree to which the word appears a small number of times or not at all in other topics [36].

We then carried out the qualitative phase, with both authors agreeing in 89% (16/18) of the cases. Table 2 shows the results obtained in the classification.

In Figure 4, each line is a topic, and each dot represents the percentage of accounts in each topic. Topic 1 contained tweets with information on the outbreak. The messages were focused on providing information about the advance of the pandemic and what actions need to be taken to stop it. The most common words were *stay*, *home*, and *family*. Other tweets shared this kind of information but for specific regions. For example, Topic 9 was focused on regions in Africa, and Topic 13 was focused on the lockdown in India.

These 2 topics have the most substantial differences between self-declared bots and the rest of the accounts. Topic 9 accumulated the highest percentage (1581/8690, 18.2%) of self-declared bot accounts, compared to bots (896/8616, 10.4%) and nonbots (20,115/187,992, 10.7%). Likewise, the percentage of self-declared bots in Topic 13 is 5.7% (495/8690), whereas the percentage for bots is 3.4% (293/8616) and 3.8% (7144/187,992) for nonbots.

Topic 2 contained information about the evolution of the pandemic. This topic was focused on the second wave and information on the number of deaths. The most common keywords were *case*, *death*, *report*, and *total*. In the following topics, the model groups' contents were related to specific measures to curb the pandemic. Topic 3 mentioned the lack of testing. Some topics reminded people to stay at home (Topic 4), of the importance of wearing a face mask (Topic 11), or of washing one's hands (Topic 12).

Other messages were related to US politics or President Trump. Most of the tweets in Topic 17 were about decisions by the US Congress. Topic 18 mentioned certain national political scandals. Topic 8 was focused on criticizing President Trump's policies. These tweets cast President Trump as a liar and irresponsible. Some of the most common keywords were *president*, *Trump*, *China*, *virus*, *year*, and *world*. This topic had the biggest difference between the percentage of bots and the rest of the accounts. In Topic 16, most of the tweets mentioned the lack of honesty of the US President. There were also complaints about the need to share true information and disregard rumors (Topic 15). In these last 2 topics, the percentage of bot accounts was slightly higher than the rest of the accounts.

Figure 3. Word distribution along with topics.

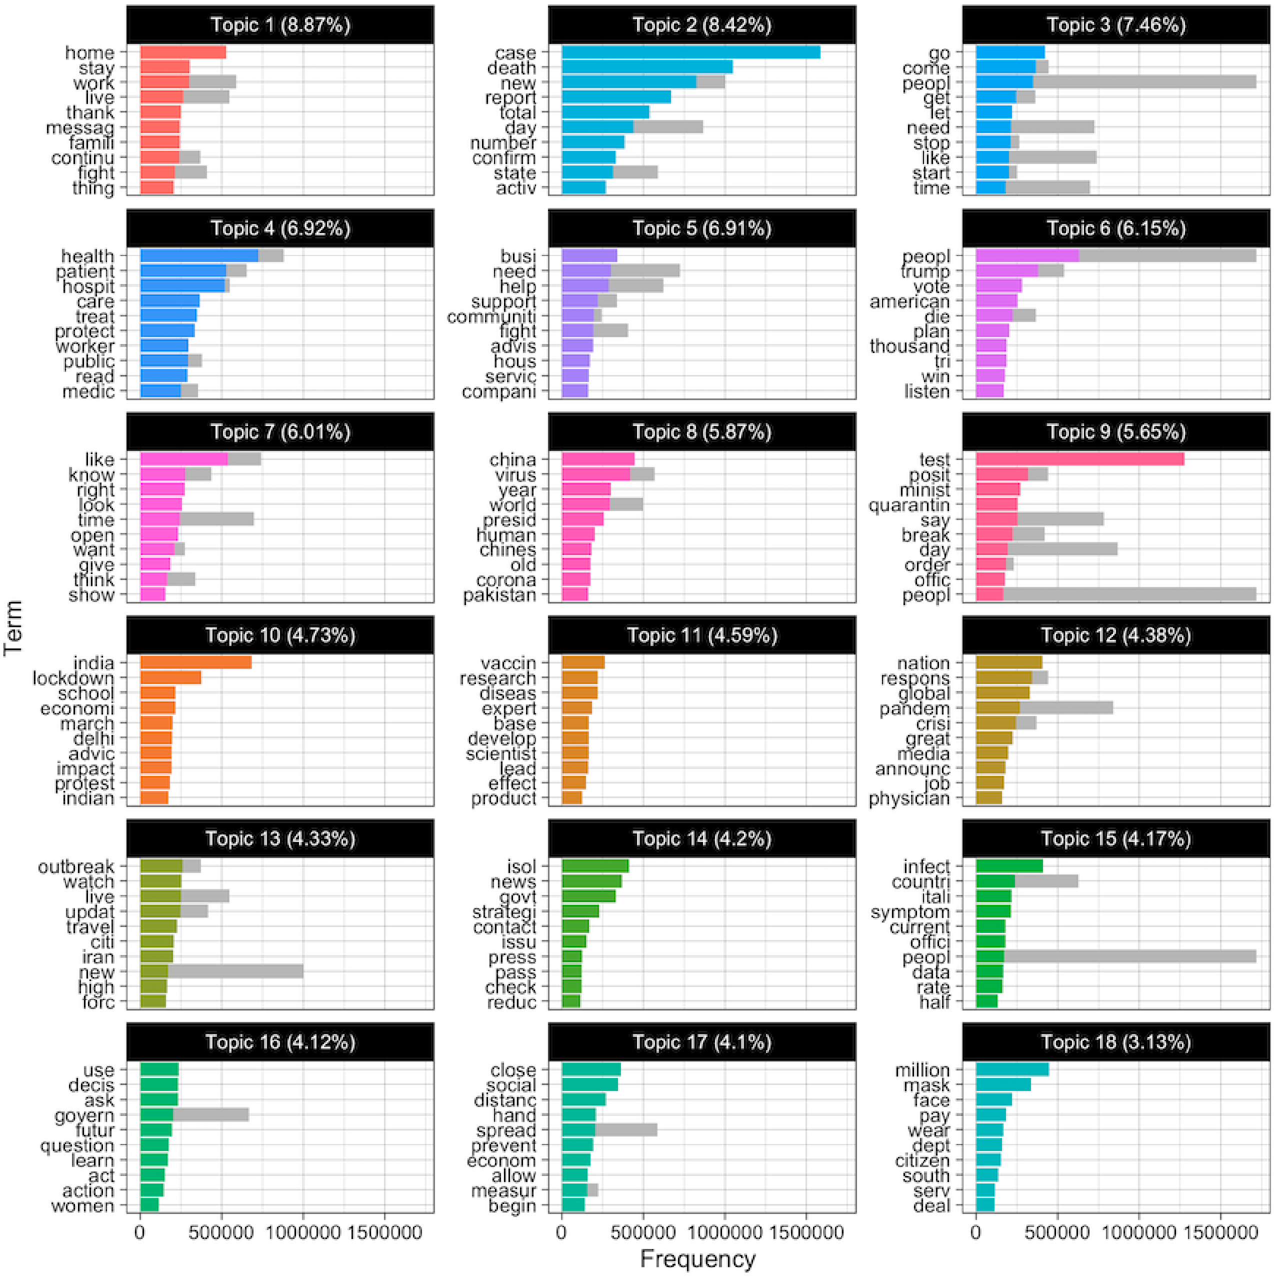


Table 2. Main idea for each topic.

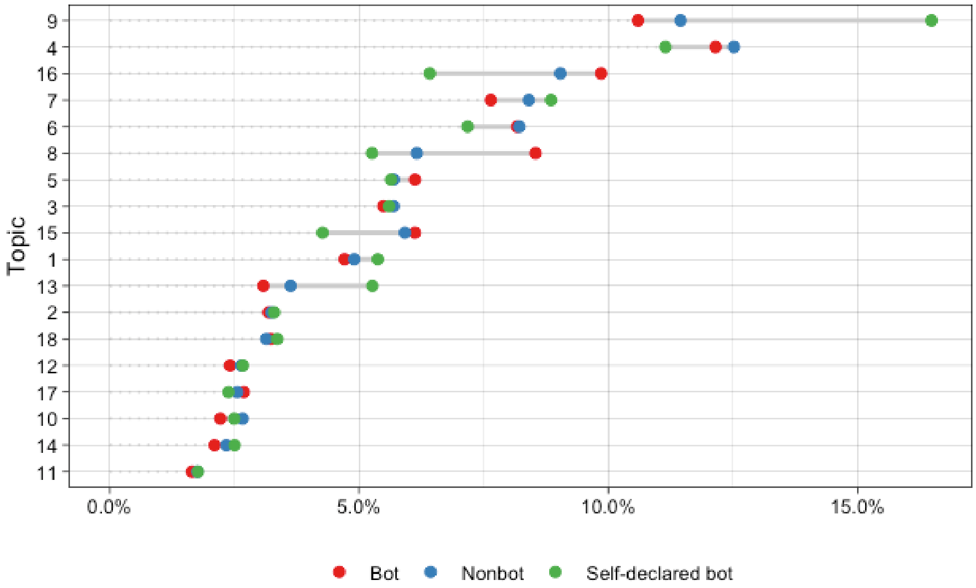
ID	Topic
1	News about coronavirus
2	Second wave and vaccines
3	Complaints about lack of COVID-19 testing
4	Stay home
5	China and its relationship with the virus
6	Respect health care workers
7	Financial aid and charity during the pandemic
8	Trump and the pandemic
9	Reporting positive cases in Maharashtra and Africa
10	Pointing out that COVID-19 is different from influenza
11	Wearing face masks
12	Tips to prevent spreading COVID-19
13	Lockdown in India
14	Death of a famous person
15	Calls for real leadership
16	A call for honesty
17	Decisions in the US Congress
18	A national scandal

Figure 4. Account distribution within topics.



Sentiment Analysis

The mean value of the VADER score for each group was 0.0109 (SD 0.414) for nonbots, 0.00784 (SD 0.383) for self-declared bots, and –0.0155 (SD 0.427) for bots. An ANOVA test was used to check for statistically significant differences in the mean values of the groups ($F_{2,284,814}$=5216; P<.001). Figure 5 shows the evolution of the average scores over the period. The mean value was almost always lower in the case of bots, indicating a greater presence of words associated with negative feelings in this group. Accounts classified as self-declared bots were closer to values of 0. On the other hand, accounts classified as bots scored negatively.

These differences in sentiment between nonbots, self-declared bots, and undeclared bots are better understood if we consider the different topics that made up these conversations. Although most of the tweets posted by nonbots were focused on sharing the situation people were experiencing due to the outbreak, self-declared bots tended to inform and post news on the outbreak all over the world, and undeclared bots were generally focused on criticizing political measures, interpersonal blame between senators or governors, and criticism directed at governments or political leaders in relation to the mismanagement of the health crisis. At this point in the analysis, it seemed more likely that undeclared bots spread messages of disagreement, criticism, and complaints regarding the political and health authorities in view of the difficulties to adequately control the pandemic.

Discussion

Principal Findings

This study has allowed an assessment of the role of social bots on Twitter during the early stages of the COVID-19 pandemic. There were consistent differences between the different account types identified (self-declared bots, undeclared bots, and nonbots). Although the percentage of undeclared bots on Twitter is relatively low compared to the large number of human users, it has been established that bots are generally linked to web-based conversations characterized by controversy and polarization. In this sense, the role of these automatic agents is far from negligible, considering the role they play in the amplification of ideas and opinions that generate conflict in our societies [42,43].

The classification adopted has allowed the comparison of the different topics arising in the conversations of 3 different profiles of Twitter users during the initial months of the pandemic. Furthermore, to the best of our knowledge, this study has several advantages compared to other works that analyze sentiment in a general manner and regardless of the information source and type [44-46]. First, our study provides additional information on the information sources (nonbots, self-declared bots, and bots), particularly concerning the credibility of the different Twitter users. Second, it allows a deeper analysis of the Twitter conversation based on topics and the associated sentiments during the outbreak of the COVID-19 pandemic. Third, the comparison of the topics according to source shows there is internal consistency between the different types of accounts. Therefore, the differentiation of topics and sentiments linked to different Twitter user accounts (and particularly those relating to bots) is relevant for the identification, characterization, and monitoring of possible sources of disinformation that could emerge in the event of an infodemic [47].

On the other hand, the sentiment analysis also gives an idea of the strategy of undeclared bots or automated accounts in the context of the first months of the COVID-19 pandemic. Our study shows that social bots were used to criticize and harass political opponents rather than to provide useful information on health measures and self-protection behavior in a context where quality information was sorely needed in the face of widespread misinformation [47]. In-line with our results, a recent study indicates that right-wing self-media accounts and conspiracy theorists may give rise to this opinion polarization, whereas malicious bots may foster the diffusion of noncredible information [42]. We have not found large amounts of misinformation on health issues but rather major divisions regarding political decision-making processes and the measures to address the COVID-19 pandemic (eg, vaccines and protective measures, etc). In this sense, the conversation on automated accounts is directed more toward generating conflict and disagreement [43].

Despite these findings, additional evidence is needed to determine the social and health impacts of the misuse of social bots during the early months of the pandemic. Likewise, it is necessary to determine to what extent these agents have hindered the prevention and control of the health crisis by the different governments. In any case, this is a new working hypothesis that remains open and should be analyzed in detail in future studies.

Limitations and Strengths

This study is subject to several limitations. First, the data collected from Twitter is limited by the technical characteristics of the Twitter streaming API. Although the streaming API is more accurate than the REST API, it never returns the total number of tweets about the conversation [48]. Moreover, due to technical limitations, it is impossible to analyze the entire conversation. In addition, by selecting only tweets written in the English language, the content of the conversations is strongly focused on topics in the United States and United Kingdom. Second, the period analyzed is in the early stages of the outbreak, and the conversations tended to evolve just as the pandemic did. Third, when observing self-expression over the internet, only the thoughts and feelings the users chose to express at the time can be captured, which may be strategically composed to project a public persona [49]. Still, many mental health studies have shown that social media is a valuable outlet and source of support for its users [50]. Topic modeling is a good technique to obtain a general idea of the different topics within a conversation. However, the downside of this technique is that the number of topics must be preselected. In our case, we used the coefficient of variation to identify the optimal number for each group.

On the other hand, this study also has several strengths. First, it takes into account the credibility of the information source. This aspect is rarely addressed in studies of social media platforms [2]. Second, this study analyzes conversations regarding the outbreak of a pandemic, and social media sites are hot spots in such situations [5], with users increasing their information searches on these platforms.

Conclusions

By classifying the accounts according to the likelihood of being bots and applying topic modeling, we were able to segment the Twitter conversations regarding the COVID-19 pandemic. Nonbot accounts, for example, tended to share information or give advice on how to deal with the pandemic. The accounts declared as bots mostly shared information and statistics on the pandemic. Finally, accounts not declared as bots tended to criticize the measures imposed to curb the pandemic, express disagreement with politicians, or question the veracity of the information shared on social media platforms. We also used sentiment analysis to compare the tone of the conversations in these different groups. Self-declared bots had conversations with a neutral tone. The tone of messages written by nonbot accounts tended to be more positive than the former. On the contrary, the tone of undeclared bots was always more negative than the tone of self-declared bots. Therefore, it is necessary to work on the identification and monitoring of these agents in times of infodemics.

KEYWORDS

activity recognition; machine learning; health monitoring; gait analysis; wearable; sequence classification; mobile health; mHealth; neural network

Introduction

It is challenging to routinely assess gait unless dedicated measuring devices are available. Inspired by a recent study that reported high classification performance of activity recognition tasks using smartwatches [1], we hypothesized that the recognition of gait-related activities in older adults can be formulated as a supervised learning problem. To quantify the complex gait motion, we focused on hand motion because disturbed hand motions are frequently reported as typical symptoms of neurodegenerative diseases [2].

Methods

Data Acquisition

We recruited 39 older adult participants (age: 80.4, SD 6.5 years; n=38, 73.7% women) from a local community. The number of participants for each class was as follows: cane-assisted gait (C0) (n=7), walker-assisted gait (C1) (n=5), gait with disturbances (C2) (n=21), gait without disturbances (C3) (n=6), and gait without disturbances in young controls (C4) (n=12). During the experiment, participants were asked to wear a smartwatch (DW9F1; Fossil Group, Inc) on each wrist and walk at a normal speed similar to their usual walk. Figure 1 shows example photographs taken during the experiment.

Figure 1. Five different gait styles: cane-assisted gait (C0), walker-assisted gait (C1), gait with disturbances (C2), gait without disturbances (C3), and gait without disturbances in young controls (C4).

Classification

The multivariate time-series (MTS) signals captured at a sampling rate of 50 Hz were segmented into . Here, represents the inertial motion at a specific moment, *t*. In this study, *D* was 12 (=6×2), since each smartwatch measures the 6-DOF (6 degrees of freedom) motion separately, and *T* was 100 (approximately 2s) so that each **x** could contain at least a full gait cycle. The task in our study was to infer the type of gait activity, , where *C* was 5. Our neural network systems, tailored to learn gait features from MTS data, were trained in an end-to-end fashion using state-of-the-art deep learning architectures, including Conv1D [3], long short-term memory (LSTM) [4], and an LSTM with an attention mechanism [5].

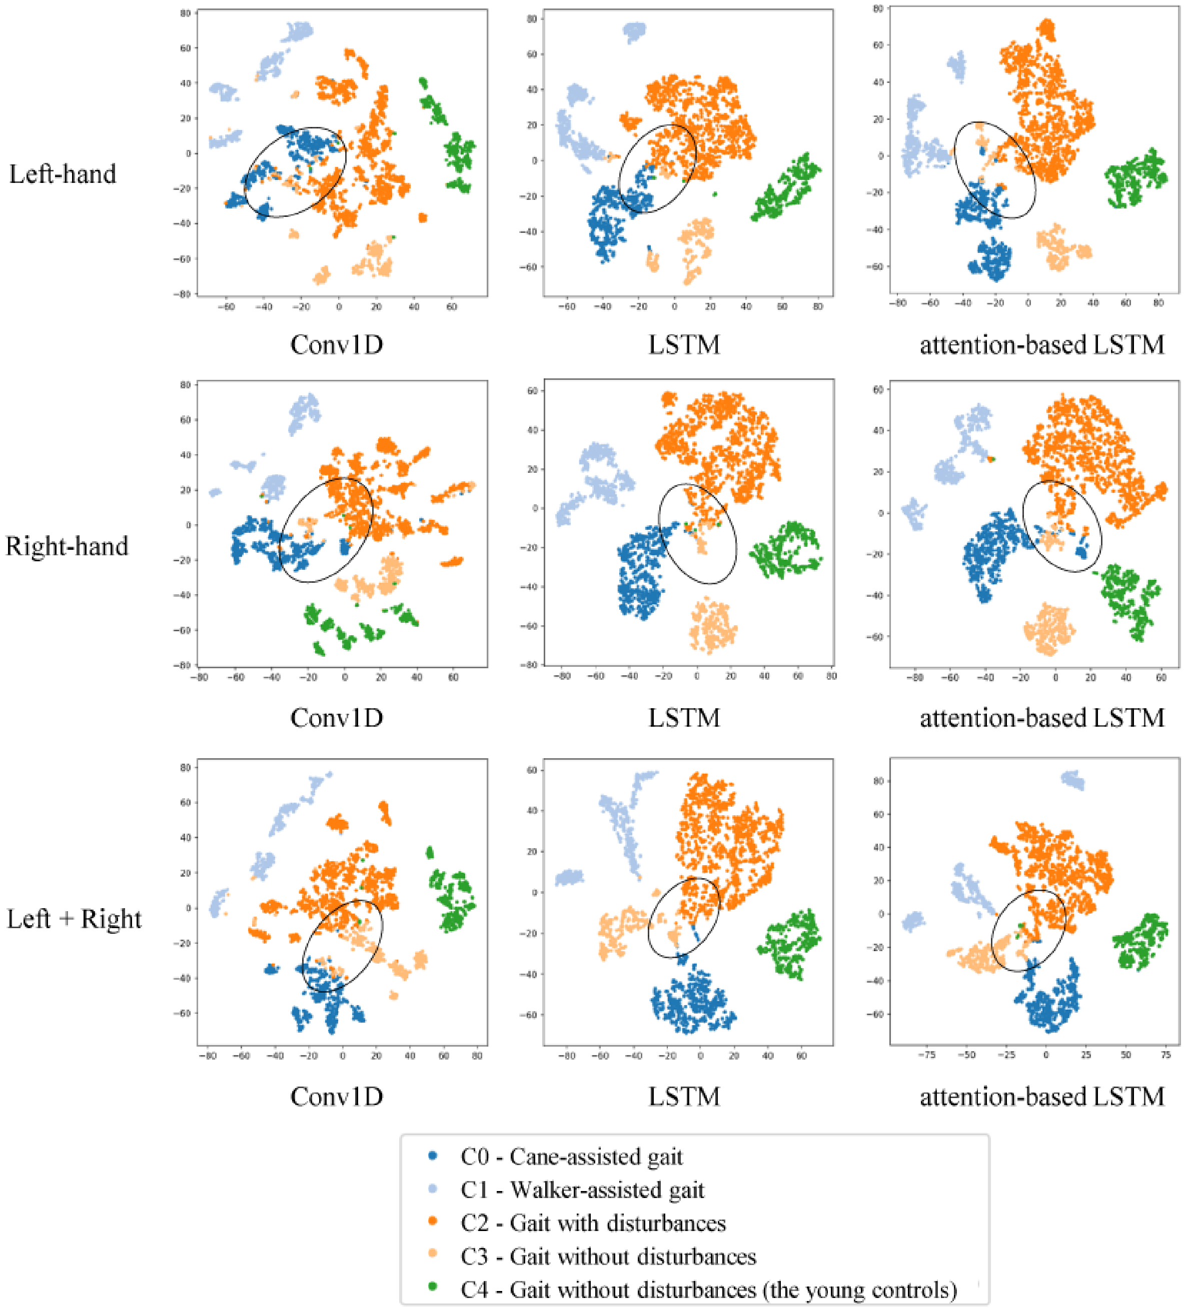
Ethics Approval

All participants were enrolled after institutional review board (IRB) approval (Sungkyunkwan University IRB approval number: SKKU 2021-12-014).

Results

We employed the accuracy and macro average of the F_1-score, F_m, as a measure of performance. For the both-hands condition, the accuracy (F_m) was 0.9757 (0.9728), 0.9736 (0.9699), and 0.9771 (0.9738) when Conv1D, LSTM, and attention-based LSTM were employed, respectively. In the case of the left-hand and right-hand conditions, the accuracies (F_m) obtained in the left-hand condition were 0.9652 (0.9623), 0.9611 (0.9583), and 0.9630 (0.9592), respectively. In the right-hand condition, the accuracies (F_m) were 0.9724 (0.9706), 0.9673 (0.9643), and 0.9673 (0.9635) for the same employed models, respectively. We also examined the learned representations as shown in Figure 2 using t-distributed stochastic neighbor embedding (t-SNE) [6], which visualizes the high-dimensional vectors by projecting them into a 2D space in such a way that similar points cluster together.

Figure 2. Feature visualization using t-distributed stochastic neighbor embedding. Each point is colored according to the predicted class. LSTM: long short-term memory.



Discussion

The experimental results demonstrated an acceptable classification performance (ie, both accuracy and the F_m score were higher than 0.95). However, there is systematic confusion, such as recognizing C3 as C2 (0.03-0.04 for the left hand, 0.05-0.07 for the right hand, and 0.05-0.06 for both hands, respectively) as shown in Figure 2 (see the region highlighted in black). It is noteworthy that the classification performance of the single-hand condition was similar to that of the both-hands condition, suggesting that wearing a single smartwatch is sufficient for the proposed gait assessment task. From the t-SNE plot, it was found that points from the LSTM and attention-based LSTM exhibit a more clustered distribution than those from the Conv1D model. We expect that the proposed approach can be applied to various health care applications for older adults (eg, wearable detection of gait disturbances).

Acknowledgments

This work was supported by a grant from the National Research Foundation of Korea (#NRF-2020R1C1C1010666). This work was also supported by Sungkyunkwan University and the BK21 FOUR (Graduate School Innovation) funded by the Ministry of Education (Korea) and the National Research Foundation of Korea.

Authors' Contributions

SCK and BO were responsible for the study concept and design; SCK and HK were involved in development; SCK, HJK, and JP conducted the analysis and interpreted the data; HK provided the visualizations; and all authors helped write the manuscript.

Conflicts of Interest

None declared.

The authors are retracting “Assessing the Dissemination of COVID-19 Articles Across Social Media With Altmetric and PlumX Metrics: Correlational Study” (J Med Internet Res 2021;23(1):e21408) in alignment with COPE guidelines and based on an honest error that invalidates the results.

Authors’ statement:

> *We sincerely regret our honest misunderstanding of the Altmetrics variables as it was discussed in our manuscript. As a team that values honest and ethical research, we are grateful to JMIR for bringing this grave error to our attention and appreciate our fellow peers for holding us to the highest standard of research. We strive to uphold integrity in our research and agree with the decision of the editors of JMIR to retract our original manuscript. We look forward to the opportunity to edit our work so our research accurately reflects the intention behind the Altmetrics variables.*
