Some limitations should be considered. First, this study only included randomized controlled trials published in English and Chinese, with no incorporation of gray literature such as unpublished studies, conference abstracts, and theses. This exclusion may have contributed to publication bias, particularly in the evaluation of quality of life, as gray literature often includes negative or null results that are less likely to be published in peer-reviewed journals. Consequently, the omission of such studies may have led to an overestimation of the intervention effect. Furthermore, the lack of grey literature may have reduced the diversity of the evidence base, potentially underestimating the heterogeneity among studies and limiting the generalizability of the findings to broader populations or settings. Second, the substantial heterogeneity observed in the pooled outcomes of interest, which resulted from the considerable differences in methodological quality and clinical characteristics of the included patients, could not be clearly explained by subgroup analysis, as no definitive source of heterogeneity was identified. Finally, as the majority of studies included in the meta-analysis were conducted in low- and middle-income countries, the applicability of the findings to high-income countries may be limited.

Implications

eHealth interventions have attracted growing attention worldwide, with numerous studies highlighting their significant potential in the health care of chronically ill patients [23,56]. This meta-analysis provided the first quantitative synthesis of research findings on the administration of eHealth interventions in HD patients and found that these interventions were effective in improving quality of life and treatment adherence, as well as reducing anxiety and depression levels. These findings emphasize the value of integrating eHealth interventions into clinical nursing practice as a valuable and effective strategy. Despite significant heterogeneity in the included studies, this study consolidated the findings of the impact of eHealth interventions on different health-related outcomes among HD patients and would constitute valuable evidence for health care practitioners and researchers to understand the range of areas where eHealth interventions could make a difference, and the magnitude of the impacts that they would have made. While additional research is required to validate these findings, eHealth interventions continue to show great promise in enhancing quality of life, improving treatment adherence, and alleviating anxiety and depression in HD patients. In addition, we also observed that the duration and format of eHealth interventions had a remarkable effect on their efficacy, prompting the notion that we might have to determine the optimal balance to foster patient health outcomes. Notably, the methodological appraisal revealed a high risk of bias in nearly all included studies, underscoring the urgent need for improvements in study design and intervention delivery. Therefore, when designing and implementing eHealth interventions in the future, it is crucial to incorporate appropriate strategies to enhance patient motivation and adherence, thereby ensuring the effectiveness of the interventions.

Conclusions

In conclusion, this meta-analysis highlighted that eHealth interventions may serve as an effective strategy for enhancing quality of life, improving treatment adherence, and alleviating anxiety and depression in HD patients. Thus, health care providers should consider eHealth interventions as a pivotal strategy for facilitating HD patient health outcomes. Furthermore, the efficacy of eHealth interventions for HD patients varied significantly depending on the duration and format of the intervention. Therefore, further in-depth research on eHealth intervention strategies for this population is essential to enhance intervention effectiveness and address the growing health care needs of HD patients. Last but not least, it is essential that future high-quality studies be conducted to provide more robust evidence regarding the clinical benefits of eHealth interventions for HD patients.

Acknowledgments

The authors thank all those who contributed so much to the literature search, data extraction, and analysis.

Data Availability

The datasets used in this study are publicly accessible, with detailed information provided in the Methods section.

Authors' Contributions

XHZ contributed to the conceptualization, data curation, formal analysis, methodology, software, validation, visualization, and writing of the original draft. HC contributed to the data curation, validation, and writing – review and editing. WWY contributed to the data curation, formal analysis, methodology, validation, and writing – review and editing. LW contributed to the data curation, methodology, supervision, and writing – review and editing. LC contributed to the conceptualization, methodology, supervision, and writing – review and editing. YZ contributed to the conceptualization and data curation. YJZ contributed to conceptualization, data curation, and methodology. MS contributed to the conceptualization, data curation, methodology, supervision, validation, and writing – review and editing. QZ contributed to conceptualization, data curation, and validation. All authors read and approved the final version of the manuscript.

Abstract

Background: The advent of social media has significantly transformed health communication and the health-related actions of older adults, offering both obstacles and prospects for this generation to embrace eHealth developments.

Objective: We aimed to investigate the correlation between social media and eHealth literacy in older individuals and answer four research questions: (1) What are the specific social media behaviors (including general use behaviors and health behaviors) of older adults on social media? (2) How do these behaviors impact their eHealth literacy? (3) How does eHealth literacy influence older adults' social media behaviors? and (4) What factors influence older adults' use of social media for health-related purposes?

Methods: Using predetermined keywords and inclusion criteria, we searched Scopus, Web of Science, and PubMed databases for English-language journal articles published from 2000 to 2024, following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) principles. The initial search identified 1591 publications, and after removing duplicates, 48.21% (767/1591) of publications remained. Ultimately, 1% (16/1591) of studies met the inclusion criteria. A research question–driven manual qualitative thematic analysis was conducted, guided by the categorization of social media use behaviors, the definition of eHealth literacy, and the social-ecological model to provide direction for coding and thematic analysis. In addition, attention was given to identifying unanticipated behaviors or phenomena during the coding process, and these were subsequently incorporated into the analytical framework.

Results: The results indicated that older adults' general social media use behaviors are primarily characterized by social media preferences, with 2 subthemes identified. Their social media health behaviors revealed 5 main themes and 14 subthemes. Among the primary themes, health information behavior appeared most frequently (12/16, 75%), followed by self-management (8/16, 50%). Other themes included health decision-making (4/16, 25%), telemedicine (3/16, 19%), and health interventions (2/16, 13%). Cross-thematic analysis confirmed that older adults' social media use behaviors and their eHealth literacy had a reciprocal relationship. Finally, the study revealed that the use of social media to improve eHealth literacy among older adults was influenced by individual, interpersonal, institutional or organizational, and social factors.

Conclusions: The reciprocal relationship between older adults' social media use and eHealth literacy highlights the importance of establishing a long-term positive mechanism that mutually reinforces social media health practices and eHealth literacy. Based on the findings, this review proposes key directions for efforts to achieve this goal: (1) leveraging postpandemic momentum to enhance eHealth literacy among older adults through social media, (2) reconsidering the dimensions of eHealth literacy among older adults in the context of Web 2.0, (3) actively developing age-friendly integrated social media health service platforms, (4) optimizing social media for engaging and reliable health information for older adults, and (5) integrating social support systems to foster lifelong eHealth learning for older adults.

KEYWORDS

eHealth literacy; digital health literacy; older adults; social media; health information; systematic review

Introduction

Background

The continuous proliferation and extensive use of social media have deeply revolutionized the dissemination of information, transformed the health care industry, and advanced the progress of eHealth. Social media platforms refer to online platforms that enable individuals to engage in interactions and present themselves selectively, either in real time or with a delay, to both wide and specific audiences [1], which have had robust expansion in recent years. Presently, the global monthly active users of the 2 prominent social media platforms, Facebook and Twitter, have attained sums of 3.06 billion and 2.5 million accordingly [2]. Especially during the COVID-19 pandemic, the adoption of social media in health areas was maximized. In the presence of lockdown and social distancing measures, social media emerged as the most effective platform for individuals to obtain health-related information [3,4]. The introduction of social media signaled a fundamental change in the field of eHealth communication. Its widespread use and robustness have established social media as a potential platform for the public to obtain health information [5,6], improve their health behaviors [7], promote social support [8-10], manage diseases, and choose health care institutions [11].

For older adults, who are often marginalized in digital innovation, social media offers a potential solution to bridge the health communication gap and promote active aging. According to the Pew Internet report [12] released in 2021, older adults are among the fastest-growing groups using social media. Moreover, social media use among older adults has grown further with the outbreak of the COVID-19 pandemic [13]. With the increasing use of social media among older adults, their opportunities to engage in eHealth are also expanding. Unlike younger individuals, who prefer a variety of software options, older adults tend to favor a single platform [14]. Therefore, compared to other specialized digital health platforms, social media serves as a more familiar and user-friendly integrated platform for health information, social support, and health care services for older adults. This effectively lowers the barriers for older adults to adopt eHealth technologies. Recently, some research has indicated that social media can effectively enable older individuals to access health information and knowledge, thereby improving their health management [15,16]. Moreover, the experience of social media has been found to be associated with older adults' willingness to adopt telemedicine [17].

However, it does not mean that there is no threshold for older adults to truly benefit from eHealth technology via social media. eHealth literacy, which is a crucial determinant of an individual's use of health technology [18], is an essential competency that older adults need to possess to successfully integrate into the eHealth trend. The notion of eHealth literacy, initially introduced by Norman and Skinner [19], refers to the "ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem." However, the definition was presented in the context of Web 1.0, ignoring the internet-based nature of technology in Web 2.0. The definition has subsequently been updated by several scholars [20-26]. The interactivity of eHealth systems is an important element that most scholars focus on in the new definition. In particular, Paige et al [26] developed the concept and content of eHealth literacy based on the transactional model of communication, further emphasizing the interactivity factor. They define eHealth literacy as "...the ability to locate, understand, exchange, and evaluate health information from online environments in the presence of dynamic contextual factors and to apply the knowledge gained across ecological levels for the purposes of maintaining or improving health" [26]. Their conceptualization not only preserves the fundamental elements of conventional eHealth literacy but also underscores that *communication* refers to the capacity to establish connections and identities with other internet users by exchanging health-related information, which sheds light on our understanding of eHealth literacy based on the setting of Web 2.0.

eHealth literacy profoundly influences the effectiveness of an individual's use of social media to engage in eHealth. Because the credibility of information on social media is lower than that of professional websites, eHealth literacy, particularly critical health literacy, is essential to help evaluate the reliability of the information [27,28]. In addition, high eHealth literacy enables individuals to be better informed and equipped to access, share, and discuss health-related information and issues [29] and gain better satisfaction with the health information [30]. Therefore, eHealth literacy is a crucial skill that older adults must possess to successfully integrate into the eHealth trend through social media.

However, a harsh reality is that eHealth literacy among older people is generally found to be low compared to the younger generation [31-33]. Research has found that lower eHealth literacy makes it challenging for older adults to participate in eHealth, widening the digital divide in eHealth [34-36]. Older adults are perceived to be targets of misinformation and fraud on social media platforms and are more vulnerable to online scams [37]. They are very concerned about their privacy and security when sharing information on social media, and they consider this conduct to be highly risky [37,38]. Moreover, older adults tend to lack the perceived usefulness and ease of use of new technologies, making them slower to adopt these technologies compared to younger individuals [39], and thus they are more likely to encounter technical difficulties. These challenges not only prevent older people from truly benefiting from eHealth but may also lead to a digital divide in eHealth.

Another trend worth noting is the significant potential of social media itself to enhance eHealth literacy. Previous studies have

XSL•FO
RenderX

found a positive correlation among individuals' proficiency in using social media, their level of activity, and the number of social media platforms they use with their eHealth literacy [9,10]. In particular, the frequent use of social media to search for and engage with health information holds great potential for improving individual eHealth literacy [40]. Furthermore, the social support provided by social media can effectively enhance individuals' understanding of health information and their ability to make informed health decisions, thereby improving eHealth literacy [9]. Social media is also an essential tool for eHealth literacy interventions. For example, Jiang [41] found that health interventions implemented through community-based, proactive health management apps on social media not only increased patients' engagement in health management but also improved their eHealth literacy. Similar findings have been observed in studies involving older adults. Research indicates a significant association between older adults' health-related behaviors on social media and their eHealth literacy levels [42]. A notable characteristic is the heightened use of social media and enhanced eHealth awareness among older individuals following the COVID-19 pandemic [13,43,44].

Therefore, within the context of Web 2.0, a highly promising approach to effectively integrating older adults into the eHealth landscape is to establish a virtuous cycle where their effective use of social media for health-related behaviors reinforces their eHealth literacy. On the one hand, older adults can use familiar social media platforms to access health information and engage in health management or health interventions, gradually enhancing their eHealth literacy through practice. On the other hand, as their eHealth literacy improves, their ability to effectively use social media for eHealth engagement and their satisfaction with these interactions will also increase, ultimately bridging the digital divide in the eHealth domain.

To achieve this goal, it becomes urgent to explore the relationship between social media and eHealth literacy among older adults. Understanding older adults' social media use patterns—such as frequency of use and platform preferences—along with the impact of health information–seeking behaviors, health management, and health interventions conducted via social media on their eHealth literacy, is essential for identifying both the potential and barriers of social media in promoting health and enhancing eHealth literacy for this population. Simultaneously, examining the influence of eHealth literacy on older adults' ability to effectively use social media for health-related engagement can help identify current gaps in their eHealth literacy and propose targeted interventions. By deeply grasping the relationship between social media and eHealth literacy, older adults can comprehensively and systematically build a social media–based eHealth integration platform that meets their level of eHealth literacy. Ultimately, a virtuous cycle of mutual promotion between social media and eHealth literacy of older individuals will be formed.

Existing systematic literature studies on eHealth literacy in older individuals have mostly concentrated on examining the determinants that impact eHealth literacy in this population [45] or the intervention [32,46]. Some studies on social media and older adults' health primarily focus on the impact of social media on their mental health [47,48]. However, few studies systematically and comprehensively review the behaviors of older adults using social media for health purposes, nor do they summarize the correlations between these behaviors and health outcomes. In particular, research on behavioral patterns and preferences of older adults engaging with health-related content on social media; the role of platform design in promoting health literacy; how older adults' eHealth literacy influences their health-related behaviors on social media; and how these behaviors, in turn, affect their eHealth literacy is limited. Without a clear understanding of these dynamics, the significance and potential of social media as a tool for enhancing older adults' eHealth literacy and bridging the digital divide in eHealth remain insufficiently elucidated. This gap may ultimately turn social media from a promising tool for improving older adults' health into a potential weapon that harms this vulnerable population. Furthermore, with the outbreak and end of the COVID-19 pandemic, the user landscape of social media and the developmental landscape of eHealth technology have both changed, necessitating a reassessment of social media use patterns and older individuals' eHealth literacy.

Research Questions

This systematic literature review addressed these gaps by focusing on the correlation between older adults' social media behavior, including general social media use behavior (eg, social media use patterns or habits) and social media health behaviors (eg, health information behaviors, self-management, or interventions), and their level of eHealth literacy. Specifically, this study aimed to answer the following research questions (RQs):

RQ1: What are the specific social media behaviors (including general use behavior and health behaviors) of older adults on social media?

RQ2: How do these behaviors impact their eHealth literacy?

RQ3: How does eHealth literacy influence older adult's social media behaviors?

RQ4: What factors influence older adults' use of social media for health-related purposes?

Methods

Overview

Through a comprehensive literature review following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) criteria [49], this review investigated the relationship between social media and older individuals' eHealth literacy and associated characteristics. PRISMA checklist is provided in Multimedia Appendix 1. We did not register the procedure for this review to a systematic review database.

Data Resources and Search Strategy

Scopus, Web of Science, and PubMed were selected as databases for this review. The online database search was conducted on May 17, 2024. Although the notion of eHealth literacy was initially presented in 2006 [19], there is some previous literature that may use other vocabularies, such as computer health literacy

XSL•FO
RenderX

and internet health literacy, to refer to eHealth literacy. To ensure the thoroughness of the assessment, the literature search was conducted within the period framework of 2000 to 2024. Search terms were generated around the following research themes: "social media," "eHealth literacy," and "older people." Because eHealth literacy is a broad concept, this study not only covers the synonyms of eHealth literacy but also expands on the definition provided by Norman [19] and Paige [26] by adding related content about what eHealth literacy encompasses, such as health literacy, digital literacy, information literacy, and media literacy. Furthermore, the objective of this study was to investigate the correlation between social media and the eHealth literacy of older adults, as well as associated elements. Consequently, the primary focus was given to social networking platforms that facilitate communication and interaction with the public regarding health matters, health information, and health management. Therefore, the definition provided by Carr and Hayes [1] was adopted, and the latest global user activity rankings were used to filter the top-ranked social media as search extensions [2]. All keywords were searched in the database in combination with Boolean logic. A comprehensive list of search queries is presented in Textbox 1. A separate search string for each database is provided in Multimedia Appendix 2.

Textbox 1. Keywords search strings (the asterisk is a wildcard used to include multiple word variations in the search query).

Older adults

- "old*" OR "elder*" OR "senior*" OR "aging*" OR "ageing*" OR "aged*" OR "geriatric*" OR "gerontolog*" OR "retiree*" OR "baby boomer" OR "pensioner*" OR "silver generation"

AND

eHealth literacy

- "eHealth literacy" OR "eHealth literacy" OR "telehealth literacy" OR "mHealth literacy" OR "health literacy" OR "medic* literacy" OR "digital literacy" OR "information literacy" OR "media literacy" OR "internet literacy" OR "computer literacy" OR "virtual literacy" OR "intelligent literacy" OR "technolog* literacy" OR "online literacy" OR "web based literacy" OR "Web 2.0 literacy" OR "ICT literacy" OR "Information and Communication Technology literacy"

AND

Social media

- "social media" OR "social network*" OR "social platform*" OR "social web*" OR "web 2.0" OR "online social*" OR "digital social*" OR "virtual social*" OR "social channels" OR "social apps" OR "community media*" OR "community platform" OR Facebook OR "YouTube" OR WhatsApp OR Instagram OR WeChat OR "TikTok" OR Douyin OR Telegram OR Snapchat OR Kuaishou OR "Sina Weibo" OR QQ OR Twitter OR Pinterest

Study Selection Criteria

The selected papers for review had to adhere to the pre-established inclusion criteria. First, the included papers should have been primary research articles written in English and published between January 2000 and May 2024. Other document types, such as reviews, editorials, conference papers, letters, notes, commentaries, book chapters, books, or study protocols, were excluded from the considered literature. Second, the participants under study must have been older individuals. Given the absence of a universally defined age for older individuals, the United Nations generally designates individuals aged ≥60 years as older individuals [50]. However, some articles use national retirement ages as criteria for the research population [42] or define older people as those aged ≥50 years from the perspective of cognitive aging [51]. Considering the diversity in defining older people and the current minimum retirement age of 50 worldwide [52], this review included participants aged ≥50 years to ensure a broader spectrum of articles. Furthermore, it is anticipated that the papers will pertain to eHealth literacy among older persons who are active on social media and investigate the elements that impact their use of social media to enhance their eHealth literacy. Considering this criterion, the following articles were omitted: (1) discussions concerning phone calls, SMS text messages, email, web portals, and telemedicine or mobile health (mHealth) without social media engagement; (2) articles that were not based on health contexts, such as internet literacy, media literacy, digital literacy, and information literacy, for older adults; and (3) articles that were based on internet or social media behaviors of older adults unrelated to eHealth literacy. Furthermore, this paper identified a correlation between eHealth literacy and the social media activities of older people. Details on the particular inclusion and exclusion criteria can be found in Textbox 2.

XSL•FO
RenderX

Textbox 2. Study selection criteria.

Inclusion criteria

- Research topic: eHealth literacy and social media use in the older population
- Research content: articles that investigate the influence and associated variables of social media on eHealth literacy in the older population; articles that examine the effect of older individuals' eHealth literacy on their social media activities
- Target group: various community groups, including marginalized migrant populations, retirees, and those aged ≥50 years
- Article type: primary research journal articles
- Language: English
- Timeline: between 2000 and 2024

Exclusion criteria

- Research topic: topics such as internet literacy, media literacy, digital literacy, and information literacy among older adults in non–health-related contexts; health behaviors of older people based on nonsocial platforms, such as phone calls, SMS text messages, email, web portals, and telemedicine or mobile health without social media engagement; internet or social media behaviors of older adults unrelated to eHealth literacy
- Research content: articles in which the correlation between eHealth literacy and social media use among older people was not explicitly referenced
- Target group: children, adolescents, middle-aged group, and other young groups aged <50 years; study population without a clear age range
- Article type: reviews, editorials, conference papers, letters, notes, commentaries, book chapters, books, or study protocols
- Language: non-English
- Timeline: before 2000

Literature Screening

There were 3 steps in literature screening. The first step was removing duplicates. Articles identified in the database were filtered into Microsoft Excel and duplicates were removed. Following this was the process of screening the title and abstract. A preliminary screening was conducted by 2 reviewers (CZ and AW) who independently identified important themes in the title and abstract. The age range of the study population was first identified, and studies where the population was not aged ≥50 years were excluded. If the age range could not be identified from the title and abstract, the article was reviewed for relevance to the topic, and theme-related studies were included for full-text review; otherwise, they were excluded. For example, the study by Willis [53] was included for full-text review because the abstract mentioned interviews with online health community members without specifying their ages. However, the full-text review revealed that participants were aged 37 to 85 years, resulting in this study's exclusion.

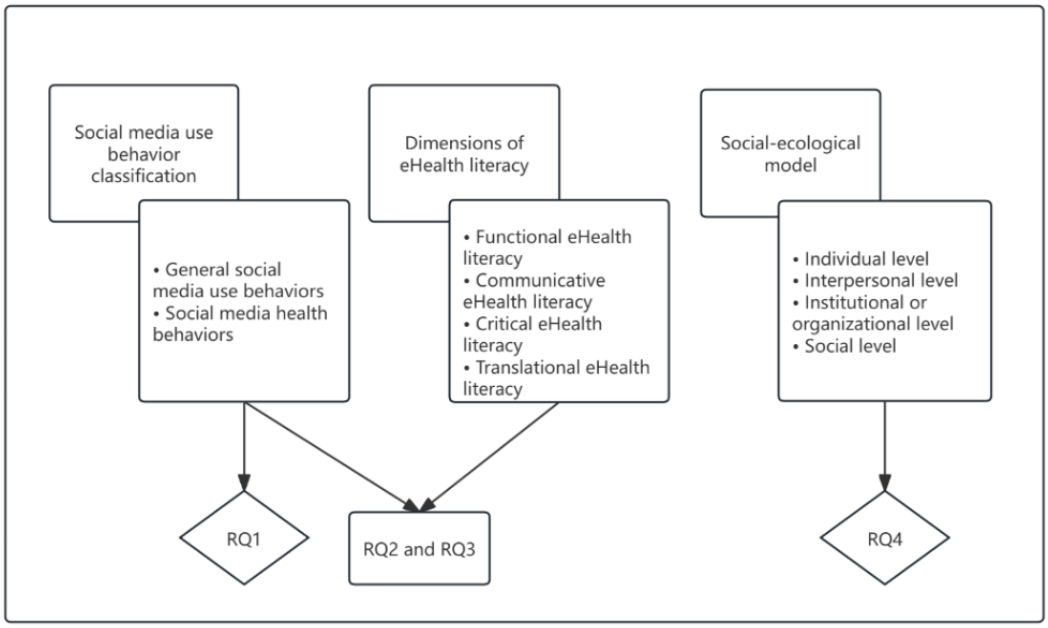
The last step was full-text screening. Following the initial screening, the selected articles were reviewed in full text. During this process, 2 independent researchers carefully and comprehensively reviewed the full texts of the selected studies. This stage prioritized the exclusion of literature that did not fit the language, type of article, and age of the study population. Among them, the study conducted by Aung et al [54] was omitted from consideration because it was only a research plan.

Subsequent full-text reviews primarily excluded literature that did not address social media or was not explicitly about social media, as well as literature from nonhealth contexts. For example, some (39/153, 25.5%) articles, such as Mao et al [55] and Evans et al [56] discussed the association between telemedicine or mHealth and eHealth literacy in older adults, but these technologies did not involve social media platforms and were, therefore, excluded. Moreover, a few (4/153, 2.6%) articles discussed internet behaviors and eHealth literacy among older individuals, but it was unclear whether internet behavior related to social media was excluded [57-60]. In addition, some (3/153, 2%) articles, while exploring important components of eHealth literacy in older adults, such as digital literacy, information literacy, or media literacy, were not based on a health context and were, therefore, excluded [61-63]. Notably, several (3/153, 2%) papers examined the influence of social media on alleviating loneliness among older individuals, which did not address eHealth literacy and were excluded [64-66]. Finally, some (3/153, 2%) articles, while dealing with social media and eHealth literacy, did not allow the interaction between the 2 to be judged and were, therefore, excluded [67-69].

For articles that met the inclusion criteria in the full-text review, we annotated the study population, the research methodology, and the relevant factors in preparation for subsequent data extraction. To ensure the reliability of the study, a cross-review was conducted, and YM was introduced to resolve any discrepancies.

Quality Appraisal

This review used the quality assessment (QA) tool developed by Sirriyeh et al [69] to evaluate the quality of the included studies. The QA tool establishes 6 QAs and assigns scores on a 3-point scale from 0 to 1 (0=no, 0.5=partly, and 1=yes). Studies with an overall score of >3 points are recognized as being of sufficient quality. Two researchers (CZ and AW) independently scored the included studies, and the sum of the scores obtained was used to assess the study quality. Inconsistent results were resolved by third-party (YM) intervention.



XSL•FO
RenderX

Data Extraction and Analysis

To capture the basic information and trends of the studies included, we developed a standardized table summarizing the fundamental characteristics of the research. This table extracted details, such as the authors, publication year, country, participants' age, and research methods, from the included literature. Furthermore, to clarify the roles played by different types of social media, we extracted and categorized the social media platforms mentioned in the articles. In addition, as no restrictions were imposed on the research methods of the included studies, which covered qualitative, quantitative, and mixed methods approaches, thematic analysis [70] was used to describe and analyze the literature. According to Braun and Clarke [70], thematic analysis is a flexible research tool with a high degree of theoretical freedom, making it applicable within various theoretical frameworks and capable of providing rich and detailed data descriptions.

We conducted a manual, qualitative content analysis guided by the RQs, integrating classifications of social media health behaviors, definitions of eHealth literacy [26], and the social-ecological model (SEM) [71] to inform the coding and thematic analysis. At the same time, we paid attention to identifying new behaviors or phenomena not initially anticipated and incorporated them into the analytical framework. The qualitative thematic analysis framework is illustrated in Figure 1.

Figure 1. Qualitative thematic analysis framework map. RQ: research question.

Specifically, guided by RQ1, in addition to focusing on older adults' general social media behaviors (including use habits, such as frequency of use and platform preferences), we reviewed the literature on the application of social media in the health domain. This allowed us to extract consumer-related behavioral manifestations resulting from the use of social media in health contexts. As both health consumers and professionals can act as providers or recipients of support during interactions on health platforms [72], we examined health behaviors not only from the perspective of consumers or patients but also from the perspectives of health care professionals or other organizations interacting with consumers or patients. Our analysis identified key consumer-related applications of social media in health, including health information (searching, sharing, and evaluating); telemedicine; health management; health education; health promotion; and health intervention [73-76]. These applications served as the foundation for our coding and thematic extraction. To ensure rigor, we used the "conceptual matrix" proposed by Webster and Watson [77] (Multimedia Appendix 3 [13,14,42,44,51,69,78-88]) to examine themes and systematically record emerging themes during the analysis process.

RQ2 and RQ3 explored the correlation between older adults' health behaviors on social media and their eHealth literacy. We adopted the definition of eHealth literacy provided by Paige et al [26] as the guiding framework for thematic analysis. Paige et al [26] delineated eHealth literacy into four dimensions:

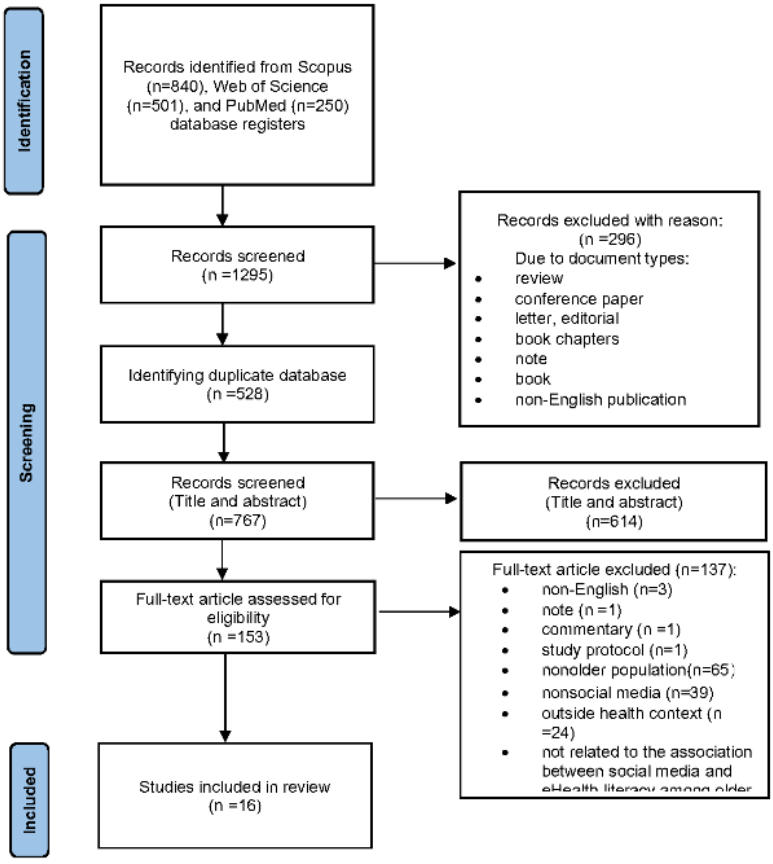
1. Functional eHealth literacy: basic skills in reading and writing (typing) about health to effectively function on the internet
2. Communicative eHealth literacy: the ability to collaborate, adapt, and manage communication about health in social online environments with multimedia
3. Critical eHealth literacy: the ability to evaluate the credibility, relevance, and risks of sharing and receiving health information on the internet
4. Translational eHealth literacy: the ability to apply health knowledge gained from the internet across diverse ecologic contexts

We extracted descriptions from the literature relevant to these 4 dimensions and performed theoretical mapping to determine the eHealth literacy dimensions they pertained to. For studies that only referred to eHealth literacy as a general concept, we assumed that they encompassed all 4 dimensions.

XSL•FO
RenderX

Finally, we conducted a cross-analysis between older adults' social media use behaviors—including general and health-related behaviors (as identified in the themes extracted based on RQ1)—and the 4 dimensions of eHealth literacy. This analysis aimed to uncover the relationships between the 2, focusing on whether older adults' social media use behaviors enhance or hinder their eHealth literacy and whether their eHealth literacy strengthens or diminishes their health-related behaviors on social media. Given the diversity of research methods in the included studies, our qualitative content analysis not only focused on explicit conclusions from studies that directly examined these relationships but also considered implicit or related findings within the research.

Guided by RQ4, we examined the factors influencing older adults' use of social media to access health information or health services in each article. Because these factors included not only barriers and facilitators but also neutral factors, we adopted the SEM to enable a more comprehensive extraction and integration of these influencing factors. SEM, developed by Bronfenbrenner [71], provides a systematic framework for understanding the impact of various environmental elements on individual behavior and development. According to SEM, the influencing factors are categorized into 4 dimensions: individual, interpersonal, institutional or organizational, and social levels.



CZ and AW analyzed all the articles and extracted the relevant themes. AAA and YQ reviewed the full text of the articles to validate the extracted themes. All conflicts were resolved by EM. Finally, multiple meetings were held to discuss the results of the thematic analysis and reach a consensus.

Results

Search Results

Search results and data collection process are shown in the PRISMA flow diagram in Figure 2. Initially, 1591 articles were identified (Scopus, 840/1591, 52.79%; Web of Science, 501/1591, 31.49%; and PubMed, 250/1591, 15.71%). A total of 48.21% (767/1591) of articles were screened by excluding certain articles based on the exclusion criteria, such as article type, language, and date, and after duplicates were removed. Subsequently, 38.6% (614/1591) of articles were eliminated following the screening of the title and abstract, while 8.6% (137/1591) of articles were eliminated after the assessment of the entire text. Publications were eliminated throughout the full-text screening process for the following reasons: (1) non-English (3/153, 2%), (2) note (1/153, 0.6%), (3) commentary (1/153, 0.7%), (4) study protocol (1/153, 0.7%), (5) younger population (65/153, 42.5%), (6) non–social media (39/153, 25.5%), (7) outside health context (24/153, 15.7%), and (8) not related to the correlation between eHealth literacy and older population (3/153, 2%). Although a considerable amount of research was identified at the outset, many articles used social media only as a tool for the recruitment of research participants or for distributing questionnaires, without discussing social media, and were, therefore, excluded.

Figure 2. PRISMA (Preferred Reporting Item for Systematic Reviews and Meta-Analyses) flow diagram depicting the process of study selection.

Description of Studies

Comprehensive information regarding the included research is provided in Table 1.

Generally, most (15/16, 94%) articles were published between 2020 and 2024, namely, after the COVID-19 pandemic. Only 1 (6%) study was conducted in 2015 [78]. Nearly two-thirds (11/16, 69%) of the studies were from Asian countries, including China (6/16, 38%) [14,42,44,79-81], Korea (2/16, 13%) [82,83], Thailand (2/16, 13%) [13,84], Singapore (1/16, 6%) [59]. In total, 13% (2/16) of studies were from the United States [85,86], and 1 (6%) study was from Italy [87]. Concerning the age definition of older individuals, except for 2 (13%) papers that did not provide a specific age criterion [87,88], the age definition ranges of the studies mainly used ≥50 years (5/16, 31%) [14,79,80,84,86] or ≥60 years (5/16, 31%) [13,44,80,83,84], and a few studies used ≥65 years (2/16, 13%) [82,85] or ≥55 years (1/16, 6%) [81]. Moreover, 1 (6%) Chinese study used the retirement age as the range of the study population, that is, ≥55 years for women and ≥60 years for men, respectively [42]. Most (12/16, 75%) studies were quantitative (Textbox 2), including surveys (10/16, 62%) [13,42,78-80,82,84,86-88] and experiments (2/16, 13%) [51,83], while 2 (13%) studies used mixed methods [44,85]. Only 2 (13%) studies were qualitative, using interviews [14,81].

Regarding features related to social media, most (11/16, 69%) articles discussed a wide range of social media platforms [13,44,78-82,84,86-88], and a few (5/16, 31%) articles explored the role of individual social media only [14,42,51,83,85], covering WeChat (2/16, 13%) [83], Facebook (1/16, 6%) [51], The BAND app (NAVER Corp) (1/16, 6%) [83], and Virtual Online Communities for Aging-Life Experiences (1/16, 6%) [85]. Moreover, social media was mostly (11/16, 69%) regarded as both a medium for health information and health-related relationships [13,42,44,51,78,79,81,82,84,86,88]. Furthermore, 1 (6%) study examined the dual role of social media as a medium for health-related interactions and information [80]. Social media was discussed as a health intervention or health education tool (2/16, 13%) [83,85], and a health management and communication tool (1/16, 6%) [14]. Only 1 (6%) article did not discuss the role of social media [87].

To further capture the characteristics of older adults in using social media platforms, this review extracted and categorized the social media platforms mentioned in the studies included (Table 2). Kordzadeh [72] categorized social media platforms applied in health care into 2 types: online social networks and virtual health communities (VHCs). The former includes large-scale, general-purpose internet platforms, such as

XSL•FO
RenderX

Facebook, Twitter, Instagram, and YouTube, which are designed for broad collaboration among internet users. In contrast, the latter consists of social media sites specifically designed for individuals to discuss health-related topics.

On the basis of the included studies, most (11/16, 69%) explored the role of general social media in the health of older adults without specifying the particular platforms. Among the studies that addressed online social network platforms, the most commonly mentioned were WeChat and Facebook. These platforms are widely popular among older adults in their respective regions and are frequently used for accessing and sharing health-related information. Conversely, VHC platforms exhibited a more distinct health-focused orientation. Only 2 (13%) studies in the included literature specifically examined VHC platforms, namely BAND and Virtual Online Communities for Aging-Life Experiences, highlighting their value as tools for online support groups and health interventions [83,85].

Table 2. Social media platforms and categorization included in literature (N=16).

Social media	Social media types		Studies	Studies, n (%)
	OSN[a]	VHC[b]		
Unspecified	✓	✓	Ye [80], 2024; Oh et al [86], 2023; Vitolo et al [87], 2023; Jang et al [82], 2023; Kachentawa [13], 2023; Liu et al [44], 2022; Chai [81], 2022; Tan et al [88], 2022; Ubolwan et al [84], 2020; Shang and Zuo et al [79], 2020; and Tennant et al [78], 2015	11 (69)
WeChat	✓	—[c]	Wang and Zhang [42], 2023 and Wu and Yu [14], 2021	2 (12)
Facebook	✓	—	Matchanova et al [51], 2024	1 (6)
BAND	—	✓	Lee and Ryu [83], 2023	1 (6)
VOCALE[d]	—	✓	Chen et al [85], 2021	1 (6)

[a]OSN: online social network.

[b]VHC: virtual health community.

[c]Not applicable.

[d]VOCALE: Virtual Online Communities for Aging-Life Experiences.

Quality of the Included Studies

According to the results of the quality appraisal (Multimedia Appendix 4 [13,14,42,44,51,69,78-88]), the scores of the included studies ranged from 3.5 to 5.5, with all of them exceeding 3, which is considered to be of sufficient quality. Moreover, none of the studies obtained a score of 0 on the individual evaluation items. This suggests that the included studies effectively elucidated the purpose, interest, utility, methodological process, approach concept, comparison and measurement with other similar studies, and limitations of the study on a high level of clarity.

Social Media Use Behaviors of Older Adults

As this study focused on the relationship between social media and eHealth literacy among older adults, an analysis of their social media use behaviors was conducted. This thematic analysis included both the general use behaviors of older adults and their health-related behaviors stemming from social media use. Table 3 presents the results of the thematic analysis, identifying 2 themes related to general social media use behaviors and 5 themes associated with health-related behaviors.

XSL•FO
RenderX

Table 3. Social media use behaviors of older adults (N=16).

Theme, description, and subtheme	Sample quotes	Studies	Studies, n (%)
Social media use habit			
The frequency of older adults' social media use, their platform preferences, and so on			
Frequency of social media use	"Frail and pre-frail patients used digital tools less frequently and accessed the Internet less frequently compared to robust patients." [87]	Vitolo et al [87], 2023; Ubolwan et al [84], 2020; and Tennant et al [78], 2015	3 (19)
Social media platform preference	"The most widely adopted function for senior citizens was instant messaging... Compared with the diversity of software applications that the younger generation use, older adults were more interested in a limited range of software affordance which benefited them most." [14]	Wu and Yu [14], 2021	1 (6)
Health information			
The fundamental behaviors of older adults related to health information on social media, including searching, sharing, learning, and evaluating health information			
Health information acquisition	"...participants obtained information about COVID19 and general health from various resources...." [44]	Ye [80], 2024; Oh et al [86], 2023; Jang et al [82], 2023; Kachentawa [13], 2023; Wang and Zhang [42], 2023; Liu et al [44], 2022; Chai [81], 2022; Tan et al [88], 2022; and Tennant et al [78], 2015	9 (56)
Health information sharing	"Among older adults, a higher likelihood of sharing false COVID-19 headlines was associated with lower verbal IQ and numeracy skills." [51]	Ye [80], 2024; Matchanova et al [51], 2023; Kachentawa [13], 2023; Lee and Ryu [83], 2023; and Wang and Zhang [42], 2023	5 (31)
Health information evaluation	"...interviewees were able to evaluate pandemic rumors as false information, but they may not understand the underpinning scientific logic." [81]	Matchanova et al [51], 2023; Liu et al [44], 2022; Chai [81], 2022; Tan et al [88], 2022; and Tennant et al [78], 2015	5 (31)
Health knowledge learning	"Abundant health knowledge resources are available on social media to facilitate technology-enhanced knowledge learning among older adults." [79]	Shang and Zuo [79], 2020	1 (6)
Health information resource trust	"...trust in formal sources of information on its own positively predicts vaccination status..." [88]	Tan et al [88], 2022	1 (6)
Frequency of health information use	"...the frequency of using online health information also has a positive influence on the three levels of e-health literacy of older adults." [80]	Ye [80], 2024	1 (6)
Self-management			
Older adults are engaged in social media–based behaviors to manage symptoms, treatments, and lifestyles			
Health prevention	"All the older adults consciously followed the prevention and control strategies they had learned..." [44]	Jang et al [82], 2023; Kachentawa [13], 2023; Chai [81], 2022; Liu et al [44], 2022; Chen et al [85], 2021; and Wu and Yu [14], 2021	6 (38)
Lifestyle management	"In this study, participants expressed greater appreciation of physical activity and the need to be more proactive about self-management, which could lead to a healthier lifestyle." [85]	Ye [80], 2024; Chen et al [85], 2021; Chai [81], 2022; and Liu et al [44], 2022	4 (25)
Medical management	"During the lockdown, citizens managed their living needs and medical requirements by the 'grid managed' online community facilitated by SNS chat groups..." [14]	Wu and Yu [14], 2021 and Oh et al [86], 2023	2 (12)
Telemedicine			
Older adults access health care through social media			

XSL•FO
RenderX

Theme, description, and subtheme	Sample quotes	Studies	Studies, n (%)
Communicating with health care providers	"Among the health communication factors, social media use, face-to-face PPC, electronic PPC, and use of electronic communication through electronic patient platforms were facilitating communication factors of CRC screening among NHWs." [86]	Oh et al [86], 2023	1 (6)
Access to health care	"A face-to-face visit with health care providers was limited due to home quarantine and isolation, so older adults also learned to seek medical care through the Internet." [44]	Liu et al [44], 2022 and Wu and Yu [14], 2021	2 (12)
Health decision-making			
Older adults integrate relevant information from social media with their personal knowledge and beliefs to make health decisions that meet their needs			
Medical decision	"...those who placed greater trust in social media being less likely to have received at least 1 dose of the vaccine." [88]	Tan et al [88], 2022 and Kachentawa [13], 2023	2 (12)
Addressing general health issues	"With regard to problem-solving, participants mentioned effects they experienced, including that the discussion affected participants' behavior, either in terms of provoking a more active approach to addressing health issues, or considering the use of the skills in their own lives." [85]	Ye [80], 2024 and Chen et al [85], 2021	2 (12)
Health intervention			
Systematic behavioral changes to improve health outcomes among older adults using social media			
Online group interventions	"...a gamified walking program, called the MSG walking program (mHealth devices and Social media apps using Gamified walking program), was designed to enable socializing in conjunction with mHealth apps and devices to operate an online walking program for retired older adults during COVID-19." [83]	Lee and Ryu [83], 2023 and Chen et al [85], 2021	2 (12)

The general social media use behaviors of older adults describe their use patterns, including frequency of use, platform preferences, and other related habits. Among the included studies, 19% (3/16) [78,84,87] investigated the time spent or frequency of social media use by older adults. Wu and Yu [14] explored platform preferences among older adults, noting their inclination toward instant text messaging features on social media. Unlike younger users, older adults tended to prefer platforms with limited features and familiar interfaces, rather than overly complex or feature-rich social media platforms.

For the thematic analysis of older adults' health behaviors on social media, we adopted a combined approach of using predefined themes and identifying emergent themes. Drawing from previous research on the application of social media in health communication, certain themes were established in advance. These themes were further refined and expanded during the full-text review stage. Ultimately, 5 primary themes emerged: health information, health interventions, health decision-making, self-management, and telemedicine—all of which aligned with our predefined themes.

However, in the extraction of subthemes, we uncovered more nuanced information. For instance, while the predefined theme of health information behavior initially encompassed information-seeking, sharing, and evaluation behaviors, the coding process revealed additional discussions by researchers on older adults' learning of health knowledge, trust in health information sources, and frequency of health information use. For example, the study by Tan et al [88] examined how trust in different information sources influenced older adults' decisions regarding COVID-19 vaccination [88].

Notably, health information behavior was the most frequently discussed theme, appearing in 75% (12/16) of the studies. Within this category, particular emphasis was placed on information-seeking (9/16, 56%), sharing (5/16, 31%), and evaluation behaviors (5/16, 31%). Furthermore, social media information also impacted older adults' health decision-making. These decisions were not only limited to medical choices, such as vaccination [13,88], but also extended to addressing daily health-related challenges [80,85].

Self-management emerged as the second most frequently discussed theme (8/16, 50%), referring to older adults' health management behaviors related to their diseases and lifestyles through social media. Among the aspects of self-management, health prevention was the most extensively explored subtheme (5/16, 31%), primarily due to the prevalence of the COVID-19 pandemic as the context in many studies. In addition to health prevention, older adults use social media for managing their lifestyles [81,85] and medical needs [14,86].

Finally, social media also serves as an important platform for older adults to engage in telemedicine and for implementing health interventions targeted at this population. Health interventions refer to planned efforts to modify older adults' health behaviors via social media to improve their health outcomes. For instance, Lee and Ryu [83] and Chen et al [85] conducted online group health interventions for older adults using VHC platforms, demonstrating the potential of such platforms in facilitating health-related behavioral changes.

Correlation Between Social Media Use and the eHealth Literacy in Older Individuals

Overview

Figure 3 [13,14,42,44,51,78,80-88] presents the comprehensive correlation between social media use and the eHealth literacy in older adults. The included studies revealed that social media and older adults' eHealth literacy are mutually influencing and interacting. In total, 56% (9/16) of the articles examined the influence of social media on the eHealth literacy of older individuals [13,14,78,82-87], 13% (2/16) only discussed the value of older adults' eHealth literacy on their social media use [42,51], and 31% (5/16) covered the interplay between the two [14,44,80,81,88].

Figure 3. The correlation between social media use and eHealth literacy (eHL) in older individuals. Reference sources for these data include (9/16, 56%) [13,14,78,82-87]; (5/16, 31%) [14,44,80,81,88]; and (2/16, 13%) [42,51].

Impact of Social Media on eHealth Literacy of Older Individuals

Overview

The overwhelming majority (13/16, 81%) of the research included confirmed the impact of social media on the eHealth literacy of older individuals (Table 4), and the pathways to impact included social media use habits (4/16, 25%), social media health information behaviors (7/16, 44%), social media–based health interventions (2/16, 13%), telemedicine (2/16, 13%), and health decision-making (1/16, 6%).

Table 5 categorizes and counts the behavioral themes.

XSL•FO
RenderX

Table 4. The impact of social media on eHealth literacy (eHL) of older individuals.

Study and social media behavioral dimensions that affect eHL	Theoretical mapping: dimensions of affected eHL	Mechanism of association and key findings
Ye [80], 2024		
• Frequency of health information use • Health information acquisition • Health information sharing • Self-management (lifestyle management)	• Translational eHL: application ability, decision-making ability • Critical eHL: critical judgment ability	The social media health information behavior of older adults (including frequency of use, acquisition, and sharing of health information) and self-management behavior through online health information significantly affect their translational eHL and critical eHL.
Oh et al [86], 2023		
• Telemedicine (communicating with health care providers)	• Communicative eHL: health communication	Older adults' use of social media to communicate with health care providers enhances their communicative eHL.
Vitolo et al [87], 2023		
• Frequency of social media use	• eHL: digital health literacy	A lower frequency of social media use is correlated with lower eHL in older persons.
Jang et al [82], 2023		
• Health information acquisition	• Translational eHL: application of digital resources and health prevention	Older adults with limited sources of health information (unable to diversify their use of digital information resources, including social media, and traditional resources) exhibit lower digital resource use and health prevention behaviors, hindering their eHL to some extent, especially translational eHL.
Kachentawa [13], 2023		
• Health information evaluation • Health information sharing • Self-management (health prevention) • Health decision-making (medical decision)	• Critical eHL: understanding and evaluation of health information • Functional eHL: ability to learn new things on social media, basic technical skills for using social media, ability to solve basic problems on social media, ability to understand how family explains using social media • Translational eHL: ability to apply health information	Literacies related to social media, including media and information literacy, as well as computer and social media literacy (corresponding to critical eHL, functional eHL, and translational eHL), should be included as indicators of older adults' eHL.
Lee and Ryu [83], 2023		
• Health intervention (online group intervention)	• eHL	Social media–based, online group health interventions can provide social support for older adults and enhance their eHL.
Liu et al [44], 2022		
• Health information acquisition • Telemedicine (accessing health care services) • Self-management (health prevention)	• eHL	During the COVID-19 pandemic, older adults' use of social media for health information acquisition, telemedicine, and self-management contributed to their higher eHL regarding the COVID-19 pandemic.
Chai [81], 2022		
• Health information acquisition • Self-management (lifestyle management)	• eHL: health literacy • Translational eHL: ability to apply health information	Older adults' access to health information through social media (both directly from social media platforms and from social connections maintained by social media platforms) and self-management using this information promotes their eHL.
Tan et al [88], 2022		

XSL•FO
RenderX

Study and social media behavioral dimensions that affect eHL	Theoretical mapping: dimensions of affected eHL	Mechanism of association and key findings
• Health information trust	• Translational eHL: decision-making and applied behaviors based on health information	Older adults who are more trusting of social media and have limited access to other sources of information are likely to make poor health decisions, suggesting that inaccurate information on social media may hinder translational eHL among older adults.
Chen et al [85], 2021		
• Health intervention (online group interventions)	• eHL: health literacy and health self-efficacy • Translational eHL: applying health literacy for problem-solving and self-management	Social media–based, online group health interventions can improve eHealth literacy among older adults, as evidenced by increased health literacy, health self-efficacy, and translational eHL.
Wu and Yu [14], 2021		
• Self-management (medical and lifestyle management) • Health prevention • Platform preference	• Functional eHL and Translational eHL: ability to use online communities for health purposes • Functional eHL: perceived ease of use	Social media promotes the ability of older adults to familiarize themselves with digital technology and use digital tools for health prevention and self-management by linking their online social connections; that is, it promotes their functional eHL and translational eHL. At the same time, older people prefer the perceived ease of use of digital technologies and are more inclined to adopt familiar social media platforms, which lowers their threshold for digital technology adoption, that is, increases their functional literacy.
Ubolwan et al [84], 2020		
• Frequency of social media use	• eHL	The more frequently older adults use social media, the higher their level of eHL.
Tennant et al [78], 2015		
• Frequency of social media use • Health information acquisition • Social support (general) • Health information evaluation	• eHL • Functional eHL: computer literacy • Critical literacy: media literacy	The use of social media, the social support provided by social media, and social media–based health information behaviors can improve eHealth literacy among older adults, especially finding and evaluating health information can improve their functional literacy and critical literacy.

XSL•FO
RenderX

Health decision-making		1 (6)
Medical decision	Kachentawa [13], 2023	1 (6)

Social Media Use Habits

Social media use habits are themes extracted based on older adults' general social media use behaviors, which mainly concern older adults' social media use frequency and platform preferences. Of the 16 included literature, 4 (25%) papers discussed the social media use habits of older adults, 3 (19%) focused on the frequency of social media use by older adults, and 1 (6%) focused on older adults' preferences for social media platforms. The findings indicated a substantially positive correlation between social media use patterns and eHealth literacy.

The most prominent manifestation was that increased use of social media increased the eHealth literacy of older individuals. Ubolwan et al [84] included social media use in assessing the level of eHealth literacy and its correlates in the older population in Thailand. This research revealed a statistically significant positive correlation between the duration of internet or online social media use among older people and their eHealth literacy status. Similarly, Tennant et al [78] discovered that, compared to those who seldom use social media, individuals who used social media regularly had better eHealth literacy. Vitolo et al [87] discussed the adverse effects of reduced frequency of social media use on eHealth literacy in older adults from the opposite perspective, that is, frail older patients had limited use of digital technology and the internet and poorer digital health literacy.

In addition, the study by Wu and Yu [14] was the only study that specifically examined older adults' preferences for social media platforms. Their findings revealed that the most commonly used social media feature among older adults was instant text messaging. Unlike younger generations, who tended to use a wide variety of apps, older adults preferred a limited selection of platforms, often opting for those they were already familiar with. The study also highlighted that older adults place greater emphasis on the perceived ease of use of eHealth technologies rather than their practicality.

Social Media Health Information Behaviors

Health information behavior on social media was the most frequently discussed social media activity influencing older adults' eHealth literacy. This behavior encompasses various aspects, including health information–seeking, sharing, evaluation, trust, and use frequency. Studies consistently suggest that older adults' health information behaviors on social media positively impact their eHealth literacy, particularly functional eHealth literacy, critical eHealth literacy, and translational eHealth literacy.

In particular, Ye [80] thoroughly assessed the influence of older individuals' behaviors of using health information on social media. The study examined the correlation between 4 aspects of older persons' online health information use habits, including social media (frequency of using online health information, forwarding and sharing online health information, using online

XSL•FO
RenderX

health information to regulate one's behavior, and positive attitudes toward online health information), and 3 dimensions of eHealth literacy (the ability to apply eHealth literacy, the ability to make critical judgments and decision-making ability) [80]. A notable positive association was observed among the 7 variables, namely, stronger habits of internet use of health information among older persons corresponding to better eHealth literacy. Among these practices, the dissemination and interchange of internet health information among older people had the most significant influence on their eHealth literacy. Moreover, the habits of older individuals' internet health information use had a significant impact on older people's health decision-making ability. The study further affirmed that older individuals' adoption of social media to browse health content was an effective path to enhance their eHealth literacy because they would improve their understanding of health information in various ways during browsing to regulate their health behaviors.

Kachentawa [13] further recognized the important positive impacts of social media use on older individuals' eHealth literacy and suggested that 2 important literacies related to social media should be included in the system of indicators of older people's eHealth literacy in Thailand within the setting of the new normal lifestyle. These 2 indicators include media and information literacy and computer and social media literacy. The former elucidates the capacity of older Thai individuals to assess the reliability of the COVID-19 pandemic information shared on social media platforms and to comprehend tactics and demonstrations of technology associated with social media. The latter focuses on the capacity of older individuals to acquire new knowledge on social media, including the ability to use relevant apps, communicate with others, obtain accurate information regarding the COVID-19 pandemic, and resolve fundamental challenges encountered on social media. It can be concluded that these 2 indicators encompassed older adults' behaviors related to understanding, evaluating, sharing, and seeking health information on social media. This further underscores the significant impact of health information behaviors on social media in shaping eHealth literacy among older adults.

The increased social media–based health information behaviors among older adults were also found to help them improve their eHealth literacy. Tennant et al [78] analyzed social media health information–seeking behaviors and noted that using social media to obtain and evaluate eHealth information contributed to their eHealth literacy, especially for functional eHealth literacy and critical eHealth literacy. The study conducted by Liu et al [44] investigated older individuals' eHealth literacy during the COVID-19 epidemic. The findings demonstrated that more than half of the older adults had better eHealth literacy during this period. The study also identified several key factors, such as advancements in IT and efforts in epidemic prevention and control, that enabled older adults to effectively use digital technologies, including social media.

In addition, social media impacts the eHealth literacy of older adults by expanding their sources of health information. The study by Chai [81] indirectly demonstrated the impact of social media on improving older individuals' eHealth literacy by exposing how social media facilitated their access to health information. This study pointed out that social media enhanced health literacy among older adults by providing them with direct health information, on the one hand, and helping them to access health content and health promotion resources from social networks by maintaining social connections, on the other hand. Jang et al [82] supported this view from the opposite perspective. Their study found that older adults who had less access to digital resources, among others, had restricted health sources and exhibited lower preventive behaviors that were needed to enhance their eHealth literacy.

Finally, it is worth noting that older adults' trust in the sources of health information on social media can significantly influence their translational eHealth literacy. Tan et al [88] highlighted that older adults who exhibited greater trust in social media and had limited access to alternative information sources were more likely to make suboptimal health decisions. This finding suggests that the presence of inaccurate information on social media may impede the development of translational eHealth literacy among older adults.

Self-Management

Older adults' self-health management behaviors on social media, including health prevention, medical management, and lifestyle management, had a positive impact on their eHealth literacy, particularly their translational eHealth literacy. Given that some (12/16, 75%) studies were conducted in the context of the COVID-19 pandemic, they specifically highlighted how older adults' use of health information for health prevention influenced their eHealth literacy [13,44,81].

Kachentawa [13] proposed a media and information literacy indicator within the framework of eHealth literacy for older adults in the "new normal." This indicator highlighted the ability of older adults in Thailand to effectively use health information from social media to protect themselves from COVID-19 infection. Similarly, focusing on older adults during the COVID-19 pandemic, Wu and Yu [14] explored the use of social media as a grid-based management platform during this period. This platform reconnected older adults to an online model of a familiar social network, enabling them to become accustomed to digital technologies and access eHealth services. It not only supported health prevention efforts but also facilitated the management of their medical needs.

Liu et al [44] noted that the normalization of the pandemic prevention and control measures encouraged older adults to adopt electronic devices and ITs for health management and prevention, thereby enhancing their eHealth literacy. Chai [81] focused on how older adults applied health information obtained from social media to their daily practices during the COVID-19 pandemic, improving their health behaviors and outcomes. This process, in essence, represents an enhancement in their translational eHealth literacy.

Furthermore, Ye [80] explored the mechanisms through which older adults enhanced their eHealth literacy via self-management on social media. The study highlighted that, through the process of acquiring health information on social media platforms, older adults gained increased health knowledge, improved their health

XSL•FO
RenderX

awareness, and developed stronger problem-solving abilities related to health issues. These advancements enabled them to effectively use online health knowledge for self-management, such as regulating their own health behaviors. In addition, this process fostered a heightened sense of health self-efficacy, ultimately leading to improved eHealth literacy.

Health Interventions

In total, 13% (2/16) of health intervention studies conducted on social platforms had validated the efficacy of social media in augmenting eHealth literacy among older individuals [83,85]. Lee and Ryu [83] incorporated social media into a walking program for older adults, which included mobile medical devices and gamification elements. Findings showed that participants' eHealth literacy improved, and the positive impact of social media was generally appreciated by older adults. Similarly, the study by Chen et al [85], while not directly measuring changes in older adults' eHealth literacy levels after intervening in older adults' health through social media, quantified substantial improvements in health literacy and overall health self-efficacy while also noting a rise in older persons' understanding of the significance of health, as well as their capacity to address health issues.

Telemedicine

Social media platforms hold significant potential as telemedicine platforms, facilitating communication between older adults and health care providers while helping them access online health services. Only 13% (2/16) of studies had discussed the role of social media as a telemedicine platform in enhancing eHealth literacy among older adults [44,86]. Oh et al [86] revealed that Asian Americans improved their confidence and capabilities by communicating with health care providers through online platforms, such as social media, thereby enhancing their health information literacy. This finding reflects the potential of social media communication with health care providers to promote communication literacy among older adults. Furthermore, during the COVID-19 pandemic, the role of social media in telemedicine was effectively demonstrated. Liu et al [44] found that home isolation measures during the COVID-19 pandemic, which restricted in-person medical consultations, encouraged older adults to adopt telemedicine practices. These online health behaviors played a critical role in improving their eHealth literacy during the COVID-19 pandemic.

Health Decision-Making

Health decision-making emphasizes the specific decision-making behaviors of older adults based on health information obtained from social media, fundamentally reflecting the application of health information. This corresponds to the dimension of translational eHealth literacy. Kachentawa [13] identified media and information literacy as a key indicator of older adults' eHealth literacy in the new normal. This indicator included their health decision-making abilities, particularly their capacity to use health information from social media to make treatment decisions after contracting COVID-19. This, to some extent, reflects the translational dimension of eHealth literacy.

Impact of eHealth Literacy on Older Individuals' Social Media Health Behaviors

According to the results, eHealth literacy, in turn, affects older adults' performance of health behaviors on social media. Of the 16 studies, 8 (50%) were involved, and the details are provided in Table 6. The most discussed dimensions of eHealth literacy were critical eHealth literacy (4/16, 25%) and functional literacy (4/16, 25%).

XSL•FO
RenderX

Table 6. The impact of eHealth literacy (eHL) on older adults' social media behaviors.

Study	Theoretical mapping: dimensions of eHL	Influenced social media health behaviors	Mechanism of association and key conclusions
Ye [80], 2024	• eHL	• Health information acquisition	The level of eHealth literacy among older adults is directly proportional to the diversity of their access to information.
Matchanova et al [51], 2023	• Functional eHL and critical eHL: verbal IQ, numeracy skills, knowledge	• Health information sharing • Health information evaluation	Older adults who lack functional literacy and critical eHL inaccurately assess health information on social media and are more likely to share incorrect health information.
Wang and Zhang [42], 2023	• eHL: digital literacy • Communicative eHL: interactive health literacy • Critical health literacy	• Health information acquisition	eHL was positively associated with older adults' social media health information acquisition behaviors, as evidenced by communicative eHL predicting older adults' passive and long-term health information gathering behaviors and critical eHL predicting older adults' active information acquisition behaviors.
Liu et al [44], 2022	• Functional eHL: barriers to the use of digital technology • Critical eHL: distinguish health information	• Health information acquisition • Telemedicine (accessing health care services) • Health information evaluation • Health decision-making	Older adults who lack functional eHL have difficulty in accessing health care services through social media, and the lack of critical eHL makes it difficult for them to properly evaluate health information and make sound health decisions.
Chai [81], 2022	• Critical eHL: understanding and evaluation of health information • Functional eHL: know little about new digital technologies	• Health information evaluation • Frequency of social media use	Older adults who lack critical literacy struggle to understand the scientific logic of health rumors on social media and tend to reject new communication technologies, such as social media, due to a lack of digital literacy.
Tan et al [88], 2022	• Critical eHL: trust in health information sources	• Health decision-making (medical decisions)	Lack of critical eHL diminishes the ability of older adults to make sound health decisions.
Wu and Yu [14], 2021	• Functional eHL: unfamiliarity with the new digital technology	• Telemedicine (accessing health care services)	Lack of functional eHL affects attitudes and willingness to adopt telemedicine among older adults.
Shang and Zuo [79], 2020	• eHL	• Health knowledge learning	Self-efficacy and perceived benefits partially moderate the relationship between eHealth literacy and willingness to learn about health.

First, critical eHealth literacy directly affects older adults' assessment of social media health messages. Matchanova et al [51] discovered that persons with little knowledge and fundamental numeracy abilities might have had impaired accuracy in assessing the truthfulness of news headlines about the COVID-19 pandemic on social media and were more prone to disseminating false information on social networks. Chai [81] found inconsistencies in older adults' understanding and evaluation of the COVID-19 pandemic–related rumors. While some older adults were able to identify misinformation about the pandemic, they often lacked an understanding of the underlying scientific logic. This highlights a gap in critical eHealth literacy among older adults.

Second, a lack of critical eHealth literacy can also affect older adults' ability to make sound health decisions. Tan et al [88] noted that older adults' trust in social media disinformation affected their hesitancy to take a new coronary vaccine. Although the findings showed that social media only slightly predicted vaccination intention among older adults, the study also found that trusting only formal sources and distrusting informal sources was associated with higher vaccination intentions. Therefore, improving older individuals' ability to discern health information on social media can eliminate their trust in false health information, thereby shaping their health behaviors.

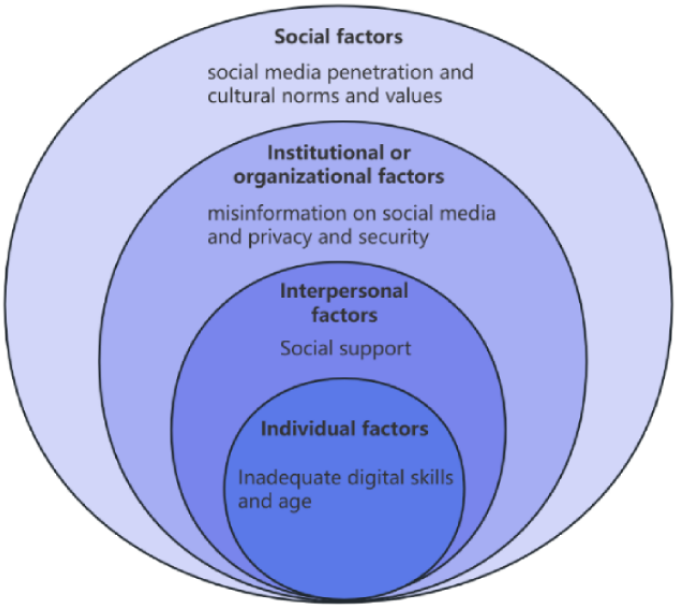
Similarly, Liu et al [44] observed that older persons predominantly relied on information to avoid COVID-19 infection and to enhance their well-being. They also highlighted that their limited capacity to understand and assess health-related information hindered their ability to distinguish between reliable information on social media, thus impacting their capacity to make informed health choices [44]. Similarly, critical eHealth literacy is essential for older people to effectively access health information on social media. Insufficient skills can hinder

XSL•FO
RenderX

accurate information assessment, increase vulnerability to misinformation, and complicate the health decision-making process.

Furthermore, research has revealed a correlation between functional literacy and the inclination of older populations to use social media platforms (3/16, 19%) [14,80,81]. Ye [80] demonstrated that older people who relied heavily on online health information exhibited a more favorable and hopeful outlook toward their health. Moreover, they were more inclined to use internet-based platforms, such as social media, to obtain health-related information. In contrast, Chai [81] argued from the opposite perspective that older adults who lacked functional eHealth literacy showed rejection of new communication technologies, such as social media, as most of them have had unpleasant experiences with the adoption of new technologies. Similarly, Wu and Yu [14] found that the lack of functional eHealth literacy affected attitudes and willingness to adopt telemedicine through social media among older adults.

Finally, eHealth literacy directly affects older adults' health information behaviors [42,51,79]. Matchanova et al [51] revealed that eHealth literacy also affected health information sharing behaviors. The study conducted by Shang and Zuo [79] primarily aimed to investigate the inclination of older individuals to acquire knowledge about health through the use of social media platforms. Using self-efficacy and perceived benefits as mediating variables, they examined the effect of eHealth literacy as a cognitive state on older people's willingness to acquire health knowledge through social media. Research indicated that older individuals who possessed greater eHealth literacy tended to view themselves as having greater self-efficacy and perceived benefits in their health-related knowledge. Self-efficacy and perceived benefits exerted a minor moderating effect on the association between eHealth literacy and the inclination of older individuals to acquire knowledge about health via social media.



Wang and Zhang [42] found that older adults usually browsed health information passively, while those with higher digital literacy were more likely to actively seek health information online. In addition, positive correlations were observed between interactive literacy and functional literacy in health literacy and the health information acquisition habits of older persons. Thus, higher eHealth literacy among older people led to more proactivity and improved performance in using social media to access eHealth information.

Factors Influencing Older Adults' Use of Social Media to Improve eHealth Literacy

Overview

Previous articles dealing with the factors affecting eHealth literacy in older adults have tended to list points based on empirical results and lacked theory-guided categorization. The study by Shi et al [45] adopted a SEM to classify the factors affecting eHealth literacy among older adults, which provides inspiration for this review. In this review, the elements influencing the use of social media by an older adult to enhance eHealth literacy were classified into four main areas: (1) individual factors, including older adults' inadequate digital skills (7/16, 44%) [13,14,42,44,51,79,87] and age (3/16, 19%) [14,51,87]; (2) interpersonal factors, involving social support (6/16, 38%) [14,78,80,81,83,85]; (3) institutional or organizational factors, including misinformation on social media (7/16, 44%) [13,42,44,51,78,82,88] and privacy and security (1/16, 6%) [14]; and (4) social factors, including social media penetration (8/16, 50%) [13,14,42,44,79,82,84,86] and cultural norms and values (1/16, 6%) [14]. Figure 4 [13,14,42,44,51,78-88] presents the framework of these factors.

Figure 4. Framework diagram of the influencing factors on older persons' use of social media to enhance their eHealth literacy. This figure categorizes key factors affecting eHealth literacy, with reference sources as follows: (1) social factors: social media penetration [13,14,42,44,79,82,84,86] and cultural norms and values [14], (2) institutional and organizational factors: misinformation on social media: [13,42,44,51,78,82,88] and privacy and security [14], (3) interpersonal factors: social support [14,78,80,81,83,85], and (4) individual factors: inadequate digital skills [13,14,42,44,51,79,87] and age [14,51,87].

XSL•FO
RenderX

Individual Factors

In the context of SEM, the individual level refers to individual characteristics [89,90], including knowledge and skills, attitudes and beliefs, demographic factors, and self-efficacy [90-92]. Inadequate digital skills among older adults and age are identified as individual factors in this review.

Inadequate Digital Skills Among Older Adults

The prevalence of inadequate knowledge and proficiency in using digital devices among older people poses a significant obstacle to their eHealth literacy. The first obstacle is the reluctance of older individuals to use social media to acquire health information and services. Ubolwan et al [84] contended that the limited social media abilities of older persons might result in hesitancy to use social media for eHealth participation. This, in turn, could negatively influence older people's eHealth literacy, as there exists a direct relationship between the frequency of social media use and eHealth literacy. Wu and Yu [14] pointed out that older people are deprived of lifelong learning environments and have relatively low confidence in digital technology after retirement. A prominent manifestation is that, unlike the younger generation, who care about the practicality of digital health care, older people are more concerned with the perceived ease of use of digital technology [14]. Moreover, the lack of digital experience leaves older adults with high health management needs facing low technology adoption. Second, it hinders older adults' effective access to health resources. Chai [81] noted that older adults' lack of skills in using digital technology can make them face challenges in health information retrieval. Similarly, Wang and Zhang [42] argued that older individuals with little digital literacy are less able to access health information via the internet or technological devices.

Furthermore, the lack of proficiency in digital skills among older individuals can result in the digital divide among them extending to eHealth, therefore impeding the achievement of health equity [13,42,78]. Kachentawa [13] argued that perceived self-efficacy and digital competence affected older adults' adoption of digital technology. While perceived self-efficacy is primarily related to older people's enjoyment of using digital technology, the core problem remains in older adults' lack of digital skills. This issue is reflected in the indicators developed by the author related to the eHealth literacy of older persons, namely computer and social media literacy [13]. It suggests that in the new normal, older adults must not only have the knowledge and skills to use digital devices, such as computers and social media, but also have the ability to solve basic problems with social media. Tennant et al [78] highly emphasized the important role of digital literacy (computer literacy) in the older adult population, arguing that lower digital literacy among older adults prevents them from truly benefiting from health care innovations and may reopen the digital divide, exacerbating current health disparities.

Age

Another individual factor is age. However, the results of the studies were not consistent. While the study by Wu and Yu [14] identified aging as a significant determinant of older people's digital technology use and their attitudes toward telemedicine, Vitolo et al [87] found that digital literacy was only partially influenced by age. The role of age was further weakened in the study by Matchanova et al [51], where the findings did not demonstrate a substantial impact of age on the probability of sharing false or accurate information online. Nevertheless, it was observed that this phenomenon could be attributed to the age of the study participants (aged 50 years), but most of the significant effects on susceptibility to misinformation and sharing were centered at the age of 65 years. Thus, there may be differences in perceived susceptibility to social media misinformation about health by age.

Interpersonal Factors

The interpersonal dimension of SEM emphasizes the influence of social networks and social support systems on individual behaviors [89-91]. In this review, social support plays a crucial role in enabling older people to use social media to enhance their eHealth literacy.

The social supportive role of social media is manifested first and foremost in increasing the health information resources available to older adults by linking their relationships on online platforms. Social relationships, the traditional way for older individuals to obtain health information or resources, have achieved rapid dissemination on online platforms with social media connections. This model played an important role during the COVID-19 pandemic. Wu and Yu [14] noted that during the COVID-19 pandemic, social media platforms, such as WeChat, expanded offline community management to online, creating a new model of online acquaintance relationships and, therefore, continued maintaining health support through social networks. Chai [81] also noted that older adults accessed health information through online social relationships during the COVID-19 pandemic.

Furthermore, the effect of social support is reflected in the interactive advantages of social media in facilitating health communication and health information sharing behaviors among older adults. Tennant et al [78] argued that the greater social support that older adults derive from social media is based on stronger Web 2.0-connected support networks and the multifunctionality factor of social media. Older adults can enhance their understanding of their health status and connect with online friends with similar experiences through social support venues built on interactive social media. Ye [80] further clarified that older adults' online health information sharing and exchange behaviors had the greatest impact on their eHealth literacy, outweighing the effect of the other dimensions (frequency of use of online health information, use of online health information to regulate their behaviors, and the impact of favorable attitudes toward online health information) on eHealth literacy.

Finally, the facilitating role of social support provided by social media is reflected in the strength of social media as a medium for group-based health interventions. Of the 16 studies, 2 (13%) social media–based health intervention studies found that social media was effective in motivating older adults to participate in health intervention programs [83,85]. Lee and Ryu [83] found that mHealth apps incorporating social media allowed older adults who were socially isolated during the COVID-19

XSL•FO
RenderX

pandemic to feel socially connected again, as they shared and interacted with their peers and encouraged them to use these apps. The rationale for the finding was explained in more detail in the study by Chen et al [85]. They pointed out that interacting with others is a key incentive for older adults to engage in health interventions. Older adults enjoy sharing experiences and opinions in online discussions on social media and, over time, they develop a sense of socialization that enhances feelings of connectedness and engagement.

Institutional or Organizational Factors

Overview

On the basis of the SEM, institutional or organizational factors refer to the influence of institutional or organizational settings individuals are embedded in on personal behaviors [89,90]. In the health context, organizational structures and processes, as well as the environment within the organization, including safety, have an impact on people's health behaviors [90]. This review revealed that misinformation on social media and privacy and security concerns associated with social media pose possible obstacles that hinder older people from enhancing their eHealth literacy using social media.

Misinformation on Social Media

The issue of information credibility on social media has attracted a great deal of attention from researchers, who have argued that the proliferation of false information on social media is a serious threat to effective access to health information by older adults [13,42,78,79]. This was especially true during the COVID-19 pandemic, when false news on social media was rampant and caused great harm to older adults [13] and affected their health decision-making abilities and health behavioral norms. For example, studies by Jang et al [82] and Tan et al [88] found that trust in misinformation on social media increased new coronary vaccine hesitancy in older adults. Social media also contributes to the dissemination of misinformation about health among older adults. Matchanova et al [51] noted that the social media sharing function does not require the involvement of subjective agency other than motivation, which may influence the reflective accuracy of older adults to spread misinformation about health.

Part of the literature identifies the lack of older adults' ability to assess social media information, such as media literacy or information literacy, that is, the ability to assess the trustworthiness of social media. Kachentawa [13] included this competency as one of the indicators of eHealth literacy among the new normal older adults and emphasized the importance of assessing the trustworthiness of the information in the context of social media to improve eHealth literacy among older adults. Similarly, Tennant et al [78] noted a real lack of confidence among older adults in assessing the quality of social media health information. Furthermore, Liu et al [44] found that older adults had the lowest information judgment scores. Nonetheless, Wang and Zhang [42] revisited the relationship between key health literacies related to the ability to assess health information and older adults' health information acquisition behaviors from the perspective of the motivation of older adults' health information acquisition behaviors. The study yielded a different and interesting finding that critical health literacy was not significantly correlated with health information acquisition behavior; that is, even if older adults are unable to critically analyze health information, they are able to facilitate their health information access behaviors as long as they have basic literacy and communication skills.

Privacy and Security

Wu and Yu [14] identified financial security as a barrier that hinders older persons from the adoption of digital services. Older adults are anxious about the potential loss of money through the use of online payments.

Social or Community Factors

Overview

The social or community level in SEM refers to societal influence and cultural or subcultural norms and values [89]. Regarding social influence, the development of social media technology can affect personal health behaviors. In this review, this influential factor is identified as social media penetration. Meanwhile, the influence of cultural norms was reflected in a study in China [14].

Social Media Penetration

The high penetration of social media among older adults is a notable trend that has been the focus of most studies, and this trend's development establishes a crucial basis for the function of social media in enhancing eHealth literacy among the older population. Given the growing population of older individuals using social media, it has become a crucial medium for them to obtain and exchange health-related information [13,44,82] and creates novel avenues for older individuals to acquire health advice [79]. This high penetration is mainly achieved through 2 aspects: one is driven by IT (5/16, 31%) [42,44,79,84,85], and the other is catalyzed by the COVID-19 pandemic (2/16, 13%) [13,44]. One consequence of the swift advancement of IT is the establishment of a technological framework that enables older people to use social media. Various studies have indicated an increase in the frequency of social media use among older adults in recent years [44,79,84,85]. Moreover, this IT push is inadvertently creating social pressure on older people to learn to use digital technology tools [14]. Furthermore, the outbreak and normalized management of the COVID-19 pandemic further increased the adoption of social media by older adults. During the COVID-19 pandemic, older adults faced physical health risks and social isolation situations, and social media became not only a tool for them to maintain social relationships but also an important platform for them to obtain health-related information and health services [13,44].

The high penetration of social media is also evident in the significant expansion of channels for accessing health information, which has transformed the ways they obtain it. Ye [80] pointed out that social media can bring more health channels to older adults and increase their access to health information. Furthermore, Oh et al [86] argued that social media can serve as an effective channel to supplement older patients' health information and knowledge when they have poor communication with their health providers, thus improving their communicative eHealth literacy.

XSL•FO
RenderX

Cultural Norms and Values

Wu and Yu [14], in the study of older adults in Wuhan, China, found that China's social culture of acquaintance profoundly influenced older adults' adoption of digital health care. Chinese older adults were more likely to adopt programs based on acquaintance relationships and traditional health care processes than those in other countries. The acquaintance relationship in Chinese society is a distinct cultural phenomenon characterized by the dichotomous connection between acquaintances and the line between insiders and strangers [14]. During the COVID-19 pandemic, the "grid management" model facilitated through social media chat groups linked a new type of online acquaintance relationship that could help manage the health care needs of older adults by providing them with a sense of trust and setting common rules. To this end, their study indicates the need to take into account the cultural environment while encouraging the acceptance of digital health among older individuals.

Discussion

Principal Findings

This study is the initial systematic literature review that investigates the correlation between social media use behaviors and eHealth literacy in the older adult population. The increasing global aging population, the proliferation of digital technologies, and the COVID-19 pandemic have significantly immersed older adults in the social media and eHealth phenomenon. This situation offers them both prospects and obstacles to fully benefit from digital health technologies. On the one hand, the advantages of social media have expanded the channels for older adults to engage in eHealth and, on the other hand, older adults' eHealth literacy greatly influences their willingness to adopt social media, as well as their performance of health behaviors based on social media platforms.

To further integrate older adults into the eHealth trend and achieve active aging, it is essential to establish a positive feedback loop between social media behaviors and eHealth literacy. This involves enabling older adults to gradually enhance their eHealth literacy through health-related practices on social media, which, in turn, improves their social media health behaviors and experiences, ultimately bridging the digital divide. Therefore, this study aimed to synthesize and analyze recent research on this relationship, uncovering patterns and influencing factors to identify both the potential and barriers of using social media to enhance eHealth literacy among older adults. The findings are expected to inform targeted eHealth literacy interventions for this population, fostering a sustainable cycle of mutual reinforcement between health practices and health skills.

We extracted themes related to older adults' social media behaviors and the dimensions of their eHealth literacy for cross-analysis. The findings reveal that older adults' social media behaviors and eHealth literacy are mutually influential and interactive. Specifically, this review provides comprehensive answers to the RQs.

Regarding the first RQ, we identified that older adults' social media behaviors encompass general use behaviors and health-related behaviors. General use behaviors include habits such as use frequency and platform preferences, while health-related behaviors involve a range of activities aimed at health purposes, such as health information behaviors, health decision-making, self-management, participation in health interventions, and engagement in telemedicine. Among these, health information behaviors are the most common and widely discussed health activities.

For the second RQ, most (14/16, 88%) of the reviewed studies confirmed the positive impact of older adults' social media behaviors on enhancing their eHealth literacy. First, regarding general use behaviors, the frequency of social media use significantly improves older adults' eHealth literacy, aligning with previous research that observed a positive correlation between the frequency of internet technology use and eHealth literacy [93,94]. In addition, familiar social media platforms enhance older adults' perceived ease of use of digital technologies, thereby increasing their willingness to engage in health-related activities on social media [14].

Second, health-related behaviors on social media are the most effective and direct practices for improving older adults' eHealth literacy. These practices include health information behaviors, health management, health interventions, telemedicine, and health decision-making, with health information behaviors being the most frequently (7/16, 44%) discussed. Older adults' self-management and health decision-making activities are often built upon their understanding and application of health information obtained via social media. Furthermore, social media serves as a highly effective platform for group-based, online health interventions, where its interactive features enhance older adults' participation in interventions and their willingness to adopt digital technologies [83,85]. The platform's potential as a telemedicine tool, especially during the COVID-19 pandemic, has been highlighted as older adults began using social media for telemedicine and, through these practices, improved their eHealth literacy.

For the third RQ, the findings revealed that older adults' eHealth literacy reciprocally influences their social media behaviors. This includes their willingness to adopt social media and other digital technologies [14,44,81], their ability to understand and evaluate health information on social media [44,51,88], their willingness to learn health knowledge through social media [79], and their proactivity in acquiring health information [42]. Among these, functional and critical eHealth literacy have the most significant impacts. A lack of functional eHealth literacy not only hinders older adults' effective use of social media and other digital technologies but also reduces their willingness to adopt them. A deficiency in critical eHealth literacy affects their ability to understand and evaluate information, which further impacts their health decision-making and self-management behaviors.

By integrating the insights from RQs 2 and 3, we conclude that older adults' eHealth literacy and their social media behaviors exhibit a reciprocal relationship, highlighting the need for

XSL•FO
RenderX

interventions that leverage this dynamic to enhance both dimensions.

For the fourth RQ, older adults' use of social media for health participation is influenced by individual, interpersonal, institutional or organizational, and social factors. At the individual level, inadequate digital skills [13,14,42,44,51,79,87] and age-related challenges [14,51,87] limit their ability to access and use social media effectively, contributing to the digital divide. Interpersonal factors, such as social support [14,78,80,81,83,85], enhanced health information acquisition or sharing and participation in health interventions, which are vital for improving eHealth literacy. Institutional barriers, including misinformation [13,42,44,51,78,82,88] and privacy concerns [14], further hinder their engagement, emphasizing the need for critical eHealth literacy. Moreover, the high penetration of social media, driven by technological advancements and the COVID-19 pandemic, has expanded access to health information and services, offering new opportunities to bridge these gaps [13,14,42,44,79,82,84,86]. Finally, promoting the use of eHealth technologies among older adults also requires consideration of cultural contextual factors at the societal level [14].

Considerations for Establishing a Reciprocal Mechanism Between Social Media Health Practices and Older Adults' eHealth Literacy

Overview

The findings reveal the immense potential of social media to enhance older adults' eHealth literacy. To further promote their active use of social media for health interactions, information acquisition, and service use, it is essential to enable older adults to continually improve their eHealth literacy through social media–based health practices. This improvement, in turn, can lead to positive feedback in their social media use experiences, ultimately establishing a reciprocal reinforcement system between social media use and eHealth literacy. To this end, theoretical and practical efforts can be made in the following areas.

Leveraging Postpandemic Momentum to Enhance eHealth Literacy Among Older Adults Through Social Media

The high penetration of social media and the catalyst of the COVID-19 pandemic have facilitated changes in older adults' technology's use behaviors and health behaviors, laying the groundwork for improving older adults' eHealth literacy. The continuous development and popularization of social media have revolutionized the traditional pattern of health information dissemination [95,96] and changed the habits of older adults in accessing eHealth information or services [44,97]. Especially with the COVID-19 outbreak, this pattern has deepened further. On the one hand, the social blocking measures forced older adults to rely on social media for information and lifestyle services, as well as social support, among others [98]. On the other hand, the epidemic posed multiple risks to older adults [99-101], who were forced to step out of their comfort zones and start using social media and engaging in eHealth activity practices. The COVID-19 pandemic is arguably a major reason for the rise in social media use among older adults [13]. Moreover, during this period, older adults showed unprecedented enthusiasm for learning about eHealth tools [102]. Interest is an important reason for improving eHealth literacy [103]. Therefore, the present moment, that is, after the end of the COVID-19 pandemic and in the context of older people's heightened experience of and interest in eHealth technologies, as well as social media, is an optimal time to improve eHealth literacy among older people. Countries around the world should take this opportunity to lay and plan to encourage older adults to use social media more to participate in eHealth activities and to accelerate the pace of active integration of older adults into the trend of eHealth technology.

Reconsidering the Dimensions of eHealth Literacy Among Older Adults in the Context of Web 2.0

Findings regarding the impact of eHealth literacy on older adults' social media health behaviors bring more serious practical considerations to the achievement of this goal. According to the review, eHealth literacy among older adults can, in turn, affect older adults' social media use behaviors and performance, including influencing older adults' understanding and evaluation of social media health information [44,51,88], willingness to use social media to access or learn health information [79-81], and access to health information initiative [42]. More importantly, the lack of digital skills and misinformation on social media, the 2 prominent factors affecting older adults' use of social media to improve eHealth literacy, are closely related to 2 important components of eHealth literacy: digital literacy and critical health literacy, respectively. The lack of these 2 literacies not only prevents older adults from truly benefiting from eHealth but also has the potential to exacerbate health disparities by extending the digital divide into the eHealth domain [42,79]. Kachentawa [13] innovatively included social media literacy in the indicators of eHealth literacy for older adults in the new normal. In his opinion, social media literacy among older adults included not only the ability to assess information but also the skills in understanding, using, and dealing with problems in social media. However, there is still no consensus on the concept of social media literacy. Some scholars define the concept of social media literacy as encompassing the technical and practical skills required for using social media [104,105], while others prefer to use the concept of media literacy as a substitute for social media literacy [106,107]. As the use of social media among older adults increases, social media literacy should be further emphasized as a component of eHealth literacy among older adults. In addition, relevant interventions should be centered on how to adapt functional and critical eHealth literacy for older adults.

Actively Developing Age-Friendly Integrated Social Media Health Service Platforms

Self-efficacy has been confirmed by previous research to be positively associated with older adults' willingness to use digital health technology [108]. In turn, self-efficacy in older adults was positively associated with the perceived ease of use of eHealth technology [109]. Thus, digital literacy among older adults can be achieved by lowering the threshold of eHealth

XSL•FO
RenderX

technologies. In addition to further strengthening IT infrastructure, efforts should be made to actively develop social media health service features and digital tools tailored to the needs of older adults.

Existing research on intelligent health and medical services for older adults has extensively investigated their needs, with a primary focus on developing diverse mHealth apps. For instance, Zhou et al [110] developed a home health management app tailored to the needs of older users, which promoted self-health management among this population. Similarly, Blinka et al [111] designed a sensor-based mobile app to help older adults assess frailty. However, this review reveals that older adults' digital platform preferences significantly influence their willingness to adopt technology. Wu and Yu [14] highlighted that older adults prefer limited and familiar digital platforms, which enhance their perceived ease of use and, consequently, their willingness to engage in health activities via social media. In addition, among the 16 included studies, 2 (13%) articles focusing on health interventions that used specialized health platforms. Although the intervention results showed improvements in older adults' eHealth literacy, there remains a potential risk of low adoption willingness if these interventions are to be widely implemented among the older population.

Older adults who have experienced the COVID-19 pandemic are already familiar with social media platforms, and further investigation into their preferences for these platforms is warranted. Aging impacts cognitive abilities, leading to slower reactions and increased cognitive vulnerability [112,113]. The proliferation of mobile apps can negatively affect their perceived ease of use. Therefore, effectively leveraging the social media platforms that older adults are already familiar with to create an integrated mHealth platform—incorporating features such as health information dissemination, online consultations, health monitoring, and interactive support—can enhance their willingness to adopt and use these technologies. For example, Samad-Soltani et al [114] proposed integrating Telegram-based smart bots into health care, which not only minimizes the need for app installations but also supports a variety of health-related tasks while fostering interaction with contacts. Another example is the hospital WeChat official account in China, which is a platform for embedding the hospital's eHealth system into WeChat, China's most popular social media, to facilitate older adults' access to health care information and services [79,115]. In the future, the integration of mHealth and social media is expected to become a new generation of eHealth trends, and related studies can pay more attention to this trend.

Last but not least, the development of a social media health integration platform should take into account other factors that influence the adoption of technology by older adults. Although the influences of privacy and security, age, and culture were not widely discussed in the included literature, they still play an important role in previous work on factors affecting eHealth literacy among older adults [45,116]. Therefore, future research should focus on the influence of these factors on older adults' use of social media for eHealth engagement. Previous studies have found that issues of privacy and security have been widely identified as a barrier to older adults' use of digital health technologies [109,117], and social media amplified this challenge [38]. Accordingly, the resolution of privacy and security issues will potentially have a direct impact on older adults' willingness to use social media to engage in eHealth. In addition, age, as well as cultural factors, may affect older adults' attitudes toward using social media to enhance eHealth literacy. Relevant technology development should also fully consider the characteristics and needs of older adults at different age stages and in different cultural contexts.

Optimizing Social Media for Engaging and Reliable Health Information for Older Adults

The findings indicate that health information behaviors on social media are the most common and direct form of health practice for enhancing eHealth literacy among older adults. Behaviors, such as self-management and health decision-making, are often built upon their understanding and evaluation of the health information or knowledge they acquire. Previous studies have highlighted that the type and source of information are crucial contextual factors influencing older adults' online health information–seeking behaviors [118,119]. However, in this review, as most studies were published during the COVID-19 pandemic, there is a predominant focus on older adults' acquisition and application of COVID-19 pandemic–related information, with limited attention to other types of health information. Future research should place greater emphasis on older adults' preferences for other health information types. In addition, the review reveals that trust in health information sources significantly influences older adults' health decisions [88]. Moreover, due to a lack of critical eHealth literacy, older adults are more susceptible to the negative impact of misinformation on social media [44,51]. Therefore, establishing engaging and trustworthy social media health information channels tailored to older adults is imperative.

Currently, machine learning algorithms have been introduced into health management and monitoring for older adults, demonstrating positive effects in promoting self-management and preventing health risks [120,121]. For instance, the research by Zhao et al [122] used high-order hybrid clustering algorithms that integrated physical activity and medical perspectives, advancing personalized health care and rehabilitation for older adults. However, studies on optimizing social media algorithms for health information targeted at older adults remain relatively limited. Future research could enhance social media algorithms by prioritizing accurate, clear, and relevant health content tailored to older adults. Personalized recommendations could encourage older users to use reliable medical resources and participate in health promotion activities, thereby reducing their exposure to misinformation.

In addition, older adults are considered more inclined to trust health information disseminated through authoritative channels [81]. While social media provides an abundance of health information and convenience for older adults, the prevalence of misinformation often undermines their judgment. Therefore, it is crucial to encourage authoritative health care institutions to play a more active role in creating health content on social media. These institutions should regularly disseminate reliable health information through social media platforms while leveraging the social features of these platforms to offer

XSL•FO
RenderX

knowledge-based question and answer sessions and interactive opportunities, such as expert online consultations.

Furthermore, the study by Nassetta and Gross [123] found that labels on social media can help mitigate the impact of misinformation, but this requires users to pay attention to the source of information. Thus, governments and health care institutions could collaborate to introduce reliable information verification mechanisms on social media platforms. Examples include implementing "trusted source" labels or certification marks for health information verified by authoritative organizations. These labels should be prominently displayed to enhance older adults' trust in the credibility of information sources.

Integrating Social Support Systems to Foster Lifelong eHealth Learning for Older Adults

The findings of this review indicate that the potential of social media to enhance older adults' eHealth literacy primarily lies in the social support it provides. First, social support serves as an important supplementary channel for older adults to access health resources. In this review, health information behaviors emerged as the most frequently discussed theme influencing older adults' eHealth literacy. In addition to the health information directly obtained by older adults from social media, many health resources are accessed through the online social networks maintained by social media platforms [14,81].

Second, the social support older adults gain from the interactive advantages of social media can promote their health-sharing and communication behaviors, which have a significant positive impact on their eHealth literacy [80]. Moreover, as a crucial platform for online, group-based health interventions, the greatest advantage of social media lies in leveraging social support to encourage older adults to consistently use digital health technologies [83,85].

Although social support through social media has been found to have a positive effect on older adults' mental health, health management, and health education in previous studies [15,124,125], it is still controversial whether social support is directly related to older adults' eHealth literacy. Arcury et al [93] found no direct association between social support and eHealth literacy, whereas Kim and Sung [126] found that peer support was significantly related to the eHealth literacy of older individuals. This review did not find a direct association between the 2 but observed that social support provided by social media has the potential to promote the continued use of eHealth devices among older adults; however, this relationship has not been rigorously confirmed in the included literature [14,78,80,81,83,85]. Moreover, studies do find that peer support increases internet use among older adults [98]. Thus, the correlation between social support provided by social media and eHealth literacy among older adults may have been moderated through ongoing eHealth device use behaviors, and the relationship between the 3 could be explored in depth in the future.

While the direct relationship between social media and older adults' eHealth literacy remains unclear, social media does reshape older adults' health behaviors by linking their social networks and social support on online platforms. Studies suggested that the perceived positive effects of social support on health outcomes are not only limited to face-to-face interactions but are also applicable in the social media context [127,128]. However, a relatively small portion of the studies in this review (6/16, 38%) focused on the positive impact of social support on eHealth literacy among older adults. Most studies (10/16, 63%) lacked an exploration of older adults' health-related interactions on social media, such as peer-to-peer interactions and interactions with health care professionals. To effectively leverage social media in building a sustainable mechanism to enhance older adults' eHealth literacy, further exploration of their interactive behaviors on social media is needed, with an emphasis on the critical role of social support in encouraging older adults to actively engage in eHealth practices.

To this end, communities or health care institutions could use social media to establish virtual support groups focusing on different health topics, where volunteers regularly share health knowledge and encourage older adults to exchange their health experiences. Previous studies have called on hospitals and clinics worldwide to develop social media–supported medical apps, establish support groups, and encourage users to actively engage in social interactions with peers and health care providers [72].

In addition to the social support offered by online social media, offline social support remains indispensable. Despite the increased use of digital technologies among older adults driven by IT and the COVID-19 pandemic, research indicates that they still prefer traditional face-to-face interactions [129]. The development of technology should not be detached from the temperature of human beings, and the enhancement of eHealth literacy among older adults requires the intervention of "real people." For example, older adults who lack functional digital skills often rely heavily on family members for technical assistance and advice [129]. However, as the caregiver burden on families increases, it is essential to involve community resources to help older adults establish a long-term mechanism for learning and practicing eHealth technologies.

Communities could host social media health education workshops to teach older adults how to use social media for accessing health information, using telemedicine services, and identifying misinformation. In addition, the role of social work volunteers should be emphasized to provide ongoing online technical support and guidance for older adults. As older adults gain more positive experiences from using social media to participate in health practices, they will likely engage more actively in the eHealth trend. This engagement will, in turn, enhance their eHealth literacy, allowing them to refine their behaviors and ultimately achieve a long-term positive feedback loop between social media health practices and eHealth literacy.

Limitations

This review has several limitations. First, we only searched for keywords in the abstracts and titles, which, on the one hand, led to a large number of studies that used social media to recruit respondents unrelated to the topic appearing in the first search results. On the other hand, it could have resulted in the omission of articles in the primary content of the text dealing with the

XSL•FO
RenderX

correlation between social media and eHealth literacy among older individuals. Second, the sample size for this review was relatively small due to the specificity of the research topic. Third, the thematic analysis conducted in this review was qualitative, and some (6/16, 38%) of the included studies did not directly examine the relationship between social media and eHealth literacy. Instead, they provided indirect evidence or theoretical suggestions that social media might enhance eHealth literacy in older adults. Therefore, the conclusions drawn in this review are primarily based on correlation rather than causation. Finally, the scarcity of existing research investigating this specific correlation highlights the need for more empirical studies that directly explore how social media impacts older adults' eHealth literacy. Future research should address these gaps by using diverse methodologies and larger sample sizes to establish more comprehensive and definitive conclusions.

Conclusions

Given the significant potential of social media in enhancing eHealth literacy among older individuals and the need to improve eHealth literacy among this population, this review sought to investigate the correlation between the social media use habits of older adults and their eHealth literacy. The review analyzed studies conducted from January 2000 to May 2024. The results found that social media and older adults' eHealth literacy influence and interact with each other. Older adults' social media use behaviors, including social media use habits and health behaviors, have a significant impact on their eHealth literacy, suggesting that social media has significant potential to enhance eHealth literacy among older adults. In turn, older adults' eHealth literacy affects their willingness to adopt digital technologies, such as social media, as well as their performance of social media behaviors for health purposes. Promoting a virtuous cycle of interaction between the 2 fosters active aging and helps establish a long-term mechanism to enhance eHealth literacy among older adults. Achieving this goal requires a comprehensive consideration of factors that influence older adults' use of social media to improve eHealth literacy, including social media penetration, insufficient digital skills, misinformation on social media, age, privacy and safety, and cultural norms and values. On the basis of the results of the review, this study proposes several future considerations for improving eHealth literacy among older adults through social media.

Acknowledgments

The authors would like to thank the anonymous reviewers and editors for their helpful comments on the manuscript. This study did not receive external funding.

Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information files.

Authors' Contributions

CZ, EM, and AAA were responsible for the conceptualization, research design, and search strategy of this review. YQ was responsible for all database searches and result collation, and AW was responsible for paper screening, data extraction, and critical appraisal. YM was involved in conflict resolution during the screening process. EM, AAA, and YQ were involved in the data analysis and data interpretation and drafted the manuscript. All authors were involved in reviewing and editing the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Mukbang is a recent internet phenomenon in which anchors publicly record and show their eating through short video platforms. Researchers reported a tangible impact of mukbang on the psychological and physical health, appetite, and eating behavior of the public, it is critical to obtain clear and comprehensive insights concerning the use of mukbang to promote the viewers' appetite, eating behaviors, and health to identify directions for future work.

Objective: This scoping review aims to comprehensively outline the current evidence regarding the impact of mukbang consumption on dietary behaviors, appetite regulation, flavor perception, and physical and psychological well-being. Specifically, we conducted an analysis of public perceptions and attitudes toward mukbang while summarizing the reciprocal influence it has on health promotion.

Methods: This study was conducted as a scoping review following the Joanna Briggs Institute guideline and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. We comprehensively searched 8 electronic databases in Chinese, English, and Korean languages. We also searched gray literature sources like Google Scholar and ProQuest. We used a data extraction chart to extract information relevant to the impact of mukbang on health. The extracted data were qualitatively analyzed to form different themes related to health, categorizing and integrating the results based on the type of study (qualitative, observational, and experimental).

Results: This scoping review finally included 53 studies; the annual distribution exhibited a consistent upward trend across all categories since their initial publication in 2017. Based on the results of the analysis, we have summarized 4 themes, which showed that mukbang may have positive effects on viewers' appetite, food choices, and weight control; it can also meet the psychological needs of viewers and provide digital companionship and happiness. However, excessive viewing may also be harmful to viewer's health, which has also caused health concerns for some viewers.

Conclusions: This study conducted a comprehensive search, screening, and synthesis of existing studies focusing on mukbang and health across various languages and varying levels of quality, which has presented the analytical evidence of the relationship between mukbang and dietary behaviors, appetite, flavor perception, and health. According to the results, future research could consider analyzing the beneficial and harmful factors of mukbang, thereby further optimizing the existing mukbang videos accordingly to explore the potential of using mukbang for health intervention or promotion, so as to improve or customize the content of mukbang based on this scoping review, maximize the appetite and health promotion effects of mukbang videos.

KEYWORDS

mukbang; health promotion; eating behaviors; appetite; scoping review

Introduction

Background

Mukbang (or meokbang), a portmanteau of the Korean words "eat" (*meokneun*) and "broadcast" (*bangsong*), also known as "eating broadcast," is an emergent new media phenomenon that first appeared in 2008 [1]; in this phenomenon, mukbang hosts sit in front of the camera for a few hours and live stream their consumption of vast quantities of food while interacting with viewers [2]. Mukbang became popular in South Korea in 2010 and was broadcast through a video streaming platform AfreecaTV (now called "SOOP") [3]. Due to the advancement of the internet and smartphones, short video platforms, such as YouTube and TikTok are gradually gaining worldwide popularity. Short video platform development has enabled the evolution of the presentation form of mukbang from live broadcasts to prerecorded videos by facilitating the editing and release of these videos to a larger audience [4], enhancing the popularity of mukbang [5], and making mukbang a global trend in 2015 [6]. Currently, mukbang enjoys enormous web-based engagement. Popular mukbang channels have more than 5 million YouTube subscribers, and a single video often attracts hundreds of millions of views [7]. An investigation of the characteristics of mukbang audiences showed that mukbang is more attractive to adolescents aged between 18-28 years [8], and the male-to-female viewer ratio is approximately 1:2 [8]. The YouTube keyword tool indicates the average monthly numbers of searches of the term mukbang over the previous 12 months of data for the United States of America and South Korea to be 365,000 and 9600, respectively [9]. This suggests that mukbang is ubiquitous; it spreads into our living environments and imperceptibly affects people's lives and daily interactions, particularly among young people. In this study, according to the definition and origin of mukbang, we classify videos with "eating" behavior as their content as mukbang; in other words, mukbang is no longer limited to the display of eating in a live broadcast but covers all web-based videos having eating-related contents.

Earlier studies have extensively investigated and analyzed the components and contents of mukbang. According to these studies, mukbang comprises 2 essential elements: auditory and visual sensory stimulation [10] and web-based interaction [11,12]. In sensory stimulation, distinct chomping, chewing sounds made by hosts can evoke a sensation known as an autonomous sensory meridian response (ASMR) [3,13-15], which refers to experiencing a pleasantly warm and tingling sensation starting at the crown of one's head and spreading down the body [16]. In addition, the display of food in mukbang also stimulates viewers' desire for the specific food shown in the videos [17-19]. Another element of mukbang is web-based interaction, which is established by bullet chatting, giving gifts, or liking posts [10,20]. Web-based interaction enables viewers to create emotional relationships with other viewers and the host [21,22]. Further, mukbang's 2 essential elements can both affect viewers' emotions and viewing motivations [23]; closely linked to their different psychological needs; and bring them happiness, peace, and vicarious satisfaction [20].

The current trend of mukbang viewing suggests a potential correlation between watching mukbang and specific physiological or psychological needs. Many studies adopt an empirical approach to examine people's motivation to watch mukbang. Such studies divide the main motivations for watching mukbang into pursuing the thrills of hunger, vicarious eating, emotional establishment, alleviating loneliness, and relieving anorexia [24]. Due to the fact that most of the young viewers are highly educated and experiencing high social pressure and social isolation [25], alleviating the feelings of loneliness associated with eating alone is the most frequently mentioned reason for watching mukbang [21]. Mukbang hosts share fascinating aspects of their lives with their audience while eating, which alleviates the viewers' feelings of social loneliness. This was particularly relevant during the COVID-19 pandemic [26,27]. Another common motivation to watch mukbang during the pandemic period was to obtain information about food, such as its taste, nutritional value, and cooking procedures [27,28]. Today, social demands to maintain body shape are on the rise; hence, an increasing number of people watch mukbang to experience vicarious satiation, satiety, and enjoyment through visual and auditory stimuli [29]. Furthermore, some viewers watch mukbang to avoid the problems and negative feelings caused by real-life experiences [30]. Therefore, mukbang is often considered to relieve loneliness, reduce negative emotions, and provide psychological pleasure and satisfaction, all of which attract scholars' attention to the relationship between mukbang and physical and psychological health. Compared with the studies on mukbang, research on food-related videos is more comprehensive. Further, scholars use experimental designs to examine the effects of food-related videos on viewers' psychology, appetite, and eating behavior from an objective perspective [15,17,31]. According to the results of 4 separate meta-analyses on neural responses to food advertising conducted by Arrona-Cardoza et al [32], van der Laan et al [33], Yeung [34], and Yang et al [35], food images or commercials can cause stronger brain responses than nonfood images or commercials in different areas of the brain. Furthermore, a comparison between high- and low-calorie foods revealed higher neural activation on viewing high-calorie foods than low-calorie foods, particularly among individuals with overweight or obesity [32,33,35,36]. This confirmed that, by affecting neurofeedback in the brain's food-reward system, food-related videos significantly influence viewers' appetite, food intake, and eating behaviors [37-39]. Further, Boyland et al [40] and Kidd and Loxton [41] designed a randomized controlled trial (RCT) that suggested that watching food advertisements increases viewers' food intake. On this basis, some studies indicate that watching mukbang can increase food consumption by augmenting taste sensations [26]. Further,

XSL•FO
RenderX

mukbang increases flavor perceptions, help individuals suppress their desire to substitute healthy food with unhealthy ones, and, thereby, improves individuals' appetite [14].

There is a growing body of research and informational studies on mukbang that encompasses various topics such as audience psychology, food culture, communication effects, food waste, physical and mental health, and the exploration of new mukbang trends. However, the divergent research on mukbang and health yields contradictory findings and conclusions. Researchers consider mukbang a useful tool to improve appetite and food intake [13,42], while in other studies, viewers believe that mukbang has a negative impact on health and dietary behaviors [31]. Furthermore, studies on mukbang's health effects are scattered across academic fields and fail to provide a general summary or description of the topic; the quality of these studies also varies considerably; thus, due to the complexity of information, readers may struggle to obtain effective insights into the impact of mukbang on physical and mental health. They might overlook the benefits of mukbang in stimulating appetite and increasing food intake or excessively rely on it for weight loss, leading to severe consequences such as overeating. Consequently, there is an urgent need for a comprehensive review that integrates key findings from both academic and nonacademic studies on mukbang's influence on health based on a thorough screening of existing research. After conducting a comprehensive search of academic and nonacademic studies on both mukbang and health, we integrate the main aspects of each paper to identify and discuss the impact of mukbang on viewers' physical and psychological health. Further, this study aims to systematically map the research on mukbang and health promotion, identify any research gaps, and reveal the impact of watching mukbang on viewers' physical and psychological health by combining, comparing, and integrating relevant literature to lay a foundation for the application of mukbang to promote the physical and psychological health of viewers.

Research Goals

Research reveals that mukbang may affect the physical and psychological health of mukbang hosts and viewers. This study systematically maps the positive aspects of and gaps in research on mukbang's impact on health to help prevent overweight and obesity and improve the eating behaviors and nutritional status of the public. This scoping analysis addresses the following research questions (RQs).

- RQ1: What are the specific effects of mukbang watching on physical and psychological health?

We reviewed and summarized studies exploring the relationship between mukbang and health or the effects of mukbang on health. Further, we identified the potential effects of mukbang on physical and psychological health promotion and clarify different mukbang-related ideas and health-related issues.

- RQ2: What are viewers' opinions regarding the impact of mukbang on their physical and psychological health?

We examined mukbang user groups and their perceptions of the relationship between mukbang and health to identify the specific requirements that should be satisfied or improved by mukbang.

- RQ3: What are the future applications of mukbang in the field of health?

Finally, based on the arrangement of the content on the health effects of mukbang in existing studies, we discussed the future prospects of mukbang in promoting appetite, improving dietary behaviors, and enhancing mental health to lay the foundation for its application in medical and health fields.

The findings of this study are intended to benefit health care professionals, researchers, technology providers, and all (both current and potential) viewers in designing, conducting, and evaluating mukbang videos.

Methods

Study Design

This scoping review is conducted and reported following the Joanna Briggs Institute (JBI) guideline and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist (Multimedia Appendix 1) [43]. Further, this scoping review protocol was prospectively registered (INPLASY2022120109) to limit reporting bias. The initial search was conducted in March 2023, and the literature screening and data extraction processes were completed in July 2023.

Search Strategy

To conduct a comprehensive review, we considered both academic and nonacademic studies on mukbang and health issues. Textbox 1 presents the inclusion and exclusion criteria for this study. We used the keywords mukbang, meokbang, "eating broadcast," "culinary videos," "online eating," "eating show," "food media," "health," "health promotion," "eating disorder," "eating behaviors," "disordered eating," "binge eating," and "obesity" to search studies that were published before June 30, 2023, in academic databases. The same keywords in Chinese and Korean were also searched in Chinese and Korean databases, respectively, using similar strategies adjusted based on the database. For gray literature sources, we used simple terms mukbang, "eating broadcast," "online eating," ASMR, and health for more comprehensive results. The academic databases were PubMed, Embase, Web of Science, Researching Information Sharing Service (Korean), DBpia Scholarly Database (Korean), China National Knowledge Infrastructure (Chinese), China Science and Technology Journal Database (VIP Database, Chinese), and Wan Fang Data (Chinese). The following study types were retrieved from these databases using optimized searches: review, meta-analysis, observational quantitative, qualitative, mixed, and interventional studies on mukbang and health issues. Gray literature searches were conducted of databases Open Access theses and dissertations, ProQuest, OpenGrey, and Google Scholar, including commentaries, magazine papers, news, blogs, books or book chapters, and ongoing studies, to map the complete academic scope of the impact of mukbang watching on viewers' health and eating behaviors. We used "Title/Abstract" or "All Fields" as retrieval fields and a Boolean strategy to connect each identified keyword to an appropriate search strategy. We used the conjunction "or" to connect synonyms, while

XSL•FO
RenderX

parentheses were used for prioritized searches, and all the keywords with distinct meanings were linked by "and" (Multimedia Appendix 2). The bibliographies of all relevant retrieved studies were also examined to identify further relevant studies. The searched studies were written in English, Chinese, or Korean languages. The decision to consider these languages was motivated by the following consensus since mukbang originated in South Korea, the literature on mukbang in Korean is informative and, hence, should be searched. In addition, since the researchers, who are from China, were interested in identifying possible studies (in Chinese) from China and mukbang has extensive dissemination and audience in China, we decided to include studies from Chinese and Korean databases.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Studies describing the relationship between mukbang watching and dietary behaviors, disordered eating, or physical and psychological health.
- Studies demonstrating the impact of mukbang on health (eg, physical health, dietary behaviors, psychological health).
- Studies exploring the reasons for mukbang watching from the perspective of psychological or personal needs, while paying attention to the impact of mukbang on public health.
- Studies focusing on the design, development, or availability of the interventions using mukbang to demonstrate the usefulness of mukbang in the health field.
- Studies focusing on the challenges and obstacles of integrating mukbang videos into clinical practice.
- Food advertisements and food-related videos must include images of celebrities eating.

Exclusion criteria

- Studies only involve the basic concepts and situations such as the definition, origin, development, and epidemic situation of mukbang.
- Studies only cover the impact of shooting mukbang videos on the host's own physical and psychological health but do not mention the effect on the viewers.
- Studies only mention digital media, social software, or social media, but do not clearly indicate mukbang in the full text. Studies only contain food pictures (static representations of food).
- The main field of study was communication, literature, or aesthetics, rather than medicine, psychology, or health.

Study Selection

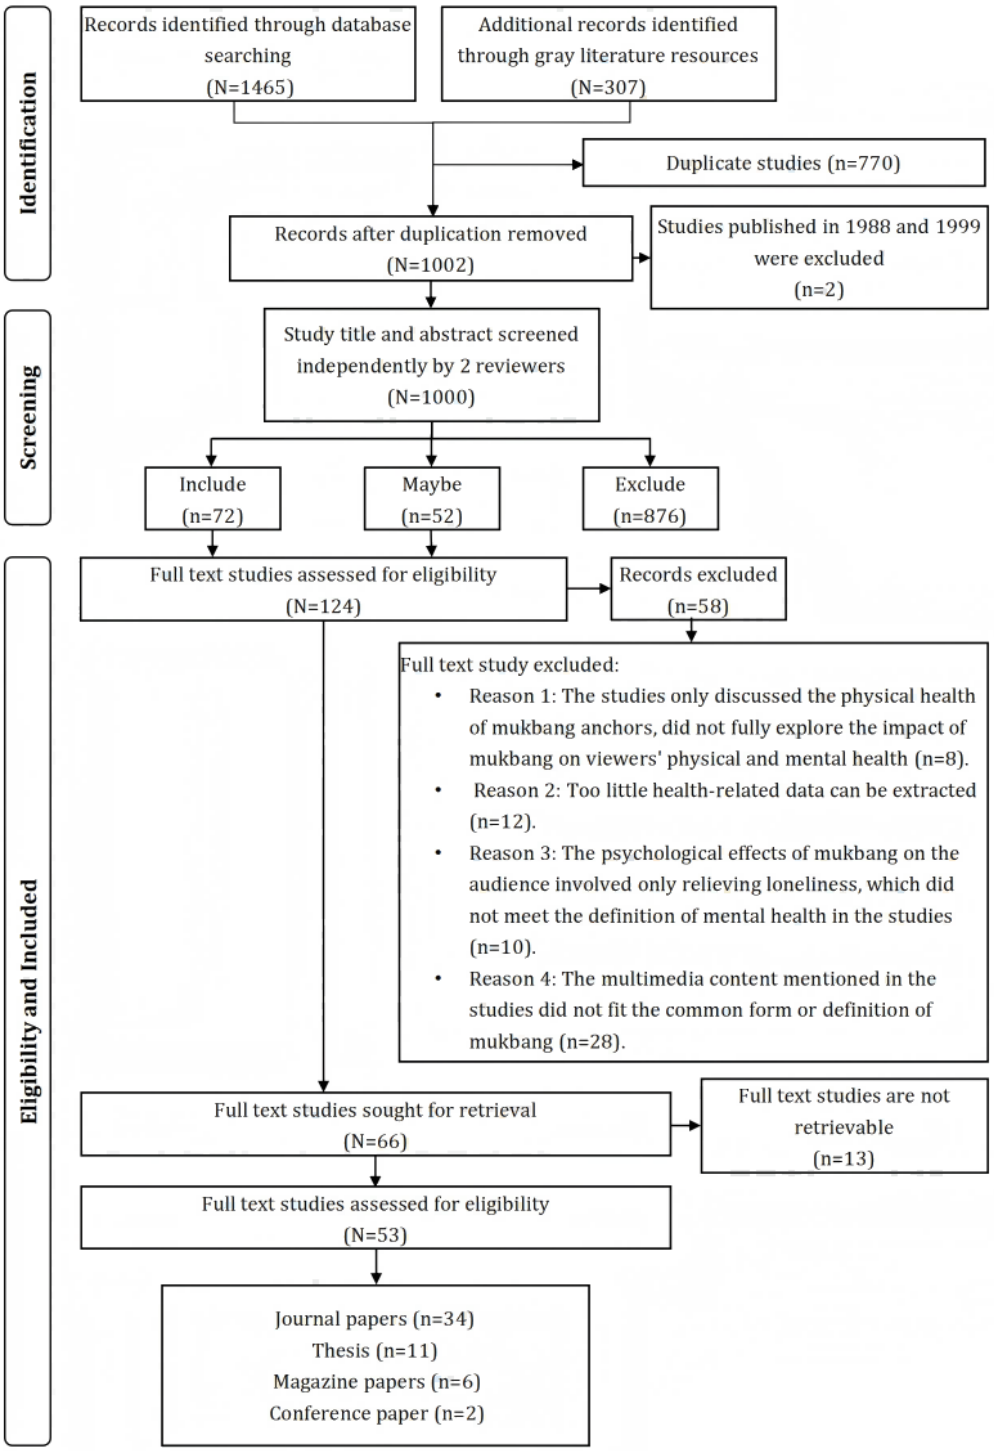
In this phase, we evaluated the retrieved studies' relevance to the review according to the independent inclusion and exclusion criteria presented in Textbox 1. All identified records from the academic databases and gray literature websites were imported into Rayyan (Qatar Computing Research Institute) and EndNote 20 (version 4.1; Clarivate) for further analysis and screening. The Rayyan platform enables multiple collaborators to independently and synchronously screen a shared set of studies, ensuring the confidentiality of each collaborator's results until the final stage of each step of the screening process. After importing all the data, duplicate results were removed. Two researchers independently screened the titles and abstracts of the retrieved studies and excluded the studies that did not contain mukbang or health elements. The studies that definitely and potentially satisfied the inclusion criteria were tagged "included" and "maybe" using the screening and classification function of Rayyan, respectively. Subsequently, an independent assessment of full-text studies was performed. The full texts of the studies that did not match the search theme or review's scope were excluded from the study. All the studies whose full texts were unavailable were excluded, as well. Disagreements were solved through discussions and consensus with a third researcher. After the full-text selection, JBI critical appraisal tools were used to evaluate the quality of the included cross-sectional studies, RCTs, quasiexperimental studies, systematic reviews, and qualitative research. We did not conduct a quality appraisal for commentaries since there is no unified writing format or standard requirements.

Data Extraction and Charting

According to a framework of the JBI template data extraction instrument [44], researchers developed and modified a data extraction chart based on the inclusion criteria, evidence source details and characteristics, information on research methods or tools, mukbang characteristics, and health-related elements (Multimedia Appendix 3). The data extraction chart was used as a research tool to manually extract and integrate useful information from the included studies. Search results were described and narratively synthesized to clarify the effects of mukbang watching on viewers' physical and psychological health and the comments of the viewers on the relationship between mukbang and health. Further, in line with the purpose of this review, the retrieved studies were sorted, analyzed, and synthesized to clarify the effects of mukbang watching on viewers' eating behaviors, appetite, food preferences, body weight, and psychological health. Accordingly, we highlighted the numbers and proportions of different types of publications and studies and the target audience, language, country of origin, publication year, disciplinary areas, specific research methods, and key findings of all the included studies (Multimedia Appendix 4). To present the results clearly, we used the year filter of each database to classify the retrieved studies by publication year and counted the numbers and types of studies published in different years. We then plotted the data of the included studies using Excel to graphically show the types of

XSL•FO
RenderX

included studies and their trends over the years. Our goal was to collect the contents of the studies describing the health effects of mukbang watching, as well as clarifying the public's views and attitudes regarding mukbang videos. Through inductive analysis, we characterized the influence of mukbang watching on viewers' physical and psychological health and described the different attitudes of viewers toward the health-related benefits of mukbang watching.



Results

Search Results

Our study search found 1465 publications in databases; 307 additional records were identified through gray literature resources, as well. Following the removal of duplicates, 1002 titles and abstracts were screened independently by 2 reviewers, and 278 ambiguous studies were discussed by reviewers together after the screening. In total, 876 studies were excluded since they did not examine mukbang watching or health; further, 72 studies were included because their titles or abstracts explicitly mentioned mukbang watching and health. In addition, 52 publications were allocated to the maybe list since these studies' eligibility criteria could not be determined completely from their titles or abstracts. Among them, 124 full-text studies were screened, and 66 publications were included in the review for result extraction and analysis based on the eligibility criteria. Among these 66 studies, since 13 were not available due to limitations such as incomplete full-text coverage, restricted access rights, or inability to establish contact with the original author, 53 publications were finally included in the review. According to the evaluation criteria of JBI [45], the quality evaluation studies basically conform to the writing format and standards of the corresponding research types, the quality evaluation of the included studies is presented in Multimedia Appendix 5 [13,15,17,18,22,24,25,27-30,46-70]. Given that the scoping review aims to ensure the most comprehensive understanding and characterization of existing research by searching for studies relevant to the topic to the greatest extent and including as many studies as possible that meet the inclusion criteria, quality evaluation results have not been used as exclusion criteria. The search and screening procedure is depicted in a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram (Figure 1), and some important details of the included studies are presented in Multimedia Appendix 6 [2,13-15,17,18,22,24-31,46,47-69,71-83].

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for studies screening.

Study Characteristics

Overall, our search results indicated that studies on mukbang first appeared in 2015, whereas those on mukbang and health first appeared in 2017. Table 1 indicates the number of included studies classified based on different research types. In general, the types of studies on the relationship between mukbang and health mainly include cross-sectional studies, qualitative studies, reviews, commentaries, and intervention studies, which indicates that research focuses on the relationship between mukbang and health becomes more comprehensive, scholars are attempting to explore mukbang's effects on health using intervention studies with higher levels of evidence. Simultaneously, however, the commentary also accounted for a high proportion of the included studies (n=10, 19%), suggesting that despite the growing academic interest in studying mukbang's effects on health, many scholars also favor commentary as a genre that allows for greater expression of opinions and insights.

XSL•FO
RenderX

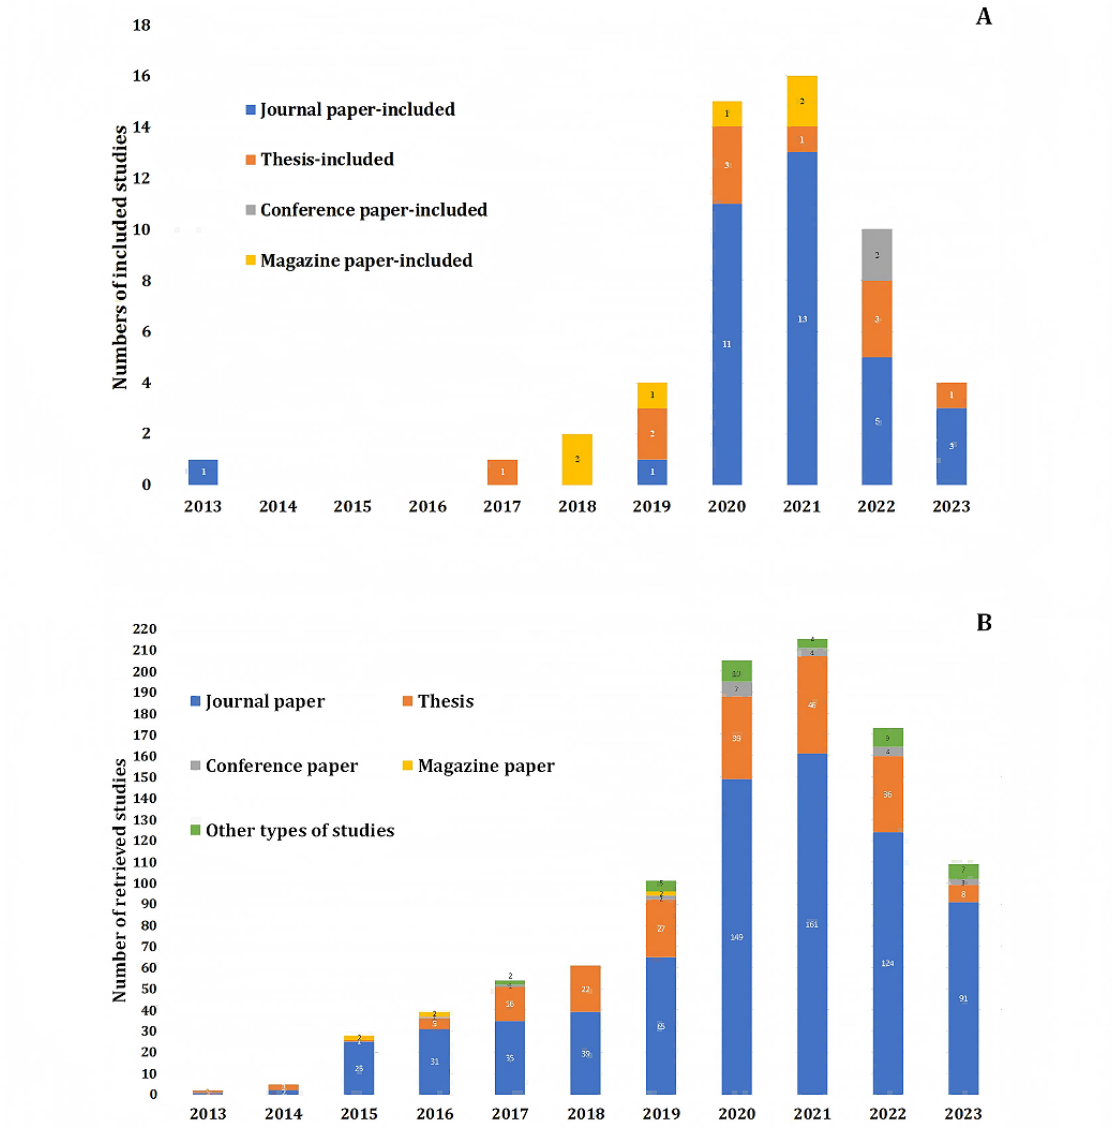


Table 1. The number of the included studies, grouped by different research types.

Research types	Studies, n (%)
Cross-sectional study	20 (38)
Interventional study	10 (19)
Commentary	10 (19)
Qualitative study	9 (17)
Review	4 (7)

This review considered studies published in scientific journals (n=34, 64.2%), master's theses (n=12, 22.6%), magazine papers (n=4, 7.5%), conference papers (n=1, 1.9%), book chapters (n=1, 1.9%), and study registrations (n=1, 1.9%). Figure 2 presents combined information on the characteristics and publication years of the included studies focusing on mukbang and health and retrieved studies. Since the earliest mukbang appeared in 2010, we excluded the studies published before 2010 (a total of 10 studies) from the search results. Consequently, the number of "all retrieved studies" amounts to 992. The stacked bar chart below represents the characteristics of all the retrieved resources; The stacked bar chart above represents the characteristics of the included studies. Moreover, to enhance the clarity of the comparison between all retrieved studies and included studies in Figure 2A, we have consolidated newspaper, book, and website studies under a category labeled "Other types of studies." According to Figure 2B, most studies examining the effects of mukbang on health and nutrition were journal papers and theses, which indicated that the content of mukbang related to dietary habits and health gradually attracted scholarly attention. The number of journal papers and theses on mukbang, which has been increasing since 2015, peaked in 2020 and 2021. South Korea was the first country to publish a mukbang-related study, probably because mukbang originated in Korea and became popular in Korean society earlier than in other countries. Korea is followed by China, which has been publishing a large number of studies every year since 2016. Most Chinese studies on mukbang were published in communication and journalism journals, whereas most English-language studies were published in journals on psychology, nutrition, and health. In this review, only the information relevant to mukbang's impact on physical and psychological health was extracted from the included studies.

XSL•FO
RenderX

Figure 2. The number of mukbang-related studies per year grouped by different characteristics: (A) all the included studies and (B) all the retrieved studies.

Mukbang's Impact on Physical Health

Studies found that mukbang has the potential to provide health-related information to the viewer, and may have positive effects on viewers' appetite [71], food choices [47], and weight control [48,72]. Based on the included cross-sectional studies, food-related programs such as mukbang and cooking shows, viewing frequency and duration [49] are commonly regarded having a positive impact on food choices, food intake, dietary behaviors [50], and overall health of the viewers [47,51], especially during the COVID-19 pandemic that many people decided to watch mukbang and cooking videos to entertain themselves and cook by themselves to diversify their meals and maintain a healthy lifestyle [27]. A cross-sectional survey also tentatively explored the potential for experiencing vicarious satisfaction through watching mukbang, which indicated that nearly a quarter of the audience watched mukbang when feeling hungry to experience satiation, satisfy their desire for food, and enjoy web-based food spuriously without gaining weight [52]. To explore the aforementioned findings further, some scholars have carried out qualitative and mixed studies. The studies have turned out that the nutritional content of food-related videos may have a positive effect on viewers' healthy eating behaviors, viewers tend to obtain interesting information about healthy eating from food-related videos [25]. Many observational studies indicated certain impacts of mukbang consumption on viewers' appetite, food intake, food choice, and dietary preference, some scholars subsequently conducted interventional studies to validate these causal relations. Kim [71] pointed out that watching mukbang with normal emotion may increase viewers' appetite and food intake. RCTs have been conducted to compare the effects of mukbang and nonfood videos, mukbang and cooking shows, and mukbang with different contents respectively on satiation, disgust, and desire for food, which found that mukbang reduced the viewer's sense of satiety and promoted their appetite to varying degrees, but it also increased the dieters' disgust to stabilize their food intake in a relatively balanced state. Interestingly, the study revealed that regardless of the food presented, watching mukbang invariably increased viewers' desire to eat fruits and vegetables [48]. The findings are further supported by other similar studies. Review and commentary studies suggested that mukbang can help people

XSL•FO
RenderX

with eating disorder symptoms experience a sense of vicarious satiation to control their appetite and, to some extent, stop endless eating [73]. In contrast, for individuals who engage in excessive dieting, watching mukbang could help them relax their strict dietary requirements and reduce their anxiety regarding dieting to avoid malnutrition [2]. These results confirm that mukbang can increase satiety, control food intake, and avoid overeating and, thereby, help viewers lose weight [2,53].

Nonetheless, mukbang was reported to licit negative effects on certain viewers in some cases. Preliminary investigations of cross-sectional studies indicated that mukbang contains large amounts of high-calorie food may cause concern that it can increase high-calorie food intake and impair the dietary behaviors of mukbang viewers [27,53,54], especially for those watching mukbang frequently [49,55]. von Ash et al [56] investigated the relationship between mukbang viewing and disordered eating behaviors using the Mukbang Addiction Scale and the eating disorders examination questionnaire, which showed a positive relationship between binge eating or purging tendencies and problematic mukbang viewing; moreover, mukbang viewing, and additional characteristics of mukbang viewing (eg, frequency of watching, average watch time, eating while watching), also be found that may be associated with eating disorder symptoms. On this basis, qualitative studies using content analysis and textual analysis to further explore the possible negative impact of mukbang on viewers found that about 83.5% of mukbang presented substantial content showing harmful eating habits like overeating, excessive exposure to it may change the original dietary preferences and eating habits of viewers and increasing their desire to consume amounts of unhealthy foods [18,57]. While some famous mukbang hosts demonstrate excessive food consumption, they are still energetic and keep in shape (particularly in Big Eater Mukbang videos), this contrast may mislead viewers to believe that overeating does not pose any risks to their health and physique [24]. These perspectives above are supported by some commentary studies that look upon mukbang in an unfavorable manner [72,74,75]. Intervention studies shed insights on the impact of food-related videos (like mukbang) and nonfood-related videos on viewers' eating behavior, food choices, and food intake. They found that mukbang watching increased the consumption of unhealthy food and negatively affected the eating behaviors and physical health of viewers, particularly unsuccessful restrained dieters [17,31,48]. Over time, such unhealthy eating habits can injure the viewers' stomachs and make them overweight and obese, which seriously affects their health and leads to binge eating, bulimia nervosa, and anorexia nervosa [76].

Mukbang's Impact on Psychological Health

Numerous studies have examined mukbang's impact on mental health. Cross-sectional studies demonstrated that mukbang viewers often choose to watch videos when they feel lonely and desire companionship to satisfy their spiritual needs [58]. Based on the cross-sectional study, the researchers conducted qualitative research by analyzing comments and web-based posts of mukbang videos and conducting semistructured interviews. The findings not only supported that mukbang can release pressure and loneliness and provide enjoyable entertainment, but also revealed that mukbang can digitally enhance viewers' immersive experience and taste sensations, and help them experience a sense of vicarious satisfaction [30,59]. Researchers also conducted several interventional studies to explore mukbang's potential effect on the viewer's taste sensations and found that mukbang has the potential to improve viewers' perceptions of the taste of food and make the food taste delicious [22,26,60,61]. One of the interventional studies has investigated how different video types (including mukbang) affect the taste sensations of viewers eating plain white rice. The trial's results revealed that both mukbang and cooking videos can enhance viewers' taste sensation of spiciness and help them find the food is mouthwatering, satisfy their cravings, and attain psychological satiation [14]. Further, reviews and commentary studies both discussed how mukbang meets the psychological needs of its viewers. The integrated results showed that mukbang watching can provide digital companionship to viewers, and relieve their loneliness and daily life pressure, making them feel relaxed and happy [2,62,63,77-80]. In addition to relieving negative emotions, the distinct chomping sounds made by hosts can help relax viewers' brains and make them fall asleep easily [64,81], the sound made by ASMR mukbang hosts, the attractiveness of mukbang hosts and the presentation of food elicit visual and auditory contentment has been found can make the viewers feel involved in the warm dining atmosphere shown in the video, which further enhances the food's taste and viewers' appetites to some extent [62,72,81,82].

Public Perceptions of the Role of Mukbang in Health Promotion

By using the bullet chatting and commenting functions of short video platforms, people can interact with mukbang hosts and express their thoughts and opinions on the relationship between mukbang and health. Scholars have conducted interviews and text analyses to clarify viewers' attitudes toward mukbang [13,24,25,46]. An et al [83] used big data and text analysis methods to examine viewers' comments on popular mukbang videos on YouTube; results indicated that mukbang contents stimulating unhealthy eating behaviors led to negative reactions from viewers, whereas contents featuring healthy eating gained more viewers' favor and sympathy. The results of some studies on the comments for mukbang content reveal that solitary viewers generally consider mukbang a dining companion who creates a warm dining atmosphere and relieves their feelings of loneliness and social isolation [62]. Other viewers consider mukbang a tool that provides psychological gratification to help relieve immediate hunger and help them control their diet and lose weight [24]. However, regarding Big Eater Mukbang, some viewers felt that the excessive amount of food consumed at one time by mukbang hosts caused food wastage, was extremely harmful to the body, and promoted extremely unhealthy behaviors [13,24,46]. Moreover, they questioned whether the mukbang hosts ate all the food shown in the video since their slim figures suggested otherwise [46]. Along with being concerned about the hosts' health, the viewers warn themselves and appeal to others not to blindly follow the unhealthy eating behavior shown in the videos. Further, the results of qualitative interviews suggest that most viewers watch mukbang mainly for entertainment and to gain positive emotional value [65].

XSL•FO
RenderX

They were curious about the taste of the food presented in the videos, developed cravings for these specific foods after watching mukbang, and expressed their doubts regarding the very high food intake of mukbang hosts [46].

Future Applications of Mukbang

Scholars have started analyzing and discussing the advantages and disadvantages of these videos from different perspectives and indicating the future direction of mukbang research by analyzing the shortcomings of their own research in their studies. Some scholars opine that future research should consider various aspects of the mukbang-watching experience, particularly the mechanisms of mukbang-induced overeating and problematic eating [66]. Other scholars clarify that the different dietary statuses and watching motivations of mukbang viewers strongly affect health. James et al [14] and Yoo et al [55] found that extreme and failed dieters are more likely than other dieters to damage their physical health and lead to eating disorders after watching mukbang videos. They indicate that future research can further examine the factors and elements that can help promote healthy behaviors in mukbang videos, spread the concept of a healthy diet through these videos, and incorporate such concepts in medical and health care fields [14,55]. Scholars should focus on the creation of enjoyable and useful content that encourages people to continue watching mukbang and making dietary changes [67]. In addition, mukbang can be considered for future clinical use to address the nutritional problems caused by loss of appetite and picky eating [26].

Discussion

Overview

This scoping review addressed and resolved all its research questions, including examining the specific effects (RQ1) and viewers' opinions (RQ2) of mukbang watching on physical and psychological health, and examined the future applications of mukbang in health promotion (RQ3). In summary, this review addressed and resolved all its research questions. This scoping review synthesized the evidence of the impact of mukbang watching on viewers' dietary behavior, eating disorders (if any), and overall health. Mukbang is both beneficial and harmful to the viewer's health and eating behavior, which mainly depends on the viewer's own attitude toward food and weight loss, as well as their attention to their own body. Additionally, it identifies the viewers' attitudes toward and concerns about mukbang watching, which facilitates the regulation and improvement of mukbang video content and lays a foundation for the videos' application in health promotion.

Principal Findings

Many studies cited in this review agree that watching mukbang can positively affect viewers' dietary behaviors, appetite, food preferences, and physical and psychological health. This may be due to the fact that mukbang can elicit a communal dining experience that contributes to the viewer's relaxation during consumption; and the visual, auditory, and other sensory stimuli may stimulate the viewer's brain to synthesize hunger-inducing hormones, consequently reducing satiety and promoting appetite [15,64,68,81]. This result suggests the possibility of using mukbang positively to develop healthy eating habits and appetites by enhancing taste experiences and reducing negative emotions [15,30,81], which might be beneficial for people attempting to improve the taste of a bland diet without indulging in overeating or using unhealthy food additives [13]. The impact of mukbang watching on dietary behaviors and health promotion primarily may depend on the characteristics of mukbang viewers and the content of mukbang videos [46]. Several studies indicate that the main viewers of mukbang are young individuals, who often develop food cravings, dissatisfaction with their body shape, and an obsession with weight loss or dieting behaviors [68]. This may be due to the dietary and sociocultural characteristics of teenagers because they tend to prioritize taste over nutritional value when making food choices, thus they can be easily influenced by mukbang content [69]. For individuals suffering from anorexia nervosa, mukbang can be an effective physical therapy method to increase food intake by stimulating appetite [30]. In addition to the characteristics of mukbang viewers, the content of mukbang videos plays an important role in shaping eating habits, appetite levels, mood states, and overall health [46]. Hence, it is important to change the types of food shown in mukbang videos and gradually incorporate nutritional information to enhance the nutritional value of displayed food and the dietary behaviors of viewers. Additionally, the eating behaviors exhibited by hosts potentially influence viewer behavior. Extreme practices, such as binge eating, should be avoided or corrected to display clean and harmonious dining scenes so that mukbang videos positively influence the audience's eating behavior [59].

However, the impact of mukbang on its viewers is not uniformly positive. Some mukbang videos continue to propagate unhealthy concepts and behaviors, such as excessive consumption of high-calorie foods, misleading viewers to blindly imitate and lead to obesity and gastrointestinal disorders [28,42,72]; further, the overreliance on psychological gratification can lead to mukbang video addiction and endless dieting [29,53]. This means that individuals who achieve weight loss through dieting frequently may choose mukbang as a substitute for conventional eating. However, long-term compensation can engender binge eating, which may culminate in guilt and even depression. This pattern can initiate a cycle of weight loss attempts and mukbang indulgence, ultimately culminating in excessive dietary intake. Thus, mukbang is a double-edged sword that may cause both positive and negative influences on viewers' dietary habits and mental health. To elucidate this phenomenon, several scholars have presented their own perspectives in the research, a potential rationale for this may be posited as the ambivalence of young individuals toward the pursuit of a desirable physique and the indulgence in delicious food [59]. However, there is a lack of studies investigating the mechanisms underlying the influence of mukbang on eating behavior from an objective perspective, thus making it unclear whether watching mukbang has positive or negative effects on viewers. Based on the findings of this study, these 2 opposite effects of mukbang may be attributed to factors such as content variation, exposure levels, viewer's self-discipline, and dieting status. Future studies can further explore these influencing factors that contribute to the dual nature of mukbang, helping viewers watch mukbang in a

XSL•FO
RenderX

healthier way [48]. Thus, mukbang must be used cautiously in health promotion.

Implications for Future Research

According to the results of our study, the majority of studies on mukbang and its impact on health primarily focus on the perspective of mukbang anchors or clarify the deleterious effect of performing mukbang on anchors' health, and only a few studies examine the negative effects of mukbang on viewers' eating behavior and health by using questionnaires and interviews. Future research can further investigate the variations in psychological states among individuals of diverse age groups and genders when exposed to mukbang, as well as examine the impact of mukbang on their psychological well-being [68]. Besides, to date, no scholar has thoroughly investigated whether the negative effects of mukbang on health are real, or clarified which aspects of mukbang videos are responsible for these negative effects; existing studies also do not provide accurate conclusions on the relationship between mukbang and health, researchers have not yet conducted experimental studies from a physiological perspective to examine the objective effects of mukbang videos on viewers' eating habits, food preferences, and physical and mental health and clarify the mechanisms by which the videos affect viewers' health. Future studies can focus on exploring the effects of mukbang watching on the physical health of the viewers, or the relationship between disordered eating psychopathology and different mukbang viewing characteristics (eg, frequency of watching, average watch time, eating while watching), using laboratory methods or other rigorous experimental designs with the aid of objective instruments or tools [56]. As excessive problematic food intake is increasingly viewed as an addictive disorder, mukbang is thought to have a potential risk of inducing binge eating, the relationship between mukbang watching and addiction, as well as the influencing factors both worth further investigations to keep mukbang viewers away from addictive behaviors [29,30]. Meanwhile, excessive or problematic mukbang viewing may serve as an indicative signal of potential eating disorders, which can guide clinicians to identify and diagnose eating disorders more effectively. Therefore, mukbang content that may cause the development of eating disorders could be explored and establish criteria for evaluation, so as to help mukbang viewers stay away from those unhealthy mukbang and maintain healthy eating habits while enjoying the pleasant dining atmosphere presented by mukbang [56].

Future research can provide insights into the effect of different mukbang content on different taste perceptions, which can help clarify which mukbang content enhances a particular taste sensation among viewers [14,26]. Additionally, given the specific effect of mukbang on food preference, scholars can further test whether some particular types of mukbang might be useful for dieting and whether mukbang with fast food is the most harmful given these likely increase unhealthy food intake; more work is also needed to address the impact of the feature of web-based communication between anchors and viewers, the figure of the host and the food stimuli in mukbang [48]. In addition, according to Yoon [50], future research can focus on the development of mukbang that integrates nutrition and medicine and assess its impact and satisfaction levels. Simultaneously, studies have found that ASMR mukbang has the potential to reduce viewer's stress levels, and improve their sleep quality, future research may consider exploring the mechanisms involved or comparing the differences in the physical or mental health of viewers between ASMR videos and ASMR mukbang.

Strengths and Limitations

This is the first scoping review that systematizes studies on the relationship between mukbang and health and is, therefore, the first study to expand the research possibilities in this field. Studies relevant to the review were identified from both academic databases and gray literature websites in different languages. Since mukbang originated in Korea, Korean databases were specifically searched to obtain a more comprehensive perspective on mukbang-related studies, which might have contributed to the inclusion of studies with different contexts and origins. The term mukbang is not yet a descriptor indexed in databases; however, this was not an impediment to identifying the main studies related to the research objective. Our study comprehensively concluded the potential impact of mukbang on viewers' health and synthesized the possible causes of mukbang's negative effects on health by integrating and analyzing the included studies; however, we also found that there is a lack of rigorous investigations into the influencing factors of these negative impacts or potential relationships between positive and negative effects of mukbang on health. Meanwhile, this review identified methodological limitations in existing studies, suggesting that future studies could consider using clinical trials and other objective indicators to further explore the actual implications of mukbang on viewers. Furthermore, this review clarifies the role of mukbang in health promotion and, hopefully, eliminates some viewers' prejudice against mukbang videos and guides the country and media to supervise and manage unhealthy content in mukbang videos.

However, this scoping review has some limitations. First, the major limitation of this study is the uneven quality of the included studies. Considering the potential possibility of using mukbang as a future health intervention, existing high-quality studies on the health effects of mukbang are insufficient to support the conduct of systematic reviews or meta-analyses, thus, we tried to use scoping review to provide direction for future research. Second, in addition to the limitations of the number and quality of mukbang-related studies, this review included several studies focusing on food-related videos (or advertisements), which might have affected the accuracy and specificity of the review's conclusions. This is because a clear definition of differences between food-related and mukbang videos was not available in the early stages of research. Therefore, we redefined mukbang and clearly distinguished it from food-related videos (or advertisements) to ensure the relevance of our conclusions to the field of study. Third, the categories and associated keywords (eg, health, eating behavior, and eating disorder) might have limited the search results. Hence, we adopted a method to search the results and simultaneously performed manual secondary screening to capture more results pertaining to health promotion. However, we might have missed relevant materials that use other terms or do not explicitly use the searched keywords. Nevertheless,

XSL•FO
RenderX

we could present a representative overview of the existing studies on the subject in question.

Conclusions

This scoping review comprehensively searched databases and other sources for studies on mukbang and health and extracted and summarized the effects of mukbang on viewers' dietary behaviors, appetite, flavor perception, food preference, and health promotion, as well as their perceptions of and attitudes toward mukbang. The results of this study indicate that mukbang has both positive and negative implications for health. Factors such as the content of mukbang videos and the characteristics and physical states of viewers play crucial roles in influencing health outcomes and dietary behaviors. These findings provide valuable guidance to mukbang hosts and health care providers and promote their collaboration in developing healthy mukbang content and assisting viewers in adopting appropriate viewing habits. Finally, this scoping review underscores the potential benefits of using mukbang videos to promote healthy eating habits and emphasizes the need for future research, which will contribute to our understanding of these videos' impact on human health.

Acknowledgments

The authors would like to thank Shengjun Sun for the contributions he made in the selection of Korean studies. The authors would also like to thank Duoduo Yang for her great contributions in study screening and data extraction. The study was funded by Guangdong Provincial Philosophy and Social Science Planning Project (WX, GD22YSH06), Natural Science Foundation of Guangdong Province (WX, 2024A1515012147), Guangzhou Basic Research Program Basic and Applied Basic research Projects-General Projects (WX, 202201011311), Youth Talent Support Programme of Guangdong Provincial Association for Science and Technology (WX, SKXRC202314), Fundamental Research Funds for the Central Universities, Sun Yat-sen University (WX, 23qnpy111), and Special Funds for the Cultivation of Guangdong College Students' Scientific and Technological Innovation (XW, pdjh2023b0020). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Data Availability

All data generated or analyzed during this study are included in this published paper (and Multimedia Appendices 1-6).

Authors' Contributions

WX conceived the idea for the review, supervised the study, and provided methodological guidance.
TZ executed the draft search strategy and provided data for Multimedia Appendix 2.
DT established the inclusion and exclusion criteria and provided data for Textbox 1.
SN provided assistance in the search for Korean literature.
XW drafted and wrote the initial protocol and manuscript, summarized the main information and evaluated the quality evaluation of the included studies, and provided data for Multimedia Appendix 5 and Multimedia Appendix 6.
XW and YX completed the study screening and data extraction and provided data for Multimedia Appendix 4.
WX and XW critically revised this scoping review. WHCL conducted the data extraction chart and provided Multimedia Appendix 3.
PS conceptualized the study and provided feedback on it.
All authors reviewed and provided input on drafts, subsequently revised it for publication, and read and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Food and beverage marketing is an important influence on the health and diets of adolescents. Food and beverage companies spend billions of dollars annually on advertisements to promote their products and are increasingly focusing on social media influencers. Influencer product endorsements blur the line between entertainment and marketing.

Objective: This study aimed to quantify how often TikTok influencers promote products from food and beverage brands and document the range of ways they disclose brand relationships in their content.

Methods: We collected up to 100 videos posted on or before July 1, 2022, from each of the top 100 influencers on TikTok in the United States and recorded information about the influencer (eg, number of followers) and video (eg, number of views and likes). For each video that contained food or beverage products, we identified the main product featured. A team of research assistants then coded each video for how the product was featured (ie, in the video, audio, or caption) and, for branded products, whether the video was accompanied by any disclosures of brand relationships. Average pairwise percentage agreement among coders was 92%, and average pairwise Cohen κ was 0.82.

Results: Among the 8871 videos from 97 influencers that made up the final analytical sample, we identified 1360 videos (15.3%) that featured at least one food or beverage product. These 1360 videos were viewed >9 million times and received >1 million likes each. Nearly half (n=648, 47.6%) of the videos featured a branded product. Most videos featuring a branded product did not contain a brand relationship disclosure (n=449, 69.3%). Among videos that disclosed a brand relationship, influencers used 10 different types of disclosures. Tagging a brand in the video's caption was the most common disclosure method (n=182, 28.1%). Six types of caption hashtags were used to disclose brand relationships, including #[brandname] (n=63, 9.7%) and #ad (n=30, 4.6%). Only 1 video (0.2%) made use of TikTok's official disclosure label and only 1 video (0.2%) verbally mentioned a contractual agreement with a brand.

Conclusions: Among the food and beverage videos with disclosures we identified, the most frequently used mechanism—tagging the brand—did not clearly differentiate between sponsored content and the influencer trying to attract a brand or followers who may like that brand. Social media users, particularly adolescents, need clearer, more robust disclosures from influencers to protect against the undue influence of food marketing. These findings may also inform calls for the Children's Food and Beverage Advertising Initiative—the largest self-regulatory pledge to reduce unhealthy food marketing—to include older adolescents, who are heavily targeted by food and beverage companies on social media.

KEYWORDS

social media; social media marketing; social media influencer; food and beverage marketing; adolescent health

Introduction

Food and beverage companies spend billions of dollars annually on advertisements to promote their products [1]. Food marketing (including beverages) is an important influence on the health and diets of children and adolescents. Advertisements affect brand preferences and eating behaviors [2]. Experimental evidence shows that children and adolescents consume significantly more calories when viewing television advertisements featuring unhealthy foods compared to nonfood products [3-5]. In 2006, the Institute of Medicine recognized food marketing toward children as "out of balance" with healthy eating, putting children and adolescents' health at risk [1].

Most food advertisement studies have focused on television [1,3-6], but adolescents are shifting toward digital entertainment and social media [7]. Half (51%) of adolescents in the US spend an average of 4.8 hours daily on social media [8]. One popular social media platform among adolescents is the short video–sharing app TikTok. The social media company's internal documents indicate that, in 2020, one-third of their 49 million US daily users were younger than 14 years [9]. Since then, the app's popularity has grown exponentially, with 150 million users in the United States, excluding children under the age of 13 years [10]. TikTok's growing popularity makes it poised to overtake YouTube as the most-used app among adolescents [11], but to date there is little research on the effect of food advertisements on this platform [12-14].

Following this shift in media consumption by adolescents, food and beverage companies are increasingly focusing on social media marketing [15]. A study in Australia found that adolescents were exposed to roughly 17 food advertisements for every hour they spent on the internet or on social media and video-sharing apps on their phones [16]. One food company advertising strategy is to pay "influencers," who are "regular, everyday people" who become online celebrities with large followings, with posts that generate billions of views, to promote products either discreetly or overtly on their social media accounts [14,17]. Adolescents are especially susceptible to social media advertisements from influencers [18] because they are likely to evade adolescents' media literacy skills. The processing of commercialized media content model [19] purports that when children recognize what they are seeing as a commercial, they are able to use their defenses (eg, skepticism, recognition of persuasive intent) to reduce an advertisement's influence. But influencers blur the boundary between entertainment and marketing, which may reduce adolescents' ability to recognize and defend against the persuasive intent associated with their messaging. Because social media influencers are seen as regular, everyday people, their product endorsements may be experienced as credible recommendations rather than commercial advertisements [20].

The Federal Trade Commission (FTC), the government agency that regulates marketing on social media platforms in the United States, requires influencers to disclose sponsored posts, but these disclosures may not operate as intended. The FTC permits very subtle disclosures, such as adding the words "#ad" or "#sponsored" at the bottom of posts [21], so viewers may not even notice them among the other text surrounding the image.

Little is known about how TikTok influencers disclose food brand partnerships. Our goal in this study was to quantify how often TikTok influencers promote products from food brands and document the range of ways they disclose brand relationships in their content.

Methods

Data Collection

We collected up to 100 videos posted on or before July 1, 2022, from each of the top 100 influencers on TikTok in the United States. Each video was collected by capturing the full video and captions on a research assistant's phone. Research assistants noted the date the video was posted and the numbers of views, likes, comments, and "saves" or bookmarks. They also collected profile information, such as whether the influencer was "verified" with a blue checkmark and the total number of likes and followers.

Ethical Considerations

This study was determined to be non–human subjects research and used preexisting data that included publicly available information and therefore does not require institutional review board review per Federal Regulations for the Protection of Human Research Subjects (45 CFR 46.104(d)(4)) [22]. TikTok allows users to select whether their accounts are public or private. All collected data (ie, videos) were publicly available to anyone on TikTok. No user (ie, follower) data were collected. Only deidentified and aggregated data are presented.

Content Analysis

Using a 3-step approach, we first identified whether a food product was featured. Second, we identified the main product, based on whether it was (1) the only featured food product; (2) a sponsored product; or (3) the most prominent or dominant product (eg, the first to appear or to grab the viewer's eye). For each main product, the research team then noted whether it was branded (eg, Coke bottle vs banana). Third, a team of research assistants viewed each food product video to capture information about how the product was featured (ie, in the video, caption, or audio) and, for any branded product, where the brand or logo was featured and whether the video was accompanied by any brand disclosures.

Statistical Analysis

Using ReCal3 [23], we calculated interrater reliability among coders in the third step using a small sample of "practice" videos

XSL•FO
RenderX

(n=6) that reflected the range of disclosures used [24]. Average pairwise percentage agreement was 92%, and average pairwise Cohen κ was 0.82. We deemed these to be acceptable given the descriptive and exploratory nature of this work. We report descriptive statistics.

Results

From the initial potential pool of 10,000 videos across 100 influencers, we had a final analytical sample of 8871 videos from 97 influencers (Multimedia Appendix 1, Figure S1). We identified 1360 videos (15.3%) that featured at least one food product. These 1360 videos originated from 89 unique influencers (median 9, IQR 4-21 videos per influencer), each with >17 million followers and >526 million profile likes. The videos themselves were viewed >9 million times and received >1 million likes (Table 1).

Table 1. Follower engagement with videos featuring food or beverage products, overall and for branded products only.

Engagement	Featuring all food or beverage products (n=1360), mean (SD)	Featuring branded food or beverage products (n=648), mean (SD)
Views	9,249,401 (14,963,961)	8,924,298 (15,584,292)
Likes	1,062,903 (1,777,784)	1,099,153 (1,826,587)
Comments	7524 (14,437)	7189 (13,530)
Bookmarks or "saves"	30,144 (59,915)	33,542 (67,666)

Nearly half (n=648, 47.6%) of the videos with food products featured a branded product. Product brands or logos were most often featured in the video itself (n=606, 93.5%), followed by the video caption (n=224, 34.6%), and/or the accompanying audio (n=126, 19.4%).

Most videos featuring a branded food or beverage product did not contain a brand relationship disclosure (n=449, 69.3%). Among videos that disclosed a brand relationship, influencers used 10 different types of disclosures (Table 2). Tagging a brand in the video's captions was the most common disclosure method (n=182, 28.1%). Six different types of caption hashtags were used to disclose brand relationships, including #[brandname] (n=63, 9.7%) and #ad (n=30, 4.6%).

Table 2. The 10 different types of brand relationship disclosures used in videos featuring branded food and beverage products[a] (n=648).

Types of disclosure	Disclosures, n (%)
No disclosure	449 (69.3)
Caption hashtags (#)	
#[brandname]	63 (9.7)
#ad	30 (4.6)
#[brand]partner	22 (3.4)
#[brand]ambassador	3 (0.5)
#sponsored or #sponsorship	1 (0.2)
Other hashtag (eg, brand slogan)	39 (6.0)
Brand tags (@)	
Brand tagged in video	4 (0.6)
Brand tagged in caption	182 (28.1)
Official TikTok disclosure label	1 (0.2)
Contractual agreement verbally disclosed	1 (0.2)

[a]Not all disclosures represent actual brand relationships; disclosures are not mutually exclusive.

Discussion

Principal Results

Nearly half of the TikTok posts by top influencers that included food and beverage products featured a branded product. The majority (69.3%) of these posts, however, did not include any brand relationship disclosures, suggesting either that no relationship existed or that they purposely or accidentally omitted its disclosure. By comparison, a recent study of food-related Instagram posts by celebrities (athletes, actors, and musicians) found that less than 5% of the identified posts that were sponsored by a food company were identified by hashtags (eg, "#ad") or related terms (eg, "paid advertisement") below the post [25].

Among the food videos with disclosures we identified, the most frequently used mechanism—tagging the brand—did not clearly

XSL•FO
RenderX

differentiate between sponsored content and the influencer trying to attract a brand or followers who may like that brand. These findings have implications for how social media marketing should be regulated. The ambiguity around brand relationship disclosures makes it difficult for social media users, particularly adolescents, to make informed decisions about the products they see [18]. This concern has been recognized by the FTC in the most recent iteration (July 2023) of its endorsement guides [26], which emphasize that marketing practices geared toward adults may not be appropriate for children. In fact, bigger and clearer disclosures would likely work better among children and adolescents. A qualitative study among participants aged 12-16 years reported that they did not mind if influencers were paid, but they did not like seeing explicit disclosures that were "...too pushy, like, this is advertising, because then you will keep this in mind all the time" [27].

Limitations

Given the dearth of information on influencer marketing, our study set out to systematically collect and record information on how social media influencers disclose relationships with food brands. However, our study has limitations, including (1) the use of a convenience sample of influencers and posts, (2) the focus on only the most prominent food product in each video, (3) the inability to infer intentionality in whether a product was meant to be featured in a video (eg, when the only food product featured was in the background), and (4) the inability to distinguish whether the presence or lack of a disclosure implied the presence or lack of a brand relationship.

Conclusions

Social media users, particularly adolescents, need clearer, more robust disclosures from influencers to protect against the undue influence of food marketing. These findings may inform calls for the Children's Food and Beverage Advertising Initiative—the largest self-regulatory pledge designed to reduce unhealthy food marketing—to extend its protections to older adolescents, who are heavily targeted by food companies [28,29].

Abstract

Background: Health care innovation faces significant challenges, including system inertia and diverse stakeholders, making regulated market access pathways essential for facilitating the adoption of new technologies. The German Digital Healthcare Act, introduced in 2019, offers a model by enabling digital health applications (DiGAs) to be reimbursed by statutory health insurance, improving market access and patient empowerment. However, the factors influencing the success of these pathways in driving innovation remain unclear.

Objective: This study aims to identify the key performance factors of the innovation system shaped by the *patient-relevant structural and procedural improvement* (pSVV) pathway within the DiGA model. By examining how this pathway supports the entry of innovative digital health technologies, we seek to uncover the systemic dynamics that influence its effectiveness in fostering patient-centered digital health solutions.

Methods: This study, conducted from May 2023 to November 2024, used a mixed methods approach. A descriptive analysis assessed how DiGA manufacturers use positive health care effects, giving a market overview of the pSVV technology. A qualitative analysis using grounded theory and Gioia methodology provided insights into stakeholder perspectives, focusing on manufacturers and regulatory bodies. A functional-structural analysis examined how components of the innovation system, such as actors, institutions, interactions, and infrastructure, interact and impact the effectiveness of the pathway.

Results: The descriptive analysis showed that only 11 (20%) of the 56 DiGAs available in Germany used the pSVV pathway, with only 1 (2%) provisionally listed DiGA using pSVV as a primary end point; 6 of 9 (67%) pSVV key areas were used. The qualitative analysis revealed that manufacturers prioritize demonstrating medical benefits over pSVV due to evidence requirements and uncertainties around pSVV acceptance. Operational barriers hindered the adoption of pSVV, despite a positive reception among stakeholders. The systemic analysis identified key issues, including a lack of entrepreneurial focus on pSVV, limited regulatory experience, inadequate measurement methods, and entrenched practices prioritizing medical benefits, that hinder market formation and legitimacy.

Conclusions: This study identifies key factors for effectively implementing innovation systems through regulated market access pathways, including content and format security, clearer framework specification, active innovation process management, and market formation stimulation. Addressing these factors can reduce uncertainties and promote wider adoption of digital health technologies. The findings highlight the need for future research on patient empowerment and the development of methodologies beyond traditional therapeutic outcomes.

Introduction

Background

Innovation in health care is well known for being challenging. The complexity is driven by factors such as the involvement of diverse stakeholders in highly regulated markets [1,2], the need to address "wicked problems," complex issues without straightforward solutions [3], and substantial "system inertia," meaning resistance to change, which is especially pronounced in health care systems [4]. Policy approaches have been shown to act as inertial forces that can significantly shape the development of innovative technologies in health care [5], particularly digital health technologies, where patient access is greatly limited without broad and scalable market access pathways [6]. Mobile health apps are becoming increasingly available to consumers worldwide [7-9]; however, significant barriers, including regulatory complexity, insufficient evidence of clinical benefit, and data privacy concerns, still prevent their full integration into health care systems, leaving them underused in clinical practice [10-14].

To address these challenges, health policy approaches are being adopted globally to standardize regulatory processes and speed up market access, particularly in the rapidly evolving field of digital health [15-18]. Notable examples of health policy approaches include regulated market access pathways, such as *the fast-track process for digital health applications* pathway in Germany [19] and the *Prise en Charge Anticipée Numérique* (PECAN) pathway in France [20], which aim to facilitate the entry of digital health applications (DiGAs; German: Digitale Gesundheitsanwendung) into their respective markets. These new approaches are gaining significant international attention as pioneering models in the field [6,21].

To illustrate, the German Digital Healthcare Act (DVG), introduced in 2019, established the DiGA pathway to foster the integration of so-called DiGAs into the health care system. This pathway allows DiGAs to be reimbursed by statutory health insurance when prescribed by health care professionals or provided by health insurers. With approximately 90% of the German population covered by statutory health insurance [22], these "apps on prescription" are widely accessible at no cost to patients. Eligible DiGAs are included in the national DiGA Directory [23], which is managed by the Federal Institute for Drugs and Medical Devices (BfArM; German: Bundesinstitut für Arzneimittel und Medizinprodukte) to ensure transparency and oversee the approval process [24,25]. To qualify, a DiGA must be Conformité Européenne (CE)–marked (classes I and IIa or IIb), be based primarily on digital technology intended for direct patient use, and support the detection, monitoring, treatment, or alleviation of diseases, injuries, or disabilities [26]. Following a recent regulatory update in April 2024, digital medical devices classified as class IIb have been added to be eligible for recognition as a DiGA. However, this inclusion comes with specific stipulations; these devices are required to demonstrate medical benefit only, and they are eligible solely for permanent listing, excluding the option for preliminary listing. In addition, a DiGA must meet stringent requirements for safety, quality, functionality, privacy, and data security as defined in the respective DiGA ordinance (DiGAV; German: Digitiale Gesundheitsanwendungen-Verordnung) [24]. To enhance transparency around the assessment criteria and specific requirements established by BfArM, a DiGA guide [27] for manufacturers, service providers, and users was published. This guide provides a concise overview of the applicable ordinances and regulations, detailing how BfArM interprets the normative requirements set forth in the DVG and DiGAV.

Despite some emerging research examining the market dynamics following the implementation of regulated market access pathways, such as the number of products entering the market, time to market, pricing, and study designs used to demonstrate efficacy [28,29], as well as factors contributing to the success of specific DiGA products [30], broader factors influencing successful technology integration remain underexplored. This study addresses these gaps to better inform future policy and innovation strategies. To identify potential success factors, it is crucial to consider not only the regulated market access pathway itself but also the surrounding elements that influence its effectiveness. The broader network of actors, institutions, and resources involved in the creation, diffusion, and use of new technologies is defined as the technology innovation system [31]. A health policy approach, such as the creation of a regulated market access pathway that "brings about processes of change and stimulates technological innovation," can be characterized as a systemic instrument [32]. Systemic instruments are mechanisms designed to shape the conditions under which technological innovation systems operate. Understanding the dynamics that a systemic instrument brings to a technological innovation system requires the consideration of various functional and structural components, all of which must be in place to effectively implement the targeted technological innovation [33]. These components, as outlined by Wieczorek and Hekkert [34], include the structural components, such as actors, institutions, interactions, and infrastructure, as well as the functional components, such as entrepreneurial activities (F1), knowledge development (F2), knowledge diffusion (F3), guidance of the search (F4), market formation (F5), mobilization of resources (F6), and creation of legitimacy (F7) [35].

This exploratory study aimed to identify factors contributing to the success of an innovation system shaped by a regulated market access pathway in the digital health sector. Through an exemplary case study, we sought insights to support ongoing improvements in digital health policy, focusing on optimizing market access pathways for digital health technologies. The central research question is as follows: What are the performance factors of an innovation system created by a regulated market access pathway that supports the market entry of innovative digital health technologies?

XSL•FO
RenderX

To address this question, we selected a specific case from the 2019 German policy innovation DVG, particularly the "patient-relevant structural and procedural improvements" (pSVV; German: Patientenrelevante Struktur- und Verfahrensverbesserung) pathway. The pSVV pathway is a targeted segment within the DiGA pathway, specifically modifying the element of product value assessment, 1 of the 4 "full-stack" elements (regulatory authorization, product value assessment, pricing and reimbursement, and patient access) that define a comprehensive market access pathway [6], promoting innovations aimed to specifically elevate DiGAs that enhance patient–health care provider interactions and support patient health behaviors.

Unlike traditional pharmaceuticals, which require evidence of "therapeutic efficacy" through clinical studies for coverage eligibility [36], DiGAs are allowed to demonstrate their effectiveness through "positive health care effects" defined as either "medical benefit" or pSVV. While the medical benefit criterion focuses on outcomes, such as improved health status, reduced disease duration, prolonged survival, or improved quality of life, the pSVV criterion introduces 9 additional areas to demonstrate the value that is equally eligible as defined in the DiGA guide. These areas include improving care coordination, adherence to guidelines and standards, enhancing patient adherence, facilitating access to care, increasing patient safety, and promoting health literacy and autonomy. This expansion of the traditional product value assessment beyond the traditional therapeutic benefits is further complemented in the DiGA guide by explicitly broadening the acceptable methods of evidence beyond the traditional randomized controlled trials. We selected this case due to the maturity of the evolving DiGA ecosystem [28] in Germany, which offers greater transparency and availability of data on use and uptake compared to other countries. Within this context, the pSVV pathway was chosen as a focal point because it represents a well-defined component within the DiGA pathway, involving a manageable number of stakeholders while offering sufficient accumulated experience to provide valuable insights into the factors influencing digital health innovation.

In addition, the introduction of the pSVV pathway is groundbreaking as it extends beyond traditional treatment parameters, embracing a holistic approach to health care that prioritizes patient empowerment and streamlined care processes [19,37,38]. This aligns with the global trend toward patient empowerment, emphasizing the importance of patient agency and involvement in health care processes [16,39,40].

Our research used a mixed methods approach to provide a comprehensive exploration of the factors at play. We began with a descriptive analysis of the innovation success of the targeted pSVV technology, which helps contextualize the case and assess the effectiveness of the policy intervention [41]. Following this, a qualitative analysis of the perception and use of the market access pathway was conducted to develop theoretical insights into the factors that influence the adoption of specific innovation pathways [42,43]. In addition, a functional-structural analysis of the technological innovation system was performed to uncover broader factors beyond the pathway itself that are essential for successful technological innovation [34].

Contribution

This study contributes to the field by providing a comprehensive analysis of factors that support the successful integration of digital health innovations. Our findings will provide policy makers and stakeholders worldwide with practical insights to improve regulated market access pathways and drive innovation strategies that better meet the needs of health care systems and patient empowerment.

Methods

Setting and Study Design

This exploratory study used a mixed methods approach to investigate factors influencing the success of a regulated market access pathway for digital health technologies. We conducted a descriptive analysis to assess the adoption of pSVV technology, followed by a qualitative analysis to explore stakeholder perspectives on the pSVV pathway, using grounded theory and Gioia methodology to ensure neutrality and objectivity. Finally, we performed a functional-structural analysis to identify additional success factors within the broader technology innovation system. Each method is described in detail subsequently.

This study was carried out between May 2023 and November 2024 with interviews being conducted between May 2023 and November 2023.

First, a descriptive analysis of the use of positive health care effects by DiGA manufacturers was conducted to establish an understanding of the current developmental status of the pSVV technology in the market.

Second, a qualitative analysis was performed to explore the success factors of a regulated market access pathway by subsequently analyzing the perception and use of the pSVV pathway of key stakeholders. Since the pSVV pathway was only introduced in 2019 and has not been studied yet, a qualitative research approach was adopted. This approach allows for deep exploration of complex and less understood topics [44]. Unlike quantitative methods, which rely on larger sample sizes and predefined variables, qualitative methods provide flexibility for exploring nuanced, context-specific insights, particularly valuable given the relatively small number of relevant stakeholders (35 DiGA manufacturers as of early 2023). By using the inductive grounded theory method [45] alongside the Gioia methodology [42,43], we objectively analyzed the views of market participants on the pSVV pathway, avoiding any imposition of preconceived theories and ensuring neutrality in the analysis. For the qualitative analysis, we followed the Consolidated Criteria for Reporting Qualitative Research-32 (COREQ-32) checklist [46].

Building on the dataset from the qualitative analysis, we conducted a functional-structural analysis of the technology innovation system established by the pSVV pathway to identify additional success factors related to regulated market access pathways. This analysis followed the systemic policy framework

XSL•FO
RenderX

established by Wieczorek and Hekkert [34], enabling a comprehensive examination of the innovation system's functional dynamics and structural components within the current policy context.

While this study provided valuable insights into potential strategies to improve the pSVV pathway in particular, the international focus of this study precluded detailed insights into Germany-specific factors. To address this, we conducted a subsequent analysis focusing specifically on the question, "What factors facilitate or hinder the implementation of pSVV within the approval process for DiGA?" and "What specific requirements and expectations of relevant stakeholders must be addressed to establish the concept of pSVV in the market?" The results of this specific analysis were published in a German-language journal to inform stakeholders in this context [47].

Sampling and Data Collection

For the execution of our descriptive analysis regarding the state of adoption of pSVV, we evaluated publicly available data on the positive health care effects of DiGA from the DiGA directory [23]. The data were retrieved via an application programming interface provided by BfArM for scientific use.

In our qualitative study, we used a hybrid approach of criterion sampling and snowball sampling for participant recruitment. We aimed to engage with stakeholders who have a direct influence on which digital health products enter the market and, if entry occurs through the DiGA pathway, determine the associated positive health care effects. The inclusion criteria are defined subsequently.

The first inclusion criterion was organizations that are directly involved with the DiGA ordinances and regulations, whether developing it, ensuring or supporting its implementation, or actively using it.

The second criterion was individuals, within these organizations, whose professional roles directly involve the development, implementation, or use of the DiGAVs and regulations.

The third inclusion criterion was additionally individuals who have actively decided against using the DiGA pathway, provided they have extensively engaged with the ordinances and regulations and are potentially qualified to use it (eg, manufacturers of DiGAs not listed as DiGA).

Individuals without direct and active influence over the selection of products entering the DiGA market or the choice of the positive health care effect were excluded.

Consequently, the exclusion criteria led to the exclusion of stakeholder groups in the DiGA market, such as DiGA users, prescribers, and researchers in the field, while the inclusion criteria led to the identification of the stakeholder groups presented in Textbox 1.

Textbox 1. Stakeholder groups included in qualitative analysis.

- Digital health application (DiGA) manufacturers with patient-relevant structural and procedural improvement (pSVV; DiGA with pSVV): This category includes decision makers from manufacturers of DiGAs that are listed in the DiGA directory and have implemented pSVV as a positive health care effect.
- DiGA manufacturers without pSVV (DiGA without pSVV): This category comprises manufacturers who are listed in the DiGA directory but have not used pSVV as a positive health care effect.
- Manufacturers of mobile health applications not listed in the DiGA directory (non-DiGA): This group consists of manufacturers whose CE–certified mobile health apps are not, or are not yet, listed in the DiGA directory.
- Consultants: This group refers to professionals from advisory firms who specialize in assisting manufacturers in the process of getting listed in the DiGA directory.
- Regulatory bodies: This group encompasses public institutions that are deeply involved in the development and management of the DiGA pathway and the evolution of the guiding ordinances and regulations (Digital Healthcare Act [DVG], DiGA ordinance [DiGAV], and DiGA guide).

Due to the very small size of stakeholder groups 1 and 5, yet their significant relevance to our research questions, we contacted all organizations in these groups in accordance with our inclusion criteria. For groups 2 to 4, given the novelty and niche nature of the topic, we opted for snowball sampling [48] to achieve the highest possible participation rate. Individuals were excluded if someone from the same organization had already participated in the study, to avoid multiple responses from the same context. This combined approach resulted in a 66% positive response rate to our participation invitations. Participant recruitment began with initial email contacts, followed by referrals from existing participants in line with snowball sampling. Efforts were focused on ensuring a diverse representation of the identified stakeholder groups.

Our outreach targeted 29 individuals, with 19 (66%) agreeing to participate. Reasons for nonparticipation included lack of response (n=9, 31%) and time constraints (n=1, 4%). The distribution of speakers across groups and their organizational roles are detailed in Table S1 in Multimedia Appendix 1.

For the interviews, a semistructured approach was used with decision makers who had consented to participate and endorsed a data protection declaration. Efforts were made to ensure neutrality, with no prior relationships between interviewers and participants. An interview guide with 7 open-ended questions was prepared to facilitate conversation while ensuring neutrality and objectivity in the analysis. The themes of the questions were developed after preliminary data gathering, which included limited literature research and initial conversations with 2 experts in the field (a managing director from a manufacturer's association and a member of an organization that has 1 DiGA listed in the DiGA directory), adhering to the standards of the Gioia methodology [42]. These experts were not part of the subsequent interviews, ensuring that the development of the interview guide was informed yet independent of the interview

XSL•FO
RenderX

process itself (Multimedia Appendix 1). In total, 2 central themes emerged from this process: the general approval process for DiGA and the specifics of the pSVV pathway. For each of these themes, we formulated specific questions, which were refined during the initial interviews to ensure clarity and neutrality. Interviews were scheduled at the convenience of the participants and conducted via Zoom (Zoom Video Communications, Inc), with only the participant and the primary interviewer (SG) present, though 3 selected interviews had a second researcher (MG) present for quality assurance. No interviews were repeated.

Conducted in German, interviews lasted 25 to 35 minutes, audio tracks were recorded, transcribed using the software Whisper Transcription (Good Snooze), and anonymized. Data saturation was reached when no new first-order concepts or second-order themes emerged during analysis, as reflected in field notes and initial coding. This indicated that the data structure, developed through the Gioia methodology, was comprehensive, and additional data collection would not yield further insights. Following the analysis, data triangulation was enhanced through additional discussions with 4 experts from regulatory and digital health sectors to refine the results. This included a conversation with leading representatives from BfArM, which, due to confidentiality agreements, cannot be directly cited in this study. Insights from these discussions were used to cross-verify emerging themes and validate our interpretations, ensuring robustness in our conclusions.

Ethical Considerations

Informed consent was obtained from all participants who were interviewed strictly as representatives of their respective employers. Participants were selected based solely on their relevance to the research question and their experience in the field, with no consideration of personal or socially sensitive attributes. No personal data or socially relevant information were collected, and all data were fully anonymized to ensure privacy and confidentiality. No compensation was provided for participation in the study.

Furthermore, the study did not involve vulnerable populations, health care professionals, medical procedures, health-related data, or any form of deception, manipulation, or intervention that could impact participants' well-being. In addition, there was no risk of physical, psychological, social, or economic harm to participants. Following consultation with the head of the Institute for Ethics in Technology at Hamburg University of Technology and a review by the German Association for Experimental Economic Research eV (certificate number kNjYR7Ag), it was confirmed that specific ethics approval was not required. This approach fully aligns with best practices for ensuring ethical compliance in socioeconomic research.

Descriptive Analysis

For this analysis, we included all DiGA listed in the DiGA directory at BfArM as of November 8, 2024. This study specifically aimed to compare how often medical benefits are used versus pSVV, as published in the DiGA directory [23]. To further refine our understanding of the adoption levels of pSVV, we also examined the use rates across the 9 key areas of pSVV detailed in the DiGA guide [27].

Qualitative Analysis

Transcripts were methodically analyzed in a 3-step procedure using the grounded theory and the well-established Gioia methodology [42,49] to ensure qualitative rigor in inductive research. After familiarization with the primary data, a codebook was developed by generating codes in an iterative process using the software MaxQDA (VERBI Software). SG coded all (19/19, 100%) interviews, and 2 (11%) randomly selected interviews were cocoded by MG. In addition, SG and MG regularly discussed and reflected on the data collection process and preliminary findings throughout all phases of the research. A consensus on all codes was eventually reached by the research team.

After agreeing on a coding scheme that best captured the diversity of the material, the transcripts and codes were analyzed again to identify second-order categories. First-order concepts included concepts, such as "lack of methods is the biggest hurdle for proof of pSVV" or "pSVV good ideas but difficult to operationalize." First-order concepts were combined into second-order themes, such as "study design for pSVV difficult due to lack of measurement instruments." Ultimately, second-order themes were merged hierarchically into five aggregate dimensions that best summarize the theoretical contribution in the data: (1) "key aspects for manufacturers within the regulated market access pathway," (2) "key aspects for study design," (3) "reasons for considering possibilities within new pathway," (4) "hurdles for considering possibilities within new pathway," and (5) "targeted innovative technology important for the health care system" (refer to Figure S1 and Table S3 in Multimedia Appendix 1).

Following the analysis, a triangulation of the results was conducted with 4 individuals from institutions involved in the process: 1 interview participant and 3 additional experts with extensive subject matter expertise, who had not participated in the initial interview study. All 4 experts were selected from the regulatory field, as many of the derived implications pertained to regulatory issues.

Functional-Structural Analysis

The first-order concepts, originally derived from the previous qualitative analysis as elucidated earlier, were subject to an additional analysis using the functional-structural systemic problem analyses framework [34], a methodology specifically tailored for the exploration of technology innovation systems [50,51]. Our analytical focus centered on the innovative pSVV technology, concentrating on the first-order concepts that laid the foundation for dimensions 2 to 5. Notably, the first dimension, "Key aspects for manufacturers within the regulated market access pathway," was excluded from this analysis, as it did not provide insights specific to the pSVV aspects of the DiGA pathway, but rather addressed the pathway in general.

In step 1, to facilitate a comprehensive analysis, all first-order concepts corresponding to dimensions 2 to 5 were systematically organized into a 4×7 matrix. This matrix integrates the 4 structural elements and 7 functional dimensions of an innovation

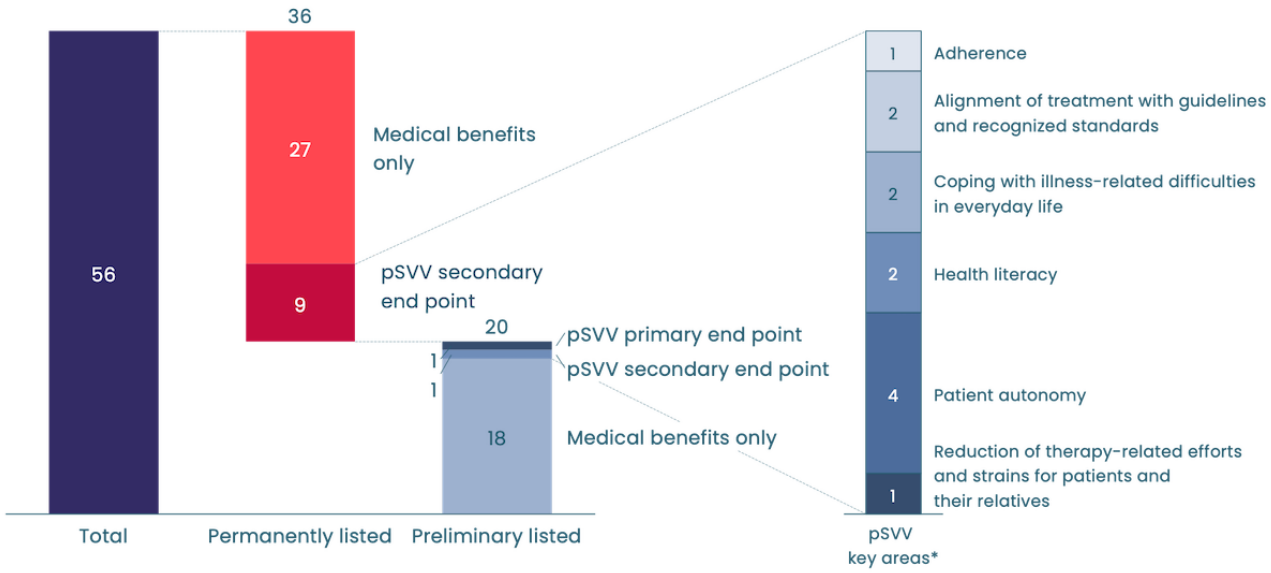
XSL•FO
RenderX

system [34,50,52]. Following the analysis framework, the objective was to elucidate overarching "systemic problems" hindering the intended innovation within the innovation system for pSVV. Refer to Table S4 in Multimedia Appendix 1 for the comprehensive assignment of concepts to the functional and structural dimensions of the innovation system and the derivation of "systemic problems." The sorting of concepts, derivation of instruments, and clustering into strategic factors were conducted by SG and subsequently agreed upon by the research team.

In step 2, to address the identified "systemic problems," we first identified "systemic instruments" within the functional-structural framework of Wieczorek and Hekkert [34], tailored to specific systemic issues.

In step 3, we organized the "systemic instruments" identified in step 2 into 3 strategic factors to form actionable clusters. A detailed overview of the derivation process is available in Table S5 in Multimedia Appendix 1.

Results



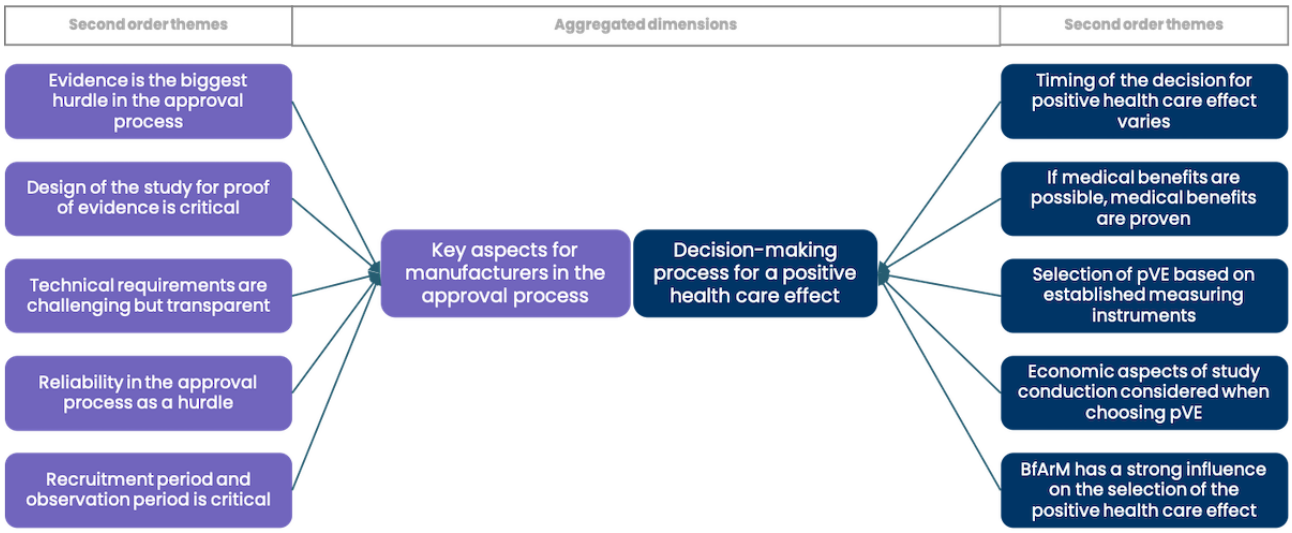
Current State of pSVV Adoption in the DiGA Market: Descriptive Analysis

As of November 8, 2024, out of the 56 DiGAs available in Germany, only 1 (2%) provisionally listed DiGA uses pSVV as its primary end point, with none in the permanently listed category. While 10 (19%) DiGAs incorporate pSVV as a secondary end point, the predominant focus remains on traditional medical benefits. The adoption of pSVV in comparison to medical benefits stands at 11 versus 45, meaning only 20% (11/56) of all currently listed DiGAs use pSVV. Moreover, only 1 (2%) of 56 DiGA exclusively focuses on pSVV as a primary end point [23].

The 11 (20%) of the 56 DiGA currently listed that use pSVV as a primary or secondary end point have collectively used 12 pSVV end points (Figure 1). Among these, 6 (67%) of the 9 possible key areas outlined in the DiGA guide have been used. In total, 4 (44%) of these areas have been used more than once, namely "patient autonomy," "health literacy," "coping with disease-related difficulties in everyday life," and "alignment of treatment with guidelines and recognized standards."

The 11 (20%) of the 56 DiGA currently listed that use pSVV are owned by 10 organizations, with 1 organization using pSVV end points in clinical trials to prove the positive care effect for 2 of their DiGA products. We estimated the timing of the adoption of the pSVV pathway by examining the time frame of clinical studies and found that 2 DiGA demonstrating a pSVV had already been conducting their clinical studies before the pathway was introduced in 2019 (velibra and vorvida, both developed by GAIA AG).

Figure 1. The number of digital health applications (DiGAs) listed in the DiGA directory in Germany based on positive health care effects and status of listing (as of November 8, 2024), including the breakdown of specific key areas used within patient-relevant structural and procedural improvements (pSVV). *Eleven DiGAs using pSVV use 12 pSVV end points with 1 DiGA using 2 pSVV key areas.



Analyzing Perception and Use of the pSVV Pathway by Key Stakeholders: Qualitative Analysis

Overview

The results are presented based on the data structure developed through the Gioia methodology (Figure S1 in Multimedia Appendix 1), which organizes findings into first-order concepts, second-order themes, and overarching dimensions. In the subsequent sections, findings are systematically presented separating the data structure into 3 segments of aggregated dimensions and further detailed by their corresponding second-order themes. To illustrate our approach, Figures 2-4 provide a visual representation of the respective parts of the data structure. In addition, Table S3 in Multimedia Appendix 1 includes selected codes that were instrumental in forming the data structure.

XSL•FO
RenderX

Figure 2. Graphical illustration of selected parts of the data structure derived from Gioia methodology illustrating key aspects for manufacturers within the regulated market access pathway as well as the key aspects of choosing the health care effect. BfArM: Federal Institute for Drugs and Medical Devices; pVE: positive health care effects.

Key Considerations in the Approval Process for DiGAs: Evidence as the Key Aspect

Being asked about the key considerations a DiGA manufacturer needs to face during the approval process, most (14/16, 88%) of the surveyed manufacturers and consultants concurred on a central theme—evidence takes the forefront, serving as the primary concern for manufacturers as "...(evidence) is the crucial point, which often determines the inclusion or non-inclusion (in the DiGA Directory)" (Consultant_5). In conjunction with this, the DiGA study design for evidence generation is deemed critical. The execution of the study is recognized as one of the primary cost drivers for manufacturers and the approving authority (BfArM) has a strong influence on the final design, as described by a participant, "And one can clearly see that an evidence level is crystallizing, which, within the framework that is possible, is already on the strictest side" (DiGA without pSVV_4).

While technical requirements, such as data privacy, interoperability, and accessibility were also mentioned, discussions in these domains with the BfArM were described as negligible due to the "clear and transparent" (Consultant_2) nature of the requirements. One respondent encapsulated this sentiment by stating the following:

> *The key issue is undoubtedly the matter of evidence. Less so is data privacy and security, as these are issues that can be adequately addressed.* [DiGA without pSVV_3]

Nevertheless, a certain level of planning uncertainty was identified in the process, stemming from updates to the DiGA guide or alterations in statements during consultations with the BfArM, as articulated by a manufacturer:

> *One of the most challenging aspects is the disparity between what is theoretically granted regarding research design and the actual decision practices of the BfArM.* [DiGA without pSVV_2]

In addition, insights into the procedural aspects revealed that both recruitment and observation periods are critically constrained.

Key Aspects of Study Design: Strong Tendency Toward Traditional End Points

Regarding the decision on which positive health care effect a future DiGA will be evaluated for and therefore which end point is used in the study design, significant timing variations are observed. DiGA manufacturers, especially those who began developing their product after the DVG was introduced in 2019, typically determine the positive health care effect early in the development phase, often before initiating the coding process:

> *Ideally, I make the decision before the development begins, as the entire development process needs to be built around this choice.* [DiGA with pSVV_1]

In contrast, manufacturers with established products leveraging the new DiGA approval pathway as a market entry point did not have this advantage.

In the selection of the clinical end point, manufacturers strongly lean toward medical benefits:

> *The medical aspects always take precedence.* [DiGA with pSVV_2]

Demonstrating a positive health care effect without proof of medical benefit is perceived as challenging in 2 ways. One way is to find the appropriate instrument for evidence generation for proving pSVV, "If I look at the list of pSVV, then I wonder for 80% of the things, how am I supposed to prove that?" (DiGA without pSVV_1), while the other lies in finding an agreement with the BfArM on a study design aiming to prove pSVV, "We have to advise relying on the medical benefit...it is not fundamentally that they (BfArM) reject it (pSVV), but we also experience that they...are not so certain about it" (Consultant_5). In addition, it is perceived that other stakeholders in the system are better equipped to evaluate medical benefits compared to pSVV, which could be relevant for price negotiations:

XSL•FO
RenderX

> *If you believe you can demonstrate medical benefits, that is probably the better path towards price negotiations because it's something the system understands and can perhaps evaluate better.* [Consultant_6]

The perceived challenges conclude in a perception of a stronger acceptance of evidence that substantiates a medical benefit, highlighting a potential current bias toward well-known, medically oriented outcomes.

Manufacturers and consultants choose the end points, if possible, based on the example of other DiGA that are already listed and where validated measurement instruments are available:

> *[The selection criteria are] essentially hard facts in the sense that it has worked before, and there are validated measurement instruments.* [Consultant_3]

In addition, both listed DiGA and unlisted health applications prioritize economic considerations:

> *Ultimately, we paid attention to...economic aspects, like the speed at which the study is conducted.* [DiGA without pSVV_2]

At present, pivotal guidance in the process emanates from consultations with the BfArM. The influence of the conversations is underscored by the following statement:

> *So as a manufacturer, you would never do anything where the BfArM advice said otherwise.* [DiGA without pSVV_5]

Reasons for Considering a New Pathway: Additional Evidence

Both, consultants and DiGA manufacturers, currently view the use of pSVV primarily as an opportunity for generating additional evidence alongside medical benefits. This perspective was succinctly expressed by one participant, who mentioned the following:

> *pSVV is included as a secondary endpoint in such a study. If possible, you confirm it, but you would always prefer to demonstrate medical benefits.* [Consultant_3]

DiGA manufacturers and consultants have pinpointed 3 substantial benefits associated with the implementation of the possibilities given within the new pSVV pathway. Potential differentiation from providers of similar DiGA was mentioned:

> *But in the case of [indication X], it could well be that with our DiGA, other DiGA are also approved or provisionally approved. In such instances, I could envision that a pSVV might serve as a consideration for or against a DiGA.* [DiGA without pSVV_4]

Overall positive impacts on sales were also mentioned:

> *Distribution is also a crucial task we undertake when engaging with physicians, ensuring a clear delineation of what is effective beyond standard practices. Particularly with DiGA, the argument hinges on the fact that the pSVV dimension precisely provides the benefit.* [DiGA without pSVV_3]

Moreover, there is an expectation of a positive impact on the official price negotiations occurring later in the process between manufacturers and payers. It is highlighted that "The more evidence you have, the greater the likelihood of maintaining certain price points" (DiGA with pSVV_1) and "Possibly, pSVV can indeed be an enhancing criterion (during the price negotiation process) for the respective product" (Regulatory body_2).

Hurdles for Considering a New Pathway: Operational Insecurities

When asked about the reasons why manufacturers tend to not use the new possibilities within the pSVV pathway, many (5/7, 71%) manufacturers and consultants referred to a lack of clarity on operationalizing pSVV as outlined in the DiGA guide, particularly concerning the methods applicable for assessing the impact:

> *But when I look at them [the pSVV key areas], I wonder with about 80% of them, how am I supposed to prove that? And yes, how do I actually incorporate that into studies?* [DiGA without pSVV_1]

In addition, there is skepticism among DiGA manufacturers and consultants regarding the economic impact of demonstrating pSVV. One participant succinctly expressed this viewpoint by stating the following:

> *Purely from the procedural and financial perspective—if you were to ask our boss, who is responsible for finances—there is a clear answer: this is an absolute disaster.* [DiGA with pSVV_1]

At the same time, introducing and establishing new measurement tools like the use of real-world data is deemed too expensive and risky for DiGA manufacturers:

> *If you had to essentially innovate methods and also deal with the uncertainty...in the worst-case scenario, you would end up with three studies.... That alone costs you a million, just for these studies. No one is willing to foot that bill. And then, if it goes wrong...* [Consultant_3]

In addition, manufacturers and consultants observed a general uncertainty within the system regarding the concept of pSVV:

> *Not that they (BfArM) fundamentally reject it, but we experience that they, how should I say, are not so certain about it.* [Consultant_5]

Moreover, they observed a general lack of knowledge about pSVV that leads to the need for explanation:

> *There is a significant need for explanation, actually, among the different stakeholders. Both with patients and with doctors. What is it exactly? Why is it good? What is in it for me?* [DiGA with pSVV_1]

Consultancies sometimes actively discourage the choice of pSVV in the clinical trial:

> *If you believe you can demonstrate medical benefits, that is probably the better path towards price negotiations because it's something the system*

XSL•FO
RenderX

> *understands and can perhaps evaluate better.* [Consultant_6]

Relevance Perception: Targeted Innovative Technology Is Important for the Health Care System

Looking at the general perception of pSVV as a concept, stakeholders highlighted the systemic benefits, emphasizing the impact on the overall health care system efficiency and supply effects:

> *It...makes sense from the overall health care system perspective.* [Non-DiGA_2]

Patient-centric advantages emerged, revealing the influence of DiGA beyond conventional medical outcomes. A consultant illustrated this by pointing out the positive impact of patient empowerment on intervention success:

> *Individuals with higher health literacy typically respond more effectively to interventions, as they have a better understanding and feel a greater sense of control.* [Consultant_1]

DiGA might also address practical challenges like long waiting times, presenting substantial value beyond traditional medical considerations:

> *But if we now say we would compare ourselves to a traditional intervention...then the pSVV...plays an even greater role. Because when I say, I have something here with a positive effect, and it is more accessible than the therapy, that is already a value where I say, it makes a difference.* [DiGA with pSVV_2]

However, the unique benefits of DiGA, such as the improvement of patient adherence and reduction of therapy-related efforts, often eluded recognition in conventional benefit assessments:

> *pSVV is crucial for the system, but the evidence must focus on it. Thus, the usability of the product must be ensured and tailored to that. The evidence must reflect the particular added value of these applications.* [DiGA without pSVV_5]

Regulatory bodies acknowledged this oversight, emphasizing the need to broaden evaluation criteria to encompass these critical aspects:

> *DiGA can have medical benefits, but they are not solely limited to medical utility.... And these are points that get lost in traditional benefit assessments.* [Regulatory body_1]

In addition, the political and collaborative nature of the development process that led to the pSVV concept was highlighted: “We had many stakeholders involved there. On the one hand, we had colleagues from self-administration, but we also had the manufacturers [stretching the collective effort] in understanding potential, addressing challenges, and bridging the gap between traditional assessment methods and innovative logics” (Regulatory body_1).

Analyzing the pSVV Technology Innovation System: 5 Systemic Problems Identified

Actors’ Presence Problem in “Entrepreneurial Activities” and “Market Formation”

Examining the participants presently engaged in the pSVV innovation system reveals a discernible pattern. Only one of the DiGA entrepreneurs within this emergent system has developed a product with a primary emphasis on pSVV. Notably, some manufacturers have established market longevity before the introduction of the DVG and thus pSVV; therefore, orienting their product toward medical benefits. Moreover, some actors are concurrently navigating evidence-generation endeavors while exploring alternative pathways for market access in Germany, such as individual “selective contracts” with statutory health insurance under §140a SGB V (Sozialgesetzbuch 5; a German law that covers all regulation concerning statutory health insurance and therefore also covers DiGA and selective contracts), which lacks the concept of pSVV. The absence of *entrepreneurial activities* singularly centered on pSVV emerges as a contributory factor hindering the *formation of a distinct market* for dedicated pSVV-related regulated digital medical devices.

Actors’ Capability Problem in “Knowledge Dissemination”

The supervising governmental institution, in its role as advisor for manufacturers before and during the admission process, has limited experience with pSVV but rather a strong focus on medical benefits. This emphasis can be attributed to its dual role, as the BfArM in Germany oversees admissions not only for DiGAs but also for traditional pharmaceuticals. The lack of experience with pSVV in this key role as a knowledge multiplicator and also in this specific innovation system hampers *knowledge dissemination*. In addition, practitioners prescribing DiGA as well as end users of the products have limited experience with products focusing on pSVV, which leads to a need for significant efforts to explain the concept while the demand from potential users is unclear.

Infrastructure Presence Problem in “Knowledge Development” and “Guidance of Search”

The suitability of existing measurement methods designed for therapeutic effects in assessing pSVV is often limited, contributing to its restricted adoption. Simultaneously, the lack of positive examples for products in the pSVV category hampers *knowledge development*. In addition, the absence of positive price examples not only further constrains manufacturers’ support for pSVV but also contradicts the *guidance of search*.

Institution Intensity Problem in “Knowledge Development” and “Resources Mobilization”

In the *institutional* dimension, it was noted in particular that the existing *instructions* (DiGA guide) pose challenges to the operationalization of pSVV. The *established practices* and formed *expectations* regarding pSVV are perceived as counterproductive, particularly for cost-sensitive manufacturers who cannot afford to allocate their limited resources toward pSVV despite existing barriers. The limitations of the DiGA

XSL•FO
RenderX

guide concerning pSVV, namely lack of examples or standards and possible end points for evidence demonstration, are identified as a challenge in *knowledge development*, while the *established practices*, inclined toward medical benefits, hinder *resource allocation* for the advancement of pSVV.

Institution Intensity and Interaction Intensity Problem in "Guidance of the Search," "Market Formation," and "Creation of Legitimacy"

Established practices in the approval process that make it difficult to enter the market without proven medical benefits diverge from the introduced laws and regulations, creating a misalignment. Interactions within the approval process, especially with the official advisory body, tend to emphasize medical benefits. Notably, consultancies actively guide manufacturers toward prioritizing medical benefits over pSVV, thus steering the guidance of the search away from pSVV and hindering market formation.

Positive expectations on the value of using pSVV that would support the *creation of legitimacy* remain mainly hypothetical. The economic effect, specifically, was formulated in the subjunctive by interviewees. Coupled with the pervasive *established practices*, this poses a significant obstacle to *creating legitimacy* for pSVV.

Discussion

Principal Findings

Our research explored the factors that need to be considered when bringing a specific digital health technology innovation to market through the implementation of a regulated market access pathway as a health policy approach.

For this example case study, the pSVV pathway, the descriptive analysis revealed that only a few DiGAs currently in the market have demonstrated a pSVV. Of the 11 currently listed DiGAs that have entered the market with a pSVV as one element of a positive health care effect since the introduction of the pathway in 2019, only 1 DiGA has a primary focus on pSVV (ie, pSVV as the primary end point of the positive health care effect). Notably, 2 of the products (developed by the same DiGA manufacturer) that demonstrate pSVV as a secondary end point conducted their clinical studies before 2019. This indicates that few manufacturers have taken the initiative to develop a product with a special focus on improving structures and procedures for patients, even though the introduction of the pSVV pathway was intended to encourage this. To date, pSVV is mostly used as an additional end point to medical benefits. To provide a basis for interpreting the results in further analyses on the performance factors of innovation systems shaped by regulated market access pathways, our initial conclusion is that the innovation in DiGAs targeting pSVV, which the pSVV pathway was designed to foster, has not yet been fully realized within the system. This is particularly daunting, as previous studies emphasize the need to focus more on products that address structural and procedural improvements for patients [53-55] and consider the concept of pSVV to be a "fundamental mechanism of action for DiGAs" [56].

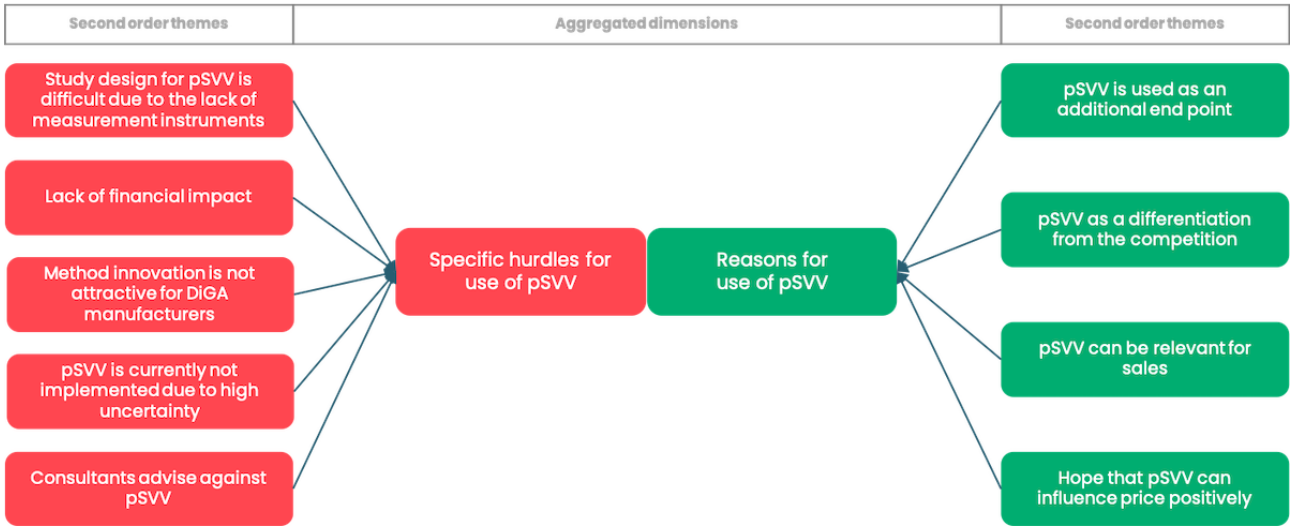
Our qualitative analysis of stakeholders' perspectives during market access reveals that evidence generation is the most critical component of the DiGA approval process. While multiple factors are considered in determining a positive health care effect, our findings suggest that, at the operational level, manufacturers of DiGAs primarily focus on demonstrating medical benefits as evidence for positive health care outcomes (Figure 2). Economic considerations, in light of the lack of established methodologies for measuring the defined key areas and uncertainty about the acceptability of the proposed study design, including pSVV, lead to more cautious use. Bearing the cost for methodological innovation is not considered attractive among manufacturers, particularly as DiGAs with pSVV so far do not negotiate substantially higher prices than DiGAs without pSVV [28]. Consistent with the findings of the descriptive analysis, the use of pSVV is often considered "incidentally" as an addition to medical benefit, only when a methodology for demonstrating one of the pSVV key areas exists for a specific product (Figure 3). It can be concluded that the specific challenges associated with proving the efficacy of pSVV, particularly the lack of established methodologies, currently outweigh its potential benefits. Previous studies have highlighted content and format security [57] as a critical factor, particularly for pioneers in medical technology, which also appears to hold true for the market entry of innovative products in DiGAs. The fact that only one company has attempted to pioneer a product specifically targeting benefits under pSVV may be attributed to the innovators' need for content and format security, in this case specifically the lack of standards to generate evidence for the targeted technology innovation. Without such security, the costs for pioneers become prohibitively high.

However, the implementation of the pSVV concept is recognized as vital for the health care system's evolution itself (Figure 4).

Our qualitative analysis highlights a common gap in health care innovation between the perceived importance of new technologies and their actual implementation. This gap is often influenced by systemic factors, such as regulatory conditions and inherent system inertia, alongside a general openness to innovation among stakeholders [58]. For the pSVV pathway, while there is strong stakeholder support for introducing products that demonstrate pSVV, significant operational hurdles, particularly concerning content and format security, have delayed its adoption. These barriers suggest that, despite a willingness to embrace this innovation, the pathway's practical challenges currently limit its broader impact (Figure 5).

XSL•FO
RenderX

Figure 3. Graphical illustration of selected parts of the data structure derived from Gioia methodology illustrating hurdles of DiGA manufacturers for considering possibilities within the new pathway as well as reasons for doing so. DiGA: digital health application; pSVV: patient-relevant structural and procedural improvement.



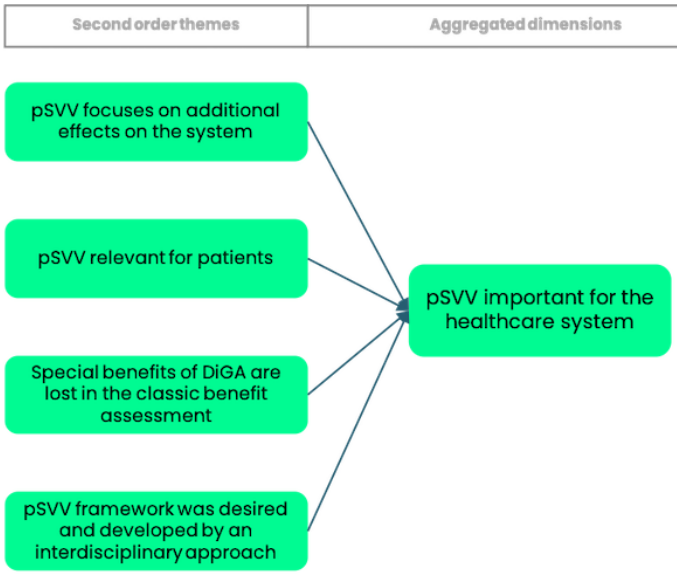


Figure 4. Graphical illustration of a selected part of the data structure derived from Gioia methodology illustrating the perception of the importance of patient-relevant structural and procedural improvements (pSVVs) in the health care system. DiGA: digital health application.

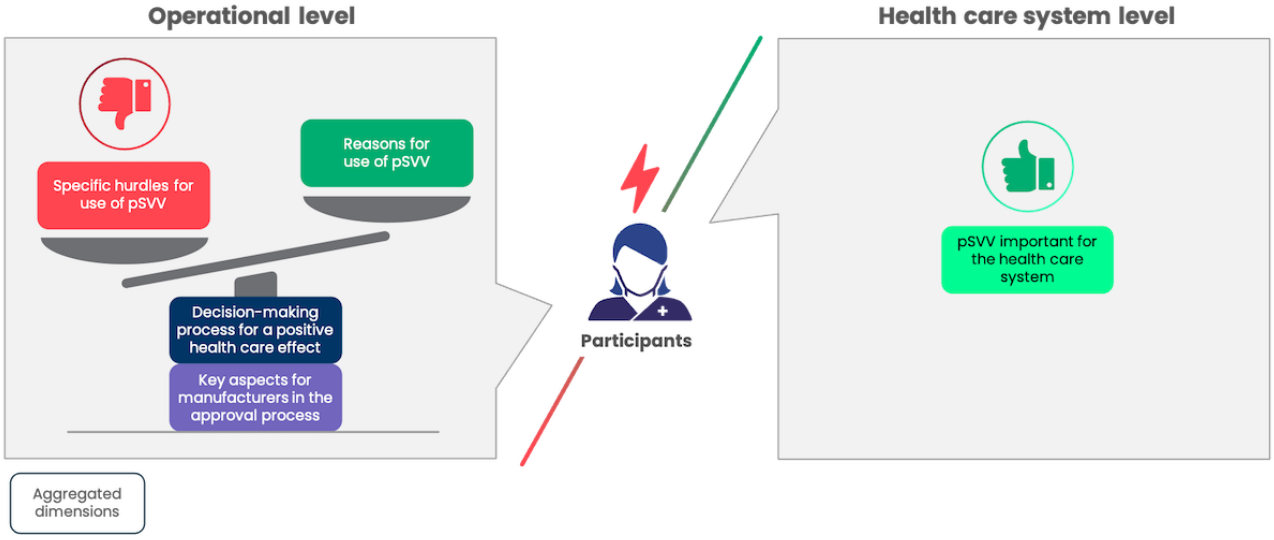


To further explore performance factors in the innovation system shaped by the pSVV pathway, we conducted an analysis of the innovation system's maturity level in relation to pSVV. Our findings indicate 3 central strategic factors of an innovation system in which we can expedite the adoption of innovative technology: *framework specification*, *active innovation processmanagement*, and *market formation stimulation*

While previous work has highlighted the general need for frameworks [16,59], our emphasis is on the degree of specificity required for the successful implementation of a market access pathway for DiGAs. In our example, the specification of the pSVV pathway, defined in the DiGA guide, requires 2D adjustments. First, the creation of a knowledge infrastructure would enable entrepreneurs to navigate the DiGA market, including pSVV, better if the development of exemplary models for pSVV products and especially congruent methodologies for demonstrating the evidence base of pSVV would exist. In addition, a multitude of studies highlight the ongoing challenges associated with identifying appropriate study designs that are capable of measuring effects solely attributable to the use of digital products [60-62]. We conclude that the presence of a specific level of knowledge infrastructure, which underpins the innovation driven by the introduction of a regulated market access pathway, can affect how widely it is adopted [6,63].

XSL•FO
RenderX

Figure 5. Underlying conflict leading to the underuse of patient-relevant structural and procedural improvements (pSVVs).

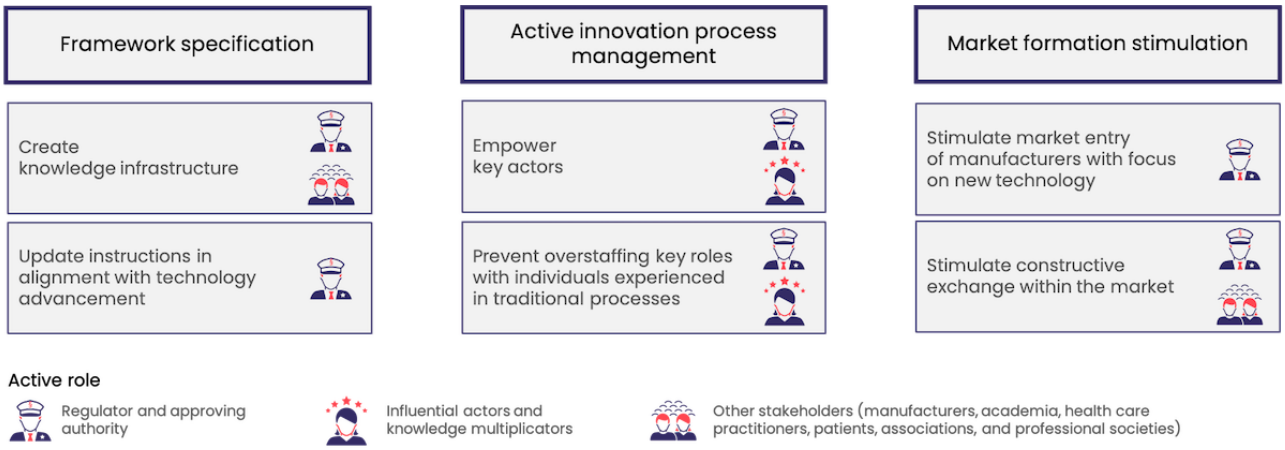
Second, studies in the field of regulated medical products have indicated that the uncertainty about the accepted content and format during the approval of new products can make the pathway into the market unattractive for first movers [57]. Our analysis has shown that the DiGA guide, which serves as the most relevant instruction at the operational level in this system, requires timely updates to keep pace with advancing knowledge development and ensuring up-to-date format and content security. Simultaneously, for the successful implementation of a pathway, *active innovation process management* is crucial. Providing training to key actors in the defined process, such as the BfArM or consultants, has been shown to be essential for empowering stakeholders to support and advance pSVV as an innovation. In addition, as previous work has highlighted the importance of education and awareness as well as patient and health care provider support while training for physicians on digital health solutions is limited [25,64], the inclusion of user groups and prescribing physicians can be focused to sharpen the objectives of pSVV. Conversely, it is crucial to ensure that involved actors are not overly familiar with traditional processes, as this can lead to inflexible adherence to these methods. The involvement of key actors with an excess of experience in medical benefits (ie, experienced regulatory assessor previously involved in assessing pharmaceutics) could potentially impede innovation speed if their participation is overly predominant.

Furthermore, targeted *market formation stimulation* can aim to introduce manufacturers into the DiGA market, focusing primarily on addressing pSVV key areas [65]. Creating positive examples can accelerate innovation at multiple levels. In addition, stimulating constructive exchange regarding the pSVV concept can expedite knowledge generation and distribution, contributing to faster market formation.

In summary, our study revealed that the lack of established methodologies for proving pSVV has led to significant uncertainty for manufacturers regarding the acceptable formats and evidence required, contributing to slower adoption. To complement these findings on the specific pathway level, the functional-structural analysis identified 3 key factors critical to enhancing the total innovation system: clearer framework specification to provide precise guidelines, active innovation process management to support stakeholders in navigating the regulatory process, and market formation stimulation to foster positive examples and increase engagement with the pSVV pathway. These factors are essential for overcoming both the operational and systemic barriers to successfully introducing innovative digital health technologies into a market.

As initiators of the systemic innovation of pSVV, the regulatory body can implement additional measures to promote its further establishment. This includes stimulating the development of a knowledge infrastructure by involving all stakeholders in the innovation system. Academia can actively contribute to advancing the definition of the pSVV and particularly developing suitable methodologies for evidence generation [66-68]. Existing mechanisms to promote scientific progress, such as dedicated research funds (eg, in Germany by the Federal Ministry of Education and Research or the Innovation Fund of the Federal Joint Committee), could be set up for this objective [69].

Initiating a public debate on pSVV can engage relevant stakeholders, such as professional societies and associations in a discourse to further develop the pSVV framework [13,66]. Economic measures, such as granting financial support for conducting clinical trials assessing pSVV or even tax incentives for implementation, can provide additional incentives for manufacturers driving innovation and initiating the pSVV market until these products are established in the standard of care. Furthermore, spaces can be created for key stakeholders in the system to educate themselves about pSVV. This could include offering policy laboratories or training programs for knowledge multipliers.



Consultancies and the BfArM, as influential players in the system, can provide room for their employees to further educate themselves about the possibilities of pSVV, to prevent disproportionately biased inclinations toward medical benefits. Ensuring a balanced wealth of experience regarding the use of medical benefits within the workforce can promote openness to innovative processes. It is critical to ensure that the experience of the staff responsible for evaluating the proof of benefit of

XSL•FO
RenderX

DiGAs is balanced in assessing medical quality [70]. Previous work has shown that the Food and Drug Administration might actively aid in similar innovation processes [71]. This assistance is rendered through the administration's in-depth knowledge to improve study designs and by championing innovative methods. Although the breadth of authority and scope of the regulated processes vary, BfArM or other regulatory agencies involved in the approval process and specifically in evaluating coverage eligibility can also contribute their expertise. For manufacturers seeking to use the potential of pSVV in their DiGAs, it is important to prioritize evidence of positive health care effects early in the development process. Identifying the "active ingredient" and its mechanism is crucial for crafting studies effectively assessing DiGA [60].

Besides proposing solutions for individual stakeholder groups within the health care system (Figure 6), the collaboration and coordination among all involved parties should be underscored as crucial for success. As highlighted on an international scale, effective collaboration between regulatory agencies, academia, app developers, payers, and health care providers is essential to truly leverage advances in science and technology and to translate the vision into reality, guided by the right incentives and guidelines [69,71,72].

Figure 6. Central strategic factors for progress exploration in the innovation system derived from an exemplary analysis of the patient-relevant structural and procedural improvement pathway.

Our analysis suggests that the strategic factors identified are valuable considerations for the establishment of a regulatory market access pathway, to ensure its widespread and successful adoption. Drawing on previous research, the strategic factor of content and format security [57] is highlighted, alongside the adoption of recognized and accepted methods for measuring proposed parameters [59,61,68,73-76]. This is particularly relevant in digital health technology aimed at patient empowerment, where significant progress is still needed [68,74]. Furthermore, it is advantageous to strike an optimal balance between leveraging established processes and frameworks allowing room for innovation [77]. As indicated by the strategic factor of innovation process management, it is crucial to carefully select and train key players and individuals in pivotal roles, equipping them with the specific skills and mindset needed to drive innovation. Finally, the strategic factor of market formation stimulation points to the critical need to consider the practicality of a framework in enabling a viable business model, particularly within the context of systemic innovation [21,60,78].

Limitations

Acknowledging the limitations of this study, a conclusive assessment of the economic value of pSVV is precluded, as no product with pSVV as a primary end point has undergone final price negotiation yet (Table S2 in Multimedia Appendix 1). In addition, it could be questioned whether pSVV can ever be the primary end point of a DiGA, as all DiGAs must also be CE–certified medical devices with the corresponding intended purpose. We have not explored this discussion in detail, as it can certainly be conducted more effectively with selected examples of products focusing on pSVV, once these are available in the market. Furthermore, our qualitative analysis, conducted through semistructured interviews, did not encompass all functional-structural dimensions of innovation systems. Entities, such as academia or associations were not mentioned by any interviewees and were thus not part of the evaluation. In addition, our sampling strategy did not include patients or physicians, as the study concentrated on identifying reasons for the scarce number of products targeting the pSVV key focus areas. This decision acknowledges the limited familiarity of end users and prescribers with the pSVV concept at this point and their marginal impact on market entry decisions shortly after the introduction of a new framework designed to facilitate market access.

Conclusions

This exploratory study examined critical factors for bringing digital health technology innovation to market through a regulated market access pathway, with a focus on the pSVV pathway as an example case. Key success factors identified included content and format security, the need for precise framework specification, active innovation process management, and market formation stimulation. These elements collectively help reduce uncertainties for manufacturers and promote broader adoption of digital health innovations. Our findings revealed that although the pSVV pathway was intended to encourage a focus on pSVVs, the current use remains limited, with most manufacturers prioritizing medical benefits as evidence of positive health care outcomes.

XSL•FO
RenderX

The mixed methods approach enriched the analysis by allowing a deep exploration of stakeholder perspectives through qualitative analysis, complemented by the functional-structural analysis of the technology innovation system. The combination of grounded theory and Gioia methodology enabled an objective and detailed examination of how market participants view and use the pSVV pathway, while the systemic analysis highlighted additional success factors in the broader innovation system context.

Our findings contribute valuable insights for stakeholders in the digital health sector, providing recommendations for policy adjustments that can strengthen innovation pathways. With this work, we contribute by identifying critical areas for improvement, including the need for clearer guidelines, the development of a knowledge infrastructure, and enhanced training for stakeholders to help overcome operational barriers. In addition, fostering public discourse on pSVV and introducing economic incentives, such as financial support for clinical trials, may further drive innovation. These recommendations are valuable for health care systems and regulatory bodies seeking to support similar pathways and advance patient-centered digital health solutions.

Furthermore, the impartial perspectives gathered from stakeholders, combined with a holistic analysis of the innovation system, contribute to identifying clear fields for action and proposing solutions relevant beyond this specific case. Our findings provide transferable insights for health care systems embarking on similar systemic innovations, as seen in countries like France, Belgium, and Austria, where comparable concepts to pSVV are being introduced. The implications of our research extend to other systemic innovation initiatives in health care systems facing significant adoption challenges that could otherwise lead to initiative failure. Ongoing efforts from national and international scholars are critical in supporting the success of these initiatives. In Germany, for example, a reimbursement pathway for digital nursing care applications (DiPA), a “regulatory sibling” to DiGA, has been established. While speculative, similar challenges may emerge for DiPA manufacturers, particularly concerning the nursing benefit that aligns with both medical benefit and pSVV, possibly contributing to the current absence of DiPA in the marketplace and highlighting gaps in this systemic innovation approach.

Acknowledgments

The authors are grateful to the 2 anonymous reviewers whose insightful comments and suggestions contributed substantially to the quality of this manuscript. Furthermore, the authors extend their heartfelt thanks to all the participants of this study, whose time, effort, and invaluable contributions made this research possible.

The study was part of a doctorate program at our university. Publishing fees were supported by the Funding Programme Open Access Publishing of the Hamburg University of Technology.

The authors used generative artificial intelligence (ChatGPT, version 4o; OpenAI) to incorporate minor improvements in sentence structure and wording throughout the publication; the contents and conclusions have purely been developed by the authors [79].

Data Availability

The datasets generated and analyzed during this study are not publicly available due to data protection reasons but are available from the corresponding author on reasonable request.

Authors' Contributions

SG conceived and designed the study, interviewed the participants coded the interviews, analyzed the data, and drafted the manuscript. MG transcribed the interviews using Whisper Transcription (Good Snooze). MG cocoded on randomly selected interviews and took part in reflexive discussion and consensus building together with SG. MG supervised the project. SG and MG interpreted the results and finalized the manuscript. All authors approved the final manuscript.

Conflicts of Interest

SG is employed at a statutory health insurance company in Germany. She declares that her work at the statutory health insurance is unrelated to this topic. MG has previously worked as a consultant for digital health application (DiGA) manufacturers. He declares that his previous work is unrelated to the results of the conducted work.

Multimedia Appendix 1

Semistructured interview questionnaires, overview of interview participants, full data structure based on Gioia methodology, negotiated digital health application prices and health care effects, selected interview codes generated using grounded theory, functional-structural analysis of patient-relevant structural and procedural improvement as a systemic innovation, and derivation of strategic fields using the functional-structural framework by Wieczorek and Hekkert [34].

Abstract

Large language models (LLMs) are rapidly advancing medical artificial intelligence, offering revolutionary changes in health care. These models excel in natural language processing (NLP), enhancing clinical support, diagnosis, treatment, and medical research. Breakthroughs, like GPT-4 and BERT (Bidirectional Encoder Representations from Transformer), demonstrate LLMs' evolution through improved computing power and data. However, their high hardware requirements are being addressed through technological advancements. LLMs are unique in processing multimodal data, thereby improving emergency, elder care, and digital medical procedures. Challenges include ensuring their empirical reliability, addressing ethical and societal implications, especially data privacy, and mitigating biases while maintaining privacy and accountability. The paper emphasizes the need for human-centric, bias-free LLMs for personalized medicine and advocates for equitable development and access. LLMs hold promise for transformative impacts in health care.

(J Med Internet Res 2025;27:e59069) doi:10.2196/59069

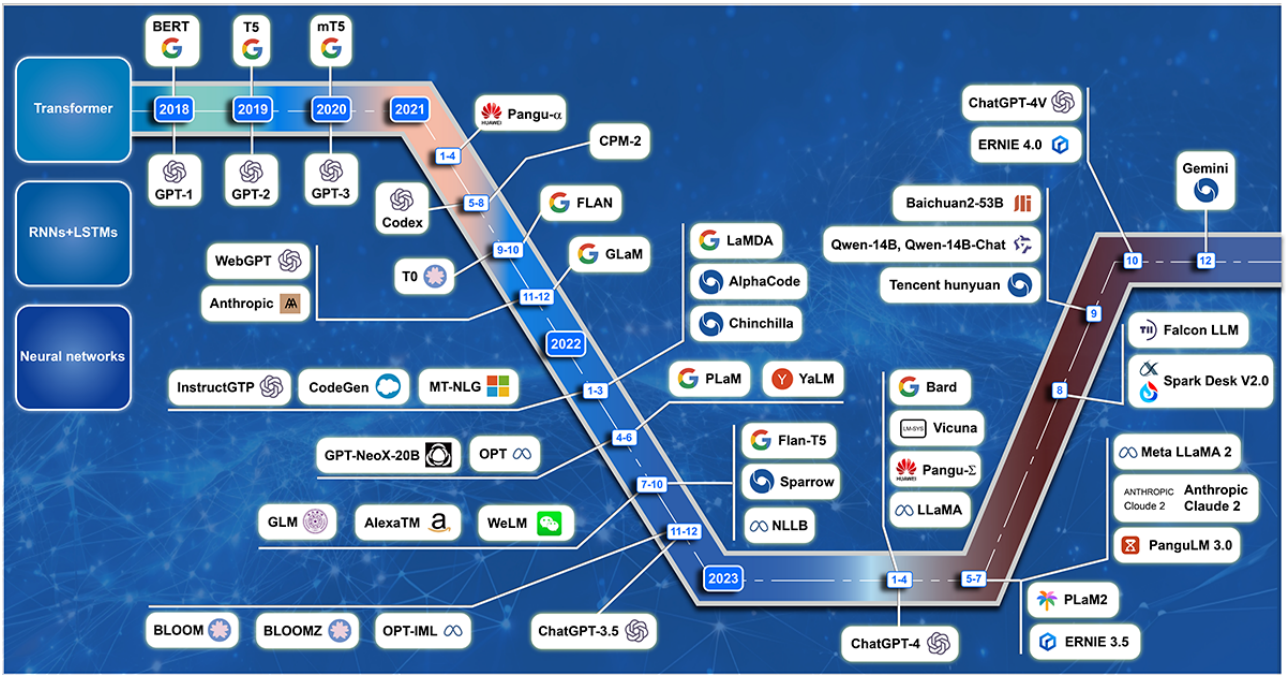
Introduction



Recent advancements in artificial intelligence (AI) have catalyzed the development and significant breakthroughs of large language models (LLMs), placing them at the forefront of AI research [1-4]. LLMs are deep learning models that generate human-like text by predicting the next word in a sequence based on statistical patterns learned from vast text data. These models leverage deep learning algorithms to interpret and generate natural language, using extensive corpus data to enhance pretrained language models, a cornerstone of natural language processing (NLP) [5,6]. Characterized by their immense scale, these models often consist of hundreds of millions to billions of parameters and are trained on vast textual datasets [7,8]. Their ability to efficiently process natural language data with minimal human intervention, capturing intricate grammatical structures, lexical nuances, and semantic contexts, is noteworthy. Globally recognized LLMs include the ChatGPT series, BERT (Bidirectional Encoder Representations from Transformer), PaLM, LaMDA, and Meta's Llama series, with China contributing models such as Baidu's "Wenxin Yiyan," 360's LLM, Alibaba's "Tongyi Qianwen," and SenseTime's LLM [9]. The evolution of LLMs represents over 7 years of relentless technological innovation and research, marking a significant milestone in AI development since the inception of the Turing machine.

LLMs primarily function to comprehend, generate, and interact through language. In NLP tasks, such as text classification, named entity recognition, and sentiment analysis, their proficiency is unparalleled [10-12]. Beyond these applications, LLMs are expanding their influence. In mathematics, they assist in solving complex problems and contributing to mathematical proofs [13]. In software development, their capabilities include automatic code generation, debugging assistance, and complex algorithm explanation [14]. Intriguingly, LLMs are venturing into artistic creation, exhibiting talent in generating poetry, stories, and music [15,16].

In the medical domain, LLMs are poised to revolutionize clinical decision support. They can assist health care professionals in diagnosing diseases with enhanced accuracy and speed, provide treatment recommendations, and facilitate the analysis of medical records by processing large volumes of medical data [17-20]. They are instrumental in swiftly navigating vast medical literature, providing health care professionals with essential research, guidelines, and information, thus saving time and grounding medical treatments in current knowledge [21-25]. Additionally, LLMs can interact directly with patients, offer medical consultations, and handle document processing efficiently [26-28]. For example, health care professionals use LLMs to assist in diagnosing diseases by quickly processing and interpreting large volumes of patient data such as electronic health records and imaging results. Clinicians also leverage LLMs for treatment planning, where the models suggest potential treatment options based on the latest medical guidelines and patient-specific data. Moreover, LLMs are used in streamlining administrative tasks, such as generating and managing medical documentation, allowing clinicians to spend more time with their patients. Their role in drug research and development is also emerging, aiding in new drug discoveries through detailed analysis of chemical and biological data [29,30]. As such, LLMs are reshaping research methodologies and applications across various fields, particularly in medicine, equipping doctors with advanced tools for more accurate and efficient diagnosis and treatment, while offering patients more convenient and effective medical services. The potential for broader applications of LLMs in the medical field is vast, and there is a strong rationale to expect their significant impact on future health care advancements (Figure 1).

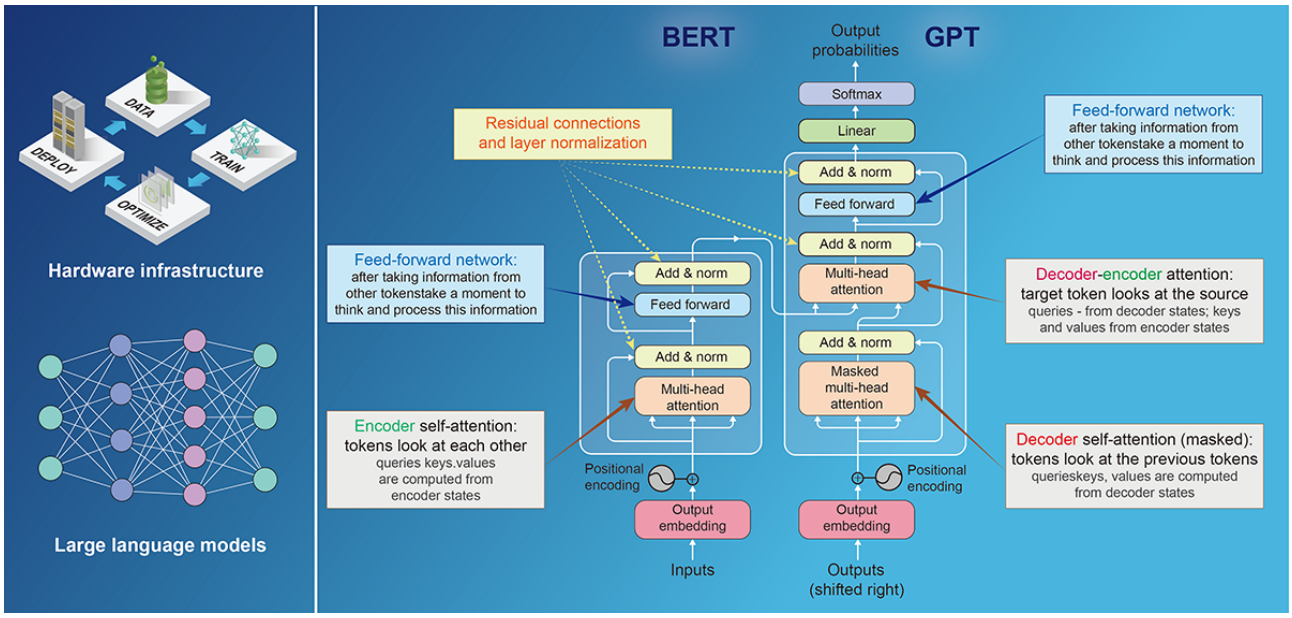
Figure 1. Timeline of mainstream LLMs commercially available to the public. The technological evolution of LLMs, highlighting several key technologies and models. It includes RNNs and LSTMs from the 1990s, Google's Transformer model introduced in 2017, Google's BERT model released in 2018, and the GPT series by OpenAI. Specific emphasis is placed on three major milestones: the first open-source LLM—GPT-2, and the first widely acclaimed LLM—GPT-3. These developments signify major advancements in LLMs within the field of natural language processing. BERT: Bidirectional Encoder Representations from Transformers; LLM: large language model; LSTM: long short-term memory network; RNN: recurrent neural network.

LLM Technical Background and Hardware Infrastructure

The evolution of LLMs, like OpenAI's GPT-3 and Google's BERT, has been monumental, driven by advancements in AI chip computing power and large, high-quality datasets [31]. The Transformer model, introduced by Google in 2016, underpins this progress, predicting words in sentences based on statistical correlations [32,33]. Notably, GPT-3 in 2020 showcased the significance of model size and data quality.



The operation and training of LLMs, such as ChatGPT, require substantial hardware infrastructure [34]. This includes graphics processing units (GPUs) or tensor processing units (TPUs) with thousands of cores, extensive RAM (several terabytes), over 48 GB of VRAM on GPUs, high-performance solid-state drives, and fast, low-latency networks (10 to 100 Gbps) [35,36]. Effective cooling systems and reliable power supplies are also essential. Compatibility with software frameworks, like TensorFlow and PyTorch, is necessary for optimizing training and deployment. The training of GPT-3, for instance, costs around US $1.4 million, and operational costs for models, like ChatGPT, can reach up to US $700,000 daily, with significant energy consumption.

Future technology advancements are expected to reduce the costs and improve the efficiency of LLMs. Progress in GPU and TPU technologies, along with hardware tailored for LLM training, will drive efficiency. Compact model structures through knowledge distillation, model pruning, transfer learning, energy-efficient practices, distributed training, and edge computing are anticipated. Semisupervised and self-supervised learning methods will also play a role in training models with fewer labeled datasets [37,38]. ChatGPT's recent updates showcase improvements in response speed, handling complex queries, multimodal functionality, global language support, and enhanced privacy and security measures [39].

In health care, deploying large-scale medical models faces unique challenges due to data security and privacy concerns. Hospitals typically have CPUs for general computing, with limited access to GPUs. Medical LLMs, generally smaller than general-purpose LLMs, still require substantial investment in operational hardware [40,41]. For instance, a model with 13 billion parameters might cost under US $138,000 while larger models for entire hospitals may require advanced GPU solutions costing around RMB 10 million. Effective deployment demands careful consideration of model scale, computational resources, data security, and cost control (Figure 2).

RenderX

Figure 2. The architectural designs of LLMs: a study of self-attention mechanisms and structural variations. The image depicts the hardware infrastructure for LLMs and their implementation in the BERT and GPT models. On the left, there is a network diagram showing servers and computing devices needed to run these models, labeled with hardware such as TPU and GPU. On the right, the structure of BERT and GPT is compared in detail, including positional encoding, self-attention mechanisms, feed-forward networks, addition and normalization layers, and the computation of output probabilities. Although these models have different approaches to processing text, both are large neural network models based on deep learning and self-attention mechanisms. BERT: Bidirectional Encoder Representations from Transformers. GPU: graphics processing unit; LLM: large language model. TPU: tensor processing unit.

Advancing the Integration of LLMs in Health Care: The Imperative for Evidence-Based Research and Collaborative Evaluation

Overview

In the contemporary health care landscape, the paradigm of evidence-based medicine is instrumental in shaping medical decision-making processes. This methodology integrates top-tier research evidence with clinical expertise and aligns it with patient values and expectations, thereby informing patient care decisions. Evidence-based medicine ensures that medical interventions are grounded in scientific evidence rather than solely relying on a physician's experience or intuition, enhancing patient safety and the efficacy of treatments [42-45].

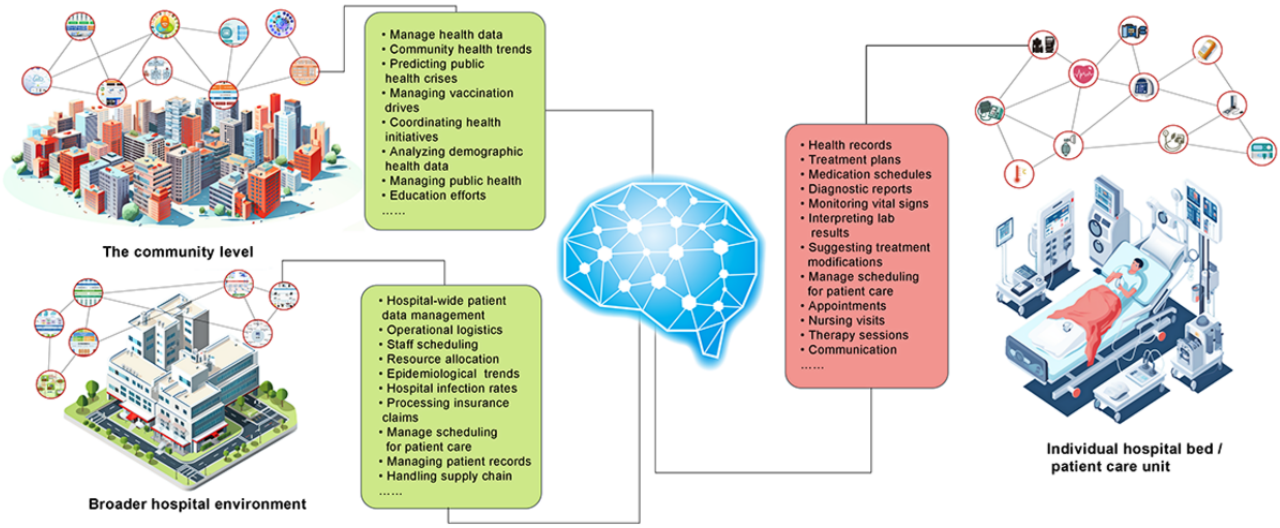
The integration of LLMs into the medical field introduces a significant challenge: the current scarcity of evidence-based medical research concerning the application of LLMs in health care settings [46]. Although LLMs have shown remarkable efficacy in various sectors, the unique context of medicine, with its direct implications for human life and health, necessitates a cautious approach to the introduction of untested technologies or methods into clinical practice [47]. Despite their robust data processing capabilities, LLMs present a potential risk for prediction errors in clinical environments. The medical domain, with its complex interplay of biology, physiology, and pathology, might be challenging for machine learning models to fully encapsulate, especially considering the intricacies and variability inherent in medical data [48]. Furthermore, the realm of medical decision-making often requires a high level of expertise and experience, aspects that may not be entirely replicable by LLMs. The consequences of medical decisions far surpass those in other sectors, where a misdiagnosis or incorrect treatment recommendation could directly jeopardize a patient's life. Hence, it is imperative to back any new technological innovation, including LLMs, with solid scientific evidence before they are implemented in medical practice.

Currently, empirical studies examining the application of LLMs in the medical field are limited. This scarcity of research implies an inability to definitively assess the accuracy, reliability, and safety of LLMs within a health care context. Model reliability refers to the consistency and dependability of a model's outputs across different datasets or under varying conditions. In medical applications, the reliability of LLMs is critical, as it directly affects the accuracy of diagnoses and treatment recommendations, where any inconsistency could have serious consequences for patient care. To comprehensively understand the potential benefits and risks associated with LLMs in medicine, a more robust body of clinical research is required. This research should encompass randomized controlled trials, observational studies, and extensive collaborative research, which are critical to evaluating the clinical utility of LLMs accurately [49].

To accelerate the empirical evaluation of LLMs in the medical field, fostering collaboration between medical institutions, research organizations, and technology companies is essential. This interdisciplinary collaboration ensures the comprehensiveness and quality of the research, facilitating the rapid advancement and application of LLM technologies. To enhance the transparency, trustworthiness, and ethical application of LLMs in health care, it is crucial to address the societal implications, particularly in terms of data privacy. Publicizing research findings and fostering interdisciplinary

XSL•FO
RenderX

collaboration among doctors, researchers, and ethicists will be key to ensuring that LLMs are used responsibly and equitably. Furthermore, the integration of robust data privacy measures and adherence to ethical standards must be a priority to prevent potential misuse or unintended consequences that could undermine public trust. Such an approach ensures that LLMs' application in the medical field is underpinned by scientific rigor, is safe, and genuinely benefits both patients and the health care system.



Integrated Application of LLMs in Medical System

As we witness ongoing advancements in medical technology, the integration of LLMs with other tools and platforms within health care systems becomes increasingly crucial [50]. This fusion provides health care professionals with powerful tools to process, analyze, and effectively use vast amounts of health care data [23,51-54]. The integration of LLMs, such as ChatGPT, into medical systems has the potential to drive transformative progress in health care delivery. First, LLMs can potentially enhance diagnostic accuracy and clinical decision-making by analyzing comprehensive medical data to identify relevant information and suggest potential diagnoses based on presented symptoms [55-57]. Second, their proficiency in text processing and generation assists medical professionals in efficiently summarizing medical literature, facilitating research, and improving communication between health care providers and patients [58-61]. The rapid adoption of readily available LLMs, such as ChatGPT, within the medical community, signifies recognition of their potential to transform health care delivery [62-66].

However, the application of LLMs in clinical settings is not without challenges [67]. A primary concern is the generalizability of these models. Although LLMs have shown outstanding performance in numerous standard tasks, the complexity and diversity of the medical field suggest that these models may be susceptible to prediction errors in real clinical scenarios. Such errors can have serious implications, particularly when they influence critical health and life decisions. Additionally, the medical field encompasses a vast array of domain-specific knowledge that might exceed the training scope of LLMs, potentially leading to misunderstandings in complex medical scenarios.

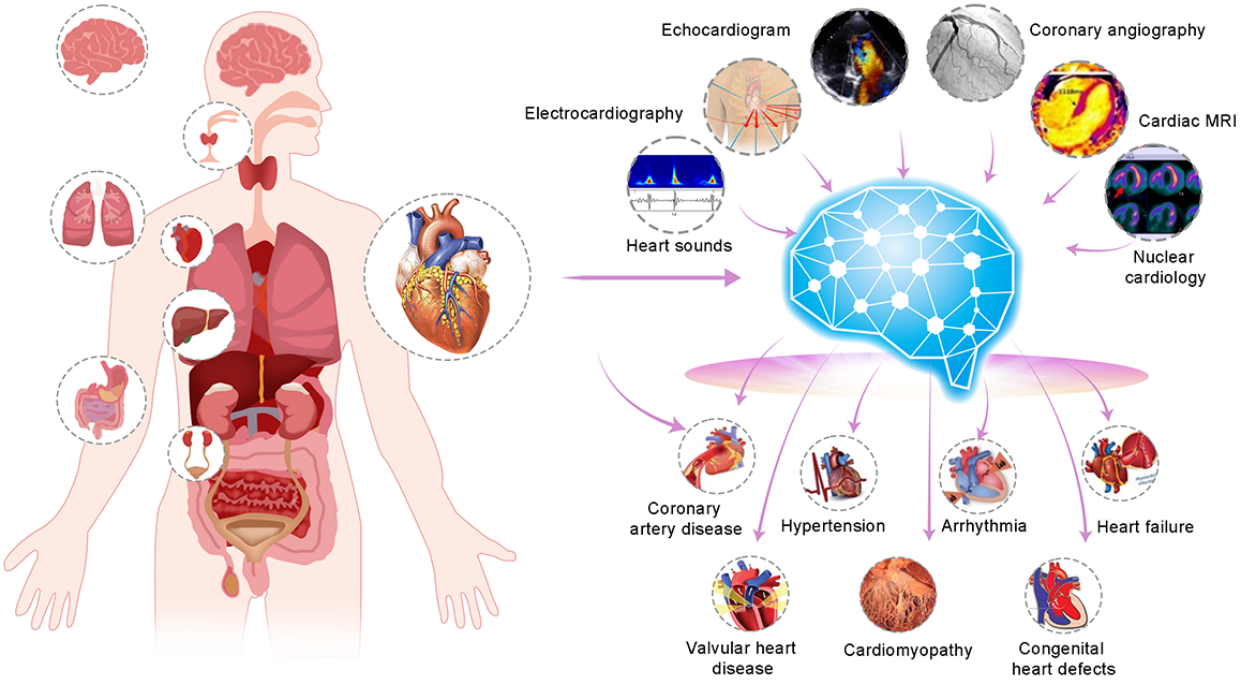
Despite these challenges, the potential benefits and impact of LLMs in health care are considerable. LLMs can notably enhance the efficiency of medical workflows by automating routine processes such as appointment scheduling, diagnosis, and report generation [68]. Their data-driven recommendations provide powerful decision support to doctors, assisting them in making more accurate and timely decisions. Current digital health workflows often burden physicians with extensive data entry, querying, and management tasks, leading to information overload and fatigue. LLMs can alleviate these burdens by automating these tasks, thereby saving valuable time for health care providers. Moreover, by analyzing and integrating patients' medical data, LLMs can offer tailored diagnoses and treatment recommendations, improving the overall quality of health care delivery. LLMs also play a crucial role in enhancing doctor-patient interactions. Leveraging NLP technology, they can better comprehend patients' needs and concerns, offering more personalized medical advice [69]. This not only boosts patient satisfaction but also enhances the overall effectiveness of medical services. The potential of LLMs to optimize digital health care workflows is undeniable. With further technological advancements and empirical research, LLMs are expected to play an increasingly significant role in the future of health care (Figure 3).

Figure 3. Integration of LLMs in health care systems across different scales. LLMs can assist in monitoring and analyzing patient health records, treatment plans, and laboratory results at the individual bed level while managing care schedules and facilitating doctor-patient communication. At the hospital level, LLM helps manage patient data, operational logistics, staff scheduling, and resource allocation, while analyzing epidemic trends and hospital infection rates. At the community level, LLM can be used to predict public health crises, manage vaccination campaigns, coordinate community health initiatives, and analyze population health data to improve health policy. LLM: large language model.

XSL•FO
RenderX

Multimodal LLMs in Real-World Medical Scenarios

The advent of multimodal LLMs is bringing about a paradigm shift in the medical field by offering the capability to process and generate diverse data types such as text, images, sounds, and videos. This integration of multiple data types enables LLMs to provide more comprehensive and accurate predictions, thereby unlocking unprecedented potential [70-73]. To understand their role, it is essential to define what multimodal LLMs entail. Multimodal LLMs excel in processing, interpreting, and generating a wide array of data types, which significantly enhances their predictive capabilities. For instance, in the medical field, combining textual data from patient records with imaging data from magnetic resonance imaging (MRI), computed tomography scans, and x-rays allows these models to provide more nuanced and precise diagnoses. Additionally, integrating audio data from patient interviews or video data from medical procedures can further enrich the model's understanding, leading to more accurate and personalized treatment recommendations. By leveraging the strengths of various data types, multimodal LLMs can offer a holistic view of a patient's condition, which is often crucial for complex diagnoses and treatment planning.



The utility of LLMs is increasingly becoming a focal point in medical imaging [74-76]. For instance, when a patient undergoes an MRI or computed tomography scan, an LLM can swiftly analyze and integrate the image data with the patient's textual medical records, thereby providing more comprehensive and detailed diagnostic insights. Additionally, LLMs have the capability to automatically identify and highlight crucial areas in medical images, thus providing clinicians with clear references that aid in identifying potential issues [77]. Moreover, LLMs can generate automated image reports, offering initial interpretations and treatment suggestions based on the analyzed image data, significantly boosting the efficiency and accuracy of medical diagnoses and treatments.

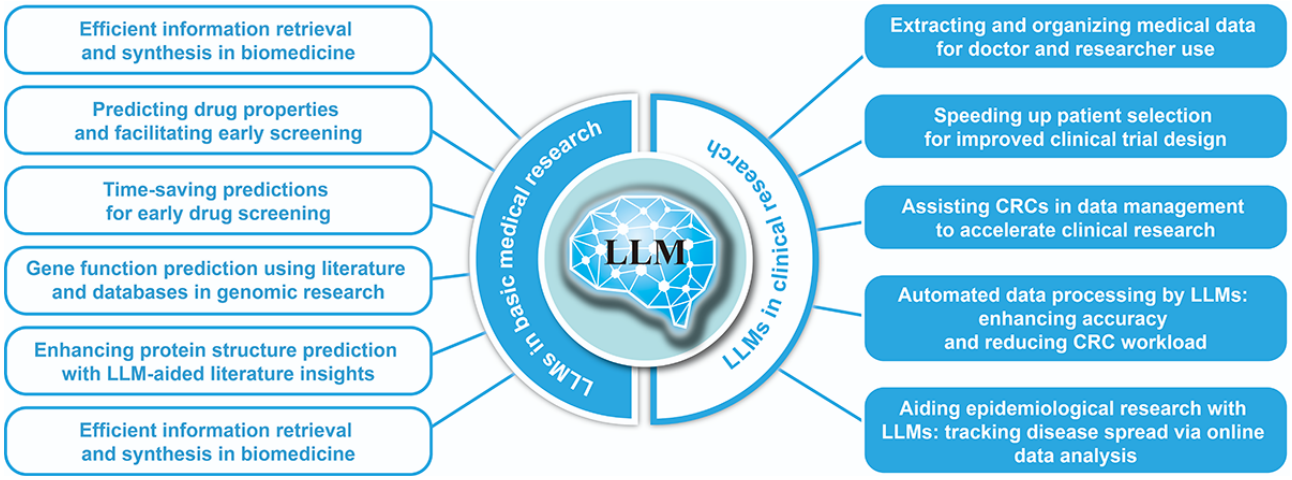
Multimodal LLMs are revolutionizing the field of telemedicine, transforming the dynamics of doctor-patient interactions [55,78]. For instance, LLMs have been successfully integrated into MRI analysis, where they can rapidly interpret imaging data and provide diagnostic recommendations. This has significantly reduced the time required for diagnosis and improved accuracy. However, the use of LLMs is not without its challenges. A notable example is Google BARD, which recently demonstrated racial bias in patient diagnosis, disproportionately affecting minority groups. This case highlights the dual-edged nature of LLMs in health care—they offer substantial benefits in efficiency and accuracy, yet they also pose significant risks if not properly validated and monitored for biases. Furthermore, the integration of LLMs with smart sensors and devices enables the continuous monitoring of patient's physiological data, such as heart rate and blood pressure, facilitating early detection and intervention for any health anomalies, thus significantly bolstering patient health management.

In summary, multimodal LLMs offer a novel and efficacious approach to diagnosis, treatment, and health care management. Their robust capabilities in data processing and integration allow medical professionals to deliver more precise and efficient services to patients. At the same time, these models enable patients to access medical advice and care with greater convenience. As these technologies continue to evolve and improve, their significance and impact in the medical field are expected to grow exponentially (Figure 4).

XSL•FO
RenderX

Figure 4. The importance of multimodal large language models in medical applications. The central heart represents the cardiac health status of the human body. The surrounding circular icons depict various cardiac conditions including coronary artery disease, hypertension, arrhythmia, heart failure, valvular heart disease, cardiomyopathy, and congenital heart defects. These conditions are detected and analyzed through different medical imaging and diagnostic technologies such as electrocardiography, heart sounds, echocardiogram, coronary angiography, cardiac MRI, and nuclear cardiology. The results from these diagnostics are processed by an AI system to determine the type and severity of cardiac disease, assisting physicians in formulating treatment plans. MRI: magnetic resonance imaging.

The Key Role of LLMs in Medical Research



In the field of fundamental medical research, the capabilities of LLMs in AI are being increasingly recognized [79-82]. LLMs can swiftly retrieve and organize crucial information from vast biomedical literature, providing researchers with an efficient tool to access and synthesize the latest research findings on specific drugs, diseases, or genes [83]. In drug discovery, LLMs can predict the activity, toxicity, and pharmacokinetic properties of new compounds, facilitating early-stage drug screening [84]. These predictions not only save time but also facilitate the early-stage screening of potential drug molecules. LLMs can use existing literature and databases to predict the potential functions of newly discovered genes, a crucial aspect of genomic research, given the daily discovery and study of new genes. While protein structure prediction depends primarily on specialized models, such as AlphaFold, LLMs can enhance these models by supplying pertinent information from literature, thereby increasing prediction accuracy. In epidemiological research, LLMs can aid researchers in tracking and predicting disease spread by analyzing social media and other web-based text data, offering data support for public health decision-making. Finally, in bioinformatics applications, LLMs can assist researchers in predicting patterns, functional domains, and similarities to known biological sequences. Despite their extensive applications in biomedicine, LLMs cannot entirely replace laboratory experiments or in-depth biomedical expertise. Instead, they should be considered powerful supplementary tools, rather than replacements.

LLMs play a pivotal role in clinical research. They aid doctors and researchers by extracting essential information from medical records, and by organizing and categorizing data for easier analysis and application. For instance, they can expedite the selection of suitable patients for enrolment, thereby enhancing the design and implementation of clinical trials. In the role of a clinical research coordinator, these models assist with data entry, verification, and analysis, thereby accelerating the clinical research process. Through automated data processing and real-time analysis, LLMs can ensure data accuracy and completeness, while also reducing the workload of clinical research coordinators. This, in turn, speeds up the clinical research process and enhances research quality.

Although LLMs have revolutionized biomedicine by simplifying literature searches, aiding drug discovery, annotating gene functions, and supporting epidemiological studies, they experience certain drawbacks. Their ability to swiftly parse large datasets and make predictions may be counterbalanced by potential limitations in real-world validation [85]. For example, while they can predict a drug molecule's properties, the actual biological response may vary. Similarly, despite gene function predictions being well grounded, they may not fully encapsulate the breadth of gene interactions. Moreover, using LLMs to analyze epidemiological trends without correlating them to underlying data could misdirect public health interventions. Therefore, while LLMs are undeniably beneficial to biomedicine, it is essential to adopt a balanced approach, combining their computational prowess with rigorous experimental validation and expert review, to fully harness their potential without sacrificing scientific rigor (Figure 5).

XSL•FO
RenderX

Figure 5. The crucial role of LLMs in medical science: bridging basic research and clinical trials. This illustration highlights the versatile roles of LLMs in medical research. LLMs analyze medical texts to uncover trends and inform research directions, facilitate hypothesis generation, and enhance clinical trial designs. They personalize medicine through data-driven treatment plans and use predictive modeling to inform clinical trial outcomes. LLMs also streamline research by integrating data and maintaining regulatory compliance. They assist in medical communication and education and evaluate the societal impact of clinical research. LLM: large language model.

Great Challenges of LLMs in Medical Scenarios and Feasible Roadmap

The integration of technology in health care invariably brings a mix of anticipation and challenges, particularly given its direct impact on human life and health. As a leading exemplar of current AI technology, LLMs present a complex array of opportunities and challenges in the medical field, warranting thorough exploration and discussion [86-88].

Handling medical data, some of the most private and sensitive information about individuals, is a significant challenge for LLMs. As LLMs are increasingly integrated into health care, ethical considerations surrounding data privacy and societal impact must be prioritized during their development and deployment. The key lies not only in using this data to enhance medical efficiency but also in implementing robust data protection frameworks to prevent misuse, leakage, and unauthorized access. Furthermore, addressing these ethical challenges requires ongoing dialogue among technologists, health care professionals, policy makers, and the public to ensure that LLM deployment aligns with societal values and legal standards [80,89]. A potential technical solution involves anonymizing patient data, ensuring that neither processing nor transmission stages can be linked to specific individuals. Concurrently, medical organizations and technology providers must establish robust data management and access protocols, ensuring clear authorization and purpose for each data access.

Interpretive challenges loom large with LLMs in medicine. Medical decision-making is distinct from other fields due to its complexity and direct implications for patients' lives and health. When LLMs provide diagnostic or treatment suggestions, it is vital that the rationale behind these recommendations is transparent and comprehensible [90-92]. This brings us to the concept of interpretability in machine learning, which refers to the ability to understand and explain how a model makes its decisions. In the context of health care, interpretability is a significant challenge because clinicians must trust and validate the outputs of LLMs, especially when these models influence critical medical decisions [93]. Developing mental models can aid LLMs in presenting their decision-making logic in a manner that is more accessible to human users. Leveraging deep learning and other machine learning technologies, LLMs can extract disease pathophysiological mechanisms from a vast corpus of medical literature and data, providing a scientific basis for their outputs. To further enhance interpretability, LLMs could use visual tools, like graphics and animations, to clarify the logic and evidence underpinning their decisions for both physicians and patients [94,95].

The issue of technical bias and the possibility of generating misleading information or "hallucinations" are inherent challenges in LLMs. In this context, hallucinations refer to instances where LLMs produce outputs that are factually incorrect or misleading, often because the model attempts to generate an answer despite lacking sufficient context or knowledge. These hallucinations can be especially problematic in medical scenarios, where inaccurate information can have severe consequences. The data sources for these models, often anonymized consultation data and digital materials, are not uniform and vary in quality, sometimes containing erroneous samples. Fine-tuning LLMs based on such data may lead to biased or skewed medical recommendations [96,97]. Addressing this requires rigorous data auditing and the establishment of continuous bias-correction mechanisms. To mitigate the risk of hallucinations, knowledge enhancement methods, such as integrating a knowledge retrieval library or search enhancement tools, can be beneficial. The LLM's responses can be cross-referenced with retrieved data to filter out inconsistencies with reality. Another approach involves reinforcement learning based on human feedback, where high-quality feedback is provided to fine-tune and correct model outputs in collaboration with medical experts [98,99].

The potential of AI to create "information cocoons" through personalized content, potentially reinforcing biases, is another critical aspect that needs to be addressed, especially in the medical domain [100]. AI technologies, including LLMs, in medicine require stringent scrutiny and continuous evaluation

XSL•FO
RenderX

to align with the field's unique characteristics and ethical standards. Ensuring privacy protection, eliminating biases and discrimination, and establishing clear accountability are essential. The use of LLMs should be guided by respect for life, aiming to enhance patient well-being and treatment outcomes, without compromising individual interests. A continuous monitoring and evaluation system is crucial for assessing the effectiveness of LLMs and managing potential risks. Regulations should be regularly updated to keep pace with AI advancements, ensuring medical safety and patient rights. By prioritizing safety, fairness, and effectiveness, we can fully leverage LLMs and other AI technologies to facilitate a transformative revolution in medicine, while upholding human values and rights.

In the era of information and intelligence within the medical field, the application of LLMs harbors immense potential [101]. However, the accompanying challenges are equally noteworthy and merit careful consideration. The ongoing discourse should emphasize not only the deeper integration of LLMs into medical practice but also their alignment with both the professional needs of health care providers and the experiential needs of patients [102,103].

Incorporating the theory of mind into LLMs can significantly enhance their utility in the medical field. This concept, which involves understanding others' thoughts, feelings, and intentions, is crucial for fostering trust and empathy within health care interactions. Medicine is not solely a science; it is also an art, deeply influenced by each patient's unique emotional, value-based, and experiential landscape. An AI system endowed with the capability to appreciate and respond to these individual differences can offer more personalized and compassionate medical advice [104,105]. By using the theory of mind, LLMs can gain deeper insights into patients' inherent needs and respond with more attentive and empathetic advice [106-108]. When LLMs can emulate the thoughts and feelings of both doctors and patients, their outputs transcend mere data; they become imbued with empathy and human care, enhancing the patient's treatment experience and fostering stronger trust and communication between doctors and patients. For example, in interactions with terminal patients, LLMs could suggest more compassionate communication strategies, aiding both doctors and patients in navigating these sensitive and complex situations.

LLMs can be synergistically combined with other advanced technologies, such as virtual reality and augmented reality, to transform medical consultations into more immersive and informative experiences. This integration can provide patients with a deeper understanding of their health conditions, empowering them to make more informed decisions regarding their treatment. The evolution of LLMs is also contingent upon the development of efficient and precise algorithms capable of adeptly handling complex medical data, which is essential for accurate and timely medical decision-making. As technology progresses, the use of LLMs in the medical field is expected to become increasingly intelligent, efficient, and personalized, thereby enhancing not only the quality of medical services but also the overall patient experience and driving the evolution and transformation of the health care industry.

In our pursuit of technological progress, we must adhere to a fundamental principle: ensuring that technology is accessible to all. This is particularly pertinent in the context of LLM adoption, where it is crucial not to overlook those who may be marginalized by the technology gap [109,110]. Whether addressing the needs of rural farmers or urban older adults, every individual should have the opportunity to benefit from LLMs. This broad adoption must span various geographical regions and encompass diverse languages and cultural contexts, catering to users speaking English, Chinese, or local dialects [111,112]. Achieving this objective is not solely a technological challenge but also a social imperative. We must ensure that the design and application of LLMs overcome language and cultural barriers, truly reaching and benefiting a diverse global populace. Additionally, addressing technology accessibility issues is vital. For individuals in technologically underserved areas or older adults unfamiliar with new technologies, simpler access methods and more user-friendly interfaces are needed to facilitate effortless use of LLMs.

While the potential of LLMs in health care is significant, realizing this potential requires ongoing research, innovation, and dedication. Continuous efforts are necessary to refine LLM technology continually and ensure its broad adoption across all sectors of society. We firmly believe that with sustained commitment, LLMs will catalyze transformative changes in health care, benefiting society at large. By championing technological inclusivity, we can not only enhance the quality and efficiency of medical services but also promote overall societal health and well-being.

Economic Considerations in the Deployment of LLMs in Health Care

LLMs require significant computational resources for training and maintenance, which translates to substantial financial costs. In the medical domain, these costs can be particularly prohibitive due to the need for specialized data, high levels of accuracy, and continuous updates to ensure model relevance and safety.

Training a state-of-the-art LLM, such as GPT-3, requires access to extensive hardware infrastructure, including thousands of GPUs or TPUs, large amounts of RAM, and high-speed data storage solutions [113,114]. According to estimates, the training cost of models, like GPT-3, can reach up to US $1.4 million, with operational costs amounting to several hundred thousand dollars per day when deployed at scale. In a medical context, where accuracy and reliability are paramount, these costs are even higher due to the additional requirements for data security, privacy, and compliance with health care regulations.

Several studies have documented the economic challenges associated with deploying LLMs in health care [115,116]. For instance, the cost of implementing LLMs in hospital settings, including the necessary infrastructure upgrades, staff training, and ongoing maintenance, has been reported to be a major barrier to widespread adoption. Moreover, the need for regular updates to the models, which involves retraining them with new medical data, adds to the operational expenses [1].

As technology advances, it is expected that the costs associated with LLMs will decrease, making them more accessible to a

XSL•FO
RenderX

broader range of health care providers. The development of more energy-efficient hardware, combined with advances in machine learning techniques, is likely to contribute to this trend. However, until these cost reductions are realized, careful planning and resource allocation will be essential for any institution looking to implement LLMs in their health care practice.

Conclusions

The era of digitalization and informatization underscores the transformative potential of LLMs in medicine. The evolution of this technology signifies a paradigm shift in medical services, offering unique opportunities and challenges to the medical community. LLMs, with their advanced NLP capabilities, have a wide range of applications including emergency triage, older people care, and the enhancement of digital medical workflows. As the diversity of medical data expands, LLMs' ability to process multimodal data will play a crucial role in enabling more precise, personalized medical diagnoses and treatments.

Despite the promising trajectory of LLMs in the medical field, ensuring their safety and effectiveness in clinical practice remains a critical challenge. Currently, the regulation of LLMs in health care is still in its early stages, with several frameworks being developed to address the unique risks and challenges they pose. Regulatory bodies, such as the US Food and Drug Administration, European Medicines Agency, and China's National Medical Products Administration, have begun to formulate guidelines that apply to AI-driven medical devices including LLMs. These guidelines typically focus on the validation of the models through rigorous clinical trials, ensuring that they meet specific safety, efficacy, and ethical standards before they can be deployed in clinical settings. However, the growth potential of LLMs in the medical arena is significant. They can enhance patient experiences through the integration of virtual reality and augmented reality, offer comprehensive medical advice through multimodal research, and humanize doctor-patient interactions using the theory of mind. With ongoing advancements in algorithms and computational power, we anticipate considerable improvements in LLMs' processing speed and accuracy.

However, the path to technological advancement is not always linear. To ensure the benefits of LLMs are accessible to all, it is imperative to promote equitable development and address the digital divide, particularly for economically and technologically disadvantaged regions and groups. This goal requires the collective efforts of health care professionals, computer science experts, government regulatory bodies, patients, and their families. Such a collaborative approach will ensure that the application of LLM technology in the medical field genuinely contributes to the betterment of humanity, significantly enhancing health and well-being.

Abstract

To ensure that an eHealth technology fits with its intended users, other stakeholders, and the context within which it will be used, thorough development, implementation, and evaluation processes are necessary. The CeHRes (Centre for eHealth and Wellbeing Research) Roadmap is a framework that can help shape these processes. While it has been successfully used in research and practice, new developments and insights have arisen since the Roadmap's first publication in 2011, not only within the domain of eHealth but also within the different disciplines in which the Roadmap is grounded. Because of these new developments and insights, a revision of the Roadmap was imperative. This paper aims to present the updated pillars and phases of the CeHRes Roadmap 2.0. The Roadmap was updated based on four types of sources: (1) experiences with its application in research; (2) literature reviews on eHealth development, implementation, and evaluation; (3) discussions with eHealth researchers; and (4) new insights and updates from relevant frameworks and theories. The updated pillars state that eHealth development, implementation, and evaluation (1) are ongoing and intertwined processes; (2) have a holistic approach in which context, people, and technology are intertwined; (3) consist of continuous evaluation cycles; (4) require active stakeholder involvement from the start; and (5) are based on interdisciplinary collaboration. The CeHRes Roadmap 2.0 consists of 5 interrelated phases, of which the first is the contextual inquiry, in which an overview of the involved stakeholders, the current situation, and points of improvement is created. The findings from the contextual inquiry are specified in the value specification, in which the foundation for the to-be-developed eHealth technology is created by formulating values and requirements, preliminarily selecting behavior change techniques and persuasive features, and initiating a business model. In the Design phase, the requirements are translated into several lo-fi and hi-fi prototypes that are iteratively tested with end users and other stakeholders. A version of the technology is rolled out in the Operationalization phase, using the business model and an implementation plan. In the Summative Evaluation phase, the impact, uptake, and working mechanisms are evaluated using a multimethod approach. All phases are interrelated by continuous formative evaluation cycles that ensure coherence between outcomes of phases and alignment with stakeholder needs. While the CeHRes Roadmap 2.0 consists of the same phases as the first version, the objectives and pillars have been updated and adapted, reflecting the increased emphasis on behavior change, implementation, and evaluation as a process. There is a need for more empirical studies that apply and reflect on the CeHRes Roadmap 2.0 to provide points of improvement because just as with any eHealth technology, the Roadmap has to be constantly improved based on the input of its users.

eHealth development; eHealth implementation; CeHRes Roadmap; participatory development; human-centered design; persuasive design; eHealth framework

Introduction

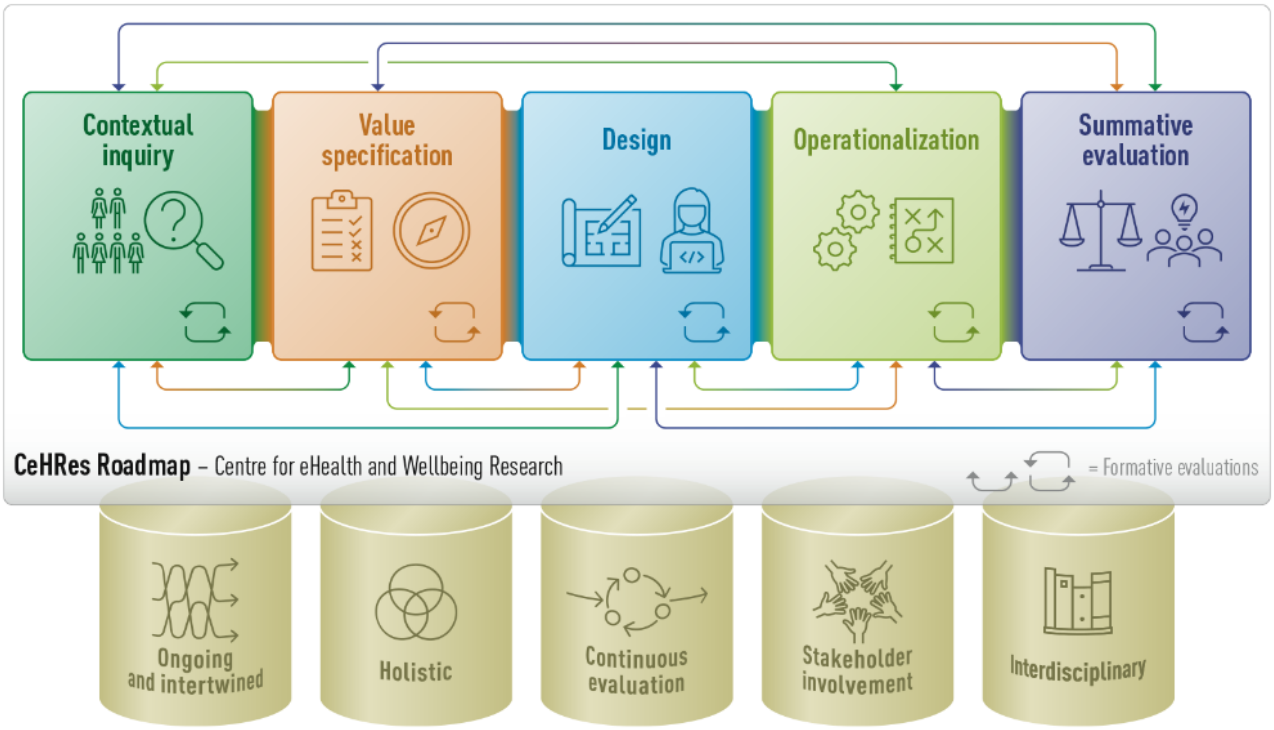
eHealth refers to the use of information and communication technology to support health, well-being, and health care [1]. If used well, eHealth technologies such as internet-based interventions, virtual reality, wearables, and mobile apps can be used to improve the quality and efficiency of care [2-6]. By achieving the intended effects, they can be used to target global challenges for health care, for example, limited access to care, an increase in the number of people living with (chronic) diseases, and shortages of staff and funding [7,8]. Over the past years, much attention has been paid to improving the impact and uptake of eHealth by academia, health care, and commercial companies. Yet, there still is room for improvement as expected benefits are often not (fully) achieved in practice [9,10].

An explanation for eHealth interventions not reaching their full potential is a suboptimal fit between the design of the eHealth technology, the characteristics and needs of its users, and the demands of the context in which it is used [11]. Therefore, thorough development, implementation, and evaluation processes are recommended to increase the fit between technology, people, and context and thus to realize the full potential of eHealth [12]. Unfortunately, this does not always happen. For example, despite the importance of participatory development for creating eHealth technologies, end users and other stakeholders are often not involved at all or not in the most optimal way [9,13]. Furthermore, during eHealth development, sufficient attention is not paid to behavior changes by integrating evidence-based behavior change theories [12,13]. In addition, the implementation of eHealth is a major challenge but often receives insufficient attention in research and practice [14,15]. Implementation is often seen as a single, postdesign activity, as opposed to an ongoing, iterative process that involves complex ecosystems and starts with the development of a technology. In addition, because eHealth technologies are quite new, there is an urgent need for more insight into if, why, how, when, and for whom they work, using innovative research methods that are suitable for answering these types of complex questions [16,17]. Finally, in research and practice, development, implementation, and evaluation projects are often conducted separately from each other, overlooking their interrelationships. Consequently, bolstering the impact of eHealth requires the use of comprehensive frameworks that guide interrelated development, implementation, and evaluation processes [12,18].

The CeHRes (Centre for eHealth and Wellbeing Research) Roadmap 2.0 is one such holistic framework and is specifically aimed at developing, implementing, and evaluating eHealth technologies that fit the needs and characteristics of people and their contexts. The original CeHRes Roadmap was first published in 2011 and is based on a comprehensive systematic literature search, resulting in 60 papers and 16 frameworks (van Gemert-Pijnen et al [11] provide a complete overview of the search process and outcomes). It included frameworks focused on, for example, user-centered design of teleconsulting systems [19], continuous evaluation of eHealth [20], usability engineering [21], interdisciplinary design and evaluation [22], and implementation and behavioral science [23]. These frameworks' target groups, goals, foundations, and strategies and principles can be found in the study by van Gemert-Pijnen et al [11]. An analysis of the strategies and principles was used to create the original CeHRes Roadmap and its underlying pillars. The Roadmap consists of 5 interrelated phases: contextual inquiry, value specification, design, operationalization, and summative evaluation [11,24,25]. These phases are connected using formative evaluation cycles. The original Roadmap is supported by pillars that highlight the importance of participatory development, continuous evaluation, and intertwining development and implementation, accounting for changes in the organization of health care because of eHealth, the importance of persuasive design, and the use of advanced methods to assess impact. These pillars are illustrative of the interdisciplinary nature of the Roadmap, which draws from domains such as psychology, persuasive technology, engineering, human-centered design, and business modeling. Over the past years, the original CeHRes Roadmap has been applied to a broad range of contexts and has proven to be a useful tool for researchers and practitioners in the field of eHealth (refer to the study by Kip et al [13] for a partial overview). The broad and extensive use of the Roadmap has led to multiple lessons learned and suggestions for improvements by researchers [26,27]. In addition, since 2011, there have been developments within the interdisciplinary domain of eHealth. For example, participatory development has become more common; there is an increase of well-substantiated design principles and guidelines; knowledge on innovative implementation and evaluation approaches has increased; there is more interdisciplinary collaboration and knowledge; and collaborations between researchers, commercial companies, and health care organizations have resulted in new methods and frameworks [14]. In addition, in the last decade, the terminology has changed and there is a new classification of digital interventions, services, and applications [28]. These new developments and insights call for an update of the CeHRes Roadmap, embracing novel perspectives and advancements. It is important to note that, for consistency reasons, we have decided to use the term "eHealth" instead of digital health (interventions).

In this paper, we present an updated version of the phases and pillars of the CeHRes Roadmap. This update is based on 4 different types of resources. First, we used experiences, lessons learned, and points of improvement that were reported in studies that used parts of the original Roadmap [26,27,29-42]. Second, literature reviews on eHealth development, implementation, and evaluation in general were used [13,14,16,43]. Third, we gathered input from discussions with eHealth researchers from different domains (eg, psychiatry, informal caregiving, planetary health, health psychology, and health sciences) on their

XSL•FO
RenderX



experiences with and viewpoints on development, implementation, and evaluation. Fourth, we updated and added new frameworks, models, and methods from the different disciplines that are relevant to the CeHRes Roadmap [11]. More specifically, chapters on psychology and behavior change, technology development models, human-centered design, business modeling, value-based design and requirement engineering, implementation science, and evaluation methods grounded in behavioral sciences were used as foundations for the revisions and updates of the Roadmap [24].

The main objective of this paper is to present the updated version of the CeHRes Roadmap: the CeHRes Roadmap 2.0. The CeHRes Roadmap 2.0 should not be viewed as a new framework or a major revision but as a fine-tuned, improved version of the original Roadmap. In this paper, first, the revised pillars will be presented and explained, including references to the studies on which they are based. Second, the updated phases of the CeHRes Roadmap 2.0 are described, starting with a short explanation of their main objectives, followed by examples of relevant methods and frameworks from different disciplines.

The CeHRes Roadmap 2.0

In Figure 1, the new visualization of the CeHRes Roadmap 2.0 is provided. In this section, the revised underlying pillars will first be discussed, after which the 5 phases and formative evaluation cycles will be explained.

Figure 1. The CeHRes Roadmap 2.0. CeHRes: Centre for eHealth and Wellbeing Research.

The Pillars of the CeHRes Roadmap 2.0

The Roadmap's pillars provide the foundation upon which it is built. They are the underlying assumptions that are kept in mind throughout all phases of the CeHRes Roadmap 2.0.

eHealth Development, Implementation, and Evaluation Processes Are Ongoing and Intertwined Rather Than Phases Containing Separate and Sequential Activities

While it might sound like development, implementation, and evaluation are separate and consecutive stages, this is not the case; they are highly interrelated activities that are all relevant from the start [44]. This also applies to the visualization of many development frameworks; while, for overview purposes, processes or phases are visualized as separate activities, in reality, they are all intertwined [11,24,44,45]. In particular, implementation is seen, still too often, as a postdesign activity, while it plays a role from the start, for example, by identifying potential implementation issues as early as possible to ensure that they can be accounted for during development. In line with this, eHealth development, implementation, and evaluation processes are never really completed; there will always be room for improvement and new questions will keep on arising. However, in practice, this is often difficult to realize because of limited resources, such as time or money.

eHealth Development, Implementation, and Evaluation Processes Require a Holistic Approach, Focused on the Fit Between Technology, People, and Context

Regardless of the type or goal of an eHealth intervention, there are interrelationships between the design and content of a technology, the needs and preferences of the people involved, and the context in which it is used [46]. These interrelationships warrant a holistic approach, in which the different elements are all interdependent and part of one whole instead of separate constructs [47]. First, technology and the behavior of people are interrelated. The introduction and sustained use of technology ideally influence the way end users behave, resulting in, for example, better health outcomes or increased well-being. To enable this behavior change, adherence is an important

XSL•FO
RenderX

concept, which means that eHealth should be used as intended, which can be viewed as use behavior. Concepts such as engagement—the extent to which someone is involved or occupied with an eHealth technology from an emotional, behavioral, and cognitive perspective—are important to consider as well [48]. Second, the use of eHealth is never isolated, but influences and is influenced by the context in which it is used. The introduction of eHealth creates novel structures and processes for health care delivery, and as a result, an adapted or new ecosystem for health care emerges [49]. Furthermore, the content of a technology can be influenced by contextual factors, such as new treatment protocols.

eHealth Development, Implementation, and Evaluation Processes Require a Multimethod, Iterative Approach With Continuous Evaluation Cycles

eHealth development, implementation, and evaluation are not linear processes with consecutive steps; they are iterative, flexible, and dynamic, with constant changes to the process and products [50,51]. This is in line with an agile approach, which is characterized by the division of large tasks into rapid, shorter phases and constant adaptations of plans based on the outcomes of evaluations [52]. To realize this, a multimethod approach is key. Ideally, researchers need to be able to draw from a broad toolkit of qualitative and quantitative research methods and products and select the method that best fits their research objective, the practical demands of the context, and the characteristics, needs, and wishes of the participants [13]. To ensure a coherent approach and to prevent the project team from "getting lost," there is a need for continuous formative evaluations in which outcomes of activities are critically analyzed, evaluated, and adapted with stakeholders [12]. Such an iterative, agile approach might be challenging and complex and can seem very different from a rigorous scientific approach in which all research activities are meticulously planned. However, such an iterative, agile approach is not a synonym for unstructured or messy; it is a way to shape systematic, structured yet dynamic high-quality research processes that are able to adapt to changes and new insights [52]. Such new insights may lead to the development of new technologies, but this approach is also applicable when new insights lead to re-evaluation and redesign of existing technologies. Consequently, while a broad research plan with potentially suitable methods can definitely be developed, it might be necessary to deviate from this plan based on outcomes at any point during the process or new insights regarding the needs of stakeholders or possibilities of a technology.

eHealth Development, Implementation, and Evaluation Processes Require Constant Active Involvement of Stakeholders

To create eHealth that meets the needs and wishes of users and other stakeholders, a participatory approach is recommended, in which stakeholders are actively involved throughout the process, from development to evaluation [30,45,53,54]. Emerging approaches, such as action research and design science highlight that the active involvement of stakeholders goes beyond merely involving end users; stakeholders such as managers, health care insurers, and technology developers are also involved to ensure a holistic approach [40,55,56]. In participatory development, stakeholders can take on different roles, ranging from an informant who mostly provides input on products when invited by researchers to a cocreator who is actively involved in creating ideas and products [57]. While ideally, stakeholders have an active role, in some cases a more passive role might be more suitable for a specific objective. How a stakeholder is involved is not fixed and will differ depending on the phase of the process and the type of activity that is conducted. It is important to ensure that stakeholders are only involved when it truly is of added value. Merely involving end users for the sake of involving them does not benefit anyone involved and takes up the valuable time of participants and researchers [58]. Ideally, stakeholders should be part of an interdisciplinary project team that coordinates the entire eHealth process. Finally, participatory development does not always have to be about creating new technologies, because existing technologies can be redesigned and reused in different contexts as well, which also requires active stakeholder involvement.

eHealth Development, Implementation, and Evaluation Processes Are Based on an Interdisciplinary Approach

To capture the complexity of eHealth, an interdisciplinary approach toward research and development is required [12,14]. In such an approach, theories, methods, and models from different disciplines are combined and ideally merged and integrated, resulting in new frameworks, concepts, and models [59]. While there are multiple domains that can be relevant for eHealth, there are some main paradigms that underpin the CeHRes Roadmap 2.0, which are psychology and behavioral sciences, human-centered design, engineering, persuasive technology, implementation science, and business modeling [11,24]. Furthermore, domain-specific theories that are relevant to a specific context or target group often play an important role and should be integrated as well [29]. Finally, the interdisciplinary nature of eHealth is important when composing the project team that coordinates the development, implementation, and evaluation processes. Putting together a team with members (and stakeholders) from different disciplines is deemed essential to ensure that all relevant perspectives are actively involved throughout to prevent tunnel vision [29,60,61].

Changes Compared to the Original CeHRes Roadmap

Compared to the first version of the Roadmap, several changes are made to the pillars while retaining the main essence of the original Roadmap. An important change is that the pillars were broadened to better reflect the vision that development, implementation, and evaluation aspects of eHealth are interrelated. For example, in the initial pillars, the term "eHealth development" was used, but in the new version, we broadened this to "eHealth development, implementation, and evaluation processes." Furthermore, the terminology was adapted to better fit the iterative, interdisciplinary nature of eHealth. For example, the term participatory development was replaced by the term "active involvement of stakeholders." The phrasing and changes of the updated pillars better capture the essence of the CeHRes Roadmap 2.0.

RenderX

The Phases of the CeHRes Roadmap 2.0

Overview

Before diving into the phases of the CeHRes Roadmap 2.0, it is important to explain how the Roadmap should be used. It is not a step-by-step guideline but more of a set of underlying assumptions that are relevant to any eHealth process. Strictly speaking, the first 3 phases of the Roadmap 2.0 are related to the development of eHealth, operationalization fits best with implementation, and summative and formative evaluation are most aligned with the Evaluation phase. This distinction into 5 phases is made for visualization and overview purposes, in practice, the first phases will also be relevant for implementation and evaluation efforts and vice versa. In line with this, the visualization of the phases as separate blocks does not in any way imply that the process is sequential; this is also done for overview purposes. In reality, phases overlap and project teams will go back and forth between the different phases, as represented by the arrows in Figure 1. Therefore, it is important to note that the description of the phases of the CeHRes Roadmap 2.0 is not a concrete guideline for creating impactful eHealth interventions. It is meant to serve as a structured overview of principles and methods that can be used by researchers and practitioners to shape their own and unique development, implementation, and evaluation processes. Consequently, methods or frameworks that are not described in this paper can most definitely be used too. A key feature is that they fit within the process and are aligned with relevant research questions. To conclude, the information mentioned subsequently is aimed to support eHealth researchers through inspiration, guidance, and concrete input for guiding eHealth development, implementation, and evaluation processes.

Contextual Inquiry

Overview

The first step in any eHealth-related project is a thorough investigation of the context in which it will be used. A contextual inquiry is required to paint a picture of the (groups of) people that will come in contact with the technology and their context and to identify the main points of improvement for which an eHealth technology can be of added value. A thorough contextual inquiry assists researchers and developers in keeping a focus on the people and their context from the start of the development process [30,62]. This increases the chances of developing an eHealth technology that provides a solution for relevant issues, fits within a specific context, and is accepted by relevant stakeholders [12,63]. Consequently, the outcomes of a contextual inquiry provide the foundation for all following development, implementation, and evaluation activities. The objectives of the contextual inquiry are described in subsequent sections, including several illustrative examples of suitable methods, frameworks, and concepts that might be used within this phase.

To Identify and Gain Insights Into the Roles and Activities of Relevant Stakeholders

Due to the importance of actively involving stakeholders in every phase of the CeHRes Roadmap 2.0, a clear overview has to be provided from the start of the development process. Stakeholder identification can be conducted, using methods such as expert recommendations on stakeholders, snowball sampling with stakeholders, and literature studies [40]. Once an initial overview is created, the roles and tasks of stakeholders have to be analyzed. An example of a useful approach is the stakeholder salience model, in which stakeholders are mapped based on their power, legitimacy, and urgency [64]. On the basis of analyses, key stakeholders who should be involved more intensively throughout the process can be selected.

To Analyze the Current Situation Regarding the Involved People, Organizations, Wider Context, and Technologies

A thorough understanding of the current situation is essential to ensure that the project team knows for whom and for what context they are creating eHealth and to specify the focus of the project. Using multiple methods, an overview can be created of the involved people (eg, their daily lives, attitudes, behavior and determinants of behavior), the organizations in which eHealth will be implemented (eg, organizational characteristics, protocols, and domain-specific theories), the wider context (eg, national policies, legislation, and funding possibilities), and information on relevant technologies and technological infrastructures that are or might be used in the intended or other contexts (eg, working mechanisms, experiences with similar technologies, and technological possibilities) [13]. It is important to truly understand the context before going into specific solutions to prevent tunnel vision and to ensure a good fit between the eHealth technology and the involved stakeholders. To achieve this, a context should not be viewed as a single entity but as a complex ecosystem of interrelated platforms, technologies people, organizations, and other stakeholders. Finally, it is important to pay attention to (potential) ethical points of attention from the start of the development process, such as privacy, accessibility, or data ownership.

To Identify the Main Points of Improvement for Which an eHealth Technology Could Be a Solution

Merely describing a context is not sufficient for developing eHealth; the project team needs to gain insights into what the points of improvements are in the current situation that can be addressed by a to-be-developed eHealth technology. These points can be related to, for example, efficiency, effectiveness, patient satisfaction, safety, or quality improvement. An important aspect of this activity is to describe the behavior that needs to be changed to improve the situation and identify accompanying determinants that can be targeted by eHealth technology [45]. When identifying and describing points of improvement and accompanying behavior, newly gathered information from stakeholders is combined with scientific sources to increase the robustness of the findings. By integrating methods such as desk research, (systematic) literature reviews, focus groups, interviews, and observations, a complete, multifaceted picture of what has to be changed can be painted [13].

Value Specification

Overview

In the Value Specification phase, the topics that were identified in the contextual inquiry are narrowed down and translated into

XSL•FO
RenderX

values and specific requirements for a to-be-developed eHealth technology. This is again done in close cooperation with the identified stakeholders; however, other stakeholders might also pop up in this phase. Information from the literature is required to be able to incorporate evidence-based behavior change techniques (BCTs) into a technology that facilitates behavior change. Moreover, in this phase, the development team needs to take the first concrete steps toward implementation, among other things, by initiating the development of a business model. While the value specification can be quite complex and time consuming, it is important to put effort into laying the groundwork for the content and design of a technology before diving into its actual creation. This again ensures that the technology is in line with the preferences and characteristics of stakeholders, incorporates evidence-based working mechanisms, and remains in line with the identified points of improvement. The objectives of this phase and examples of accompanying methods are described in subsequent sections.

To Formulate and Prioritize Values From All Identified Key Stakeholders and Set Concrete Goals Based on These Values

While there are many definitions of values, in relation to eHealth development, values can be viewed as what stakeholders find important regarding the technology from their personal or professional perspective, also related to, for example, ethics and morality. In other words, values are abstract concepts that represent the ideals or interests of stakeholders and summarize what they find important on an abstract level [38,65]. Values can be related to social, behavioral, cognitive, emotional, economic, or health care issues. Examples are saving costs, increasing access to health care, or improving autonomy [39,65]. Values can be uncovered through (ideally) a combination of multiple methods such as interviews, focus groups, or questionnaires [65]. When collecting data, it is pivotal to carefully consider the intended target audience when finding a fitting way to discuss values. For some target audiences (eg, clients in forensic psychiatry), discussing values in an abstract way (eg, “increase self-control”) can be very complex [66]. In that case, it can help to show and discuss concrete examples of existing or potential technologies [29]. Because different stakeholders are involved, conflicting values are expected to arise, for example, the manager’s perspective might differ from that of the patient. This is not problematic but requires deliberate decision-making and prioritizing by the interdisciplinary project team. To ensure that these more abstract values are translated into a concrete technology, more specific requirements are formulated. Furthermore, to guarantee that values are incorporated throughout the further implementation and evaluation activities, it is useful to formulate accompanying objectives that are formulated in a specific, measurable, achievable, realistic, and timely (SMART) way. These objectives can serve as the basis for evaluation and implementation studies.

To Select Initial BCTs and Persuasive Features That Fit With the Values and Needs of the Key Stakeholders

In previous activities, the behavior that needs to be changed was analyzed and the values of the key stakeholders that play a role in doing so were identified. On the basis of that information, fitting behavior change methods can now be selected to increase the chances of actually reaching the intended behavior change and to improve adherence and engagement to the eHealth technology. This is important because changing behavior is highly complicated. To increase the chances of an eHealth technology’s success in actually changing behavior, the chosen strategy should fit the users and what they are trying to achieve. BCTs are derived from behavior change theories from psychology and can be defined as a general technique to influence or create changes in the predictors of specific behavior [67]. Examples of BCT categories are goals and planning, social support, feedback and monitoring, and reward and threat. In addition, persuasive features from the Persuasive Systems Design (PSD) model can be selected [68]. The persuasive features are divided into 4 categories: primary task support, dialogue support, credibility support, and social support. BCTs partly overlap with persuasive techniques because they both target behavior change, but the main difference is that the PSD model is specifically aimed at technology, while BCTs are applicable to any kind of behavior change intervention. Finally, depending on the project, domain-specific theories can also be used to support behavior change. Identifying and integrating behavior change methods in technology is a complex and highly iterative process that will remain relevant throughout the process, but the foundation is laid in the Value Specification phase.

To Translate the Values Into Specific Requirements to Describe the to-Be-Developed eHealth Technology

Requirements describe what an eHealth technology should do, what data it should store or retrieve, what content it should display, and what kind of user experience it should provide [38]. There are different types of requirements related to functionality and modality, service, organization, content, usability, and user experience. Particularly due to the increasing importance and the use of (big) data, attention should be paid to data-related topics, such as data ownership, the way data are collected, and how and where to save generated data. Requirements should be related to values; an abstract value is often related to multiple more specific requirements. When formulating requirements, data that were used to formulate values can be used, but new data are often collected as well, for example, through focus groups, interviews, card sorting, and literature reviews [13]. It is also important to integrate the selected potential behavior change mechanisms into requirements to ensure that they are integrated into the technology. A specific product that can help in designing for the end users and facilitating requirement formulation is a persona: a hypothetical archetype of a user presented by means of a short biography with a photo, sociodemographic information, and their values [69,70]. Scenarios can be used to link personas to the technology, because they describe the potential, envisioned use of an eHealth technology by the end users. Scenarios can contain information about how the end user uses a technology in relation to their characteristics and values, what activities are supported by a technology, which steps a user follows, in which context this happens, and what the technology’s main functionalities are [71].

XSL•FO
RenderX

To Create the First Version of a Business Model for the eHealth Technology

To prevent a technology from not being used after it has been introduced in practice or not even being introduced at all, it is important to start developing a business model as soon as possible. A business model can be defined as "the rationale of how an organization creates, delivers, and captures value" [72]. A frequently used method to create a business model is the business model canvas, which consists of 9 blocks. These blocks represent the value proposition (eg, the eHealth technology), the organizational activities that are necessary to deliver the eHealth technology to practice, the main customers and users, and financial aspects and cost-benefit ratios. A business model can be filled in using multiple methods, such as focus groups, desk research, and outcomes of earlier development activities [32]. While the initiation of the business model takes place in the value specification, it is adapted throughout the entire process of eHealth development, implementation, and evaluation.

Design

Overview

While this is not a "hard" transition, the actual eHealth technology is created in the Design phase based on the output of the contextual inquiry and the value specification. This is an extremely dynamic, iterative, creative, and collaborative phase during which there is an active collaboration between end users, other stakeholders, researchers, designers, behavior change experts, content experts, and perhaps even funders. While there are many ways to guide this process, the Double Diamond Model (or framework for innovation) can be used to shape the cycles of iteration between design and testing that are relevant for this phase [73,74]. It is important to note that the final technology is not developed all at once. If that is done, important problems may be missed and arise only after the technology has been introduced in practice, thus wasting a lot of time and effort. Therefore, multiple prototypes, visual representations of the to-be-developed technology, are developed based on the requirements. These prototypes are evaluated by users and experts and are constantly updated in an iterative process. It must be stressed that throughout the prototyping process, outcomes of previous phases (eg, requirements, BCTs, and stakeholder lists) can be adapted or complemented because of new insights, related to, for example, usability, new organizational opportunities, or technological possibilities or impossibilities. To support this process, design principles for digital developments can be used [75]. Furthermore, in the Design phase, insights into barriers that might arise during implementation are gathered, illustrating the interrelatedness between development and implementation.

Both Low-Fidelity and High-Fidelity Prototypes of the eHealth Technology Are Developed

Prototypes are visual representations of a technology. They can be crude and more sketch like (low fidelity) or can resemble the to-be-developed technology more closely (high fidelity), but they are in any case based on previously formulated requirements [76]. The first step in the prototyping process is to come up with initial design ideas by means of ideation. These ideas are increasingly specified based on input from stakeholders in formative evaluations throughout the prototyping process. There are several methods to create prototypes, such as paper-based prototyping (eg, sketching), computer-based digital prototyping, storyboards that show how the technology can be used, or 3D prototyping with materials such as cardboard, clay, or 3D printing. Content for the prototypes can be initiated via, for example, literature studies, desk research on existing protocols, card sorting, Delphi studies with experts, and further refined during the design process [13].

Persuasive Features, BCTs, and Domain-Specific Theories Are Operationalized and Integrated Into the Design of the eHealth Technology

While an initial overview of potentially useful BCTs and persuasive features was made in the value specification, this set of techniques will most likely be adapted throughout (and even after) the prototyping process, in line with the complexity of behavior change. Furthermore, the techniques have to be operationalized and integrated into prototypes of the design [33]. Integrating persuasive features and BCTs in the design of an eHealth technology requires an iterative and creative approach, for example, using brainstorming and cocreation sessions with stakeholders, involving experts on design and behavior change, and investigating techniques and features in similar technologies. Once these techniques and features are integrated into prototypes, they are evaluated with stakeholders and experts to investigate if they are potentially effective and fit the skills and preferences of end users. While doing so, it is important to also consider checking if the BCTs and persuasive features are integrated successfully into the design according to experts and stakeholders. An example of this is to analyze perceived persuasiveness according to stakeholders [77].

Usability Tests of the Prototypes Are Conducted With End Users, Experts, and Other Stakeholders

Prototypes are evaluated with stakeholders to gain insights into their opinions and thus iterate toward the most suitable version of an eHealth technology for a specific target group in a specific context. This can be done by means of usability tests, which can be used to study, for example, how someone interacts with the system, to test the ease of use and user-friendliness of the technology, or to assess whether requirements are correctly translated into the design. There are multiple methods for usability testing [78]. The think-aloud method lets intended end users navigate through a prototype guided by a scenario, a task that is to be dealt with by using the prototype, while verbalizing their thoughts, actions, and ideas. In a heuristic evaluation, design experts assess usability by comparing it to a predefined set of principles such as "recognition rather than recall" or "minimalist design" [79]. In a cognitive walk-through, experts are asked to execute tasks that a user would want to perform [80]. These are just a couple of examples of the multitude of available methods for usability testing.

Operationalization

Overview

Operationalization refers to the planning and actions for the introduction, dissemination, adoption, and internalization of (a

XSL•FO
RenderX

first functioning version of) the technology in the intended context. In this phase, the technology is launched, marketing is set into motion, and organizational working procedures are put into practice. In this phase, the business model is completed and applied to practice, using input from earlier phases as well as by collecting new data. In addition, previously collected data and new research are combined into a concrete implementation plan with specific activities, ideally structured by means of an implementation framework.

Complete the Business Model With Input of the Stakeholders and Put It Into Practice

The business model, which was initiated in the Value Specification phase, is made as complete as possible and is rolled out in this phase. Concrete plans on how to act upon the content of the 9 blocks of the business model canvas are created, in close cooperation with stakeholders, using methods such as focus groups, desk research, or interviews [32]. While the business model is made as complete as possible, this does not mean that the model is fixed: chances are that it will be updated constantly, in line with, for example, new insights, policy changes, new customer groups, or new financing structures. Finally, it is important to carefully consider matters related to data in a business model, who owns the data that are collected by technology, and what is the potential value of these data [81].

Create an Overview of Implementation Barriers and Facilitators Using Input From the Previous Phases, New Data, and Implementation Frameworks

Because implementation is not a postdesign activity, information on, for example, implementation barriers and facilitators has already been collected throughout the previous activities. In this phase, previous outcomes are combined with newly collected data on implementation factors and strategies to provide an overview of factors to account for when planning, executing, and evaluating implementation processes [43]. The process of planning for implementation can be structured by means of implementation frameworks. A much-used framework is the Consolidated Framework for Implementation Research (CFIR), which incorporates a broad range of factors from existing theories and divides them into 5 domains: innovation, outer setting, inner setting, individuals, and implementation process [82]. Another approach, which is focused on value-based technology in health care, is the Nonadoption, Abandonment, Scale-Up, Spread, and Sustainability (NASSS) framework, consisting of 7 domains: condition, technology, value proposition, adopters, organization, wider system, and embedding and adaptation over time [83]. While there are different implementation frameworks, they all highlight the multilevel nature of implementation and emphasize that it is important to pay attention to a broad range of stakeholders and organizations.

Develop a Concrete Implementation Plan Based on the Previously Identified Implementation Factors and Apply It to Practice

On the basis of the previously identified implementation barriers and facilitators, a concrete plan for implementation is comprised, including implementation outcomes and strategies. While there is no step-by-step approach to do this, specific implementation outcomes can be determined to steer and evaluate the process, related to, for example, acceptability, cost, and sustainability [84]. To achieve the objectives, specific implementation strategies are identified, which can be linked to the previously identified barriers and facilitators (ie, factors) [36]. Overviews of implementation strategies can be used to guide this process [85]. Active stakeholder involvement in identifying suitable activities for implementation is important, partly because there is not much evidence-based information on which strategies can be effectively used for overcoming implementation barriers [43,85]. Examples include training health care providers, development of technology-enhanced treatment protocols, or practical support of clinicians in using the intervention [15]. The accompanying materials, such as flyers or training sessions, are ideally cocreated with stakeholders.

Summative Evaluation

Overview

While summative evaluation is visualized as the final part of the CeHRes Roadmap 2.0, it is not a postimplementation and development activity but an iterative, multimethod process that is highly intertwined with and based on activities and outcomes from development and implementation processes [16]. In evaluation processes, researchers investigate to what extent the eHealth technology succeeds in addressing the objectives formulated in previous phases. For overview purposes, a rough distinction can be made between 3 aspects of eHealth evaluation, although they overlap. The first aspect is the evaluation of the *impact* of eHealth on its users, stakeholders, and their context, mostly aimed at assessing its benefits and effects on different types of outcomes (eg, clinical, organizational, and behavioral). The second aspect is related to assessing the *uptake* of eHealth to gain insight into how, by whom, and when a technology was used. The third element is related to the evaluation of *working mechanisms* to gain insight into why an eHealth technology was effective or not and why it was used. By combining these types of evaluations, insights can be gained into if, why, how, for whom, and when eHealth works, and points of improvement for its design and implementation can be identified. Several frameworks can be used to shape these complex, multifaceted evaluation processes. Examples are the Multiphase Optimization Strategy (MOST) framework, which consists of 3 phases: preparation, optimization, and evaluation [86]; Process evaluation, in which attention is paid to the relationship between context, implementation, and mechanisms of impact, and their influence on the outcomes of an intervention [87]; or realist evaluations, in which information is collected to build Context-Mechanism-Outcome configurations to explain how a specific context triggers specific mechanisms that lead to particular outcomes [88]. These approaches can all be used for the evaluation of complex interventions and account for the role of the context, the technology, and people when evaluating an eHealth technology.

Determine the Impact of the eHealth Technology on the Users, Other Stakeholders, and Their Context

To assess the impact of eHealth, it is important to translate the previously formulated values and accompanying objectives into research questions. These can relate to, for example, clinical

XSL•FO
RenderX

values, lifestyle behaviors, quality of care, efficiency, or other types of benefits. To paint a comprehensive picture of the influence of eHealth on the users and contexts, a multi- or mixed methods approach can be used. The choice of a method depends on the research questions and characteristics of the target group and context. Some examples of methods that can be used are randomized controlled trials (RCTs), interviews or focus groups, single-case experimental designs, or health technology assessments. When choosing what method to use, it is important to thoroughly consider the context in which a technology is used and keep an eye on the limitations of a specific method [89].

Analyze the Uptake of the eHealth Technology in Terms of Adoption or Use of the Technology by Its Intended Users

Evaluations of uptake are used to gain insight into by whom, how often, when, and how an eHealth technology is used. This type of evaluation can be used to answer questions about, for example, how often users logged in, how often a technology was used by different organizations, and what features of it were used or not and in what order. While there are multiple ways to answer these questions, log data analysis is a commonly used method [37,90]. By gaining more insights into the use of technology and by connecting it to outcomes, the black box of eHealth can be made more transparent. To illustrate, if an RCT shows no significant effects for an intervention, evaluation of uptake can be used to explain if this is because the intervention itself does not work or if (an element of) the intervention was simply not used. To incorporate these types of data in evaluations, it is important to carefully determine how data are collected and stored from the start of the development process [90]. Furthermore, this type of evaluation also provides points of improvement for implementation in practice or the design of an eHealth technology.

Investigating Relevant Working Mechanisms That Explain Why an eHealth Intervention is Effective or Not for Its Users

Understanding why an eHealth technology achieves a certain effect, rather than "just" evaluating *if* it achieves an effect, can provide generalizable insights into how health behavior change can be achieved via an intervention [87]. This knowledge can be used to make future interventions more effective or targeted. There are many different concepts that can be used to gain insights into working mechanisms, for example, related to sociodemographic characteristics of its users, such as age or personality, but ideally, these concepts are more overarching. Examples are previously mentioned BCTs and persuasive features or broader concepts such as adherence, the extent to which a technology is used as intended [91], and engagement, the extent to which someone is involved or occupied with an eHealth technology from an emotional, behavioral, and cognitive perspective [48]. There are several methods that can be used to gain more insights into the working mechanisms of eHealth technologies, such as mixed methods approaches with in-depth qualitative research or (fractional) factorial designs in which different versions of an intervention (eg, one with and one without a specific BCT or persuasive feature) are evaluated. It is important to note that identifying working mechanisms is extremely difficult because there are many combinations of factors that influence the effectiveness or ineffectiveness of a technology, such as characteristics of a specific context, the technology itself, or a broad range of individual factors.

Formative Evaluation

Overview

While the previously described phases are visualized as blocks in the CeHRes Roadmap 2.0, formative evaluation is represented by the arrows within and between these blocks, also see Figure 1. This is in line with the nature of formative evaluation; it is a principle that is intertwined in and part of all phases of the Roadmap. The basic assumption of formative evaluation is that information on how to improve the process and the eHealth technology itself is continuously collected. This information assists the project team in ensuring that there is a constant focus on the context and people involved and can be referred to as "creating by evaluating." A distinction can be made in formative evaluation within activities in a phase, related to ensuring that outcomes are aligned with perspectives of stakeholders and contexts, and between activities, referring to ensuring consistency between outcomes of different activities and the different phases.

Using Methods to Gather Information From the Stakeholders and Context to Continuously Account for Their Perspectives Within the Activities and Phases of the CeHRes Roadmap 2.0

Formative evaluation within activities and phases emphasizes the importance of gathering stakeholder input and verifying outcomes with them to ensure that products fit the involved people and context. For example, requirements are verified by stakeholders in the Value Specification phase, usability tests of prototypes are executed in the Design phase, and stakeholder input is gathered to create and finetune a business model in the Operationalization phase.

Checking Whether the Outcomes of Previous Phases of the CeHRes Roadmap 2.0 Have Been Accounted for in the Current Phase and Ensuring That the Outcomes of all Phases Form a Coherent Whole

Formative evaluations between phases ensure consistency and a clear relationship between the outcomes of all phases. For example, in the Design phase, the project team makes sure that the designed technology incorporates the requirements and addresses the values. This can be done through focus groups with stakeholders or project team meetings. There are no specific methods that must be used, but thorough, transparent documentation of activities and outcomes is essential. If no clear documentation is available, it is hard to retrieve what the main outcomes of previous phases were and what the grounds for specific decisions were.

Changes Compared to the Original CeHRes Roadmap

On the basis of the revised pillars and researchers' experiences, adaptations were made to the objectives, frameworks, and methods within the phases of the Roadmap: contextual inquiry, value specification, design, operationalization, summative evaluation, and formative evaluation. Generally, the objectives of the phases were fine tuned and clarified throughout. Notable modifications include that first, more attention is paid to creating

XSL•FO
RenderX

a theoretical foundation for eHealth technologies [14,92,93]. Among other things, the importance of the use of evidence-based BCTs, integration of domain-specific theories, and connection to existing treatment protocols is emphasized. Second, the role of implementation is further elaborated on highlighting the importance of integrating technology in practice to create impact [14,43,89]. For example, implementation frameworks are now described in the Operationalization phase, and the importance of implementation during development and evaluation is further explained. Third, more attention is paid to novel evaluation methods and approaches [16,94]. To illustrate, attention is paid to methods for impact and uptake evaluations, but also to methods for identifying underlying working mechanisms. In addition to that, evaluation models that can be used to shape multimethod, iterative processes are now introduced.

Discussion

Overview

In this paper, the CeHRes Roadmap 2.0 was introduced and substantiated based on experiences with the Roadmap and new developments within disciplines that underpin it. The CeHRes Roadmap 2.0 consists of the same phases as the first version, but their objectives have been adapted, reflecting the increased emphasis on BCT, implementation, and evaluation as a process [14]. The pillars have been revised to better reflect new insights regarding the ongoing and intertwined, holistic, iterative, participatory, and interdisciplinary nature of eHealth development, implementation, and evaluation processes. Consequently, while the foundation of the CeHRes Roadmap 2.0 has remained the same, it has been thoroughly updated to better reflect needs from practice and research. The CeHRes Roadmap 2.0 specifically highlights the importance of interdisciplinary collaboration with other researchers and stakeholders from practice; the need for agile, iterative processes; and the importance of accounting for implementation and evaluation from the start of any development process.

Comparison With Prior Work

The Importance of Flexibility

When using any framework for eHealth development, it is important to use it as a set of guidelines to guide unique processes as opposed to a static step-by-step guideline with predetermined methods and frameworks. Ideally, the choice of methods used depends on the phase in the process, characteristics and skills of participants, and practical preconditions such as time and money and not on the methods which the involved researchers happen to be familiar with [13,29,95]. Such a flexible approach is particularly relevant for the CeHRes Roadmap 2.0 due to its holistic nature, in which context, people, and technology are intertwined, highlighting the importance of matching methods and frameworks to the specific technology, people, and organization that are involved [11]. In addition, the iterative nature of eHealth development in general implies that the choice of a method also depends on the outcomes of a previous phase. This means that while the broad outlines of an eHealth project can be planned, the specific methods and their outcomes cannot be planned in detail in advance [1]. To illustrate, at the start of a development process, it is often not yet known what the specific requirements of stakeholders are and what the to-be-developed eHealth technology will look like. Consequently, there also cannot be a concrete plan for its implementation and evaluation in practice. This approach requires flexibility from researchers and perhaps also a change in mindset, shifting from meticulously planned study designs to a more agile, adaptive approach with multiple interrelated methods [50,51]. Of course, to ensure transparency, replicability, and robustness, these smaller steps should be documented well, for example, by publishing protocols in advance on open-access platforms. This mindset shift toward agile science is also relevant for many organizations and funding agencies that often desire or require a specific research plan for multiple years with detailed descriptions of products or outcomes. Fortunately, this agile approach to research is gaining ground, and with this revised version of the Roadmap, we hope to contribute to this much-needed shift. To conclude, while for overview purposes, eHealth frameworks such as the Roadmap are visualized as a sequential set of phases, and specific examples of methods and frameworks are provided, this does not mean that this process should be followed strictly. The exact way of shaping eHealth development, implementation, and evaluation processes is the task of an interdisciplinary project team and requires constant weighing and re-evaluating the aims and limitations of a specific project.

Interdisciplinary Collaboration

To tackle wicked societal problems, researchers from different disciplines have to join forces. Consequently, multi- or even interdisciplinary approaches are necessary to address complex, multifaceted challenges, such as developing, implementing, and evaluating effective and efficient eHealth technologies to address problems in health care. eHealth research is often multidisciplinary, in which input is provided by different disciplines, but this is done rather independently from each other, that is, there is not much integration of different methods, approaches, or theories, and people keep working within the boundaries of their discipline. However, to capture the complexity of eHealth, an interdisciplinary approach is advocated [12,14,22,41], in which input from different disciplines is actively integrated, creating a synergy that goes beyond the sum of the individual, disciplinary contributions [59]. Due to the integration of different disciplines, the CeHRes Roadmap 2.0 can be considered an interdisciplinary framework [11]. An example is the combination of BCTs (psychology), persuasive features (persuasive design), and their integration into requirements (engineering and human-centered design) within the Value Specification phase. To further complicate the already intricate task of interdisciplinary work, many researchers also advocate active collaboration with experts by experience such as patients and health care professionals, and other stakeholders such as technology developers or policy makers [12,14,44]. Consequently, people with different backgrounds and points of view have to actively work together, combine their different perspectives, and be willing to look beyond the borders of their paradigm. An important precondition for this is that eHealth researchers have to be able to speak the language of other disciplines [96]. For example, while a psychologist

XSL•FO
RenderX

does not have to fully master programming skills, they do have to understand its basics to effectively communicate with developers and prevent misunderstandings. On top of that, eHealth researchers also have to be able to adapt their communication to fit the specific skills of specific groups of stakeholders, such as vulnerable, hard-to-involve patient populations [66]. It is also recommended that researchers be acquainted with and sometimes even skilled in using different types of qualitative and quantitative research methods from different disciplines to be able to select the most appropriate method or at least understand the rationale behind a decision for a method. The domain of eHealth—including the Roadmap—is already shifting from interdisciplinary to transdisciplinary collaboration, where traditional disciplinary boundaries fade even more, and entirely new approaches are developed. This transdisciplinary process also involves close collaboration with community partners on a shared, "wicked" problem [97]. Particularly when working in a transdisciplinary way, researchers should have the ability to look beyond the boundaries of their discipline and really collaborate with societal stakeholders to contribute to a collaboration that is more than the sum of its parts.

Continuous Improvement of the CeHRes Roadmap

eHealth technologies and their development, implementation, and evaluation are never really finished. The same goes for eHealth frameworks such as the CeHRes Roadmap 2.0. New insights that urge their further adaptation will arise during the upcoming years not only because of developments of theories and models that are part of the interdisciplinary Roadmap and the fast pace of technological innovations that open up new arrays of opportunities and challenges but also because the Roadmap's application to practice will result in points of further improvement. To constantly improve frameworks such as the CeHRes Roadmap 2.0 in a systematic way, there is a need for studies in which multimethod development, implementation, and evaluation processes are presented and reflected upon [13,95]. Examples are reflections on the application and suitability of specific combinations of research methods or lessons learned about the operationalization of specific frameworks in a specific health care setting [29]. However, to date, most studies related to eHealth development, implementation, or evaluation only describe the outcomes of a single study, for example, an RCT. Outcomes from smaller studies, such as single-case studies, pilot studies, or qualitative research, that were used to set up the larger study are not reported, either because these types of studies were not performed at all or because authors (or journals) do not feel that publishing them is relevant or important [13,14,98]. However, just as is the case for eHealth technologies, input from stakeholders with different backgrounds is required to constantly improve the Roadmap to ensure that it fits the needs and wishes of its end users. Consequently, there is a need for more multimethod studies that report on the application of (large parts of) eHealth frameworks, critically reflect on their application, and provide points of improvement. To achieve this, future research can focus on creating a standardized way of reporting on multimethod eHealth processes [13,14] comparable to guidelines, for example, systematic reviews [99], RCTs [100], or qualitative research [101], of which an overview is provided by the EQUATOR Network.

Limitations

Despite its usefulness for eHealth development, implementation, and evaluation, the CeHRes Roadmap 2.0 has some limitations. First, the update was not based on a new systematic review of the literature. Yet, the initial version of the Roadmap was based on a comprehensive review of relevant models and frameworks, and a preliminary exploration of the literature indicated that a repetition of this review would likely not lead to any major new insights. Furthermore, although no new review was conducted, we did ground the CeHRes Roadmap 2.0 on reviews about important elements of the Roadmap, for example, on participatory development [13], implementation [43], evaluation [16], or eHealth frameworks in general [14]. In addition, models and frameworks that were already part of the Roadmap were updated based on new insights, resulting in a comprehensive updated version that covers the most important points of improvement. Regardless of these efforts, the fact remains that, as mentioned before, new suggestions and points of improvement will arise, warranting multiple future recurring updates of the Roadmap.

Second, currently, the Roadmap has mostly been used for the development, evaluation, and implementation of digital health interventions for persons and health care providers. Therefore, the revisions within this second edition are also based mostly on experiences with the development processes of these types of eHealth technologies. Although in principle, the Roadmap 2.0 is also applicable to, for example, the development of digital health interventions for health management and support personnel, and for data services, its value for these areas should be studied more thoroughly.

Another point of attention is that using the CeHRes Roadmap 2.0 does not guarantee the development of effective eHealth interventions that will be widely used in practice. Development, implementation, and evaluation are all extremely complex processes, and while the Roadmap can help to improve them and provide guidance, failures or undesired outcomes might (and will) still occur. In line with this, it is neither possible nor feasible to investigate if using the Roadmap results in better eHealth technologies than using other frameworks such as the person-based approach [53], the Accelerated Creation-to-Sustainment model [44], intervention mapping [45,92], or agile science approaches [50,51]. A comparison of frameworks would require the evaluation of multiple parallel, similar processes. Such similarities are practically impossible to achieve because of the very nature of the CeHRes Roadmap 2.0 and related frameworks and their application to practice, which are all highly dependent on research teams, contexts, objectives, and even periods in time. This makes reliable cross comparisons virtually impossible. Therefore, gaining insights into the added value of frameworks like the Roadmap mostly requires sharing experiences with and lessons learned from its application, which again emphasizes the importance of systematically reporting and reflecting on development, implementation, and evaluation processes, in line with reporting guidelines [13,14,31].

XSL•FO
RenderX

Conclusions

This study addresses the need for an up-to-date version of the CeHRes Roadmap using the most recent insights and most relevant approaches and models. The changes made in the updated version of the CeHRes Roadmap 2.0 compared to its original version address the need for more attention to behavior change theory in eHealth design; the increased emphasis on implementation; and the importance of iterative, multimethod evaluation processes. To ensure that eHealth frameworks are optimally aligned with experiences and best practices from researchers, there is a need for more studies that apply and reflect on the application of these frameworks because, just as any eHealth technology the CeHRes Roadmap 2.0 has to be constantly improved based on the input of its users.

Authors' Contributions

All authors contributed to the content of the manuscript, that is, the update of the CeHRes Roadmap. The first version of the manuscript was written by HK and NBdJ, and SMK and LJEWCvG-P gave feedback. All authors approved the final version of this manuscript.

Abstract

User trust is pivotal for the adoption of digital health systems interventions (DHI). In response, numerous trust-building guidelines have recently emerged targeting DHIs such as artificial intelligence. The common aim of these guidelines aimed at private sector actors and government policy makers is to build trustworthy DHI. While these guidelines provide some indication of what trustworthiness is, the guidelines typically only define trust and trustworthiness in broad terms, they rarely offer guidance about economic considerations that would allow implementers to measure and balance trade-offs between costs and benefits. These considerations are important when deciding how best to allocate scarce resources (eg, financial capital, workforce, or time). The missing focus on economics undermines the potential usefulness of such guidelines. We propose the development of actionable trust-performance-indicators (including but not limited to surveys) to gather evidence on the cost-effectiveness of trust-building principles as a crucial step for successful implementation. Furthermore, we offer guidance on navigating the conceptual complexity surrounding trust and on how to sharpen the trust discourse. Successful implementation of economic considerations is critical to successfully build user trust in DHI.

KEYWORDS

trust; economics; digital health; digital health innovation; artificial intelligence; AI; economic evaluation; public trust; health data; medical apps

Introduction

Public trust is a cornerstone of successful health systems [1,2]. Public trust is a key enabler for the introduction of trustworthy health data spaces for sharing and using health data in research, national electronic health record systems and the introduction of artificial intelligence (AI) systems in medicine. In 2023, the World Health Organization (WHO) in the European Region stated that 77% of its Member States believe the lack of trustworthy sources to access effective medical apps is a substantial implementation barrier to digital health transformation: "Trust is paramount – trust in technology, trust in data protection and, most critically, trust in the respect and safeguarding of privacy rights pertaining to personal health data" [3]. Trust in public health systems legitimizes these activities. Public trust is predicated on the belief that those

XSL•FO
RenderX

systems provide a net benefit, where benefits include individual benefit, societal benefit, and health system benefit [4]. The increasing discourse on trust and trustworthiness of digital health systems interventions (DHI) has been met with an increase in nonbinding professional guidelines and codes of conduct. These guidelines are designed to guide users toward the ethical and trustworthy use of DHIs. Adhering to such guidelines can help foster public trust which, in turn, can foster their practical adoption. Some purposefully sampled guidelines in the area of AI as a prominent example of DHIs are highlighted in Table 1. The guidelines were selected to make sure national and international as well as government and nongovernment organizations were represented but we fully acknowledge that these reflect only a subset of the guidelines that exist.

Table 1. Overview of example guidelines about the trustworthy use of health data and artificial intelligence in relation to digital health system intervention.

Guideline	Providing organization	Context	Relevance for trust in digital health
Ethics guidelines for trustworthy Artificial intelligence [5]	European Commission	Strengthening national systems (including the health system) through artificial intelligence	"Trustworthy AI technologies can be used – and are already being used – to render treatment smarter and more targeted, and to help preventing life-threatening diseases. Doctors and medical professionals can potentially perform a more accurate and detailed analysis of a patient's complex health data, even before people get sick, and provide tailored preventive treatment. […]"
Digital Trust Framework [6]	World Economic Forum	Companies willing to commit to earning digital trust of citizens and customers	"A technology provider's reliability and security can have a significant impact on individuals' safety, including on their physical or mental health. […]"
Global strategy on digital health 2020-2025 [7]	World Health Organization	Strengthening national health systems through digital health technologies	"The appropriate use of digital health takes the following dimensions into consideration: health promotion and disease prevention, patient safety, ethics, interoperability, intellectual property, data security (confidentiality, integrity, and availability), privacy, cost-effectiveness, patient engagement, and affordability. It should be people-centred, trust-based, evidence-based, effective, efficient, sustainable, inclusive, equitable and contextualized. […]"
Guidance on the rights-based and ethical use of digital technologies in HIV and health programs [8]	United Nations	Human rights, technical, and ethical considerations for countries adopting digital technologies for health and HIV	"A core component of successful HIV responses, trust is also a key element in the adoption and success of digital technologies for health. Without trust, the implementation and uptake of digital health will be weak, even if all other aspects of infrastructure, as well as legal and regulatory frameworks, are effective. Trust must be built for all types of relationships related to digital health – between patients and health-care providers; within the health sector institutions; between the State and its residents; and between a State, its residents and the private sector. […] Data breaches violate an individual's right to privacy and erode trust in the health-care system. As technology evolves and health systems become more complex, the likelihood of data breach occurrences increase. Health systems should invest in information security and keep up to date on the latest in data protection to prevent breaches."
A guide to good practice for digital and data-driven health technologies [9]	United Kingdom Department of Health and Social Care	Guiding document on "good practice" for digital health technology innovators in the United Kingdom	"When building an algorithm, be it a stand-alone product or integrated within a system, show it clearly and be transparent of the learning methodology (if any) that the algorithm is using. Undertake ethical examination of data use specific to this use-case. Achieving transparency of algorithms that have a higher potential for harm or unintended decision-making, can ensure the rights of the data subject as set out in the Data Protection Act 2018 are met, to build trust in users and enable better adoption and uptake."
Code of Ethics for Data-Based Value Creation [10]	Swiss Alliance for Data-Intensive Services	Companies and organizations that offer products or services based on data	"Data management is networked. The quality of companies' data-based products and services depends in many ways on other organisations. Accordingly, it is important that in this network of interdependence that companies can trust each other. […] Transparency requires ensuring that customers are informed about all aspects of data handling – storage, management, and protection – thus creating (well-placed) trust."

Such guidelines cover a range of trust-building principles, for example, the need to implement accountability mechanisms, security, or privacy measures, the importance of public and user-centered communication strategies, and the appropriate implementation of the regulation. One example is the Digital Trust Framework published by the World Economic Forum [6] which identifies principles along 8 dimensions: cybersecurity, safety, transparency, interoperability, auditability, redressability, fairness, and privacy. These principles aim to foster security and reliability, accountability, and oversight, as well as inclusive, ethical, and responsible data use for DHIs. The guiding principles are usually at an abstraction level that allows transferability across different contexts, necessitating careful tailoring during the implementation process. In practice,

XSL•FO
RenderX

however, resources are limited. How do we determine which trust-building principles to prioritize, and which digital health policies should take precedence, especially when guidelines conflict? These guidelines are typically silent on the economic implications of trust-building, which could provide guidance on the costs and benefits of implementation. A clear need for economic guidance persists. This observation is underscored by anecdotal observations made by FG in Switzerland in the past few years during workshops and meetings discussing trust in DHIs.

After attending an expert workshop aiming at identifying a list of trust-building principles comprising a trustworthy data space, a fellow participant asked: "This list looks convincing, but I am the only IT (Information Technology) security employee in a small firm, we have limited resources, so which of the principles are cost-effective?" (Workshop on trustworthy behavior, Bern, Switzerland)

While exploring a research collaboration with an industry partner where we aimed to test the performance of a nonbinding trustworthiness codex, the industry counterpart asked: "If our company adheres to a non-binding trustworthiness codex, isn't there a risk that we face a competitive disadvantage compared to our competitors that do not commit to these measures but still adhere to the present legislation?" (Business meeting on the performance of a nonbinding trustworthiness codex, online, Switzerland).

Discussing trustworthiness principles to conceptualize Digital Trust, workshop members from the industry suggested that what we have today is robust conceptual evidence, but we clearly lack implementation experience and evidence showing what trust-building measures are costeffective. (Workshop exploring digital trust, Zurich, Switzerland).

When it comes to the implementation of trust-building measures and the economic evaluation of their effectiveness, we stumble upon a yawning knowledge gap. Three important unanswered questions require our attention: What are the costs of implementing trustworthiness guidelines? With limited resources at hand, which measures are cost effective? What instruments exist to gauge success?

We argue that the failure to address these questions risks undermining both the implementation of trust-building guidelines and their success. What is needed is a clear understanding of trust linked to a robust economic assessment of trust building activities. Furthermore, any economic assessment of the costs and benefits should acknowledge that different stakeholders, such as investors, industry participants, policy makers, or end users, will prioritize these impacts differently.

In this article, we offer direction on how to close this gap by improving the conceptual understanding of trust, implementing actionable trust performance indicators, and sharpening the trust discourse. While the importance of trust in DHI is commonly recognized, we argue that we still need more evidence-based policies to ensure the trustworthiness of these programs are implemented efficiently and effectively. With this viewpoint, we aim to initiate further development of economic thinking in trust building. More specifically we aim to transfer and adapt knowledge from economic research to other domains where trust building matters, but economic considerations have not yet entered the professional discourse and implementation practice of trust building activities.

Shortcomings and Remedies

Trust has been part of economic research for centuries [11]. Ample research exists investigating the relationship between trust and societal prosperity [12], the causal impact of trust on economic development [13,14], and how trust lowers transaction costs [15]. As Arrow [16] stated in 1972, "Virtually every commercial transaction has within itself an element of trust, certainly any transaction conducted over a period of time. It can be plausibly argued that much of the economic backwardness in the world can be explained by the lack of mutual confidence…"

While the existing research provides arguments for the economic incentives for trust-building, the costs and benefits of trust-building in digital health have not been well studied. In some emerging economic evaluation guidelines tailored to DHIs, trust can be a component of an impact inventory in user experiences or considered as a non–health-related impact [17]. Yet, trust as an outcome variable is not a well-established component of economic evaluation of digital health. We argue that the lack of focus on the economics of trust-building in this domain include conceptual and methodological challenges that need to be addressed.

We Need Conceptual Clarity of Trust in Digital Health Interventions as a Prerequisite for Economic Evaluation

Embedded in wider sociopolitical as well as cultural norms and values, the concept of trust is complex and influenced by the context in which it evolves. No commonly accepted definition of trust exists. We suggest that trust in a person or institution is a belief about the trustworthiness of that individual or entity. It is a belief that makes one willing to take a risk and make oneself vulnerable, to rely on that person or institution for one's future benefit. The trustworthiness trait is defined as having characteristics that are conducive to cooperation. What traits count as trustworthy differ by the situation. Still, we can categorize them as either traits relating to competence (the ability to fulfil the tasks expected of them) and traits related to integrity, the commitment to prioritize the best interests of the other [11,18].

Trust is volatile, and while the set of trust-building principles might remain unchanged over time, the relative importance of individual principles can vary depending on the context. In particular, trust repair after health system scandals or negative shifts in societal sentiments toward the government require different approaches [19]. The trait of trustworthiness, often the main target of guidelines, should not be conflated with trust. Trustworthiness is a precondition of trust-building but not a guarantee for trust. Trust-building can be based on calculated decisions and rational thinking [20]. At the same time, a body

XSL•FO
RenderX

of literature highlights the importance of emotions in building trust [21]. Combining calculated and emotional motivations to establish trust broadens the spectrum of possible measures available to policy makers and health system actors. Trust research and guidelines in the digital health domain tend to neglect the emotional motivations of trust-building.

Many guidelines contain a comprehensive portfolio of trust-building principles which reflect the overall complexity of the topic but also reflect the lack evidence about which principles work best in practice. Without considering economic constraints and trade-offs, the guidelines may be biased toward presenting too many trust-building principles that are too broad for fear of missing out, with too little guidance on how to prioritize them. As a result, the guidelines may be perceived by users as overwhelming due to the number of principles included or to their high abstractness, with too much onus placed on the implementer to figure out how to navigate the guidelines.

On the receiving end of the guidelines, we see discussions emerging around which organizational units are most suitable to take on the implementation task. The broad spectrum of trust-building principles, from user centered communication and IT security measures to adherence to the rule of law, places responsibility on different organizational units to lead the implementation of guidelines in areas as diverse as public relations, law, compliance, and IT services. Table 2 provides handpicked examples of specific trust-building activities recommended by the guidelines presented in Table 1 that we categorize about accountability for past mistakes, transparency about the present, and promises and benchmarks for the future [11].

XSL•FO
RenderX

Table 2. Examples of what trustworthiness guidelines call for.

Guideline	Example trust-building activities according to this guideline		
	Accountability for past mistakes	Transparency in the present	Promises and benchmarks for the future
Ethics guidelines for trustworthy AI[a] [5]	• Mechanisms should be put in place to ensure responsibility and accountability for AIa systems and their outcomes. • Auditability, which enables the assessment of algorithms, data and design processes plays a key role therein, especially in critical applications. • Furthermore, adequate and accessible redress should be ensured.	• The data, system and AIa business models should be transparent. Traceability mechanisms can help achieve this. • AIa systems and their decisions should be explained in a manner adapted to the stakeholder concerned. • Humans need to be aware that they are interacting with an AIa system and must be informed of the system's capabilities and limitations.	• Adopt a Trustworthy AIa assessment list when developing, deploying or using AIa systems. • Adapt it to the specific use case in which the system is being applied.
Digital Trust Framework [6]	• Good accountability and oversight mechanisms can both remediate any harms that result from technology use. • Auditability serves as a check and is particularly useful in both the development stage and in the deployment stage. • Redressability allows for recourse to address any harms. • Good accountability builds up the trust necessary for more widespread adoption of useful technologies.	• Information is shared about how the technology is developed, implemented and how the data are used. • Design is user-friendly with transparency in mind.	• Adopt best practice frameworks for security and reliability norms. • Digital trust programs that account for the impact of societal expectations.
Global strategy on digital health 2020-2025 [7]	• Develop an ethics framework to strengthen public trust.	• Use of digital health trust based on authentication and authorization that guarantees trust.	• Build trust by placing importance on quality, safety and ethical considerations facilitate evidence-based decisions to improve public trust.
Guidance on the rights-based and ethical use of digital technologies in HIV and health programs [8]	• Establish impartial, effective accountability and oversight mechanisms for breaches of data privacy and other rights violations.	• Be consultative and transparent in decision-making related to governance and management of digital technologies. • Be transparent about and accountable for the factors that influence algorithmic decisions. • Co-design digital technologies and systems with affected communities. • Create opportunities for digital rights literacy for communities and individuals to understand their rights and take ownership of their data, including the right to withdraw their data from use and to data portability.	• Create monitoring and evaluation systems that allow the technologies to adapt based on feedback.
A guide to good practice for digital and data-driven health technologies [9]	• Undertake ethical examination of data use specific to this use-case.	• Be fair, transparent and accountable about what data is being used. • When building an algorithm, show it clearly and be transparent of the learning methodology (if any) that the algorithm is using.	Absent
Code of Ethics for Data-Based Value Creation [10]	• If your product depends on data from other companies, make sure that this data has been collected in an ethical manner. • Do not use data from untrusted sources.	• Only acquire data from partners who are transparent about both their data collection practices, and any restrictions associated with the use of the data. • Make it clear to your customers how their data is protected and how access is logged. If it is necessary to store data for a very long time (eg, for legal reasons), explain this to your customers at the time of data collection.	Absent

[a]AI: artificial intelligence.

The intersection between digital health and trust is somewhat consistent regarding accountability for past mistakes and transparency about the present. Benchmarks for the future are less well-articulated across specific trust building activities [7-9], or their scope is limited.

The choice of who within an organization is responsible for the management and implementation of specific guidelines has implications for how financial resources get allocated and how the guidelines get interpreted. A joint effort across different units may be preferable as different trust-building principles require collaboration between different organizational units. Research suggests that a collaborative approach involving a range of actors across the organization enhances trust-building [22].

In response to these requirements, we need implementation evidence. Systematically collected evidence, case studies, and experience reports can inform how resources are allocated for different trust-building principles and identify successful trust-building mechanisms in a given context. Given the context specificity of trust, this evidence will not be a blueprint that can be copied and pasted across contexts. Instead, the evidence can help disseminate experience from comparable settings and is an essential step toward better informed resource allocation.

We Need Actionable Trust Performance Indicators to Collect Meaningful Evidence

To gather better evidence to inform resource allocation and make judgments about cost effectiveness, we need appropriate methods to collect data about trust-building from the implementation to the evaluation phases. The standard methodology to gather evidence about trust in the context of health care and medicine is survey instruments. Unfortunately, studies have repeatedly shown that the existing instruments have weaknesses. Goudge and Gilson [23] called for advancements in the quantification of trust; Ozawa and Sripad [24] showed in their review of 45 trust measures in health systems that half of the measures used qualitative methods in the design process, and only 33% were pilot tested; Aboueid et al [25] found in a meta-analysis of 26 publications on trust in health professionals and health systems, 10 studies did not mention the dimensions explored and of those that did, some did not define them. Taylor and colleagues [1] call for conceptual clarity and methodological creativity after reviewing 50 years of trust research. Considering the stagnation in methodological development in the field and the increasing inclusion of guidelines regarding trust in digital health, we see a need for refined methods to address questions of cost effectiveness and resource allocation.

An understanding of the resources invested, and outcomes gained is essential. Since we cannot pin a price tag on trust, we need to agree on sensible indicators that we understand as evidence informed. Table 3 gives an overview of currently applied indicators regarding trust in DHIs that have been developed by some of the essential stakeholders in the field, such as the World Bank or WHO. These indicators are the result of a systematic search on indicators to measure digital health system maturity conducted by Maaß et al [26]. The review identified that trust toward digital health applications, AI, the government, and health care providers plays an essential role among assessment tools for digital health system maturity. However, the indicators rarely reported their methodology and data source, thereby limiting their applicability. We require well designed indicators with transparent methodology and a clear definition on what is meant by “trust.”

XSL•FO

Table 3. Currently used indicators on trust in digital health system interventions.

Indicator	Data source	Reference
Number of individuals identifying false or unreliable information, such as untrustworthy sources, fake news, or fraudulent emails	Quantitative national Computer assisted telephone interviewing survey of 1000 adults aged 18 years or older	Accenture Digital Index by Accenture [27]
You can recognize what information or content online may, or may not, be trustworthy (eg, fact checked information, "fake news" or assess the trustworthiness of a company based on customer reviews)	Qualitative telephone interviewing survey among 4172 adults aged 18 years or older living in the United Kingdom	UK Consumer Digital Index by Lloyds Bank [28]
Regulations and ethical frameworks in place to implement AI[a] in a way that builds trust and legitimacy	UNCTAD Data Protection and Privacy Legislation Worldwide data overview	Government AI[a] Readiness Index by Oxford Insights [29]
To what extent do you trust the information you receive from government websites/apps online?	4910 respondents from 98 countries	Inclusive Internet Index by Economist Impact and Meta [30]
To what extent do you trust the information you receive from nongovernment website/apps that are based in your country online?	4910 respondents from 98 countries	Inclusive Internet Index by Economist Impact and Meta [30]
To what extent do you trust that online privacy is guaranteed?	4910 respondents from 98 countries	Inclusive Internet Index by Economist Impact and Meta [30]
Are opportunities available to link data sources safely at the subject level and perform comprehensive analyses – for example, through a closed controlled working environment operated by the statistical office, or through anonymization and linkage by a trusted third party	No data source published	Support tool to strengthen health information systems by the World Health Organisation Regional Office for Europe [31]
Share of population that trusts medical and health advice from the government	Wellcome Trust Global Monitor [32]	Global Health Security Index by the Nuclear Threat Initiative [33]
Share of population that trusts medical and health advice from health professional	Wellcome Trust Global Monitor [32]	Global Health Security Index by the Nuclear Threat Initiative
The number of distinct, publicly-trusted TLS/SSL certificates found in the Netcraft Secure Server Survey	Netcraft and World Bank population estimates	Worldwide Governance Indicators by the World Bank [34]
The share of a population that trusts Artificial Intelligence	Quantitative survey among 62 countries	The Global AI Index by Tortoise [35]
The share of adults in each market saying they trust public bodies using generative AI[a] technology at least moderately	No data source published	The Network Readiness Index by the Portulans Institute [36]
The trust users hold in institutions, businesses, and policy makers to protect online privacy, harness technology to create jobs, and advocate for consumers	Survey among 42 economies	The Digital Intelligence Index by the Fletcher School at Tufts University [37]
The extent to which institutions create an environment which enables trust	Survey among 42 economies	The Digital Intelligence Index by the Fletcher School at Tufts University [37]
The level of generalized social trust and trust in science and technology in any given economy	Survey among 42 economies	The Digital Intelligence Index by the Fletcher School at Tufts University [37]

[a]AI: artificial intelligence.

Furthermore, most of the guidelines we identified and discussed in Tables 1 and 2 are not published or sponsored by governments or international institutions, raising the question who's interest it actually is to understand the economics of trust-building in digital health? Without appropriate performance indicators that show whether trust-building principles are successful, we cannot evaluate trust building mechanisms or make decisions about prioritization. Indicators are considered instrumental in driving health system improvements and for running comparative evaluations across the health system [38,39]. DHI investors and developers have good economic incentives to adopt trust performance indicators as it allows them to make better informed decisions about resource allocation for trust building and allows them to better monitor whether trust building actions are successful. Indicator sets are based on robust conceptual frameworks "that set out the rationale and design principles for an indicator set" [40] with the intention to provide standardized benchmarks for the systematic evaluation and monitoring of quality, performance, and outcomes. Addressing company executives, Deloitte argues that trust itself should be a key performance indicator for companies, as drops in consumer trust can considerably erode the market value of the firm [22]. Van der Schee et al [41] suggest public trust in the health system is an important performance indicator for assessing national health systems. Several other examples of indicators in specific areas of the health system exist, such as in digital health care, which include indicators relating to trust at least at the margins [27,28,30,31,33,35-37,42-46]. Discussion is currently centered

XSL•FO
RenderX

around identifying useful performance indicators for trust in DHIs and determining the optimal methods for evidence collection. The crucial task is to navigate conceptual complexity and to accommodate context specificity, ensuring the identification of indicators that are suitable for a diverse range of DHIs while aligning with trust-building guidelines.

Survey measures of trust levels can indicate changing trust levels over time [24]. Such measures are useful for assessing the level of trust before and after implementing trust-building principles. Similarly, qualitative user interviews and broader citizen engagement can provide rich information about perceptions and experiences regarding the trustworthiness of a DHI and the effectiveness of its associated trust-building measures [47]. The use of routinely collected data generated from digital health technologies needs to be harnessed and leveraged for better decision-making around trust-building and should include measures of the user experience at different levels of the system. The evidence should inform both the design phase of trustworthy DHIs and for continual assessment of their safety, effectiveness, and quality assurance [48]. This potpourri of methods allows us to think creatively about meaningful performance indicators for various contexts, actors, and DHIs. A comparable example of a newly developed indicator set is the Digital Public Health Maturity Index [49]. This index provides initial indications of possible architecture for an actionable and stakeholder-supported set of performance indicators in an area that faces the same kinds of problems as trust. Developing a trust index and performance indicators with appropriate methods to collect evidence must be integral to future implementation research on trust-building in digital health.

We Need to Sharpen the Trust Discourse

The increased use of the word “trust” by politicians, industry, and researchers alike raises the question of whether the use of the word trust is always justified. The inflationary use of trust in the public sphere, as seen in commercials, labelling, news articles, and media campaigns, possibly undermines trust’s value in settings where trust discussions are essential [50]. If we are not cautious, we may see the trust debate in the digital health sphere drift into symbolic actions and “trust washing,” similar to experiences in “green washing” and “ethics washing” [51]. Trust degenerates into a hollow marketing term when health system actors invest resources merely to chase trends without meaningfully engaging with internal trust-building procedures and actions leading to overall trustworthiness.

Trust is vital for adopting DHIs, but it is not a panacea. Health system actors can act to the best of their knowledge, and policy makers can design evidence-informed policy, including incorporating trustworthiness guidelines in their policy designs, but that does not mean the public or users will trust us [52]. Trust cannot be enforced or demanded. The public and the users decide how to assess trustworthiness and where to place their trust [53]. That insight implies that investments in trust-building in the context of DHIs carry the risk of failure.

Even if trust building is successful, it may not result in material benefit. For example, if several alternative health system actors adhere to trustworthiness guidelines and are all judged equally trustworthy, users will likely make choices not based on trust but on convenience, price, accessibility, or other adoption enablers. Trust is not the only reason we engage with DHIs. We might depend on a DHI and, consequently, engage with it because we have no other choice. We might assess the risk of misplaced trust and its associated consequences to be low and, therefore, not really care about trust. We might carryover the trust we have for more comprehensive health system to new DHIs, allowing us to spontaneously engage with the new and unfamiliar, similar to the concept of spontaneous sociability [12]. Such considerations are essential and require those aiming to build trust to assess the context carefully and to understand user motivations.

Realistic expectations about the capabilities of trust-building are critical in deciding which trust-building measures to adopt and how best to efficiently deploy the necessary resources.

Conclusions

Meaningful guidance for trust-building in digital health must go beyond proposing principles to build trust. We argue that the costs and benefits of trust-building measures are currently missing to a large extent. Health system actors and the research community need trust performance indicators to appropriately collect evidence about resources invested and trust gained in return. We need to be mindful of the present inflated use of the term “trust” in the public sphere when designing new trust building efforts, and to acknowledge that trust cannot be guaranteed. To successfully navigate the complexity of trust-building, we need more engagement in the economics of trust-building in digital health. Economics of trust-building needs to be a deeply integrated and structured part of DHI policy making and health system governance at large to develop sustainable trust building processes while bearing in mind resource scarcity. Furthermore, stakeholders across the health system from regulators, to health organizations, to end users need to have guided access to relevant and comprehensive information about these guidelines in order for meaningful progress to be made.

Abstract

The integration of artificial intelligence (AI) into health communication systems has introduced a transformative approach to public health management, particularly during public health emergencies, capable of reaching billions through familiar digital channels. This paper explores the utility and implications of generalist conversational artificial intelligence (CAI) advanced AI systems trained on extensive datasets to handle a wide range of conversational tasks across various domains with human-like responsiveness. The specific focus is on the application of generalist CAI within messaging services, emphasizing its potential to enhance public health communication. We highlight the evolution and current applications of AI-driven messaging services, including their ability to provide personalized, scalable, and accessible health interventions. Specifically, we discuss the integration of large language models and generative AI in mainstream messaging platforms, which potentially outperform traditional information retrieval systems in public health contexts. We report a critical examination of the advantages of generalist CAI in delivering health information, with a case of its operationalization during the COVID-19 pandemic and propose the strategic deployment of these technologies in collaboration with public health agencies. In addition, we address significant challenges and ethical considerations, such as AI biases, misinformation, privacy concerns, and the required regulatory oversight. We envision a future with leverages generalist CAI in messaging apps, proposing a multiagent approach to enhance the reliability and specificity of health communications. We hope this commentary initiates the necessary conversations and research toward building evaluation approaches, adaptive strategies, and robust legal and technical frameworks to fully realize the benefits of AI-enhanced communications in public health, aiming to ensure equitable and effective health outcomes across diverse populations.

KEYWORDS

messaging apps; public health communication; language models; artificial intelligence; AI; generative AI; conversational AI

Introduction

Health communication and information dissemination are essential for global risk mitigation during public health emergencies. The pandemic highlighted the necessity for effective worldwide communication networks in support of the public health agencies (Center for World Health Organization [WHO] and Global Public Health Intelligence Network), and furthermore, the need for more integrated and global systems for timely warnings and responses to health crises [1]. For this purpose, messaging services have been vital tools for disseminating information, monitoring disease spread, and promoting informed health decisions [2]. Historically, SMS- and app-based text messaging platforms have long been recognized for their potential to deliver scalable health interventions for diverse populations, exemplified by RCTs on substance abuse intervention and promoting the COVID-19 pandemic vaccination [3,4]. These examples illustrate the established value of messaging services in engaging populations and promoting health behaviors.

The emergence of artificial intelligence (AI) has brought innovative and personalized methods in health communications,

XSL•FO
RenderX

with chatbots and AI-driven messaging services presenting personalized, timely, and internet-based health interventions [5]. More specifically, conversational artificial Intelligence (CAI) interventions have exhibited significant positive effects on behavior change, such as smoking cessation, healthy eating, sleep quality, and physical activity [6,7]. CAI models have emerged to complete tasks through natural language using rule-based, hybrid, or unsupervised learning models [8,9]. However, as CAI has been widely used for personalized health intervention, a public health perspective has yet to be studied.

During the pandemic, the emerging value of CAI has been observed as being a scalable, easy-to-use, and accessible dissemination tool [10-12]. In addition, the long-term value of CAI through chatbot tools and voice assistants in public health management has been emphasized [13,14]. A widely observed implementation was a WHO-deployed WhatsApp (Meta) chatbot, as a preventative mechanism, that disseminated critical health information to millions globally, providing multilingual support and real-time updates to address misinformation [15]. However, none of the intelligent systems covered earlier has envisioned the impact of generative AI at scale where it can lead to highly accessible, decentralized, and scalable implementations. Recent applications of widely adapted generative AI models, large language models (LLMs), presented evidence of the effectiveness of generated responses to answer public health questions [16,17], contributing to the trend of using AI to augment the impact of public health interventions.

Envisioning the future, its impact could exponentially grow by wide-scale adoption and implementation across the population by its integration into our daily communication tools (ie, messaging apps). We hypothesize that such LLM-based CAI services (namely, “Generalist CAI” from hereon) through messaging apps, the most commonly used tools on a daily basis, may overtake other means of internet-based information seeking and public information dissemination and sharing mechanisms, toward improving public health communications.

Unlike previous implementations of CAI before the wide adoption of LLMs, Generalist CAI models rely on generative AI (ie, LLMs) or foundation models that are trained on extensive and diverse datasets to perform a myriad of natural language tasks with human-like interaction and a broad understanding across various domains, including health care. These models transcend the limitations of their predecessors, which were constrained to specific tasks, by exhibiting proficiency in varied domains, from casual dialogue to expert-level engagements. These models’ broad applicability is underpinned by their capacity to comprehend and respond in a human-like manner across different conversational contexts. As such, generalist CAI models are not only poised to enhance user interactions but are also likely to supplant multiple task-specific agents (multiagents), heralding a shift toward more unified and contextually aware conversational AI systems in diverse applications. Table 1 outlines the key features of generalist AI.

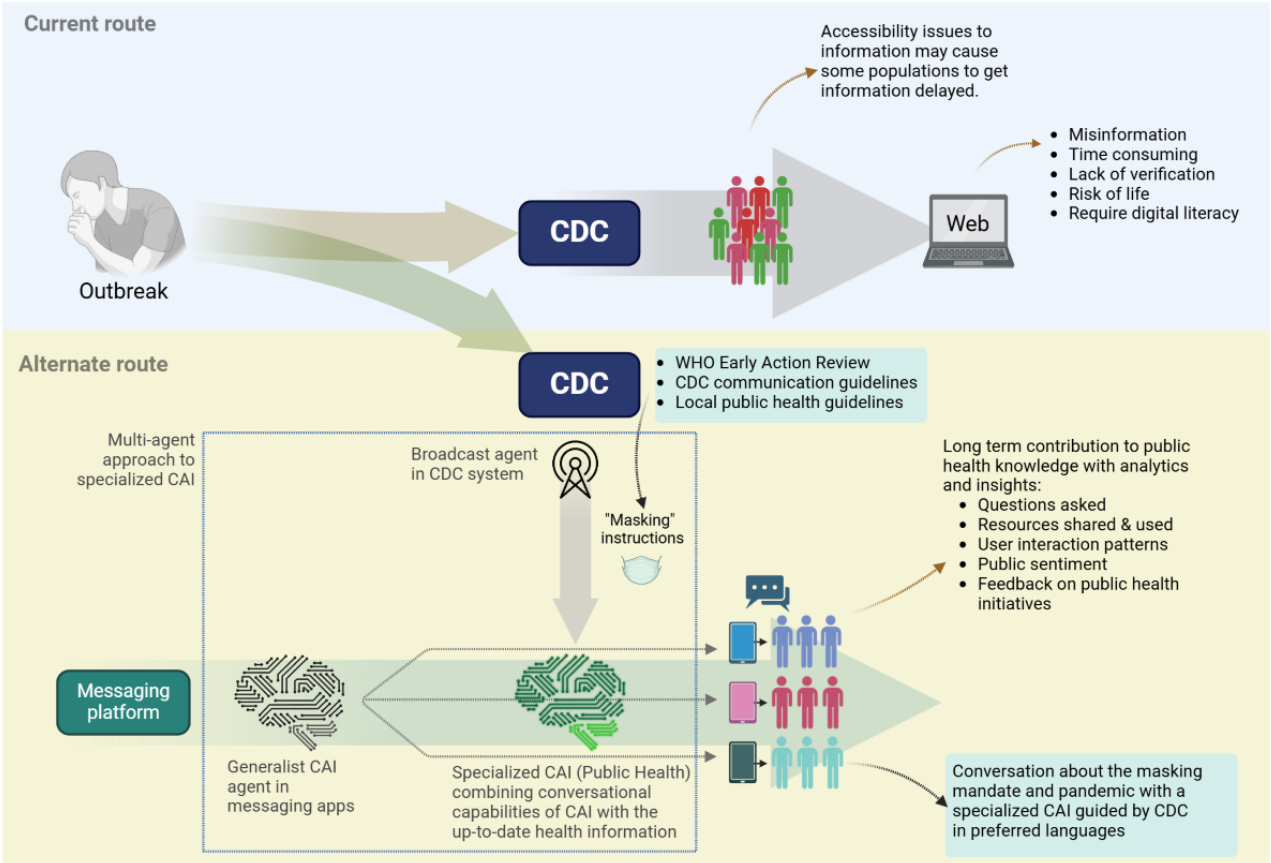
Table 1. Key features and descriptions of generalist conversational artificial intelligence (CAI) applications.

Key features	Descriptions
Natural language understanding and generation	They can understand a broad range of user prompts that can be expressed in various different ways, allowing a higher level of flexibility and ease-of-use.
Generalist	They can converse about a large range of topics and transition between them smoothly.
Dialog management	They can excel in multiturn conversations more effectively than their rule-based alternatives with the ability to respond to follow-up questions.
Emotional intelligence	They can detect subtle cues in language that indicate a user’s emotional state, allowing the chatbot to provide empathetic responses.
Personalization	Generalist CAI can extract user profile information and use it to generate tailored responses effectively.
Multilingual support	They can support multiple languages, making them accessible to a wider audience.
Scalability	They can handle an unlimited number of queries simultaneously, providing instant information on a wide range of public health issues.

The Advantage of Generalist CAI in Messaging Services

AI has already transformed the ways in which individuals seek health information. Today, we observe that generalist CAI or LLM applications (eg, chatGPT) simplify access to health advice [18], by breaking down barriers associated with traditional web searches.

The next step appears to be messaging tools with generalist CAI assistance, like WhatsApp, Signal (Signal Technology Foundation), iMessage (Apple Inc.), and Telegram (Telegram FZ-LLC Telegram Messenger Inc), which would offer a “familiar” platform to billions of people, with the potential to improve access to health information and services. Messaging apps’ simplicity in terms of user interface and the use of natural language inherently reduce digital literacy and accessibility barriers. Therefore, messaging services with generalist CAI can surpass previous implementations of task-specific CAI services regarding capabilities, user access and adoption, lower barriers to use and provide personalization through self-learning and conversation adaptation (Table 1). For example, instead of just providing preprogrammed answers, a generalist CAI can engage in a dynamic dialogue to understand a user’s specific concerns, clarify ambiguities, and provide tailored advice based on the conversation’s context. Furthermore, mobile device-based dialogue services (eg, automatic speech recognition and text-to-speech) further improve the usability of the service



XSL•FO
RenderX

through natural language conversations. This means, in a public health emergency, the widespread use of apps like iMessage and WhatsApp (billions of active users daily) can facilitate immediate access to personalized health advice, circumventing barriers to accessing urgent public health information. The integration with generalist CAI, as seen in Meta AI's LLM-powered generalist CAI or personal assistant, positions these services in a favorable spot as a convenient tool for information seeking and health communication, potentially offering equitable access to personalized health information across diverse populations. To further extend these opportunities, small language models (eg, Phi-3) [19] can be leveraged to build capable generalist CAI for individuals in remote areas or those with limited access to internet bandwidth, who could still benefit from text-based interactions with the CAI.

Envisioning Generalist CAI Use in Public Health Emergencies

As the AI tools and applications are rapidly growing and immersing in our daily lives, it is necessary to plan and strategize for the use of generalist CAI services in public health emergencies. Given the fact that the current LLMs and CAI are trained on publicly available data on a massive scale with less attention to information quality or specific domains like health care, we need to approach cautiously in promoting safe and reliable information pipelines over these messaging platforms for public health information sharing, communication, and dissemination. To improve CAI accuracy and reliability in public health communications, a multiagent approach could be used [20,21]. This includes specialized AI agents collaborating, some provide general health information, while others ensure compliance with health guidelines. We envision the integration of generalist CAI assistants into public health messaging services through such a multiagent approach to streamline future interventions. Figure 1 illustrates a 2-agent arrangement where a CAI agent in a messaging app uses the public health information provided by the Centers for Disease Control and Prevention (CDC) to compose its response.

Figure 1. Current practice and the proposed alternative routes for public health communications during an outbreak CAI: conversational artificial intelligence; CDC: Centers for Disease Control and Prevention; WHO: World Health Organization.

Public Health Emergency Case: the COVID-19 Pandemic

During the COVID-19 pandemic, we observed that the dissemination of comprehensive and accurate information is crucial for educating the public and combating the pandemic [12]. This period highlighted the potential of basic chatbot applications in enhancing public health communications, especially in diverse and low-resource settings. As aforementioned, WHO released a chatbot over WhatsApp providing up-to-date COVID-19 information in multiple local languages extending across several low- and middle-income countries [15]. In Nigeria, an SMS-based chatbot, offered by the Nigeria Centre for Disease Control, with support from

XSL•FO
RenderX

UNICEF (United Nations International Children's Emergency Fund), provided localized guidance and timely information about pandemic [22]. Similarly, India released an app with chatbot features to engage rural and urban Indian residents for the COVID-19 pandemic safety practices and checking symptoms, updates, and access helplines [23]. These implementations demonstrate the scalability and potential of digital conversational intervention in public health emergencies. With generalist CAI, personalized public health intervention can be achieved, bridging communication gaps and supporting public health agencies during emergencies.

A strategic plan for effective communication during a health crisis is required, leveraging a multiagent approach. In a partnership between the public health agencies (eg, WHO and CDC) and technology providers, we may create an information dissemination pipeline during a public health crisis (Figure 1). For instance, by adhering to CDC's guidelines for communication and dissemination and using only vetted information sources [24], generalist CAI agents can be designed to deliver messages accurately, empathetic, and action oriented. CDC-defined key elements for developing outbreak-related messages include expressing empathy, outlining clear actions, delineating what is known and unknown, explaining public health actions and their rationale, committing to ongoing communication, and guiding the public on where to find reliable information [24]. For example, regarding the need to "outline clear actions," a specialized agent could be programmed to ensure that every informational response includes actionable steps the user can take. This framework could be used to prompt the agents and ensure that the generated messages are fine-tuned to deliver intended messages toward not only informing and educating but also to build trust and encourage compliance with health advisories. Furthermore, aligning with WHO's early action review guidelines that are designed to optimize early detection of public health emergencies, such agents could be deployed to intervene timely and tailored to the target audience in compliance with the local or national guidelines across the globe [25]. Ideally, a trained generalist CAI acting as a public health support agent can be simultaneously activated across the populations, including low-resource countries, rural and urban areas, served in any preferred language through text or speech. In the long term, such agents can contribute to the knowledge of public health agencies and the data they provide can help learn more about the effectiveness of communications with real-time feedback from the public. Future research should focus on developing frameworks that facilitate the integration of multiagent CAI systems into existing public health infrastructures. Some of the viable approaches could be through interoperability with electronic health records, collaboration with public health databases and registries, and using standardized communication protocols like Fast Health care Interoperability Resources [26], embedding CAI agents into communication platforms preferred by health professionals, and establishing governance mechanisms to ensure ethical and efficient operation [27,28].

Multimedia Appendix 1 for our brief experiments and observations toward the opportunities and limitations with current generalist CAI applications in response to some of the emerging public health problems including pandemic response, unmet social needs, mental health support, and vaccinations.

Risks and Ethical Considerations

The deployment of generalist CAI assistants in messaging apps presents multifaceted challenges, including risks of bias, misinformation, hallucinations, and ethical pitfalls, which have been observed earlier with Snapchat's personal assistant [29]. The models behind these CAI assistants pose a critical challenge due to inherent biases arising from skewed or incomplete training data, flawed algorithmic design, or the reinforcement of societal prejudices [30]. These biases risk distorting health communications and exacerbating health disparities [31,32]. For example, an earlier study [33] revealed that a widely used health care algorithm exhibited significant racial bias by predicting costs instead of health needs, leading to unequal care allocation for Black patients. Such bias could pose a risk for generalist CAI providing less comprehensive (or even inaccurate) information to individuals from underrepresented racial or ethnic backgrounds. In addition, a culturally sensitive and inclusive design is also important to mitigate the risk of inherent biases that may exist in the training data of generalist CAI. These issues underscore the importance of accountability, fairness, equity, and regulatory oversight [34]. Moreover, ethical concerns extend beyond privacy to include user autonomy and the transparent use of data, necessitating clear guidelines and user consent. To support user autonomy, implementing verification mechanisms and ensuring the source data originating from authoritative health organizations can help maintain the trustworthiness of the AI-generated information. One step further, a multiagent approach can help control the CAI behavior regarding user location and profile, ensuring that advice and data handling procedures comply with the local rules and regulations. Even though messaging services are one of the most accessible and used communication technologies, the FCC Affordable Connectivity Program or similar global programs can be used to address the digital divide and affordability issues [35]. While some messaging apps offer end-to-end encryption, overall, the lack of governance or medico-legal compliance (eg, HIPAA [Health Insurance Portability and Accountability Act], HITECH [Health Information Technology for Economic and Clinical Health] or GDPR [General data protection regulation] rule on processing sensitive data requirements for public health information), unless integrated with telehealth services, raises significant privacy concerns, similar to those of standard text messaging services. Technical standards and ethical frameworks should be developed to ensure AI systems are transparent and fair [36]. Further considerations are outlined in Table 2.

XSL•FO
RenderX

Table 2. Technical challenges and potential solutions in deploying generalist conversational artificial intelligence (CAI).

Challenge	Description	Potential solutions
Language diversity	• Developing CAI systems that can understand and generate responses in multiple languages and dialects is complex. Language nuances, slang, and regional expressions can hinder accurate communication [37].	• Multilingual training: Incorporate extensive multilingual datasets during training. • Local expertise collaboration: Partner with local linguists and community experts. • Adaptive learning: Implement adaptive learning algorithms based on user interactions.
Technological infrastructure	• Variability in technological infrastructure, such as outdated devices or limited computational resources, can impede effective CAI deployment [38].	• Lightweight models: Develop optimized, lightweight, and specialized AI models. • Edge computing: use edge computing to perform data processing closer to the user. • Offline capabilities: Incorporate offline functionalities where possible.
Internet connectivity	• In many low-resource settings, unreliable or limited internet access can restrict the usability and accessibility of CAI-powered messaging services [39].	• Data-efficient communication: Design CAI systems requiring minimal data usage. • SMS or voice integration: Integrate CAI functionalities with SMS-based platforms or text-to-voice calls. • Caching and preloading: Implement caching strategies to store essential information locally [40].
Integration with existing systems	• Integrating CAI with existing public health information systems and workflows can be technically demanding [41].	• API[a] development: Develop robust APIs for smooth integration. • Modular architecture: Adopt a modular system architecture. • Standardization: Promote standardized protocols and data formats for interoperability.
Data privacy and security	• Ensuring the privacy and security of user data is paramount, especially when dealing with sensitive health information [42].	• Encryption and access controls: Establish strict access controls, authentication mechanisms, and end-to-end encryption. • Compliance frameworks: Adhere to international and local data protection regulations (eg, GDPR[b], HIPAA[c]). • Small local models: Support the development of smaller models that can be run locally (eg, Mistral 7B and Microsoft Phi-3) [43].
Bias and cultural sensitivity	• AI algorithms can inadvertently conserve social prejudices and cultural insensitivities present in training data, leading to biased or inappropriate responses [44].	• Diverse training data: Curate datasets that represent diverse populations and cultural contexts [45]. • Bias audits: Regularly conduct bias assessments and audits of CAI models [46]. • Inclusive design practices: Incorporate principles of inclusive design to ensure cultural relevance and sensitivity [47].
Stakeholder engagement	• Engaging community stakeholders is essential to ensure that CAI systems meet the needs of diverse populations and promote equitable outcomes [48].	• Participatory co-design: Involve community members in the design and development process. • Feedback mechanisms: Establish channels for continuous feedback from users. • Collaborative partnerships: Partner with local organizations and leaders to guide CAI development and deployment.

[a]API: application programming interface.

[b]GDPR: General data protection regulation.

[c]HIPAA: Health Insurance Portability and Accountability Act.

The contentious nature of AI governance and accreditation of service providers for multiagent AI services might require a legal infrastructure as much as a technical one, to reduce perceived legal risks and liabilities with government agencies accrediting private sector tools. However, the recent initiative by the Biden Administration to form task forces aimed at shaping policies for AI in health care signals a promising direction for overcoming these hurdles in the United States [49], suggesting that improvements in the medicolegal landscape could pave the way for safer AI implementations in public health communication [50]. Internationally, regulatory bodies are also beginning to take similar steps, aiming for a cohesive global

XSL•FO
RenderX

response to AI challenges [51]. It is crucial to address how these technologies might disproportionately affect marginalized groups, ensuring inclusive and equitable AI development. The long-term societal impacts, such as the erosion of public trust through AI missteps, must also be considered in developing sustainable AI strategies. Engaging a broad spectrum of stakeholders in AI discussions can enhance the legitimacy and effectiveness of governance structures. This evolving scenario highlights the critical need for a balanced approach to harnessing AI's potential while addressing its ethical, legal, and social challenges.

Conclusions and Future Directions

AI-enhanced messaging apps hold significant promise for advancing public health by improving access to health information, supporting health behavior change, and addressing diverse community needs. Their scalability and adaptability have already demonstrated impact during public health crises, such as the COVID-19 pandemic, where CAI systems facilitated rapid and multilingual information dissemination. Generalist CAI, with its ability to handle diverse conversational tasks and adapt to user needs with its human-like interaction capability, represents a transformative opportunity to create equitable and accessible public health communication tools. However, realizing their full potential requires addressing critical challenges, including biases in training data, risks of misinformation, ethical concerns around equity and transparency, and the need for robust legal and technical frameworks. To unlock these opportunities, AI messaging services must be developed and continually updated to address evolving requirements on fairness, accountability, and culturally sensitive design, ensuring they uphold the principles of reliability, equity, and justice in public health.

Key research priorities should include evaluating the efficacy of multiagent systems, understanding user interaction and trust dynamics, addressing biases, assessing impacts on health equity, and exploring innovative applications beyond basic information delivery. Observational studies can help identify how individuals engage with CAI systems and guide improvements in public health applications. To ensure equitable access, public health agencies should advocate for culturally sensitive and linguistically diverse CAI systems. Collaborations with local organizations and the establishment of global repositories of vetted health information are critical to minimizing misinformation and aligning CAI outputs with public health guidelines. Eventually, public health agencies and researchers can create a roadmap for leveraging CAI effectively and equitably, paving the way for a transformative approach to public health communication. Continued research on user engagement and the optimization of AI models for public health is essential to fully leverage the capabilities of these ubiquitous tools.

Abstract

Current literature is unclear on the safety and optimal timing of delivery for pregnant individuals with gestational diabetes mellitus, which inspired our study team to conduct a web-based survey study exploring patient and provider opinions on delivery options. However, an incident of fraudulent activity with survey responses prompted a shift in the focus of the research project. Unfortunately, despite the significant rise of web-based surveys used in medical research, there remains very limited evidence on the implications of and optimal methods to handle fraudulent web-based survey responses. Therefore, the objective of this viewpoint paper was to highlight our approach to identifying fraudulent responses in a web-based survey study, in the context of clinical perinatal research exploring patient and provider opinions on delivery options for pregnancies with gestational diabetes mellitus. Initially, we conducted cross-sectional web-based surveys across Canada with pregnant patients and perinatal health care providers. Surveys were available through Research Electronic Data Capture, and recruitment took place between March and October 2023. A change to recruitment introduced a US $5 gift card incentive to increase survey engagement. In mid-October 2023, an incident of fraudulent activity was reported, after which the surveys were deactivated. Systematic guidelines were developed by the study team in consultation with information technology services and the research ethics board to filter fraudulent from true responses. Between October 14 and 16, 2023, an influx of almost 2500 responses (393 patients and 2047 providers) was recorded in our web-based survey. Systematic filtering flagged numerous fraudulent responses. We identified fraudulent responses based on criteria including, but not limited to, identical timestamps and responses, responses with slight variations in wording and similar timestamps, and fraudulent email addresses. Therefore, the incident described in this viewpoint paper highlights the importance of preserving research integrity by using methodologically sound practices to extract true data for research findings. These fraudulent events continue to threaten the credibility of research findings and future evidence-based practices.

Introduction

Gestational diabetes mellitus (GDM) is one of the most common complications associated with pregnancy. In Canada, GDM is on the rise, with a near doubling of GDM diagnoses from 4% in 2004 to 7% in 2014 [1]. Globally, the rate of GDM is estimated to be 14.7%, according to the International Association of Diabetes and Pregnancy Study Groups [2].

Current literature is unclear on the safety and optimal timing of delivery for pregnant individuals with GDM. Canadian guidelines for delivery of GDM pregnancies differ from that of other countries, and discourse remains, even amongst health care providers [3-6]. Furthermore, literature exploring the perspectives of pregnant individuals and care providers on induction of labor (IOL) at 38 weeks compared with expectant management is limited.

Therefore, our study team initially sought to conduct a survey study exploring the topic of IOL and delivery options for pregnant individuals diagnosed with GDM. However, a significant and rapid influx of responses to the survey in mid-October 2023 prompted further investigation for fraudulent responses, shifting the focus of the study team's objectives with this research project.

Therefore, the goal of this viewpoint paper is to highlight our experience and approach to identifying fraudulent responses in a web-based survey study in the context of perinatal clinical research regularly conducted by the study team.

Challenges of Preserving Data Integrity in Studies With Vulnerable Populations

Particularly when conducting research with vulnerable populations such as pregnant individuals, there is a tension between maintaining participant anonymity while using techniques to prevent data fraud and protect study integrity [7]. Pregnant individuals have traditionally been excluded from research trials due to ethical concerns and misinformed ideas about clinical research [8]. Safety measures have always been at the forefront of pregnancy clinical research due to the medical complexities that pregnant individuals possess, and the additional consideration for fetal and newborn wellbeing. Therefore, providing a protected space where pregnant individuals can participate in research aimed to improve the health outcomes of themselves and their infants is integral for equitable and evidence-based practices [8]. However, breaches in data security and incident of fraudulent activity threaten this safe space.

Despite the significant rise of web-based surveys used in medical research, there remains very limited evidence on the implications of, and optimal methods to handle, fraudulent survey responses [9]. Unfortunately, there are no optimal methods or guidelines to address fraudulent incidents in research ethics or protocols [10-13]. Oftentimes, when these incidents take place, research teams must resort to less robust measures to address areas of fraud, such as filtering based on selection criteria, feasible participant timelines, duplication, repetitive responses, etc [10-13]. Therefore, challenges remain to systematically distinguish fraudulent from true responses to ensure research integrity and credibility of findings.

There is limited discourse on the incidence rates and impact of fraudulent responses to web-based surveys in the literature, making it difficult for researchers to raise awareness of these threats to data integrity. Reported incidents of data fraud in web-based studies are limited but suggest the need for rigorous protocols to distinguish fraudulent from true data to protect research integrity [7,9,11,12,14]. Less sophisticated methods used to differentiate fraud from true data have included tracking timestamps and time to completion of survey responses, using the Completely Automated Public Turing Test to Tell Computers and Humans Apart (CAPTCHA), and including several required open-ended questions to identify unusual responses [13,15,16]. More sophisticated methods have included logic checks to assess survey respondents' attentiveness, using skip logic, or using redundant questions to ensure consistency of responses to demographic questions [13,15,16].

Back to the Beginning: Methods for a Pregnancy Survey Study

Our team, composed of perinatal clinicians, researchers, and practicing obstetricians and gynecologists, originally sought to conduct a survey study exploring the perspectives of pregnant individuals and health care providers on their willingness to participate in research studies comparing elective IOL at 38 weeks of gestation versus expectant management for individuals diagnosed with GDM. However, we shifted our focus to explore the challenges of preserving data integrity in web-based research studies upon the discovery of a fraudulent incident with our survey responses.

Ethical Considerations

Ethics approval was obtained from the Ottawa Health Science Network Research Ethics Board (protocol ID: 20230075-01H). We updated recruitment to allow for compensation in the means of a CAD $5 (US $3.50) gift card to a local coffee shop upon completion of the survey for eligible participants. This required that participants provide their email address in a separate survey to which a link was made available upon completion of the main survey. We advertised this monetary incentive on all recruitment materials and in the participant consent form upon accessing the web-based survey. Any information provided by participants was kept strictly confidential and only available to the research team.

XSL•FO
RenderX

Participant Sample

Our initial survey study included 2 study groups: a patient population and a provider population. Patients were eligible to participate if they were currently pregnant with a diagnosis of GDM at the time of survey completion or up to 12 months postpartum with a diagnosis of GDM in their most recent pregnancy. Providers were eligible if they routinely provided care to the pregnant population and held a professional status that allowed them to counsel pregnant people on delivery recommendations. We sought to recruit a target sample size of 100 participants in each group (100 patients and 100 providers), totaling 200 participants. This sample size was selected to optimize study feasibility while sufficiently capturing the perspectives of pregnant people with GDM and health care providers.

Methods of Recruitment

We used convenience and snowball sampling to recruit participants. We conducted recruitment using various strategies, including posters in hospitals, social media posts on Twitter and Facebook, active recruitment at in-person clinics, review of electronic medical records, and the leverage of existing professional colleagues of the study team.

Survey Elements

We developed web-based surveys using Research Electronic Data Capture (REDCap) software and they took approximately 10 minutes to complete [17,18]. REDCap is a secure, web-based software platform designed to support data capture for research studies [17,18]. The surveys were cross-sectional in nature and were available as 2 different URL links (1 for each study group). The surveys were publicly available, thus anyone with access to the URL links had access to the surveys.

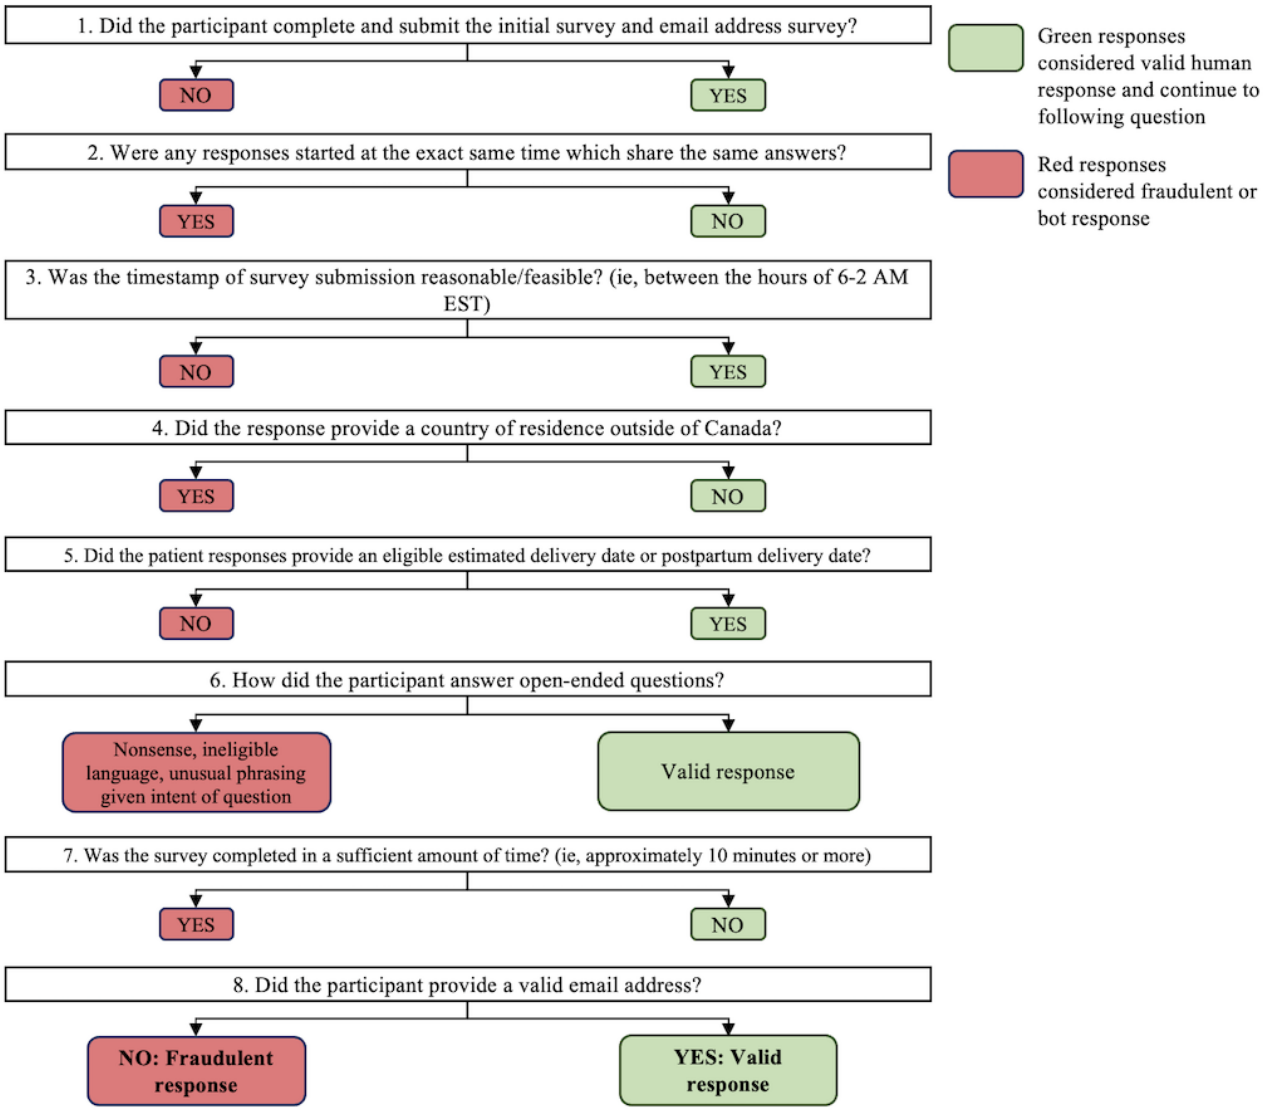
Survey Measures

Data was measured using a combination of Likert scale responses, free text response options, and multiple-choice questions. Data pertaining to demographic characteristics and likelihood to participate in or support a future randomized trial comparing induction of labor and expectant management for pregnancies impacted by GDM was obtained for both patient and provider groups.

Security Measures

In our survey study, to dissuade automated fraudulent responses, we included the CAPTCHA test, made available through the REDCap system. The URL links were made secure by generating them in REDCap, a data capture software that supports data security for research studies. In addition, the surveys were created in such a way that individuals deemed ineligible would not be allowed to advance to the next questions. This was accomplished using forced fields to ensure only eligible participants continued to survey questions.

The Incident and Aftermath



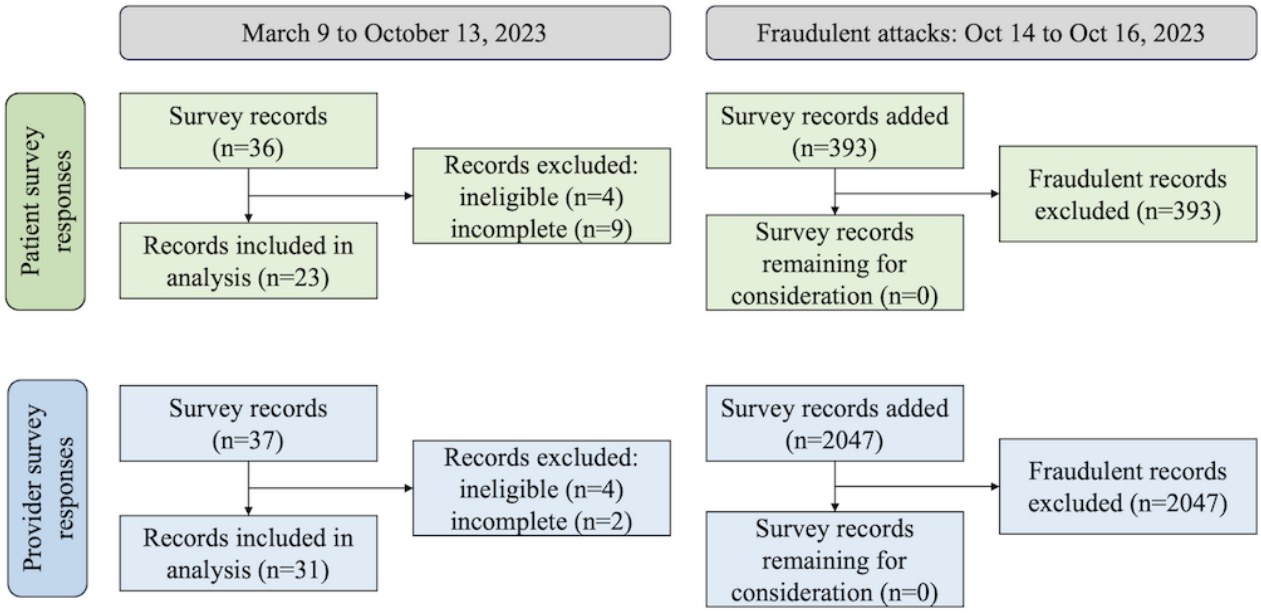
The GDM-related surveys were initially launched on March 9, 2023, and remained active until mid-October, 2023. Upon approval of an amendment on October 4, 2023, surveys were updated on October 11, 2023, to include a monetary incentive.

Part of our data management plan included a team member monitoring the survey responses on a regular weekly basis. Therefore, we were able to identify the onset of the fraudulent incident within a short timeframe. Once it was determined that the rapid influx of responses between October 14 and 16, 2023, was in fact a fraudulent incident, the research team swiftly deactivated the survey that same day and removed posters from clinical settings as well as social media posts. Our team reported the incident to the OHSN-REB for guidance on the next steps to address the fraudulent survey responses. The information technology teams were also alerted to help to address fraudulent responses.

We created a systematic guideline to filter fraudulent responses from true responses, by exporting the data from REDCap into Microsoft Excel and using criteria to indicate reasons for flagging responses as fraudulent (Figure 1). The responses were tallied according to their criteria and are summarized in the results.

XSL•FO
RenderX

Figure 1. Approach to fraudulent response filtering.



Our Findings

From March 9 to October 13, 2023, we had a total of 36 patient responses and 37 provider responses to the survey. Upon preliminary screening, 23 patient responses and 31 provider responses were deemed eligible and included in our analysis. Between October 14 and October 16, 2023, there were an additional 393 patient survey records and 2047 provider survey records submitted (Figure 2). Given the rapid influx of responses in such a short timeframe and the nature of our recruitment before this event, our team determined this to be an incident of fraudulent activity and used a systematic guide to identify fraudulent responses. Possible reasons for the drastic difference in the ratio of patient to provider fraudulent responses included: (1) the provider survey was shorter than the patient survey, (2) the provider survey asked fewer demographic questions, and (3) the provider survey required that fewer eligibility questions be completed to advance to the next survey questions.

XSL•FO
RenderX

Figure 2. Timeline for survey response influx and screening. See Multimedia Appendix 1 for reasons why patient survey records were flagged as fraudulent. See Multimedia Appendix 2 for reasons why provider survey records were flagged as fraudulent.

In consultation with the research ethics board and IT services, our team constructed a system to flag responses according to their fraudulent activity criteria (Figure 1). Criteria for filtering according to fraudulent versus true responses were applied. Following advice from the research ethics board, the surveys were inactivated and the study was closed to prevent further potential compromise to our results. Due to the limited discourse that exists on optimal methods for handling fraud in survey research, there was no obvious software that our team determined was best suited for addressing the incident. Therefore, we used Microsoft Excel files and applied a multireviewer, multidisciplinary, and multistep approach to filter fraudulent responses.

We reported reasons for why patient responses were flagged as fraudulent and tallied our findings using frequencies and percentage descriptive statistics (Multimedia Appendix 1). Reasons included an ineligible country provided or country not provided, ineligible estimated delivery date or postpartum delivery date (eg, date listed as “2004-02-01” or “1988-10-25,” which did not fall within the eligible 12 months postpartum as outlined in the eligibility criteria), same timestamp with exact same responses, same timestamp and similar responses with only slight variations in wording, responses not aligned with the intent of questions, fraudulent email address provided, and suspicious timestamp (eg, a multitude of responses being submitted between the hours of 2-6 AM Eastern Standard Time).

Reasons for why provider responses were flagged as fraudulent were also tallied and reported (Multimedia Appendix 2). Reasons included same timestamp with exact same responses, same timestamp and similar responses with only slight variations in wording, similar timestamp and similar responses, ineligible language, fraudulent email address provided, suspicious timestamp, and incomplete responses.

Criteria used to filter out fraudulent responses was defined in consultation with study team members. For example, the criteria “same timestamp and responses” was defined as any response that was written the exact same way with the same wording and submitted at the same time as any other response. Fraudulent email addresses were determined using the built-in Excel data validation function and email verification software to identify invalid mailboxes, invalid domains, spam traps, and syntax errors.

Given the significant number of fraudulent responses and the limited number of responses deemed to be “true,” the research team decided against conducting a between-group analysis of the responses included compared with those excluded.

Fraudulent Online Bots: A Black Box in Medical Research

This paper contributes to an unfortunately limited body of evidence supporting the need for increased data security measures when conducting medical research in the technological era. Despite the significant rise of web-based surveys used in medical research, there remains very limited evidence on the implications of, and optimal methods to handle, fraudulent survey responses [9]. However disappointing, adverse fraudulent events will likely continue to occur. These events therefore obscure the true results of medical research and pose a threat to the integrity of future evidence-based practices.

Unfortunately, there are no optimal methods or guidelines to address fraudulent incidents in research ethics or protocols [10-13]. Oftentimes, when these incidents take place, research teams must resort to less robust measures to address areas of fraud, such as filtering based on selection criteria, feasible participant timelines, duplication, repetitive responses, etc [10-13]. Therefore, challenges remain to systematically distinguish fraudulent from true responses to ensure research integrity and credibility of findings.

XSL•FO
RenderX

Previous literature highlights the importance of security measures to ensure the integrity of web-based survey responses. Such security measures have included using CAPTCHA to distinguish humans from bot responses, using software that collects IP addresses of its survey user, requiring the completion of an open text response to assess individuality, or requiring email verification for the completion and submission of the survey [9,11,14,19]. Furthermore, measures to avoid the attention of fraudulent respondents may include keeping recruitment periods short and avoiding advertisement of the survey in public spaces such as on social media or on posters in the hospitals [19]. Incidents such as these indicate the need for study protocols to outline contingency plans in the case of cyber-attacks that may compromise the credibility of their findings [11,19]. Manual validation, in addition to the automatic validation techniques used to filter duplicate survey responses, should be implemented and strengthened in future web-based research studies [11,19].

We recognize that many factors likely contributed to the influx of fraudulent activity. For example, the amendment to include a monetary incentive was activated at the end of a work week, providing more weekend time for individuals to submit responses. In addition, the survey was available as a single public link rather than a disposable link, providing a convenient means to share the surveys amongst other potential users. Another limitation to our study, and what was a potential factor for the influx of fraudulent responses, was the limited eligibility criteria, since patients were eligible if they were currently pregnant, or had been pregnant in the past 12 months, and diagnosed with GDM. Due to this restriction in selection criteria and our desired sample size of 200 participants, the recruitment period was prolonged to obtain an adequate sample size, increasing the risk for fraudulent responses to be submitted to the survey. However, despite evidence to suggest that recruitment of pregnant people in research studies is most effective through face-to-face means, our team determined that using multiple recruitment strategies would limit selection bias and increase the likelihood of reaching our desired sample size [13,20-22]. Finally, REDCap software, although useful for many research studies, does not collect the IP addresses of participants accessing surveys generated through its system. This posed a limitation to our team's ability to use robust methods to decipher fraudulent from true responses.

This viewpoint paper is unique in that it brings to light a rising concern for data security and research integrity in an era of mounting technological involvement in medical research. It highlights the real and raw experience of a group of medical researchers who pride themselves on conducting methodologically sound and scientifically robust perinatal health research. Therefore, this paper provides an example of the vulnerability of web-based medical research, and the extent of precautions that are necessary to prevent such incidents from occurring.

Conclusions

Overall, this fraudulent incident highlights the importance of preserving research integrity by using methodologically sound practices to extract true data for research findings. Despite numerous measures used to avoid fraudulent data in medical research, findings may still be compromised, particularly in web-based studies. We hope this case example provides future researchers with a cautionary tale to consider when conducting their own survey studies. Researchers must be aware of and actively work to prevent potential threats to the credibility of their research findings and future evidence-based practices.

Acknowledgments

Our study team would like to thank all patients and providers who participated by providing their genuine responses. Our team would also like to thank the Ottawa Health Science Network Research Ethics Board and Information Technology teams at the Ottawa Hospital Research Institute for their support and guidance of the fraudulent activity reporting protocol. This study was funded by a grant from the Canadian Institutes of Health Research (FRN 148438).

Abstract

There is a critical need for community engagement in the process of adopting artificial intelligence (AI) technologies in public health. Public health practitioners and researchers have historically innovated in areas like vaccination and sanitation but have been slower in adopting emerging technologies such as generative AI. However, with increasingly complex funding, programming, and research requirements, the field now faces a pivotal moment to enhance its agility and responsiveness to evolving health challenges. Participatory methods and community engagement are key components of many current public health programs and research. The field of public health is well positioned to ensure community engagement is part of AI technologies applied to population health issues. Without such engagement, the adoption of these technologies in public health may exclude significant portions of the population, particularly those with the fewest resources, with the potential to exacerbate health inequities. Risks to privacy and perpetuation of bias are more likely to be avoided if AI technologies in public health are designed with knowledge of community engagement, existing health disparities, and strategies for improving equity. This viewpoint proposes a multifaceted approach to ensure safer and more effective integration of AI in public health with the following call to action: (1) include the basics of AI technology in public health training and professional development; (2) use a community engagement approach to co-design AI technologies in public health; and (3) introduce governance and best practice mechanisms that can guide the use of AI in public health to prevent or mitigate potential harms. These actions will support the application of AI to varied public health domains through a framework for more transparent, responsive, and equitable use of this evolving technology, augmenting the work of public health practitioners and researchers to improve health outcomes while minimizing risks and unintended consequences.

Introduction

While public health has a rich history of innovation in areas such as vaccination, sanitation, and epidemiology [1], the field has been cautious in the widespread adoption of emerging technologies like generative artificial intelligence (GenAI). Calls for updated approaches to public health funding, programming, and research have been pervasive amid the changing landscape of health in the United States and globally [2]. The field of public health is at a crossroads, with growing recognition of the need for innovation to afford greater agility and responsiveness to emerging problems [3].

GenAI applications are expected to impact all sectors of society. Many public health practitioners and researchers are understandably cautious about these developments and how they will affect the discipline and the communities we serve—the exception is in bioinformatics and biostatistics, where machine learning and other techniques have long been applied to medical and health care data [4]. Given the speed of technology, there is a risk that significant portions of the population—particularly those with the fewest resources—will be marginalized by the incursion of GenAI technologies. An analogous example is the burden placed on individuals to use emerging technological tools for health care (eg, patient portals, telehealth visits, pharmacy apps), which disproportionately exclude low-income and aging populations. The present danger is that the AI revolution in public health may exacerbate well-known health disparities, both through new generative tools as well as common AI or informatics techniques being applied more broadly. As public health professionals, we must educate ourselves and engage communities in knowledge seeking around AI and its impact on their lives, to fulfill the goals of promoting and protecting the health of all people and their communities.

Adoption of technological innovations may be challenging, but working with communities has been a strength of the contemporary public health profession. The field has embraced community engagement and participation as a norm, in a way that can be leveraged to ensure that AI and all its applications are an innovation that benefits society and promotes health equity. Given that community-engaged design and participatory methods have become embedded in many public health projects [5], the field is primed for outreach to communities to ensure that individuals understand the benefits and risks of AI in public health. Community involvement in AI design and implementation is key for helping ensure that AI is developed in a person-centered way, particularly addressing the needs and desires of underrepresented and minoritized communities that often face greater health disparities [6]. Beyond health care applications, where tools have often been used for clinical decision-making, outcome prediction, and clinical record summarization, there are numerous use cases for AI in public health. Infectious disease surveillance and risk assessment have been a key area for the use of this technology [7,8]. The use of AI in global health has also been described for improving vaccine delivery and community health care efficiency [9], and as the digitalization of public health continues, the use of AI applications for monitoring and evaluation will become more frequent [10,11]. Chatbots developed with GenAI are another increasingly common approach to providing health education and behavior change support [12]. Large language models are being used to support question answering over large health datasets, allowing more informed decision-making [13]. There is also an urgent need to combat health-related misinformation and disinformation through understanding and using GenAI, as experts predict it could generate up to 90% of web-based content by 2026 [14].

But what about the ethics of using this technology when both public health professionals and people whose data are being used to build applications of AI do not have an understanding of how these systems work? Public health researchers, practitioners, and community partners will need to understand the basics of AI applications and use cases in public health, to be able to prevent and mitigate harm to fully realize the potential benefits of AI as a social innovation. Promoting the responsible and ethical use of AI in public health will require a proactive approach to learning that requires openness. Public health practitioners may view AI applications as the domain of technologists or informaticists only, but communities must be involved in codeveloping these technologies. The ethical implications of AI in public health necessitate transparency, accountability, and equity, all of which require the involvement of scholars, practitioners, and people with lived experience [15]. Education and awareness for communities and public health researchers are urgently needed.

While there are both real and perceived risks of privacy violation posed by using AI in health [16], another important potential harm is the risk of introducing or perpetuating biases and thus exacerbating existing health disparities. There are cases where such biases have led to individuals being denied access to health services or insurance, which may result in discrimination and violations of individual rights [17]. Statistical models are based on underlying assumptions, and these can have far-reaching consequences. Knowledge of community engagement, health inequalities, and strategies for improving equity are crucial to avoid inadvertent reinforcement of biases embedded in data. A well-known example is a racially biased single health care algorithm that drives important chronic care management for over 70 million people in the United States [18]. Because of significant racial bias in this widely used algorithm, White patients with the same health as Black patients were far more likely to be enrolled in a care management program and benefit from its resources. Public health domain knowledge in social determinants and structural inequities must be part of the developing uses of AI in population health science and practice.

How the Public Health Community Can Take Action

For safer and more effective integration of AI in public health, a multifaceted approach should involve the following: (1) inclusion of the basics of AI technology in public health training and professional development; (2) community engagement for co-design of AI technologies applied to public health; and (3) introduction of governance and best practice mechanisms by

XSL•FO
RenderX

public health organizations that can guide the use of AI in public health and prevent or mitigate potential harms.

First, public health programs and organizations should begin incorporating training on the fundamentals of AI technology into public health education and professional development. This will help ensure that public health professionals possess a foundational understanding of AI, allowing for critical assessment and effective use of AI tools in population health work. This training should not only cover the technical aspects of AI but also include a critical study of ethical considerations, known and unknown biases, and a component of the sociocultural implications of AI-driven decisions. Schools of public health are beginning to develop centers and training initiatives for this purpose, including the authors' institutions, UNC Chapel Hill Gillings School of Global Public Health and Tulane University. A scoping review to map the literature from both public health and computer science databases is currently underway by the authors and will provide additional sources of training material for public health and AI education efforts. Furthermore, as a field, we must not only educate ourselves but ensure communities are informed about evolving AI use in public health and its impact on their lives by incorporating this into public health education.

Second, engagement and collaboration between technologists, public health professionals, and community members are vital in the development of AI technologies for public health. Involving community stakeholders from the outset will develop applications with a better understanding of the specific needs, desires, and values of the populations they are intended to serve [19]. Co-design processes can promote transparency, and when done responsibly and with care, can build trust, as they allow for the direct input of those who will be most affected by the technology [20,21]. An example of this is the partnership between the AFL-CIO and Carnegie Mellon University Human-Computer Interaction Institute, which engages workers in the innovation process around AI tools to address critical challenges and open pathways for collaboration. Hospitality workers partnered with university faculty to explore the potential impacts of AI in the daily execution of their jobs. Algorithmic managers, which focused on optimizing operations and the workflow of cleaning rooms, inadvertently increased work, creating potential health hazards, and decreased worker autonomy. In the partnership, stakeholders from the community, labor leaders, and academics engaged to mitigate potential health and occupational harms created by the application of AI [22]. This participatory approach, often a hallmark of contemporary public health approaches, enhances the relevance and acceptability of AI solutions that touch individuals and communities while also identifying and addressing potential biases or risks for disparity early in the development process.

Finally, the introduction of governance frameworks and best practice mechanisms by public health organizations is essential for guiding the responsible use of AI. These mechanisms should be designed to prevent or mitigate potential harms associated with AI, such as privacy violations, biased outcomes, or the exacerbation of health disparities. Governance structures should include clear guidelines on data management, algorithmic transparency, accountability, and ongoing monitoring and evaluation of AI applications. Additionally, the establishment of interdisciplinary oversight committees, including ethicists, data scientists, public health experts, and community members, can provide ongoing surveillance and ensure that AI tools are aligned with public health goals and ethical standards. One example is the National Institute of Health's Artificial Intelligence/Machine Learning Consortium to Advance Health Equity and Researcher Diversity Ethics and Equity Workgroup. The Ethics and Equity Workgroup developed a set of ethics and equity principles, a glossary, and an interview guide. The ethical and equity principles comprise 5 core principles that articulate best practices for working with stakeholders from historically and presently underrepresented communities [23].

Together, these actions can potentiate the application of AI to varied public health domains, and likewise improve outcomes, through a framework for more transparent, responsive, and equitable use of this evolving technology, augmenting the work of public health practitioners and researchers to improve health outcomes while minimizing risks and unintended consequences. Without such safeguards, the application of AI technology in public health may continue to be dominated by technologists whose domain expertise does not include biomedical ethics training, a human rights framework, or an understanding of health equity and social determinants as they inform the central work of improving population health.

Abstract

The US COVID-19 Public Health Emergency ended on May 11, 2023. Lawmakers and regulators extended some flexibilities while they deliberate effective long-term telemedicine policy. Here, we discuss critical challenges in telemedicine compliance and regulation grounded in scholarly literature and current events. We specifically consider obstacles and progress toward solutions in telemedicine law and regulation regarding privacy and security issues, care across state borders, and prescribing over telemedicine in the United States. We conclude that simplified policies are needed to keep telemedicine accessible to providers and patients and that current privacy and security measures need refinement to protect patients appropriately.

(J Med Internet Res 2025;27:e53558) doi:10.2196/53558

Introduction

Background

Smartphones and the internet have had a transformative impact on telemedicine over the decades, but the tipping point for telemedicine adoption was the COVID-19 pandemic [1]. During the pandemic, numerous health professionals adopted telemedicine to provide care while decreasing exposure to the virus [2]. In the US, legal and regulatory flexibilities enabled the shift of health care services to telemedicine. The Coronavirus Aid, Relief, and Economic Security Act and the Public Health Emergency (PHE) protocols of 2020 implemented most pandemic-era policy flexibilities in the United States, including (1) relaxation of HIPAA (Health Insurance Portability and Accountability Act) compliance requirements, (2) permission to prescribe certain controlled substances via telemedicine, (3) reimbursement for telemedicine equivalent to that of in-person visits, (4) promotion of telemedicine expansion for Medicare, (5) allowances for providers to offer care across state borders regardless of licensure, and (6) new protocols and *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) codes for telemedicine visits [3,4]. Lawmakers made these changes to increase access to health care nationwide during the pandemic and based these flexibilities on previously considered legislative, regulatory, and policy updates [5].

The expiration of the PHE in May 2023 created a dilemma for lawmakers, who were unprepared to make decisions about long-term telemedicine policy. To avoid negative impacts and allow more time for decision-making, they extended many telemedicine-related policy flexibilities through December 31, 2024 [6,7]. Now, regulatory leaders are tasked with assessing current evidence (eg, telemedicine research, stakeholder needs and experiences, security concerns, cases of crime, and fraud)

XSL•FO
RenderX

to make informed decisions about permanent federal and state regulations and rules related to telemedicine [8].

At this critical juncture, it is essential that we consider outcomes, experiences, perspectives, and other evidence resulting from pandemic-era telemedicine policy. By doing so, we can identify critical challenges and potential solutions and ultimately make informed, long-term policy decisions. Here, we summarize high-priority, policy-related challenges, and proposed solutions, focusing on providers and patients. We argue for US federal and state policy that protects patients in the context of new technologies and supports providers' inclusion of telemedicine in their health care services. We highlight how ambiguities and complexity of laws and regulations effectively obstruct providers and organizations from using telemedicine. This viewpoint is grounded in a literature review of US telemedicine laws and regulations between 2000 and 2022 using legal and scientific databases (ie, HeinOnline, LexisNexis, PubMed, and Google Scholar) and includes post-PHE literature and events to ensure the relevancy of the topics discussed.

Security and Privacy

HIPAA—known for its privacy and security rules establishing national standards for protecting personal health information (PHI)—mandates providers use telemedicine platforms that provide privacy and security by not storing or having sufficient ways to prevent breaches of PHI [9]. The PHE flexibilities waived the need to use HIPAA-compliant telemedicine platforms. This flexibility eased the rapid, large-scale transition to telemedicine use during COVID-19 [9,10]. Unfortunately, HIPAA does not cover all facets of digital practices in health care delivery. For example, third-party digital apps for patients to complete therapies or exercises may not be required to comply with HIPAA, even if providers use it as an adjunct to care [11-13]. Providers may use a HIPAA-compliant platform, but patients may be unknowingly in a nonprivate space. Simply expanding the scope of HIPAA to include PHI shared outside of a direct patient-provider relationship may not be enough protection [13]. Even in 2018, legal commentary noted that updating the laws and regulations to protect PHI through more rigorous cybersecurity expectations, such as requiring encryption of transmissions and concrete language regarding security measures, is critical in ensuring the security and privacy of PHI [13]. HIPAA's security rules should stipulate the use of feasible cybersecurity measures rather than the basic health care standards [13]. A health care practice could determine the best cybersecurity measures that would balance the importance of privacy and security of their patients while ensuring such measures are not a costly burden. To protect patients and providers, we must reconsider emphasizing the best instead of minimum necessary practices regarding privacy and security laws in this new age of digital health telemedicine and apps.

While providers have stated expectations that HIPAA amendments increase protections [14,15], the proposed changes focus on improving patient access to their PHI and easing administrative burdens [16]. These proposed changes would only apply to the current definition of covered entities, and therefore, will not address the challenges regarding third-party health apps. Though HIPAA is the federal standard for PHI protection, state laws can enhance protection above this minimum requirement.

At the state level, the issue of PHI protection has led to the enactment of Washington state's My Health My Data Act (HB 1155), whereby the state protects PHI beyond the scope of HIPAA [17]. Specifically, this law prevents businesses from inferring health data about an individual based on purchases. It requires regulated entities or businesses to have information on this law within their privacy policies [17]. The My Health My Data Act reflects a general movement toward increased security of individual health information. As the first to pass, the law broadly applies to consumer health data and includes information that may be inferred to determine a person's past, current, or future health [18]. Based on the discussions around this and similar proposed laws, we expect to see more proposed state and federal legislation with varying degrees of protection, greatly based on the ability of the government and institutions to enforce such protections [19-21]. With no current tangible proposal to amend HIPAA in this way, state legislatures are stepping up their security and protections of PHI: Nevada passed their consumer health law in 2023, though their definitions of health data and protections are more narrowly defined than those of Washington's law [22].

At this time, planned HIPAA amendments focus on increasing patient access to their PHI and would not directly address concerns related to digital tools. Some states are attempting to remedy privacy and security issues identified with the increased use of telemedicine and new technologies. Though their initiative raises awareness and discussion of privacy and security related to telemedicine, the lack of streamlining may increase legal complexities. Until there is a concrete effort to streamline these issues, telemedicine providers must ensure compliance with new state laws and regulations, and patients must be mindful of how they share PHI.

Prescribing Over Telemedicine

The PHE flexibilities waived the requirement to see a patient in person before prescribing controlled medication including schedule II-V drugs. Before the flexibilities, the Drug Enforcement Administration (DEA) required providers to obtain a waiver for each state where they prescribe medication. The DEA waived this step during the PHE [23]. Still, providers had to consider different state laws regulating their prescribing ability [24]. The DEA expects to promulgate its final rule incorporating provider and patient expectations since the PHE into its regulations in 2025. Due to this extended timeline, experts' expectations of a third extension of PHE flexibilities was confirmed with the DEA's clean extension of these flexibilities through December 31, 2025 [23,24].

Patient and provider experiences with these flexibilities have led to robust discourse, especially over the dangers—or lack thereof—of prescribing buprenorphine (schedule III drug) without in-person visits [25]. During the pandemic, providers reported that reduced steps in monitoring made them rely more on patients' decision-making and confront the issue of trust in their patient-provider relationships [26]. However, the same

XSL•FO
RenderX

providers noted the ability to see patients in their homes provided them with a new level of insight that they used in assessing their patients [26]. Similarly, a qualitative analysis of provider experiences in prescribing medications for opioid use disorder indicated both positive—including increased insight into patients' daily lives—and negative experiences, noting issues with patients viewing telemedicine as a less professional encounter [27]. Providers additionally experienced stress due to their uncertainty regarding prescribing laws [27].

Research on prescribing over telemedicine considered patient outcomes, as well as provider experiences. A study examining Medicaid data during the beginning of the pandemic found that patients who began buprenorphine treatment over telemedicine had higher treatment retention, and there was no change in the odds of opioid-related nonfatal overdose [28]. A recent review concluded that most providers favored having the ability to prescribe buprenorphine over telemedicine with little to no issues [29]. While the evidence is not definitive, providers appear to favor having the option of prescribing buprenorphine over telemedicine. However, providers note certain contextual misgivings such as the potential for increased liability and lack of legal clarity [29]. Though evidence appears to show that telemedicine increases access and results in similar efficacy as in-person treatment using medications for opioid use disorder, the research is still ongoing [30,31].

Ideally, there will be a continuation of rigorous research to determine how prescribing buprenorphine—and other controlled substances—over telemedicine affects efficacy, access, health inequalities, and patient safety [31]. Unfortunately, with the DEA's current timeline, new research is unlikely to inform the final rule. Instead, the DEA will make its decision based on current evidence, the 38,000 written comments providing feedback to its proposed rule, and the two days of public listening sessions that occurred in September 2023 [6]. The DEA's final rule is the first step to simplifying the laws and regulations surrounding prescribing over telemedicine, mainly controlled substances. We expect to see moderately more expansive flexibilities than the initially proposed ruling to support the necessary accessibility of opioid use disorder treatment for individuals. Additionally, should the DEA remove the requirement for individual waivers to prescribe in each state, there would be a significant streamlining of procedures providers must follow to prescribe over telemedicine. Considering the DEA's development of a federal ruling, eliminating the required multiple waivers would align with the premise of reducing federal compliance and regulatory complexities.

The DEA's final rule also affects how states make rules and regulations. For example, in late 2023, the Georgia Medical Board planned to revert its prescribing policies to prepandemic times. After discussions with the community, it decided to extend PHE flexibilities on the state level through January 31, 2025. The board is waiting to see the DEA's final ruling before determining its state policy on the subject [32]. As with many federal and state dynamics, states will examine national rules and regulations to determine their policies. Based on the DEA's final ruling, we expect to see further changes to laws and regulations at the state level.

Expansion of Medicare, Coverage, and Reimbursement

A widely cited barrier to telemedicine use is the issue of payment, both for coverage and reimbursement. Parity laws relate to payment for telemedicine services and include coverage parity (insurers must pay for services) and payment parity (insurers must pay for services at an equal rate to in-person visits) [33]. With the PHE flexibilities, coverage parity ensured that telemedicine services were provided in all states and through Medicare [34]. Additionally, the flexibilities implemented payment parity for telemedicine services through Medicare so that providers were paid at the same rate as they would for an in-person visit [35]. During this time, most commercial insurers also provided payment parity [36].

Payment parity on the state level has changed during the COVID-19 era (Table 1) [35]. On a federal level, Medicare payment parity continues through the end of 2024; however, reimbursement after this extension will depend on Medicare's telemedicine code categories [37].

XSL•FO
RenderX

At this point, it is unknown whether Medicare will implement permanent changes on the federal level and whether certain states will permanently continue payment parity for telemedicine services. Differences in state and federal laws can impede health care providers' ability to navigate payment, reducing patient health care access [37]. These laws burdened providers with understanding the changing legal landscape of telemedicine and determining whether it is fiscally feasible.

Overall, there is federal coverage parity through Medicare, and all 50 states and Washington, DC, offer coverage parity with some variation in language [34]. While there is uncertainty regarding payment parity continuance through Medicare, the physician fee schedule for 2024 posted for Medicare included payment parity and granularity in types of telemedicine visits [38]. On the state level, payment parity continues to evolve. States look to one another to determine what has worked effectively and what has not in choosing and implementing their parity laws. State and federal legal definitions of telemedicine visits may differ. Still, there is clear support for ensuring that telemedicine is sustained as a health care delivery option in the United States. We see the trend that state laws will eventually conform to those of Medicare, resulting in unified definitions of telemedicine and its reimbursement. Until this happens, providers may continue to view payment parity as a hindrance to implementing telemedicine in their workflow.

Care Across State Borders

During the PHE, providers could deliver health care nationwide with any state license. Unlike the DEA's extension of the flexibility—allowing a provider to have a single waiver to prescribe controlled substances nationwide—lawmakers did not extend the PHE flexibility that allowed providers to care for patients across state lines without a license in each state. States have varied in their regulation of telemedicine across state borders [39]. For example, if a provider is licensed in New York and treats a patient who is in California for college or lives part-time in Florida, they can only see the patient within New York (even if the provider is out of state during the visit) [40]. In the same example, if the New York provider has a patient in New Jersey, that patient would have to drive into New York to be seen over telemedicine. Such requirements have created the telemedicine parking lot phenomenon wherein patients drive to the nearest location within the provider's state and park to be seen via telemedicine to comply with state laws and licensure [41].

Regulatory changes allowing providers to see patients outside their states may increase patient safety and continuity of care [42,43]. A policy initiative, supported by professional organizations, such as the American College of Physicians and the American Medical Association, would ease regulatory compliance and eliminate a significant barrier to telemedicine care delivery across US state borders [13,43-46]. Licensure compacts exist for health professionals outside physicians, that is, nurses, physical therapists, occupational therapists, speech-language pathologists, audiologists, psychologists, and emergency medical professionals, that enable practice across multiple states [47]. Unfortunately, not all compacts act in the same way: while the Interstate Medical Licensure Compact for physicians only helps to streamline the licensing process, the Nurse Licensure Compact allows nurses to hold one license and practice in all participating states [33]. The larger scope of the Nurse Licensure Compact overcomes the additional barriers of time, complexity, and money that providers face. Of course, with each licensure compact, there are rules and regulations at the state level that would require amendment including definitions and functions of noncompete agreements and standards of care [48-51]. Ultimately, licensure compacts help simplify and codify the laws and regulations surrounding practice across state lines. Lawmakers and regulators need to remedy the level of complexity in the state and federal legislation in the face of the patient's needs and the providers' abilities [52]. Since the PHE, more states have joined or are in the process of joining these licensure compacts. For example, the Interstate Medical Licensure Compact currently includes 39 states and Washington, DC, and the Nurse Licensure Compact consists of 41 states [40,53].

Conclusions

With the end of the PHE, US Congress and regulators allowed certain telemedicine policy flexibilities to continue temporarily. At the same time, lawmakers and regulators work to align pre-PHE policies with current provider and patient needs relating to telemedicine. Over 100 pieces of proposed federal legislation currently address aspects of telemedicine, with more proposals from state lawmakers [39]. This viewpoint reviewed how COVID-19–era PHE flexibilities paved the way for telemedicine adoption, summarized the policy challenges that arose, and described how policy leaders are attempting to resolve the challenges.

In the coming months and years, we anticipate changes to privacy and security laws, potential changes to HIPAA, and increasing consideration of how privacy laws function concerning emergent digital health technologies. After the DEA's final ruling regarding prescribing over telemedicine, expected in 2025, we anticipate further state-level changes in laws and regulations to better align with the federal standard. We anticipate that current regulatory trends supporting telemedicine coverage and payment parity will continue and that more states will adopt interstate licensure compacts for their health care professionals. Overall, our assessment of these critical topics reveals that while telemedicine is now an unmistakable part of health care, there is a need to codify the laws and regulations on a federal and state level. Such a move would ensure patient privacy, security, and quality of care and ensure provider support through definitive, clear pathways to comply with telemedicine laws and regulations.

Abstract

Personal accounts of health care experiences posted to online platforms are a rich source of patient-reported data. Noninteractive narratives, published as one-off accounts, often describe an entire patient journey in one story, featuring transitions through health care settings from prediagnosis to outcome. These coherent perspectives may not be visible or captured in fragmented social media posts or episodic blogs. For researchers seeking patient-reported accounts of care quality across a clinical trajectory, noninteractive online narratives can be an invaluable, easily accessible resource. The challenges and limitations of research utilizing these data may differ from working with interactive patient narratives and include source transparency and credibility, limited or no information about authors, and ambiguity about the health care context and time frames. We outline a framework for addressing these issues in 5 key phases of the research cycle: the conceptual-theoretical approach; locating sources of data; accessing and collecting the data; quantitative profiling to establish demographics, health care events, and time frames; and qualitative analysis utilizing multiple modes of narrative inquiry. We explain the use of this framework in a real-world example: our study of 273 online patient narratives describing health care trajectories in early-onset bowel cancer.

KEYWORDS

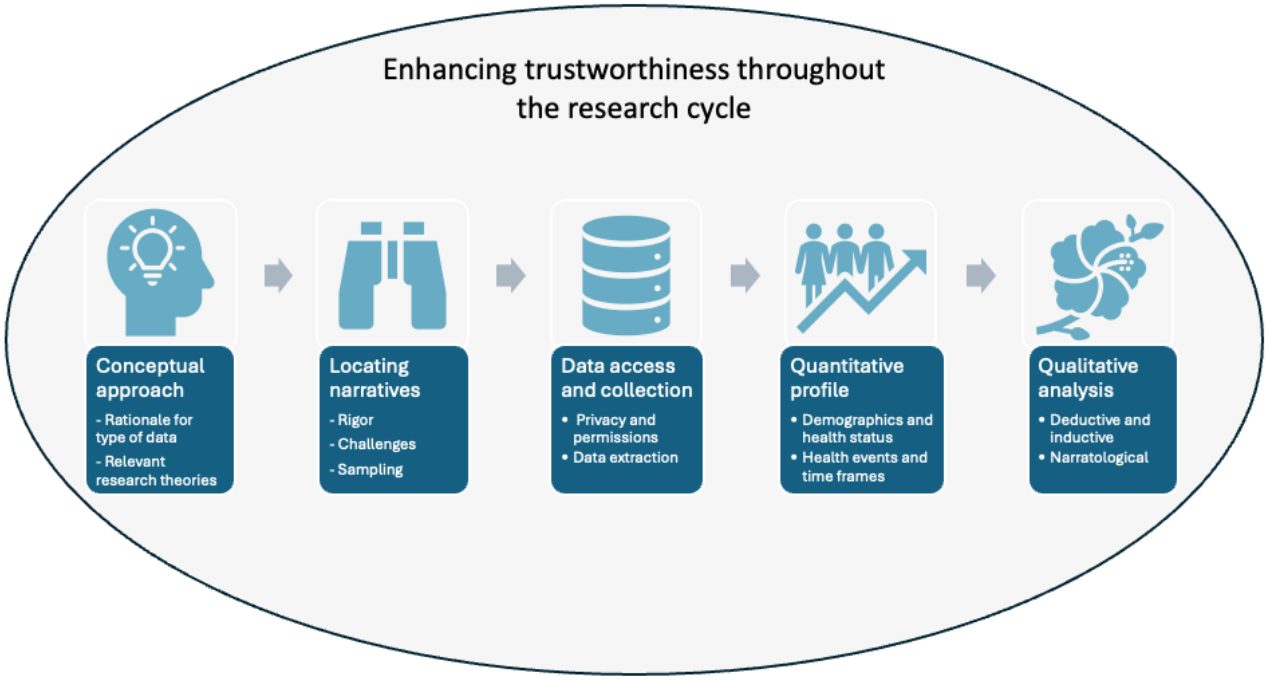
online research; exploratory study; patient experience; patient narratives; narrative analysis; mixed methods; young-onset colorectal cancer; cancer; oncology; internal medicine

Introduction

Online patient narratives have been categorized as interactive or noninteractive [1,2], each offering distinct advantages and challenges for health care research. Interactive narratives, typically shared through social media, blogs, and forums, allow patients to update their stories, respond to feedback, and report evolving experiences. Noninteractive or static narratives, published to websites as one-off reports, typically encapsulate the entire patient journey over time. This coherent, patient-framed perspective on the progression from prediagnosis to outcome may not be visible or captured in the fragmented or episodic formats of interactive narratives.

For researchers investigating patient-framed perceptions of care across a clinical trajectory, noninteractive online narratives, which can also be referred to as online pathographies [3,4], offer an invaluable resource. The holistic narrative structure allows the representation of both a psychological transition and a

XSL•FO
RenderX



physical movement through various phases of biomedical intervention and health care settings. They can expose health service delays and continuity gaps that only patients can observe as sole witnesses to the entirety of their experiences. Importantly, the global availability of online patient narratives allows researchers ease of access and, potentially, insights into the diversity of health system experiences.

The value of these pathographies for researchers must be weighed against unique challenges to validity and trustworthiness that share common elements with, but also extend beyond, typical issues in qualitative research, and potentially even beyond challenges with the use of interactive narratives. Noninteractive online narratives present risks such as source credibility, limited or no information about authors, and uncertainty about the health care context and time frames. These aspects of the data may present constraints on analytic interpretation.

We navigated these challenges in an exploratory study to understand the causes of delays in the diagnosis of early-onset bowel cancer, defined as a diagnosis in patients younger than the age of 50 years [5]. Our study drew on narratives published on prominent bowel cancer support websites in the United Kingdom, Australia, and New Zealand, published under banners such as “Real life stories” and “Your Story” [6,7]. The findings of our study, reported elsewhere [6,7], highlighted a critical need to lower the threshold age for public bowel cancer screening programs and revise clinical guidelines for diagnostic pathways.

To help structure the research process in ways that enhance reliability, we developed a framework featuring 5 key phases throughout the research cycle requiring heightened attention to issues of validity and reliability (see Figure 1). The framework developed by Zoolnoori et al [8], for use with interactive online patient narratives, focuses on 4 of the main phases of research: data collection, data preparation, content analysis, and interpretation of the results. We found that a different set of focal points were needed to address the unique challenges of research investigating noninteractive online narratives. Below, we describe each of the 5 focal points in our framework through the lens of our work with noninteractive, early-onset bowel cancer narratives.

Figure 1. A framework of five key focal points in the research cycle for addressing the credibility and enhancing the trustworthiness of research involving noninteractive, online patient narratives.

Ethical Considerations

Ethical and scientific approval was granted by Macquarie University Human Research Ethics Committee (reference 52020666115757).

Conceptual-Theoretical Approach

The framework begins in the conceptualizing phase, establishing a rationale for the use of online pathographies and highlighting a detailed theoretical framework for the research. **As** exploratory research, the rationale for utilizing online patient pathographies was to determine the relevance of progressing to purposively sampled studies [9]. The rationale was further supported by literature indicating that patients younger than the age of 50 years are drawn to, and are adept at using, the internet for information seeking and sharing [10].

Narrative inquiry is an apt overarching methodology for research that leverages online narratives; it focuses on exploring and interpreting phenomena through stories of lived experience [11] and features flexibility in blending qualitative and quantitative elements to support trustworthy findings [12,13]. Key theories validating singular narratives as evidence of phenomena [14] include constructivism (knowledge through experiences),

XSL•FO
RenderX

phenomenology (shared experiences), hermeneutics (text interpretation), and narratology (narrative structures).

Locating Authentic Narratives

We included a focal point on the source of the pathographies because the **credibility** and **authenticity** of noninteractive narratives are closely tied to the reliability of the source. It is crucial to establish some means of locating pathographies that can be assumed to be authentic. We looked to institutional oversight as a way to verify authenticity. We followed the Internet Mediated Research (IMR) search strategy outlined by Obrien and Clark [15], using comprehensive search terms and multiple platforms, as well as systematically applying inclusion and exclusion criteria to locate relevant pathographies published on the websites of well-established institutions. We excluded pathographies from health care organization websites that presented exclusively positive views for marketing purposes.

Demographics and clinical information about the authors were typically embedded within the narratives and not necessarily explicitly stated; we had to review all pathographies identified on validated sites line by line to confirm they met the criteria for early-onset colorectal cancer.

Data Access and Collection

We highlight this phase in the research cycle because the unsolicited, often anonymous, and noninteractive nature of the data necessitated careful negotiation of consent. We contacted each organization to ensure that the conditions for consent were met and to obtain explicit approval for empirical investigation and dissemination of our findings. Permission from individual authors was not required, aligning with the principles of "unobtrusive" IMR [16,17] and the concept of "human-generated data" [18], which individuals willingly produce as they engage in various online and offline activities. This approach met the ethical guidelines of the Australian National Statement on Ethical Conduct in Human Research 2007 (Updated 2018) [19] and the British Psychological Society's principles for IMR [20].

Where technically possible, we used the website's export options to extract narrative text from the online platform and download it into an analysis software program, NVivo 12 (version 12; QSR International Pty Ltd). Alternatively, we used a cut-and-paste function, creating a Microsoft Word document for each narrative, which was then imported into NVivo.

Quantitative Profiling

We specify that a quantitative approach is needed to resolve the likely anonymity of authors. As noted, authors' demographics and health status characteristics were not always evident in the unsolicited data, which presented the risk of over- and underrepresentation of subpopulations and particular types of diagnostic experiences. To ensure the transparency of any data bias, we used NVivo to quantify the demographic and health status information in the narratives and cataloged the *type*, *frequency*, and *time frames* of diagnostic events described in the texts, including first event of seeking help for symptoms, types of tests and screening events, and referrals to specialists.

In extracting demographic and health status data from narratives and cataloging diagnostic events by type, frequency, and time frame, we identified a gender disparity of authorship, with over 70% of narratives written by people identifying as female, despite approximately equal gender diagnoses of early-onset colorectal cancer [21]. Additionally, the quantitative profile identified that most narratives were written by people aged younger than 40 years, although there is a higher incidence of early-onset colorectal cancer in the 40-49 years age group. This finding highlights the relevance of online methods when investigating younger populations but acknowledges the potential for bias when generalizing across sets of unsolicited data. In our reporting of our findings, we openly discussed these biases and hypothesized others, such as potential underrepresentation of culturally and linguistically diverse and special needs populations.

Qualitative Analysis

We assert that manual qualitative analysis of pathographies continues to offer the greatest potential for sensitivity to textual nuances and tonal idiosyncrasies indicating facilitators and barriers to quality care over time [8]. Pathographies embed time in 3 key narrative layers: the subjective account of chronological time, detailing the sequence of events from symptom onset to treatment; the passing of time, represented in evolving observations of illness and health care experiences; and subtle references to historic time, which places the patient's experience within broader societal trends or health care issues [22]. Complex, highly customized programming would be required to automate the extraction of time-related meaning from these texts.

Unsolicited online narratives, unlike interview data, contain large amounts of content that may be extraneous to the core interests of the research. Integrating deductive and inductive methods analysis [23] allowed us to efficiently extract relevant data while allowing for unexpected insights. In NVivo, the data were first categorized into a basic deductive framework [23] comprising the 2 key domains of care assessed in patient-reported experience measures: functional (clinical care and the practical delivery of services) and relational (relationships with clinicians and health care service providers) experiences of care. We then inductively sought emergent themes in the data categorized into each of these domains, following the conventions established by Braun et al [24].

Finally, we propose a narratological component in the qualitative analysis because personal experience is conveyed not only through story content but also through the choices made in storytelling [25,26]. Our narratological component examined the storytelling structure used by the authors. Typically, this structure followed Western narrative conventions: a prologue depicting life before the first symptom, the main story describing events leading up to diagnosis, and an epilogue expressing closure to the story [27]. We observed that epilogues served as spaces for authors to reflect on lessons learned and the broader implications of their experiences. Our epilogue-only analysis identified a substantial set of patient-reported views on the need for self-advocacy and changes to the views of clinicians on colorectal cancer among young people. These findings were

XSL•FO
RenderX

published in a second paper arising from the study [7] and were used in a campaign by Bowel Cancer Australia to lower the screening age for bowel cancer from 50 to 45 years.

Conclusions

Noninteractive online narratives can provide a singular, comprehensive perspective on patient journeys, capturing transitions across health care settings and services. As we found in our study of 273 noninteractive online narratives, this perspective offers researchers unique insights into systemic delays and gaps in continuity. In our study, we demonstrated the value of a framework tailored to address the specific challenges and limitations of noninteractive data throughout the research cycle. The 5 focal points of the framework offer a model for researchers navigating the complexities of these data. In future work, utilizing this framework can ensure the integrity and value of exploratory studies that seek to identify emerging issues exposed in longitudinal patient accounts published online. The framework may provide collaborative stakeholders—researchers, health care providers, policy makers, and patient advocates—with a structured means of understanding how credible, patient-centered insights be drawn from these data. Additionally, the 5 focal points are adaptable to new digital environments for patient narratives and advanced analytical technologies. In these ways, the framework reinforces the potential for online patient journey narratives to inform health care research and affirms that patients' stories can guide solutions to health care problems.

Acknowledgments

The authors thank the following advocacy organizations for patients with colorectal cancer: Bowel Cancer UK, Bowel Cancer Australia, and Bowel Cancer NZ, for facilitating our access to patients' stories and to the patients who wrote about their experiences. This work was supported in part by a National Health and Medical Research Council of Australia (NHMRC grant 1135048—the Centre of Research Excellence in Implementation Science in Oncology), which is administered by the Australian Institute of Health Innovation, Macquarie University, Sydney. JB reports multiple grants funded by the National Health and Medical Research Council and other providers.

Data Availability

The datasets used and/or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Health recommender systems (HRS) have the capability to improve human-centered care and prevention by personalizing content, such as health interventions or health information. HRS, an emerging and developing field, can play a unique role in the digital health field as they can offer relevant recommendations, not only based on what users themselves prefer and may be receptive to, but also using data about wider spheres of influence over human behavior, including peers, families, communities, and societies. We identify and discuss how HRS could play a unique role in decreasing health inequities. We use the socioecological model, which provides representations of how multiple, nested levels of influence (eg, community, institutional, and policy factors) interact to shape individual health. This perspective helps illustrate how HRS could address not just individual health factors but also the structural barriers—such as access to health care, social support, and access to healthy food—that shape health outcomes at various levels. Based on this analysis, we then discuss the challenges and future research priorities. We find that despite the potential for targeting more complex systemic challenges to obtaining good health, current HRS are still focused on individual health behaviors, often do not integrate the lived experiences of users in the design, and have had limited reach and effectiveness for individuals from low socioeconomic status and racial or ethnic minoritized backgrounds. In this viewpoint, we argue that a new design paradigm is necessary in which HRS focus on incorporating structural barriers to good health in addition to user preferences. HRS should be designed with an emphasis on health systems, which also includes incorporating decolonial perspectives of well-being that challenge prevailing medical models. Furthermore, potential lies in evaluating the health equity effects of HRS and leveraging collected data to influence policy. With changes in practices and with an intentional equity focus, HRS could play a crucial role in health promotion and decreasing health inequities.

Introduction

Overview

Health recommender systems (HRS), information retrieval systems that often use artificial intelligence, are an increasingly popular method to provide patient-centric personalized health services [1-3]. HRS predict the relevance of recommendations (eg, for exercise, healthy foods, and mental health exercises) for a given user profile [4]. HRS base recommendations on what the user might like, typically using various sources of data such as personal (eg, age, gender, and socioeconomic status [SES]), health (eg, medical history and health surveys), contextual (eg, time, weather, and location), and interaction data (eg, information searched, liked, or rated) [1,5]. HRS can minimize the burden of delivering recommendations by only doing so when there is a real benefit (eg, when an individual is motivated and capable of following a recommendation) and can target multiple related behaviors at once (eg, diet, physical activity, and mental health). HRS have shown growth since 2012, particularly in the fields of lifestyle, such as personalized healthy nutrition recommendations, and personalized health promotion, such as recommending treatments of clinical diagnoses [2]. With increasing interest in using artificial intelligence to improve health promotion and prevention, and more than 50% (1 in 2 European Union citizens, aged 16-74 years) of individuals using the internet to find health information [6], the use of HRS, although still an emerging area, is expected to grow in digital health [7,8].

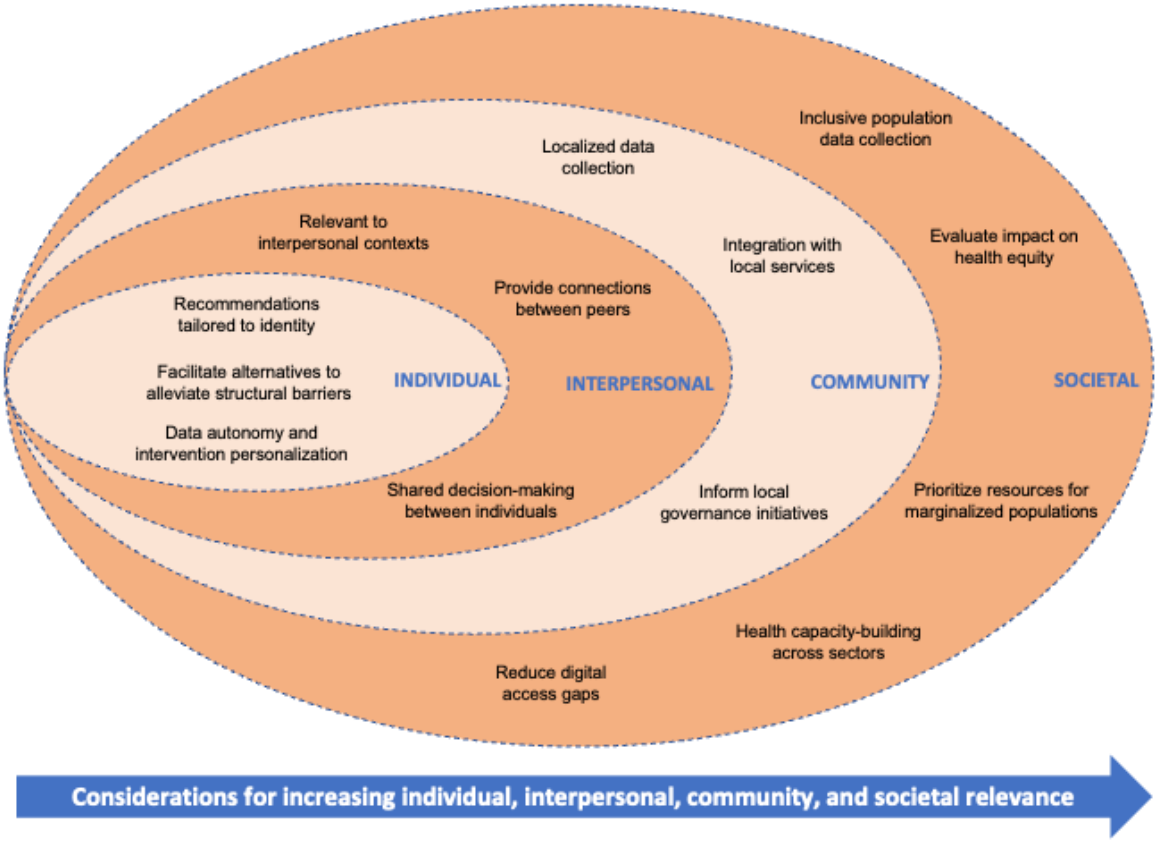
The Need for a Health Equity Lens

However, digital health interventions, including HRS, are often not developed to target health inequities, "systematic differences in the health of groups and communities occupying unequal positions in society that are avoidable and unjust" [9]. For instance, HRS have scarcely been tested in populations that are marginalized, such as those belonging to low SES and racial and ethnically minoritized individuals [10]. This is a widespread issue, including in high-resource settings, with evidence from European countries and the United States showing that White individuals and those with higher education levels, income, and English proficiency tend to have higher access to and use digital health technologies more often, instead of the groups who would benefit from these solutions most [11]. There is a lack of attention to issues of equity and inclusion, and a tendency to develop from a technology-centered (instead of a human-centered) perspective in the HRS field [2].

The Socioecological Model to Illustrate the Health Equity Potential of HRS

One way of working toward a perspective with an equity lens is the use of the socioecological model—a conceptual framework depicting spheres of influence over human behavior. This model is widely used in public health for scaling health promotion and implementation initiatives, to enable more effective public health interventions for complex social issues [12]. It has also been adapted for digital health equity [10,13]. It provides representations of how multiple, nested levels of influence (eg, community, institutional, and policy factors) interact in dynamic ways to shape individual health [14]. The socioecological model is based on a systems view of health—individual health is impacted by interactions with immediate peers and surroundings as well as broader institutional and societal norms [15]. It helps illustrate how HRS could address not just individual health needs but also the underlying conditions—such as access to health care, social support, and healthy lifestyles—that shape health outcomes. As far as we are aware, this framework has not been applied to HRS. Although some of these arguments can be applied to all digital health interventions, HRS have a unique role in the field because of their data-driven personalization and capacity to be strongly personalized due to profile- and context-crucial information.

Here we adapt the model to examine the unique potential of HRS to target and influence all its levels and thereby have great potential to promote health equity across society. We explain and illustrate how HRS can contribute to health equity by collecting data and targeting health at the systems level, integrating the context of individuals, families or peers, communities, and societies. We provide selected examples of previous work that could contribute to different layers of the framework and discuss challenges. Based on our analysis, we provide future research opportunities for HRS to target multiple levels of influence.



The novelty of this perspective is the intersection of recommender systems and public health, in particular health equity. HRS are still developing but starting to become integrated into medicine and public health [2]. There have been discussions about ethical considerations of recommender systems [16], but their potential on healthy equity, remains underdiscussed. With growing societal health inequities, and the World Health Organization's recent call for equitable participation in a digital world [17], investing in equitable development of this new technology is essential now. As the field moves forward, we argue that an explicit health equity lens is needed from the start, not as an afterthought.

Overview

The paper is structured as follows. First, we illustrate the potential of HRS for decreasing health inequities based on the socioecological model (individual, interpersonal, community, and society; in "The potential of HRS using the socioecological model" section). Through an exploratory literature search, we provide selected examples of how HRS can contribute to health equity, by situating these examples into the different layers of the framework. We then investigate challenges and provide future research priorities for the HRS field based on the gaps we identify ("Recommendations for Research Priorities" section). Alongside Figure 1 [18], Table 1 presents implications of relevant factors that encompass each level and main actions for research priorities. We then provide a general conclusion.

Table 1. The potential of health recommender systems and main actions.

Socioecological level	The potential of HRS[a]	Main actions
Individual	• Make tailored recommendations associated with identity (eg, healthy food associated with cultural traditions) • Include alternative recommendations to overcome structural barriers (eg, based on budget and neighborhood safety) • Allow individuals to determine what data they provide and which health domains (eg, physical, mental, and social) to focus on	• Incorporate structural barriers to good health in personalization (social determinants of health) • Centering intervention designs in the lived experience of the potential users (participatory design) • Prioritize culturally appropriate interventions (eg, by considering decolonization of predominant approaches)
Interpersonal	• Account for influence of family (eg, households) and social networks (eg, work environments) • Leverage role and data on relationships (eg, connecting patients with similar challenges and demographics and peer endorsements) • Provide opportunities for shared decision-making (eg, between patients and their caregivers)	• Centering intervention designs in the lived experience of the potential users and other stakeholders (participatory design)
Community	• Incorporate data on health factors relevant to a particular community (ie, localized data collection) • Foster collaboration with local institutions (eg, grocery stores) to improve health equity (eg, access to fresh produce) • Guide local governance initiatives for community health initiatives (eg, usage of parks)	• Centering intervention designs in the lived experience of the potential users and other stakeholders (participatory design)
Societal	• Address "health data poverty" through inclusive data collection (eg, marginalized populations • Enable policy makers to build capacity between sectors to address social determinants of health through targeted interventions (eg, identifying key areas or populations in need of public health interventions)	• Report and evaluate impact health inequities (eg, what disadvantages or privileges are perpetuated) • Consistent and high-quality internet access • Planning and delivery of HRS to marginalized populations • Advocate for health equity policies based on HRS data

[a]HRS: health recommender systems.

The Potential of HRS Using the Socioecological Model

The potential of HRS for decreasing health inequities based on the socioecological model (individual, interpersonal, community, and society) is described further in this study (Figure 1).

Individual Level

The individual level includes individual personal characteristics, such as age, education, income, and health history [19]. Using individual-level data from phones and wearables, HRS can provide personalized suggestions that integrate and recognize structural barriers to good health that marginalized groups face more often. For example, for lower SES individuals, HRS for nutrition can combine budgetary restrictions with culture and familiarity motives (eg, food associated with cultural traditions, or a sense of safety and comfort), which are more important to individuals with fewer resources and diverse cultural identities [20]. For individuals living in areas where outdoor activities may be unsafe or impossible because of weather conditions, physical activity HRS could offer alternative options, such as indoor exercises, community-centered physical activities, or free web-based classes. Furthermore, HRS can also empower users through prioritizing user decisions over system performance, which is related to digital self-efficacy, and facilitates trust in HRS. For example, in a previous study, an HRS for health coaching allowed participants to pick their own health domain to work on, and only use the information they wanted to provide, such as not using sensors or answering all health-related questions [21]. Thus, the use of HRS can lead to more equitable health care recommendations and empowered health decisions surrounding different lifestyle factors (eg, physical, mental, and social).

Interpersonal Level

The interpersonal level includes an individual's closest social circle, such as friends, partners, family members, and colleagues, all of whom can influence their health behavior [19]. HRS has the potential to positively influence the health of families, households, work environments, and other small social networks by leveraging the data of interpersonal relationships [22]. For example, HRS can provide recommendations based on what worked for others with similar health [23]. HealthNet, a patient social network platform, used a recommender system to allow patients to find others with similar conditions, learn about what treatments were useful for them, and suggest health facilities or doctors consulted by patients with similar health status [24]. However, the demographic background of patients, and the incorporation of this information into the HRS, was not reported. Basing recommendations on others with similar socioeconomic and ethnic or racial minoritized backgrounds may make HRS even more effective. Furthermore, social media network data can be used, as shown by Oliva-Felipe and colleagues [25], who

XSL•FO
RenderX

developed an HRS with educational content tailored to their specific profile of dementia caregivers. HRS could also leverage peer endorsements, allowing users to see recommendations or reviews from their social connections or members of a community with similar health goals [22]. Tapping into the power of social influence and community may specifically benefit lower SES individuals by making recommendations more relevant to them and trustworthy.

Community Level

The community level includes the settings in which people work, live, and have social relationships, such as schools, workplaces, and neighborhoods, which affect health [19]. HRS can play a pivotal role in facilitating health promotion and preventive strategies tailored to the community-specific risk and protective factors by capturing data specific to a community (ie, localized data collection). For example, Wayman and Madhvanath [26] describe an HRS that makes dietary recommendations based on grocery receipt data. Leveraging this kind of data, HRS developers could collaborate with local businesses, such as grocery and convenience stores, to tailor the amount of fresh fruits and vegetables guided by food purchasing data [27]. HRS developers can also work with local governments to develop systems that allow low-income residents to receive recommendations on where to shop for healthy and affordable foods. The data collected from HRS can also be used to work with the city or county to identify the most suitable walking trails, parks, and indoor exercise sites and publicize these to the community. Thus, the ability of HRS to leverage localized data provides ample opportunities for community-level interventions.

Societal Level

The societal level includes societal factors that influence health, such as the economic, educational, and social policies that help to create, maintain, or lessen health inequities [19].

HRS can contribute to the societal level by collecting data from individuals to build inclusive data sets with trends in health behaviors on a population level, which can be leveraged for policy making. Currently, individuals of lower SES and ethnic or racial marginalized individuals are systematically underrepresented in (open) health data sets (eg, the UK Biobank, with half a million UK participants) [28]. If HRS become widely used, by collecting data on the health of these marginalized populations in combination with contextual data, HRS can help to solve the problem of "health data poverty", the inability of individuals, groups, or populations to benefit from discovery or innovation due to a scarcity of adequately representative data [29]. Policymakers can, for example, use these data to better pinpoint inadequate health care facilities, nutritional deficiencies, or insufficient infrastructure for healthy living and use this to devise social policies.

Regarding major public health issues like climate change, which disproportionately affects the health of marginalized populations [30], HRS could provide insight into human behavior that leads to high carbon emissions, such as food waste, or actions that can promote sustainable food consumption [31]. HRS could thus help policymakers allocate resources more efficiently by identifying areas or populations in need of specific public health interventions. This application of HRS aligns with the "Health in All Policies" (HiAP) approach promoted by the World Health Organization, in which policymakers in diverse sectors (eg, environment, agriculture, and urban planning) align efforts and health [32], consider the health impacts and benefits of plans to address employment, education, or housing. Furthermore, after implementing health policies, recommender systems could track their impact on health outcomes and provide policymakers with real-time feedback on the effectiveness of their policies [33]. Data insights collected through HRS could form the basis for more targeted policy interventions to reduce health inequities.

Recommendations for Research Priorities

As we have described above in this section, HRS have immense potential to decrease health inequities. However, they are currently not designed from a health equity lens. Below we describe gaps in the current literature based on our analysis. For HRS to be more useful and accessible to marginalized populations, we need new design guidelines. Future research priorities are further described in this study that span several levels of the socioecological framework (also illustrated in Table 1).

Incorporating Structural Barriers to Good Health in Personalization (Individual and Community)

Despite the potential of incorporating many data sources, as we explained above, most HRS do not integrate factors associated with the social determinants of health [34] and primarily use basic demographic information like age and gender, as well as individual health behaviors for tailoring recommendations [2]. As also mentioned by Richardson et al [10], in their digital health equity framework, this oversight could exacerbate health inequities, as marginalized individuals are less likely to benefit from interventions focused on behavioral factors, because of limited resources and competing priorities, which are greater in these populations. Future research should explore the integration of the social determinants of health into HRS, such as SES, healthy food scarcity, and digital and health literacy.

Decolonial Perspectives in HRS Design (Individual, Interpersonal, and Community)

Because of their capability to incorporate diverse data sources, HRS are very suitable to be designed to contextualize, recognize, and incorporate diverse perspectives. Scientific knowledge in the digital health field is however currently predominantly produced through the lens of Western scholars, which marginalizes diverse and Indigenous health perspectives. In the case of HRS, users themselves have been scarcely involved in the design process. For example, in a recent review of 51 HRS, only 10 recruited users in the development of HRS testing, and the majority did not define the target group of the HRS intervention [2]. Furthermore, the majority of HRS studies are conducted in the United States and China, and low-income countries or low-resource settings are underrepresented [2].

Because of the underrepresentation of marginalized groups and lack of geographical diversity, HRS likely have cultural biases, which can make them less relevant to underrepresented groups.

XSL•FO
RenderX

For example, mental health support integrated with religious or spiritual practices may be more accessible and relevant for some underrepresented groups, but it contrasts the body-mind separation of mental health dominant in a Western biomedical paradigm [35].

Decolonization involves critically re-evaluating interventions to remove cultural biases [36]. For example, mental health support integrated with religious or spiritual practices may be more accessible and relevant for some underrepresented groups, but it contrasts the body-mind separation of mental health dominant in a Western biomedical paradigm [35]. It involves centering intervention designs on the lived experience of the potential users. Thus users, especially those from marginalized backgrounds, should be included in the design and testing of HRS. This can be done through participatory research methods, where community members collaborate on all aspects of the project with researchers and other stakeholders, including feature design, testing, and dissemination [36]. This also involves examining power relationships that may underline the use of their technologies and structural and cultural factors that may broadly influence well-being [36]. Besides user involvement, technological collaborations with traditional health practitioners, such as herbalists or local healers [35] community, or faith-based organizations could help to understand and mitigate these power imbalances [37].

Evaluating the Impact of HRS on Health Equity (Community and Societal)

HRS researchers and developers should critically evaluate and report how their solutions may impact health inequities (eg, what disadvantages or privileges the research may create) [38,39]. For example, successful implementation and deployment of HRS (and many other digital health interventions) at the community level depends on structural factors such as consistent and high-quality internet access, which may be particularly challenging for resource-constrained areas [10]. If data is not available in sufficient detail or quantities, this will impact the effectiveness of HRS, leading to their lower effectiveness for marginalized populations.

Furthermore, beyond the design phase, funding for the planning and delivery of HRS to marginalized populations is necessary, to avoid that successful HRS projects fail to scale up to maturity to impact health [40]. In addition, we also need the data to track the reach and effectiveness of HRS in decreasing health inequities (metrics beyond health outcomes) [41], such as access to and quality of care, and advocate for policy changes based on these data [42]. Addressing these structural challenges and advocating for inclusive research are essential steps toward ensuring the equitable deployment and effectiveness of HRS in marginalized communities.

Conclusion

HRS have great potential in decreasing health inequities through accessible, personalized health promotion interventions, which can influence the individual, intrapersonal, community, and societal levels. HRS can leverage data from various sources to enable deep personalization of health promotion strategies based on the wider sphere of influence of health behavior and, through localized data collection, provide actionable insights for policymakers on population health. However, we argue that, with this emerging and developing field, health equity should be a priority, not an afterthought. Future research should focus on new design paradigms, including incorporating data on the social determinants of health, designing from a lens of decolonizing HRS, and evaluating the impact on health equity. Although this research does not provide definitive solutions, it lays a foundation for future studies, and we hope it benefits ongoing discourse in the field. With changes in practices and design with an intentional equity focus, HRS could play a crucial role in access to health promotion, improving the health of marginalized groups, and decreasing health inequities.

Abstract

Continuous monitoring of patients' health facilitated by artificial intelligence (AI) has enhanced the quality of health care, that is, the ability to access effective care. However, AI monitoring often encounters resistance to adoption by decision makers. Healthcare organizations frequently assume that the resistance stems from patients' rational evaluation of the technology's costs and benefits. Recent research challenges this assumption and suggests that the resistance to AI monitoring is influenced by the emotional experiences of patients and their surrogate decision makers. We develop a framework from an emotional perspective, provide important implications for healthcare organizations, and offer recommendations to help reduce resistance to AI monitoring.

(J Med Internet Res 2025;27:e51785) doi:10.2196/51785

KEYWORDS

artificial intelligence; AI monitoring; emotion; resistance; health care

Introduction

Continuous monitoring through artificial intelligence (AI) technology is becoming increasingly important in health care. AI is becoming an integral part of health care, for example, in pain monitoring [1], in creating medical imaging platforms [2], and in delivering timely medical interventions to patients [3] to increase the quality of care, that is, the ability to access effective care [4]. AI monitoring solutions use machine learning techniques to learn from data generated from adhesive patches, sensor devices, video cameras, and other devices, and identify risks of illnesses and adverse events. Given the potential benefits that AI monitoring offers to health care [5], regulators, and healthcare (we use both terms, healthcare and health care. Healthcare refers to an industry or a system that provides people with health care, whereas health care refers to the process of care or things that health professionals do) organizations strongly advocate its use. For instance, the Food and Drug Administration has been actively approving remote monitoring devices for patient care [6], while prominent hospital systems like Stanford Medical are developing AI monitoring solutions for senior care [7].

However, novel solutions such as AI monitoring often encounter resistance from users [8,9]. Such resistance is usually attributed to users' risk aversion toward innovation [10], sometimes called "liability of newness" [11], and their cognitive assessments of the costs and benefits of AI. However, we argue that emotions play an important role in AI monitoring resistance, even more than a rational evaluation of the decision, given that decision makers, specifically, patients and family members, lack extensive experience with novel AI solutions [10], which limits their ability to conduct a thorough cost-benefit analysis. Health care decisions often carry high stakes, and making the wrong choices can lead to serious consequences, including the loss of life. Therefore, making emotion-driven decisions in adopting AI-based solutions presents a significant challenge for healthcare organizations.

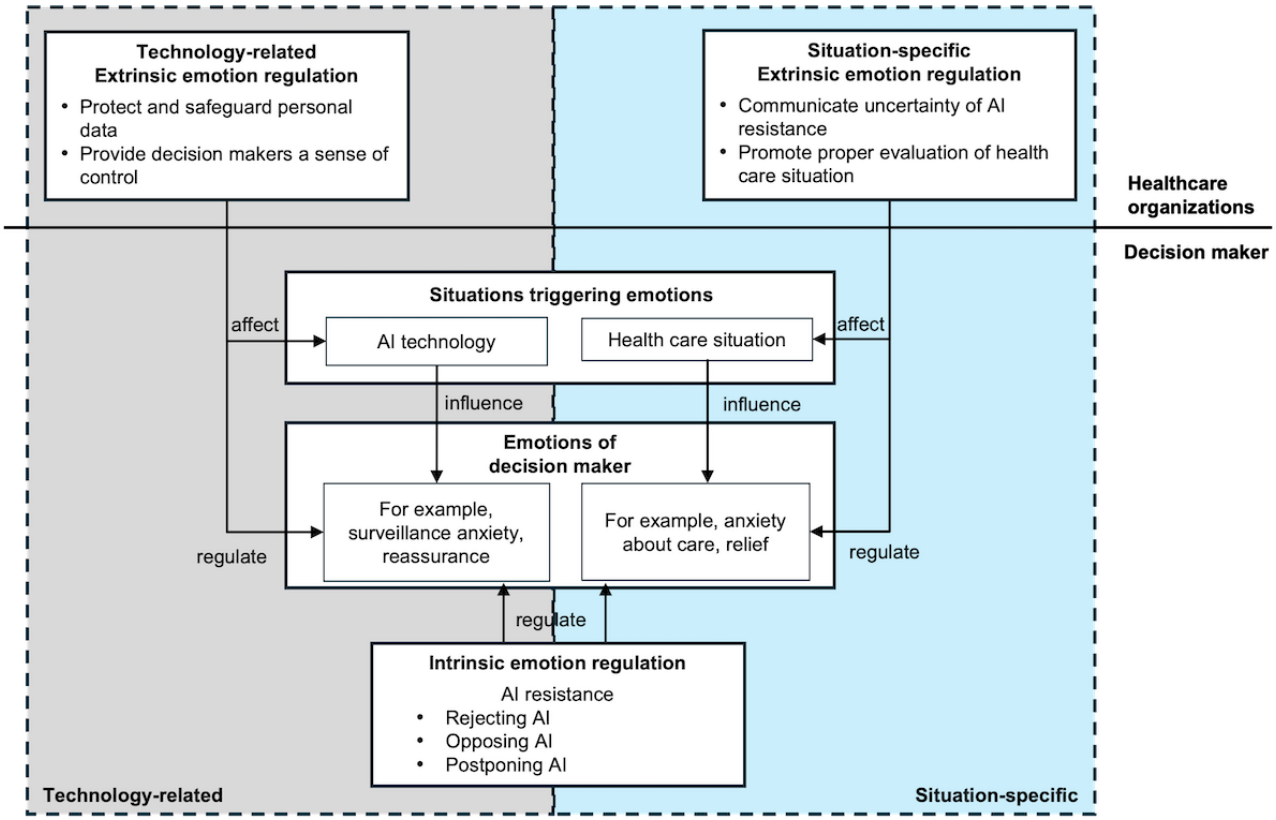
XSL•FO
RenderX

In this viewpoint paper, we discuss why the current view on resistance to AI monitoring may not fully capture the underlying reasons. We develop a framework from an emotional perspective that explains why decision makers resist AI monitoring and propose solutions that alleviate their concerns.

What Is Missing in the Current View of AI Monitoring Resistance?

Healthcare organizations often attribute resistance to patients' reluctance to accept innovative solutions to their cognitive assessment of the technology's costs and benefits [12]. For instance, prior studies have reported that some patients' resistance to AI systems results from their evaluations regarding privacy intrusion and insecurity of sensitive medical data because AI systems may be vulnerable to data breaches and data misuse [13]. Some patients may have doubts about the accuracy and reliability of AI systems [14] or do not understand and fully comprehend how AI functions, and hence, are reluctant to adopt these technologies [15]. Ethical dilemmas regarding AI decision-making in healthcare—in part, stemming from the fact that algorithms are inherently biased [16] with serious consequences of medical decisions—further contribute to the resistance of AI systems [13].

Taken together, the AI literature assumes that resistance decisions are rational and that patients themselves make the decisions about adopting the AI monitoring system. However, recent studies challenge these assumptions [8]. AI systems are opaque and often lack transparency [17], making it difficult for decision makers to rationally analyze their costs and benefits. Given the complexity of AI systems, decision makers often lack a comprehensive understanding of this advanced technology, exacerbating the challenges presented to rational decision-making [15]. Thus, we argue that alongside cognitive assessments of AI's costs and benefits, emotions play a crucial role in AI monitoring resistance [3]. Decision makers may include others such as family members because, for example, senior citizens often have limited knowledge of technology and frequently turn to surrogate decision makers, such as their adult children, for help when making technology decisions [18,19].



The AI Resistance Framework: An Emotion Perspective

Emotion is a complex psychological state that involves "loosely coupled changes in the domains of subjective experience, behavior, and peripheral physiology" [20]. Emotions are often triggered by external stimuli (eg, events or surrounding situations) [21], and they can be instrumental in directing attention to critical environmental details, refining decision-making, and aiding behavioral responses [22]. However, emotions can also be detrimental when they are inappropriate in type, intensity, or duration for a given situation. Therefore, individuals strive to regulate their emotions [22].

Emotion regulation refers to the "attempt to influence which emotions one has when one has them, and how one experiences or expresses these emotions" [20]. The goal of emotion regulation is to achieve some valued end (eg, decreasing negative emotion; Gross [20]). There are two types of emotion regulation [22]: Intrinsic emotion regulation focuses on regulating one's own emotions, while extrinsic emotion regulation involves regulating another person's emotions. According to a process model of emotion regulation proposed by Gross [23], there are five types of emotion regulation strategies: situation selection, situation modification, attentional deployment, cognitive change, and response modulation. These strategies can influence both the individuals practicing them and those around them [20]. This view on emotion regulation has attracted considerable interest across various domains, such as psychology, business, sociology, and healthcare, because of its potential to improve mental health, job performance, and social harmony, among others [20]. Focusing on the emotions experienced and regulated by decision makers, as well as policies and practices used by healthcare organizations that impact patients' emotions, we present a framework that explains how emotions significantly impact resistance to AI monitoring (Figure 1).

XSL•FO

Figure 1. A framework of AI resistance from an emotion perspective. AI: artificial intelligence.

Decision Makers in Health Care

Health care is a complex process involving various stakeholders who may take on decision-making responsibilities based on a given situation. Patients are typically responsible for their own health decisions, such as following medical advice, using technological aids, or seeking further professional support. However, patients can also rely on others to guide them and sometimes even make important decisions on their behalf. For example, senior citizens often rely on family members for important medical and technology-related decisions. They may ask their adult children to install medical apps or help them navigate through their electronic healthcare records. Thus, key decision makers include patients and family members who act as surrogate decision makers [8,24].

Emotions of Decision Makers and Their Triggers

Overview

Emotions, both positive (eg, happiness and joy) and negative (eg, anxiety and fear), are triggered by specific experiences or events [25]. For example, decision makers may become anxious about adverse health outcomes. In the context of AI monitoring, emotions arise in response to the criticality of a given situation [26] and the capabilities of the AI solution [27]. Thus, we suggest that emotions play an important role in resistance to AI monitoring.

Figure 1 presents two noteworthy sources triggering negative emotions, such as anxiety or fear, and positive emotions, such as happiness and joy. The first source relates to AI technology. Emotions triggered by AI monitoring systems encompass both negative and positive emotions. Anxiety about patients' surveillance and apprehension about transferring the responsibility of patient monitoring from the caretaker to the AI solution are common [8]. Conversely, positive emotions such as reassurance and comfort can arise from the continuous monitoring and alerts provided by AI systems, enhancing the sense of security for both patients and their families. The second source is specific to health care. Emotions triggered by the care process and its outcomes depend on the criticality of the health care situation. A critical health care situation, for example, would involve the possibility of the patient being hospitalized [8]. Conversely, positive emotions such as hope and relief can emerge when effective care processes and interventions are in place. In the following, we discuss some exemplary emotions triggered by both sources, AI technology and the health care situation.

Emotions Triggered by AI Technology

AI technology can trigger a range of emotional responses. For example, reassurance is fostered by enhanced efficiency and reliability in patient care enabled by AI monitoring. With AI monitoring, specific care activities are managed by the system, which allows caretakers and health care providers to focus on more complex and personalized care tasks [28]. For example, AI monitoring can provide real-time alerts and updates about a patient's condition, ensuring timely interventions and reducing the risk of human error. Decision makers feel reassured by the increased accuracy and efficiency that AI brings, as it supports health care providers in delivering high-quality care.

XSL•FO
RenderX

However, AI can also trigger negative emotions. Many decision makers are anxious because they do not know what information will be recorded. Surveillance anxiety is caused by sensor-based AI systems that provide extensive tracking of users and their behavior [27]. It is a feeling of tension and worry from thoughts resulting from the use of monitoring solutions. Many decision makers experience surveillance anxiety and worry about the continuous monitoring of patients and the collection and analysis of patient's data, leading to privacy and possibly security concerns. Surprisingly, a recent study [8] has found that the level of health risk has a limited impact on surveillance anxiety. Rather, many worry about their patients being monitored even under conditions of high uncertainty, such as the high possibility of being hospitalized.

Delegation anxiety is caused by the delegation of some health care tasks to AI, leading to a loss of personal interaction between health care providers and patients [29]. With AI monitoring, certain care activities are delegated to the system, which reduces the workload of caretakers and care providers [28]. For example, AI monitoring can automatically communicate critical patient information to health care providers. Decision makers worry about a loss of personal interaction because technology use reduces the interaction between health care providers and their patients. Similar to surveillance anxiety, research has found that they experience delegation anxiety even when uncertainty is high, even though they are less likely to resist AI monitoring [8].

Technology can also provide positive emotional experiences. For example, when designing monitoring technology, providing rewards for goal attainment can reinforce self-efficacy and provide positive emotional responses that support a patient in managing their diabetes medication [30]. Reinforcements and reiterations of success are common techniques used in gamification, increasing positive emotional responses and motivation [31].

Emotions Triggered by Health Care Situation

The health care situation of a patient also affects the emotions experienced by decision makers [8]. For example, anxiety about health care is experienced when decision makers worry about whether patients receive appropriate health care and monitoring of their health in highly uncertain situations. The process of care involves monitoring the health status [32] and providing physical, psychological, social, and spiritual support [33]. This was particularly acute during the pandemic, when decision makers were anxious about the prospect of their own or relatives' health problems going unnoticed especially when they belonged to a high-risk population [34].

Anxiety about health outcomes is experienced when decision makers worry about the potential negative health outcome for the patient. The health outcome includes positive developments (eg, improvement of symptoms) and negative developments (eg, deterioration of symptoms and hospitalization) [35]. Anxiety about health outcomes varies with the level of uncertainty of health outcomes, that is, decision makers experience more anxiety about health outcomes when uncertainty is high and less when uncertainty is low.

Conversely, relief and hope can be experienced when decision makers are provided with sufficient care and treatment information. For example, knowing that patients receive continuous, attentive care and having access to clear, timely updates about their treatment progress can foster feelings of relief [36]. This information helps patients feel more secure about their health care situation and strengthens their trust in the health care received, enhancing their overall emotional comfort.

Intrinsic Emotion Regulation With AI Resistance

Some emotions can be beneficial while others can be detrimental as they influence how decision makers perceive and interpret sensory information and shape their decisions based on such information, leading to either adaptive or maladaptive behaviors [20]. For example, decision makers' emotions can increase and decrease resistance [8]. Resistance decreases with technology-induced relief, increases with technology-induced anxiety, and decreases with health care situation-specific anxiety. Since decision makers are motivated to regulate their own emotions, particularly negative emotions, such as anxiety, anger, and fear, it is crucial to guide them toward beneficial regulation activities [20].

To regulate emotions, decision makers can use an emotion regulation strategy called situation selection, where they take actions to increase or decrease the likelihood of being in a situation that is expected to elicit desirable or undesirable emotions [20]. For example, decision makers may postpone, reject, or oppose AI monitoring. Postponing the adoption of AI monitoring solutions can be a form of passive innovation resistance, allowing them to avoid the emotion-inducing situation altogether [37]. This strategy works when there is an alternative system in place and there is no mandate to move to the new system. Often, the decision to postpone is driven by the decision maker's resistance to change as they feel more comfortable with the status quo.

However, decision makers often cannot delay a decision. Consequently, they may decide to reject AI monitoring due to a lack of prior experience. Decision makers' resistance to change and satisfaction with the status quo can catalyze this, as well as contextual factors, such as functional or psychological barriers [37]. Functional barriers can occur when decision makers perceive substantial challenges or drawbacks associated with adopting an innovation, such as difficulties in use, perceived lack of added value, or potential risks. On the other hand, psychological barriers emerge when the innovation clashes with decision makers' existing beliefs or perceptions, which may be influenced by sources like rumors or media [38]. Decision makers may oppose AI monitoring when they believe it is inherently unsuitable for their needs, even prior to a thorough evaluation. This resistance can manifest as attacking AI monitoring and the spreading of negative opinions about it [39].

XSL•FO
RenderX

Extrinsic Emotion Regulation Through Managerial Actions

Overview

Healthcare organizations and governmental institutions, as well as external entities with significant influence, have a vested interest in regulating decision makers' emotions. As collective actors, these organizations engage in cognitive reasoning and shape emotional understanding to guide thinking and actions [40,41]. They also practice collective emotion regulation to ensure informed decision-making [42]. In addition to regulating the emotions of their collective members, these organizations can also engage in extrinsic emotion regulation. This involves managing the emotions of external individuals, such as decision makers including patients and their families, to mitigate the rejection of AI innovations given their benefits and performance gains. We suggest the following emotion regulation strategies for organizations to manage decision makers' emotions and mitigate AI resistance.

Protect and Safeguard Personal Data for Responsible AI Solutions

Organizations can manage decision makers' emotions by adopting the emotion regulation strategy called situation modification. This involves actively changing situations and reshaping events that induce negative emotions to reduce their effects [20]. More precisely, organizations need to be cognizant of decision makers' emotions that may arise from a specific health care situation and the use of AI monitoring. A significant technology-related emotion is anxiety about the unauthorized disclosure and use of personal data. Healthcare organizations should carefully evaluate and choose an AI monitoring solution that is designed to protect and safeguard personal and other sensitive data collected from decision makers and others involved in a patient's care, for example, by blurring images or deidentifying the data before they are stored [8]. As AI monitoring solutions collect, store, and process data to provide predictions and recommendations, organizations need to balance ethics, personal privacy, and data security considerations against gains in quality of care and health outcomes [43]. In addition, healthcare organizations should make sure that there are sufficient human interactions with patients when deploying AI monitoring solutions. Healthcare organizations should make decision makers aware that AI monitoring can even be used to enhance engagement by enforcing personal interactions and providing personalized care.

Governmental institutions should proactively establish proper laws and regulations to manage AI monitoring. Examples include a blueprint from the White House that seeks to prevent negative implications of AI and its monitoring [44] and a draft from the European Union that seeks to ban AI for mass monitoring [45]. These initiatives are in response to criticism about some AI monitoring practices [46]. Seemingly, organizations are often too lax when managing personal data. However, when organizations take these concerns seriously, they can develop and deploy responsible AI solutions [47]. For instance, increasing transparency of essential algorithms, their data, and data processing allows others to evaluate the appropriateness of the AI solution and engages them in an open debate about corporate and governmental responsibilities concerning the design and deployment of AI solutions.

Provide Decision Makers a Sense of Control

Organizations can also manage decision makers' emotions by giving them a sense of control [8], that is, the feeling of being empowered and having the capability to influence or manage the operation of AI systems and their impact on decision makers' personal or professional lives. Decision makers typically regulate their emotions by choosing situations that either enhance or reduce the chances of experiencing favorable or unfavorable emotions [20].

Here, organizations can support decision makers by creating environments where they experience this sense of control. For instance, healthcare organizations should ensure that AI solutions are designed to provide decision makers with options to change the schedule, frequency, and type of data collected. Providing sufficient choice, freedom, and autonomy regarding what is monitored can alleviate decision makers concerns and reduce their negative technology-induced emotions, such as surveillance anxiety [8].

Additionally, regular training and educational resources on AI systems can help decision makers understand and confidently engage with these tools. These resources should cover how AI operates, the available options, and the benefits and limitations of the technology. By fostering a thorough understanding, organizations can help decision makers feel more in control and less anxious.

Communicate the Risk of AI Resistance

Healthcare organizations should communicate the potential consequences of not using AI monitoring to address resistance and foster adoption. First, healthcare organizations need to communicate the risk with the status quo. Health risks might already be present and decision makers seek to manage such risks. Many decision makers may even lack a clear understanding of the risks faced by the patients. For example, more than one out of four people aged 65 years or older falls each year [48], but less than half tell their doctor and caretaker [49] about these incidents. Therefore, it is important to communicate to decision makers the risk of adverse health outcomes such as a fall that may go undetected in the absence of adequate monitoring.

Second, healthcare organizations need to communicate the risk of AI resistance, that is, they need to articulate how AI capabilities can alleviate existing risks through its innate ability to act. For example, in addition to educating the decision makers about the ability of AI monitoring systems to continuously monitor potential symptoms and provide early detection of serious illnesses [50], healthcare organizations can ask decision makers to think about what would happen if patients' abnormal activities and adverse events such as falls are not noticed on time. When healthcare organizations also communicate the risk of AI resistance, decision makers can assess the existing risks more comprehensively, and thus, may choose to adopt AI monitoring.

XSL•FO
RenderX

Promote Proper Evaluation of Health Care Situation

Despite the threats and challenges presented by AI, the technology offers significant advantages, such as assistance in identifying health problems, monitoring for adverse events (eg, falls), and detecting abnormal behaviors (eg, wandering). When decision makers focus on these advantages and the opportunities AI provides in a given health care situation, they experience positive emotions such as reassurance and are more likely to evaluate the systems in a positive light. To assist decision makers in navigating healthcare processes and associated AI tools, organizations should enhance communication by providing clear, consistent updates about AI-powered healthcare procedures, patient status, and quality measures [51,52]. This transparency helps reduce concerns and anxiety, ensuring decision makers feel informed and confident in the AI systems. They should also develop personalized care plans that integrate AI system capabilities to address each patient's unique needs and involve family members in the planning process [53]. Tailoring care with AI support fosters trust and reassures decision makers by demonstrating a commitment to their needs.

In addition, establishing robust crisis management protocols that incorporate AI tools for real-time monitoring and response provides immediate support and reassurance [54]. This helps decision makers feel secure about the organization's ability to manage emergencies effectively. By implementing these strategies, healthcare organizations can mitigate AI resistance by enhancing trust, reducing anxiety, and fostering a positive emotional response toward AI-assisted care.

Abstract

This article discusses the extensive use of publication counts as indicators of trends in the scientific activities of individual researchers, research groups, and entire disciplines. However, with the growing number of articles in general, these counts might produce false impressions among scientists. We propose a straightforward yet effective normalization method, which enables further context of publication counts by using a query and a reference term. Additionally, an open access implementation is readily available on the PubMed Normalization website.

publication database; science communication; citation; H-index; normalization; publication; trend; scientometrics; scholarly

Problem Definition

PubMed is a widely used literature database that provides access to a vast repository of biomedical and life sciences literature. Publication counts on PubMed can be visualized through simple plots that display the number of publications over time, providing an easy way to track trends and patterns in scientific output. Publication counts over time are often used in science communication, research applications, original articles, or reviews to illustrate trends in scientific activity in a particular field [1-4]. A search on PubMed readily generates corresponding publication counts from year to year (Figure 1). To indicate growing scientific output of individuals or even joint consortia on a particular topic, the search can be further specified by author names, research sites, or affiliations. This yearly summary plot can and probably will be used as a valuable overview for (1) individual researchers or research groups to claim the success of recent research activities and (2) for policy makers or research funding organizations for initial decision-making or judging on research applications.

However, apart from its usefulness and simplicity, the plot can generate a false impression, which the authors of this viewpoint paper would like to stress on as they are frequently experiencing this type of illustration in presentations or publications without mentioning 2 important issues.

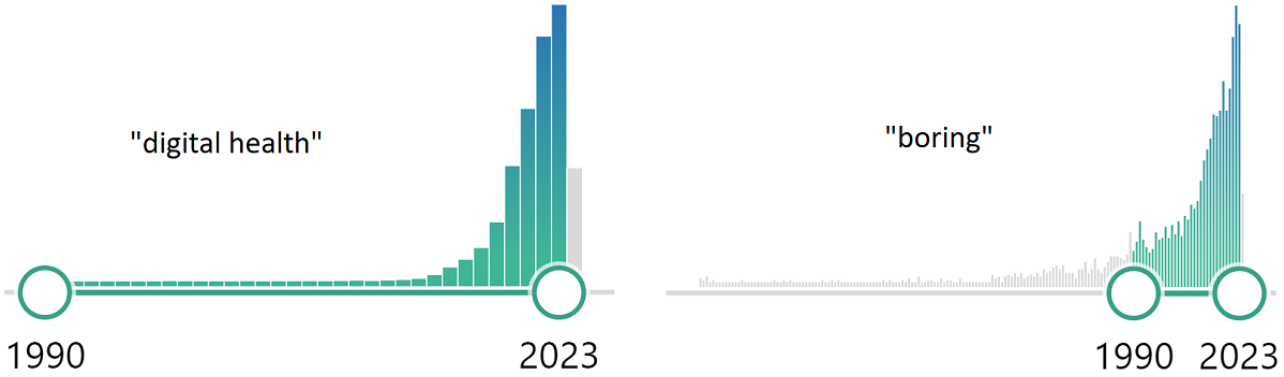
First, it does not take into account the fact that the overall number of publications have increased disproportionally. Figure 1 illustrates the problem for 2 query terms “digital health” and “boring” with a similar progression of publication counts.

The second issue is the potential textual growth per article over time, for example, by increasing the abstract’s length or further searchable metadata per article. For instance, there is evidence that the abstract length of articles has increased over time in Cochrane Reviews [5], and some articles may even exceed the abstract length that is allowed by a medical journal [6]. We are dealing with an increase in not only article counts but also textual growth per article, illustrated in Figure 2A by using the search term *boring*. Textual growth per article increases the base probability of a query term to be found and thus artificially increases publication counts per year.

XSL•FO
RenderX

While the available advanced search functions on PubMed allow for more targeted approaches, they do not provide a normalization of publication counts and their visualization, which is essential for accurately interpreting trends in the context of overall publication growth over time.

Figure 1. Original plot of PubMed counts per year, executed on May 2, 2024. Search terms: “digital health” (left) and “boring” (right).



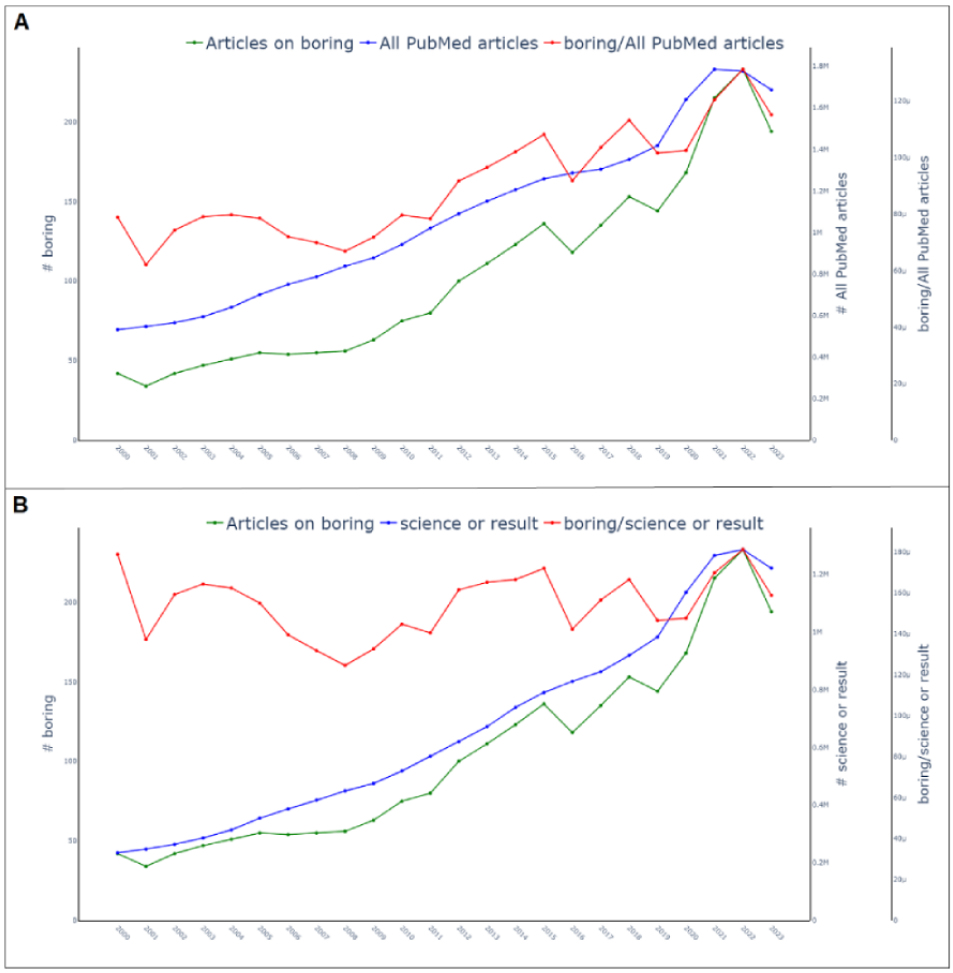


Figure 2. Article counts for the query term boring. (A) A simple correction when dividing the number of articles per year by the number all PubMed articles per year still shows an increase (red graph). (B) Correction applied by using a reference term, for example, science" or result. See Multimedia Appendix 1 for larger-resolution images.

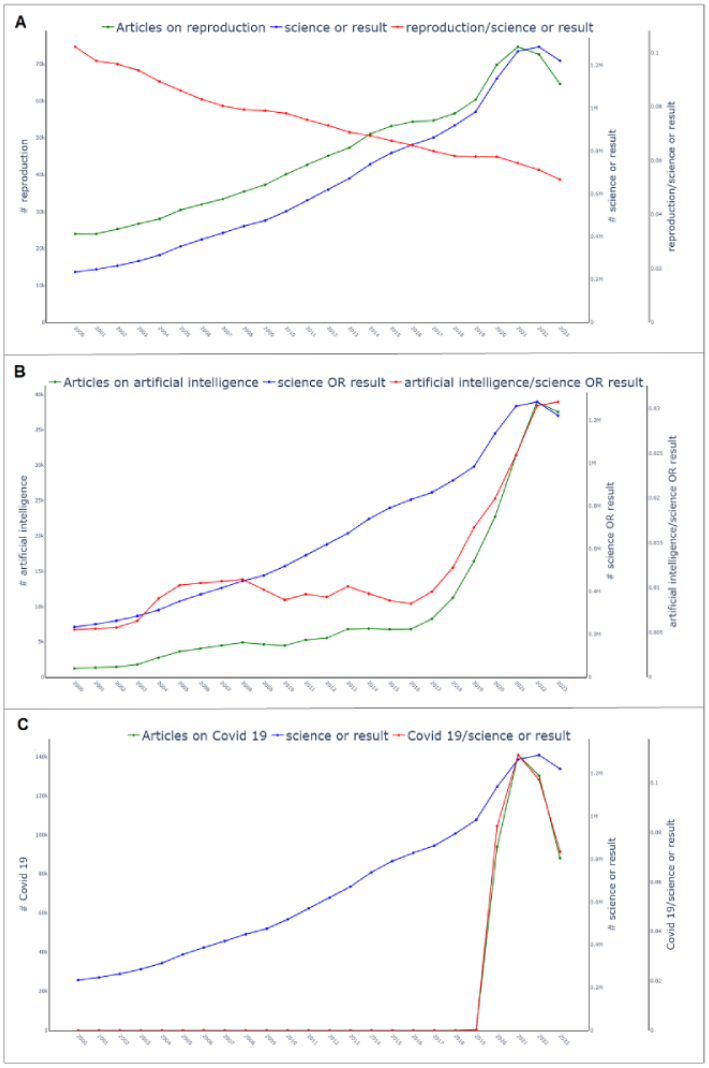
Pragmatic Solutions

Certainly, there are numerous correction measures involving advanced statistical and semantic analyses, which could add deeper insights for a more differentiated way of interpreting search results. Moreover, commercial tools are available, such as SciVal by Elsevier or Web of Science and Insight by Clarivate, which use more comprehensive datasets from larger literature databases and citation data to generate individual research portfolios or analyze publication trends. Here, we propose a noncommercial, pragmatic approach, which does not

XSL•FO
RenderX

overwhelm the user with statistical details but retains the simplicity of the original approach as illustrated in Figure 1.



This issue of the overall increasing number of publications can be tackled by dividing the counts by the number of all PubMed publications within the corresponding year. This straightforward correction is already applied in implementations such as the web-based tool PubMed by Year [7], which also offers the user to query and compare publication counts of other search queries. This does, however, not solve the issue regarding textual growth per article. Figure 2A shows that counts over time for the query term *boring* are increasing despite the aforementioned correction.

To overcome both issues, we suggest calculating and visualizing a normalization ratio, in which the counts of a query term are divided by the counts of a reference term. Both the query and the reference terms can be specified by the user, for instance by using a basic set of frequently used unspecific terms, such as *research*, *science*, or *results*. These reference terms provide a more robust correction because they are also impacted by the 2 aforementioned issues, leading to an adjustment where errors cancel out. Users have the flexibility to modify the reference term to better suit their specific needs or areas of interest.

Figure 2B shows an example plot that presents the normalization ratio. The search term *boring* now shows a steady publication count with minor variations per year. Figure 3 provides complementary examples for the search terms *Reproduction*, showing an established field with a decreasing normalization ratio; *Artificial Intelligence*, showing a continuously growing field; and *COVID-19*, showing a short-term steep increase followed by a decrease as the result of a pandemic.

A ready-to-use tool that calculates and visualizes the corrective normalization ratio for any user-specified PubMed query term is provided on the PubMed Normalization website or as a Docker container with open-source code [8].

Figure 3. While the query terms reproduction (A) and artificial intelligence (B) both show an increase in the number of publications per year (green line), the normalization ratios (red line) reveal a steady decrease for reproduction (A). For artificial intelligence (B), the red line indicates steady growth since 2016. After 2022, the growth rate slowed down. For the query term Covid 19 (C) the green and the red lines are almost perfectly aligned, indicating a steep increase followed by a steep decrease in the number of absolute publications and relative publication counts. See Multimedia Appendix 2 for larger-resolution images.

XSL•FO
RenderX

Discussion

PubMed search counts can generate a valuable overview of research trends but should be treated with caution as they represent nonnormalized and therefore potentially misleading output. The main advantage is its simplicity regarding usage and initial interpretation. For more insightful interpretation, we have pointed out 2 issues, namely the increasing article count and the textual growth per article. With this viewpoint paper, we would like to raise awareness when interpreting such publication counts. The rising number of articles published each year can lead to an overwhelming amount of data, making it difficult to identify meaningful trends without further statistical analyses and domain-specific knowledge.

We suggest adding more context to publication counts by using a normalization ratio graph that uses a reference term to account for both aforementioned issues. All parameters can be specified by the user to account for subject-related queries or reference terms. Moreover, PubMed's advanced search function is integrated as well, as our ready-to-use demonstrator supports the original PubMed queries as an input. It should be noted that this analysis cannot replace deeper analyses that address well-known drawbacks from literature searches, such as publication and accessibility bias, language bias, field-specific variations regarding publishing practices, or query and reference term selection. Nevertheless, we believe that a combined graph provides the same simplicity as the naïve search and provides more robust results when presenting publication counts and comparing them to the general research output.

In our search for related bibliometric analyses tools on the web, we have found numerous and highly valuable commercial tools such as SciVal by Elsevier or InCites by Clarivate, or open-source tools like bibliometrix [9] and PubMed by Year [7]. While these come with extensive analyses features to analyze individual or network-based research output and collaboration patterns, not only on PubMed but also on many different literature databases, we could not find a free and readily available web-based tool with a specific way to normalize and instantly visualize PubMed counts against a reference term. For quick demonstration, we have provided an exemplary implementation, which is accessible on a sustained web-based infrastructure. We encourage the scientific community to view the proposed method as a foundational tool, designed to address the key limitations of current article count presentations. While this approach offers a basic correction, we advocate for further customization to meet the specific demands of diverse research landscapes.

Abstract

Implementation of patient-reported outcome measures (PROMs) in clinical practice is challenging. We believe effective communication is key to realizing the clinical benefits of PROMs. Communication processes for PROMs in clinical practice typically involve (1) health care professionals (HCPs) inviting patients to complete PROMs, (2) patients completing PROMs, (3) HCPs and patients interpreting the resulting patient-reported outcomes (PROs), and (4) HCPs and patients using PROs for health management. Yet, communication around PROMs remains underexplored. Importantly, patients differ in their skills, knowledge, preferences, and motivations for completing PROMs, as well as in their ability and willingness to interpret and apply PROs in managing their health. Despite this, current communication practices often fail to account for these differences. This paper highlights the importance of personalized communication to make PROMs accessible to diverse populations. Personalizing communication manually is highly labor-intensive, but several digital technologies can offer a feasible solution to accommodate various patients. Despite their potential, these technologies have not yet been applied to PROMs. We explore how existing principles and tools, such as automatic data-to-text generation (including multimodal outputs like text combined with data visualizations) and conversational agents, can enable personalized communication of PROMs in practice.

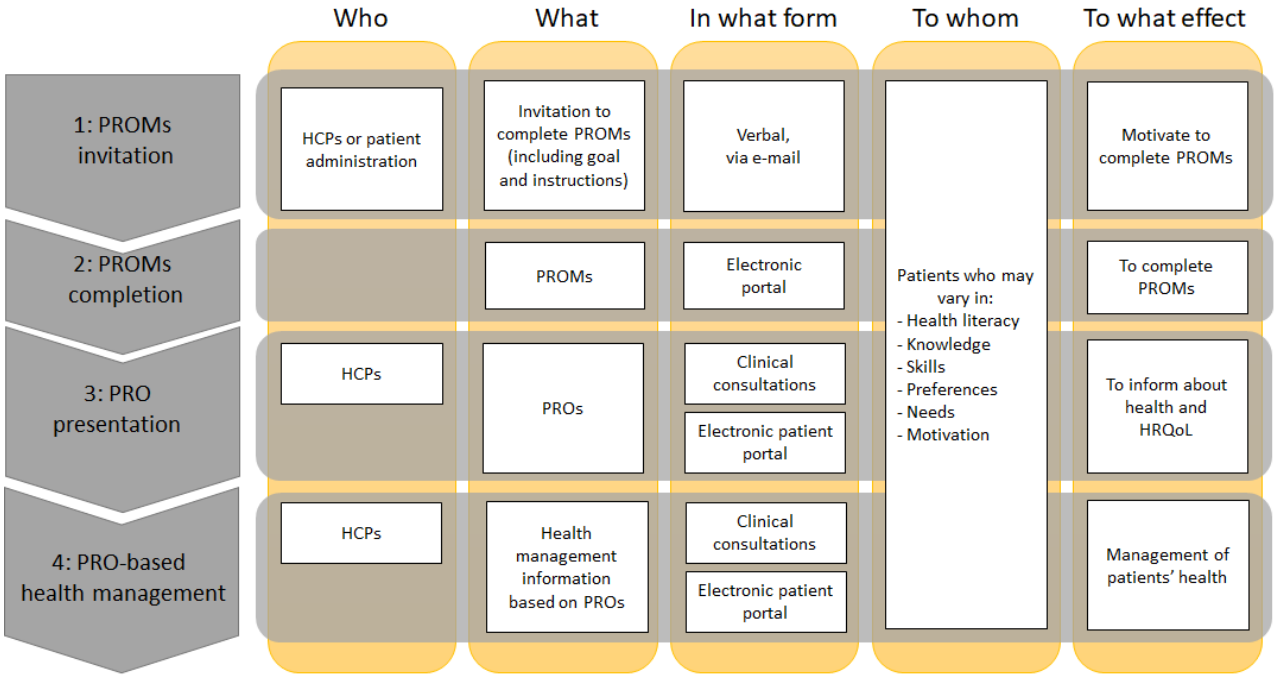
Introduction

Patient-reported outcome measures (PROMs) are instruments that can capture patients' health status directly through digital administration [1-3]. Patients vary in their skills, knowledge, preferences, and motivations to complete PROMs, as well as their ability to interpret and use the resulting patient-reported outcomes (PROs) for health management. However, PROMs and PROs are not designed to accommodate these differences, often excluding certain populations [4]. This includes older adults, nonnative speakers, individuals with poor health, those lacking social support, people in less privileged socioeconomic positions, or those with low health literacy—defined as "the degree to which individuals can obtain, process, and understand the basic health information and services they need to make appropriate health decisions" [4-6].

XSL•FO
RenderX



Communication is crucial for achieving the clinical benefits of PROMs, for instance when health care professionals (HCPs) discuss PROs with patients. However, the communication processes involved in using PROMs in clinical practice are underexplored [7-9]. We therefore argue that improving communication processes can enhance PROMs implementation. Specifically, personalized communication (information that is customized to the individual) is essential to address the diverse information needs, preferences, and capacities of a broad population [10]. However, personalizing information manually is labor-intensive and costly, which may explain its limited application to PROMs.

To address this, we propose leveraging existing digital technologies to streamline personalized communication for PROMs. Tools such as data-to-text generation, multimodal communication, and conversational agents can offer innovative solutions to improve communication and, in turn, support the broader implementation of PROMs in clinical practice. This paper begins by summarizing communication processes for PROMs in clinical practice and identifying their shortcomings. These shortcomings highlight the limitations of a one-size-fits-all approach, which fails to meet the needs of a diverse patient population. We propose solutions rooted in personalized communication and suggest several digital technologies to support the implementation of these strategies in clinical practice.

Communication Processes for PROMs in Clinical Practice

From many available frameworks, we use the framework of Lasswell [11] to outline key aspects of communication for PROMs in clinical practice: who communicates what, in what form, to whom, and to what effect (Figure 1). We distinguish 4 communication processes, that are PROMs invitation, PROMs completion, PRO presentation, and PRO-based health management.

Figure 1. Communication processes for PROMs in clinical practice. HCPs: health care professionals; HRQoL: health-related quality of life; PROMs: patient-reported outcome measures; PROs: patient-reported outcomes.

First, HCPs or administrative staff ("who") invite patients ("to whom") verbally or by email ("in what form"), including the goal and practical guidance on how to complete PROMs ("what") [11,12]. This aims to engage patients to complete PROMs ("to what effect").

Second, PROMs ("what") are administered through online portals ("in what form") for patients ("to whom") to complete ("to what effect").

Third, HCPs ("who") should consistently discuss PROs ("what") with patients ("to whom") during consultations ("in what form") [12,13], providing insights into their health and health-related quality of life (HRQoL; "to what effect") [12]. Alternatively, patients can occasionally access their PRO reports directly via electronic portals ("in what form"), bypassing HCPs.

Fourth, HCPs ("who") can translate the PROs into actionable health management information ("what") to aid patients' ("to whom") health management ("to what effect"). Similarly, patients may independently access this information ("what") through electronic portals ("in what form"), bypassing HCPs.

Shortcomings, Solutions, and Digital Technologies to Improve Communication Processes

The shortcomings of each communication process are detailed below, along with solutions based on personalized communication and digital technologies to support implementation. Table 1 summarizes the identified

XSL•FO
RenderX

shortcomings, proposed solutions, and relevant digital technologies.

Table 1. Improving communication processes around PROMs[a]: identified shortcomings, proposed solutions, and relevant digital technologies.

Identified shortcomings	Proposed solutions	Digital technologies to support implementation
1: PROMs invitation: tailoring invitations by data-to-text to accommodate more patients		
Not all patients understand the purpose of completing PROMs, when PROs[b] will be discussed, and how they benefit, resulting in varying levels of motivation to complete PROMs.	Written invitations could be tailored to accommodate different reading and health literacy levels to better serve patients with varying literacy and health literacy levels.	"Data-to-text" can tailor PROMs invitations to better serve patients with varying literacy and health literacy levels in an automated, data-driven way.
2: PROMs completion: multimodal communication principles to support PROMs completion		
Not all patients are able to complete PROMs, as they have diverse skills, knowledge, and preferences. Yet, PROMs are presented in a single, standardized format.	Presenting PROMs in other formats other than text could better serve patients with lower (health) literacy.	Multimodal communication, such as a video of an interviewer reading the questions, with written text that changes color in synch with the audiovisual playback.
Not all patients are able to complete PROMs, as they have diverse skills, knowledge, and preferences. Yet, PROMs are presented in a single, standardized format.	Allowing patients to verbally complete PROMs could better serve patients with lower literacy.	Conversational agents integrated into PROMs administration systems would allow patients to complete PROMs verbally.
3: PRO presentation: data-to-text to convert numeric PROs into comprehensible texts		
Not all patients understand PROs because of the way these are presented, and HCPs[c] frequently omits to explain PROs to patients.	Presenting PROs in a more patient-friendly way to patients.	Data-to-text applications can convert numeric PROs into written texts or narratives.
4: PRO-based health management: from PROs to health management by conversational agents		
HCPs fail to guide patients to use PROs for health management, or patients perceive health management information as not relevant as their information needs differ between patients.	Both HCPs and patients require guidance on how to use PROs for health management.	Conversational agents can break down information into smaller bits, highlight relevant PROs, and provide self-management advice. By tailoring PROs and self-management actions to individual patients, information becomes more relevant.

[a]PROMs: patient-reported outcome measures.

[b]PROs: patient-reported outcomes.

[c]HCPs: health care professionals.

PROMs Invitation: Tailoring Invitations by Data-To-Text to Accommodate More Patients

Not all patients understand the purpose of completing PROMs when PROs will be discussed, and how they will benefit, leading to varying levels of motivation to complete PROMs. Some patients may perceive PROMs as tools for research or to train HCPs [12-15]. Written invitations could be tailored to different reading and health literacy levels to better serve patients with varying literacy and health literacy levels, ensuring information about the goal and use of PROMs are clearly communicated, potentially improving completion rates.

"Data-to-text" is a digital technology with the potential for tailoring PROMs invitations to diverse audiences in a data-driven manner. A form of natural language generation (NLG), it uses insights from computational linguistics and artificial intelligence (AI) [16]. This technology automates the conversion of data into coherent natural language, typically achieved through a series of computational steps [17]. A standard data-to-text pipeline processes a patient's data, using a sequence of algorithms to determine the content and structure of the output text. By incorporating self-reported or clinically obtained information about patients' education, literacy, and health literacy levels, the system could generate texts at various readability levels to accommodate a range of reading proficiencies [18].

PROMs Completion: Multimodal Communication Principles to Support PROMs Completion

Patients have diverse skills, knowledge, and preferences for completing PROMs [4] (Table 1). While digital PROMs can be offered through multiple completion methods [19,20], and flexible administration is recommended [21], often only a single method is provided. As a result, not all patients can complete PROMs. Those facing barriers are particularly older, non-White, lower-educated patients, and those with low health literacy [4,22]. Reducing these barriers could improve completion rates in these groups.

Data-to-text could tailor PROMs to patients' reading levels, but textual PROMs may still be too lengthy, information-dense, or intimidating for some patients. According to dual coding theory [23] and the cognitive theory of multimedia learning [24],

XSL•FO
RenderX

multimodal communication (especially combining text with visuals) may help alleviate these issues [18]. These theories suggest that our working memory processes different types of information through separate channels, each with limited capacity. Using multiple channels, such as visual and verbal information, enhances information transfer. For example, integrating images with text can significantly improve comprehension, as long as the visuals and text are presented together and complement each other [24-27].

Examples of multimodal PROMs already exist [20,28-31], such as the multimedia program of Thumboo et al [28], which delivers PROMs via a touchscreen device. Each question is paired with visual and auditory stimuli – a video of an interviewer reading the question, with accompanying text that changes color in sync with the audio playback. The playback speed can be adjusted to accommodate patients with different reading levels. This approach could be extended to PROM invitations, questions, and PRO-related texts, improving accessibility and comprehension.

Furthermore, conversational agents, which emulate human conversation through text or speech [32], can be integrated into PROMs administration systems, allowing patients to complete PROMs verbally using familiar devices such as computers, smartphones, or tablets [31]. We believe this approach could be especially effective when combined with multimodal or interactive voice response systems that read questions aloud [20,31,33], making PROMs completion more accessible, especially for less literate patients. In addition, conversational agents can overcome language barriers by supporting multiple languages, promoting inclusivity for nonnative speakers [34]. Examples of this have been demonstrated by Mlakar et al [30] and Fenza et al [35], though formal evaluations of their relevance and efficiency are still needed.

PRO Presentation: Data-To-Text to Convert Numeric PROs Into Comprehensible Texts

Although patients want to reflect on their health and HRQoL before discussions with their HCP [13,14], many are unable to do so. That is, digital PROMs typically grant HCPs but not patients' access to PROs [7]. Despite this, HCPs often neglect to discuss PROs [8], and patients are generally hesitant to initiate these conversations [13]. When patient do have access to their PROs, these are typically presented in numerical or graphical formats. While patients have expressed a need for personalized numerical information [36,37] and can interpret basic line or bar graphs [19], such formats often lack context and evaluability (ie, how good or bad the scores are) [38], leading to misinterpretation [19,39]. PRO comprehension is influenced by patient's health literacy [40] and statistical literacy or numeracy skills [41]. However, despite patients' varying levels for both, PROs are typically presented in a single, fixed format [19]. We believe that improving how PROs are presented will enhance their relevance and value for patients, providing better and more equitable access to the potential benefits of PROs in patient care.

Data-to-text applications could convert numeric PRO scores into written texts, combining numerical information with verbal descriptors to enhance understanding and improve information transfer [42], as studies suggest [12,18,19,43]. We believe both patients and HCPs could benefit from this approach. When discussing individualized outcome data, it is recommended to combine numerical or visual information with verbal descriptors to better align with patients' needs and capacities [44]. While some patients and HCPs prefer verbal descriptors over "cold" numbers or graphs for discussing outcomes and HRQoL data [36,45], relying solely on words can lead to varied and inaccurate perceptions. Despite its potential, the practical use of NLG for converting PROs into coherent texts is not yet common in clinical settings. The Dutch "Data2Text" project represents an initial exploration into this promising field [46].

Patient narratives, or stories about other patients' experiences, can help patients understand the meaning of their own PROs [37,42]. When patients recognize PROMs as reflections of their health experiences, HCPs can engage in discussions about how PROs can enhance HRQoL and care [14]. As a form of data-to-text, personalized narratives could be generated based on patients' PRO scores. This approach was explored in previous research by our group, where it was found to be feasible for clinical practice. Importantly, we discovered that narratives can provide emotional support, complementing numeric data to facilitate discussions about HRQoL during clinical consultations [37]. With further development, a decision algorithm could select relevant stories from a collection of patient narratives, using a patient's PROs as input.

PROs Presentation—Based Health Management: From PROs to Health Management by Conversational Agents

In one-third of studies reviewed by Anatchkova et al [3], HCPs failed to guide patients on PRO-based health management. In addition, patients typically use health information in decision-making only when the information is relevant to them, and information needs vary between patients (Table 1) [42]. Improving patients' access to personalized health information could potentially enhance their care and support better health-related outcomes.

Both patients and many HCPs need guidance on how PROs contribute to care, and how to interpret, discuss, and act on PROs [8,13,14]. Conversational agents can break down information into smaller, manageable pieces, acting as intermediaries by highlighting relevant PROs and providing self-management advice [42,47]. Examples include conversational agents developed for asthma self-management [48] and to promote healthy eating behaviors [49]. For patient dashboards, cognitive load can be reduced by highlighting key information and enhancing evaluability [42]. When PROs are presented numerically or graphically, emphasizing the clinical significance of scores aids interpretation. This can be achieved through color-coding (eg, red for alarming and green for non-alarming scores), using exclamation marks or red circles for critical scores, and adding threshold lines to indicate scores relative to clinical thresholds [19]. We believe this approach could facilitate PRO interpretation and clinical decision-making, accelerating the use of PROs in health management. In addition, for patients, simply receiving health information is not enough — it must be interesting and relevant to them, which varies

XSL•FO
RenderX

between patients [42]. Based on patients' predefined goals and preferences, conversational agents can tailor PRO scores and self-management actions to meet their specific information needs.

Implementation of Technology-Assisted Communication Processes Around PROMs

With increasing pressure on health care, digital strategies for patient self-management are expected to play a larger role [50,51]. Paradoxically, those who would benefit the most from enhanced self-management support (such as vulnerable populations) are often the ones facing barriers to participation. For instance, lower health literacy is associated with worse health outcomes and healthcare service utilization [52], while lower digital health literacy correlates with lower overall survival rates in cancer patients [53]. While PROMs have the potential to improve symptom management, HRQoL, patient-HCP communication, and patient satisfaction [7,12,13,54,55], vulnerable patients may currently lack access to these benefits. By implementing personalized communication strategies and leveraging digital technologies, we believe PROMs can become more accessible and easier to complete, thereby increasing completion rates. Furthermore, making PROs easier to interpret can improve their usability and value for patients, ensuring that PROMs can more effectively support patient care, particularly for those currently left out.

Despite promising advances, the use of the digital applications described here is not without risks. Data-to-text algorithms, particularly those based on data-driven approaches, present certain challenges. Traditionally, data-to-text systems relied on hand-crafted rules, which were difficult to scale. However, recent advances in machine learning, driven by increased computing power, have streamlined this process, enabling scalability and efficiency [18,56]. Large language models, such as exemplified by ChatGPT, are arguably the culmination of this approach. While these models generate fluent text, they are not always accurate and may contain harmful biases. Large language models rely on massive volumes of human-authored texts, typically sourced from the internet, raising concerns about the exclusion of underrepresented populations (eg, those with a small presence on the internet) and the inclusion of biased or toxic language [57,58]. Therefore, rule-based NLG might be preferable for converting PROs into text, offering more control and reliability. Similarly, while advances in machine learning have enhanced conversational agents with increased dialogue complexity, they introduce risks in natural language understanding, response generation, and patient interpretation, necessitating rigorous monitoring and validation [59]. The safety of conversational agents for patients remains inadequately evaluated [32]. We emphasize that these digital applications require further exploration and testing, despite their clear promise.

In addition to personalized communication, patient-centered communication could improve the use of PROMs in practice [21]. Currently, patients face issues with wording, length of questionnaires, and formatting of PROMs, which can hinder their understanding of questions and answer choices [15,34,39]. Over half of the commonly used cancer-related PROMs to not follow best-practices for plain language use [60]. To improve completion rates, existing PROMs should be revised to use simple, concrete language, avoiding jargon and negations, and eliminate redundant or distracting information [15,61]. Instructions should also be simplified [61-63] and structured with clear orientation statements (eg, "First I will explain the goals of PROMs, then I will show you what the questions are about") to aid understanding [61,62]. Resources like the "health literacy universal precautions toolkit" can help assess readability and convert medical terms into plain language [63].

To reduce patient burden, PROM should be relevant for individuals [21]. Computer adaptive testing can ensure follow-up questions are tailored to each patient, rather than asking the same set for everyone. The formatting of PROMs should prioritize clarity, with large fonts, clear headings, and ample white space [15,61]. Patient-preferred modifications include removing or altering items, using visuals, simplifying language, and adjusting layouts for better comprehension [29]. Using user-centered design can help meet the diverse needs of patients, considering factors such as clinical conditions, culture, languages, and literacy levels [4]. This approach should also explicitly involve individuals with low literacy skills or learning disabilities, as they are often excluded from PROMs development [64]. By doing so, we can ensure that PROMs are accessible to a wide range of patients, including those with disabilities [20].

Training HCPs about the goals, tasks, and responsibilities related to PROMs is essential for motivating their engagement with PROMs [65,66]. In general, HCPs should discuss or, at a minimum, briefly mention PROs with patients, even when no new clinical information arises from the data [13]. HCP engagement plays a significant role in patients' motivation to complete PROMs [67]; failing to follow up on PROMs may negatively affect patients' HRQoL [68]. Further research is needed to assist HCPs in interpreting PROs and converting them into actionable steps for health management [3,13]. That said, some patients may avoid engaging with detailed PRO data [36], highlighting the need for tailoring information to meet patients' individual preferences for how they receive and process information. Although digital technologies can support communication around PROMs in clinical practice, they may not be able, now or ever, to replace the HCP in addressing patients' HRQoL.

Future Implications and Next Steps

Implementing the proposed technologies in clinical practice might present some practical hurdles. For instance, many of the identified applications have not been seamlessly integrated into electronic health records (EHRs) [47,69]. Future health care systems will require EHRs that can safely incorporate digital applications. However, models could be trained without sharing data from EHRs, using techniques like federated learning [70]. Furthermore, trust, which is crucial for patient adherence [71], is challenged by the perceived "black box" nature of AI models.

XSL•FO
RenderX

Therefore, it is essential to have human oversight of AI outputs and to maintain transparency about data sources and methods [59]. Both HCPs and patients should become more AI-literate, and have a basic understanding of the capabilities and limitations of AI models [70]. To ensure that readers can assess the credibility of generated texts, it is essential to explain that texts come from a computer model, and not a fellow human [57].

The successful implementation of PROMs in clinical practice involves complex interactions between care processes, technological development, and human behavior [66]. Often, PROMs implementation is led by HCPs or researchers, potentially resulting in a lack of recognition of these complex interactions. This paper was written by a multidisciplinary team with expertise in PROMs, implementation science, health communication, and digital technologies. We have provided a comprehensive overview of key communication processes around PROMs. Future work could deepen this assessment by studying the effects of context and noise in communication, which are aspects currently missing from the application of the Lasswell model [11]. With ongoing advancements in AI, which may help mitigate the risks associated with the proposed digital applications, we envision a future where personalized communication strategies and digital tools can overcome current implementation challenges, ensuring that PROMs are applied inclusively to benefit all patients.

Abstract

Sensor-based digital health technologies (sDHTs) are increasingly used to support scientific and clinical decision-making. The digital clinical measures they generate offer enormous benefits, including providing more patient-relevant data, improving patient access, reducing costs, and driving inclusion across health care ecosystems. Scientific best practices and regulatory guidance now provide clear direction to investigators seeking to evaluate sDHTs for use in different contexts. However, the quality of the evidence reported for analytical validation of sDHTs—evaluation of algorithms converting sample-level sensor data into a measure that is clinically interpretable—is inconsistent and too often insufficient to support a particular digital measure as fit-for-purpose. We propose a hierarchical framework to address challenges related to selecting the most appropriate reference measure for conducting analytical validation and codify best practices and an approach that will help capture the greatest value of sDHTs for public health, patient care, and medical product development.

(J Med Internet Res 2025;27:e58956) doi:10.2196/58956

KEYWORDS

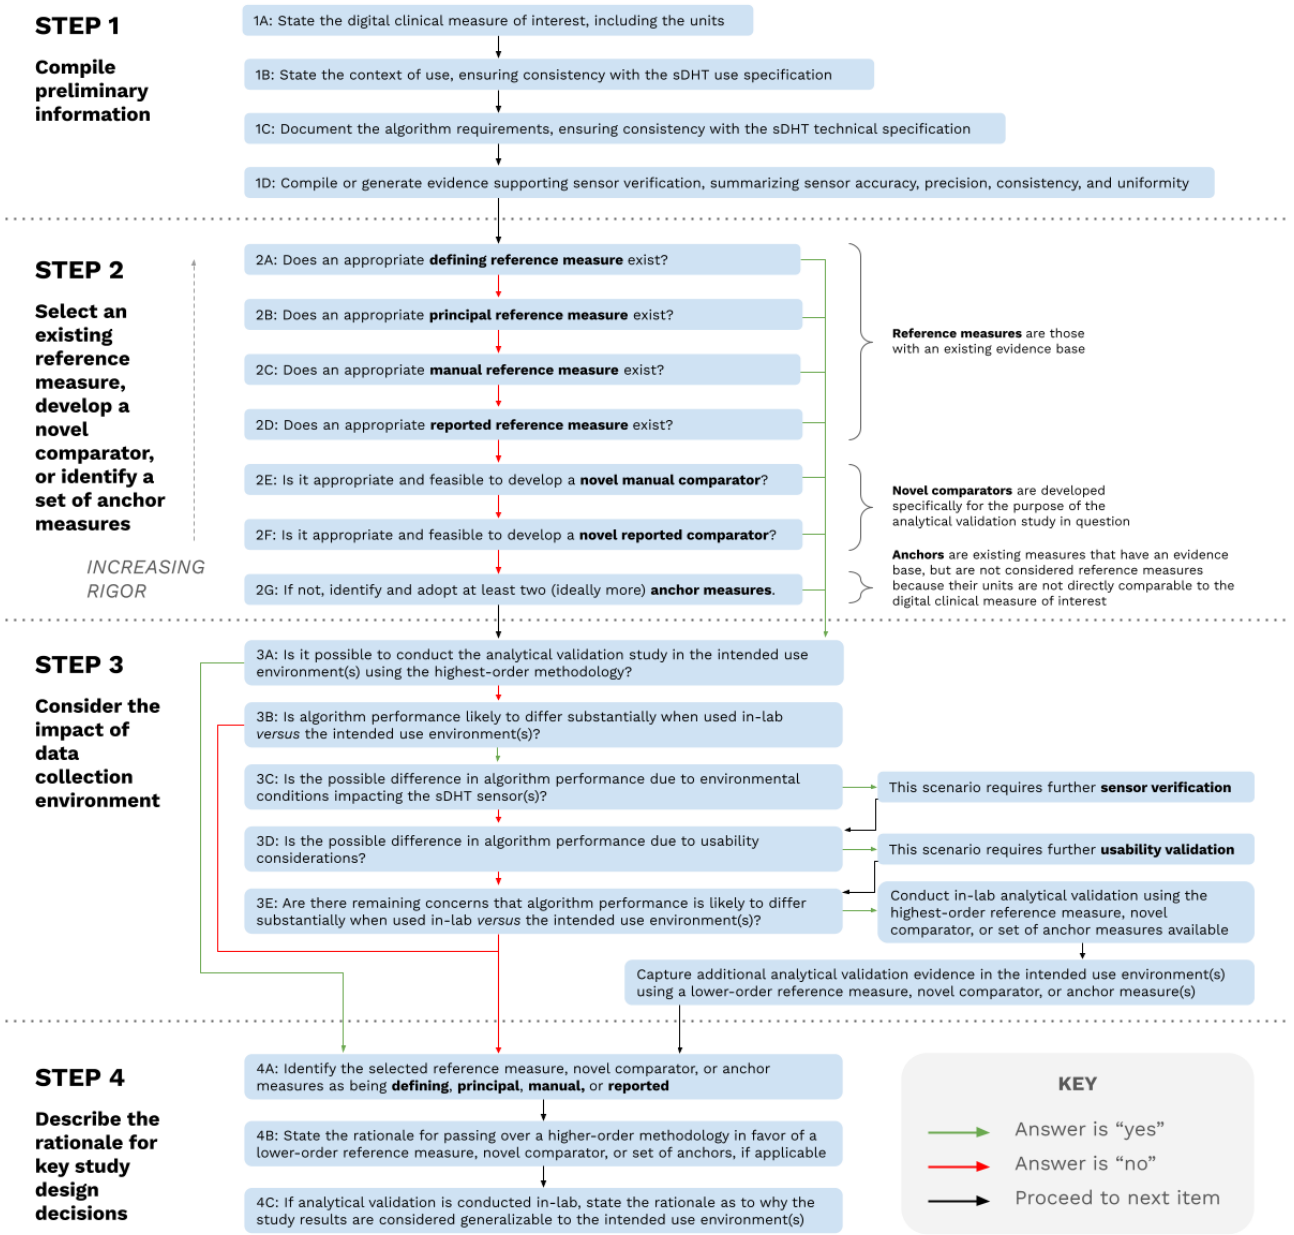
digital health technologies; analytical validation; digital medicine; reference measures; fit-for-purpose digital clinical measures

Introduction

The proliferation of sensor-based digital health technologies (sDHTs) in clinical research and health care delivery has been bolstered by the recent finalization of regulatory guidance supporting their use for remote data acquisitions in clinical investigations [1], qualification of the first sDHT-derived clinical trial endpoint by the European Medicines Agency [2], qualification of the first sDHT-derived medical device development tool by the US Food and Drug Administration (FDA) [3], and the expansion of reimbursement pathways for the use of digital clinical measures in remote patient monitoring [4-6]. For an sDHT to be used to support scientific and clinical decision-making, evaluators must conduct verification of the sensors, usability validation of the user interface (defined as all points of contact a user may have with the sDHT as a whole), analytical validation of the algorithms, and clinical validation of the measures of behavioral or physiological function generated by the sDHT in the proposed context of use. This evaluation process has been codified in the modular V3+ framework by the Digital Medicine Society (DiMe). Since the publication of V3 in 2020 [7] and its extension in 2024 [8], V3+ has become the international methodological standard for sDHT evaluation, having been adopted by dozens of organizations [9] and cited over 250 times [10], including by the European Medicines Agency [11] and FDA [12].

Analytical validation relies on the selection of an appropriate reference measure representing “truth,” against which to compare the output of the sDHT algorithm in the same or directly comparable units. This selection process can be challenging, given that the digital clinical measure of interest may relate to biological and physiological variables, symptoms

XSL•FO
RenderX



status, or functional status according to the Wilson and Cleary (1995) [13] conceptual model. In some cases, there may be multiple potential reference measures available, and in the case of a novel digital clinical measure, there will be no extant reference measure at all. We therefore recognize the need for an evidence-based framework to guide decision-making when identifying an appropriate reference measure during analytical validation. The original description of V3 emphasized that not all potential reference measures are of equal quality [7], and as such we believe that a hierarchical step-by-step approach should be adopted to prioritize those representing the highest level of scientific rigor.

We developed a preliminary version of a hierarchical framework to support selection of a reference measure for analytical validation and presented it to experts representing regulators, health technology assessment organizations, sDHT developers, clinicians, and clinical researchers during a workshop convened by the Digital Health Measurement Collaborative Community (DATAcc by DiMe) in November 2023 [14]. Our goal was to seek feedback to improve the framework and ensure uptake across the digital medicine community. Based on this feedback, we describe our hierarchical framework that closes a key gap in the science underpinning the analytical validation of sDHTs.

Description of the Hierarchical Framework

Our framework is designed to sequentially move an investigator or developer through a series of steps laid out in Figure 1 to ensure that the most rigorous reference measures applicable to their study objectives and proposed context of use are prioritized.

Figure 1. The hierarchical framework for selecting reference measures for analytical validation.

XSL•FO
RenderX

Step 1: Compile Preliminary Information

Step 1 guides the investigator to compile the preliminary information required to determine their analytical validation study objectives and guides subsequent steps. First (Step 1A), the digital clinical measure (a physiologic process or behavioral construct) is described, including the units. Next (Step 1B), the proposed context of use is clarified. The context of use fully and clearly describes the way the sDHT is to be used and the purpose of the use, including the intended populations of interest and the intended use environments. Although some sDHTs may be legally marketed medical devices with an indications for use statement compiled by the technology developer and endorsed by a regulatory body, here we are referring to the context of use proposed by the stakeholder undertaking the analytical validation study. Finally (Steps 1C-1D), the requirements and specifications of the sDHT algorithm are documented in detail, which should include any methods for dealing with missing data, alongside a summary of the verification evidence for each sensor that will feed data to the subject algorithm.

Step 2: Select an Existing Reference Measure, Develop a Novel Comparator, or Identify Multiple Anchor Measures

Step 2 of the framework classifies potential comparator methods hierarchically according to certain attributes that contribute to their scientific rigor (see Table 1). The first 4 categories represent existing reference measures, while the next 2 categories are required for scenarios in which a reference measure does not yet exist. We describe the latter as novel comparators, because their suitability as an established reference measure cannot be ascertained until they are developed and evaluated. The seventh and final category describes anchor measures, which may be adopted when it is not possible to develop a novel comparator. Unlike reference measures and novel comparators, anchor measures generate data in units that are not directly comparable to those of the digital clinical measure of interest, and therefore analysis is limited to examining associations.

Table 1. Hierarchical categorization of reference measures, novel comparators, and anchor measures for analytical validation.

Category	Definition	Attributes	Examples	Rationale for position in the hierarchy	Supporting documentation
Reference measures					
Defining	A defining reference measure emerges when a physiologic process or behavioral construct is dependent on the technology used to capture it to such an extent that it sets the medical definition for that process or construct [15]	Data capture is objective, meaning that it does not rely on human measurement, observation, or perception for acquisition. In some cases, however, human analysis or scoring may be required to generate the measure of interest. It is always possible to retain the source data	The medical definition of sleep staging refers to electrical activity of the brain (EEG), eyes (EOG), and muscles (EMG), as described by the American Academy of Sleep Medicine in the *Manual for the Scoring of Sleep and Associated Events* [16,17]. As such, polysomnography is considered the defining reference for measures of sleep staging, such as total sleep time	Defining and principal reference measures share the same attributes; however, defining references are considered superior as they will always have an associated standards document or equivalent	Standards or guidelines developed by a respected professional body describing the reference measure methodology
Principal	A principal reference measure directly and objectively measures the physiologic process or behavioral construct of interest	Data capture is objective, meaning that it does not rely on human measurement, observation, or perception for acquisition. In some cases, however, human analysis or scoring may be required to generate the measure of interest. It is always possible to retain the source data	Capnography is considered the defining reference measure for respiratory rate [18], while placement of a nasal pressure transducer, oronasal thermistry, and respiratory inductance plethysmography are considered principal reference measures, as each involves objective data acquisition and the ability to retain the source data	Principal reference measures are considered superior to manual reference measures because the objective method of data capture is not prone to observer bias. Further, the source data can be reanalyzed at will and rescored by multiple raters (where applicable), thereby promoting standardization and minimizing measurement variability	Descriptions of the reference measure from the peer-reviewed literature, with evidence of standardized implementation in many laboratories and centers. *Or* Standards or guidelines developed by a respected professional body describing the reference measure methodology (in cases where a defining reference measure already exists)
Manual	A manual reference measure relies on the measurement, observation, or perception of a physiological process or behavioral construct by a trained health care professional, with or without the use of equipment or technology	The measure of interest can be seen, heard, or felt; taste and smell have been relied on historically but are not routinely used in modern medicine. Although it may be possible to retain source data (such as a video that is then manually annotated), many manual reference measures are made in real time	Respiratory rate may be captured by auscultation or by visually assessing chest wall movement [19]	Manual reference measures are considered superior to reported reference measures because they are made by trained health care professionals which promotes standardization. In some cases it may also be possible to obtain manual measures from multiple raters, thereby reducing measurement variability	Descriptions of the reference measure from the peer-reviewed literature, with evidence of standardized implementation in many laboratories and centers. *Or* Standards or guidelines developed by a respected professional body describing the reference measure methodology (in cases where a defining reference measure already exists)

XSL•FO
RenderX

Category	Definition	Attributes	Examples	Rationale for position in the hierarchy	Supporting documentation
Reported	A patient-reported reference measure is based on a report that comes directly from a patient about the status of their health condition, while an observer-reported reference measure is based on a report from another individual based on observable signs, events, or behaviors related to a patient's health condition [20]	The identification or quantification of the measure is subjective in nature. Reports are made either in real time or retrospectively	The presence or absence, frequency, or duration of a particular experience or event is typically captured through diaries; for example, use of the Consensus Sleep Diary to capture time in bed [21]	Reported reference measures are considered inferior to manual reference measures because they typically involve a high degree of subjectivity or interpretation, and each measure can be generated only once per timepoint	Peer-reviewed evidence of psychometric performance of the instrument used for data capture
Novel comparators					
Manual	If the digital clinical measure of interest is based on a characteristic that can be observed or perceived by a trained health care professional, it may be possible to develop a novel manual comparator	A novel manual comparator shares the attributes of a manual reference measure described earlier	Manual annotation of a video captured overnight to identify measures of nocturnal scratch [22,23]	See rationale for manual reference measures described earlier	Study protocol, including all data acquisition, data processing, and scoring or annotation methods, developed *a priori*. We recommend collaborating with patient representatives when developing a definition for the characteristic of interest
Reported	If the digital clinical measure cannot be observed or perceived by a trained health care professional and is instead best captured by a report from the patient themselves or by an observer, it may be possible to develop a novel reported comparator	A novel reported comparator shares the attributes of a reported reference measure described earlier	Self-report of the time intervals for daily activities in a diary developed for the purpose of analytical validation [24]	See rationale for reported reference measures described earlier	Peer-reviewed publication, study report, white paper containing evidence supporting face validity. As described earlier, we recommend collaborating with patient representatives when developing the novel reported comparator
Anchor measures					

XSL•FO
RenderX

Category	Definition	Attributes	Examples	Rationale for position in the hierarchy	Supporting documentation
Anchors	An anchor measure is any interpretable measure of a physiologic process or behavioral construct in units that are not directly comparable to the digital clinical measure of interest. Units considered directly comparable are either identical or able to be translated for the purposes of comparison, such as via calibration	Anchor measures may possess any of the attributes listed earlier for defining or principal, manual, or reported reference measures	MDS-UPDRS Motor Assessment Item 3.15 involves a trained health care professional evaluating Parkinsonian postural tremor of the hands by visually determining tremor amplitude, returning a score of 0-4 [25].This score is not directly comparable to a digital clinical measure of tremor amplitude in units of acceleration; as such, it should be used alongside at least one more anchor measure of tremor severity, such as the Patient-Reported Outcomes in Parkinson's Disease rating scale [26]. Readers should note that in this particular example, a reference measure (3D motion capture) already exists	Anchor measures are not directly comparable to the digital clinical measure of interest, and therefore analysis is limited to examining associations. Unlike reference measures and novel comparators, anchors are not suitable for analytical validation in isolation; instead, multiple anchors should be identified in order to strengthen the assertion that the algorithm measures what it purports to measure	Supporting documents may be in the form of anything listed earlier for defining or principal, manual, or reported reference measures

The highest position of the hierarchy is assigned to *defining* reference measures (Step 2A), which are objective measures that emerge when the medical definition of a clinical measure is dependent on the technology used to capture it [15]. These measures do not rely on human observation or perception for data capture, although in some cases human analysis or scoring may be required to generate the measure of interest. Defining references are those that are widely accepted, endorsed by at least one acclaimed professional body, and described within a standards document or equivalent. For example, the American Academy of Sleep Medicine describes polysomnography (the measurement of brain, eye, and muscle activity through electroencephalography, electrooculography, and electromyography, respectively) as the defining method for capturing sleep staging data [16,17]. Similarly, the International Organization for Standardization (ISO) identifies CO-oximetry, based on light absorption of arterial blood samples typically obtained during hypoxia challenge, as the defining method for measuring blood oxygen saturation [27].

The next highest level of rigor is assigned to *principal* reference measures (Step 2B), which share the attributes of defining reference measures but typically do not have a dedicated standards document; instead, there are in-depth descriptions of the methodology in the peer-reviewed literature along with evidence of standardized implementation in many laboratories and centers. In some cases, a reference measure that does have an associated standards document may be considered a principal reference measure because a superior defining reference measure also exists. Examples of the latter scenario include transmissive and reflectance pulse oximetry; although data capture is objective and the methodology is referred to in both ISO 80601-2-61:2017 and regulatory guidance [27,28], these methods are considered inferior to CO-oximetry (the defining reference measure), because they are not capable of distinguishing functional and nonfunctional hemoglobin [29]. As this example illustrates, there may be more than one principal reference measure available to choose from—unlike defining reference measures, of which there can only be one—each of which may perform differently depending on the context of use.

Next, *manual* reference measures (Step 2C) rely on observation or perception by a trained health care professional in the absence of a source of objectively acquired data. Manual reference measures may or may not be aided by equipment or technology; for instance, respiratory rate can be measured manually through visual inspection of breaths or through auditory interpretation of auscultation using a stethoscope.

Next, *reported* reference measures (Step 2D) are based on reports that come directly from a patient (study participant) about the status of their health or a report from a lay observer such as a parent or care partner, using data capture instruments supported by appropriate psychometric evaluation. We have based our definition of reported reference measures on the BEST resource definitions of patient- and observer-reported outcomes [20]; however, it is important to note that many patient-reported outcomes and observer-reported outcomes are generated using

XSL•FO
RenderX

questionnaires that are not suitable as reference measures because they do not adopt units that are directly comparable to those of the digital clinical measure of interest. For example, sDHT-derived nocturnal scratch in units of events/hour cannot be directly compared against the Patient-Oriented Eczema Measure, which generates a score of 0-28 [30]; instead, investigators have relied on annotated videos [22]. Reported reference measures are therefore limited to reports of the presence or absence, frequency, or duration of a particular experience or event, typically captured using diaries supported by appropriate psychometric evaluation.

If no suitable reference measures exist, the investigator should consider developing a novel comparator, which should be completed and documented before beginning analytical validation. When developing a *novel manual comparator* (Step 2E), which shares the attributes of a manual reference measure, the investigator should develop a protocol for capturing and analyzing the comparator measure *a priori*, using existing technology where applicable. If it is not possible to create a novel manual comparator, the investigator should consider the development of a *novel reported comparator* (Step 2F), which shares the attributes of a reported reference measure and should be supported by evidence of face validity (at minimum). We recommend working with patient representatives when developing novel manual or reported comparators.

If it is not possible to develop a novel comparator, the only remaining option is to adopt *anchor measures* (Step 2G), which are defined as any interpretable measures of a physiologic process or behavioral construct in units that are not directly comparable to the digital clinical measure of interest. This broad definition means that an anchor measure may share attributes with defining, principal, manual, or reported reference measures. Because the data generated by an anchor measure cannot be directly compared to the digital clinical measure, it is critical to adopt multiple anchors in order to strengthen the assertion that the algorithm measures what it purports to measure. The use of multiple anchor measures for analytical validation purposes aligns with the concept of an anchor variable described by the FDA in their Patient-Focused Drug Development guidance for identifying meaningful score differences of clinical outcome assessments [31].

Step 3: Consider the Impact of the Data Collection Environment

Step 3 of the framework guides the investigator through a series of questions regarding the impact of the data collection environment. First (Step 3A), the investigator should determine whether it is possible to conduct analytical validation in the intended use environments using the highest-order reference measure, novel comparator, or anchor measures available. If so, they should plan to do so and proceed to Step 4.

If the highest-order reference measure, novel comparator, or anchor measures require the analytical validation study to be conducted in the laboratory, the investigator should determine whether the performance of the algorithm is likely to differ substantially when the sDHT is implemented in the intended use environments (Step 3B). If this is not the case and the investigator determines that algorithm performance assessed in the laboratory is generalizable to the intended use environment, they should complete the analytical validation study in the laboratory and proceed to Step 4.

Alternatively, if the investigator is concerned with generalizing analytical validation results from the laboratory setting to the intended use environments, they should first determine whether the possible difference in algorithm performance is due to environmental conditions impacting the sDHT sensors (Step 3C). If so, this scenario requires additional verification data and is not a reason to perform analytical validation in the intended use environment. Next, the investigator should determine whether the possible difference in algorithm performance is due to usability considerations (Step 3D); for example, they may be concerned that participants will place the sDHT incorrectly when using it at home unsupervised, leading to excessive signal artifact. If so, this scenario requires usability validation, and is similarly not a reason to perform analytical validation in the home environment.

Finally, if the investigator determines that the possible difference in algorithm performance is due to environmental characteristics impacting the relationship between algorithm input (sensor data) and output (the digital clinical measures of interest) (Step 3D), the investigator should proceed with in-laboratory analytical validation using the highest-order reference measure, novel comparator, or anchor measures, and plan to capture additional analytical validation evidence in the intended use environments using a lower order alternative. In other words, the investigator should first determine algorithm performance using the most rigorous methodology available and perform supplementary testing to support generalizability to the intended use environments, rather than relying solely on the lower order methodology. It is acceptable for supplementary evidence of this nature to rely on a single anchor measure, if applicable, although multiple anchors are preferable.

Step 4: Describe the Rationale for Key Study Design Decisions

The final step of the framework prompts the investigator to describe their rationale for key study design decisions by identifying their selected reference measure, novel comparator, or anchor measures according to the categories described in Step 2 of this framework (Step 4A); provide a rationale for passing over a higher order methodology in favor of their selected methodology, if applicable (Step 4B); and, if the analytical validation study is conducted in the laboratory, provide a rationale as to the generalizability of their results to the intended use environments. Step 4 is particularly important, as it encourages transparency and allows evaluators, peer-reviewers, regulators, and payers to understand the quality of the resulting analytical validation data and the extent to which it may be relied upon for decision-making.

Discussion

The Scientific Rigor of Reference Measures Is Driven by Attributes That Reduce Measurement Variability

The categories of reference measures in Step 2 are laid out in order of superiority to signify that the highest-ranked reference

XSL•FO
RenderX

measure that is available should be used whenever possible, as according to the definitions in Table 1, it is the best method for capturing the measure of interest. Our goal was to rank the categories according to attributes that contribute to reduced measurement variability.

Both *defining* and *principal* reference measures rely on objective methods of data acquisition, and the ability to retain source data means that these reference measures can be re-analyzed or re-scored at will, including by multiple health care professionals when applicable in order to create an average or consensus measure, thereby reducing measurement variability [32]. The next category, *manual* reference measures, involves human perception and is therefore prone to observer bias, but likely not to the extent of *reported* reference measures, as these typically involve a high degree of subjectivity or interpretation, and each measure can be generated only once per timepoint. Although we champion the importance of the voice of the patient during the selection of measures that matter to scientific and clinical decision-making [33-36], it is expected that the processes of usability and clinical validation will sufficiently assess these important concerns, which are out of scope for analytical validation.

We have positioned anchor measures as the lowest-order methodology, even if an anchor under consideration is well-established and widely used as illustrated by the example in Table 1 describing a comparison of sDHT-derived postural tremor (in units of acceleration) against MDS-UPDRS Motor Assessment Item 3.15 (in units of a 0-4 score). If this scale were to be adopted as the sole anchor measure, the developer would be motivated to create an sDHT algorithm that aligns as closely as possible with the clinician's visual assessment of tremor amplitude, thereby perpetuating the known limitations of this methodology. Thus, it is essential that multiple anchors be adopted for the purpose of evaluating a novel digital clinical measure, although under some circumstances it may be sufficient to adopt a single anchor if the intent is to generate supplementary evidence to support the generalizability of more robust analytical validation results from the laboratory to the intended use environments. Readers should note that comparison of a digital clinical measure against anchor measures is not a form of analytical validation given the noncomparable units but is a suitable approach to addressing this component of V3+ when reference measures do not exist and it is not possible or feasible to develop a novel comparator.

Circumstances Under Which a Lower Ranked Reference Measure May Be Appropriate for Analytical Validation of an sDHT

Our hierarchical framework will enable investigators conducting analytical validation to make the most rigorous claims associated with their products and position them to deliver the greatest value in support of scientific and clinical decision-making. Importantly, however, the hierarchical nature of Step 2 is not meant to be rigid. In some circumstances, there may be reasons for passing over a reference measure of the highest rigor to select a reference measure or novel comparator that is ranked lower. However, we posit that the only acceptable reasons for doing so are when (1) the selection of the higher ranked reference measure creates an unacceptable risk-benefit ratio, thereby compromising the ethics of the study or (2) the higher ranked reference measure is not recommended and applicable to the context of use, which includes the patient population.

Consider, for example, the analytical validation of an sDHT developed to capture blood pressure (BP). The *defining* reference measure involves placement of an arterial catheter [37], which is invasive and in some circumstances may be considered unnecessarily risky to participants. Because automated sphygmomanometry (a *principal* reference measure) is such a common and well-validated technology, it may be appropriate to use in place of arterial BP in some cases. Automatic sphygmomanometers, however, may not be suitable for use in some individuals, such as those with arrhythmias [38], in which case traditional sphygmomanometry (a *manual* reference measure) may be the most appropriate methodology. An investigator may select any reference measure or novel comparator of their choosing, with the understanding that adoption of a lower order methodology will limit the rigor of their analytical validation study.

It is rarely a requirement to select a reference measure that allows analytical validation to be conducted in remote settings, such as at home, particularly if this choice would result in the use of a reference measure that is lower in the hierarchy. However, when analytical validation is conducted in the laboratory, it is important to determine whether the performance of the algorithm is likely to differ substantially when the sDHT is implemented in its intended use environments as described in Step 3.

In summary, it is up to the investigator or developer to justify their choice by carefully considering the scientific or clinical decisions that the sDHT-derived measure is intended to support and the rigor of the analytical validation claims they wish to make (Step 4). Factors such as cost, feasibility, patient or participant preference, and resource availability are rarely sufficient reasons to select a lower order reference measure or novel comparator but might be relevant to investigators seeking to decide between reference measures within a single category.

The Quality of the Reference Measure or Novel Comparator Affects What Claims Can Be Made About the Performance of the sDHT

A key value driver of sDHTs is their ability to capture digital clinical measures that provide information that was previously difficult or impossible to capture, such as the measurement of nocturnal scratch in individuals with atopic dermatitis [39]. In such cases, available reference measures for analytical validation are likely to be ranked lower per the framework if they are available at all. The development and use of a novel comparator does not preclude the substantiation of rigorous claims associated with these measures but does require careful development of the novel comparator *a priori*. Over time, a novel comparator may "up-level" to be considered a reference measure as evidence to support its use builds over time. Manual annotation of video to identify nocturnal scratch events, even if performed by multiple trained health care professionals, can currently be considered a novel manual comparator despite

XSL•FO
RenderX

being adopted in more than one study [22,23]. Eventually, assuming this line of work continues, the field may coalesce around a video scoring protocol that allows for a high level of interrater agreement, at which point the method may be considered a manual reference measure.

Applicability of the Framework to All sDHT Regulatory Categories and All Measure Categories

As described in regulatory guidance and the literature [1,40], sDHTs used for remote data acquisition in clinical investigations may be regulated medical devices, low-risk products designed to promote a healthy lifestyle and typically marketed towards consumers (referred to by the FDA as "general wellness products" [41]), or products developed specifically for research data capture. Although the term "claims" may be used to refer to statements that fall under regulatory purview, such as medical device labeling claims, throughout this document we use "claims" to refer to any statement or conclusion made regarding the performance of an sDHT. The principles of analytical validation apply in all cases, and therefore the process of selecting a reference measure or novel comparator does not differ according to the regulatory status of the sDHT.

Similarly, the principles of analytical validation do not differ according to whether the digital clinical measure of interest is intended for use in clinical care or clinical research. If the latter, the categorization of the measure as a digital biomarker or an electronic clinical outcome assessment also has no bearing on the applicability of our framework.

Future Directions

During development of this framework, we considered the suitability of a scoring method that would allow an investigator to rank reference measures quantitatively, rather than qualitatively according to the categories described in Step 2. Ultimately, we decided against this approach due to concerns that a scoring system would be unnecessarily rigid and may quickly become outdated as technology evolves. As the field matures, however, a quantitative scoring system may be warranted.

The hierarchical framework presented here will help investigators support the most rigorous claims for both novel and established digital clinical measures and is intended to drive the capture of the greatest value of sDHTs, whether from their use in clinical trials [42] or patient care [43]. As the selection of reference measures or development of novel comparators for the analytical validation of sDHT algorithms becomes increasingly rigorous through the use of this framework, it is important to highlight a key remaining gap in the science of analytical validation: the selection of a suitable statistical technique for evaluating an algorithm's performance against the appropriate reference measure. Despite this remaining gap, the state of the science supporting the evaluation of sDHTs as fit-for-purpose is strong. This framework offers a pathway to bolster the impact of the broad adoption of best practices, such as the Measures that Matter [44] and V3+ frameworks [7,8], alongside advances in regulatory policies and decisions [1,2], placing the benefits of digital clinical measurement firmly within the reach of both researchers and clinicians seeking to improve the health-related quality of life of their patients. Ultimately, the value of our proposed framework will be determined according to its impact on improving the rigor of sDHT analytical validation science.

Abstract

A number of seismic shifts are expected to reshape the future of medicine. The global population is rapidly aging, significantly impacting the global disease burden. Medicine is undergoing a paradigm shift, defining and diagnosing diseases at earlier stages and shifting the health care focus from treating diseases to preventing them. The application and purview of digital medicine are expected to broaden significantly. Furthermore, the COVID-19 pandemic has further accelerated the shift toward predictive, preventive, personalized, and participatory (P4) medicine, and has identified health care accessibility, affordability, and patient empowerment as core values in the future digital health era. This “left shift” toward preventive care is anticipated to redefine health care, emphasizing health promotion over disease treatment. In the future, the traditional triad of preventive medicine—primary, secondary, and tertiary prevention—will be realized with technologies such as genomics, artificial intelligence, bioengineering and wearable devices, and telemedicine. Breast cancer and diabetes serve as case studies to demonstrate how these technologies such as personalized risk assessment, artificial intelligence–assisted and app-based technologies, have been developed and commercialized to provide personalized preventive care, identifying those at a higher risk and providing instructions and interventions for healthier lifestyles and improved quality of life. Overall, preventive medicine and the use of advanced technology will hold great potential for improving health care outcomes in the future.

(J Med Internet Res 2025;27:e59165) doi:10.2196/59165

KEYWORDS

preventive medicine; personalized prevention; digital health technology; digital health; artificial intelligence; wearable devices; telemedicine

Introduction

As populations age and chronic diseases become more prevalent, societies will face challenges in providing equitable health care. Currently, a shift in the medical paradigm is ongoing, with more focus on keeping people healthier for longer and preventing diseases rather than just curing them. This approach acknowledges the importance of maintaining, improving, and promoting health throughout the natural progression of diseases and the increasing importance of preventive medicine.

In this new paradigm, cutting-edge technologies such as big data, informatics, and medical digitalization will allow for personalized and precise health care recommendations based on a patient’s clinical, biological, and genomic information. In addition, the availability of health-related information and the use of wearable devices have further encouraged individuals to take proactive measures in preventing health problems. The COVID-19 pandemic has also highlighted the importance of telemedicine in remote patient monitoring and providing more equitable health care.

XSL•FO
RenderX

Overall, preventive medicine and the use of advanced technology will hold great potential for improving health care outcomes in the future. However, the implementation of such technologies presents challenges such as addressing disparities in technology access, managing overuse and overreliance on digital tools, safeguarding patient data, and ensuring clinical validity, which call for further research in this area.

This review aims to elucidate the role of preventive medicine through the integration of digital health technologies and provide insights for the changing landscape of preventive health care in the digital era. By examining current trends, technological advancements, and case studies, we will explore how these innovations can lead to a more proactive, personalized, and patient-centered approach to health promotion and disease prevention.

Future Trend and Emerging New Technologies

Rise in Older Adult Population

The global population is aging, with people worldwide living longer lives. Nowadays, most individuals are expected to reach their 60s and beyond, a trend that is prevalent in every country. By the year 2030, approximately 1 out of every 6 people around the world is expected to be 60 years or older. The number of individuals in this age group is projected to increase from 1 billion in 2020 to 1.4 billion by 2030, and to double to 2.1 billion by 2050. Moreover, the number of individuals aged 80 years or older is anticipated to triple, reaching 426 million by 2050. Some countries such as Korea and Japan have been labeled as "super-aged societies" due to their pronounced aging trend, with 30% or more of their population being older than 65 years by 2050 [1].

This change in population composition is expected to have far-reaching health implications. The most striking is the increased burden of chronic diseases [2]. One study has projected that by 2035, 36%, and by 2050, 48% of adults older than 50 years will have at least 1 chronic disease [3]. As the global population ages and the burden of chronic diseases rises, medical costs have also increased worldwide due to longer care duration and health-related productivity loss. This has led to an annual growth of US $4 in the average Organization for Economic Cooperation and Development health expenditure per capita over the past decade [4]. In the case of the United States, 1 study has estimated that approximately 20% of health care spending growth will be attributable to aging by 2025 [5].

Shift From Cure to Prevention

There is currently a general shift of health care away from merely providing cure to that of prevention, as the definition of health transitions from "the absence of disease" to "realizing the full potential of one's capacity." The paradigm change in medicine has been attributed to the humanization movement in medicine, which has contributed to changes in medical education, patient care, and the management of several medical conditions [6]. Nowadays, there is a steady transition from "cure-seeking medical care" to "cure and support-seeking medical care" [7], which has necessitated the development of new models of conceptualizing behavior change, emphasizing assessment of multiple risks, and treating the whole patient to optimize health outcomes [8,9].

The recent change in medical paradigms has impacted various aspects of health toward a more patient-centered approach, emphasizing patient engagement, health maintenance, and the restoration of daily activity. Specifically, where the health care of the past was episodic, focused on service providers and individual patients at independent and isolated institutions, health care is expected to increasingly shift toward a continuous care model. In this model, the general public and the community as a whole come to prevent diseases and maintain their health, and, if the need for treatment or hospitalization arises, are closely followed through after their discharge [10]. The patients are also expected to be better informed, with health care workers and patients sharing a more equal footing (Table 1) [10,11].

Table 1. Current and future health care.

Categories	Current	Future
Goal	• Disease treatment	• Health promotion
Continuity of care	• Episodic cure • Fragmented care	• Continuing care • Comprehensive care
Focus of care	• Focus on service provider • Individual approach	• Focus on well-informed patient • Team-based approach
Care setting	• Hospital-centered care	• Patient-/home-oriented care
Payment system	• Pay for procedures	• Pay for value

Usage of Digital Health Technology

The convergence of life sciences and engineering disciplines has ushered in an era of medical technology integration, where genomics, artificial intelligence (AI), bioengineering, wearable devices, and telemedicine are used for various medical applications (Table 2). Advancements in technology have greatly impacted the medical field, with the development of bionic eye devices or 3D bioprinting technology used in various medical fields or wearable devices such as Google Glass have been used in surgical settings, offering benefits such as improved surgical

XSL•FO
RenderX

education, training, consultation, patient monitoring, and audiovisual recording, among others [12].

Table 2. New technologies used for future medicine.

Domain	Description	Application
Genomics	• Study of an individual's entire genome. • Revealing inherited traits and susceptibility to diseases.	• Whole-genome sequencing for personalized medicine. • Identification of genetic markers associated with diseases.
Artificial intelligence	• Mimic human intelligence based on algorithms and computational models. • Application in big data analysis, image recognition, and problem-solving.	• Machine and deep learning algorithms for medical image analysis. • Predictive models for disease diagnosis and prognosis.
Biomedical devices	• Integration of engineering principles with biological systems. • Design and development of devices to enhance medical treatments.	• Artificial organs and tissue engineering for transplantation. • Biomedical implants for drug delivery or physiological monitoring.
Wearable devices	• Collect real-time data related to health and activities. • Enhance continuous monitoring and personalized health care.	• Smartwatches monitoring sleep, ECG[a], and stress patterns. • Medical wearables for continuous glucose monitoring or ECG recording.
Telemedicine	• Delivery of health care services remotely. • Comprises video consultations, remote monitoring, and virtual care.	• Video calls for remote doctor consultations. • Remote patient monitoring for disease management.

[a]ECG: electrocardiograms.

The expansion and use of digital health is evident in daily life through mobile health applications for wellness, nutrition, medication adherence, fitness tracking, and access to personal health information. Health information technology includes electronic medical record systems and cloud storage, which improve the accessibility, sharing, and accuracy of patient data. Electronic prescriptions and communication between doctors and patients are also improved. Wearable devices, wireless sensors, and diagnostic products play a role in monitoring health and diagnostics, such as continuous blood pressure, glucose, or sleep patterns monitoring.

Hence, a key goal of digital technology in health care is digital therapeutics, which uses evidence-based therapeutic interventions software integrated with mobile devices, apps, sensors, and virtual reality to prevent, manage, and treat diseases or disorders. These can be used alone or in combination with mechanical devices, pharmacological treatments, or in-person therapy, having a positive impact because they are designed to cater to the specific needs of patients. Therefore, the customization of health services through digital technology is essential for personalized health care, including patient-reported outcomes, predictive analytics, and clinical decision support.

Advancements in internet of things sensors and health tech wearables have made it easier to collect and transmit health data. The decreasing cost of internet of things sensors, along with the improved capabilities of consumer-grade devices such as the Apple Watch, has made it more affordable to equip individuals with tools to monitor their health. For example, the Apple Watch's electrocardiogram functionality can detect irregular heartbeats and even send notifications for conditions such as atrial fibrillation. Other wearable devices, such as smart continuous glucose monitors and connected inhalers, offer benefits such as insulin-level monitoring and medication adherence. In addition, researchers are exploring the use of smartphones for "digital phenotyping" to identify individuals at risk of mental health problems [13,14]. With increased data access and sharing, these devices have the potential to provide highly personalized care based on individual patient profiles.

As digital technology continues to advance, personalized prevention and patient engagement in health monitoring and treatment management will become more feasible. Telemedicine and telehealth have become increasingly popular, especially for non–face-to-face virtual visits, remote patient monitoring, and remote care programs, which have been particularly relevant during the COVID-19 pandemic. The future of health care is heavily reliant on digital health, particularly for preventive medicine, as health information becomes more accessible to everyone and patient health empowerment increases.

Changes in Health Care After COVID-19

Telemedicine was previously used in limited cases where access to in-person health care was difficult. However, the COVID-19 pandemic highlighted its importance in addressing health care labor shortages, reducing the risk of new infections in clinics, and providing care to vulnerable populations. As a result, telemedicine usage significantly increased during the pandemic and has a more widely discussed and used tool in health care [15]. This accelerated adoption of telemedicine now includes various medical specialties, including preventive medicine.

The future of health care in the post–COVID-19 era relies on 3 key aspects: accessibility, affordability, and empowerment

XSL•FO
RenderX

(Table 3) [16]. Telemedicine has greatly improved accessibility by bringing care and remote monitoring closer to patients, regardless of their location. It has also facilitated rapid diagnoses and disease treatments, reduced costs, and prepared health care systems for future pandemic situations. For example, a report on the adoption of telehealth in Australia during the COVID-19 pandemic noted that for every in-person consultation replaced with telemedicine, up to 2.5 days of travel time and US $215 in societal productivity were saved [17]. Similar findings were echoed in the United States [18] and Canada [19].

Table 3. Key aspects of the future of health care after COVID-19.

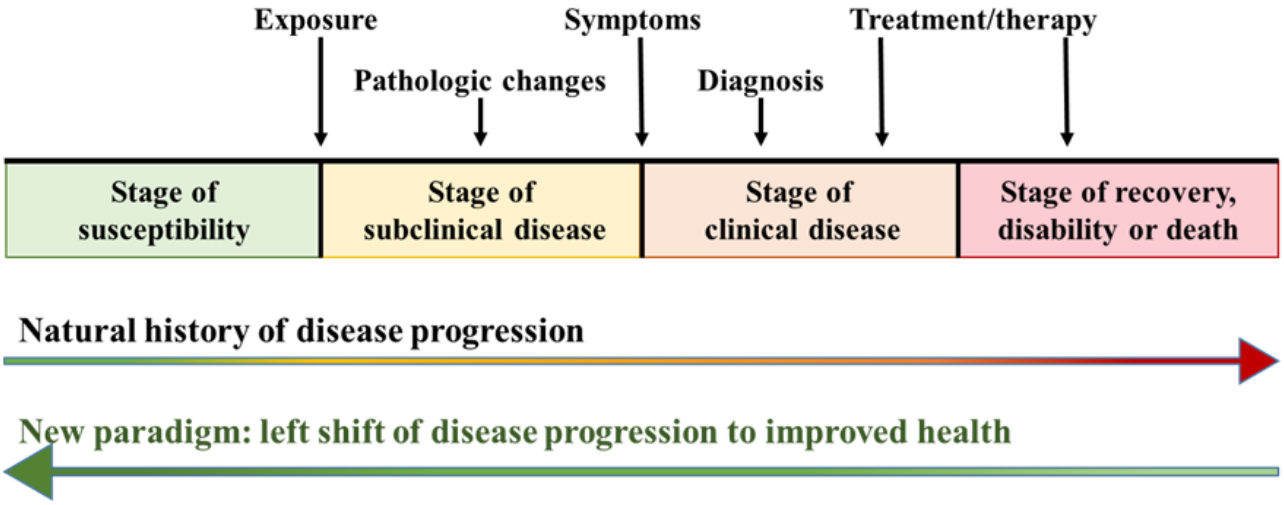
Key aspects and implementations	Effects
Accessibility	
Telemedicine	• Bring care closer to patients • Remote monitoring
Point-of-care diagnostics	• Rapid diagnosis and treatment • Reduced cost • Quick response for future pandemic
Affordability	
Cost-effective medical devices	• Innovative, low cost, and easy-to-use portable devices
Self-health management	• Empowered health seekers • Lower the cost by avoiding hospitalization
Empowerment	
Personalized health records	• Support mass screening and epidemiological programs • Automatization for an efficient health care ecosystem
Patient engagement and education	• Health awareness with education • Disease awareness with wearables

As medical technology continues to advance, more affordable and innovative devices are becoming available in the market. There is a growing emphasis on developing portable medical devices that are cost-effective, easy to use, and accessible to everyone. The popularity of digital technology and smart wearables is steadily increasing, as they complement clinical care and provide valuable health data, such as vital signs, sleep patterns, and physical activity levels. These data can help predict disease progression and enable a shift toward preventive health care, empowering patients to actively manage their own health and reduce health care costs and limit health facilities use.

Furthermore, empowering patients in health care in the future involves leveraging electronic health records and integrated medical and digital devices to support mass screening and epidemiological programs. It also involves automating supply chains, where blockchain technology may be a vital asset, to improve efficiency across the health care ecosystem. Patient education and health-disease awareness are crucial components of the health care ecosystem and can be facilitated through web-based health content platforms and the use of smart wearables.

The advancement of medical technology, coupled with the impact of telemedicine following the COVID-19 pandemic and the shift in the medical paradigm, is set to transform the health care industry and the future of medicine. This transformation will result in a shift toward predictive, preventive, personalized, and participatory (P4) medicine, with a focus on individualized patient profiling and tailored prevention strategies. This new paradigm emphasizes patient-centered care, aims to improve overall health outcomes, and will highlight even more the importance of preventive medicine in the future of health care [20,21].

Left Shift of the Natural Progression of Disease



The field of medicine has evolved since the age of epidemics from the age of complex diseases to the current age of postgenomics [22]. In the age of epidemics, the control of pathogens was the main treatment approach highlighting the importance of public hygiene. In the age of complex diseases, disease was based on multifactorial living conditions and lifestyle factors and care was empirically derived from trial and error experience of prior practice or observations. During this era, the distinction between treatment and prevention in the field of medicine became clearer. The growth of genetics research and completion of the Human Genome Project have introduced the concept of genetic susceptibility and gene-environment interaction to the age of postgenomics. In this era, the development of personalized medicine accelerated and the definition of health and disease began to shift. The new disease paradigm is a shift in the natural progression from treatment to health promotion and prevention.

A few decades ago, the main goal of medical practitioners was to accurately diagnose and treat diseases. The focus was on the clinical stage, with the aim of finding the best treatment, ensuring quick recovery, and preventing disease recurrence. However, the medical care paradigm has since shifted to the left (Figure 1) to focus on the stage before clinical symptoms appear, where there are subclinical manifestations and

XSL•FO
RenderX

pathological changes. Medical care at this stage, that is, early detection, involves identifying pathological or structural changes that occur before symptoms manifest over the progression of the natural history of the disease. The discovery and integration of biomarkers have played a significant role in this approach. However, even at an earlier stage, some people are more likely than others to be affected by carcinogens or substances; therefore, understanding individual variations in susceptibility to risk factors has become crucial for disease prevention.

Figure 1. Left shift of natural history of disease progression.

This shift in the paradigm of medical care is also reflected in our understanding and diagnosis of diseases. For instance, autism spectrum disorder (ASD), one of the most common neurodevelopmental disorders, has been diagnosed and named differently in previous versions of the *DSM* (*Diagnostic and Statistical Manual of Mental Disorders*) published by the American Psychiatric Association [23]. In earlier *DSM* versions, modern-day ASD was considered schizophrenia occurring before puberty. From *DSM-III* (*Diagnostic and Statistical Manual of Mental Disorders* [Third Edition]) to *DSM-IV-TR* (*Diagnostic and Statistical Manual of Mental Disorders* [Fourth Edition, Text Revision]), autism was distinguished from schizophrenia with the introduction of pervasive developmental disorder under which specific diagnoses expanded from 3 to 5. Eventually, the term "spectrum" and clinical characteristic specifiers were adopted to capture the wide range of symptoms and severity in ASD (*DSM-V* [*Diagnostic and Statistical Manual of Mental Disorders* {Fifth Edition}]). This highlights the importance of a diagnostic classification that can tailor interventions and care to individual needs [24]. In the future, we will see diseases on a continuous scale, and treatment will be personalized to each case. The focus of future medicine will be on providing continuous care rather than a one-time single type of care.

Overall, the prevailing paradigm for natural disease progression is steadily shifting toward health promotion and prevention, making preventive medicine, early diagnosis, and early detection, strategies that aim to reduce the burden of mortality and morbidity from diseases, essential. The value of disease prevention has been highlighted by evidence that suggests that prevention is more valuable than treatment. In the future, the paradigm of medical care is expected to increasingly shift from the stage of treating illness, disability, or death toward promoting overall health and disease prevention.

Future of Preventive Medicine

Current and Future Preventive Medicine

The American Board of Preventive Medicine defines preventive medicine as "the specialty of medical practice that focuses on the health of individuals, communities, and defined populations" and cites protection, promotion, and maintenance of health and well-being, and prevention of disease, disability, and death as some of the field's core goals. In practice, these goals are achieved through 3 distinct types of prevention. Primary prevention aims to prevent the development of diseases in healthy individuals. It includes measures such as smoking cessation programs, vaccinations, and reducing alcohol consumption. Secondary prevention focuses on early detection of diseases to minimize their severity and complications. Examples include cancer-screening programs, tumor biomarkers, and diet or exercise programs to prevent further cardiovascular disease complications. Tertiary prevention aims to reduce the impact of existing diseases or ongoing injuries. It involves prompt treatment and additional approaches such as rehabilitation to prevent complications and minimize lasting effects.

While the conventional prevention triad's approach is still valid, preventive medicine needs technological updates to enable personalized prevention strategies and better disease management, focusing on individual and public health needs. In fact, technology plays a crucial role in the current focus on disease prevention (Table 4). For one, the future of primary prevention care lies in the implementation of disease risk prediction services that use genomic information, such as polygenetic risk scores for cancer risk. 23andMe, for one, provides genetic health screening, offering "Health Predisposition Reports" that screen for genetic risk factors for diabetes; breast, ovarian, prostate, and pancreatic cancer; and

XSL•FO
RenderX

chronic kidney disease, among many others, allowing formation of informed health plans and healthy life choices.

Personalized coaching services to reduce weight, control diet, or shape individual training programs will also play a significant role. Digital health care can overcome the limitations of traditional health care services by creating tailored services that are easy, affordable, efficient, and shaped according to individual needs. KakaoHealthcare Pasta, for example, provides app-based diet management service specialized in diabetes prevention, analyzing which foods most influence blood glucose levels and providing dietary suggestions accordingly. The current and future use of devices will also allow continuous monitoring of body vitals and biomarkers such as glucose, heart rate, and blood pressure. Collected information can be used to keep track of the user's health trend, healthy and unhealthy activities, and provide guides to lead a healthy lifestyle. Noom is one such a personalized health record app that records diet, physical activity, and mood, and provides healthier recipes, encourages and reminds its users to exercise, and offers psychological tools for lasting health improvement.

Table 4. Classical and digital-based preventive medicine based on prevention types.

Prevention type	Classical	Digital-based
Primary	• Smoking/alcohol abstinence advice • Unstructured exercise recommendations • Generic dietary recommendations	• Genetic health risk screening • Personalized health record apps • App-based diet management
Secondary	• Human operator–dependent cancer screenings • Demographic-based cancer screening routines • Annual health checkups	• AI[a]-enhanced medical screening • Personalized cancer screening • Continuous monitoring
Tertiary	• In-person rehabilitation clinics • Standardized cancer chemotherapy • Intermittent blood glucose testing	• Telerehabilitation • Gene-based prognosis/treatment • Continuous blood glucose monitoring

[a]AI: artificial intelligence.

Digital technology could aid secondary prevention, detecting diseases in their early, asymptomatic stages and allowing for timely intervention before symptoms develop. This proactive approach aims to identify risk factors and prevent the progression of the disease and to detect noncommunicable disease complications early. Artificial intelligence, specifically machine learning (ML), has made significant advancements in using large amounts of patient data to enhance decision-making and predictions. ML is already being used in clinical settings to support health care professionals in tasks such as diagnosing respiratory issues from computed tomographic scans [25,26] or assisting with triage decisions through chatbots [27].

ML can also identify patterns and indicators that predict which patients will require more intensive medical interventions in the future [28]. ML also helps make better therapeutic decisions by pinpointing the treatments with the highest chances of success for each patient and their specific condition [29].

One example is Vuno, which provides AI-assisted medical imaging interpretations and diagnoses in a wide range of applications from simple chest radiographs to identifying signs of cardiac arrests and degenerative brain diseases. Chronic diseases such as diabetes and hypertension are recognized as conditions that exist on a continuous spectrum between health and disease. By using serum biomarkers and regular clinical checkups, people spend years in borderline states such as "prediabetes" or "prehypertension." Today's technology can help ascertain these conditions at these early stages, allowing for preventive measures.

In addition, advancements in genomics have allowed for the identification of genetic susceptibility to diseases such as breast cancer. This knowledge enables individuals to take proactive measures to prevent the disease. HexaMed is one such solution that collects anthropometric measurements and lifestyle choices in a simple questionnaire to predict cancer risk and suggests genomic, imaging, biomarker screening, and lifestyle changes.

Medical technology will also help shape individual rehabilitation for tertiary prevention. Individual dose calculations and drug delivery strategies based on each patient's characteristics and diseases, including risk factors; genetic, genomic, and biomarker information; and social, behavioral, and economic conditions, will drive individualized treatment approaches. OncoFree, for example, provides breast cancer prognosis prediction using next-generation sequencing, and in addition, its results can be used to form postsurgical plans by providing clinicians with an estimate of how effective chemotherapy will be.

Case Study 1: Breast Cancer

Breast cancer is the most common cancer and cause of cancer mortality globally [30]. Its rising prevalence is in part driven by lifestyle factors such as poor diet and inactivity [31,32]. Although mammography screening has enhanced early detection and improved prognosis, in many countries, the screening method is recommended through a one-size-fits-all approach. However, the absolute risk for breast cancer for the majority of the population is lower than average, whereas a small portion is at a significantly higher risk. Identifying who is at a higher risk and providing a more personalized screening based on each individual's risk factors can optimize health care resources allocation, ensuring appropriate preventive interventions for high-risk individuals and enhancing overall breast cancer prevention efforts [33].

Technological advancements in digital health could significantly enhance the prevention, early detection, and treatment of breast

XSL•FO
RenderX

cancer—that is, primary, secondary, and tertiary prevention (Table 5). For example, telehealth and telemedicine, actively used for monitoring and follow-up of patients with cancer during and after COVID-19 [34], have been shown to be effective for primary and secondary breast cancer prevention. In aiding patients with *BRCA* mutations, while the level of satisfaction toward counseling for cancer-specific psychological distress was found to be comparable whether the counseling was delivered in-person or remotely, the participants perceived remotely delivered genetic counseling as more convenient and less expensive [35].

Table 5. Prevention strategies and commercial applications according to the level of prevention.

Prevention type	Prevention strategies
Primary	• General advice for a healthy lifestyle. • Mammography screening frequency tailored to risk.
Secondary	• Discuss preventive therapies. • Individual counseling.
Tertiary	• Preventive interventions and endocrine therapy. • Enhanced screening and surveillance.

Telehealth applications can be extended to tertiary prevention of breast cancer as well. Using a face-to-face videoconference strategy to supervise physical exercise in women undergoing primary treatment for breast cancer stages I-III (ABRACE) has been hypothesized to yield better physical and psychological outcomes compared with a health education program alone [36]. Similarly, wearable devices have been shown to significantly improve physical activity, weight control, and overall health in breast cancer survivors [37]. In the future, medical wearables with AI and advanced sensors may be able to detect early-stage breast cancer through noninvasive procedures. For example, a proof-of-concept ultrasonic breast patch (cUSBr-Patch) has been developed that can detect cysts as small as 0.03 cm in diameter, providing a noninvasive way to monitor real-time changes in breast tissue [38].

Another application of technology in breast cancer prevention is in identifying higher-risk individuals for recommendation for screening via risk prediction models (Table 6). Predominantly developed and validated within Caucasian populations, these models have shown modest discriminative power in validation studies with area under the curve values generally ranging between 0.7 and 0.8. The risk factors used are a composite of nonmodifiable elements—age, age at menarche, age at first live birth, additional birth history, family history, age at menopause, and mammogram outcomes—and modifiable elements, notably alcohol consumption and BMI, which provide avenues for risk reduction interventions.

Table 6. Breast cancer risk prediction models.

Model	Study design	Study size (cases/controls)	Remarks
Gail et al [39]	Nested case-control	2852/5998	• Pioneering modeling study. • Focus on reproductive factors.
Rosner and Colditz [40]	Cohort	2249/91,381	• Inclusion of age at multiple birth and has been validated with the inclusion of modifiable risk factors.
Breast Cancer Surveillance Consortium; Kerlikowske et al [41]	Cohort	14,766/1,110,250	• Inclusion of radiologic findings such as BI-RADS[a].
Eriksson et al [42]	Case-control	433/2165	• Emphasis on short-term risk prediction. • Used computer-generated BI-RADS[a].
Breast and Ovarian Analysis of Disease Incidence and Carrier Estimation Algorithm; Antoniou et al [43]	Case-control	1484/156 multiple-case families	• Focus on mutation carrier (BRCA1/BRCA2) probabilities.

[a]BI-RADS: Breast Imaging Reporting and Data System.

The use of risk prediction techniques has enabled us to provide general advice on factors that can lower the risk of breast cancer and to recommend tailored mammography screening frequencies for each woman based on her individual risk level, as a primary prevention strategy. The polygenic risk score (PRS) has been particularly helpful in identifying individuals at a high risk of

XSL•FO
RenderX

developing breast cancer. This allows for targeted interventions aimed at primary prevention, such as personalized lifestyle modifications, preventive therapies, and individual counseling.

In addition, PRS has enabled the stratification of individuals for enhanced screening and surveillance, thereby aiding in the early detection of breast cancer, which aligns with secondary prevention efforts. Furthermore, PRS has the potential to guide tertiary prevention strategies by identifying those who may benefit from more aggressive treatment or preventive measures, such as chemoprevention or risk-reducing surgery both before and after cancer diagnosis to decrease the advanced or recurrent cancer disease burden. Electronic breast cancer risk assessment tools are commonly used to estimate an individual's risk of developing breast cancer. However, it is important to consider both genetic and environmental factors in order to accurately assess the absolute risk for each person in the population [44]. This comprehensive approach allows women to make informed decisions about lifestyle choices and preventive interventions based on their personal risk level and values [33]. Women with a family history of cancer and who are in good overall health should receive personalized care and risk management, while patients with cancer should be educated about how genetic germline mutations may impact their ongoing treatment, follow-up care, and secondary prevention [45]. With the advancement of patient-driven platforms such as HexaMed and DCGen, risk assessment is becoming more personalized and tailored to each individual.

Mobile apps are also used for prevention in breast cancer, especially among marginalized populations and women at increased risk. These apps have been proven effective in increasing mammography awareness and positive decision-making [46]. In addition, mobile apps for primary prevention aim to promote healthy behaviors that reduce the risk of breast cancer [47,48]. These apps primarily target women at high risk for breast cancer, such as postmenopausal women with high Gail risk scores [45] and *BRCA* mutation carriers [49,50]. Recently, studies such as the PREVENTION e-platform have been developed to provide personalized breast cancer information and support tailored to different risk levels [51].

Mobiles apps for tertiary prevention of breast cancer focus on clinical care coordination and health-related quality of life interventions [52]. Cancer care coordination focuses on support and communication between patients with breast cancer and physicians. Specific aspects of coordination include symptomology management, medication adherence, and ambulatory surgery. Health-related quality of life apps targeted general lifestyle management, weight management, depression, and breast cancer-related distress, social support, sleep, and physical activity during and after breast cancer diagnosis. Patients and survivors expressed a preference for receiving clinical care coordination support and quality-of-life interventions through mobile apps, indicating a shift away from standard practices [52].

Case Study 2: Diabetes

Diabetes management, amidst its increasing global burden, presents challenges for both individual patients and the broader public health landscape [53]. The global surge in obesity and sedentary lifestyles has amplified the incidence of diabetes [54,55]. Meanwhile, our understanding of and diagnosis of the disease have advanced to recognize the need for earlier, more personalized care. This is reflected by the American Diabetes Association's changing both the naming and the diagnostic criteria of various stages of hyperglycemia, including hemoglobin A_{1c} (HbA_{1c}) as a diagnostic standard and accepting the concept of "prediabetes" (Table 7) [56,57]. However, traditional health care approaches have encountered significant limitations in preventing, diagnosing early, and mitigating complications associated with the disease. Owing to its gradual onset, lifestyle-related risk factors, and the absence of early symptoms, diabetes proves challenging to both prevent and detect in its initial stages. Moreover, its management is complicated by the necessity for frequent blood glucose monitoring, which yields only intermittent data on glucose levels. Furthermore, treatment regimens typically require strict adherence to medications that are prescribed based on generic guidelines. These guidelines do not accommodate individual patient differences, potentially compromising the effectiveness of the treatment [58].

Table 7. The American Diabetes Association evolution of diabetes as diagnosis.

Definitions	Diagnosis criteria	Year
IGT[a]	2-hour glucose levels 140-199 mg/dL	1979-1997
IFG[b]	Fasting glucose 110-125 mg/dL	1997, 1999
IFG	Fasting plasma glucose 100-125 mg/dL	2003-2006
Borderline HbA_{1c}[c]	HbA_{1c}[c] 6.0%-5.7%	2009-2010
Prediabetes	IGT or IFG or borderline HbA_{1c}[c]	2010

[a]IGT: impaired glucose tolerance.

[b]IFG: impaired fasting glucose.

[c]HbA_{1c}: hemoglobin A_{1c}.

Digital health technology may be capable of improving how diabetes is prevented, screened, and managed. For one, digital health technology offers a promising avenue for primary prevention of diabetes by enabling personalized lifestyle and dietary interventions. Wearables and mobile apps are crucial for encouraging lifestyle changes, such as increasing physical

XSL•FO
RenderX

activity and aiding in smoking cessation, by providing real-time feedback and monitoring. Furthermore, AI-driven personalized nutrition plans, tailored to an individual's glycemic responses and microbiota profiles, play a vital role in optimizing metabolic health. Noom, for instance, is an app that provides personalized recommendations for nutrition, weight loss, and physical activity by improving user engagement and self-improvement [59,60]. Through these technologies, health care can adopt a more proactive and preventive stance, targeting key dietary and lifestyle risk factors effectively.

Digital health technology can also enhance secondary diabetes prevention by enabling noninvasive diagnosis and identifying individuals at high risk. Traditionally, the identification of individuals at high risk of diabetes depended on statistical models, some of which required fasting blood glucose tests (Table 8). These diabetes risk prediction models incorporate a mix of nonmodifiable risk factors, including age, family history of diabetes, comorbidities such as hypertension and cardiovascular disease, and laboratory test results, including blood glucose, lipids, and uric acid levels.

Table 8. Diabetes risk prediction models.

Model	Cohort name	Study size (cases/control)	Remarks
Lindström and Tuomilehto [61]	FINRISK	182/4253	Model based only on lifestyle factors.
Balkau et al [62]	DESIR[a]	203/3611	Genetic polymorphisms included as a risk factor.
Hippisley-Cox et al [63]	QResearch database	78,081/2,462,672	Recognized socioeconomic status as a risk factor.
Kahn et al [64]	ARIC[b]	1821/7766	Offers multiple models for varying levels of available clinical data.

[a]DESIR: Data from an Epidemiological Study on the Insulin Resistance Syndrome.

[b]ARIC: Atherosclerosis Risk in Communities.

More recently, modifiable risk factors such as alcohol consumption, smoking, physical activity, waist circumference, and BMI have been integrated, offering opportunities for risk reduction interventions. Unfortunately, traditional models have demonstrated modest discriminative ability, with area under the curve values typically ranging from 0.6 to 0.7. On the other hand, recent AI-developed models have shown themselves to be capable of predictive population risk stratification, allowing for targeted interventions and showing high sensitivity and specificity. One model, for example, was developed to predict prediabetes and type 2 diabetes based on 1415 Indians and reported 99.5% sensitivity and 99.07% accuracy [65]. This approach of using technology to identify individuals at high risk of diabetes streamlines resource allocation and improves prevention efforts, marking a shift toward proactive diabetes management.

Tertiary prevention of diabetes using digital health technology has shown the most progress in recent years. One example is continuous glucose monitoring (CGM), a wearable device that provides continuous, noninvasive monitoring of glucose levels and is capable of alerting patients to significant blood glucose swings. One such instance, Freestyle Libre, a CGM device, measures glucose levels in cellular fluids instead of serum glucose, offering real-time, noninvasive readings and hypo- and hyperglycemia alerts. The adoption of CGM devices has shown significant reductions in HbA_{1c}, as well as improved participant-reported quality of life [66].

AI has also been used to work in conjunction with existing clinical practices, namely, facilitating the diagnosis of diabetic complications such as retinopathy and foot ulcers. For example, Lam et al [67] used a convoluted neural network to develop a system for identifying retinal lesion from ophthalmologic photographs, reporting 98% accuracy and a receiver operating characteristic curve of 99%. In another instance, Keel et al [68] reported 92% and 94% sensitivity and specificity, respectively, in identifying diabetic retinopathy in outpatient conditions. Siren Care's Siren Socks is a particularly creative approach to managing diabetic ulcers, using socks to measure foot temperature of patients with diabetes to detect diabetic foot neuropathy, ulcer, and injury [69].

Key Considerations for Digital Health Technology Applications

Despite its potential benefits, the application of modern digital health technology in preventive medicine must proceed with caution. For one, since access to digital devices, the web, and digital literacy depend on socioeconomic factors, adopting technology to provide preventive medicine services may further exacerbate existing health disparities. Services such as mobile apps for cancer prevention or diabetes management, despite their potential, will be of limited use if they are not accessible or effectively promoted to marginalized groups. Conversely, digital health technology has the potential to contribute to health equity when used correctly. Telemedicine, for example, significantly enhances health care access for remote populations, individuals with disabilities, and low-income groups by reducing travel costs and barriers to care. To provide digital health care where it is needed, it is important to advocate for the development of communications and technology infrastructure in marginalized communities and support policies that promote inclusive medical practice [70,71].

Another point of concern is the potential challenges posed by an overreliance on digital devices. Excessive use of electronic devices has been associated with both physical and mental health

XSL•FO
RenderX

hazards, such as computer vision syndrome, obesity, and developmental disorders [72-74]. Overuse of digital health devices may cause harm instead of promoting health. There is also the risk of overreliance on electronic systems for health care decisions and delivery, which could detract from the judgment of experienced health care providers. Despite developments in AI and self-health management mobile apps, these electronic devices must be recognized as tools to aid, not replace, the therapeutic efforts of patients and health care providers.

Ethical concerns also warrant attention. The integration of genomics and personal data into health care platforms raises concerns, especially due to possible discrimination. Although genetic data can aid in prevention, there have been concerns that they could be used to deny insurance or employment to individuals or their families [75], as has materialized in some legal cases [76]. Unauthorized access to and misuse of health records could also lead to discrimination and breaches of confidentiality, ultimately undermining trust in digital health systems. There is already a robust body of literature addressing concerns about patient data security [77-79]. Future and continuous efforts must be focused on establishing robust safeguards and ethical guidelines to protect against such discrimination, breaches, and misuse, as well as on policy to ensure that the advancement of digital health technologies does not compromise health care ethics.

Finally, as much as the field of digital technology and its applications in preventive medicine are exploding, there is a critical need for rigorous testing of safety, efficacy, and data validation. One study found that most digital health startups (44%) scored zero, the lowest score, in clinical robustness as measured by regulatory filings and clinical trials [80]. To move past being a mere buzz and truly become future health care, digital health technology requires in-depth, longitudinal studies and user experience research.

This review provides a comprehensive, forward-looking perspective on the future of preventive medicine. By examining current trends, technological advancements, and case studies, this study offers valuable insights into how preventive health care is evolving in the digital era toward a more proactive, personalized, and patient-centered approach to health care. Furthermore, this study identifies the potential of digital health technologies to transform preventive medicine, providing concrete examples of how digital tools are being leveraged for primary, secondary, and tertiary prevention and highlighting the need to address disparities in technology access, prevent overreliance on digital tools, safeguard patient data, and ensure clinical validity of digital health applications.

Despite these strengths, this viewpoint is based largely on observations and trends within the field rather than empirical research. As such, while it is an expert opinion familiar with industry trends and the applications of technology in preventive medicine, this perspective may not fully capture all dimensions of digital health application in prevention. Despite this limitation, we have sought to avoid potential biases by drawing on diverse sources to provide a balanced assessment of the role of digital health in preventive medicine.

Given the rapid advances in digital health technology and its potential to transform preventive medicine, further investigation is warranted. This exploration must focus not only on improving technological capabilities but also on addressing concerns related to health equity, responsible usage, ethics, and clinical validation that accompany such advancements. Only then can we better guarantee that these innovations deliver safe, effective, and equitable health outcomes for all sections of society.

Summary

The future trend of health care is expected to be that of a rise in the older adult population, a shift from cure to prevention, increased use of digital health technology and telemedicine, and a gradual left shift of diseases and the focus of health care. In this review, the concept of primary, secondary, and tertiary prevention in the scope of digital health care was highlighted, as well as breast cancer and diabetes prevention as case studies of the actual application of digital technology in the realm of health care.

The role of preventive medicine is changing as new medical and digital technologies are developed and integrated with health care. These advancements have expanded the reach of preventive services, allowed for remote monitoring, and enabled personalized health interventions, leading to a more patient-centric and data-driven approach to prevention and health care. As a result, health care is closer, faster, and delivered at a lower cost to patients, while patients are empowered with personalized health records and improved patient engagement.

In this study, we have seen that the integration of digital technologies into preventive medicine marks a pivotal evolution in health care. The pace at which technology is evolving is unprecedented. It should be noted, however, that the practical application of these innovations requires robust research to validate the efficacy and safety of digital health technologies in preventive medicine, ensuring that future health care systems are both innovative and inclusive, as well as rigorous validation through large-scale population studies. Looking ahead, we anticipate a transformative health care landscape where personalized preventive measures become fundamental, supported by evidence of efficacy and applicability of digital technologies in preventive medicine.

Abstract

Health data integration platforms are vital to drive collaborative, interdisciplinary medical research projects. Developing such a platform requires input from different stakeholders. Managing these stakeholders and steering platform development is challenging, and misaligning the platform to the partners' strategies might lead to a low acceptance of the final platform. We present the medEmotion project, a collaborative effort among 7 partners from health care, academia, and industry to develop a health data integration platform for the region of Limburg in Belgium. We focus on the development process and stakeholder engagement, aiming to give practical advice for similar future efforts based on our reflections on medEmotion. We introduce Personas to paraphrase different roles that stakeholders take and Demonstrators that summarize personas' requirements with respect to the platform. Both the personas and the demonstrators serve 2 purposes. First, they are used to define technical requirements for the medEmotion platform. Second, they represent a communication vehicle that simplifies discussions among all stakeholders. Based on the personas and demonstrators, we present the medEmotion platform based on components from the Microsoft Azure cloud. The demonstrators are based on real-world use cases and showcase the utility of the platform. We reflect on the development process of medEmotion and distill takeaway messages that will be helpful for future projects. Investing in community building, stakeholder engagement, and education is vital to building an ecosystem for a health data integration platform. Instead of academic-led projects, the health care providers themselves ideally drive collaboration among health care providers. The providers are best positioned to address hospital-specific requirements, while academics take a neutral mediator role. This also includes the ideation phase, where it is vital to ensure the involvement of all stakeholders. Finally, balancing innovation with implementation is key to developing an innovative yet sustainable health data integration platform.

(J Med Internet Res 2025;27:e68083) doi:10.2196/68083

Introduction

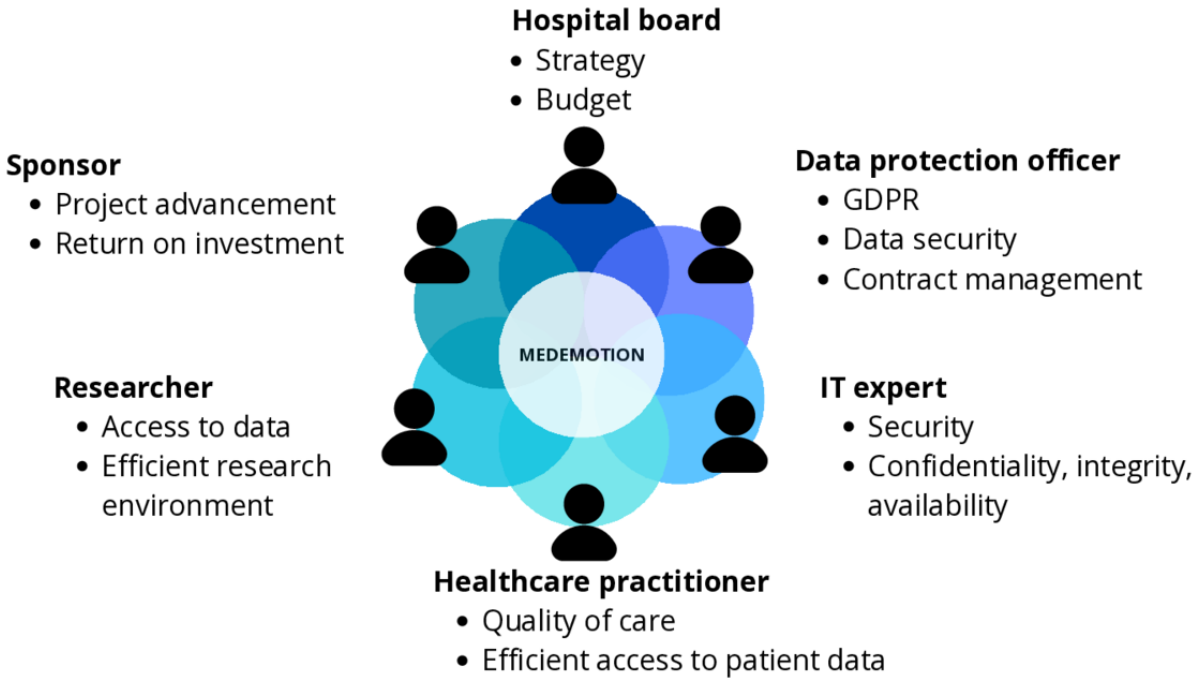
Accurate and well-formatted data are key to delivering high-quality health care and fueling medical research [1-3]. All health care actors acquire real-world data, defined as any health care-related information captured from the patient [4]. The volume, velocity, and variety of acquired data, however, raise challenges for data processing systems [5]. Data engineers work in interdisciplinary environments to ensure that users receive data in the right format, at the right time and place to generate real-world evidence [4]. Health data engineering is a complex and time-consuming task that cannot be managed without IT solutions tailored to environment-specific requirements [6]. Consequently, health data integration platforms are a hot topic in medical informatics research [7-11]. Health data integration commonly refers to finding relevant and rich patient information on time with appropriate interfaces [6]. In this paper, we present our design and development approach to building such a platform.

The medEmotion project was a collaborative initiative among 3 hospitals (Jessa Ziekenhuis, Noorderhart, and Ziekenhuis Oost-Limburg), 2 academic institutions (Hogeschool PXL, and UHasselt), and 2 industry partners (LRM, and BioVille) from the region of Limburg, Belgium. The primary objective of medEmotion was to establish a comprehensive data integration platform designed to effectively address a wide array of health data-related inquiries and challenges encountered by various stakeholders within the health care ecosystem. The medEmotion platform aggregates medical data from hospitals and general practitioners, personal health information collected through wearable devices, and environmental data. It enables researchers, health care professionals, and entrepreneurs to test innovative data-based concepts and generate real-world evidence. We built the medEmotion platform to be secure and compliant with legal standards to be fit for purpose for real-world health data. The platform enhances decision-making and stakeholder collaboration by facilitating comprehensive analysis of integrated real-world health data.

To guide and showcase the data integration platform developed in medEmotion, we defined 2 real-world use cases for distinct disease areas. First, with the Noorderhart hospital, we approach the multiple sclerosis data connect (MSDC) use case, focusing on the health care process of people with multiple sclerosis. MSDC is characterized by a relatively low total amount of patients just below a thousand where each patient is described with a high amount of diverse information in the form of structured clinical data, evoked potential time series data, magnetic resonance images, and para-clinical data, such as information collected during physiotherapy. We thus obtain a broad dataset that brings a distinct set of challenges from the second use case in medEmotion, Cardio. Developed in collaboration with Jessa Ziekenhuis and Ziekenhuis Oost-Limburg, we consider the postclinical workflows of cardiology patients. Cardio is characterized by a low variety and high velocity of data collected per patient. Next to a basic set of clinical variables, most data are acquired through wearable sensors. We thus have a data source that continuously generates new data points.

In this paper, we outline the medEmotion project, focusing on our chosen development approach. In particular, we describe a team of personas and a set of demonstrators. Personas are fictional stakeholders whose requirements and unique perspectives we implemented into the project. Demonstrators describe sets of functional requirements of the medEmotion platform aiming to solve real-world use cases. Each demonstrator's requirements are affected by one or more personas.

Furthermore, we discuss our approach, combining personal reflections on our challenges during medEmotion. With these reflections, we reminisce about our experiences that we believe present common pitfalls of health care-related projects that handle real-world data. We aim to shed light on the tension between stakeholders from health care, academia, industry, and investment societies and give advice for future efforts.



The paper is structured as follows. We introduce the personas and the demonstrators of medEmotion alongside a summary of its implementation. Afterward, we discuss our development approach and the result. We end with distilling key takeaway messages from the medEmotion project.

Personas

Stakeholder management is a core project management task that aligns the requirements and visions of stakeholders. A stakeholder may be part of the core project team or take a consultant role, advising the project team regularly. From our experience, most stakeholders combine multiple personas. Each stakeholder might take on a different "hat," sharing their view and arguments in different, situation-specific ways to drive the project forward. Therefore, we define 6 personas that represent the different "hats" a stakeholder may represent in the following (Figure 1). The following personas are based on observations during medEmotion, we thus do not claim this list to be exhaustive. We think this list will serve as a starting point to identify personas in other projects.

XSL•FO
RenderX

Figure 1. Personas involved in the different demonstrators, with some of their focus points indicated. GDPR: General Data Protection Regulation.

Data Protection Officer

The Data Protection Officer persona is concerned with keeping information up to date, private, secure, and traceable. These concerns can be enforced by law, such as the General Data Protection Regulation (GDPR) of the European Union, or can be intrinsic in the sense that keeping data well governed makes aspects such as data security and contract management easier. People who represent this persona are Data Protection Officers of hospitals, contract managers, or data stewards.

Researcher

The Researcher persona is concerned with conducting research more efficiently or easily. In health data integration, conducting research typically means running experiments on real-world health data. Thus, the researcher aims to get easier access to health data, larger amounts of health data, more computational resources, or access to software tools that accelerate data processing. A common example of a researcher is a PhD student.

Health Care Practitioner

The health care practitioner is concerned with delivering the best health care quality to the patient. To do so, they need recent, correct, and sufficient information about a patient while they consult with them or decide on future medical interventions. For example, clinicians and nurses represent this persona.

IT Expert

The IT Expert persona is concerned with efficiently and reliably running the hospital information system (HIS). The IT-security aims of confidentiality, integrity, and availability are of major concern, which results in a more reluctant attitude toward new and unknown systems. The hospital's chief information officer represents this persona.

Hospital Board Member

The hospital board member persona is concerned with the strategic advancement of the hospital within the resources available. As such, this persona will wage strategic and long-term goals, such as participating in international research studies, against short-term available resources, such as the workforce and budget of a hospital. For example, a hospital's chief executive officer represents this persona.

Sponsor

The Sponsor persona is concerned with the success of the investment. In a research project such as medEmotion, this includes ensuring that project resources are well-spent and securing potential return on investments about the project results. This persona is represented by project sponsors, such as venture capital, pharma, or insurance companies.

During medEmotion, we found that defining personas and assigning them to our stakeholders made discussions more transparent and efficient. The set of people participating in discussions and meetings changes frequently during a project. A list of predefined personas allowed us to ensure we included all distinct perspectives to decide on the next steps. In particular, we assigned these personas to demonstrators to gain well-structured functional requirements, which we will list in the following section.

Demonstrators

We defined a series of real-world demonstrators to facilitate the requirement engineering process. Each demonstrator represents a bundle of related technical requirements that include the unique perspectives of all personas involved. In particular, our demonstrators are disease-agnostic and can be applied to any real-world dataset. By contrast, the use cases we used in

XSL•FO
RenderX

medEmotion describe higher-level and disease-specific requirements that affect multiple demonstrators. We present a short description of each defined demonstrator, and the personas involved.

Orchestration of Complex Pipelines

In biomedical research projects, (para-)clinical data must be processed through complex data integration steps. Researchers often implement these steps ad hoc using different programming languages (eg, Python [Python software foundation], R [R foundation], MATLAB [MathWorks]), and software frameworks (eg, Torch [PyTorch Foundation], Pandas [Pandas project], dplyr [posit]) or reuse existing implementations as black boxes [12]. The resulting software code is complex and difficult to automate, orchestrate, and reproduce, pushing it out of reach for IT experts. Further, data protection officers see a lack of in-depth documentation, essentially losing real-world data due to missing knowledge. With this demonstrator, we showcase the platform's capabilities to orchestrate complex data integration pipelines automatically.

Private Research Environments

Access to real-world data greatly increases the efficiency of exploratory research tasks. With strict privacy regulations such as the GDPR of the European Union or the HIPAA (Health Insurance Portability and Accountability Act) of the United States, data access is often achieved by sharing datasets after bilateral contracts between the data custodians (eg, hospitals) and universities are set in place [13]. This process, however, is slow, complex, and lacks transparency, creating tension between researchers, Data Protection Officers, and IT experts. Researchers need to deal with tedious administration tasks, while data privacy officers and IT experts are concerned with keeping sensitive data secure. With this demonstrator, we showcase the platform's ability to create private research environments that allow researchers to access data, tooling, and compute resources while keeping real-world health data secure.

Observational Health Data Sciences and Informatics Observational Medical Outcomes Partnership Common Data Model

Transnational medical research can be facilitated with internationally standardized data schemas, such as the Observational Medical Outcomes Partnership (OMOP) common data model (CDM) developed by the Observational Health Data Sciences and Informatics (OHDSI) research community. Transforming health care records to OMOP is a highly operational task, enabling data custodians to participate in federated, transnational research projects without sharing sensitive datasets [14]. Transforming and maintaining data structured according to the OMOP CDM is desirable for researchers and hospital board members, as it allows for simple access, privacy perseverance, and increased hospital visibility in the academic landscape. With this demonstrator, we showcase the platform's ability to facilitate transforming data to and maintaining data in the OMOP CDM, including running a suite of software tools developed by the OHDSI community.

Visualization of Integrated Datasets to Support Care

Providing high-quality health care necessitates large amounts of integrated, patient-centric data that facilitate informed decision-making. Analyzing these extensive amounts of patient data and gathering insights on the evolution of the patient's medical conditions over time in a few minutes is only possible with data-rich visualizations [15]. The clinical decision-making process remains health care practitioner–specific as well as multidisciplinary. Hence, visualizations must be adaptable per individual and still sharable within a multidisciplinary team to stay helpful. Privacy remains essential in the eyes of Data Protection Officers, hence, sophisticated methods to share information according to therapeutic relationships between health care practitioners and patients are needed. With this demonstrator, we showcase the platform's ability to facilitate online visualizations of rich datasets that can be tailored to individual needs and shared among multidisciplinary teams.

Data Ingestion From Hospital Data

The primary sources of real-world data meant to generate real-world evidence are HISs. Even for clinical studies that collect data with study-specific case report forms, HIS data helps provide important context information, such as demographics or comorbidities [1]. Due to the value of HIS data, one of the sponsor's main targets is integrating such data into the platform. This real-world data is highly sensitive and the prime target of data protection measures set up by data protection officers and IT experts. Researchers aiming to access the data naturally clash with data protection measures, as they tend to over-request data. With this demonstrator, we showcase the platform's ability to ingest data from multiple pseudonymized data sources.

Data Ingestion From Devices

With eHealth solutions on the rise, data integration platforms receive more interest from sponsors to include data collected outside the traditional boundaries such as the hospital or the practice. Patients collect data themselves, either actively using health apps or passively using wearable devices [16], both using lifestyle and software-as-medical device apps [17]. Providing richer datasets for clinicians and researchers, IT experts face challenging data integration tasks of high volume and erroneous-prone data streams. Of course, these data streams are sensitive and thus are a concern of Data Protection Officers. With this demonstrator, we showcase the platform's ability to include data streams from home monitoring devices that are not part of traditional hospital information systems.

Connection With High-Performance Computing Centers

High-performance computing (HPC) enables researchers to use machine-learning approaches [18]. Those can ramp up costs quickly when acquired from public cloud providers such as Microsoft Azure, Google Cloud, or Amazon Web Services. Many academic institutions operate HPC centers to meet the demand for HPC. To keep research projects using machine learning feasible, data transfer to and from academic HPC centers needs to be simple while retaining IT security standards set by data protection officers. With this demonstrator, we

XSL•FO
RenderX

showcase the platform's ability to transform data between the Vlaams Supercomputer Center, an HPC center operated by and for the 5 Flemish universities.

Summary

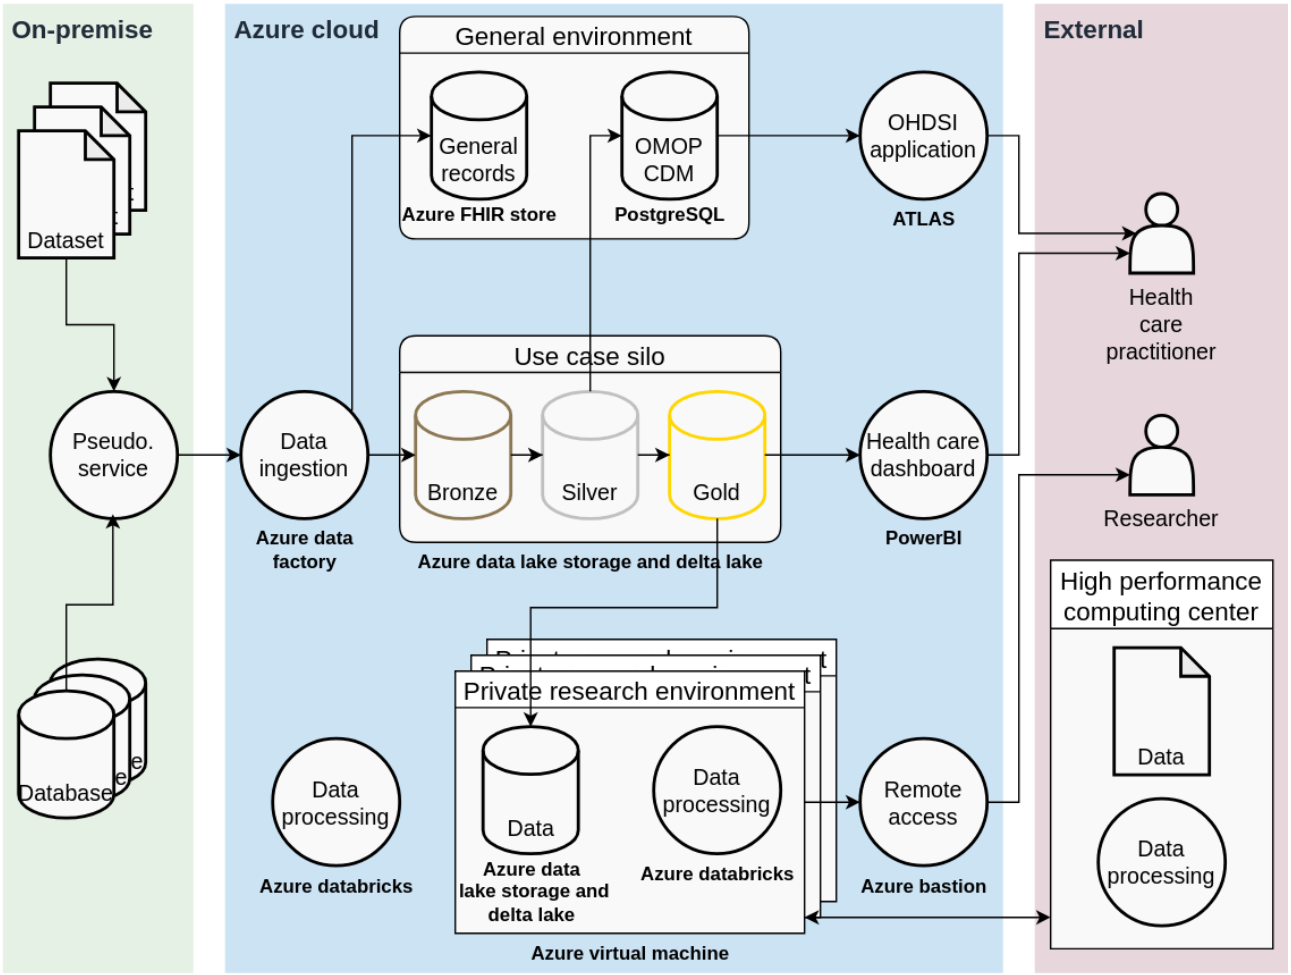
The demonstrators guided discussions and the implementation of the medEmotion platform. Based on the personas, we could identify which stakeholders to include in discussions. Hence, we were able to have more ad-hoc discussions in smaller groups, replacing large and time-consuming meetings to discuss the entirety of the platform components. Combining personas and demonstrators allowed for a rapid implementation process, which we summarize in the following.

Implementation

We implemented the medEmotion platform with an industry partner using Microsoft's Azure Cloud Platform components. The platform's architecture foresees a general environment and multiple use case-specific data silos. We find modules and tools in a general environment that handle pseudonymized, cleaned, and integrated data. In the hospital-specific data silos, we find modules and tools to preprocess datasets either for the general environment or for hospital-specific projects. The implementation process was guided and managed by using case-specific task forces that met at regular intervals. Each task force consisted of relevant stakeholders from multiple partners that covered all personas as described above. Each task force meeting was attended by a member of the medEmotion core team which summarized the discussions and extracted feedback, suggestions, and additional requirements that were reported to the implementing industry partner.

To ensure data privacy, data from different source systems is pseudonymized with source-specific keys on entering the data platform, such that the data in the medEmotion platform cannot be linked without additional effort. The platform retains encrypted quasi-identifiers, information irrelevant to answer clinical questions that potentially reveal the identity of a patient, to allow for ad-hoc record linkage if needed. The encrypted identifiers are locked away in a protected zone in the platform, and the keys to decrypt the identifiers are locked away in Azure Key Vaults. Next to the security guarantees provided by Microsoft Azure with respect to the Key Vaults, the medEmotion platform could also be implemented with on-premises Key Vaults, granting full control to data custodians with respect to the decryption keys used to link data that stems from their systems. In our proof-of-concept implementation, we used a Key Vault operated within the Microsoft Azure public cloud.

The figure shows components from 3 environments: On-premises (eg, a partner hospital), the Azure cloud, and External, which shows users outside the platform. Where applicable, we name the Microsoft Azure product used written in bold. The arrows indicate data flows, starting with the data sources on the left and flowing to the data users on the right.



The demonstrators were implemented exclusively with public or mock datasets, that was synthetically generated data modeled after real-world datasets. We created a mock data source following health level-7 FHIR (Fast Healthcare Interoperability Resources) [19] for the data ingestion demonstrators. The Azure FHIR Store is a natural fit for this data source. Further, an industry partner that offers wearable eHealth devices supplied us with a mock data stream for our eHealth device demonstrator. We generally use a decentralized lightweight pseudonymization service that runs on-premise at a hospital. This service polls for and pulls data in scheduled intervals from the sources, pseudonymizes it, and ingests it into the platform using Azure Data Factory.

To showcase the OHDSI OMOP CDM demonstrator, we generated a mock dataset based on a multiple sclerosis–specific data acquisition system, which we transformed into the OMOP CDM format. With this data, we operationalized OHDSI tools such as ATLAS to test the transformed data [14].

We used the datasets described by Yperman et al [18] for the remaining demonstrators. We use the Yperman et al [20] open-access dataset and an open-access magnetic resonance image dataset from the MICCAI [21] 2016 challenge. We use these datasets to showcase the orchestration of complex pipelines with Azure Databricks, as this enables our existing preprocessing scripts to be automated, orchestrated, and monitored. We encapsulate Azure Databricks in Azure Virtual Machines, where we block all connections to public networks (such as the web) to showcase private research environments. With the same tools but less stringent blocking rules (ie, we allow connection to selected HPC centers using virtual private network connections), we enable the use of HPC resources from within the platform. Finally, we use Microsoft's PowerBI to create dashboards per health care practitioner's requirements. In particular, we built an online, data-rich dashboard that respects therapeutic relationships (Figure 2).

XSL•FO
RenderX

Figure 2. A high-level overview of the medEmotion platform implementation. The figure shows components from 3 environments: On-premises (eg, a partner hospital), the Azure cloud, and External, which shows users outside the platform. Where applicable, we name the Microsoft Azure product used written in bold. The arrows indicate data flows, starting with the data sources on the left and flowing to the data users on the right. CDM: common data model; FHIR: Fast Healthcare Interoperability Resources; OHDSI: Observational Health Data Sciences and Informatics; OMOP: Observational Medical Outcomes Partnership.

Limitations

We combined personas and demonstrators to effectively steer the development and implementation of the medEmotion platform, resulting in a feature-rich yet adaptable solution. The use of mock-up datasets has proven particularly useful to accelerate development, as access to patient-level data remains a time-consuming process. While we focused on showcasing the technical feasibility of a data integration platform, the support for organizational tasks is currently missing from the medEmotion platform. The medEmotion platform does not enforce any data governance rules and does not offer any user-friendly user interfaces to manage data access rules. We put these organizational aspects out of scope, and we note that tackling these questions is essential to implementing the medEmotion platform in practice. During medEmotion, we focused on a proof-of-concept data integration platform. Hence, we did not tackle technical aspects to make the medEmotion platform production-ready, such as data redundancy or a multitier architecture. We acknowledge that these questions are important to answer in production environments and note that they are limited by a hospital's strategy, budget, and IT resources. Therefore, we do not present an answer to these aspects as they are highly hospital-specific and ultimately need to be decided per hospital.

In the remainder of this paper, we review the development process of the medEmotion platform.

Discussion

One of the key successes of the medEmotion project was its pioneering role in bringing together a diverse group of partner hospitals, academic institutions, and industry stakeholders, for the first time in a concrete, collaborative effort. This collaboration allowed us to gain invaluable insights into the distinct needs and concerns of various stakeholders, paraphrased as personas as mentioned before, ranging from data protection and privacy issues to the practical demands of health care practitioners. Through this partnership, we also learned a great deal about the organizational challenges that remain unaddressed in multistakeholder health data initiatives. To give 2 examples, we have seen that hospital-specific IT strategies vary significantly. While one hospital works within a cloud-based IT infrastructure, another prohibits using cloud-based components in favor of an exclusively on-premise infrastructure. The same can be said for data management strategies. Where

XSL•FO
RenderX

one hospital aims to keep data per department in distinct and tailored information systems, another aims to centralize as much information as possible into a single monolithic system. Personas apply these strategies in discussions but do not necessarily make them explicit. We believe that learning these implicit factors is vital to successful initiatives. Discussions about implementing a health data integration platform gave in-depth insights into hospital-specific data flows. We outlined how patient information flows into the hospital information system, an important exercise that improved mutual understanding. Importantly, beyond the technical knowledge gained, this project fostered personal connections and mutual trust among individuals representing different areas of expertise and roles within their organizations. This familiarity and trust built over time are essential for future interdisciplinary projects.

Clarifying technical questions using our demonstrators was pivotal in making abstract concepts more tangible for stakeholders. Much like trying to build a car in a world where cars do not yet exist, stakeholders initially struggled to articulate their needs without a clear vision of what the final product could look like. In such a setting, any implementation process will fail, as the result cannot fit the stakeholders' unarticulated vision. The demonstrators provided a concrete basis for discussions, allowing individuals without extensive technical backgrounds to actively engage and provide meaningful feedback. This practical approach significantly improved communication between the partners and helped bridge the gap between different personas. As such, we were able to develop and implement an architecture consisting of individual modules that both satisfied our demonstrators and generated general approval from the stakeholders.

Despite the many successes of the medEmotion project, several frustrations and challenges emerged throughout its course. Looking back, there were decisions and approaches that, with the benefit of hindsight, could have been handled differently to overcome obstacles more effectively. In this section, these key frustrations are summarized.

Effective Communication and Collaboration in a Fluid and Diverse Team Proved Extremely Challenging

With members frequently joining and leaving, maintaining continuity of knowledge was difficult, leading to disruptions in collaboration. The large and diverse group of individuals, each bringing distinct backgrounds, interests, and expertise, made aligning perspectives and ensuring consistent communication even more complex. This constant flux created coordination barriers, making it hard to sustain productive collaboration and slowing down decision-making processes.

Conflicting Priorities Among Key Stakeholders Created Significant Challenges in Aligning Goals and Decision-Making

Some stakeholders were primarily focused on return on investment and long-term strategic gains, while others were more concerned with its innovative potential and practical usability. This disconnect led to frequent misalignments, where decisions made often overlooked the technical needs or the full potential of the platform, or led to less effective outcomes as critical insights were missing in the decision-making process. As a result, in some cases, the project appeared to be driven more by academic interests rather than the practical needs of the health care partners. While the platform seemed promising on paper, there was a disconnect between the project's goals and the real-world priorities of the hospitals. For some hospitals, the platform was unsolicited and not aligned with their internal strategic plans, leading to doubts about its relevance. Additionally, one of the partner hospitals already had a similar platform in place, reducing the added value of the new system.

The Mismatch Between the Data Demands of Researchers and the Hospitals' Reluctance to Share Sensitive Data for Secondary use Complicated the Project

From the hospital's perspective, the process of preparing data cleaning, anonymizing, and transforming it represents a costly and time-consuming task. There is limited immediate benefit while they expose themselves to significant risks concerning the GDPR. Real-world data is highly sensitive and requires highly secured IT environments, which common academic research projects fail to consider. These conflicting needs slowed progress and exposed gaps in the project's ability to balance the expectations of different stakeholders, especially regarding the complexities of data sharing.

The Project Faced Significant Hurdles Related to Funding and Intellectual Property

The traditional "project-to-project" funding model limited the potential for long-term commitment. Without a clear financial roadmap beyond the initial phase, maintaining stakeholder engagement became increasingly difficult. At the same time, intellectual property (IP) issues arose as partners contributed in different ways, intellectually, financially, or through providing real-world use cases, making it complicated to define ownership. The absence of early, transparent IP agreements led to terms of usage that were unacceptable for some partners, limiting the potential for certain project components to be used effectively post the project. This further hindered the scalability and long-term success of the initiative.

Balancing the Openness of Collaboration With the Security and Operational Needs of Health Care Organizations Remains a Critical Challenge

Investing in open science can offer significant advantages in collaborative projects. Open-source software fosters transparency and inclusivity by allowing all partners to access, modify, and contribute to the project. This transparency builds trust among stakeholders as everyone can see how their contributions are used and built upon. Open science also reduces barriers to entry, enabling partners who may lack financial resources to still contribute valuable intellectual input, leveling the playing field, and encouraging broader collaboration. Open-source environments can also drive faster innovation, as contributors freely share ideas, experiment, and improve each other's work. This collaborative approach often accelerates development and produces more robust, well-tested solutions. Furthermore, open-source projects benefit from collective maintenance and support by the community, making them more

XSL•FO
RenderX

sustainable in the long term, even after the original funding or key contributors move on. However, there are pitfalls to consider. Open-source solutions, while valuable in academic settings, often conflict with hospital policies that prioritize stringent security measures and professional support. Hospitals may require more controlled environments to meet compliance and data privacy regulations, which may not always align with open-source principles.

Rapid Scale-Up and Professionalization Impacted the Balance Between Innovation and Implementation

A small group of researchers, who had initially focused on exploring and developing innovative solutions, had to quickly shift from this exploratory work to handling operational tasks as the project grew. This sudden change required them to manage the day-to-day implementation and ensure compliance with legal and technical requirements, leaving less time for creative research and experimentation. As a result, the researchers experienced a drop in motivation, finding themselves in presentations that felt more like sales pitches than discussions of research results. With no room for experimental approaches, the rapid scale-up and professionalization of the project brought innovation to a halt, a frustrating experience for those with a research mindset, who thrive on flexibility and exploration.

Focusing on Developing a Proof-of-Concept Limited the Production-Readiness of the Platform

The development of the medEmotion platform was bounded by time and resources. Initially focused on providing a minimal viable product, we approached implementation in little increments to provide quick and tangible parts of the platform. While this allowed for rapid development, our approach omitted important elements to make the platform ready for production. The use of mock datasets allowed us to push data privacy issues to the end, the cloud-based development left sensitive data flows from the hospital to the platform untested, and the rapid implementation start left us with no comparison metrics to assess the medEmotion platform user satisfaction. All these limitations persist and now need to be tackled post implementation, increasing the difficulty of bringing the medEmotion platform into production. As such, the medEmotion platform currently remains in a proof-of-concept state, not being implemented at any of our partner hospitals.

Takeaway Messages

We believe we are neither the first nor the last researchers to experience these or similar frustrations. Therefore, we share our experiences as takeaway messages in the following. Based on our experience, we aim to offer practical advice that can help guide future multistakeholder collaborative initiatives in health care and data integration.

Invest in Community Building, Stakeholder Engagement, and Education

Creating opportunities for stakeholders to get to know each other, both at the organizational level and on a personal level, is crucial for building trust and understanding. From an organizational perspective, this helps clarify the distinct needs of each stakeholder group and ensures that strategic goals are aligned toward a shared objective where value can be realized for everyone, even if the “return on investment” may look different for each party. On a more personal level, trust is not just an institutional concept; it is a feeling that grows between individuals and thus takes time. Providing opportunities for stakeholders to form personal connections through trustworthy relationships can significantly enhance collaboration. Organizing networking events, workshops, or joint educational sessions can help foster these connections and build a strong foundation of mutual trust and respect, which will pay dividends throughout the project.

Collaboration Among Health Care Providers Is Ideally Driven by the Health Care Providers Themselves

The health care providers are in the best position to proactively share expertise and requests for assistance based on their unique needs. Academic partners can play a key role in facilitating partnerships as neutral mediators, helping to bridge gaps between institutions. While commercial partners bring valuable expertise, maintaining a focus on shared goals and minimizing potential conflicts of interest can be achieved by ensuring that collaboration remains centered on the needs and priorities of health care providers. However, when it comes to implementation, there are additional challenges that need to be addressed, particularly within health care settings. Health care providers must establish secure data transfer protocols and ensure that patients are informed about how their data will be shared.

Ensure All Stakeholders Are Involved in the “Ideation Phase”

It is essential to spend adequate time understanding the problem and the real needs and expectations of all stakeholders and future users. One effective approach is to use qualitative research methodologies, such as semi-structured interviews and focus groups, before moving into the IT development phase. For example, methodologies from the newly launched educational program “System and Process Innovation in Healthcare” at Hasselt University could be leveraged to guide this process. In addition, involving legal departments early, particularly those within health care organizations is vital for ensuring compliance and managing risks effectively. It’s also critical to align IP ownership and a long-term funding strategy at the outset. Establishing clear IP agreements and a roadmap for continued financial support ensures the sustainability of the platform beyond the initial project phase. Finally, it is equally important to sanity-check technical plans with experts to guarantee feasibility, especially given the usual constraints of a fixed budget. Early input from all relevant parties helps prevent misalignments and avoids costly revisions later in the project.

Balance Innovation With Implementation

To ensure long-term success, it is important to strike a balance between pilot projects that foster innovation and the implementation of existing, proven solutions. These are fundamentally different activities, requiring distinct profiles and skill sets. Innovation thrives when motivated partners are eager to try new methods and solutions. This kind of exploratory work benefits from a small, focused group of individuals with

XSL•FO
RenderX

an innovation and research mindset who can freely experiment and iterate based on the real-world needs of partners. In this context, both parties gain from the trial-and-error process that allows them to explore potential breakthroughs in a mutually beneficial environment. Implementing novel methods and solutions requires a different approach, one focused on operational efficiency and compliance, rather than experimentation. It is also crucial to recognize that different people excel at different stages of the process. Some individuals thrive in the innovation phase, where flexibility and trial-and-error approaches are key. Others are better suited to perform structured, detailed work implementing established solutions. Attempting to blend these mindsets can lead to frustrations as the focus shifts from creative exploration to a more rigid, professionalized implementation. Understanding these distinctions and assigning the right people to the right phases can help maintain momentum and preserve the power of innovation while ensuring successful implementation.

Conclusions

Multistakeholder initiatives like the medEmotion project highlight the complexity of managing diverse roles, expectations, and goals. Stakeholders are rarely confined to a single role, and roles themselves are often shared among multiple individuals, which can complicate communication and decision-making. We introduce personas to clarify these different roles. Further, it is essential to communicate through full end-to-end use cases, ensuring that all parties understand how the platform functions within the broader ecosystem. In response, we introduce demonstrators to communicate technical requirements efficiently. The project highlighted the importance of building upon existing technical advancements rather than reinventing the wheel. Despite the availability of proven solutions, there was often a reluctance to fully embrace these innovations. This hesitation, driven by a desire to retain ownership of specific platforms or initiatives, leads to fragmented efforts and ultimately diminishes the overall impact. Collaboration, when done openly and transparently, benefits everyone involved, teamwork is crucial to achieving shared success. While technical sandboxes facilitate communication and experimentation, translating these ideas into real-world applications can be a slow and frustrating experience. The journey from concept to implementation requires patience and ongoing commitment. Ultimately, the lessons learned from medEmotion, building on existing successes, fostering collaboration, and maintaining a clear vision, lay the groundwork for more effective and sustainable initiatives in the future.

Acknowledgments

We thank our 3 partner hospitals Jessa Ziekenhuis, Noorderhart, and Ziekenhuis Oost-Limburg for their contributions toward the medEmotion project. Further, we thank the Limburg Clinical Research Center for sharing their expertise in clinical research projects. The software development of the medEmotion platform was funded by LRM, with the support of the European Regional Development Fund (EFRO-1308). This research received funding from the Flemish Government under the “Onderzoeksprogramma Artificiële Intelligentie (AI) Vlaanderen” program.

Authors' Contributions

All authors were contributed to conceptualization, methodology, investigation, writing–original draft, writing–review and editing. LMP handled supervision and funding acquisition.

Abstract

The benefits and challenges of electronic health records (EHRs) as data sources for clinical and epidemiologic research have been well described. However, several factors are important to consider when using EHR data to study novel, emerging, and multifaceted conditions such as postacute sequelae of SARS-CoV-2 infection or long COVID. In this article, we present opportunities and challenges of using EHR data to improve our understanding of long COVID, based on lessons learned from the National Institutes of Health (NIH)–funded RECOVER (REsearching COVID to Enhance Recovery) Initiative, and suggest steps to maximize the usefulness of EHR data when performing long COVID research.

(J Med Internet Res 2025;27:e59217) doi:10.2196/59217

Introduction

Postacute sequelae of SARS-CoV-2 infection, colloquially known as long COVID, refers to ongoing, relapsing, new symptoms, or other health effects after the acute phase of SARS-CoV-2 infection (ie, present 4 or more weeks after the acute infection). Because long COVID is heterogeneous in presentation and may occur after a mild or even asymptomatic infection, it has posed unique and significant challenges for clinical research, including an overarching lack of data that are accessible and analyzable in a rigorous and reproducible manner to inform diagnostic criteria and care guidelines.

SARS-CoV-2 continues to impact populations globally with new and recurrent infections. While studies have provided a wide range of estimates regarding the proportion of patients with COVID-19 who develop long COVID [1], even conservative estimates point toward an enormous burden. Without established treatments targeting underlying pathophysiologic mechanisms, patients and clinicians have largely focused on treating symptoms [2] and managing organ damage, highlighting an urgent need to expand our knowledge of COVID-19 infection's long-term effects.

Electronic health records (EHRs) contain large quantities of clinical data that can be used for research without significant delay, making them an important data source for accelerated insight into emerging health conditions. However, challenges associated with leveraging EHR data for research can become amplified when mobilizing rapidly to study these conditions, particularly when they are multifaceted and lack clear hallmark traits or biomarkers.

The National Institutes of Health (NIH)–funded REsearching COVID to Enhance Recovery (RECOVER) Initiative was launched in 2021 [3] to advance research into long COVID. Broadly, RECOVER supports prospective clinical studies of adult and pediatric cohorts and real-world data studies that leverage EHR networks to study long COVID. These studies have been developing and validating algorithms to identify patients with long COVID within EHR networks for clinical and epidemiological characterization, risk factor prediction, and identification of prevention and treatment opportunities. RECOVER's real-world data efforts are led by 3 participating EHR research networks: the National COVID Cohort Collaborative (N3C); the National Patient-Centered Clinical Research Network (PCORnet); and PEDSnet, a pediatric learning health system within PCORnet. These networks are coordinated by a Clinical Science Core (CSC) at NYU Langone Health.

In this paper, we highlight opportunities and challenges of using EHR data to improve our understanding of long COVID, with a focus on analytical resources and scenarios we've encountered as US-based researchers, and conclude with some next steps for maximizing the usefulness of EHR data for long COVID research. Similar considerations may pertain to other chronic infection–associated diseases, that is, complex multisystemic conditions often occurring in the context of infection with other pathogens, including myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS).

EHR-Based Research Networks

Overview

The widespread adoption of heterogeneous health information systems across the United States hinders large-scale EHR-based research efforts. To overcome this, federal funding from the Patient-Centered Outcomes Research Institute (PCORI), Centers for Disease Control and Prevention (CDC), and NIH has facilitated the growth of networks that transform data into a common data model to facilitate aggregation across participating institutions. These networks are often referred to as clinical research networks (CRNs).

While such networks are a focus of this paper, we recognize that other successful international [4-7] and national models have been leveraged for large-scale long COVID studies. Domestically, the Department of Veterans Affairs (VA), which operates the largest integrated health care system in the United States, has made important contributions characterizing long COVID, its burden, and risk after reinfection, immunization or nirmatrelvir (Paxlovid) use [8-11]. The interoperability across many VA hospitals and clinics allows for data aggregation without the extensive harmonization or loss of data depth that usually accompanies a research network, though VA patients (military experience, mostly men) are not representative of the general population. Similarly, researchers have used claims data and outpatient laboratory results from UnitedHealth, a large health insurance provider, to characterize risk of long COVID in commercially insured patients [12]. The addition of claims data enables better understanding of health care use, inequities in access to care and costs associated with long COVID, though quantifying the larger economic burdens and disparities requires incorporation of data sources outside the health care system.

While researchers with access to EHR data from large clinical networks or health systems may bypass some challenges below, many national and international EHR-based collaborations wrestle with similar obstacles.

Opportunities

CRNs provide several benefits for conducting clinical research. Most significantly, they unify patient data that may otherwise be distributed across multiple health care facilities and facilitate access to large sets of timely, longitudinal patient information. This enables broad hypothesis generation, signal identification, and feasibility analysis, which is highly advantageous for emerging conditions like long COVID as such analyses can be conducted at a scale, pace, and cost that surpass traditional research methods [13]. Because CRNs use data generated during health care delivery, they are also well-positioned to study how practices evolve in ways that directly impact patients. For example, EHR data can be used to evaluate uptake and patterns of use for new diagnostic codes introduced to capture long

XSL•FO
RenderX

COVID [14], ME/CFS, and postural orthostatic tachycardia syndrome (POTS).

To overcome the lack of semantic interoperability across EHR systems and facilitate analysis, most CRNs map source data to common data schemas, such as the Observational Medical Outcomes Partnership (OMOP) [15] or PCORnet common data models [16], which provide frameworks for data standardization and are optimized for large-scale longitudinal data analysis. The popularity and extensibility of common data models helped CRNs to quickly adapt them for novel disease research at the beginning of the pandemic [17]. Use of a common data model also enables distributed network queries and analyses behind institutional firewalls, as well as centralization of the data for advanced artificial intelligence and machine learning [18].

In a relatively short time, a large amount of scientific literature has been generated regarding the clinical characterization and epidemiology of long COVID, yet efforts to synthesize this body of research have been hampered by the inconsistency of methodologic approaches, study definitions, and findings. Research conducted using a shared infrastructure or data model promotes reproducible research and exchange of clinical and variable definitions that can be harmonized and tested across multiple health systems. For example, a recent collaboration between RECOVER and NIH's All of Us study demonstrated success in reusing long COVID definitions across OMOP data environments, enabling reproduction of N3C's definition within the All of Us database [19].

Along the same lines, CRNs are often well-positioned to foster multidisciplinary collaboration [20]. They have streamlined contracting and collaboration processes that expedite research while reducing regulatory burden, and can also provide an efficient vehicle for patient recruitment into prospective cohort studies and clinical trials.

Challenges

Some broad challenges come with using CRNs for population health research and may directly impact research into long COVID, where data quality, depth, and timeliness are crucial. These largely arise from the need to standardize data across multiple institutions, which may result in a loss of detail and context from the originating EHR [21]. For example, while the OMOP and PCORnet data models support documentation of patient cause of death and discharge disposition, not all do; furthermore, not all sites collect and report these data. Analyses can also be limited by not having information such as provider specialty, medication indication, or drug dosing consistently abstracted from the EHR. However, as described earlier, the extensibility of many common data models means that new concepts can be incorporated to close priority gaps.

Aggregating data within a CRN can mask important heterogeneity due to differences in how health systems and individual practitioners provide and document care. One example is the variation in how visit data are represented across individual health care facilities. The definition of an "encounter" in a given health system's data has more to do with business rules than clinical care; for example, some systems create a separate encounter record for each day of an inpatient stay, while others use a single record to capture the entire hospitalization. As most variables in EHR data are captured at the visit level, inconsistency in the definition of encounters can lead to errors when analyzing clinical observations. Thus, to accurately classify types of visits and to quantify visits across sites, careful standardization is required [22]. Ongoing governance, documentation, and input from data experts at contributing institutions are essential to bridge syntactic and semantic differences [21].

Timeliness of data delivery represents an additional challenge. While data from CRNs are generally rapidly available, there is still a latency from participating institutions. Data must be mapped, transformed, transmitted, quality checked, and potentially resubmitted with corrections, which takes time and collaborative effort. Delays may also result from the need to incorporate data standards for new concepts (such as the long COVID *ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*] code U09.9, which was not introduced until late 2021).

Finally, real-world data present specific limitations compared with traditional research data. These include data missingness, which has been described extensively [23] and can exist for various reasons (eg, patient discontinuation of care or data points not being systematically captured in EHRs). EHR data are also subject to biases like selection bias [24], where patients accessing care may be sicker, more likely to be insured, and able to take time off work and afford transportation [13,25]. Data from nonacademic institutions, and other settings that may lack robust data systems such as nursing homes, are often underrepresented in CRNs. Careful study designs, informatics-informed approaches to transforming raw clinical data into analytical datasets [26], techniques to supplement structured EHR data with items extracted from free text notes such as social determinants [27], and advanced statistical approaches are often required to minimize bias.

Identifying Patients With Long COVID Within EHRs

Overview

Robust case definitions are essential to disease surveillance, enabling consistent use of data from collection through analysis and across population subgroups, time, and geographic jurisdictions. However, Long COVID still lacks a uniform case definition, and multiple frameworks have emerged with varying timeframes and symptoms [25]. This is partly due to the heterogeneity of long COVID's clinical presentation, which includes substantial differences between adults and children [28] and hundreds of potential signs and symptoms. The National Academies of Sciences, Engineering, and Medicine's recent report A Long COVID Definition provides updated recommendations around diagnosis, noting that long COVID can impact any organ system; follow acute infection of any severity, including asymptomatic infection; be continuous from acute infection or delayed in onset; and present as incident or worsening, mild or severe, and persistent or intermittent [29]. These broad guidelines leave room for ambiguity, and as there

XSL•FO
RenderX

is no diagnostic test for long COVID, their application at the point of care involves clinical judgement, experience, and thorough differential diagnosis to establish probable causality.

Finally, we are still learning about long COVID's disease course and trajectory, how it relates to development of clinical conditions such as diabetes, kidney disease, and POTS, and how its characteristics may evolve over time. While these complexities underlie all long COVID research, EHR-based research is particularly well-positioned to inform and validate potential definitions.

Opportunities

Researchers working with EHR data operationalize case definitions by creating computable phenotypes, which algorithmically identify cohorts of interest within an EHR system [30]. Generating, adapting, and validating computable phenotypes can be complex, even for well-characterized diseases and conditions, so multiple approaches for identifying patients with long COVID have evolved both nationally and internationally. These include building computable phenotypes using "rules-based" approaches or prespecified logic-based queries to search for specific criteria such as diagnosis codes, medications, or laboratory results based on clinical literature and expertise [31-33], and data-driven or inductive approaches, including machine learning (ML) to automatically classify long COVID without detailed prespecification of the inclusion or exclusion criteria [34,35]. These approaches can also be combined, leveraging insights from ML to shape rules-based definitions.

The lack of a formal case definition, limited SARS-CoV-2 testing information, and large amounts of rich longitudinal data within EHRs make ML approaches particularly attractive. Supervised ML models can be trained on sets of patients that are certain or highly likely to have long COVID, such as patients assigned a long COVID diagnostic code, and then used to identify patients with probable long COVID who may not have a documented or readily recognized diagnosis [35]. ML and other statistical approaches have also been applied to recognize incident diagnoses that appear more frequently in cohorts with a recent history of COVID-19 infection than those without [36,37].

Although the EHR does not capture every case (or every recurrence) of acute SARS-CoV-2 among its patients, there is still significant opportunity to use EHRs to study the potential effect of SARS-CoV-2 reinfection on risk of long COVID among those patients with multiple recorded cases. Hadley et al [38] found that across SARS-CoV-2 variants, the incidence of new long COVID diagnoses after reinfection is lower than after the initial SARS-CoV-2 infection. Bowe et al [11] found that though risk is lower with more recent variants, it is cumulative across infections. As multiple reinfections become more common, there will be continual opportunities to reevaluate these findings in the context of new variants and subvariants.

Both rules-based and ML techniques are being used to identify potential clusters or subphenotypes of long COVID [39-41]. For example, an analysis by Zhang et al [41] identified four distinct subphenotypes (including cardiac and renal, musculoskeletal, and nervous system) and specific risk predictors for each. Clustering analyses may uncover diverse symptoms that have common biological causes, and in establishing distinct groupings around them, facilitate diagnosis and treatment targeted toward specific subtypes [42].

Challenges

Within the EHR, Long COVID may not be well-documented due to diagnostic complexities, as described earlier. The initial focus among clinicians on respiratory symptoms and widespread lack of knowledge around what were initially considered to be "atypical" presentations, such as postexertional malaise, ME/CFS, POTS, and dysautonomia, also contribute to missingness of relevant diagnoses within the EHR [43], which is compounded by the absence of or delay in introduction of *ICD-10* codes for many of these conditions, including the U09.9 code for long COVID itself**.** Such manifestations can significantly impact daily function but may not be considered attributable to previous COVID-19 infection (or misdiagnosed as mental health issues), leading to their underrepresentation in research [43].

Health care professionals may be subject to implicit biases that impact documentation of patient information (eg, social determinants and symptoms) within the EHR [24]. This may also lead to underestimation of long COVID for certain populations, such as racial or ethnic minorities. Indeed, U09.9 diagnostic codes have been found to be more common among patients that are non-Hispanic White and living in areas of low poverty compared with the overall COVID-19–positive population, potentially reflecting differences in access to care and other interactions with the health care system [14]. Although we found value in using visits to a long COVID clinic as an early proxy for a long COVID diagnosis code [35], both of these markers have biases and should not be considered a gold standard for long COVID identification [44]. There is also substantial need to complement patient-reported symptoms with clinically characterized ones [45] so that physicians are not "gatekeepers" of documented symptoms.

Given that long COVID is likely underdiagnosed and underdocumented, computable phenotype algorithms must supplement formal U09.9 diagnoses with other patient data following acute SARS-CoV-2 infection. However, identifying acute infections is also not straightforward. Diagnosis codes such as the ICD-10 code U07.1 have demonstrated variable sensitivity and positive predictive value [46,47], which may be exacerbated by "rule out" diagnoses or improper coding. Even when diagnoses are correct, the true timing of the initial infection with respect to the date of the diagnosis code may be uncertain [44], and we found this to complicate EHR-based calculations of long COVID incidence. Limited availability of SARS-CoV-2 testing during the early phase of the pandemic, widespread testing at nonclinical settings (eg, kiosks and pharmacies), and the later popularity of at-home tests have all contributed to low confidence in accurately capturing SARS-CoV-2 infection (and reinfection) history within the EHR, and amplified potential misclassification of long COVID patients without documented acute COVID-19 infection. We

XSL•FO
RenderX

note, however, that misclassification of patients as uninfected is an issue that extends beyond EHR-based studies [48], broadly impacting long COVID research.

ML methods are also subject to obstacles, including the lack of a validated test set for long COVID and dependency of results on the training set used, which may limit reproducibility (although, as demonstrated by the collaboration between RECOVER and All of Us, ML algorithms can be replicated in new environments) [19]. ML models must be interpretable, so predictions can be explained instead of only existing within a "black box."

Determining Risk Factors for Long COVID Using EHRs

Risk factors for long COVID include demographic characteristics, lifestyle behaviors, underlying comorbidities, and social and environmental factors. Identifying risk factors can guide screening and prevention efforts, particularly in highly susceptible groups, and potentially facilitate tailored long COVID treatments.

Opportunities

EHR-based studies are primed to quickly reveal possible associations and risk factors for conditions like long COVID due to large volumes of available data and ability to stratify by various subgroups. For example, Rao et al [28] leveraged PEDSnet's geographical and clinical breadth to identify risk factors such as age, severity of acute COVID-19 infection, and comorbid conditions. Potential biological variables that are well-defined in EHRs and therefore, more reliably available for application in adjusted analyses include age, sex, BMI, and blood pressure, and, indeed, these variables have been shown to confound the evaluation of causal pathways for long COVID [49-51].

Where data of interest are missing from the EHR, linkage to external sources can increase data quality and completeness. Statewide vaccination or vital record data can be acquired and linked at the patient or area level to enhance the accuracy of vaccine status and COVID-19 outcomes [52,53]. Linkage with geographic information systems (GIS) can address questions about complex networks of long COVID burden that pertain to certain geographic regions, including the so-called "exposome" [54] even down to ZIP codes and neighborhoods [13,14]. Patient-reported outcomes from patient portals and surveys can improve the completeness of information on demographic, social, and behavioral factors such as race, ethnicity, substance use, exercise frequency, and smoking status [13,55]. To enhance completeness of data such as outpatient medication use, linkage to claims data can be an effective strategy. Data of interest may also be captured within free-text clinical notes, images, and other scanned documents, requiring application of natural language processing tools, including cutting-edge language models [27], or manual chart review to incorporate them.

Within EHR-based studies, several analytic approaches can address confounding and effect modification and help measure mediating influences. Researchers can match comparison groups using various approaches, including propensity scores for known confounders. In addition, causal mediation analysis methods may more accurately explain observed associations between risk factors and long COVID development.

Designing studies with appropriate comparison groups for analyses of risk factors can be challenging. If comparison groups are matched too closely, relevant differences in concurrent risk factors and outcomes may be masked. If groups are not matched well enough, then the impact of confounders may overwhelm the ability to detect differences associated with the characteristic of interest. Researchers using real-world data can conduct sensitivity analyses under different assumptions of risks and outcomes. For example, Hill et al [56] leveraged 3 different control groups and 2 definitions of long COVID to enhance an investigation of risk factors within N3C. This agility is especially useful with a novel condition such as long COVID, where our understanding is rapidly evolving. Comparison groups can be iteratively modified, and analyses rerun as new information or criteria emerge.

EHR data, especially within the context of a CRN, also facilitates the study of risk factors within rare populations and subgroups (eg, peoples indigenous to the United States). Such groups often experience a disproportionate burden of COVID-19 complications due to socioeconomic and structural factors [51,57], but are generally not well-represented in prospective studies and randomized controlled trials [58]. EHR data can similarly help overcome the methodological constraints and recruitment challenges of rare disease research [13], providing an opportunity to study rare conditions and outcomes and facilitating clinical trial cohort selection.

Finally, EHRs provide rich datasets for pragmatic clinical trials and target trial emulation to identify potential therapies [59,60]. For example, there is inconclusive data on the efficacy of Paxlovid for preventing or treating long COVID [61]; novel approaches such as target trial emulation using EHR data can help evaluate its efficacy and determine which patients should be prioritized for treatment based on risk factors for severe long COVID subphenotypes. The ability to quickly evaluate and personalize potential treatments is highly advantageous given the large burden of long COVID and its heterogeneous presentation. Because target trial emulation better reflects real-world medication adherence (or application of other interventions), comparing the results of emulated and clinical trials, and examining how the methods and populations differ, may yield insights into generalizability of clinical trial results and sources of bias within observational analyses.

Challenges

Limitations outlined earlier, such as data missingness, selection bias, and implicit biases, can directly impact the ability to evaluate risk factors using EHR-based analyses. Potential risk factors can be rigorously evaluated if well-defined and well-captured, but many important risk factors may not be completely, meaningfully, or consistently recorded within the EHR.

For example, race and ethnicity are important demographic risk factors for long COVID [51], but these data can be missing in

XSL•FO
RenderX

over 25% of patient records [55,62]. Lack of robust, structured data on social and behavioral determinants of health, such as physical activity levels, smoking status, and alcohol use [13,51,62] may necessitate supplementation with survey results or data extracted from clinical notes as described above. EHR-based assessments of symptom severity and improvement may also be of limited use without these approaches.

Imperfect data capture also impacts our ability to establish proper comparison groups. This notably includes the shrinking population of patients without previous SARS-CoV-2 infection [63]. In addition to being challenging to identify, control patients identified by negative lab tests may actually be in worse health than those with mild COVID-19 infection, likely due to routine testing of patients within the emergency department or inpatient settings. Another example applies to our work examining obstructive sleep apnea (OSA) as a risk factor for long COVID [64]. A comparison group of patients ostensibly without OSA may include some with undiagnosed, subclinical, or undocumented OSA, and sizable numbers of misclassified patients would lead to underestimation of effect size on long COVID. Similarly, slight improvements in recognition of ME/CFS throughout the pandemic may have resulted in some individuals with prepandemic long COVID–like symptoms (eg, unrefreshing sleep and postexertional malaise) having their illness misclassified as SARS-CoV-2–related. Appropriate comparison groups must be carefully considered.

The pandemic disrupted typical health care use and documentation patterns. Clinic closures and reduced access to specialty care may have masked diagnoses of chronic conditions and comorbidities and led some patients with long COVID, particularly those with milder presentations, not to seek care. This biases EHR data, especially from the first year of the pandemic, toward underascertainment of health issues; prepandemic controls (who we can say with certainty have not had COVID-19 infection) may have higher rates of clinical events than pandemic-era patients. Similarly, research about the effectiveness of vaccinations in reducing the risk of long COVID is hampered by widespread distribution in nonclinical settings [65] and reinforces the importance of ongoing data exchange between EHRs and vaccination registries in addition to dedicated linkage efforts.

These challenges also apply to potential confounding, which is particularly important within observational research on risk factors and causal mechanistic pathways for long COVID. Certain potential confounders, such as age or underlying health conditions, are easier to adjust for than others. The severity of acute COVID-19 infection, which appears in some studies to be directly associated with the risk of developing long COVID [49,50,66], is a particularly illustrative example. More severe COVID-19 infection, whether it results in hospitalization or not, may result in increased frequency of diagnosis and monitoring of long COVID and higher data density for affected patients within the EHR. These biases may contribute to the underrepresentation of asymptomatic, mild, or moderate acute COVID-19 infections, as well as greater clinician awareness of long COVID in the context of severe illness (although most cases occur among nonhospitalized patients) [43]. Analyses stratified by acute illness severity are important to differentiate between nonhospitalized and hospitalized patients.

Discussion

As SARS-CoV-2 and our susceptibility to infection evolve, sustained research efforts are needed to build our knowledge of long COVID and evaluate its presentation over time. Within a short timeframe, the use of EHR networks to study long COVID has grown rapidly, nationally and internationally. The immediate need to advance our understanding of long COVID must be balanced with a thoughtful methodological approach that leverages the many strengths of EHR data while recognizing their limitations. EHRs have been used to characterize long COVID and its subphenotypes [14,32,40,41,45], estimate its burden [28,67], identify risk factors [49-51,66], and evaluate SARS-CoV-2 vaccine efficacy for long COVID prevention [8,53,68]. Although we anticipate that the breadth and rigor of this research will increase as computable phenotypes improve through iterative validation and data linkage becomes more extensive, several innovations to effectively wield EHR data, such as improved accuracy and consistency of recording of long COVID-specific diagnoses, application of ML to identify patients with long COVID and harmonized data analyses across CRNs, have already begun increasing the capacity of investigators to study long COVID and, importantly, augment research on long COVID subphenotypes.

EHRs can be instrumental in supplementing randomized controlled trials to evaluate treatments and preventative strategies such as vaccinations, but novel approaches such as target trial emulation have not yet widely extended to long COVID. Increased data linkage to vaccination registries, survey data, and other sources can further enrich EHR-based analyses, providing more complete patient outcomes and medical history data. As recruitment into prospective RECOVER studies increases, efforts are underway to link EHR data with participant study data, enhancing both datasets for validation and analysis.

We envision a near future where the mutual benefits of clinical and real-world data research collaborations have been optimized for synergistic learning. EHRs can identify study participants and generate hypotheses that can be prospectively tested. They can also inform clinical trial feasibility, generate preliminary data around specific populations, therapeutics, and outcomes of interest, and inform the interpretation of clinical trial results through trial emulation. However, strengthening this interchange will require new workflows, collaboration, and time.

We caution that despite the dedication of the research community and high expectations for EHRs to quickly advance our understanding of long COVID, sustained, collaborative efforts are needed for this work. New treatments and vaccines are still being introduced, requiring process modifications for extraction and standardization of data. Complex clinical traits require careful development of computable phenotypes and rigorous data quality evaluation to identify specific misclassification risks. Continued coordination is necessary to converge upon reliable, repeatable insights and yield effective strategies for long COVID.

Abstract

This article aims to introduce emerging measurement domains made feasible through the electronic health record (EHR) use metadata, to inform the changing landscape of health care delivery. We reviewed emerging domains in which EHR metadata may be used to measure health care delivery, outlining a framework for evaluating measures based on desirability, feasibility, and viability. We argue that EHR use metadata may be leveraged to develop and operationalize novel measures in the domains of team structure and dynamics, workflows, and cognitive environment to provide a clearer understanding of modern health care delivery. Examples of measures feasible using metadata include quantification of teamwork and collaboration, patient continuity measures, workflow conformity measures, and attention switching. By enabling measures that can be used to inform the next generation of health care delivery, EHR metadata may be used to improve the quality of patient care and support clinician well-being. Careful attention is needed to ensure that these measures are desirable, feasible, and viable.

Introduction

Since the widespread adoption of electronic health records (EHRs) following the enactment of the Health Information Technology for Economic and Clinical Health (HITECH) Act, clinical care is increasingly mediated by health information technology (HIT) [1]. The digitization of health care has enabled not only the capture of more clinical data for use in clinical research [2], but also metadata about how those data are produced and used, giving a window into the process of health care delivery [3-7].

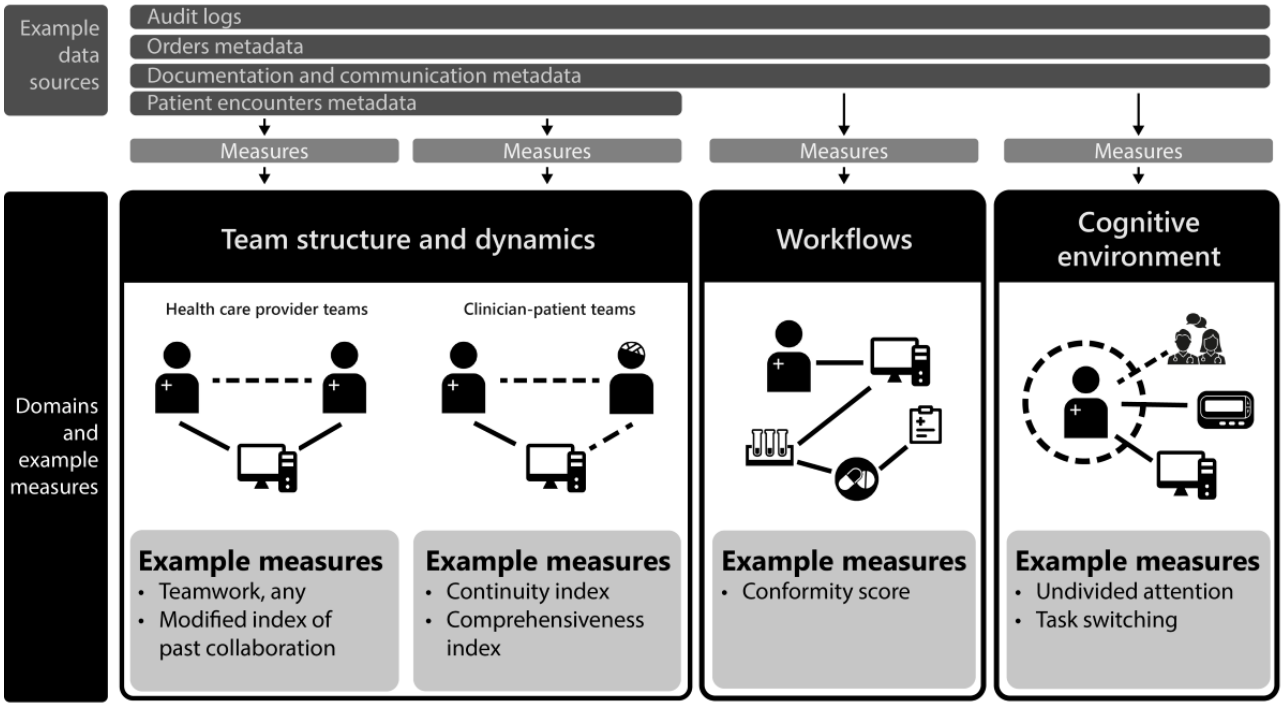
Established health care metrics focus largely on the patient process and outcome measurements (eg, health maintenance screening and preventable admissions) or outcomes for individual health care workers (eg, turnover and professional burnout). While these measures reflect important outcomes of a complex health care system, they do not reliably indicate upstream aspects and contextual factors of health care delivery, which may be leveraged to improve patient and clinician outcomes. EHR use metadata (eg, audit logs, orders metadata, documentation and communication metadata, and patient encounters metadata) contain valuable details on the complex system in which health care is delivered, with early insights primarily focused on discrete action or time-based measures [8-15].

This paper describes 3 examples of emerging domains of measurement through EHR use metadata, identified through a series of workshops facilitated by the Measures Workgroup of the National Research Network for EHR Audit Log Data [16]. These domains, health care teams, workflows, and cognitive environments, may provide a clearer understanding of modern health care delivery. We expect the value of these measures to outweigh the resources required to develop them, informing the next generation of health care delivery that improves both the quality of patient care and supports clinician well-being.

Data and Data Sources

Traditional sources of health care delivery data (eg, time and motion studies, surveys, or administrative claims) [17,18] often require high resource expenditure to capture accurately and in detail. In contrast, continuously collected EHR use metadata can facilitate widespread measurement of several domains of health care delivery [4,7,13], providing valuable data that otherwise would require direct observations that are virtually impossible to collect at scale or for extended durations [19].

At a more granular level, EHR audit logs and other event logs offer a detailed account of actions that took place within the EHR at what time and by whom [20], enabling exploration of the "path" that a clinician or team took in the EHR to complete that task. In turn, these details can be used to delineate certain workflows or team structures contributing to task efficiency and clinical outcomes, which may be the result of vendor-derived or investigator-derived measures [21]. Such approaches have been described for a variety of EHR vendors, clinical scenarios [12], methodologies [22], and health professions [23].



Although metadata are not identical across EHR vendors, and institutions often have differing customizations and third-party modules, commonalities among metadata structures make it feasible to normalize measures across institutions with sufficient considerations. In addition, recent studies from 2 of the largest EHR vendors suggest that clinician variation far exceeds organizational variation [24,25], indicating that metadata-derived EHR use measures are more reflective of individual workflows than organizational configurations. We posit here that these new horizons of measurement warrant dedicated development and prioritization of the key clinical and operational questions for which EHR use metadata can be brought to bear.

Principles of Domain Measurement

Innovative ideas need to be feasible, viable, and desirable to be successful [26]. While originally developed for commercial products, this framework can also guide EHR measure development. First, EHR use metadata to enable new measures of health care delivery that are technically feasible but also require proof that such measures are valid and reliable. Second, analyzing EHR metadata takes less time and money than many other methods of observing health care delivery, but measurement schemes based on EHR metadata still need to prove their viability (providing more value than the effort required to produce them) by generating insights that tangibly improve care [27]. Finally, measures need to be desirable, aligning with human values and providing insight into phenomena people care about. Desirable measures may answer research questions, contribute to more efficient and reliable single-center cross-sectional or longitudinal operational and quality reporting [28], or facilitate multi-institutional comparisons. This perspective demonstrates that, in health care delivery, these phenomena include not only how people spend their time but also how they interact (team structure and dynamics), organize their work (workflows), and direct their attention (cognitive environment; Figure 1) [9,21,29-33].

XSL•FO
RenderX

Figure 1. Emerging domains of measurement: team structure and dynamics, workflows, and cognitive environment, with example measures for each.

Making decisions based on social measures is fraught with risk, with a natural tendency to focus on what is easiest to measure (feasible) rather than what is most useful (viable) or meaningful (desirable) as an indicator of high-quality processes or outcomes [34]. Yet, most measures are only rough proxies for more complex phenomena, and improving the measure (eg, patient satisfaction scores) may not improve the phenomenon of interest (eg, patient satisfaction) [35]. Furthermore, poor selection of a proxy can promote bias (eg, using predicted health care costs as a proxy for clinical risk underestimates the needs of those with less access to care [36]), and measures used for social decision-making are more likely to be gamed [37].

These risks do not require that we avoid measuring health care delivery. As statistician George Box observed, "Essentially, all models are wrong, but some are useful" [38]. Developing useful measures while acknowledging the ways in which they are wrong requires careful attention to the social aspects of what cannot be easily measured and the unintended consequences of putting such measures into practice [39]. Here we describe 3 domains of health care delivery where EHR use metadata measures may be feasible, viable, and desirable, though not without risk.

Measuring Team Structure and Dynamics

Most patient care is delivered through teams of nurses, medical assistants, technicians, pharmacists, physicians, and many other staff members all of whom are integral to care delivery and outcomes. Fortunately, a byproduct of EHR auditing requirements means that EHR use metadata record details on both the clinicians and patients for whom they perform actions, making it feasible to reconstruct team structures and dynamics. This can be viewed as (1) clinician-centric models of health care provider teams, and (2) patient-centric models of clinicians involved in their care (synchronously and not), recognizing that each feeds back on the other through complex relationships. Identifying these team structures relies on inference based on shared patient access, physical locations of EHR access, temporal proximity, or direct communication records [21,40].

Health Care Provider Teams

EHR uses metadata in relation to defined team structures to allow investigation into patterns of how health care teams interact with each other. The "strength" of team structure can then be weighted (eg, through repeat interactions) to quantify team familiarity that might promote shared mental models that are essential for effective teamwork.

Researchers have the opportunity to consider the timing, intensity, and content of team-based interactions as proxies for effective teamwork. This requires a robust understanding of how EHR-based teamwork takes place in a broader framework of in-person and HIT-mediated collaboration, allowing for variance in the phenotypes of team collaboration that can reliably still be associated with provider satisfaction and patient care quality [41]. This work also requires the development of outcome measures more sensitive to the quality of team collaboration, such as care delays or therapy cycling. Valid and reliable understanding of the connections between team structure, processes, and outcomes is foundational to each measure's viability and desirability, insofar as it supports health care managers in making operational decisions and designing institutional supports that enhance team collaboration and quality of care [42].

Clinician-Patient Teams

The clinician-patient relationship is the cornerstone of health care provision, yet many essential measures of this relationship have been prohibitively difficult to measure at scale before the

XSL•FO
RenderX

emergence of EHR use metadata. For example, continuity of care is associated with patient satisfaction and a host of improved outcomes [43,44], attributed to the trust and knowledge in the clinician-patient relationship that supports tailored evaluations, accurate diagnosis, customized treatment plans, and increased medication adherence. EHR use of metadata has made more nuanced measurements in this domain feasible because system-wide records of all clinician-patient interactions now enable quantifying repeated interactions with the same clinician at a more granular level than visits, procedures, or diagnoses. These records include asynchronous messages through patient portals and documentation of telephone encounters. With the addition of domain knowledge, these detailed metadata also enable assessments of the appropriateness of a patient's encounters with primary care versus subspecialty care. These concepts of continuity of care [45-53] and comprehensiveness [31,54,55] are particularly viable and desirable as they may help physicians and operational leaders optimize care to achieve the quintuple aim [27,56] goals of quality, cost, satisfaction, patient and care team experience, and equity.

Through improved measures and stakeholder engagement, health care systems can work to optimize the relationship between clinicians and patients, to promote health care that is not only more effective and efficient but also more satisfying and rewarding for both clinicians and patients.

Health care team structure and dynamics are complex and not fully reflected within EHR use metadata, raising important limitations. The balance between HIT-facilitated and in-person interactions varies among settings, with important implications for the validity of extrapolating teamwork measures from EHR use metadata within a particular use case. In addition, value judgments on the appropriateness or quality of a particular team structure or clinician-patient interaction require additional clinical and system knowledge, much of which is not readily available within EHR data or metadata.

Measuring Workflows

EHR audit logs and other event logs contain records of timestamped granular interactions with an EHR as part of larger clinical tasks (eg, refilling a prescription or ordering bloodwork), making feasible large-scale identification of common pathways for routine clinical practices [32]. These pathways may then be evaluated for relative time spent on clinical tasks, the complexity of action sequences, engagement with decision support, variation for particular workflows, specialties, providers, or combinations of these (eg, variation in outpatient ordering workflow among physicians within 1 clinic) [57].

To be viable and desirable, workflow measures must account for the tension between unnecessary and necessary deviations of behaviors from the norm [58]. Reducing unnecessary deviations can improve efficiency and patient safety through standardized best practices [59,60]. For example, heterogeneity in physician work with medical scribes may negatively impact physician efficiency [61]. While highly variable stroke care pathways may result in therapeutic delays [32]. Yet, enabling necessary deviations from the norm may promote tailored approaches to unique or complex scenarios, promoting clinician autonomy, professional satisfaction, and precision medicine.

Key to this measurement domain is the risk of misclassifying an unhelpful workflow as "normative" or a necessary variation as "deviant," highlighting the importance of establishing clinical expertise, stakeholder buy-in, and relationships to important outcomes in the development and deployment of any workflow measures. In addition, although efforts at automated task identification within audit log data have been made [22,62,63], the diversity of clinical workflows makes reliable task identification challenging. Furthermore, due to differences in actions and tracking methods available in particular EHR instances, such measures may be poorly generalizable outside of an institution or EHR vendor unless carefully designed to be context-agnostic and may require recalibration over time with new technologies (eg, large language models and generative artificial intelligence), clinical approaches, or software functionality.

Measuring Cognitive Environment

Clinical work is cognitively complex; clinicians must synthesize ever increasing amounts of information to make diagnosis and treatment decisions amidst competing demands for their attention. Cognitive overload, which has been linked to errors and burnout, can occur easily in such environments [64,65]. Because clinical work is largely mediated by the EHR [66], EHR use metadata offers opportunities to measure clinician cognitive load at scale without laborious data collection. These measurements are critical for understanding how the clinical cognitive environment can be improved.

Cognitive load includes an intrinsic component related to the complexity of a particular task (eg, patient complexity), and an extrinsic component related to the work environment (eg, interruptions, poor EHR, or workplace design [67]). Both components may be feasible to measure using EHR use metadata. For example, intrinsic cognitive load can be approximated using audit log–derived measures of patient load [11,68], EHR time [69], and encounter or task complexity [70]. Extrinsic cognitive load is more challenging to measure; while some interruptions like secure messaging use can be observed directly within domain-specific or third-party event logs [71], many occur outside of HIT. Instead, efforts have focused on capturing task fragmentation [72,73], such as attention switching [74] or undivided attention [9,33,65,67,74-83].

While this domain has considerable promises, there are several barriers to progress. Few of the audit log-derived cognitive load measures have been validated using established instruments from the cognitive science literature (eg, surveys like the NASA-TLX [National Aeronautics and Space Administration–Task Load Index] or physiological measurements like pupillometry) [84]. In addition, difficulties with the related concept of task identification limit the ability to subsequently measure task fragmentation, with further validation of task identification needed before task fragmentation can be reliably measured.

XSL•FO
RenderX

Conclusion

EHR uses metadata to provide remarkable potential for measuring and improving health care delivery by making feasible previously inaccessible insights. By measuring team structure and dynamics using intersecting metadata on clinician EHR use, health care provider teams may be studied and optimized and clinician-patient teams can be improved to prioritize continuity of care and comprehensiveness where appropriate. Health care workflows may be better understood through better identification of tasks and measurement of paths taken to achieve them. Finally, proxies of cognitive load may be measured, to inform interventions to reduce overload and the resultant risks for burnout and medical errors. Each of these measurement domains will require further tuning to fully realize their promise of improving health care delivery through sustainably scalable measurement.

Acknowledgments

Abstract

Health communication and promotion on the internet have evolved over time, driven by the development of new technologies, including generative artificial intelligence (GenAI). These technological tools offer new opportunities for both the public and professionals. However, these advancements also pose risks of exacerbating health disparities. Limited research has focused on combining these health communication mediums, particularly those enabled by new technologies like GenAI, and their applications for health promotion and health disparities. Therefore, this viewpoint, adopting a conceptual approach, provides an updated overview of health communication mediums and their role in understanding health promotion and disparities in the GenAI era. Additionally, health promotion and health disparities associated with GenAI are briefly discussed through the lens of the Technology Acceptance Model 2, the uses and gratifications theory, and the knowledge gap hypothesis. This viewpoint discusses the limitations and barriers of previous internet-based communication mediums regarding real-time responses, personalized advice, and follow-up inquiries, highlighting the potential of new technology for public health promotion. It also discusses the health disparities caused by the limitations of GenAI, such as individuals' inability to evaluate information, restricted access to services, and the lack of skill development. Overall, this study lays the groundwork for future research on how GenAI could be leveraged for public health promotion and how its challenges and barriers may exacerbate health inequities. It underscores the need for more empirical studies, as well as the importance of enhancing digital literacy and increasing access to technology for socially disadvantaged populations.

internet; generative AI; artificial intelligence; ChatGPT; health communication; health promotion; health disparity; health; communication; internet; AI; generative; tool; genAI; gratification theory; gratification; public health; inequity; disparity

Background

Health communication on the internet has continually evolved, driven by technological advancements [1-4]. Over time, the public, along with health researchers, practitioners, and organizations, have increasingly embraced these technologies for diverse health-related purposes. The emergence of generative artificial intelligence (GenAI) represents a revolutionary development in health communication and public health promotion. GenAI, a novel communication tool, mimics human responses during follow-up inquiries. Its conversational nature is particularly advantageous for health communication, enabling it to address various health inquiries, deliver customized health information, provide education, offer consultations, assist in

XSL•FO
RenderX

disease diagnosis, simplify complex health reports, and translate health-related questions into multiple languages [5-7].

However, challenges such as accuracy, skill requirements, and access barriers persist with this technology [8-11]. GenAI operates on a large language model (LLM) built from publicly available data sources, including Google, Wikipedia, and GitHub [12]. As a result, the outputs generated by GenAI should be approached with caution to mitigate potential health risks. The quality of AI-generated results depends on the user's ability to develop effective prompts, input accurate text for inquiries, and access advanced features through subscriptions. Consequently, individuals with limited health literacy, insufficient prompt development skills, or an inability to afford premium subscriptions may miss out on these technological benefits, potentially exacerbating health disparities.

Earlier studies have examined the internet as a medium for health communication across various contexts, including persuasive health messaging via the World Wide Web [1], web-based consumer health information [13], the role of Web 2.0 in health and education [2], the internet's role in health interventions [14], the use of social media for health promotion and behavior change [15], and the integration of mobile devices in health care and interventions [16]. Additionally, a comprehensive review of social media apps and their purposes has been conducted [17]. However, recent technological advances, such as wearable devices, the Internet of Things, blockchain, and GenAI, present new opportunities as health communication mediums. Research combining these latest technologies as health communication tools and examining their applications for health promotion and understanding health disparities remains limited.

To address this research gap, this viewpoint adopts a conceptual approach by integrating existing literature and targeted web searches [4,13,18] to provide an updated overview of health communication mediums and their role in understanding health promotion and disparities in the GenAI era. Additionally, health promotion and health disparities are briefly analyzed through the lenses of the Technology Acceptance Model 2 (TAM2) [19], the uses and gratifications theory [20], and the knowledge gap hypothesis [21].

This conceptual study is organized into three sections as follows: (1) a brief overview of internet-based communication mediums and their health promotion practices, (2) the digital divide on the internet, and (3) health promotion and health disparities in the era of GenAI.

Health Communication Mediums on the Internet

The internet has become a vital medium for health communication in the era of Web 2.0 [22], evolving across various domains such as social media [17,23], mobile health [24], the Internet of Things [25], blockchain [26], wearable devices [27,28], and, more recently, GenAI [12]. These mediums also include health websites [13], health forums and communities [29], health-related webinars and podcasts [30,31], telemedicine [32,33], electronic health records [34], voice assistants [35,36], and augmented and virtual realities [37], all of which support a wide variety of health promotion practices and research [13].

Internet-based resources offer numerous features for persuasive communication aimed at promoting health behavior [1]. Therefore, an updated list of these communication mediums and their potential for health promotion practices are presented in Table 1, serving as a valuable resource from a health communication perspective.

XSL•FO
RenderX

Table 1. Major health communication mediums and their potential for health promotion practices.

Web-based health communication mediums	Potentiality	Health promotion practices (examples)
Web 2.0	Interactivity (eg, chat rooms, emails, and hyperlinks)	Responsive user interface; provision of rich content including text, images, and videos; and reusability and collaboration opportunities
Health websites	Featured health content (eg, health articles, audios, videos, images, and infographics)	Mayo Clinic, WebMD, and Centers for Disease Control and Prevention
Social media	Networking (eg, social support, community development, knowledge sharing, and doctor-patient interactions)	X, Facebook, WeChat, YouTube, WhatsApp, and Instagram
Health forums and web-based communities	Groups with common health interests (eg, mutual support, discussion of common problems, patient empowerment, anonymity, and emotional support)	ParkinsonNet, COPD.com, and PatientLikeMe
Health-related webinars and podcasts	Health knowledge dissemination through live sessions or on demand (eg, narrative communication and health education)	Cancer Council Victoria, Hidden Brain, The Blindboy Podcast, and The Two Norries
Mobile health	Easy and on-the-go access to information (eg, web browsing, audio and video calls, and text messaging)	Cellphones, smartphones, and smartphones with specific software or apps
Telemedicine	Health services provided remotely (eg, using telecommunication technology for doctor-patient communication)	Physicians, nurses, and other allied health professionals
Electronic health records	Patient health records stored in computer hard drives or web-based servers (eg, easy access from anywhere for multiple parties, and easy for health decisions and diagnosis)	Physicians, insurance companies, and patients
Blockchain	Digital ledger (eg, secured data storing and exchange platform)	Health care industry and electronic health record researchers
Voice assistants	Conversational assistance (eg, health information inquiry with voice)	Amazon Alexa, Google Home, Google Assistant, Apple Siri, and Samsung Bixby
Wearable devices	Health monitoring and remote health services (eg, glasses, smartwatches, and suits)	Emergency medical service providers, family members, patients, public, and clinicians
Augmented reality and virtual reality	Enhanced views combining real and digital objects (eg, health education, training, and assessment)	Health care industry
Internet of Things	Connectivity and automation (eg, collecting, sending, receiving, storing, and measuring data of anyone, anything, anytime, any service, in any network)	Health care and health management
Generative artificial intelligence	Humanlike interaction digitally (eg, content generation regarding text, image, audio, video, synthetic data, and code)	Public, health care industry, health professionals, and researchers

Digital Divide on the Internet

The opportunities for web-based health communication also contribute to the digital divide. The internet serves as a vast resource of health benefits for many who seek health information and use it for health purposes, depending on their access, skills, usage, and participation [38,39]. Educated, older, and tech-savvy individuals benefit the most from the internet for health-related purposes [38]. However, health content contributed by individuals without professional health knowledge or training creates complexities in finding reliable information. This can harm those who lack the ability to evaluate the credibility of information or its sources, as much of the web-based health content available is incomplete, misleading, or difficult to understand [39].

Today, people encounter misinformation in various ways, such as through search engines (eg, random searches on Google and Yahoo suggesting links based on top-matching results), visiting specific health websites (eg, the quality of information depends on whether the person is visiting a reputable site like WebMD), relying on user-generated content from social media or other websites (eg, Facebook, Twitter, Wikipedia, and Yelp), and using mobile apps that may not adhere to established medical guidelines [40]. Certain health topics are particularly susceptible to misinformation on social media, including vaccines, drugs and smoking, noncommunicable diseases, pandemics, eating disorders, and medical treatments [41].

Traditionally, the digital divide has been understood in terms of physical access to the internet, which depends on factors such as age, education, income, perceived health, and social isolation [42,43]. However, the digital divide for health purposes has widened due to low levels of health literacy (eg, the ability to understand, appraise, and use web-based information for health purposes) and inadequate internet use skills (eg, browsing and content-related skills), which are more prevalent among hard-to-reach communities. Non-English speakers, who make up around 13% of the US immigrant population, are less likely to use the internet for health purposes [44]. For example, the use of telemedicine for primary care visits by patients with limited English proficiency and digital access decreased

XSL•FO
RenderX

proportionately in New York City during COVID-19 [45]. Such digital divides may further worsen during new waves of technological advancement, such as GenAI.

GenAI: Health Promotion and Health Disparity

Overview

GenAI presents a significant opportunity for health promotion and may have a revolutionary impact on the health care system by leveraging vast amounts of medical data and knowledge to support medical decision-making, patient communication, health education, and data management [7]. However, it may also contribute to health disparities due to limited access, insufficient prompt development skills, and low health literacy among many populations [44].

This section provides an overview of the major GenAI channels, their potential for health promotion, and how their limitations, particularly lack of access and skills, may exacerbate health disparities.

GenAI and Health Promotion

Application of GenAI

GenAI is poised to transform content creation across text, image, audio, and video formats [46]. Its ability to generate humanlike responses based on prompts has created new opportunities for health promotion. Potential users of these tools include the general public, health researchers, practitioners, and health organizations [5-7,17].

A variety of GenAI tools are currently available, each with a specific focus, such as text generation, and audio, video, and image creation [5,9,46-50]. Table 2 provides a brief overview of some notable GenAI channels, their potential uses, target users, and the skill requirements for health-related purposes.

Table 2. Generative artificial intelligence (GenAI) channels and their potential use, users, and skills requirement for health purposes.

GenAI channels	Use	Users	Skills
Text generation			
ChatGPT	Humanlike conversation (eg, personalized health information, answering health-related questions, interaction with chatbots, and facilitating patient-provider communication)	Individuals, health educators, caregivers, and health organizations	Prompt development skills (eg, knowledge of medical terminology, patient communication principles, and using empathy in responses)
Gemini	Visual content creation from textual descriptions (eg, health literacy and health education)	Individuals, health care educators, health organizations, medical illustrators, and health communicators	Prompt development skills, medical concepts, and visual communication techniques
Microsoft Copilot	Development of health-related software apps and digital tools	Health IT professionals, software developers, and digital solution providers	Prompt development skills, knowledge of health care standards, Health Insurance Portability and Accountability Act compliance, and user interface and user experience design principles
Jasper	High-quality, text-based content generation (eg, blog posts and social media posts)	Content creators, patient educators, and health organizations	Prompt development skills, understanding health topics, medical knowledge, and ethical considerations
Image, audio, and video generation			
DALL-E 3 and Midjourney	Concept art, illustration, and graphic design	Artists, designers, and concept artists	Basic prompt development skills and familiarity with different artistic styles
JukeBox and MuseNet	Music composition, songwriting, and sound design	Musicians, producers, and game and film developers	Text prompt development and musical knowledge
Synthesia and Runway	Educational videos, marketing and communication, and social media content development	Educators, marketers, communicators, and content creators	Prompt development, basic video editing skills, and understanding the target audiences

Health Promotion Through GenAI

Traditionally, individuals communicated with health care professionals, family members, and friends for health-related purposes [51,52]. This communication provided immediate responses to health needs and allowed for follow-up questions. However, barriers included difficulties in reaching people in real time, time and cost constraints, limited understanding of health issues, and discomfort in discussing stigmatized health topics like addiction and sexually transmitted infections. The development of Web 2.0, social media, and mobile apps addressed many of these barriers [53-55]. These platforms offer health information from both individuals and professionals, enabling people to access information as needed, provided they possess the necessary technology, internet skills, and the ability to process web-based content [38,39].

Despite these advancements, existing mediums have limitations, such as the lack of interactive health information without human involvement, delayed responses, limited data for mobile app responses, difficulty understanding health information in specific

XSL•FO
RenderX

contexts, and limited accessibility for non-English speakers. GenAI has the potential to overcome these barriers by providing interactive, real-time responses and personalized health information based on LLMs. GenAI's ability to pass challenging exams (eg, the US Medical Licensing Exam and the USA Biology Olympiad Semi-Final Exam) underscores its capacity to deliver tailored responses aligned with human needs and inquiries [56].

Individuals can now fulfill various needs—such as health inquiries, image development, and health content creation—using GenAI tools, if they have access to these tools and effective prompt writing skills. The acceptance and use of this new technology can also be explored through theoretical frameworks.

Theoretical Application of GenAI

The application of GenAI can be examined through the TAM2 and the uses and gratifications theory. TAM2 suggests that an individual's acceptance or rejection of a system or technology depends on its perceived usefulness and ease of use [19]. Perceived usefulness is determined by factors such as the quality of the outcomes and the benefits provided, while perceived ease of use refers to how simple the technology is to operate, learn, and become proficient with, requiring minimal effort [57]. GenAI has demonstrated its usefulness by solving complex problems, generating humanlike responses to diverse inquiries, creating content, and acting as an assistant. As a result, health educators, medical professionals, and researchers have started incorporating these tools into their work. Consequently, the general public is increasingly likely to adopt GenAI for health purposes, such as obtaining personalized health information, interpreting health reports, and making informed health decisions.

The technology is also designed to be user-friendly, resembling the simplicity of a Google search. Major GenAI tools, such as ChatGPT, Gemini, and Copilot, are accessible with straightforward sign-up processes and offer basic services at no cost. The rapid adoption of this technology is evident from its widespread use. For example, since its launch on November 30, 2022, ChatGPT has amassed over 300 million users weekly, with 1 billion messages sent by its users on the platform each day [58]. In the United States, ChatGPT app downloads exceeded 32.6 million, and Gemini, launched on December 6, 2023, reached 12.67 million downloads by September 2024 [59]. However, realizing the full benefits of this technology often depends on the user's prompt development skills.

The motives behind the widespread use of GenAI can be analyzed through the uses and gratifications theory [20]. According to this theory, individuals consciously select specific media to fulfill their needs. The primary motivations for using GenAI include its humanlike responsiveness, which addresses limitations in conventional internet-based communication; its ability to deliver tailored health information, unlike standard search engines that primarily return links; and its capacity to meet personalized health needs, such as seeking health information, diagnosing conditions, making health decisions, and creating health-related content. Additionally, the ability to use AI agent services for task completion motivates individuals, particularly health researchers, campaign designers, educators, and medical professionals, to integrate GenAI into their work.

Despite its significant potential, GenAI has limitations that may contribute to health disparities.

GenAI and Health Disparity

Overview

GenAI has several limitations, including its reliance on specific databases, difficulty in understanding users' unique contexts, and individuals' inability to fully use its benefits. Some of these limitations are discussed below:

Limitations of GenAI

GenAI relies on LLMs trained on data from sources such as Google, Wikipedia, and GitHub. However, because data on the internet can include inaccurate information and misinformation—often contributed by individuals without relevant expertise or oversight—LLM-based AI tools may generate inaccurate or biased responses. For example, researchers evaluated ChatGPT-4's health-related information in the field of radiology and found that only 65% of the information was accurate [11]. Similarly, while the same tool passed the medical licensing exam, it achieved a passing mark of approximately 60% [56], suggesting a potential inaccuracy or bias rate of over 30%.

Limitations of Personalized Health Advice

Personalized health care relies on various factors specific to an individual's health condition, typically assessed through diagnostic methods such as pulse checks, blood pressure readings, blood tests, x-rays, and cultural considerations. While GenAI tools can provide health suggestions based on detailed prompts or text inputs, their recommendations are derived from universal datasets, which may not always be applicable to personalized care [9]. Furthermore, GenAI has limitations in understanding individual cultural and racial contexts [60], which are critical for determining health care needs and preferences. As a result, researchers recommend verifying GenAI-generated outputs with qualified health care professionals to ensure accuracy and relevance.

Individual Incapacity to Evaluate Health Information

Health literacy, the ability to assess information accuracy, and knowledge of reliable sources are essential for individuals to evaluate specific health information and use it effectively [61]. Individuals who possess these skills can maximize the benefits of GenAI technology. However, racial and ethnic minority groups, who often experience lower levels of health literacy and lack the skills needed to evaluate health information, may be disproportionately deprived of these technological advantages.

Limitations of Access to GenAI Tools

Although 95% of American adults have internet access [62], many individuals with lower health literacy, language barriers, or limited financial resources face challenges in accessing the full benefits of GenAI tools. These tools often require paid subscriptions to unlock advanced features and enhanced accuracy. For instance, ChatGPT Plus, a subscription-based

XSL•FO
RenderX

version, delivers more accurate outputs compared with the free version, ChatGPT 3.5 [10].

Lack of Skills in Prompt Development

The quality of GenAI output is highly dependent on effective prompt development, which involves crafting precise text inputs for the tools [8]. Individuals proficient in prompt development—using techniques such as open-ended questions and using relevant keywords—can maximize the benefits of this technology. Conversely, individuals with lower levels of education, poor health literacy, or limited technological proficiency may struggle to harness its potential benefits, leaving them at a disadvantage.

Potential Health Disparity Through GenAI

Health disparity refers to differences in health status between disadvantaged social groups—primarily individuals with low income, racial and ethnic minority groups, women, and others who consistently experience worse health and greater health risks compared with advantaged social groups [63]. In the context of web-based health benefits, health disparity is influenced by limitations in access to information technology, poor health literacy, language barriers, and inadequate internet use skills, such as browsing and content-related skills [44].

In the era of GenAI, health disparities are likely to persist among these groups due to challenges in evaluating GenAI outcomes and difficulties in prompt development. Current ChatGPT users, predominantly college students (43%) and Fortune 500 companies (80%), are likely drawn from higher social groups that benefit most from this technology. These advantaged groups, with higher levels of education, communication skills, and acceptance of new technology, are more likely to maintain superior health knowledge and better health outcomes compared with disadvantaged groups, consistent with the knowledge gap hypothesis [21]. This theory posits that individuals with higher social status acquire information faster than those with lower social status. Consequently, health disparities are compounded as higher-status individuals use new technologies more effectively for purposeful activities, while less-educated individuals often use technology primarily for entertainment [64].

To reduce these disparities, efforts must focus not only on the availability of technology but also on improving accessibility, enhancing digital literacy, fostering engagement, and building trust [3].

Conclusion

This study provides an overview of major health communication mediums on the internet, their practices, and the limitations of traditional web-based health communication tools for health purposes. It highlights GenAI as a new avenue for health promotion while addressing its potential to exacerbate health disparities. These discussions offer valuable insights for researchers, educators, and health professionals focusing on internet-based health communication and health promotion practices.

Although this research lacks extensive evidence-based claims, it serves as a foundation for further empirical studies, such as interviews and surveys with marginalized communities, to better understand health disparities in the era of GenAI. The study could be further enhanced by conducting a systematic review to provide a more comprehensive understanding of communication mediums, their health-related practices on the internet, and health disparities in the rapidly evolving context of GenAI.

Moreover, policy makers and health educators should implement targeted programs to familiarize disadvantaged groups with the latest technologies and their benefits. Efforts should focus on reducing health disparities by improving digital literacy, enhancing prompt development skills, and increasing access to technology for underserved populations.

Acknowledgments

We are grateful to all study participants for their participation. This work was supported by Fundamental Research Funds for the Central Universities and the project evaluation of Chronic Disease Health Management Policies (project 2023-SKY-A07054-0010).

Data Availability

All data generated or analyzed during this study are included in this published paper.

Authors' Contributions

JU conducted the data analysis and drafted the paper. JX and CF contributed to the study’s interpretation of the data and critical revisions of the paper. All authors have approved the final versions for submission.

Abstract

Digital maturity assessments can inform strategic decision-making. However, national approaches to assessing the digital maturity of health systems are in their infancy, and there is limited insight into the context and processes associated with such assessments. This viewpoint article describes and compares national approaches to assessing the digital maturity of hospitals. We reviewed 5 national approaches to assessing the digital maturity of hospitals in Queensland (Australia), Germany, the Netherlands, Norway, and Scotland, exploring context, drivers, and approaches to measure digital maturity in each country. We observed a common focus on interoperability, and assessment findings were used to shape national digital health strategies. Indicators were broadly aligned, but 4 of 5 countries developed their own tailored indicator sets. Key topic areas across countries included interoperability, capabilities, leadership, governance, and infrastructure. Analysis of indicators was centralized, but data were shared with participating organizations. Only 1 setting conducted an academic evaluation. Major challenges of digital maturity assessment included the high cost and time required for data collection, questions about measurement accuracy, difficulties in consistent long-term tracking of indicators, and potential biases due to self-reporting. We also observed tensions between the practical feasibility of the process with the depth and breadth required by the complexity of the topic and tensions between national and local data needs. There are several key challenges in assessing digital maturity in hospitals nationally that influence the validity and reliability of output. These need to be explicitly acknowledged when making decisions informed by assessments and monitored over time.

Introduction

Health systems are facing increasing pressure to achieve more with less, and health information technology is widely recognized to tackle existing challenges, although it is still difficult to attribute causal connections between health information technology and health care outcomes [1].

The concept of digital maturity has emerged from the field of organizational studies. It has been conceptualized as an organizational state in which processes are digitalized and accompanied by other organizational transformations [2]. The assumption underlying the concept of digital maturity in health care is that organizations that have higher levels, achieve better processes and outcomes [3,4]. This may include improved quality and operational efficiency through implementing electronic health records (EHRs) and laying the foundation for learning health care systems, artificial intelligence, and precision medicine [5]. We here define an EHR as a digital version of a patient's paper chart including medical history, treatment, and care over time.

The World Health Organization supports driving the improvement of digital maturity in health systems, aiming toward Universal Health Coverage (UHC) [6]. National approaches to measuring digital maturity have emerged in public health systems relatively recently and are now increasingly applied to inform strategic decision-making [7]. Although some measurements are widely applied (eg, those by the Healthcare Information and Management Systems Society [HIMSS]) [8], there are currently no universally accepted methods for measuring digital maturity in health systems [9]. This may partly be due to the evolving landscape of digital health, where the concept of digital maturity is difficult to define. Some have argued that it needs to be conceptualized as a journey without a definitive endpoint [10], and digital health capability is sometimes used interchangeably with maturity to reflect a continuum of digital growth [11].

To understand how best to assess digital maturity in health systems to facilitate comparisons and sharing of lessons, there is a need to compare initiatives across nations. Although approaches to measuring digital maturity have been analyzed within countries and local organizations [4,12,13], there is currently limited evidence surrounding international comparisons. A nuanced view of the role of digital maturity assessments will help to shape implementation efforts. This should include discussions on the value gained from different digital maturity assessments, focusing on their effectiveness, return on investment, and impact on the quality and safety of care.

We therefore aimed to describe and compare national approaches to assess digital maturity. We hope that this work will contribute to fostering an environment of learning and sharing lessons, which can inform future strategies and international comparisons.

Methods

Countries included in this review were sampled opportunistically through our existing networks in the International Medical Informatics Association (IMIA) and European Federation of Medical Informatics Evaluation Working Groups on technology assessment and evaluation [14,15]. Snowballing through this network identified additional stakeholders. To be included, we needed to be able to access information on the digital maturity assessment process, and we therefore in some cases worked with policy makers who were involved in the exercise within their countries to gather data. We had to find a balance between including countries that were broadly comparable in relation to existing levels of digital maturity, whilst also being sufficiently different to explore varying approaches. Whilst we acknowledge that including countries at various stages in their digital maturity assessment journey could be valuable, we here focused on countries at similar stages but with different approaches (national, regional), different population sizes, different items with various origins (HIMSS, WHO, expert stakeholder consultations) and variations in EHR systems and coverage. Each of the included countries (Australia [Queensland], Germany, the Netherlands, Norway, and Scotland) has a unique health care system shaped by different policies, regulations, and funding mechanisms. Comparing digital maturity across these varied systems, allowed us to gain insights into how different approaches to health care administration impact the adoption and implementation of digital technologies. Furthermore, cultural attitudes toward technology, patient engagement, and health care delivery differ significantly across these countries and understanding how these cultural factors influence digital maturity is important.

We assigned academic (KC, FJ, LW, TP, and EA) or policy (ML and SM) leads to each of the participating countries, who were responsible for collecting descriptive data. Using the nominal group technique with leads, we cocreated a data collection template table for each country, representing key features and learnings identified through discussions in group meetings. These included a description of the context or setting, rationale and drivers for the digital maturity assessments, tools and methods used to collect digital maturity data, methods used to analyze and disseminate the data, challenges encountered, and lessons learned likely to be relevant to the international community (Multimedia Appendix 1). Missing fields were accepted and leads unable to provide complete datasets were still considered eligible. We then coded items under each table field using NVivo 12 (Lumivero) and extracted areas of convergence and areas of divergence under each of the categories through a qualitative thematic analysis. This involved dragging and dropping information recorded for all countries under each table field as the parent node, examining the coded text from across countries for each of the parent nodes. This led to a consolidation of parent nodes under the overall themes presented in the Results section (context, drivers, methods for data collection and analysis, and challenges encountered). We then, within these wider categories, explored similarities and differences between countries which presented the child nodes. Some of these took a numerical form, in which case we

XSL•FO
RenderX

examined ranges, whilst for qualitative data we paid particular attention to summarizing the diverse spectrum of experiences across contexts.

The constructed narrative including key themes (presented below) and implications of our findings were then discussed amongst all members of the team in meetings with country leads.

Results

A comparative overview of key descriptive data across countries is provided in Table 1. We further elaborate on the emerging themes in the paragraphs below.

Table 1. Summary of key descriptive data across countries.

Heading	Queensland (Australia)	Germany	The Netherlands	Norway	Scotland
Health care model	Queensland Health (state government) funds universal free health care	Bismarck model	National Health Insurance	National health and social Insurance	National Health Insurance
Size of country or region (# inhabitants), n	~5 million	~84 million	~18 million	~5.5 million	~5 million
EHR[a] coverage in hospitals	Varied (some still have paper, but single instance of Cerner across 15 hospitals)	Varied (>10 different vendors)	100% (four core EHR systems)	100%	100%
National or regional approach	Regional	National	National	National	National
Name of EHR	Cerner	Varied	Varied	DIPS, EPIC	TrakCare
Name of digital maturity assessment	HIMSS[b] Digital Health Indicator	DigitalRadar	Dutch Interoperability Maturity Model	eHealth Monitor	Digital maturity survey
Led by	Queensland Health (government)	Digital Radar Consortium (appointed or commissioned by Ministry of Health)	Ministry of Health, Welfare and Sports	Norwegian Government	Scottish Government and Convention of Scottish Local Authorities
Origin	Bespoke, based on HIMSS	Bespoke based on HIMSS and expert review	Bespoke, based on HIMSS	Bespoke based on criteria recommended in WHO's report on the development of national e-health strategies	Bespoke drawing on methodical review of UK and global models
Number of items, n	121	234	37	30	355

[a]EHR: electronic health record.

[b]HIMSS: Healthcare Information and Management Systems Society.

Context

The size of populations in participating countries varied significantly from 5 million in Queensland, Norway, and Scotland, to 18 million in the Netherlands, and 84 million in Germany.

None of the included health systems were financed through out-of-pocket models or private insurance-based financing models, and all had UHC. Health systems varied from The Beveridge model, where health care is provided free at the point of care through taxation (Scotland, Norway), The Bismarck model which is characterized by compulsory health insurance related to earnings (Germany, the Netherlands), and mixed models where universal public health insurance funded through tax can be supplemented by private health insurance (Queensland) [16].

All participating countries had a strong governmental focus on interoperability in their national strategies, but some had made more progress than others. This was particularly apparent when looking at regional examples. For instance, Queensland had a state-wide Integrated Electronic Medical Record with Cerner. In other countries, where regions had some autonomy over budgets and procurements, there were a multitude of heterogeneous EHR systems sometimes spanning more than 1 provider organization.

EHR coverage in hospitals was hard to assess, but between 50% and 100% of hospitals used some sort of clinical information system (ie, systems designed to support the operations of specific clinical departments or functions within an organization). Norway, Scotland, and the Netherlands had 100% coverage.

Types of EHR systems varied significantly. Some countries were dominated by 1 vendor (eg, Queensland with Cerner,

XSL•FO
RenderX

Scotland with TrakCare), whereas others used a mixture of systems including US-based mega systems (Epic, Cerner) and "home-grown" systems (Norway, Germany, the Netherlands).

Digital maturity assessments were national in all countries except Australia, which assessed the region of Queensland. All were initiated and executed by the Government, except in Germany where the government commissioned a consortium.

Although the focus of this analysis was on digital maturity in hospitals, some digital maturity assessments included several health and care settings, including acute, primary, and social care (Norway, Scotland, and the Netherlands).

All assessments had a longitudinal element, although what indicators were collected at any point in time was determined by local contextual factors such as availability and feasibility. In addition, the list of indicators evolved over time as some were added, and others were removed in line with strategic objectives and feasibility (explicitly mentioned in Germany and Scotland).

Rationale and Drivers for Digital Maturity Assessments

Across countries, the primary drivers for digital maturity assessments were to inform digital health strategy and priority areas of investment, evaluate national progress, and conduct local benchmarking designed to help participating organizations compare themselves to others. In Scotland, the local use of data to guide and plan digital transformation was emphasized, and the German case also mentioned a desire to compare their digital maturity with international centers of excellence.

Some cases also mentioned the exploitation of data generated and the use of data to drive and provide evidence for progressing interoperability agendas. The Norwegian initiative was for instance designed to provide data for research and analysis in public health, and the Dutch strategy mentions the need to conduct a Societal Cost-Benefit Analysis to define if, when and how mandating digital data exchange can be implemented.

Tools and Methods Used to Collect Digital Maturity Data

Most countries assessed a combination of common elements of digital maturity, such as strategy, information technology capability, interoperability, governance and management, patient-centered care, skills and behaviors, and data analytics [11]. Which elements were assessed was often based on the context of the country. Queensland was the only region that used a HIMSS Digital Health Indicator [17].

All countries collected data through standardized electronic self-assessment surveys that were completed by local organizations and supported by national stakeholders. Some had, or were in the process of developing, bespoke electronic data collection and analysis platforms. There was significant variation both within and across countries as to which organizational stakeholders completed the survey.

Likert scales were mostly used to measure indicators, whilst some also had some multiple-choice items, percent scales, and the option for limited free text. The number of included items, however, varied significantly across countries and did not always correlate with the number of health and care settings included, the size of populations, or the number of EHR systems. Norway's national eHealth Monitor included 30 indicators, followed by the Dutch Interoperability Maturity Model with 37 items. Queensland had 121 indicator statements, Germany had 234 items, and Scotland had the largest number with 355 discrete indicators (Scotland also included the widest range of care settings).

Areas of focus also varied significantly depending on how countries divided assessment elements. It was therefore difficult for us to compare where countries placed specific items and where they overlapped. Themes commonly measured across countries included interoperability and information exchange, capabilities and applications, organizational leadership and governance, and technological infrastructures.

Specific areas measured locally in individual countries included person-enabled health and predictive analytics in Queensland; resilience management, clinical, processes, telehealth, and patient participation in Germany; skills and competencies, sustainability, and secondary uses of clinical data in Scotland; laws, regulations, and care processes in the Netherlands; and user satisfaction, and cost-monitoring in Norway.

Most assessments were voluntary but strongly encouraged. None of the countries used penalties. The only compulsory assessment was in Germany, but it was only relevant for hospitals that received national funds to support digital transformation.

Methods Used to Analyze and Disseminate Digital Maturity Assessment Data

Analysis was mostly centrally coordinated and quantitative in nature. We observed a lack of transparency in collected data and digital maturity calculations across countries.

Queensland used proprietary algorithms provided by HIMSS, which allowed a degree of international benchmarking. These were supplemented by some academically led qualitative analyses. Benchmarking by geographical region or organization was done in some countries (Queensland) but not in others (Scotland). Scotland wanted to gain an understanding of the national landscape to better focus strategic funding. They also wanted the submitting organization to develop improvement plans individually and with their linked organizations, across their local, integrated health and care system. There was an explicit agreement that ranking organizations would potentially hinder data collection and analysis. Some countries (the Netherlands and Scotland) also made (or will make) data available for analysis by local organizations themselves.

Outputs were in most cases disseminated directly to participating organizations (through dashboards and meetings) and externally through open webinars and public reports. They were explicitly designed across countries to inform ongoing eHealth strategy. Queensland was the only setting that had a systematic academic evaluation of the digital maturity assessment and associated findings were published in academic journals and conferences, as well as through HIMSS. Scotland and Queensland established an external steering group comprising of subject matter and policy experts.

XSL•FO
RenderX

Challenges Encountered and Lessons Learned

Challenges encountered included limitations in the measurements used, such as uncertainties about the validity of constructs for assessing digital maturity. The analysis and data collection process were time-consuming, and indicators evolved, raising questions about the validity of longitudinal elements. Balancing the practical feasibility of the process with the depth and breadth required by the complexity of the topic presented a trade-off. There were also challenges in making international comparisons due to limited relevance in some local contexts. The self-reported nature of measurements introduced likely biases in assessments. For example, individuals reporting may have a specific agenda driving their responses and more knowledge of parts of organizational activities than others. There may also be a degree of "gaming" where respondents either over- or underestimate the levels of digital maturity in their organization to obtain funding. In addition, an overall view of organizational structures and activities is unlikely to be possible from any individual perspective, and efforts invested in reporting activity are likely to be strongly impacted by the existence of local leadership support for the exercise. In addition, there was limited use of qualitative assessment of indicators, with qualitative follow-ups for context and clarification used only to a limited extent.

Some countries recognized that there is a need to address concerns that data might be used for performance management, which may hamper efforts to obtain accurate data.

Costs of digital maturity assessments were significant (although we did not make cost-benefit assessments), including the required resources to collect, complete, analyze, and disseminate the data. In some countries, additional costs included consultancy support for data platforms, data collection, and analysis (Queensland, Scotland, and the Netherlands).

Discussion

Principal Findings

Although countries varied significantly in population size, existing EHR systems, settings, and indicators; some common themes emerged. These included a national focus on interoperability, a desire to measure changes over time (and a concurrent difficulty keeping track of progress in line with changing circumstances), a need to inform national digital health strategy, priority areas of investment, local benchmarking and strategy development, at least some alignment of common indicators tailored to local needs, a focus on quantitative measurements, and the self-reported voluntary nature of the exercises.

Common thematic areas across countries included interoperability and information exchange, capabilities and applications, organizational leadership and governance, and technological infrastructures. Analysis was centrally coordinated but data were made largely available to participating organizations. Rigorous independent evaluation was only present in 1 instance.

Challenges encountered included the cost of assessment and time-consuming data collection, potential issues surrounding the validity of measurements, issues with reliably measuring changes over time, and potential biases introduced through self-reporting.

Strengths and Limitations

Our work is one of the first attempts to describe and compare how different countries measure digital maturity in hospitals. We included only a limited number of countries, chosen through a self-selected sample, which may limit the potential transferability of findings. Our results are also likely to only apply to relatively advanced health systems with high levels of EHR implementations and UHC.

The data for the study were collected directly by the authors in narrative form and from various sources, which is likely to have biased what was included as it was subjectively selected, and individual viewpoints may have influenced the accounts. This method of data collection also meant that the study provided limited detail and did not delve deeply into specific thematic areas and indicators. We observed a significant variation in approaches and the number of indicators used by different countries, which was difficult to account for in the analysis.

As our focus was on providing an overview of approaches, we did not collect specific information on how the data were analyzed within each country and we therefore did not obtain any insights into factors such as regional variations, or differences between digitally mature and less mature sites. This could be a subject of follow-on work.

Despite these limitations, we offer a broad analysis that provides initial insights into the various methods countries have used to assess digital maturity in hospitals and the lessons they have learned from these experiences. Building on this work, there is now an opportunity to explore the identified areas in more detail, potentially leading to a more comprehensive understanding of digital maturity assessments in health and care settings across various health systems.

Integration of Findings With the Literature

There are many commercially available models for health care providers to assess digital maturity, and there are some general practical considerations that are likely to be relevant across settings [18]. Currently, there are however limited evidence-based methods to assess the quality, use, and efficacy of maturity models and limited guidance on selecting the most appropriate model for any given context [19]. The underlying evidence base for national approaches is even less mature, highlighting the importance of our work. A degree of coordination is likely to be important to streamline efforts and remove duplication, and this will also require consideration surrounding digital infrastructures that can be delivered nationally and those that can remain local [20].

The World Health Organization has recently reviewed tools used to monitor digital health in 8 countries (including Australia and the Netherlands), but these were not specifically explored in relation to digital maturity [9]. Nevertheless, there was a degree of overlap concerning focus. For example, infrastructure and governance as well as specific applications including EHRs, telehealth, and electronic prescribing featured heavily in these

XSL•FO
RenderX

assessments, illustrating the interlinked nature of digital health strategy, systems, infrastructures, and digital maturity. The report also points out a lack of indicators for measuring health inequalities and a tendency to prioritize outcomes over processes [9]. This may partly be due to the difficulty to measure processes in health and care digitalization, and a lack of expertise to analyze such data [21].

Approaches to assessing digital maturity have in the past been criticized for relying too heavily on assessing technological capabilities, overshadowing socio-organizational aspects [22]. This imbalance is reflected in the current analysis but there appears to be an increasing recognition of socio-organizational factors such as leadership and governance and consumer or patient-centered care.

The issue surrounding the evolution of intervention maturity over time has already been recognized [23], but how digital maturity assessments can adequately account for this progression is less clear. Changing circumstances are recognized as a significant challenge in measuring the progress of digitalization in health and care, as the use and exploitation of digital systems is often accompanied by wider changes to organizational functioning, in which existing ways of working are transformed [24]. This in turn impacts the way measurements can be compared over time. The challenge is unlikely to be easily resolved and may require defining a limited set of core measurements that will not be significantly affected over time, whilst being flexible in including new emerging indicators.

Implications for Policy and Practice

There is therefore a trade-off between breadth and depth influencing the scope of assessments. There is also a need to tailor assessments of different settings, as the prevailing “one size fits all” approach whilst providing insights into overall trends, does not help to understand specific organizational circumstances.

The general lack of academic independent validation in digital maturity models and assessments is concerning and raises questions about the reliability and efficacy of existing approaches. There has also been a lack of focus on processes that lead to measured outcomes in assessments. There is further limited evidence on the interrelationships among maturity dimensions meaning that assessments do not provide evidence-based recommendations for improvement.

The role of common indicators across assessments is important. These bring a degree of international comparability, but contextual variations are significant, and digital maturity progress is determined by legal frameworks and financial resources. Scores developed by HIMSS may facilitate a degree of comparability and validation for digital maturity assessments. But standardized international tools may not pay sufficient attention to locally relevant metrics that organizations can use to inform local strategies. Such tools may also present challenges regarding equity and access and there may be commercial conflicts of interest.

Another significant challenge lies in deciding who should be responsible for collecting data, how they represent professional and organizational interests, and how a degree of uniformity across settings may be achieved. This also highlights the necessity of understanding who is best placed to answer specific questions and reiterates the leading organization (Central Government) being explicit in the purpose of the assessment and communicating this repeatedly. A degree of unpredictability regarding how data will eventually be used remains, and so does uncertainty of how individual assessments fit within a wider long-term strategy. Amongst participating organizations, there may be concerns that the data might be used for performance management or resource allocation. Such uses could lead to apprehension and resistance, potentially exacerbating existing inequities. A potential way to address this could include involving organizations more actively in the design of digital maturity assessment tools, perhaps through a process of cocreation. This could then lead to the development of datasets that satisfy both national and local demands, but it is also likely to require compromises on both sides. Policy makers may be faced with different datasets that are not necessarily comparable, but through these will gain insights into local priorities, which can help to facilitate strategic decision making in different, perhaps unanticipated ways.

Going forward, it will be important to assess how these challenges are tackled over time in individual countries, and across the evolving health and care ecosystem including primary and community care. This mapping exercise could also be followed up with more in-depth quantitative or mixed methods work, exploring how digital maturity assessments evolve over time and which aspects are most useful in guiding strategic directions. Incorporating various stakeholder perspectives will be critical, including the voices of health and care providers and patients. We hope that our work provides a steppingstone for achieving this and summarize recommendations for future research to address the challenges identified in Textbox 1.

XSL•FO
RenderX

Textbox 1. Recommendations for future research to address the challenges identified.

Recommendations

Embed real-time independent mixed methods impact, value, and process evaluations in digital maturity assessments from the start to track progress over time and adjust strategy in line with emerging findings. This should focus on:

- Assessing how digital maturity assessments influence decision making locally and nationally.
- Exploring what success means for digital maturity or transformations and develop an internationally agreed framework for measuring associated metrics.
- Assessing which measurements or activities are most impactful, valuable, and cost-effective and why.
- Determining a minimum viable dataset that can be used to make international comparisons.
- Exploring alternatives to self-assessments and clearly distinguish between national and local datasets and their purposes.
- Exploring trajectories and changes over time.
- Exploring incentives and barriers to data collection and analysis amongst various stakeholder groups.

Conclusions

Digital maturity evaluations are driven by a national or regional impetus to identify both areas of excellence and those requiring investment in digitalization. However, the process of assessing digital maturity is fraught with challenges that require transparency in decision-making and monitoring through evaluation.

Existing work is frequently based on self-reporting, is very costly, lacks academic input, and is often conducted by stakeholders with diverse and at times conflicting agendas. Despite these concerns, having some data, however imperfect, is better than none. This is especially true when it comes to making policy decisions that need substantiation.

National digital maturity assessments need to mature from being a vendor or consultancy-funded project-based exercise toward longitudinal evidence-based and academically led activity characterized by international collaboration to facilitate learning.

Acknowledgments

The authors would like to thank Henrik Moeller for reviewing the draft and providing comments.

Authors' Contributions

KC and EA conceived the paper. KC led the data collection, analysis, and write-up with all authors contributing to data collection, data analysis and various iterations of the paper.

Conflicts of Interest

KC, EA, and LS are members of the International Medical Informatics Association Working Group on Technology Assessment and Quality Development and the European Federation for Medical Informatics Working Group on Evaluation.

Abstract

Psychiatric advance directives (PAD), also known as advance statements or advance choice documents, are legal documents that enable people with mental health conditions to specify their treatment preferences in advance for possible future crises. Subtypes of PADs include crisis cards, joint crisis plans, and self-binding directives (also known as Ulysses contracts). These instruments are intended to improve service user involvement and need orientation in the care of mental crises and to avoid traumatization through unwanted treatment. The existing evidence suggests that people who complete a PAD tend to work more cooperatively with their clinician and experience fewer involuntary hospital admissions. Nevertheless, PADs have not been successfully mainstreamed into care due to multiple barriers to the implementation of PADs, mainly around the completion of PADs and their accessibility and use in crises. The reasons for this include the lack of support in the completion process and acceptance problems, especially on the part of professionals. The research to date primarily recommends support for service users from facilitators, such as peer support workers, and training for all stakeholders. In this article, we argue that while these approaches can help to solve completion and acceptance challenges, they are not sufficient to ensure access to PADs in crises. To ensure accessibility, we propose digital PADs, which offer considerable potential for overcoming these aforementioned barriers. Embedded in national health data infrastructures, PADs could be completed and accessed by service users themselves, possibly with the support of facilitators, and retrieved by any clinic in an emergency. We highlight the strengths and limitations of digital PADs and point out that the proposed solutions must be developed collaboratively and take into account digital inequalities to be effective support for people with serious mental health conditions.

Introduction

In recent decades, interest in self-determination in health care and service user autonomy has grown considerably, as evidenced by the increasing implementation of interventions to promote shared decision-making and advance care planning in health care [1,2]. In the field of mental health, this is a contested issue in view of perceived potential conflicts between the autonomy and well-being of service users. Although extensive attempts have been made for decades to reduce involuntary interventions in mental health care, this has only been successful to a limited extent [3].

A key intervention in this context is advance care planning using a so-called psychiatric advance directive (PAD), also known as an advance statement or advance choice document. PADs are legal documents that allow individuals to determine in advance how they would like to be treated in the event of a future mental health crisis or psychiatric emergency [4-6]. Subtypes of PADs include crisis cards, joint crisis plans, and self-binding directives (also known as Ulysses contracts or arrangements) [7]. Self-binding PADs are distinctive in that they contain a clause in which service users can request future involuntary hospital admission and treatment during a mental health crisis whilst recognizing that at the time these interventions are required, they are likely to refuse them [8,9]. Despite significant differences between the variants of PADs, they aim to help mental health service users ensure that their treatment wishes are heard and acted upon, particularly in situations where they are unable to express them or lack the threshold capacity to make decisions. To facilitate understanding and reduce complexity, the various forms of advance care planning in mental health care are summarized under the term PAD, unless they are specifically mentioned.

A growing body of scientific papers suggests that PADs can increase the autonomy and perceived control of service users [4,10], strengthen the therapeutic alliance and patient-physician communication [4,6,11], improve adherence [12,13], reduce coercive measures and involuntary admissions [14-17], and could possibly lead to better overall treatment outcomes [12]. In addition, various bodies of the United Nations have stated that the Convention on the Rights of Persons with Disabilities demands the implementation of PADs [18]. Against this backdrop, frameworks to promote PADs for mental health crises have been and are being created in more and more countries. For example, the UK government has enacted legislation for PADs in England and Wales and is currently evaluating its implementation [19]. The Mental Health and Wellbeing Act in Australia and Washington State's SB 5660 in the United States are intended to anchor PADs more firmly in care [4,20,21]. In Germany, PADs are legally binding under the Civil Code and the country's clinical guidelines for the prevention of coercion recommend the implementation of PADs with the highest level of evidence [22-24]. Nevertheless, the available evidence on PADs is considered to be expandable, partly due to the comparatively small sample sizes in some cases and the still small proportion of studies on the topic conducted with service users.

Despite the benefits of PADs for service users, numerous challenges remain in their practical application [14,25]. In this viewpoint paper, we identify outstanding difficulties with PADs, such as the documents not being completed, not being accessible in crises (eg, because people do not carry them with them or they are not accessible in the treating clinic), clinicians ignoring PADs, PADs not being kept up to date, or the existence of conflicting versions of a PAD (eg, because paper and pencil updates were not distributed among all parties involved) [26]. To address these problems, recent reviews suggest improving PAD implementation strategies through measures such as training for professionals, service users, and their relatives [8,14]. We consider these measures useful but argue that their impact may be limited if PADs are not accessible to all stakeholders at all times in an up-to-date form. As a solution, we propose digital PADs embedded in electronic health records and show that they may provide longer-term tangible outcomes and increase the usability, practicality, and relevance of PADs, which in turn would have a positive impact on their utility and clinical impact. We explore the strengths and limitations of digital PADs and emphasize that for the innovation to work, it is essential that the PADs are interoperable, ideally integrated into each country's health care data infrastructure via Fast Healthcare Interoperability Resources. Interoperable means in this context that the content of the PAD is stored in a digital standardized form, namely via Fast Healthcare Interoperability Resources, which permits, for example, smooth access by the different medical information systems of various health care institutions.

Current Challenges With PADs in Crisis Care

Many studies have explored the benefits and challenges of implementing PADs [4,25,27-29]. We will focus on these challenges below, as these are the key starting points for the proposed solution.

Problem With Drafting PADs

In a review of service users' perspectives on PADs, Braun et al [14] found that in 73% (30/41) of the studies, completing a PAD was a challenge for those involved. Service users reported a lack of knowledge and understanding of how PADs work [5,30-32]: they often do not know what to write in a PAD, and the templates provided are often without sufficient explanations and examples, making it challenging to complete them [6,33]. In addition, some service users find completing a PAD too complicated or time-consuming [34-36]. Doubts about one's own decision-making ability at the time of preparation also discourage service users [6,27,31,37]. Finally, the creation

XSL•FO
RenderX

process can be emotionally distressing, especially if it evokes memories of previous involuntary treatment [11,36,38,39].

Another difficulty in creating a PAD is the lack of support. For example, many service users do not have a trusted person to support them [11,36,38]. Some service users are also concerned that potential facilitators, such as the treating psychiatrist or relatives, could exert undue influence on the contents of the PAD by introducing their own potentially divergent preferences [35,39]. In addition, clinicians usually have little or no financial or time resources to draft a PAD together with the service users or even to advise them [40,41]. Professionals are reluctant to invest time in creating PADs [42]. It is, therefore, not surprising that service users report unclear or inadequate instructions and insufficient follow-up by professionals in the event of any queries [30,43].

Overall, these findings illustrate that service users need clear guidance and support to create an actionable PAD that meets their needs. Professionals should be given the necessary time to support the completion.

Problems With Accessing PADs

A key problem is that PADs are often not stored so that they are up-to-date and accessible to all relevant stakeholders during a crisis [14,27,37,41,44]. Reasons for this are that those primarily involved in the use of a PAD, such as staff in the emergency department, inpatient wards of a hospital, judges, guardians ad litem, and legal guardians often do not know whether a PAD is present or not [25,28,45], that service users cannot provide information about the presence of a PAD in the event of a crisis, that professionals are not made aware of the presence of a PAD through a corresponding notification in the hospital information system, that the PAD is not available in digitized form, or that possible standard operating procedures for crisis and de-escalation management in a hospital are either not available or do not take PADs into account. Various studies show that these considerable access problems lead to uncertainty and irritation among service users, as an exemplary statement of a service user from a qualitative focus group study shows:

> *I wasn't at the stage of going into hospital, but I'd been on a high and they were a little bit worried. And what concerns me was that they didn't have a copy of your crisis plan [26].*

The barriers to access are even higher when service users present at a hospital where they have not been treated previously [25]. In such situations, it is unknown what kind of care and medication was helpful in previous crises, nor can previous doctors' letters or PADs be accessed unless the person concerned brings these with them themselves. Particularly in the case of involuntary hospital admission or treatment or use of coercive measures, a lack of knowledge about individualized crisis treatment can lead to inadequate treatment, harm, and traumatization [46,47].

Problems With Applying PADs

Even if it is ensured that a PAD is accessible, this does not mean that it is actually taken into account in crisis management. For example, about 90% (35/41) of the studies identified in the review by Braun et al [14] that examined the service user perspective on PADs found evidence of application problems. An important factor here is that PADs are not followed in practice by professionals (approximately 61% of studies; 25/41) for various reasons. Service users reported that PADs were not endorsed by professionals in principle (approximately 17% of studies; 7/41) or PADs are not legally binding and hence could only be applied to a limited extent (approximately 22% of studies; 9/41). Another reason for not using PADs is the fear among professionals and some service users that the contents of PADs may be outdated because they are not regularly updated and therefore no longer reflect the current preferences of service users or current treatment guidelines (approximately 12% of studies; 5/41). In this context, community stakeholders expressed concern that service users would not take responsibility for keeping their PAD up to date over time [48]. Conversely, service users experienced that PADs were only initiated by professionals but not followed up, let alone integrated into outpatient treatment in the longer term, for example, through an accompanying regular exchange about the PAD [38].

In addition, the problem remains that not all contingencies of a possible future mental health crisis can be covered by a PAD [8,37,41]. Accordingly, stakeholders primarily criticize the lack of flexibility of PADs and would like them to be formulated as concretely and yet as widely applicable as possible so that they can be applied to a wide variety of mental health crisis scenarios [37]. This challenge is particularly relevant for self-binding PADs, as they can also be enforced over the dissent of a service user who lacks decision-making ability and against potentially divergent treatment recommendations from clinicians [8].

Finally, a lack of knowledge and inadequate training of clinicians in the use of PADs in emergency situations hinders their application. It is often unclear when a PAD is read by which member of the mental health team, how it is implemented, and who takes responsibility for this [49].

Currently Proposed Solutions

A number of measures are described in the literature, all of which aim to improve the implementation of PADs.

The most promising of these is the use of human support, or "facilitators," to guide the preparation of a PAD, which can significantly improve completion rates [50,51]. The role of facilitator can be assumed by professionals, peer support workers, patient advocates, or legal representatives. A recent RCT study from France shows that peer support workers-facilitated PADs can reduce the number of compulsory admissions compared to conventional PADs [52]. This might be explained by the fact that those affected can open up about this sensitive topic more confidently with a person with personal experience of mental distress or even involuntary treatment [53] than possibly their relatives or even practitioners, who may have different interests in crisis treatment than the affected person themselves. On the other hand, the use of facilitators could make the intervention more complex and time-consuming, as a considerable amount of additional training and personnel is required.

XSL•FO
RenderX

Alternatively, the literature recommends offering financial incentives, particularly for clinicians, to compensate for the additional time spent on supporting service users to complete PADs [22], or providing user-friendly templates and clear instructions for completing them—both of which have seen limited implementation in practice so far [41,54]. Furthermore, research suggests specific groups that could be targeted to increase the likelihood of PAD completion, such as those with strong social integration, those who have had negative treatment experiences in the past, and those who have recently experienced an acute mental health crisis [14]. It also suggests there are specific groups who might find it more challenging to complete PADs but are more likely to benefit from them. For example, service users from Black communities have identified additional barriers to completion, but research suggests additional benefits if service users are supported to overcome these hurdles [55].

Finally, various education and training interventions for service users and clinicians are recommended to offer more knowledge about PADs and the associated legal and ethical aspects to reduce misunderstandings and fears and increase uptake [56-58]. Training should also help to positively influence the aforementioned barriers to access, especially those aimed explicitly at ER personnel or rather detailing the use of PADs in emergency situations [25,49]. At the same time, it is important to emphasize that the existing evidence suggests that these measures are only effective to a limited extent and that administrative staff often have more knowledge about PADs than service users themselves [49,59]. Shields et al [25] therefore recommend integrating training into both undergraduate education and continuing professional development.

Overall, the currently proposed solutions can potentially promote the completion of PADs and, in principle, reduce involuntary interventions. Nevertheless, the problem remains that neither PADs nor facilitation is widely implemented in practice [15,16,51]. In addition, many trivial access problems remain unresolved, such as ensuring that the relevant stakeholders always have access to the same, up-to-date PAD version.

Integration of PADs Into the Electronic Health Record

The idea of making the PAD accessible in digital form is not new, and the following is a brief overview of efforts in this regard in various countries. As early as 2001, a US study concluded [60] that "without a computerized system for storing and retrieving service users' PAD information, preparing a PAD may do little more than the act of scrawling "help" on a scrap of paper, stuffing it into a bottle, and hurling it into the ocean." Nevertheless, there are still only a few successful implementations of digital PADs in psychiatry. The situation is different in physical medicine, especially in palliative care, where there are already several digital applications for advanced care planning. In the United Kingdom, for example, "coordinate my care" has been implemented, which enables digital creation and access to advanced choice documents. A recent evaluation of this service shows that it is also used by mental health service users and their clinicians specifically for advance care planning of mental health conditions [61], presumably also due to the lack of such tools in the mental health field.

In the field of psychiatry, Murray and Wortzel [4] report that some states in the United States are already using so-called "online advance directive registries" in both medical and psychiatric care. Comprehensive descriptions and scientific evaluations of these approaches are not yet available. In addition, the so-called "My Mental Health Crisis App" was published in 2020, by the SMI Adviser initiative, a project funded by the US Substance Abuse and Mental Health Services Administration. It enables those affected to create a PAD using step-by-step instructions and then share it digitally [62]. The app even considers the different legal regulations in the US states and the resulting differences in practice when creating PADs, such as the mandatory presence of witnesses or notarization. Finally, the PAD created using the app can be shared via a QR code. While this enables barrier-free access, it risks violating privacy if the QR code falls into the hands of unauthorized persons. We are not aware of any scientific evaluations of this offer either.

A similar but purely web-based solution is currently being piloted in Germany as part of a study [63,64], where the PAD is embedded in a digital environment regularly used by service users to test online record access. The document can only be accessed by persons who have been previously authorized by the service user, such as outpatient clinicians (general practitioners, psychiatrists, psychotherapists), legal guardians, and relatives, using their own account. In addition, staff of the mental health hospital in the respective catchment area in which the service user lives have access to the PAD. In routine care in Germany, there is currently only one type of emergency dataset stored on the physical health insurance card of those with statutory health insurance. This card can theoretically be read by any ambulance service, although it is unclear to what extent this function is currently being used.

The only known digital and interoperable implementation of PADs in the field of mental health is currently carried out in the United Kingdom, albeit only on an experimental basis, jointly by the NHS in coproduction with the startup Thalamos [26]. The initiative was prompted by recently introduced legislation that aims to address the increased number of involuntary psychiatric treatments in the United Kingdom in recent years, while also addressing significant failures to address racial inequalities in mental health care [65]. This is supported by findings that the significantly higher proportion of "Black Indigenous people of color" admitted under the law appears to benefit particularly from PADs [66,67]. Currently, a PAD culturally adapted for people from sub-Saharan Africa and the Caribbean is being piloted and stored in electronic patient records that are available to connected service providers such as acute hospital trusts and general practitioners [44,68].

Strengths of Digital Interoperable PADs

We argue that the approaches to digitizing PADs presented so far have considerable potential to improve the care situation of those affected, especially when combined. This section describes the strengths of digital PADs, based on the vision of a comprehensive digital solution from the perspective of medical ethicists and clinical researchers, and explains how digital PADs can help to overcome the key challenges of paper-based PADs.

XSL•FO
RenderX

First, every service user diagnosed with a serious mental health condition, and especially those with a history of involuntary hospital admission and treatment, should be informed about the possibility of completing a digital PAD. This could be done in a variety of ways, both through the care system and through user-led services such as self-help groups. Research has shown that PADs are better accepted when the completion process is supported [4,25]. In addition to human support, a digital, AI-based assistant integrated into the PAD form interface could guide users through the completion process, as outlined by Redahan and Kelly [69]. It could provide explanations and example wordings and ensure that the document is completed fully and correctly, meaning it makes sense in terms of content. This would address a key problem, namely that service users often do not manage to complete the PAD without support [6,39,70]. One of the reasons for the limited uptake by service users may be that research into the implementation of PADs has been conducted primarily by clinical researchers and medical ethicists, including this article. To address the priorities and concerns of service users, and to develop a viable (digital) PAD that service users find helpful, it is critical to have a design process that systematically involves service users from the outset [71,72].

One of the strengths of digital PADs is that service users control PAD access. This means that they could determine and control which people, such as outpatient practitioners (general practitioners, psychiatrists, and psychologists), other people (friends, relatives, etc), or people from other institutions involved in involuntary treatment and hospitalization (judges, guardians ad litem, community mental health investigators, legal guardians), would have read or write access to their digital PAD. One exception could be psychiatric hospitals, whose staff should be able to access the digital PAD when the respective service user is admitted or when they present to the emergency room of a hospital, whereby each read access would be logged by name. This would be necessary to protect the highly sensitive personal data contained in the PAD and to ensure that PADs are only accessed by treatment providers in a psychiatric emergency. This in turn would require a clear (technical) role concept for all actors involved, defining who is allowed to see and process what [26].

A major challenge in the implementation of conventional PADs is the lack of time or the reluctance of clinicians to invest the necessary time [42]. If service users could prepare a digital PAD at their own pace with the help of the digital assistant as outlined above or with the involvement of a trusted person, the attending psychiatrist would only need to check the digital PAD for feasibility and make any necessary suggestions for adjustments during the consultation. This would significantly reduce the time required by clinicians.

One of the main problems with analog PADs was that different versions were stored in different places, which could lead to the PAD accessed in the acute situation not being up to date. Digital access enables the service users to keep the digital PAD up to date when preferences for emergency treatment change. At the same time, a notification system could be used to notify all stakeholders with access to the PAD of changes, for example, by email, making collaboration much easier.

Digital PADs could likely play a significant role in promoting service user involvement in decision-making in mental health care. Ideally, if digital PADs were official, standardized documents integrated into the national health data infrastructure of each country, they would be difficult for institutions or professionals to overlook. This approach would also help tackle the prevalent issue of staff's lack of engagement with PADs [29].

Limitations of Digital Interoperable PADs

Although the digitization of PADs has the potential to overcome many practical barriers, it also brings new challenges, particularly in terms of implementation, acceptance, and engagement.

The existing evidence suggests that people with serious mental health conditions tend to have less access to digital health services or use them to a limited extent [71-73]. In addition, they are less likely to have access to a (desktop) computer, the internet, or a modern smartphone [74,75], and more likely to have concerns about data security and to lack the necessary digital skills [76,77] to keep a digital PAD up to date. As such, digital PADs risk increasing existing inequalities unless these access barriers are specifically addressed [26]. The solution used should therefore be flexible enough to meet the needs of the heterogeneous target group of people with serious mental health conditions and to avoid digital exclusion. To increase the acceptance and reach of the intervention, a combination of high- and low-tech approaches may be useful. For example, the facilitator could store a service user's treatment preferences in the digital PAD on the service user's behalf and provide them with a printout. At the same time, it should also be possible to fill in only selected parts of the digital PAD, such as only a free text field on treatment preferences, as it may be that a highly structured template could be overly prescriptive for some service users and may not adequately reflect how they wish to convey their PAD in terms of content and format. Furthermore, those service users who require additional digital skills to set up a digital PAD, or who have privacy concerns, should receive appropriate training. The latter should also include professionals, as they often do not have the necessary skills either or do not know how to best integrate digital tools into treatment [78].

Another potential limitation concerns the support provided during the process of completing digital PADs. If the completion of a PAD is supported by chatbots or human, nonphysician facilitators, at least some of the exchange about how to deal with emergency situations is outsourced from the patient-physician relationship. This could lead to alienation between patients and practitioners, especially after involuntary treatment or coercion. One way to counteract this would be to use debriefings of involuntary measures to also discuss the PADs and to validate the extent to which the instructions contained in them were actually implemented. This review of the (non) application of the PAD, which could also be done online, should be attended by all key persons involved in the previous involuntary action, or at least the inpatient and outpatient treatment providers in addition to the service user concerned.

XSL•FO
RenderX

In addition, there are a number of barriers to paper and pencil PADs that are likely to apply to digital PADs as well. This concerns the fear, more pronounced among psychiatrists in particular, that there may be a "lack of quality information" in PADs or that "consumers desire to change their mind during crisis" [28]. Furthermore, there are concerns that "inappropriate treatment requests" could be included in the PADs, that these requests could entail risks, that there is a "lack of time to review the document," and that additional documentation is required. These limitations can probably only be reduced by providing more training and information to all parties involved, regardless of whether the intervention is digital or analog. In general, in addition to training measures, it is essential to promote the dissemination of (digital) PADs, be it through web-based multimedia resources, such as those realized in English-speaking countries, or through appropriate educational initiatives enshrined in law, in order to improve knowledge and awareness of PADs among the population, which includes both potential service users and professionals [79].

Another problem that is not solved by digitalization is that in various jurisdictions in some countries, such as the United States and Australia, PADs are not legally binding, and medical orders (eg for measures involving deprivation of liberty, issued by the acting physician during a psychiatric emergency) overrule PADs [25]. Conversely, where self-binding directives apply, it is often not regulated which PAD contents are legally binding and which are not and can therefore be overruled by professionals [8,37]. Consequently, digitalization should be accompanied by a revision of the legislation on the application of PADs and lead to more clarity about revocability and enforceability. In this context, for example, it would be important to clarify how to proceed if service users revoke the digital PAD on their cell phone in the context of an acute mental health crisis.

Another limitation, related to the existing acceptance issues, is that digitalization could render an already complex intervention "PAD" even more complex. In addition, problems related to internet connection and technology, system interoperability, data security, and data protection must be overcome [80]. For the innovation to succeed, an overarching implementation strategy is needed that permeates the macro, meso, and micro levels and requires the will as well as the necessary IT resources and infrastructure.

While digital PADs could provide greater convenience and ease in making advanced health care decisions, there is a potential risk that people with serious mental health conditions might update their directives during acute illness episodes, which could lead to problematic or unintended decisions. In addition, due to the digital nature of these directives, there may be privacy risks and concerns about unauthorized access. This could be the case if a service user shares the access or QR code with unknown people or in public places such as social networks, which could harm the service user. How these and related risks might be managed will require greater forethought and provisions to guide and protect service users.

Future Research Directions

The introduction of digital PADs offers promising opportunities as well as new challenges that need to be further explored. Future research should focus on a participatory approach to the digitalization of PADs to ensure that the expectations and needs of all stakeholders, particularly service users, are adequately addressed to ensure the needs-based and practical nature of the solution to be developed. We argue that before measuring "hard" outcomes, such as the reduction of involuntary interventions and inpatient treatment days, which should of course be a longer-term goal, efforts must first be made that aim at a careful development and implementation of digital PADs.

First, the requirements and barriers to the implementation of digital PADs should be thoroughly researched. This must include developing strategies to reduce digital exclusion to ensure that the main target group of the intervention, people with serious mental health conditions, are not left behind. Furthermore, for a future-oriented embedding of the PAD in the health data infrastructure, transnational initiatives such as the European Health Data Space should also be considered. Finally, the legal and ethical implications of PADs must be investigated, especially in countries where PADs are not legally binding, to ensure that these digital tools improve, and do not hinder, the autonomy of the service user and the quality of care. Only when satisfactory acceptance by stakeholders can be demonstrated, as evidenced by a fully completed digital PAD and its accessibility in emergency situations, does it seem reasonable to investigate the abovementioned hard outcomes, for example, in the form of a randomized controlled trial. In this context, a comparison with the paper-and-pencil version of the PAD also seems important to demonstrate a possible differentiation and superiority of digital PADs.

Conclusions

The integration of PADs into electronic health records represents an important step toward equality in mental and physical health care. At the same time, it is in line with the trend toward increasing digitalization of involuntary psychiatric admission processes [81,82], which holds significant potential in terms of transparency, speed, and equity. Digital PADs have the potential to fundamentally change psychiatric crisis care by addressing long-standing challenges of printed PADs such as accessibility, outdated information, and limited stakeholder engagement. Their success will depend on the careful development of implementation strategies, training of professionals, and the inclusion of stakeholders in the design and evaluation process. Although digital PADs can overcome many of the barriers associated with traditional PADs, they also introduce new complexities that must be addressed through ongoing research.

Abstract

The adoption of the European Health Data Space (EHDS) regulation has made integrating health data critical for both primary and secondary applications. Primary use cases include patient diagnosis, prognosis, and treatment, while secondary applications support research, innovation, and regulatory decision-making. Additionally, leveraging large datasets improves training quality for artificial intelligence (AI) models, particularly in cancer prevention, prediction, and treatment personalization. The European Union (EU) has recently funded multiple projects under Europe's Beating Cancer Plan. However, these projects face challenges related to fragmentation and the lack of standardization in metadata, data storage, access, and processing. This paper examines interoperability standards used in six EU-funded cancer-related projects: IDERHA (Integration of Heterogeneous Data and Evidence Towards Regulatory and Health Technology Assessments Acceptance), EUCAIM (European Cancer Imaging Initiative), ASCAPE (Artificial Intelligence Supporting Cancer Patients Across Europe), iHelp, BigPicture, and the HealthData@EU pilot. These initiatives aim to enhance the analysis of heterogeneous health data while aligning with EHDS implementation, specifically for the EHDS for the secondary use of data (EHDS2). Between October 2023 and July 2024, we organized meetings and workshops among these projects to assess how they adopt health standards and apply Internet of Things (IoT) semantic interoperability. The

XSL•FO
RenderX

discussions focused on interoperability standards for health data, knowledge graphs, the data quality framework, patient-generated health data, AI reasoning, federated approaches, security, and privacy. Based on our findings, we developed a template for designing the EHDS2 interoperability framework in alignment with the new European Interoperability Framework (EIF) and EHDS governance standards. This template maps EHDS2-recommended standards to the EIF model and principles, linking the proposed EHDS2 data quality framework to relevant International Organization for Standardization (ISO) standards. Using this template, we analyzed and compared how the recommended EHDS2 standards were implemented across the studied projects. During workshops, project teams shared insights on overcoming interoperability challenges and their innovative approaches to bridging gaps in standardization. With support from HSbooster.eu, we facilitated collaboration among these projects to exchange knowledge on standards, legal implementation, project sustainability, and harmonization with EHDS2. The findings from this work, including the created template and lessons learned, will be compiled into an interactive toolkit for the EHDS2 interoperability framework. This toolkit will help existing and future projects align with EHDS2 technical and legal requirements, serving as a foundation for a common EHDS2 interoperability framework. Additionally, standardization efforts include participation in the development of ISO/IEC 21823-3:2021—Semantic Interoperability for IoT Systems. Since no ISO standard currently exists for digital pathology and AI-based image analysis for medical diagnostics, the BigPicture project is contributing to ISO/PWI 24051-2, which focuses on digital pathology and AI-based, whole-slide image analysis. Integrating these efforts with ongoing ISO initiatives can enhance global standardization and facilitate widespread adoption across health care systems.

Introduction

Cancer is one of the main causes of death in Europe and worldwide, after cardiovascular diseases. According to the World Health Organization (WHO), cancer is the second leading cause of death and morbidity in Europe, with more than 3.7 million new cases and 1.9 million deaths each year [1]. In response to the urgent need to renew European political commitment to tackle cancer, Europe's Beating Cancer Plan (EBCP; 2021-2027) was launched and structured around 4 key action areas: prevention, early detection, diagnosis and treatment, and the quality of life of patients with cancer and cancer survivors [2]. Since 2021, the European Commission (EC) has supported collaborative projects focused on cancer diagnostics and treatment using high-performance computing and artificial intelligence (AI). To maximize the potential of data and digitalization, the EBCP also addressed the interactions and alignment of cancer data projects and initiatives with the European Health Data Space (EHDS). In autumn 2023, the EC organized 3 online workshops on the reuse of health data resources in the field of cancer research and recently published the results of these workshops [3], where "fragmentation and the lack of standardization in metadata, data storage, access, and processing" were identified as key challenges facing data-driven cancer projects. The nascent infrastructure for the application of AI in medical imaging (European Cancer Imaging Initiative [EUCAIM]) reported on the experiences of 5 projects developing big data infrastructures that will enable European, ethical, General Data Protection Regulation (GDPR)–compliant, quality-controlled, and cancer-related medical imaging platforms, where both large-scale data and AI algorithms will coexist [4]. These projects include the following:

1. Chameleon: a project focused on developing AI algorithms for cancer diagnosis and prognosis.
2. EuCanImage: a project aimed at creating a large-scale cancer image database.
3. ProCAncer-I: a project focused on developing AI-based tools for personalized cancer treatment.
4. Incisive: a project contributing a significant amount of cancer image data to EUCAIM.
5. Primage: a project focused on developing AI-based image analysis techniques for cancer diagnosis.

These projects along with the RadioVal project established the AI for Health Imaging (AI4HI) network to develop cancer imaging data repositories and AI solutions based on medical imaging to improve clinical practice.

Table 1 summarizes the list of projects that participated in the EC workshop entitled "Landscaping data-driven projects and initiatives in the cancer field–rationale and directions for better collaboration and integration" [3], as well as the established project-level synergies and collaborations among ongoing projects.

The workshop also addressed the current challenges facing data-driven cancer projects [3], gaps existing in existing standards, and recommendations for future semantic interoperability (given in Table 2).

HSbooster Health Project Cluster in Cancer

In this work, we focus on the interoperability challenges and existing gaps in health care standards building on the challenges and synergies highlighted in the EC workshop [3]. Through the EC European Standardization Booster (HSbooster.eu) initiative, we create synergy among six cancer data-driven projects (ie, IDERHA [Integration of Heterogeneous Data and Evidence towards Regulatory and Health Technology Assessments Acceptance], EUCAIM, ASCAPE [Artificial Intelligence Supporting Cancer Patients Across Europe], iHelp, BigPicture, and the HealthData@EU pilot project) by using health standards. These 6 innovative projects aim to transform digital health in oncology by leveraging advanced technologies and collaborative frameworks for enhancing cancer diagnosis, treatment, and research, improving patient outcomes, and accelerating scientific advancements. We initially created a template for the EHDS for the secondary use of data (EHDS2) interoperability framework based on the new European Interoperability Framework (EIF). The recommended standards and governance model from the joint action (JA) Towards the European Health Data Space (TEHDAS) [5] for the secondary use of data were then used to harmonize the standards in the template (given in Textbox 1).

Starting October 2023, we conducted several meetings and workshops among the 6 projects to elucidate how they adopt health standards and Internet of Things (IoT) semantic interoperability. This included examining interoperability standards for health data, knowledge graphs–related technologies, the Smart Applications Reference Ontology (SAREF), the data quality framework (DQF), patient-generated health data (PGHD), AI reasoning, federated approaches, security, and privacy.

As per the TEHDAS recommendations, we compared the health-standardized models, ontologies, and terminologies used in these projects, including, Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR), Open Health Data Science and Informatics (OHDSI), Observational Medical Outcomes Partnership (OMOP)–Common Data Model (CDM), Digital Imaging and Communications in Medicine (DICOM), International Organization for Standardization (ISO) Technical Committee (TC) 215, and World Wide Web Consortium (W3C) Data Catalog Vocabulary (DCAT).

As EHDS is still evolving and its implementation is still under development, this study aims to examine how the 6 projects implement the recommended EHDS2 standards. Consequently, we introduce a new template to support the EHDS2 interoperability framework and highlight the results of comparing data standards across projects. By summarizing the

XSL•FO
RenderX

lessons learned, we provide recommendations for future directions in EHDS2 implementation.

Textbox 1. European Health Data Space for European Interoperability Framework.

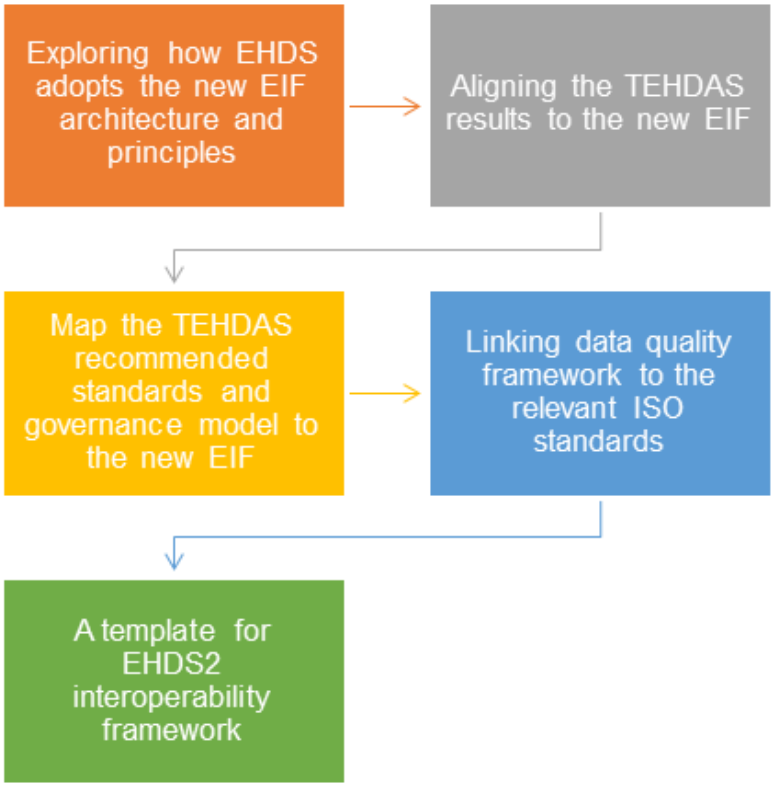
European Health Data Space

- The European Health Data Space (EHDS) [6] aims to harmonize health data usage across Europe [7]. It includes comprehensive rules, standards, practices, infrastructures, and a robust governance framework to improve health care delivery, drive research and innovation, and inform policymaking.
- A central focus of the EHDS is empowering patients by providing them greater digital access and control over their health data, fostering a more transparent and efficient health care system. In addition, the EHDS seeks to standardize health data across member states, ensuring interoperability, enhancing clinical outcomes, and accelerating medical research and innovation through a unified dataset.
- The governance framework ensures data privacy and security, addresses ethical concerns, and fosters stakeholder trust. The EHDS also aims to streamline regulatory processes and support cross-border health care initiatives by aligning national and regional policies.
- Therefore, the EHDS will significantly impact Europe's digital health landscape by promoting a more connected, efficient, and patient-centered health care ecosystem.

Joint Action Toward the European Health Data Space

- The Toward the European Health Data Space (TEHDAS) project [5] is a joint action that developed European principles for the secondary use of health data, involving 25 countries. It advocates for using existing International Organization for Standardization (ISO) standards to ensure consistency and interoperability. TEHDAS focuses on data interoperability, identifying standards for data discovery and common data models. A synthesis table details essential standards including DCAT Application Profile for Data Portals in Europe (DCAT-AP) [8], INSPIRE, FairSharing, Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT), and Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR).
- The project addresses syntactic interoperability, providing guidelines on data structure and format for seamless sharing across systems. In addition, TEHDAS emphasizes data quality, proposing frameworks to regulate and enhance the reliability of health data for secondary uses, such as research and policymaking. Overall, TEHDAS's work supports a standardized and interoperable EHDS, leading to improved health care, research, and innovation in Europe.

European Interoperability Framework



- The new European Interoperability Framework (EIF) [9] adopted on March 23, 2017, fosters electronic communication and information exchange among European public administrations by providing common models, principles, and recommendations. The EIF delineates four layers of interoperability challenges: legal, organizational, semantic, and technical. This paper concentrates on the semantic interoperability challenge, encompassing both semantic and syntactic aspects. Semantic interoperability ensures that the meaning of exchanged data is preserved and understood across different systems. This can be achieved through the use of shared vocabularies and schemas. On the other hand, syntactic interoperability involves defining the grammar and format for data exchange.
- The EIF provides guidance for European public administrations to improve interoperability, ensuring smooth data exchange and efficient digital service delivery. Conversely, ISO 23903 concentrates on semantic interoperability within Information and Communication Technology (ICT) systems, aiming to unify the interpretation of information across various platforms.
- Aligning the EIF with ISO 23903 synchronizes European interoperability principles with semantic standards, fostering easier communication and cooperation among public administrations. This alignment ensures both technical harmony and uniformity in the meaning and semantics of exchanged data, thereby enhancing the efficiency and efficacy of digital service provision for citizens and businesses across Europe.

Template for the EHDS2 Interoperability Framework Based on the EIF

Figure 1 shows the process of creating the template for the EHDS2 interoperability framework.

XSL•FO
RenderX

Figure 1. The process for creating the proposed template for the EHDS2 interoperability framework. EHDS: European Health Data Space; EHDS2: European Health Data Space for the secondary use of data; EIF: European Interoperability Framework; ISO: International Organization for Standardization; TEHDAS: Towards the European Health Data Space.

Exploring How EHDS Adopts the New EIF Architecture and Principles

Recent studies showed the importance of adopting the EIF in establishing the EHDS interoperability framework [7,10,11] (as shown in Textbox 1). In addition, several studies have investigated the interoperability requirements for heterogeneous health information systems, as well as the associated health care standards [12,13].

Aligning the TEHDAS Results to the New EIF

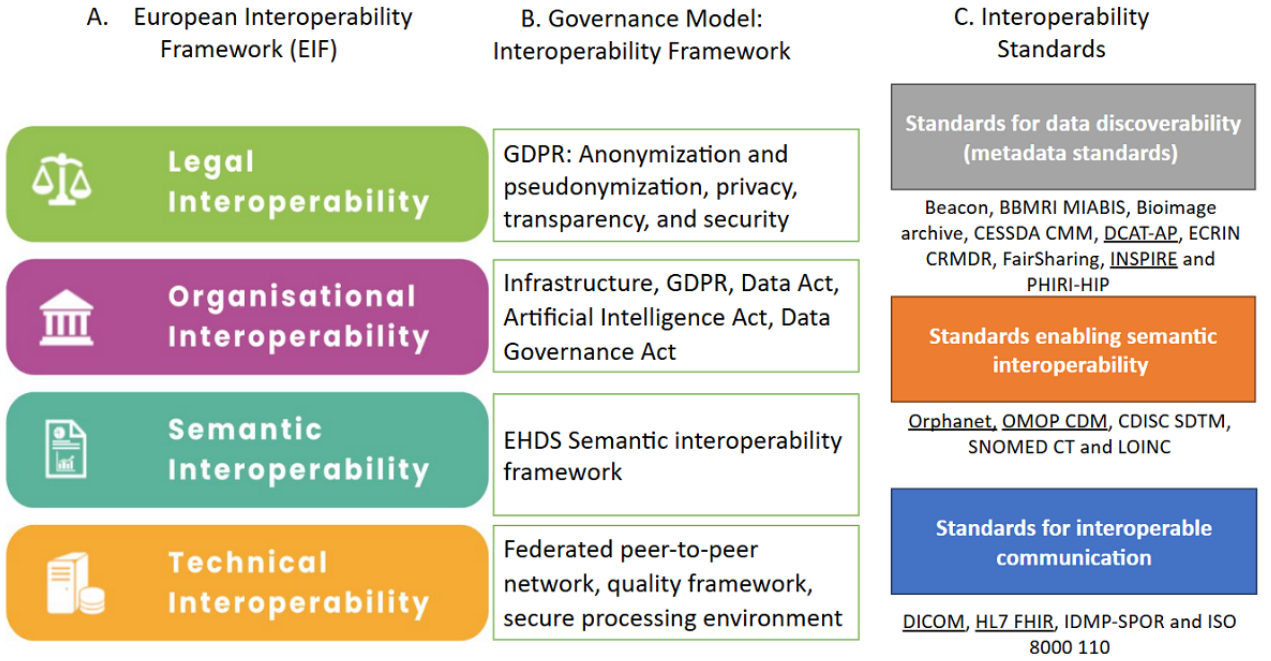
The TEHDAS JA involves 25 European countries in developing the principles that will shape EHDS2 by providing guidance and recommendations on interoperability, data quality, and standards (as shown in panel 2 in Textbox 1). In 2023, the TEHDAS JA published a report titled "Options for governance models for the European Health Data," which discusses EHDS governance using the EIF [14]. In addition, they assessed 19 standards that provide a layer of semantic interoperability, supporting the cataloging of data sources and the exchange of data between different nodes [15].

Mapping the TEHDAS Recommended Standards and Governance Model to the New EIF

Following the recommendation of the EC workshops on landscaping data-driven projects and initiatives in cancer [3], we adopted the TEHDAS results on recommended standards for EHDS2 interoperability, as well as the principles of data quality frameworks. We then mapped these results to the new EIF interoperability framework and linked the data quality framework to the corresponding ISO standards. Figure 2 shows how the TEHDAS results are mapped to the new EIF interoperability framework. Notably, TEHDAS framed the recommended EHDS2 interoperability into 3 categories of standardization:

1. Data discoverability (DCAT-AP)
2. Enabling semantics interoperability (OMOP-CDM)
3. Health data exchange (DICOM for imaging data and FHIR for health records).

The template shows the importance of incorporating and harmonizing the underpinning standards to comply with new regulations, such as the AI Act [16]. As a result, integrating advanced AI methodologies within the proposed framework enhances TEHDAS principles and advances beyond EIF by embedding robust data quality frameworks, enabling federated learning for secure and scalable data sharing, and incorporating privacy-preserving mechanisms that comply with GDPR. This framework delivers actionable templates that bridge theoretical interoperability principles with real-world AI applications, such as cancer diagnostics and personalized treatment. By aligning technical standards with semantic requirements and supporting adaptability to evolving regulations, such as the European AI Act, the framework provides a scalable, future-ready solution for health care interoperability and AI-driven innovation.



The EIF does not classify standards according to interoperability layers (technical, semantic, legal, and organizational). However,

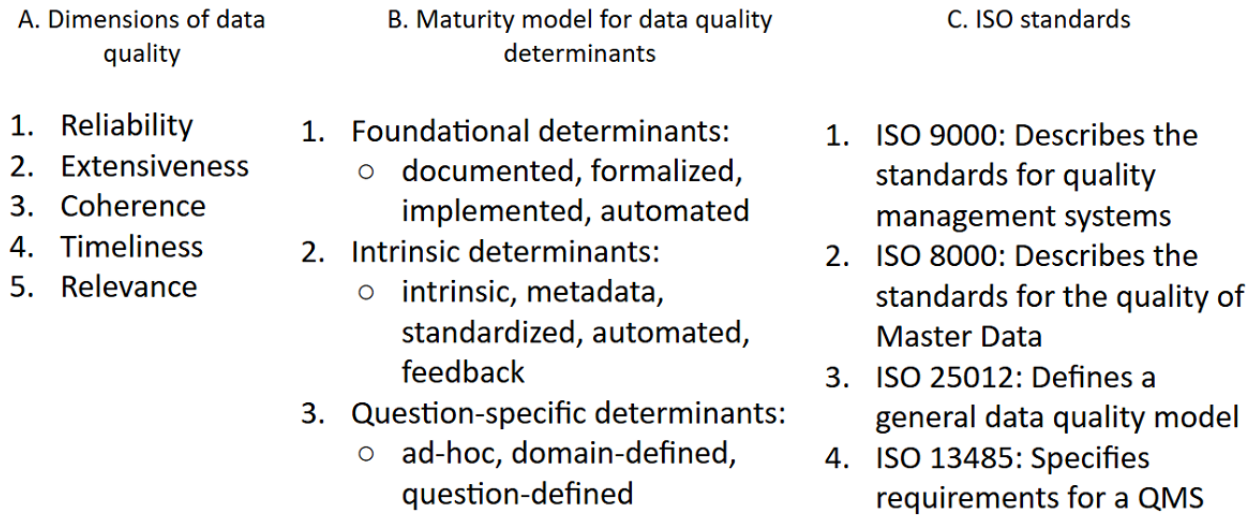
XSL•FO
RenderX

we need to consider the relevant standards for data privacy and quality assessment [10].

Furthermore, the work is a foundation for creating an interactive tool for the EHDS2 Interoperability Framework, which has been submitted to JMIR as part 2 (Towards EHDS2 interoperability framework: An interactive EIF-based standards compliance toolkit for AI-driven projects).

Figure 2. Template for the EHDS2 interoperability framework based on the TEHDAS results: (A) EIF layers; (B) TEHDAS governance model and associated interoperability framework [14]; and (C) TEHDAS 19 standards evaluation using the EIF, with the selected standards that "passed the EIF criteria evaluation" underlined [15]. DCAT-AP: DCAT Application Profile for Data Portals in Europe; DICOM: Digital Imaging and Communications in Medicine; EHDS: European Health Data Space; EHDS2: European Health Data Space for the secondary use of data; EIF: European Interoperability Framework; FHIR: Fast Health Interoperability Resources; GDPR: General Data Protection Regulation; HL7: Health Level 7; ISO: International Organization for Standardization; LOINC: Logical Observation Identifiers Names and Codes; OMOP-CDM: Observational Medical Outcomes Partnership Common Data Model; SNOMED CT: Systematized Nomenclature of Medicine–Clinical Terminology.

Linking DQF to the Relevant ISO Standards



In May 2024, the Big Data Value Association (BDVA) published a study entitled "Elevating Data Quality A Paradigm Shift for Data Spaces and AI Needs" to explore the relationships between data quality and data spaces with respect to the AI Act [17]. The study proposed that the data quality and utility label for EHDS should comply with data documentation, technical quality, data quality management processes, coverage, access and provision, and data enrichment procedures.

From the EHDS2 perspective, the TEHDAS JA provided a generic DQF [18], which includes both technical quality elements and six utility dimensions: relevance, accuracy and reliability, coherence, coverage, completeness, and timelines. This was followed by the publication of associated recommendations affecting data quality and utility implementation in HealthData@EU [19]. Based on these deliverables, the European Medicine Agency (EMA) published its own DQF for EU medicines regulation [20]. This publication provides an analysis of the data quality actions and metrics, as well as a maturity model, to guide the evolution of automation to support data-driven regulatory decision-making (as shown in Figure 3) [20].

Ensuring the accuracy, completeness, consistency, and reliability of cancer research data is of utmost importance, and adherence to data quality standards plays a crucial role in achieving this goal. These standards not only help maintain data integrity but also promote data interoperability through the use of standardized data models and vocabularies. This enables seamless data exchange and integration across different projects and platforms. In addition, adhering to these standards supports informed decision-making by providing high-quality data for clinical decisions, research insights, and policymaking related to cancer treatment and prevention. Compliance with international legal and regulatory requirements is also ensured, upholding proper data governance and ethical data usage. Finally, establishing a unified framework for data quality encourages collaboration among various stakeholders within the cancer research community. We compare data quality standards in Table S4 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 3. European Medicines Agency data quality framework in terms of the (A) dimensions of data quality, (B) maturity levels, and (C) related ISO standards. ISO: International Organization for Standardization; QMS: quality management system.

Landscape of the Involved Projects and Used Standards

In this study, we used the EHDS2 interoperability framework template to compare 6 projects with cancer use cases where AI is applied (as shown in panel 4 in Textbox 2; Table 3). The selected projects vary in scope, cancer domain, categories of health data, scale of infrastructure, AI implementation approach, and time spans [21].

We focused on semantic interoperability standards (as shown in Textbox 3), recommended by the TEHDAS JA and related ISO standards. The analysis explored how health standards support health ontologies, for example, how HL7 FHIR supports the Findability, Accessibility, Interoperability, and Reusability (FAIR) principles through the FHIR for FAIR implementation guide [28].

Textbox 2. Introduction to six key projects advancing oncology through digital health.

We explore 6 innovative projects that are transforming digital health in oncology. By leveraging advanced technologies and collaborative frameworks, these projects aim to enhance cancer diagnosis, treatment, and research, improving patient outcomes, and accelerating scientific advancements:

- IDERHA (Integration of Heterogeneous Data and Evidence Towards Regulatory and Health Technology Assessments Acceptance) [22] (2023-2028): IDERHA advances digital health in the context of lung cancer. It seeks to enhance health care delivery and improve patient outcomes by integrating various health data sources to support effective clinical decision-making and the development of improved treatments.
- BigPicture [23] (2021-2027): BigPicture aims to revolutionize pathology practice by establishing a repository of high-quality, annotated images, and developing artificial intelligence (AI) tools to improve diagnostic accuracy and efficiency. Data are collected from all types of tissues, including 1 million clinical samples and 2 million nonclinical samples from toxicology studies.
- EUCAIM (European Cancer Imaging Initiative) [24] (2023-2026): EUCAIM provides a federated infrastructure for sharing and analyzing cancer images. This supports AI research and clinical practices to advance cancer diagnosis and treatment.
- iHelp [25] (2021-2024): The iHelp project is dedicated to developing an intelligent, AI-driven health monitoring platform for early disease detection and management. It offers personalized health care solutions that enhance patient engagement and outcomes, with a specific focus on pancreatic cancer.
- ASCAPE (Artificial Intelligence Supporting Cancer Patients Across Europe) [26] (2020-2023): ASCAPE leverages AI to enhance the quality of life for patients with cancer. By using advanced analytics on health data, the project develops predictive models and personalized treatment plans to support patient care and survivorship.
- HealthData@EU Pilot [27] (2022-2024): This project aims to establish a technical infrastructure to enable cross-border health data access and use within the European Union, empowering the secondary use of health data more broadly. This initiative supports the creation of a cohesive digital health ecosystem, fostering innovation and improving health care services across Europe.

Textbox 3. Advancing semantic interoperability in digital health: a landscape of standards used in the involved projects.

Our attention is drawn to the critical role that standards play in examining semantic interoperability within the digital health realm. These standards form the foundation for seamless data exchange, ensuring consistency and coherence across various health care platforms. The main standards are as follows:

- Health Level 7 (HL7) Fast Healthcare Interoperability Resources (FHIR) [29]: Positioned as a cornerstone in health care interoperability, FHIR stands out for its efficiency, adaptable architecture, and robust data exchange mechanisms, which facilitate smooth communication across disparate systems.
- DICOM (Digital Imaging and Communications in Medicine) [30]: DICOM is widely adopted in clinical and research settings, underscoring its effectiveness in enabling image exchange.
- Common Data Model (CDM)–OMOP (Observational Medical Outcomes Partnership) [31]: While not strictly a standard, CDM-OMOP allows for data harmonization and analysis. Its synergy with established standards enhances overall interoperability.
- International Organization for Standardization (ISO) [32]:
  - ISO TC 215 and CEN TC 251 Health Informatics: These cover a range of ISO standards, such as 13606 (5 parts), 27269, and 29585, alongside the Health Informatics Service Architecture (HISA)–compliant data models.
  - ISO 13606: This focuses on exchanging information on electronic health records between different health care information systems. It has a comprehensive structure for organizing clinical data, including patient demographics, medical history, diagnoses, treatments, and other relevant information.
  - ISO/AWI TR 24305: This guideline, derived from ISO standards 13940 and 13606, offers a structured HL7 FHIR implementation framework. It strengthens interoperability infrastructure, aligns with ISO norms, and promotes uniformity and adherence to best practices.
  - ISO 23903: Titled “Health Informatics - Interoperability and Integration Reference Architecture (IIRA),” this standard addresses the integration and interoperability challenges in health information systems and services, ensuring they can communicate effectively and share data seamlessly.
  - ISO 13972: Titled “Health Informatics - Detailed Clinical Models (DCM),” this standard focuses on the standardization and interoperability of clinical information models. DCMs are specifications that represent the clinical concepts and data elements used in electronic health records (EHRs) and health information systems.
- Internet of Things and eHealth coding standards
  - ETSI SmartM2M Smart Applications Reference Ontology (SAREF) [33]: Tailored for the eHealth and healthy aging domains, representing a specialization within standardization. Its integration expands interoperability across different targeted demographic groups.
  - Systematized Nomenclature of Medicine (SNOMED) [34]: SNOMED is a comprehensive clinical terminology system that captures, encodes, and shares EHRs and other health care data. It provides a standardized vocabulary for describing clinical concepts, enabling interoperability and semantic consistency across health care systems. SNOMED facilitates accurate and meaningful exchange of clinical information, supporting clinical decision-making, research, and public health reporting.
  - Logical Observation Identifiers Names and Codes (LOINC) [35]: LOINC is a standardized system for identifying and exchanging clinical laboratory test results and other clinical observations. It provides a universal set of codes and terms for describing laboratory tests, measurements, and observations, ensuring interoperability and semantic consistency in healthcare data exchange. LOINC enables seamless integration of laboratory data into EHRs and other health information systems.
  - International Classification of Diseases (ICD) [36]: It is promoted by the World Health Organization (WHO). ICD codes are used to define diagnoses for clinical treatment, medical billing, and statistics collections. It contains codes for diseases, signs and symptoms, abnormal findings, complaints, social circumstances, and external causes of injury or diseases. These codes help physicians in determining which conditions are relevant for clinical decisions, injuries, and causes of death. However, ICD has some limitations (eg, diabetes has more than 2 dozen different codes). Patient data recorded with ICD can be used for administrative functions, epidemiologic studies, research subject recruitment, interventional protocols, and clinical decision support systems.

The other standards regarding data quality, security, artificial intelligence (AI), and wearables are listed in the Multimedia Appendix 1.

Abbreviations of semantic metadata or terminologies used by standards

- ATC: Anatomical Therapeutic Chemical Classification System; Birnlex: Biomedical Research Integrated Domain Group; CPT: Current Procedural Terminology; ICD: International Classification of Diseases; ICDO: International Classification of Diseases for Oncology; NAACR: North American Association of Central Cancer Registries; NCIT: National Cancer Institute Thesaurus; OSIRIS: Open Source Infrared Imaging System; RADLEX: Radiology Lexicon; RDFS: Resource Description Framework Schema; SPARQL: SPARQL Protocol and RDF Query Language; RxNorm: Prescription Normative Terminology; UCUM: Unified Code for Units of Measure; UMLS: Unified Medical Language System.

Comparing the Health Data Projects

To identify synergies among the 6 projects, we used the EHDS2 interoperability framework template to analyze adopted standards, highlighting similarities and differences in the implementation approach (detailed results given in Tables S1-S7 in Multimedia Appendix 1).

XSL•FO
RenderX

Mapping the Projects to the Created Template for the EHDS2 Interoperability Framework

The EHDS2 interoperability framework template identified key standards and technologies for the implementation of EHDS2, including HL7 FHIR; DICOM; OMOP-CDM; upcoming standards developed by ISO TC 215, ISO TC212, CEN TC 251; and ontology technologies, including W3C DCAT-AP. The key standards used in 6 projects, their focus areas, and planned future implementations are summarized in Table 4.

Table 4. Overview of the used, innovated, and planned health data standards in the projects (using the template of the European Health Data Space for the secondary use of data [EHDS2] interoperability framework).

Project	Used standards	Planned or future standards
IDERHA	HL7[a] FHIR[b], DICOM[c], and OMOP	ISO[d] TC[e] 215, DCAT-AP[f]: HealthDCAT-AP
BigPicture	DICOM, SNOMED[g], and *ICD*	ISO TC 212 (digital pathology and AI[h]), and Kidney Biopsy Codes
EUCAIM[i]	Using its own hyperontology and common data model based on: DICOM, DICOM Seg, OMOP, FHIR, mCODE, DCAT-AP-Health, OSIRIS	—[r]
	Ontologies used so far: LOINC[j], SNOMED, UCUM[k], RADLEX[l], ICDO3, *ICD-10*[m], CPT4, ICD10PCS, ATC[n], NCIT[o], Birnlex[p], NAACR[q], Cancer Modifier	
iHelp	HL7 FHIR, OMOP-CDM, ISO 27799:2016, SNOMED, LOINC, *ICD-9*, ICD-10, UMLS, SPARQL, RDFS[s], RxNorm	—
ASCAPE	HL7 FHIR, ISO/CEN 13606, LOINC, SNOMED	—
HealthData@EU pilot	Observing and collecting standardization efforts rather than direct implementation	The first version of the Health DCAT-AP metadata standard is being developed in the project

Main Findings and Lessons Learned

All projects support the recommended standards identified by the TEHDAS JA for EHDS2 interoperability. Although the DICOM standard is widely used for collecting, storing, and transferring medical imaging data, it lacks important information required to identify relevant images because DICOM metadata are not standardized [37]. To overcome this challenge, the EUCAIM project CDM is built upon the FHIR resources ImagingStudy and ImagingSeries, the Medical Imaging–CDM extension of the OMOP-CDM, the ProCAncer-I imaging extension [38], and the OSIRIS imaging component. In this way, proper integration of imaging and clinical data was provided in alignment with the Integrating the Healthcare Enterprise [39].

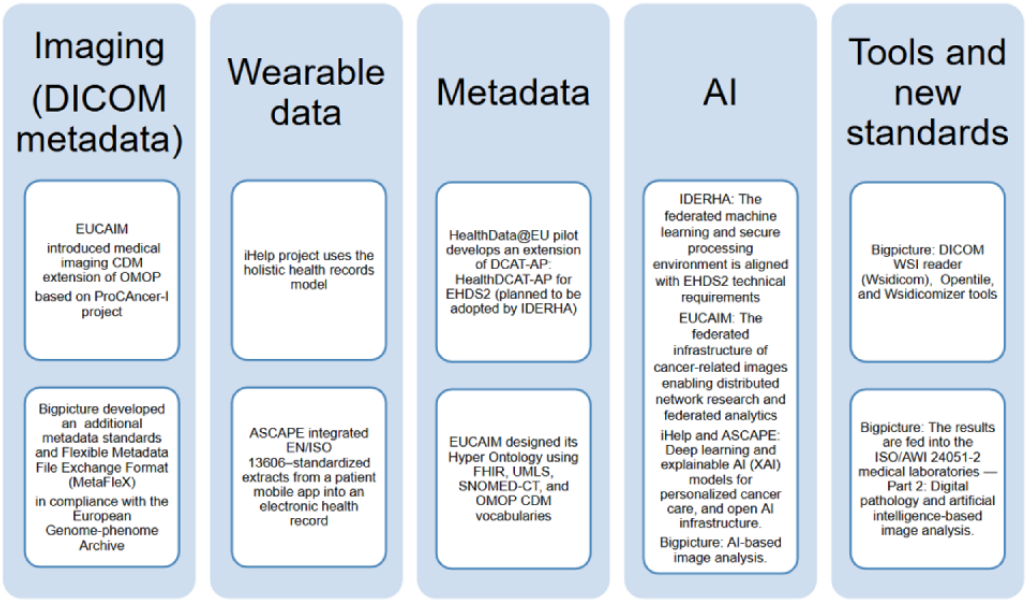
The BigPicture project selected the DICOM format as a standard for archiving whole-slide images (WSI) to support back-and-forth conversion of proprietary file formats. The BigPicture profile for DICOM WSI is based on work by the

XSL•FO
RenderX

DICOM pathology working group WG26. The format is designed to allow efficient storage of a large number of annotations, for example, generated by AI algorithms [40]. The project developed a Python tool (Wsidicom) to serve as a reference implementation of a DICOM WSI reader [41]. In addition, two tools, Opentile and Wsidicomizer, were developed to read other WSI formats and convert them to DICOM resulting in faster format conversion and maintained image quality [42].

To ensure structured data exchange and harmonized-consistent metadata interaction for data not captured in DICOM, BigPicture has developed additional metadata standards that define and comprise a set of substandards: (1) the data model (Common Mandatory Metadata Structure[CMMS]) comprising of all metadata, (2) a set of mandatory information that must be provided in relation to CMMS entities and their relations to each other, (3) a metadata file format that is used within BigPicture (flexible metadata file exchange format), and (4) a standard file structure of datasets containing metadata and data files that can be found on the repository. Standards are based on the European Genome-phenome Archive (EGA), and where possible existing standards have been incorporated (SNOMED, ICD for clinical data, Standardization for Exchange of Nonclinical Data [SEND] terminology, and International Harmonization of Nomenclature and Diagnostic Criteria (INHAND) nomenclature for nonclinical data). Results from BigPicture, such as metadata formats or quality control criteria, will feed into the ISO/AWI 24051-2 “Medical laboratories—Part 2: Digital pathology and artificial intelligence (AI)-based image analysis.”

Regarding the metadata standards, the HealthData@EU pilot published a landscape analysis of available metadata catalogs and metadata standards [43]. The pilot also develops an extension of DCAT-AP: HealthDCAT-AP that will be adopted by EHDS2 projects, like IDERHA [44]. This standard could be adopted later as the mandatory metadata standard foreseen under the EHDS regulation. The EUCAIM project designed its Hyper Ontology [45] using FHIR, UMLS, SNOMED-CT, and OMOP-CDM vocabularies.



While data from wearables are available in high volumes, a substantial amount of data is lost because the usability of the data is governed and limited by proprietary data formats from an increasing number of manufacturers, which shows the necessity of standardization to enable interoperability [46]. Among the six projects and initiatives, IDERHA, iHelp, and ASCAPE use sensors and wearables technologies. The iHelp project uses the holistic health records (HHR) model to enable the aggregation of data from different sources, sensors, and online platforms to support the seamless integration of multiple health dimensions [47].

The HL7 FHIR standard-compatible data structures were used in the context of the iHelp project to integrate primary and secondary data and to compile them into the holistic health records FHIR model [47]. FHIR can be used for clinical data and also for streaming data from sensors [48]. The ASCAPE project successfully integrated EN/ISO 13606–standardized extracts from a patient mobile app into an electronic health record [49]. IDERHA plans to extend the OMOP-CDM to address the PGHD, including patient-reported outcomes and patient-reported experience measures.

The BigPicture project highlighted that a dedicated standardization project focused on digital pathology is currently missing. It addressed the need for ISO/AWI 24051-2 “Medical laboratories—Part 2: Digital pathology and artificial intelligence (AI)-based image analysis” (under development, April 2024) that will build on ISO 20166-4:2021 “Molecular in vitro diagnostic examinations Specifications for pre-examination processes for formalin-fixed and paraffin-embedded (FFPE) tissue Part 4: In situ detection techniques” [50]. Figure 4 summarizes the main findings of the projects and how they can feed each other.

XSL•FO
RenderX

Figure 4. Key outputs and lessons learned from the six projects. AI: artificial intelligence; ASCAPE: Artificial Intelligence Supporting Cancer Patients Across Europe; AWI: approved work item; CDM: Common Data Model; DCAT-AP: DCAT Application Profile for Data Portals in Europe; DICOM: Digital Imaging and Communications in Medicine; EHDS: European Health Data Space; EHDS2: European Health Data Space for the secondary use of data; EUCAIM: European Cancer Imaging Initiative; HHR: holistic health record; IDERHA: Integration of heterogeneous Data and Evidence Towards Regulatory and Health Technology Assessments Acceptance; iHelp: Personalised Health Monitoring and Decision Support Based on Artificial Intelligence and Holistic Health Records; OMOP: Observational Medical Outcomes Partnership; SNOMED-CT: Systematized Nomenclature of Medicine Clinical Terms; UMLS: Unified Medical Language System; WSI: whole-slide imaging; XAI: explainable artificial intelligence.

It is interesting to notice that the ETSI SmartM2M SAREF extensions for health and aging well (SAREF4EHAW) and wearables (SAREF4WEAR) are not known and not used on those six projects that we compared, even projects using IoT technologies with sensors, devices.

Key reasons for this gap include insufficient promotion, perceived relevance, integration challenges, and the presence of competitive standards. ETSI should enhance outreach, showcase successful implementations, collaborate with key projects, and simplify integration processes to improve adoption.

The other aspects, AI and federated learning, security and privacy, and data quality are covered by several approaches and standards. The adoption of federated standards and AI in cancer research projects across Europe represents a shift toward collaborative yet privacy-preserving medical research. These initiatives are essential for creating robust, scalable, and interpretable AI models that can significantly advance early detection, treatment, and overall patient care in oncology. The projects leverage various AI standards to achieve these goals. Some of the key AI standards being used have been included in Table S7 in Multimedia Appendix 1. The Regulation (EU) 2018/1725, also known as GDPR, covers the fundamental requirements for access, sharing, and storage of personal data, including health data. The usage of raw health data with personal details included for research purposes remains controversial in terms of consent and audit logging. Furthermore, there is a need for standardized security and data-sharing models. Finally, conformance guidelines to ensure compliance with regulations (eg, AI Act) for manufacturers developing medical products are still needed.

Creating Synergy Among the Involved Projects

We remarked on similarities and differences as we navigated the implementation of various standards among the projects. Despite the projects' varied focuses, each project prioritizes interoperability, relying on various standards. This collective effort promotes knowledge exchange and innovation and fosters a digitally unified health care ecosystem for EHDS2. We also observed a trend towards common standards like HL7 FHIR and DICOM. While projects may vary in domain-specific standards and implementation nuances, leveraging established standards offers numerous advantages. This includes improved interoperability, streamlined development processes, scalability, and knowledge sharing.

Accordingly, intensive discussions accelerated the creation of the synergy among the groups that will be introduced in the Medical Informatics Europe 2024 conference [21]. In addition, both the HealthData@EU pilot and the IDERHA project were addressed as EHDS use cases in the white paper on "IoT/Edge Computing and Health Data and Data Spaces" published by the Alliance for IoT and Edge Computing Innovation [51], and both projects also shared expertise on informing EHDS2 development. Experience from completed projects working with standards helps ongoing projects to decide on which standards to focus on, learn from their limitations, etc. For example, BigPicture designed a new standard ISO/AWI 24051-2.

XSL•FO
RenderX

Conclusion and Outlook

Standardization and legalization are the main pillars of EHDS. The HSbooster.eu initiative enabled intensive analysis of these aspects among six data-driven EU projects focusing on cancer. We aimed to create synergy among these projects to share the lessons learned in standards and legal implementation, sustainability of these projects, and harmonization with these with the EHDS2 implementation. Furthermore, we are involved in the development of standards such as ISO/IEC 21823-3:2021 "IoT - Interoperability for IoT Systems - Part 3 Semantic interoperability" (as editors), and since there is no ISO Standard for digital pathology and AI-based analysis of (whole slide) images for medical diagnosis, BigPicture is involved in ISO/PWI 24051-2 "Medical laboratories—Part 2: Digital pathology and artificial intelligence (AI)-based image analysis."

Future work requires integration of results from TEHDAS 1&2 and HealthData@EU pilot as well as other EHDS supporting projects, such as QUANTUM [52], which is seeking to develop the EHDS data quality and utility label. Additionally, enhancements to the EHDS2 interoperability framework template are needed, with more standards covering health ontologies, wearables, personal devices, data quality, as well as the usage of FAIR principles. The template can help researchers choose appropriate standards for their projects, thereby reducing time and effort in standard selection and implementation and improving EHDS2 implementation. Moreover, the template will be used in designing and creating an interactive toolkit for the EHDS2 interoperability framework. In this way, the existing and future projects can ensure alignment with governance and interoperability requirements for EHDS2.

EHDS has recently gained additional relevance since the European AI Act that has been approved by the European Parliament by resolution on March 13, 2024, explicitly refers to the EHDS as needing to "facilitate non-discriminatory access to health data and the training of AI algorithms on those data sets, in a privacy-preserving, secure, timely, transparent and trustworthy manner, and with an appropriate institutional governance."

Acknowledgments

AG declares funding from HSBOOSTER 101058391, StandICT.eu 2026 101091933. The IDERHA (Integration of Heterogeneous Data and Evidence Towards Regulatory and Health Technology Assessments Acceptance) project is supported by the Innovative Health Initiative (IHI) Joint Undertaking (JU) under grant agreement 101112135. Abstract

As health care demands rise and resources remain constrained, optimizing health care systems has become critical. Information-driven technologies, such as data analytics and artificial intelligence (AI), offer significant potential to inform and enhance health care delivery at various levels. However, a persistent gap exists between the promise of these technologies and their implementation in routine practice. In this paper, we propose that fragmentation of the innovation ecosystem is behind the failure of new information-driven technologies to be taken up into practice and that these goals can be achieved by increasing the cohesion of the ecosystem. Drawing on our experiences and published literature, we explore five challenges that underlie current ecosystem fragmentation: (1) technology developers often focus narrowly on perfecting the technical specifications of products without sufficiently considering the broader ecosystem in which these innovations will operate; (2) lessons from academic studies on technology implementation are underused, and existing knowledge is not being built upon; (3) the perspectives of healthcare professionals and organizations are frequently overlooked, resulting in misalignment between technology developments and health care needs; (4) ecosystem members lack incentives to collaborate, leading to strong individual efforts but collective ecosystem failure; and (5) investment in enhancing cohesion between ecosystem members is insufficient, with limited recognition of the time and effort required to build effective collaborations. To address these challenges, we propose a series of recommendations: adopting a wide-lens perspective on the ecosystem; developing a shared-value proposition; fostering ecosystem leadership; and promoting local ownership of ecosystem investigation and enhancement. We conclude by proposing practical steps for ecosystem members to self-assess, diagnose, and improve collaboration and knowledge sharing. The recommendations presented in this paper are intended to be broadly applicable across various types of innovation and improvement efforts in diverse ecosystems.

Introduction

Focus and Aim of Viewpoint

Despite a sizeable increase in the development of new information-driven technologies in health care their uptake and impact in routine practice remains limited. This viewpoint argues that this failure stems from fragmentation of the innovation ecosystem which is driving a lack of synergist working between ecosystem members. This includes all stakeholders who have a role to play in conceptualizing, designing, developing, studying, implementing, regulating, and using such technologies. We propose that in order to realize the potential of new technologies in health care we need to improve how the innovation ecosystem is working. This is especially true as we tackle bigger and more impactful innovations that require a greater degree of coordinated action.

Drawing on our experiences and published literature we explore the challenge of current ecosystem fragmentation and the underlying system drivers that make collaboration and synergistic working so difficult to achieve. We make a series of recommendations as to how these challenges can be addressed

XSL•FO
RenderX

including the need to adopt a wide-lens perspective on the ecosystem and develop a shared-value proposition, a call for ecosystem leadership, and the need for local ownership of ecosystem investigation and enhancement. We finish by proposing practical steps ecosystem members can take to self-assess, diagnose, and enhance how they are working and learning together.

The recommendations presented in this paper are intended to be broadly applicable across various types of innovation and improvement efforts in diverse ecosystems.

Background

The current strain on the health care system highlights the necessity for improving quality of care, with a specific emphasis on promoting effectiveness and efficiency in a manner that best serves the needs of patients and populations while promoting the well-being of health care staff members. It is therefore imperative to address these challenges and implement strategies that not only enhance health care delivery but also ensure the sustainability of health care systems.

Within this backdrop, the advent of cutting-edge technologies, encompassing advancements in data analytics, computational capabilities, and artificial intelligence (AI), provides an opportunity to inform the provision of health care [1,2]. Information-driven technologies in health care encompass systems and tools that rely on the collection, integration, and analysis of vast volumes of data to support and enhance clinical and operational decision-making [1,2]. These technologies are fundamentally dependent on the availability of high-quality, diverse, and interoperable datasets, as their effectiveness is directly tied to the comprehensiveness and accuracy of the underlying information. Central to their functionality are advanced analytics, particularly AI techniques, which enable the processing of complex and multidimensional datasets to identify patterns, generate predictions, and provide actionable insights. For example, AI can detect subtle anomalies in diagnostic imaging, predict disease progression based on longitudinal patient data, or optimize care pathways by analyzing historical treatment outcomes. By automating these sophisticated analyses, information-driven technologies could facilitate precision medicine, improve the allocation of health care resources, and reduce inefficiencies. However, despite the potential benefits of integrating information-driven technologies into health care systems, there is limited evidence of their successful uptake into routine health care practice [3,4].

Drawing inspiration from Ron Adner's book "The Wide Lens" we propose that the limited adoption of information-driven technologies in health care stems from technology developers focusing too narrowly on their individual products without considering the entire ecosystem needed for success. Adner [5,6] argues that any innovator requires collaboration with other co-innovators, who develop complementary solutions to make the focal innovation viable, and with adoption chain partners who must adopt or support the innovation before it can reach the end user. This wide-lens perspective emphasizes that the success of an innovation depends not only on the product itself but also on external groups. To minimize the risk of failure, innovators need to identify and align with the interests of these ecosystem players and proactively manage their dependencies.

For example, Amazon's success with the Kindle e-reader contrasts with Sony's earlier failure to launch a similar product. Adner explains that Sony's focus on perfecting the device's technical specifications overlooked the broader ecosystem requirements. Without securing coinnovators like publishers to provide e-books, a smooth platform for adoption chain partners such as booksellers to distribute them, and a seamless experience for buyers (the adopters), the product could not deliver the full value customers needed, leading to its failure. To succeed, Amazon took on a key leadership role by motivating and coordinating contributions from a diverse range of ecosystem members, ensuring that all necessary innovations and activities were in place to support their new product.

We believe that such ecosystem leadership and coordination is currently lacking in health care innovation, and the failure to consider how innovations work within the broader health care ecosystem is a key reason why new information-driven technologies struggle to gain traction.

In this viewpoint, we explore challenges of fragmentation that are specific to the health care innovation ecosystem and make a series of recommendations to drive ecosystem cohesion and success.

The Challenge: Ecosystem Fragmentation

Overview

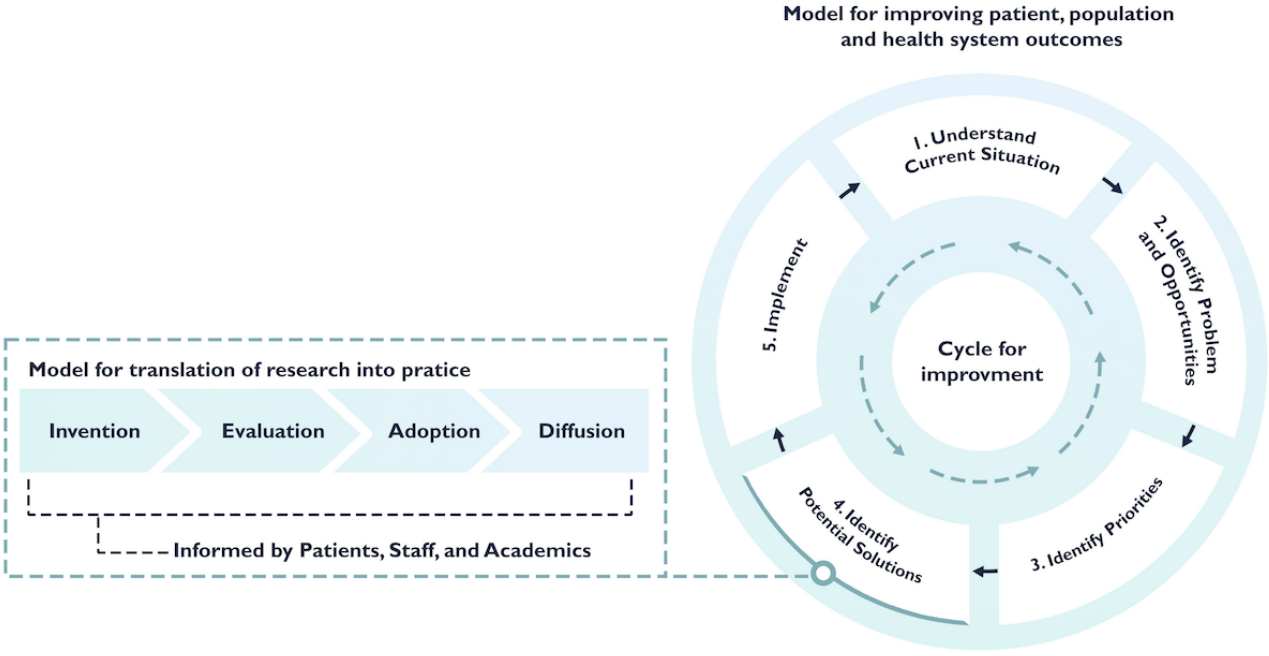
To consider the fragmentation of the health care innovation ecosystem we need to explore the relationships between different ecosystem members. The wider ecosystem of groups and organizations contributing to the health care innovation ecosystem is vast, comprising of diverse stakeholders and actors from different organizations, as well as professionals and experts from a broad spectrum of disciplines [7]. This includes health care organizations responsible for planning and delivery of care, industry organizations engaged in technology development and commercialization, academics who can contribute expert knowledge and methodological insights, and community, charitable, and voluntary organizations who play a variety of support roles to the well-being of patients and the wider population, and government and regulatory organizations who legislate and regulate activities [8,9].

For the purpose of this viewpoint, we have chosen to focus on the relationships between three main groups of ecosystem members to illustrate the challenges of ecosystem fragmentation: (1) the innovators who develop new technologies, (2) researchers who study the use and implementation of technologies, and (3) health care professionals who are the intended adopters and users of the technologies in practice. We recognize that in practice exploration of ecosystem relationships would require expansion to include all relevant members (recommendations).

Challenge #1: Not Looking Over the Fence—a Narrow Focus on Innovation Pipelines

Technology developers often adopt a narrow lens, focusing exclusively on their own innovation pipelines while neglecting

XSL•FO
RenderX



the broader ecosystem in which their innovations must operate. This tendency is particularly evident in the development of information-driven technologies in health care, where the primary emphasis is often on data availability and technological functionality [10]. Critical issues such as usability, implementation in routine care, and the interdependence with existing health care practices and processes are frequently treated as afterthoughts, only considered after the proof-of-concept stages [3,4].

Traditional conceptualizations of the innovation process exacerbate this narrow focus. The linear innovation pipeline model (Figure 1) [11] assumes a straightforward handoff between developers and adopters after invention and evaluation, or proof-of-concept, as it is often termed in technology development. This perspective perpetuates the misconception that bridging the gap between vision and practice, often referred to as "the last mile" [12], is primarily the adopters' responsibility. However, such an approach overlooks the critical dependencies and coinnovations required for successful integration into health care systems [13].

This narrow focus on technological development often results in solutions that fail to meet the real-world needs of health care staff members or patients. Technologies that ignore the routines, constraints, and practicalities of health care delivery risk being fundamentally misaligned with the requirements of adopters. Even well-designed technologies can falter without understanding the broader ecosystem changes needed to support their use.

From an innovator's perspective, this pipeline model may seem logical, it allows a focus on technical excellence within one's domain of expertise. However, it risks creating solutions based on overly simplistic notions of how health care systems function, ignoring the complexities and constraints of real-world applications. For example, health care professionals often face an overabundance of information, not a lack of it. While many information-driven technologies aim to provide more precise or accurate data, a more pressing challenge is navigating the "noise" of overwhelming information, knowing how to act on it, and having the resources and authority to do so. Thus, technology developers need to spend time understanding these challenges or the broader concerns of other ecosystem members.

Figure 1. Models for conceptualizing the innovation process: Traditional linear model of innovation-led development (left) needs to be reconceptualized as part of a more holistic cycle for improvement (right), which focuses on achieving system aims and goals and increases requirements for collaborative working between innovators and practitioners.

Challenge #2: Not Building on What we Know—Lessons From the Study of Technology Use and Implementation Are Underused

The limitations of the "narrow lens" of product development and the failure to consider the wider context of technology deployment are well-documented. For decades, health care research has highlighted the challenges of diffusing and adopting innovations in practice (eg, NASSS [Non-adoption, abandonment, scale-up, spread, and sustainability] framework) [14,15]. Studies of technology use, such as Normalization Process Theory [16] and sociomaterial approaches [17] have repeatedly emphasized the importance of understanding the interaction between technology, its users, and the wider context of deployment, echoing Adner's findings [5]. While much of this research is not specific to information-driven technologies, its insights into the enablers and barriers to innovation uptake are both relevant and generalizable.

Despite this extensive body of knowledge, it has not significantly influenced the behaviors and practices of technology developers or their collaborations with other ecosystem members. In most industries, such research would be a cornerstone of product development; yet in health care,

XSL•FO
RenderX

even with substantial investment in research, its findings often fail to be acted upon.

Awareness of these studies is low among tech developers. For example, a recent systematic review found that implementation theories were rarely applied in the or implementation of AI technologies for health care [3]. Even within academic disciplines that study health care technology and innovation, such as implementation science and sociomaterial studies, there is recognition of the limited practical impact of their findings [18-20].

The lack of uptake of such knowledge is not solely the fault of technology developers. Multiple complex factors contribute to this fragmentation. Studies often report qualitative findings, embedded in psychological, sociological, or organizational perspectives, and presented as nuanced theories written in discipline-specific language. This can feel alien and inaccessible to those outside these academic fields, including technology developers. The diversity of disciplines conducting these studies, each with distinct priorities, perspectives, and terminologies, further complicates understanding. Even for experts in health care research, navigating these different theoretical perspectives can be daunting.

In addition, many studies stop at describing problems without providing actionable guidance for solutions. While technology developers may focus narrowly on their products, researchers often focus narrowly on publishing theories, with less attention to their practical application. This leaves developers without clear, actionable steps to implement research findings in their work. Bridging the gap between research and practice requires collaborative approaches that translate theoretical insights into practical guidance, tailored to the needs of technology developers and other ecosystem members.

Challenge #3: Not Coordinating with Health Care Needs—Overlooking the Perspectives of Health Care Professionals and Organizations

Research on health care innovation consistently highlights that the success of new technologies hinges on their fit with the context in which they are introduced [21]. Yet, the perspectives of health care professionals are often insufficiently considered during development.

Health care professionals play two critical roles in this process. As adoption-chain partners, they ensure innovations integrate into practice and are used appropriately. For example, a new technology would need to be integrated into existing workflows, staff members trained on how to use it, and maintenance support systems in place. Without this work to actively support technology adoption the innovation will not be successfully implemented. As coinnovators, they create complementary innovations necessary for technologies to achieve their full value. For example, a new technology may be very powerful in identifying patients at risk of having a particular health condition, but would require coinnovation to identify how to reach out to these patients to notify them of this risk, and how to treat them. Without these coinnovations, the technology would not be realizing its value to the health care ecosystem.

Both adoption-chain partners and coinnovators should be engaged from the outset of any technology development to work collaboratively to align incentives, address technical and operational challenges, and mitigate potential conflicts. While there is some recognition of the need to engage adoption-chain partners, this process is often superficial and assumes that health care professionals can easily provide the necessary insights. In reality, this assumption is flawed. Health care systems are extraordinarily complex, with knowledge distributed across many individuals and much of it tacit. Consequently, developers and researchers often base their work on incomplete understandings of “work as imagined” rather than “work as it is.” Obtaining reliable insights into workflows, practices, and behaviors requires time, expertise, and resources that neither technology developers nor health care professionals typically have. This disconnect often results in poorly defined briefs and high-specification products that fail to meet the needs of the system, frustrating both developers and users.

Coinnovation is rarely prioritized. Many developers focus narrowly on developing accurate, effective tools, assuming these will inherently provide value. However, the true value of any technology lies not in the information it provides but in its ability to improve clinical practices and patient outcomes. Achieving this requires additional innovations, such as modifying dependent processes and practices, and changing professional behaviors, tasks that are often left to health care organizations [22]. These organizations often lack the resources, expertise, or capacity to manage such work, particularly given the competing demands of delivering care and supporting staff members well-being in under-resourced and high-stress environments. For them, technology is not the focal point but a potential enabler of better care.

Adding to these challenges, frontline teams are frequently overwhelmed by the sheer volume and variety of new interventions they are expected to adopt, often with little consideration of how these initiatives interact or how unresolved challenges might be exacerbated by new technologies [19]. At present, there is insufficient coordination within the health care ecosystem to address these challenges. Innovators often view technology as the central actor, whereas health care teams see it as a supportive tool for achieving their goals. This misalignment leads to tension and hinders the effective uptake of new innovations.

Challenge #4: Not Incentivizing People to Work Together—Individually People Are Doing Good Jobs, But Collectively the Ecosystem Is Failing

In the current health innovation ecosystem, individuals excel in their specific roles: technology developers create apps and algorithms, health researchers produce theories and publications, and health care professionals deliver services. However, the ecosystem often fails collectively because members are incentivized to focus on predetermined end points within their disciplines rather than working collaboratively across boundaries. No one is tasked with bridging the gaps between these roles or ensuring that end products are effectively integrated.

XSL•FO
RenderX

This fragmentation fosters a false sense of completion, where apps are handed off to health care teams or theories to developers without accountability for their practical impact. Crucial feedback loops, such as whether the app or theory is used and helpful, are neglected. Without this cross-disciplinary exchange, the ecosystem remains siloed, disconnected, and unable to adapt to the needs and constraints of its members.

A notable example of ecosystem failure due to the fragmentation of responsibilities, where tasks are divided into manageable parts but lack a comprehensive overview and accountability, is the collapse of the Minneapolis I-35W Bridge on August 1, 2007. Investigation into the disaster identified that all individual contractors including the original design firm, transportation officials, inspection teams, and maintenance crew had fully met their individual responsibilities, and as such could not be blamed for the disaster. However, collectively they had failed due to the fragmentation of responsibilities between multiple entities which resulted in a combination of design flaws, a lack of adaptation to the incremental increases in the bridge's weight over time, and decades of inadequate maintenance. In health care innovation, fragmentation results in frustration: developers lament the lack of adoption [23,24], researchers feel their insights are underused [25], and clinicians face an unrelenting influx of innovations that fail to address their real challenges [26]. Despite these frustrations, each group often blames other ecosystem members or assumes the problem lies outside their responsibility.

Career pathways exacerbate this issue. Academic success depends on publishing prestigious theories, not translating them into practice. Developers are rewarded for producing tools, not ensuring their usability. Clinicians focus on delivering care, not system-wide coordination. These narrow incentives discourage collaborative work and maintain the status quo. To step outside these norms often requires entrepreneurialism whilst risking personal career security.

The result is not that people are doing their jobs poorly but that they are working to end points too narrow to achieve broader ecosystem success. Effective ecosystem collaboration requires questioning assumptions, addressing gaps, and building strong relationships. Members must challenge briefs, clarify expectations, and engage in active feedback loops. A cohesive system depends on recognizing and valuing the interdependence of roles and the shared responsibility for collective success.

Challenge #5: Not Investing in Working Across Boundaries—Lack of Recognition of the Time and Effort Required

The diversity of ecosystem members is a strength, yet it also presents a significant, often unacknowledged challenge. Different scopes of interests, priorities, expertise, and practices can make it difficult for groups to share knowledge and work together effectively. It is much easier to learn from others within your own field, where shared language and mindsets foster understanding [27]. However, this specialized language can create barriers when trying to communicate with professionals from different fields [28]. At present little time and effort is invested, and few career pathway opportunities are provided to develop proficiency in navigating these boundaries or building shared understanding.

Communication efforts between ecosystem members often consist of one-way transfers of information, where one group assumes the role of "teaching" and the other as the "learner." These approaches fall short in 2 critical ways: they fail to consider the effort required to change behaviors and work processes, and they overlook the importance of 2-way, iterative learning [29]. Effective collaboration should focus on understanding the implications of each group's work for the others.

For instance, health research may highlight the need for technology developers to better understand day-to-day health care practices. However, developers typically focus on desktop work, with little direct engagement with frontline health care staff members. This shift requires them to navigate a vastly different environment, requiring new skills, communication styles, and an understanding of clinical challenges. It is not simply a matter of learning new information, it is about adjusting to a completely different way of working, which may be an unwelcome change for people who choose a technical profession.

For collaboration to succeed, stakeholders must reflect on how to adapt their practices, and the additional roles that may be required, to meet the needs of coinnovators and coadopters [30]. However, changing behaviors that are deeply embedded in professional norms is incredibly challenging. There is often an unstated assumption that new theories, models, and approaches can easily be adopted, but research from the fields of knowledge mobilization and translation challenges this view. People are not passive recipients of new ideas; [14] introducing new ways of working involves negotiation, compromise, and integration into established routines [31]. These changes can be disruptive, challenging identities, roles, and responsibilities [20]. Ecosystem members are highly skilled professionals with a large degree of autonomy to choose whether and how to engage with new ways of working [5,15]. Therefore, change requires as much attention to the human side of change, psychological, social, and political, as to the technical side [32].

Recommendations for How to Address the Challenge: Toward Ecosystem Cohesion

Overview

To address the fragmentation of health care ecosystems and systemic barriers to collaboration, we propose a set of actionable strategies to work toward ecosystem cohesion. These include adopting a wide-lens perspective to overcome silos, developing a shared ecosystem value proposition to align objectives, promoting ecosystem leadership to enhance collective accountability, encouraging local ownership of ecosystem assessment and improvement, and establishing structured pathways for continuous evaluation and enhancement.

While alternative approaches may also contribute to ecosystem cohesion, our recommendations are comprehensive and

XSL•FO
RenderX

well-founded, grounded in empirical research and practical insights. They systematically address core challenges such as fragmentation, misalignment, and inefficiency. By integrating strategic, structural, and leadership-driven solutions, our recommendations provide a robust and sustainable path forward.

Recommendation #1 Adopt a Wide-Lens Perspective

Building on Adner's research [5] we recommend that a *wide-lens perspective* is adopted. As Adner demonstrates it is not sufficient to focus on technological excellence at the expense of understanding the needs, experiences, and expectations of innovation adopters and other ecosystem members. There is a need to look over the fence to understand what else is going in the ecosystem that the success of any technological development is dependent on and to understand the implications of this learning for the initial conceptualization and design of new technologies, and the process of their development, testing, and deployment in partnership with other ecosystem members.

These insights suggest there are major limitations to the current "linear" product development mindset, and the metaphor of crossing the "last mile" [11,12]. It is not sufficient simply to attend the final handover of a product between the developers and the intended recipients. The whole ecosystem of coinnovators and coadopters needs to be actively engaged in synchronous and cooperative sense-making and problem-solving [33].

We propose that adopting an alternative process model, such as the cycle for improvement [34] can provide a helpful first step in adopting a wider ecosystem lens. (Figure 1) Rather than the linear progress implied by the innovation pipeline [11], the cycle for improvement emphasizes an iterative, cyclical process that is followed until the desired outcome or improvement has been achieved. The value of such a model is that it provides a holistic view of the entire improvement process and allows practices both upstream and downstream from the point of technology development to be taken into consideration. As such it starts to conceptualize a more holistic and cyclic view of the work required and is likely to appeal to a diverse range of ecosystem members who can see how their work orientates to different aspects of this model.

This process model is only one such example of how the ecosystem can start to be conceptualized in a more holistic manner and is intended as an embryonic starting point from which ecosystem explorations could build. Many other models could also provide valuable starting points such as sociomateriality, which focuses on the intersection of technology, work, and organization [35], and a patient work framework [36] which focuses on the interaction between end users and the innovation. These models operate on the principle that the innovation process is inherently social, integrating human, social, technical, and environmental components [37]. Such models emphasize the necessity of collaboration and coproduction at all stages of the process, rather than having discrete hand-offs between innovators and users that is implied in the linear pipeline model.

Recommendation #2: Develop a Shared Ecosystem Value Proposition

A major challenge to the health technology industry is that other people in the ecosystem do not share such a technology-centric perspective. Health care's primary goal is patient care, not the deployment of technology or profit generation, which can create tension and conflict between different stakeholder priorities and incentives.

Adner [5] recommends that the ecosystem should have a *shared value proposition* that reflects the shared aim that all ecosystem members are working toward [33]. The shared value proposition is broader than just the perspective of a focal innovation. It encompasses the entire ecosystem and reflects the interdependencies among all stakeholders focal innovators, coinnovators, and adoption chain partners. While a focal innovation can serve as the starting point for defining the ecosystem it recognizes that every player in the ecosystem must derive value from participating, and their success is interlinked. It reflects a broader focus of the collective ecosystem interests and ambitions, rather than a narrow view that prioritizes the focal innovator's benefits.

We propose that a shared value proposition could be the aspiration *to improve care with support from the introduction of information-driven technologies*. This statement reflects that any individual technology development is likely to be playing a small part of enabling a wider value proposition that will require many other coordinated actions and innovations to achieve.

The work required to achieve this shared value promotion can be conceptualized as 2 interrelated levels of operation. The first level focuses on *improving care with the support of information-driven technologies*, and the second level focuses on *enhancing the ecosystem's ability to improve care*. Successful intervention at level 1 (improving care with the support of information-driven technologies) relies on the quality of interaction and relationship between different stakeholders in working together to build a shared understanding of the challenges and potential solutions (level 2) [6].

Recommendation #3: a Call for Ecosystem Leadership

Ecosystem leaders play an important role in holding a vision for the future potential of the ecosystem, to look beyond individual cases and traditional silos—to consider the ecosystem's process for innovating and improving patient care works, and how it can be enhanced. This work will include coordinating and streamlining the interaction of ecosystem members, addressing any major gaps, and establishing clear practices, processes, and principles for overall work. It will be important to build on the knowledge and expertise of ecosystem members, while at the same time having the freedom to challenge established norms and ways of working for the benefit of the wider ecosystem. Emphasis should be placed on learning from previous efforts so that mistakes are not repeated, and to establish a forward looking and positive learning culture [38].

While there are substantial benefits to be gained from ecosystem actors working collaboratively to address challenges, there is rarely time or headspace to undertake this work of understanding

XSL•FO
RenderX

the ecosystem. As well as potentially contradicting short-term organizational goals, the investment in such boundary work can jeopardize individual career progression if the work conflicts with the expected and rewarded outputs and achievements (eg, financial investment secured each year, number of publications produced, or amount of services delivered). These incentives can be set within an organizational culture, but also often reflect expectations of the professional bodies and recruiters operating across an entire system nationally and globally. This can mean that to participate in boundary work individuals may have to take a personal risk in relation to their job tenure, financial reward, and prospects for internal promotion or career progression with other organizations [39].

Enhancing ecosystem working requires the engagement of system leaders who can remove or replace contrary incentives or create protected spaces where work to strengthen the ecosystem can happen without individuals being penalized [40]. Strategic engagement with system leaders will be important in creating protected spaces for ecosystem work to take place.

Recommendation #4: Local Ownership of Ecosystem Investigation and Enhancement

In identifying the current system deficiencies and opportunities for change we recognize that this work can only be done by people within the system; it is not something that can be conducted by outsiders and handed over to the ecosystem members to implement [33,41]. People within the system have the necessary insights to understand how things are currently done, what is working well, and what motivations and frustrations they experience. Their engagement is critical to designing and enacting any change ideas, drawing on their foresight of what is likely to work and what challenges may be encountered, in testing and feeding back on the benefits and limitations of any changes in practice, and in their persistence to address and overcome any difficulties experienced.

There is an extensive literature on the features of successful systems change, providing theory, values, principles, strategies, and practical guidance [33]. Much of this work has originated from diverse fields of application such as climate action, education, and social cohesion. While there are many different approaches, frameworks, models, and tools, there is a lot of conceptual and practical commonality between them, suggesting a convergence of thinking from research and practical experience of intervening in complex systems [33,42].

Findings suggest the importance of engaging ecosystem members in the process of investigating and diagnosing the current ecosystem. This supports stakeholders to understand and feel ownership for the identification of problems and areas requiring improvement, increasing their motivation and engagement to explore new ways of working. The engagement of ecosystem members is equally critical in designing, testing, and revising new ways of working to ensure their insights and specialist knowledge is incorporated and to enable the identification and resolution of emergent challenges and problems. No single person or group holds all the knowledge, skills, or competencies required to understand and address all aspects of the changes required. While collaborative working and ownership is view as critical it is recognized as highly challenging given the diverse perspectives and positions different groups and individuals hold, and the need for expert facilitation is recognized to enable constructive conversations between potentially contentious and conflicting views. Therefore, it is not sufficient to simply conduct research to make an objective assessment of the current situation, but necessary to use a participatory action research approach as a tool to support reflection, collective sense-making, and relationship building, in support of the stakeholders working toward system change [43].

Recommendation #5: a Pathway for Investigating and Enhancing Ecosystems

We propose that it is it helpful to envisage the work required to enhance ecosystems conducted in three stages:

- Stage 1: coinvestigation and diagnosis of current ecosystem functioning
- Stage 2: cocreation of strategies and action plans to address challenges and opportunities to enhance ecosystem functioning
- Stage 3: implementation, evaluation, the evolution of effective strategies and actions—embedding a permanent learning system to guide ecosystem enhancement.

Each of these 3 stages should be informed by bringing together an understanding of specific issues within the local ecosystem and existing knowledge, literature, and priori experiences on ecosystems and intervening in complex systems.

As well as investigating the ecosystem generally, which depending on the ecosystem could be a significant scale challenge—following specific projects developing and introducing information-driven technologies into health care can provide a powerful vehicle to understand ecosystem performance using more bounded and manageable cases (Table 1).

Before an ecosystem can be enhanced it is necessary to understand how the ecosystem is already working. This includes understanding who different members of the ecosystem are, the diversity of approaches and ways of working that they deploy, and how they currently interact with each other.

An important first step in the coinvestigation and diagnosis of the current ecosystem in stage one is to make the ecosystem explicit. This allows people to consider how the outputs of individual, group, and organizational efforts will be adopted by or influence others, and how they in turn are dependent on the efforts and innovations made by other people in the system to improve patient and population health. Research shows that for system change to take place it is necessary to understand what lies below the surface of how people behave [30]. This includes understanding the explicit aspects of the work being done (eg, policies, practices, or resource allocation), those that are semiexplicit (eg, understanding the relationships and power dynamics that inform ecosystem interactions) and implicit (eg, people habits of thought, deeply held beliefs, and assumptions that guide how they work and how they view others in the ecosystem) [44].

XSL•FO
RenderX

The cycle for improvement [24] can be used to guide research and facilitate sense-making about the innovation ecosystem: firstly, in considering what work is being done and why by different ecosystem members relates to the various the cycle stages (1) understand the current situation, (2) identify problems and opportunities, (3) prioritization, (4) identify or develop potential solutions and (5) implementation, and assessing the impact of changes as stage (1) is revisited at the next iteration of the cycle); and secondly in exploring different members and how they work together (who is doing the work and how do they interact together).

In starting to understand the diversity of the ecosystem members, their behaviors, and past experiences, insights will start to emerge as to what is working well, and where problems, frustrations, and challenges are being experienced for the ecosystem members individually and collectively. In some instances, these frustrations may be shared across ecosystem members, and lead to the identification of common goals and agreement to address them. On the other hand, frustrations may identify major gaps or conflicts in how people are working that are not so easily addressed. The latter type of situation are where ecosystem leaders will need to play an important role in either encouraging and incentivizing teams to engage in new ways of working, or by finding other solutions or resources to address the issue.

Suggestions of methods to aid this investigation and diagnosis are outlined in Textbox 1. Once a clear understanding of the current ecosystem has been developed, these methods can also be applied to assess how the ecosystem is changing over time.

In stage 2 stakeholders are engaged in co-design research to establish a shared understanding of the requirements for ecosystem evolution. The objective is to foster a collaborative agreement and commitment among stakeholders regarding strategies, practices, and resource investment to address system issues. Establishing such processes and building practical experience in working together will become increasingly important as more ambitious technologies are developed with greater potential impact and requiring greater collaboration and coordination across diverse ecosystem members. Suggestions of methods to aid this cocreation of strategies and action plans are outlined in Textbox 2.

The implementation of new information-driven technologies within the ecosystem are dealt with in stage three, focusing on achieving growth, learning, and continuous improvement. Suggestions of methods to aid the implementation, evaluation, and evolution of effective strategies and actions are outlined in Textbox 3.

Table 1. The use of projects as learning vehicles can be applied at all 3 stages of ecosystem enhancement.

Stage	Purpose of projects as focal point	Action
Coinvestigation and diagnosis	• To provide a pragmatic entry point to understand the work taking place within the ecosystem and how different stakeholders are working together.	• Review of previous and on-going projects.
Cocreation of strategies and action plans	• To provide a platform to explore new ways of working through experimentation.	• Using demonstration projects for testing, learning, and iteratively developing ideas until they become workable solutions for ecosystem enhancement.
Implementation, evaluation, and evolution	• To further inform ecosystem enhancement and evolution of new and improved ways of working to achieve ecosystem goals.	• Systematic learning from projects to increase the scale of application and rigor of evaluation.

Textbox 1. Activities in stage 1: coinvestigation and diagnosis of the current ecosystem.

Activity and their purpose

Interviews

To provide insights into the participant's unique perspectives of the ecosystem and their underpinning mental models.

Process and system mapping

To describe and visualize how the ecosystem is working, understanding who is involved and the roles that they play; how they connect to each other; where there are effective connections, and where there are disconnects. This includes mapping of key activities, actors, connections, disconnects, gaps, and incentives on both structural and organizational level.

Social network analysis

To explore the quality and extent of interactions between individuals within the ecosystem and provide baseline data to understand the growth of the ecosystem over time.

Collaborative workshops and learning events

To develop a shared understanding of the ecosystem and a collaborative diagnosis of the strengths, weaknesses, tensions, opportunities, and gaps of the current ecosystem.

XSL•FO
RenderX

Textbox 2. Activities in stage 2: cocreation of strategies and action plans.

Activity and their purpose
Formation of steering groups
To establish a focal firm to serve as the central point of coordination for the ecosystem evolution efforts, facilitating collaboration and communication among the various stakeholders.
Creation of dedicated spaces
To establish platforms for stakeholders to interact and engage in discussions, knowledge sharing, share insights, collective problem-solving, and test innovative ideas and aims to promote self-reflection, stimulate the generation of creative solutions, and build stronger working relationships.
Prospective case planning, design, and conduct
To identify the scope, objectives, and key activities for demonstration projects, developing design principles to guide the implementation of the projects and alignment with the desired outcomes.

Textbox 3. Activities in stage 3: implementation, evaluation, evolution of effective strategies, and actions.

Activity and their purpose
Development of ecosystem roadmap
To guide implementation efforts, with key steps and strategies that are refined and improved based on feedback, insights, and evolving needs.
Systematic project approach
To ensure effective execution of projects through the development and application of a systematic project approach.
Assessment of ecosystem growth
To gain evidence of the ecosystem's progress and understand the factors influencing network dynamics through evaluation of; the growth of the ecosystem, dynamics of social networks within it, remaining challenges and opportunities, and effectiveness of network interactions and relationships.

Conclusion

The successful integration of information-driven technologies into health care systems centers on increasing cohesion and synergistic working between members of the wider innovation ecosystem. This viewpoint provides steps for stakeholders to collaboratively investigate and enhance ecosystem functioning, enabling the effective deployment of information-driven technologies in routine health care practice, to advise the wider ecosystem goal of advancing the quality and efficiency of care delivery. Taking this agenda forward will require strong ecosystem leadership to challenge entrenched norms and behaviors and to engage members in creating new ways of working to enhance ecosystem cohesion and effectiveness.

Abstract

This viewpoint paper addresses the ongoing challenges and opportunities within the data-for-health ecosystem, drawing insights from a multistakeholder workshop. Despite notable progress in the digitization of health care systems, data sharing and interoperability remain limited, so the full potential of health care data is not realized. There is a critical need for data ecosystems that can enable the timely, safe, efficient, and sustainable collection and sharing of health care data. However, efforts to meet this need face risks related to privacy, data protection, security, democratic governance, and exclusion. Key challenges include poor interoperability, inconsistent approaches to data governance, and concerns about the commodification of data. While emerging platforms such as social media play a growing role in gathering and sharing health information, their integration into formal data systems remains limited. A robust and secure data-for-health ecosystem requires stronger frameworks for data governance, interoperability, and citizen engagement to build public trust. This paper argues that reframing health care data as a common good, improving the transparency of data acquisition and processing, and promoting the use of application programming interfaces (APIs) for real-time data access are essential to overcoming these challenges. In addition, it highlights the need for international norms and standards guided by multisector leadership, given the multinational nature of data sharing. Ultimately, this paper emphasizes the need to balance risks and opportunities to create a socially acceptable, secure, and effective data-sharing ecosystem in health care.

Introduction

Data are essential to the delivery of effective health care and the improvement of health outcomes. However, the power of data relevant to health has not been fully realized. There is a need to nurture and develop data-for-health ecosystems to collect and share valuable data through transformative and responsible technological systems in timely, safe, efficient, and sustainable ways that maximize data utility for the public good.

A “data ecosystem” refers to a network of entities engaged in generating, sharing, and using data resources through various technologies [1]. In the context of a data-for-health ecosystem, this network is diverse and decentralized, comprising public and private institutions, as well as individuals acting in various

XSL•FO
RenderX

roles such as citizens, patients, and consumers. Data are actively and passively generated across all levels of this ecosystem, intentionally recorded for health purposes (eg, National Health Service [NHS] patient records) or initially generated for different reasons but repurposed for health care improvement (eg, geospatial air quality data shared to assist citizens with respiratory issues). Data management within this ecosystem varies across a spectrum: from tightly controlled data, such as patient records protected by strict privacy regulations and access protocols to ensure confidentiality, to fully open data, such as anonymized census or survey data that are freely accessible to the public for research and policy-making purposes. This range encompasses well-structured databases and unstructured streams from sources such as social media and Internet of Things devices, with knock-on effects for how data can be used.

Electronic devices generate digital traces that contribute valuable insights into personal health, extending beyond traditional patient records to include data held by IT and mobile corporations, and even loyalty card accounts [2]. The wide spectrum and variety of spatial-temporal geo-located big data streams that are collected include web-based search keywords, internet and store-based purchases, sensors and Internet of Things (IoT) data, health and fitness app data, and mobile phone location data [3,4].

The rapid evolution of this ecosystem poses risks related to privacy, data protection and security, transparency, access, and exclusion, as highlighted in the 2014 United Nations report "A World That Counts" [5]. The COVID-19 pandemic heightened concerns, due to the proliferation of systems capturing personal information for public health benefit, but often at the expense of robust debate about privacy, data ownership, and technology regulation.

Despite the potential for leveraging digital traces in health care, limitations persist, revealing gaps and missed opportunities [6]. The lack of interoperability between platforms and databases hinders data sharing across sectors, disciplines, countries, and international agencies. While such data holds substantial value for individuals, clinicians, health system planners, policy makers, researchers, and innovators, restrictions on visibility, access, and sharing impede its full potential. For instance, integrating data from health and fitness apps with electronic patient records could enhance clinical understanding, but business interests often deter app companies from developing interfaces for seamless integration.

Beyond interoperability, cross-border data sharing presents another critical hurdle, particularly in addressing global health challenges. Despite its growing importance, legal, regulatory, and technical barriers continue to limit progress. The lack of harmonized data protection standards across countries complicates the sharing of health data, particularly when navigating diverse privacy regulations like the General Data Protection Regulation (GDPR) in the European Union (EU) and less stringent frameworks in other regions. Countries often have conflicting data protection laws, making it difficult to ensure compliance while enabling international data flows. In addition, concerns over data sovereignty, where countries insist on controlling their citizens' data within national borders, further limit cross-border collaboration [7,8]. In public health emergencies, such restrictions can delay data access, hindering rapid responses. For example, during the COVID-19 pandemic, differing regulations and limited cross-border collaboration created obstacles for real-time sharing of epidemiological data, impeding global tracking efforts [9].

In 2016, the "Findable, Accessible, Interoperable, Reusable" principle was introduced as a guide for improving data reusability, focusing on both machine and human accessibility by stakeholders from academia, industry, funding agencies, and scholarly publishers [10]. Nevertheless, government agencies encounter significant challenges in leveraging population-level data for decision-making due to issues like delayed and inconsistent official data collection and aggregation, and the cost of accessing commercial datasets. Such difficulties were exacerbated during the COVID-19 pandemic, particularly for agencies in low- and middle-income countries with limited funding and infrastructure [11]. Increasingly, nonofficial data is relied upon to provide timely information. This may be generated by citizens or communities as an evidence base for change or to enhance social accountability, but it is often collected by private providers, with individual consumers contributing their data either actively or passively. Increasingly, multinational technology companies engaging in "massive and passive" data collection are dominating data-for-health ecosystems. This trend was accelerated during the COVID-19 pandemic [12] when social media platforms and search tools such as Twitter, Facebook, Google, and Bing played a pivotal role in providing timely information for researchers to monitor public sentiment and assess intervention impacts [13]. While the technology industry certainly benefits from leveraging personal data for web-based marketing, digital epidemiologists demonstrate how these new data streams can also enhance understanding of citizen behavior, support decision-making, and enable reporting of disease symptoms.

The aim of this viewpoint paper is to explore the key challenges and opportunities within these evolving ecosystems, synthesizing insights from the "Data Enabled Society for Health: Challenges and Opportunities" workshop held in London by University College London. This workshop brought together health care providers, policymakers, technologists, and researchers, to consider how to create a secure and effective data-for-health ecosystem that facilitates the gathering and sharing of valuable data for both individual and population-level health benefits, while effectively managing the associated risks. We suggest that to optimize the use of health data, governments and institutions should work on three overlapping areas: data governance, interoperability, and participation and citizen engagement..

Navigating the Dual Realities of Data Governance: Public Sector Caution and Industry Data Challenges

Ongoing issues with data governance, data access, and privacy highlighted during the workshop extend beyond regulatory and technical concerns to profound ethical dilemmas. These include

XSL•FO
RenderX

the challenge of obtaining meaningful informed consent in complex data ecosystems, the risk of data commodification that reduces individuals to mere data points, and the ethical responsibility of both public and private entities to prioritize the rights of individuals over profit or efficiency. These concerns also intersect with issues of data equity, where marginalized groups may face greater risks of exclusion or exploitation.

Within the public sector, citizens are not the only ones to limit access to their data due to privacy or security concerns. Governmental organizations and health care institutions are also very wary of granting access to their datasets, sometimes even to researchers, fearing either reputational damage due to mishaps or the loss of future financial opportunities if they share their assets.

This protective attitude towards an organization's data assets reflects the perception of data as a commodity: something that can be "extracted" from individuals or communities and then traded. We think it is important to reframe this narrative and look at personal data in the same way we look at common goods, with regulated access and shared collective benefits [14,15].

Attitudes against sharing medical information can stem from confusing messages and a lack of controls in the past, as well as fear of data being shared with third parties in ways that invade privacy, lead to increased surveillance and authoritarianism, or enable personal data exploitation against the individual's interests (eg, with an insurance provider). Citizen engagement needs to be specific and honest about the risks and benefits of data sharing, rather than relying on an abstract notion of how data sharing may benefit humankind, to avoid pitfalls such as the failed launch of NHS Care.data initiatives [16] and the abandoned centralized NHS COVID-19 Test and Trace app [17]. At the policy level, the key challenges are increasing the transparency of data governance and developing robust deidentification techniques that preserve the usability of data for research, rather than anonymization. Transparency and open dialogue with citizens are paramount for regaining public trust and setting cornerstones for a balanced agenda. This must be seen as an ongoing process, as trust is never a given.

The above-described scenario of data sharing sits in stark contrast to the vast quantity of personal physiological and health data collected through social media, wearables, tracking devices, MedTech, and geo-located mobile apps. While there are differences in legal frameworks across geographies, for example, in Europe (where GDPR applies, giving more control to citizens over their data), the United States, and China, personal data are generally subject to industry-defined terms and conditions, often with no clear or accessible opt-out clauses allowing use for personalized web-based or mobile marketing. This happens without much awareness or evident concern from citizens and in the absence of robust policy debate. To rebalance the current situation, there is an urgent need for international regulation, oversight, and a restoration of user controls over personal data.

The evolving nature of data-for-health ecosystems therefore raises ethical issues that require deeper consideration. These include mechanisms for ensuring informed consent, particularly in settings where data collection occurs passively or through third-party platforms, often without clear communication with individuals. Traditional models of consent are increasingly inadequate in such ecosystems, leading to a growing call for more dynamic or granular consent mechanisms that allow individuals greater control over specific types of data use. Moreover, the balance between individual privacy and public health is a critical ethical dilemma. While sharing health data has clear societal benefits, especially during public health emergencies like the COVID-19 pandemic, it raises the risk of compromising individual privacy. Finding an ethical equilibrium requires robust deidentification techniques, transparent data governance frameworks, and public engagement in decision-making processes. Finally, we must address the ethical issues of data commodification, where individuals' health data is treated as a commercial product. This commodification risks not only violating privacy but also entrenching inequalities, as those with fewer resources may have less control over their data and greater exposure to exploitation.

Ending Data Silos: Radical Interoperability and Real-Time Access

In addition to governance and access to data, the lack of common platforms and standards for data sharing limits collaboration across institutions and countries. This can have potentially devastating consequences in public health emergencies when a rapid and coordinated response is needed.

A notable example of successful collaboration is the Innovative Medicines Initiative ConcePTION consortium (2019), a European partnership involving public and private organizations that collect or access data related to pregnancy, childbirth, and lactation. Innovative Medicines Initiative ConcePTION aims to enhance the availability of health data and transform it into actionable evidence to improve clinical practices and outcomes [18]. Another valuable framework is the Unified Information and Interoperability Governance model, which integrates principles of both information governance and interoperability. The Unified Information and Interoperability Governance framework was designed to improve adaptability, flexibility, and efficiency in health information usage across the entire health care system [19]. Similarly, the United Nations Educational, Scientific and Cultural Organization - Committee on Data for Science and Technology (UNESCO-CODATA) Global Project contributes to the UNESCO Open Science Toolkit by providing comprehensive guidance, checklists, and factsheets specifically aimed at fostering data transparency, accessibility, and collaboration during crises [20]. The project delivers tools for both policy makers and scientists to support data collection, management, and governance. Such frameworks could be instrumental in future health crises, aligning with the goals of creating more interoperable and transparent data ecosystems.

One underused approach to health data access is that of application programming interfaces (APIs), which facilitate real-time, secure data sharing between systems. When integrated with emerging technologies like blockchain and federated learning, APIs can support more secure, privacy-preserving, and decentralized data exchanges. Blockchain can provide the security backbone for APIs, ensuring that data integrity and

XSL•FO
RenderX

ownership are maintained, while federated learning can allow institutions to collaborate on data analytics without sharing sensitive raw data. Combined with machine learning algorithms, APIs can further enhance real-time data analysis, enabling rapid public health responses based on predictive insights. This is of particular importance for real-time data streams, such as those generated by social media or IoT sensors. An example of this approach was Twitter allowing free API access to 1% of its database—a bold move that provided real-time data and fueled thousands of research projects in social computing, epidemic intelligence, sentiment analysis, and network and graph computing over a decade [21]. It was also incorporated into the epidemic intelligence platforms used by the World Health Organization (WHO) and its member states, such as MediSys, Epidemic Intelligence from Open Sources (EIOS), and Global Public Health Intelligence Network. This provision ceased under Twitter's new ownership [22]. Free access to the Twitter API was suspended in February 2023, causing significant disruption to academic research that relied on social media data [23]. Other examples of real-time data gathering and integration platforms include the flights portal Skyscanner and the financial products portal MoneySuperMarket. However, real-time data access for health applications is lacking.

Blockchain offers a groundbreaking solution for managing health data by using distributed, immutable ledgers that enhance transparency, security, and trust. In a data-for-health ecosystem, blockchain technology ensures that health data remains unaltered and that individuals retain control over their personal information through the use of smart contracts. These smart contracts facilitate secure, automated agreements between data owners and users, ensuring that data sharing complies with predefined privacy rules. The decentralized nature of blockchain makes it especially suitable for secure cross-border data sharing among institutions, allowing real-time access while safeguarding data integrity. Moreover, blockchain can support granular consent mechanisms, enabling individuals to specify who can access their data and under what conditions. A notable example is Estonia's health care system, which has successfully integrated blockchain technology to secure over 1 million patient records, ensuring both data privacy and transparency [24].

Meanwhile, machine learning (ML) is revolutionizing health care by enabling the analysis of large and complex datasets to identify patterns, predict outcomes, and support better decision-making. In data-for-health ecosystems, ML can be used to analyze real-time data streams from various sources, such as social media, wearable devices, and electronic medical records, to predict public health trends like disease outbreaks or shifts in vaccination behavior. ML algorithms enhance real-time epidemiological surveillance, facilitating the early detection of potential health threats through the analysis of social media activity, internet search trends, or mobile health app data. This predictive capability aids in timely public health interventions and resource allocation. For instance, Google's DeepMind has applied ML to the NHS to improve diagnostic accuracy and predict patient outcomes by analyzing historical health records [25].

Other innovative methods enable ML models to be trained on decentralized data without requiring the sharing of raw data between institutions. Federated learning allows health care institutions to collaborate on model development while maintaining their data locally, thus ensuring data privacy and compliance with regulatory standards like the GDPR. It promotes interoperability without compromising data ownership, making it ideal for cross-institutional collaborations. For example, federated learning has been successfully implemented in medical imaging projects, improving disease detection without the need for direct data sharing across institutions [26]. Similarly, zero-knowledge proofs offer a method for verifying the truth of information without revealing the underlying data. This can significantly enhance data-for-health ecosystems by allowing health institutions to share valuable insights while preserving the privacy of sensitive patient information. For example, health systems could confirm the validity of vaccination status or other health data without exposing any personal identifiers. Cryptographic zero-knowledge proof systems have been explored in secure identity verification services, such as confirming COVID-19 results, while keeping patient identities confidential [27]. In addition, the emerging role of the Metaverse in health care is gaining attention, as its potential applications continue to grow with advancements in Web 3.0 technology [28]. The Metaverse offers an immersive, interoperable ecosystem that could redefine the traditional health care system through avatar-based meetings, simulations, and social interactions between patients, providers, and organizations. However, technological innovation, regulatory oversight, and sound governance are needed to address current challenges in its development.

Winning Citizen Trust and Public Engagement

Limited access to technology in certain sectors of society and parts of the world can be attributed to resource and infrastructure constraints. Collaborative efforts across governments and communities are essential to address these challenges and prevent exclusion based on factors such as age or socioeconomic status [29].

Recently, concerns about data use and potential misuse have intensified due to health care provider hacking incidents and a lack of transparent communication regarding consequences and damages [30]. Case studies such as the Care.data program [14] and General Practice Data for Planning and Research [30] underscore the critical role of public trust in the success of health data initiatives. Public skepticism, evidenced by opt-out rates and project pauses, demonstrates the need for responsible data use [31].

Diminishing public trust, exemplified by incidents like the NHS Royal Free Trust data privacy breach, has profound consequences for current and future health data initiatives [30]. To foster meaningful citizen participation, mechanisms such as multistakeholder platforms, cocreation exercises, and public consultations can be used. Engaging the public in deliberative discussions, as demonstrated by the Understanding Patient Data (UPD) initiative, is crucial [32]. Through cocreative workshops [33], UPD facilitates meaningful discussions among diverse stakeholders, ensuring public perspectives and concerns are not

XSL•FO
RenderX

only heard but also integrated into decision-making processes [34]. This inclusive approach cultivates trust in responsible data usage and ensures citizen expectations shape data governance practices. Collaborative governance models offer a structure where stakeholders can jointly manage and govern data processes [35]. These models emphasize shared accountability, transparency, and continuous feedback, helping to mitigate power imbalances between different groups. Such models can be adapted to include conflict-resolution strategies to address disagreements or tensions that may arise during the decision-making process. Furthermore, achieving alignment across disparate groups requires consensus-building strategies. Techniques such as participatory decision-making frameworks and deliberative processes can help in forming agreement on key issues such as data ownership, privacy, and access rights [36].

Another notable initiative that frames health data as a common good is the Our Future Health program delivered in collaboration with the NHS. This program aims to collect health information from up to 5 million adults across the United Kingdom on a voluntary basis [37]. By September 2024, more than 1.8 million people had taken part. Researchers from universities, charities, the NHS, and health-related companies can apply for access to Our Future Health resources. It is anticipated that this will enable them to explore and test innovative approaches for predicting, detecting, and treating common diseases such as dementia, cancer, diabetes, heart disease, and stroke [37].

In summary, Textbox 1 outlines the key future directions, recommendations, and research agenda emerging from the workshop discussions.

XSL•FO
RenderX

Textbox 1. Future directions, recommendations, and research agenda.

Research priorities

Several key areas require further investigation to advance the development of robust and secure data-for-health ecosystems:

- Data privacy and security: Future research should focus on developing and refining privacy-preserving technologies that enable secure data sharing without compromising individual privacy. Researchers should also explore the effectiveness of granular consent mechanisms in empowering individuals to control their data.
- Interoperability: Addressing the lack of interoperability between health care systems, both within and across national borders, is vital. Building on successful interoperability and disease coding standards such as SNOMED-CD (Systematized Medical Nomenclature for Medicine–Clinical Terminology) and *ICD-10 (International Statistical Classification of Diseases and Related Health Problems, 10th Revision)* [38,39], research should prioritize the development of standardized data-sharing protocols and application programming interface–based solutions that can facilitate real-time data exchange while ensuring compliance with differing regulatory frameworks.
- Ethical governance models: As data-for-health ecosystems evolve, the development of inclusive governance models that balance the interests of diverse stakeholders will be essential. Researchers should focus on designing collaborative governance structures that integrate citizen engagement and address concerns about data commodification and trust.
- Cross-border data sharing: Given the global nature of health challenges, it is crucial that future research addresses solutions for overcoming the legal and regulatory barriers to cross-border data sharing. This effort should focus on developing and endorsing international agreements, as well as harmonizing standards, to ensure the secure and ethical exchange of health data. Key stakeholders in this process should include organizations such as the World Health Organization, European Commission, and national Ministries of Health. An important step in this direction is building on existing frameworks, like the European Health Information Gateway [40], to facilitate greater collaboration. In addition, fostering partnerships between the World Health Organization, the Association of European Operational Research Societies, and the European Centre for Disease Prevention and Control could further enhance data accessibility, with the creation of a joint data portal and application programming interface for developers to access health data securely and seamlessly.

Recommendations for policy makers

Policy makers play a crucial role in shaping the future of data-for-health ecosystems. While this is the hardest challenge to address due to the varying priorities of member states and IT industry commercial pressure We recommend the following actions:

- Regulatory harmonization: policy makers should work toward the harmonization of data protection standards globally, to facilitate cross-border data sharing while safeguarding privacy. Collaborative efforts between international organizations and governments are key to establishing global frameworks for data governance.
- Incentivizing technological innovation: governments should provide incentives for the adoption of privacy-enhancing technologies and interoperable data systems, including the use of federated learning and blockchain for secure data sharing.
- Public trust and engagement: public trust in data systems must be a priority. Policy makers should encourage the development of transparent governance frameworks that involve citizens in decision-making processes and ensure public accountability in the use of health data.

Guidelines for practitioners and researchers

Health care practitioners and researchers should focus on the practical implementation of new technologies and frameworks. We recommend:

- Adopting best practices for data sharing: health care institutions should adopt best practices for data sharing that prioritize data security, interoperability, and patient consent, while supporting the reuse of anonymized and pseudonymized data for research, policy, and social good. These practices can be informed by pilot projects and case studies that have successfully integrated innovative technologies such as machine learning and federated learning into health systems.
- Collaborative research initiatives: researchers should pursue collaborative initiatives that bring together stakeholders from academia, industry, and government to cocreate solutions. These collaborations will be critical for testing the feasibility and effectiveness of emerging technologies in real-world settings.
- Focus on equity and inclusion: researchers and practitioners must ensure that the benefits of data-for-health ecosystems are equitably distributed. This includes prioritizing access to technology for underrepresented populations and ensuring that governance models include mechanisms for inclusive participation.

Conclusion

Perspectives on the risks and opportunities within a data-for-health ecosystem vary based on the vantage points of government agencies, private entities, and individual citizens. Balancing top-down regulation with bottom-up citizen engagement is crucial for enabling data generation, usage, and sharing while safeguarding individuals. Examining successful practices, such as the NHS's Data Utility framework, and the case studies (Textbox 2) highlighted in this paper can inform the development of adaptable models across countries.

XSL•FO

Textbox 2. Case studies in data-for-health ecosystems.

Successful interoperability: The COVID-19 vaccination rollout in Israel [41]

Israel's national health infrastructure enabled the rapid, seamless integration of vaccination data across health care providers during the COVID-19 pandemic. Interoperability between public health databases and electronic medical records allowed real-time data sharing, which facilitated efficient tracking, resource allocation, and public health decision-making. This success was driven by a well-established national health database and the effective use of application programming interfaces (APIs) that allowed data exchange between different systems. The case highlights how clear governance and technical standards can result in radical interoperability and improve public health outcomes.

- Key factors for success:

  A centralized national database, clear data-sharing protocols, and government-driven API adoption.

- Lessons learned:

  This case aligns with our proposed interoperability suggestions by demonstrating the value of standardized APIs and centralized databases in promoting real-time data sharing.

Interoperability challenges: Data sharing during the Ebola Epidemic (West Africa, 2014-2016) [42]

During the 2014-2016 Ebola epidemic in West Africa, the lack of interoperability between different health care systems and organizations severely hindered real-time data sharing and coordination among international health agencies. Various platforms were used to track the epidemic, but without standardized protocols, the response was delayed, costing lives. This case demonstrates the dangers of fragmented data systems during public health emergencies.

- Key factors for failure:

  Lack of standardized data-sharing protocols, limited use of APIs, and a fragmented health infrastructure.

- Lessons learned:

  The case reinforces the importance of adopting standardized interoperability solutions, such as APIs, to enable real-time data sharing across countries and organizations.

Governance challenges: The failure of the National Health Service Care.data program (United Kingdom) [43]

The NHS Care.data initiative, launched in 2014, intended to pool health data across general practices to improve patient care and medical research. However, the initiative faced severe backlash due to inadequate communication, a lack of clear consent mechanisms, and fears over data commodification. Concerns about patient privacy and the potential for data misuse led to public outcry, and the program was ultimately abandoned in 2016.

- Key factors for failure:

  Poor communication, lack of transparent consent processes, and public distrust.

- Lessons learned:

  This case emphasizes the need for clear, dynamic consent mechanisms and transparent governance practices. It also underlines the importance of trust-building initiatives before embarking on large-scale health data programs.

Citizen engagement: The Understanding Patient Data Initiative (United Kingdom) [44]

The Understanding Patient Data initiative in the United Kingdom is an example of effective citizen engagement in data governance. By involving the public in cocreation workshops, the initiative has fostered dialogue on how patient data should be used, addressing concerns about privacy and data ownership. Through transparency reports and educational programs, this initiative has built a stronger foundation of trust and enabled more meaningful public participation in decision-making about health data.

- Key factors for success:

  Transparent communication, active public involvement, and education initiatives.

- Lessons learned:

  This case supports our proposed citizen engagement advocacy, particularly the importance of transparency and cocreation in building trust in data governance.

The innovative deployment of transformative technologies in dynamic data-for-health ecosystems is a far-reaching goal. However, the international agenda must also focus on equity, access to technology, and IT literacy, embracing the needs of citizens of all ages and in all regions of the world, to avoid a growing digital divide. Furthermore, international norms and standards are required, given the burgeoning role of multinational companies in this space and the vital importance of transboundary data sharing when addressing public health emergencies of international concern.

Global collaboration plays a pivotal role in advancing standardized data-sharing frameworks, ensuring interoperability, and fostering mutual trust among nations. Establishing robust international partnerships can accelerate the adoption of common standards while respecting local contexts and priorities. Such collaboration will also help to harmonize efforts toward

XSL•FO
RenderX

equitable access to technology and shared public health goals. Large institutions have a key role in shaping the direction of this ecosystem and steering policies in specific directions. For example, the rapid and ubiquitous growth of efficient data collection tools—which have become an essential part of our lives—prompted the EU to devise the GDPR framework that became law in 2018. Due to the size of the market it covers and the EU's geopolitical role, it has effectively set the standard for data protection and management worldwide, building on the WHO and European Centre for Disease Prevention and Control European Health information Gateway [40]. Besides regulations and limitations, governmental bodies can promote and support private endeavors that create digital tools with a privacy-by-design approach. A recent joint statement—the European Health Data Space proposal—from health care stakeholders emphasizes the need for regulated industry access to health data for innovation and societal benefits, recognizing the interconnected nature of the data-for-health ecosystem [45]. Such initiatives, alongside the recommendations in this paper, offer the potential for effective management of this ecosystem. This is crucial to balance diverse interests and ensure that the value of health data benefits society as a whole.

Acknowledgments

The "Data Enabled Society for Health: Challenges and Opportunities" workshop was supported by the Institute of Healthcare Engineering and the Centre for Digital Public Health in Emergencies, University College London. This workshop created a platform for knowledge exchange across a community of professionals passionate about data for health. We acknowledge the commitment of the organizers and attendees. We would like to extend our gratitude to ChatGPT, an AI language model developed by OpenAI, for its assistance in proofreading and refining the language of this article. The "Data Enabled Society for Health: Challenges and Opportunities" workshop and the paper writing was financially supported by the Institute of Healthcare Engineering, University College London.

Authors' Contributions

LL, EB, SL, SLR, AC, and PK contributed to conceptualization and writing – original draft. RS, NM, SE, MS, JW, IY, GR, BG, and VM assisted with data curation and writing – review & editing.

Abstract

Tribal governments and Tribal Epidemiology Centers face persistent challenges in obtaining the public health data that are essential to accomplishing their legal and ethical duties to promote health in American Indian and Alaska Native communities. We assessed the ethical implications of current impediments to data sharing among federal, state, and Tribal public health partners. Public health ethics obligates public health data sharing and opposes data collection without dissemination to affected communities. Privacy practices, like deidentification and data suppression, often obstruct data access, disproportionately affect American Indian and Alaska Native populations, and exacerbate health disparities. The 2020-2024 syphilis outbreak illustrates how restricted data access impedes effective public health responses. These practices represent a source of structuralized violence throughout the US public health system that contributes to the data genocide of American Indian and Alaska Native populations. Good governance practices like transparent data practices and the establishment of a social license (ie, the informal permission of a community to collect and use data) is essential to ethically balancing collective well-being with individual privacy in public health.

Introduction

Advancements in digital technology have transformed the potential for real-time global data sharing, including in the field of public health. However, sharing data for public health use remains a challenge. Legal, relational, and technical barriers can impede access to the data that enable public health agencies to act for the benefit of their communities. [1-3] Most of these barriers are at least indirectly associated with a need to protect the privacy of data subjects.

Public health data custodians are acutely aware of these risks, but sometimes zealous overprotection of individuals' privacy

XSL•FO
RenderX

can harm communities [4]. In the case of American Indian and Alaska Native communities, a lack of access to public health data, data they are legally entitled to have, results in unnecessary deaths in these communities [5,6].

While this paper focuses on the ethical basis for sharing data with Tribes for public health activities, it is important to acknowledge the robust legal foundation for such action, including the treaties between the United States and various Indian Tribes that help round out the obligations of the federal government to Indian Tribes and Tribal people [7]. According to a long line of federal court cases, interpreting the Constitution, statutes, and treaties, the United States Congress has plenary and exclusive authority over Indian affairs. Within these cases, the Supreme Court has consistently held that "federal law preempts state law in the context of Indian affairs" [8]. Although Tribes and states coexist as distinct sovereigns, the legal doctrine of federal preemption requires that "Congressional power over Indian affairs supersedes conflicting state laws or state constitutional provisions" [8].

For example, when the Indian Health Care Improvement Act (IHCIA) and its subsequent amendments were enacted into law, this was construed as the federal government saying it was now preempting state action in the areas staked out within the IHCIA. Among other things, the IHCIA affirmed the trust responsibility of the federal government "to ensure the highest possible health status for Indians and urban Indians and to provide all resources necessary to effect that policy" [9,10]. Currently, the 12 Tribal Epidemiology Centers (TECs) provide epidemiologic and public health services to approximately 574 Tribes, 41 urban Indian organizations, and 9.7 million American Indian and Alaska Native people, and data are a necessary resource to support these activities [11]. The federal trust responsibility embedded in the IHCIA implicitly provides legal support for public health data sharing with Tribes and TECs as well as the ethical imperative to do so.

Federal public health law relating to Indian Tribes and federal services for Indian Tribes firmly supports Tribal governmental and TEC authority to collect and use data to promote public health [12]. This includes laws that empower governments to promote public health (eg, police powers), federal Indian law (eg, the Indian Self-Determination and Education Assistance Act of 1975 that established the federal policy of Tribal self-determination), and Tribal laws (eg, constitutions, codes, and case law) that support and shape Tribal public health authority [12].

As O'Connell and Abourezk [10] describe in detail, there is a strong federal legal foundation supporting the sharing of public health data with TECs due to their status as legally recognized public health authorities. Federal statutes that govern the receipt of identifiable data (ie, protected health information) by public health authorities from entities covered under the HIPAA (Health Insurance Portability and Accountability Act) (such as hospitals and medical clinics) apply to Tribes, TECs, and non-Tribal public health authorities.

Data access and use by Tribal governments and TECs is, therefore, legally distinct from the access and use of public health data by other entities that may work with or represent minoritized communities such as community nonprofit organizations. Tribes are sovereign nations that have the inherent right to govern their own resources, including data (ie, Tribal data sovereignty) in accordance with their cultural values and legal frameworks [13]. Restriction of data from Tribal governments, in particular, represents a failure to honor their legal status as sovereign entities that have been recognized since first contact with colonizers.

While federal and Tribal laws overwhelmingly support data sharing with Tribal public health authorities, Tribal governments, and TECs have long experienced difficulty in obtaining data from covered entities and their state and federal public health partners [10,14]. These data are central to effective public health practice and necessary for Tribal governments and TECs to fulfill their legal and ethical duties to promote health and eliminate disparities in American Indian and Alaska Native communities [15].

A 2022 US Government Accountability Office (GAO) report entitled, "Tribal Epidemiology Centers: HHS Actions Needed to Enhance Data Access," documents the difficulties experienced by TEC personnel in accessing essential public health data [15]. The GAO report found that access to and use of data varies by TEC with many TECs reporting challenges related to accessing data from the Centers for Disease Control and Prevention (CDC), Indian Health Service (IHS), and states. The report found that the work that TECs can perform and the information they can in turn provide to relevant public health decision makers is determined by their access to needed data. Consequently, when data access is limited or inconsistent, so too is the ability to address the health needs of Tribal communities. The report found that the US Department of Health and Human Services (HHS) lacked policies, procedures, and guidance related to existing data-sharing systems and agreements that resulted in barriers to Tribal HHS data access. The GAO report provided 5 recommendations for enhancements to HHS and IHS policies, procedures, and guidance to improve TEC access to public health data [15]. While HHS has taken steps to address some of these recommendations, Tribal governments and TECs still face barriers to accessing data from their state public health partners.

The consequences of these long-standing impediments to data access were tragically highlighted during the COVID-19 pandemic [5]. The failure of state and federal health departments to share timely and complete public health data during the COVID-19 response was highlighted in the 2021 Urban Indian Health Institute report, "Data Genocide of American Indians and Alaska Natives in the COVID-19 Data" [5]. A total of 15 states reported no American Indian and Alaska Native cases on their COVID-19 dashboards, and many lacked complete racial information on the fraction of cases reported to the CDC, making accurate monitoring of the COVID-19 pandemic in American Indian and Alaska Native communities impossible [5].

However, the consequences of these impediments to full data access predate and extend far beyond the COVID-19 pandemic. The prolonged dearth of actionable public health data has hampered the ability of Tribes and TECs to combat other common and preventable public health challenges and have

XSL•FO
RenderX

contributed to staggering disparities [6,16]. Tribal governments and TECs encounter systemic policy, bureaucratic, and relational barriers such as excessive privacy restrictions, data suppression practices, and paternalistic policies that impede their access to critically needed public health data.

In this paper we explore how these barriers perpetuate health inequities, examine the ethical dimensions of data sharing, and argue for a "share by default" model that aligns with public health ethics, respects Tribal sovereignty, and ensures the provision of timely, actionable information for American Indian and Alaska Native communities. Specifically, we assess the ethical and real-world implications of the status quo of data sharing impediments that exist between federal and state public health authorities and their Tribal public health and governmental partners. Currently, compared with their other public health authority counterparts, Tribal governments and TECs experience inequitable access to public health data, which severely impairs their ability to ensure the well-being of their constituent communities, fulfill their legally recognized role and responsibilities, and implement legal interventions and policy solutions that are informed by the best available public health data. While access to needed data is a challenge shared by nearly all public health authorities, the real, perceived, and sometimes intentional data-sharing barriers encountered by Tribal governments and TECs can be fairly described as structural violence perpetrated on Tribal communities.

To illustrate the deadly consequences of current data-sharing practices, we highlight the resurgence and prevalence of syphilis, a preventable and treatable disease, that has devastated American Indian and Alaska Native communities that do not have access to critically needed data that are readily available to their state and federal public health partners to effectively target preventative interventions and resources. These inequities in data access and data sharing represent an abdication of ethical responsibilities across the US public health system.

An Ethical Imperative to Share Data for Public Health Activities

Public health ethicists have long argued that there is an ethical duty to share public health data where there is a demonstrated public health need [17-19]. This ethical duty is essential to fulfilling the central purpose of public health surveillance; quickly and efficiently supplying information to decision-makers for population health.

For example, the 2017 World Health Organization (WHO) ethical guidelines on public health surveillance state, "[w]ith appropriate safeguards and justification, those responsible for public health surveillance have an obligation to share data with other national and international public health agencies" [17]. Other organizations have similarly spoken on the imperative to share data. The International Association of National Public Health Institutes called for sharing "public health surveillance data by default" and "with as few restrictions as possible" [18]. Lee et al [20] extended this point, arguing that "not using [public health] data for improving health must be justified" [20]. Both the American Public Health Association (APHA) Code of Ethics and the Public Health Leadership Society Principles for the Ethical Practice of Public Health urge prompt and appropriate data dissemination to enable public health actions [21,22]. Pisani and AbouZahr [23] argue that sharing public health data collected with public resources is important to the maximization of the public benefit from those costs.

All this underscores that collecting data without dissemination to affected communities is itself unethical. The APHA Principles of the Ethical Practice of Public Health states, "Public health institutions should provide communities with the information they have that is needed for decisions on policies or programs and should obtain the consent of the community for implementation" [22].

Certainly, as Langat et al [19] argue, there are important reasons for limiting data sharing including considerations of (1) data property and ownership, (2) just distribution of benefits and burdens, and (3) the competitive ethos of contemporary science [19]; however, they also note that these reasons are each outweighed by ethical considerations that support data sharing.

Moreover, an ethical right to be counted can countervail a right to privacy in public health contexts [24]. Accordingly, the WHO Guidelines on Ethical Issues in Public Health Surveillance recognize that there is an affirmative obligation that governments "develop appropriate, feasible, sustainable public health surveillance systems" [17]. Public health data showing an existing harm or imminent danger can shine a light on these threats and empower individuals and communities to compel a governmental response. Therefore, individuals and communities, from Love Canal, NY to East Palestine, OH, often demand to be counted [24-26]. Counting (ie, public health surveillance) informs resource allocations, and inequitable counting results in inequitable resource distributions [27]. In the context of public health data sharing, this ethical right to be counted is frustrated when barriers (or refusals) to share adequate data interfere with the ability of a government to collect the data necessary to carry out its obligations to care for its constituents.

Existing data sharing barriers that impede Tribal access to these data, whether legal, relational, political, bureaucratic, or willful, are ethically dubious at best. Instead, public health ethics imposes a default obligation to share data with public health authorities with as few restrictions as possible when there is a public health need.

Systemic Ethical Failures: Policies, Practices, and "Street-Level Bureaucrats"

Broadly, we argue that the US public health system is rife with deviations from these public health ethical imperatives [4,28,29]. These deviations manifest themselves in a variety of ways including in laws, policies, organizational practices, and discretionary decision-making that prohibits, unduly burdens, or otherwise limits ethical data sharing or access to needed data [4,30].

Here it is important to distinguish between law and ethics. Laws relate to what can or must be done, and ethics deals with what should be done. Importantly, what is ethical is not always legal,

XSL•FO
RenderX

and what is legal is not always ethical [31]. The APHA Code of Ethics implores public health practitioners to examine and deliberate such ethical considerations in the policy-making process [21]. Public health practitioners are silently complicit to injustice when they do otherwise [21].

In some cases, laws or policies (particularly at the state level) clearly restrict the authority of a public health data custodian to share data [30]. For example, Montana Code § 50-16-603, which strictly restricts disclosures of health information controlled by the public health authorities within the state, permits disclosures of protected information for public health purposes but only lists other state or local public health authorities. The omission of Tribes and TECs from the exhaustive list of recipients in the text of the law constitutes a barrier to ethical data sharing with Tribes. In this instance, the deviation of law from public health ethical imperatives is relatively transparent. This means that the ethical obligation to address the unethical law or policy is also transparent to every person who cites the law as a barrier to ethical conduct [21].

Beyond these transparent structural barriers, deviations from ethical imperatives frequently derive from opaque organizational and individual decisions [32]. The intergovernmental data-sharing landscape exemplifies this issue, characterized by "striking legislative minimalism" [32]. Consequently, data-sharing decisions are often left to the discretion of "street-level bureaucrats," with relatively low-level government agents wielding significant influence over agency actions [32]. The opacity of these decision-making processes arises from a variety of factors including data-sharing negotiations that may be shaped by (real or perceived) policies, [30] legal agreements that are not publicly accessible [33], decisions that may be hindered by unnecessarily burdensome processes that undermine public health data-sharing goals or that may be swayed by individual risk aversion, personal judgments, or interpersonal dynamics that are sometimes rooted in racism or paternalism. In each of these situations, the deviation from ethical imperatives is a product of the (often discretionary) actions of individuals and organizations within the US public health system.

Regardless of whether the ethical deficiencies are dictated by express policy provisions or products of individual or organizational actions, accepting the status quo is untenable. Such impediments and interference can amount to structural violence on native communities and are contrary to public health ethical imperatives [1,17,19,20,34,35]. Unethical policies provide only a false aegis to culpability for the individuals or organizations that cite them as justification for insufficient data sharing. Public health ethical imperatives demand actions to revise existing policies and practices that impede the sharing of timely and adequate data to Tribal public health organizations.

Outdated Approaches to Privacy Risks Impede Community Health Interests and Public Health Objectives

Privacy considerations are oft cited as a reason to withhold or redact public health data. These privacy considerations expressly or implicitly rest on bioethical concerns that have long been rejected in public health applications [1,17,35,36]. For example, consent has been the primary tool used to support and protect privacy interests in research and clinical contexts [37]. But, in public health contexts, overzealous protection of individual privacy harms the community. This is one reason why the HIPAA Privacy Rule includes a generous public health exception permitting public health use of protected health information without individual consent.

Misguided "Protections" That Cause Greater Harm

Tribal government and TEC efforts to access needed public health data are often frustrated by the misguided efforts of state and federal public health authorities to mitigate privacy risks from data sharing including discretionary deidentification, data suppression, and unnecessarily burdensome administrative access procedures.

Deidentification Can Contribute to Harm in Public Health Contexts

Deidentification can be a problematic approach to mitigating privacy risks in many public health contexts because it can cause both individual and group harm that offsets its benefits [38-40]. In the absence of informed consent, data controllers frequently rely on deidentification before sharing data.

There are 2 principal motivations for deidentifying data [27]. First, laws might allow data to be used or shared with fewer restrictions if deidentified. Second, deidentification is often used as an ethical precaution (as opposed to a legal requirement) to reduce the potential risks to data subjects (eg, when HIPAA covered entities insist on deidentifying data before disclosing protected health information pursuant to the research exception that does not legally require deidentification) [38]. But, when not legally required, the risks of deidentification must be weighed against the anticipated benefits [27]. This is why public health ethical guidelines expressly support the collection of identifiable data even in the absence of express consent under certain circumstances.

For example, the 2017 WHO [17] ethical guidelines state, "In some instances, the collection of names or identifiable data is both technically and ethically imperative." The guidelines expressly mention outbreak investigation, case follow-up, and preventive response activities as instances where disclosing names and other identifying information is appropriate [17]. Deidentification directly frustrates these important public health objectives by removing essential information, reducing the usefulness of information to provide the basis for action [41]. Moreover, the deidentification process consumes precious time so that when deidentified information is eventually shared its value for situational awareness is also diminished. Together, WHO Guidelines 11 and 14 (ie, the obligation to share data with other public health agencies, discussed above) state that there is a firm ethical duty for federal, state, and local public health agencies to share identifiable public health data with their Tribal counterparts when there is a public health need [17].

XSL•FO
RenderX

In fact, individual protections, like deidentification, often only shift the risks posed by data usage, rather than mitigate them [38,42]. For example, federal, state, and local health department practices that routinely deidentify public health data before sharing those data with Tribes or TECs for public health purposes will almost always suppress data about uncommon characteristics to reduce the risk of identifying individuals with those characteristics. This practice disproportionately affects Tribal communities. For instance, a public health agency that suppresses "small cell sizes" (a common deidentification practice) before sharing public health data will disproportionately suppress data on Tribal members because of the relatively small population of American Indian and Alaska Native people in any given area. In this way, deidentification practices contribute to social structures that systematically obscure the accurate assessment of health disparities in Tribal communities, ultimately leading to undercounting and underallocation of critically needed resources and support.

The assumption that deidentification reduces risks by rendering a data subject more difficult to identify is increasingly questionable in big data contexts [43]. For example, often the objective in big data applications is to gain group insights that can be both helpful or harmful to groups and the individuals that comprise them [43]. Deidentification cannot, however, eliminate all group risks but often will aggregate them. Thus, deidentification may result in real harm with little community health benefit.

Deidentification can also cause individual harm. Identifiable data are vital to helping public health agencies accurately monitor the spread of disease, identify persons at risk (eg, contact tracing), and target individual interventions [40]. When data holders deidentify the data provided to Tribal public health authorities, Tribes and TECs are unable to perform these basic public health interventions. The deidentification practices that are intended to protect individuals can impede the benefits that individuals can derive from these public health activities.

Data Suppression Hobbles American Indian and Alaska Native Epidemiology

Some US public health authorities that share data with Tribal public health partners exclude data on nonnative individuals, a precaution that is dangerous and problematic.

This practice directly contradicts public health ethical guidance in several ways. First, excluding nonnative persons from public health data sharing is bad epidemiological science that contradicts public health ethical guidance to share public health data. Excluding nonnative individuals from a dataset biases the data and denies Tribal epidemiologists comparison groups and the critical context needed to interpret the statistics. Informed public health decision-making requires this missing context. Moreover, excluding nonnative individuals from shared data effectively makes the identification and quantification of disparities impossible.

Second, excluding nonnative individuals from data shared with Tribal public health partners hides the health impacts that result from the interactions between native and nonnative individuals. In a world where disease regularly ignores geographic, political, and cultural boundaries, this type of data suppression simply makes no public health sense and amounts to a substantial barrier to understanding present and emerging public health threats. Excluding nonnative data makes even less sense given that many nonnative persons live on Tribal lands. Thus, excluding nonnative data from data shared with Tribal public health partners has harmful consequences for everyone.

Third, identifying Tribal members within state or local epidemiological datasets for the purpose of excluding all nonnative persons from data sharing needlessly complicates and delays data sharing. Existing electronic health records rarely record Tribal membership due to inadequate data standards, (ie, an absence of structured data fields for Tribal affiliation and inadequate documentation practices). Consequently, health departments that attempt to filter all nonnative persons from disclosures to Tribal organizations embark on a complex and protracted process that will delay timely data sharing. While we acknowledge that there is a tremendous benefit to developing data standards and systems that enable better Tribal affiliation documentation and demographic categorization, such actions are not prerequisites to better data-sharing practices.

Therefore, where federal, state, or local public health agencies refuse to share the nonnative data needed for good epidemiological investigations, they are deviating from public health ethical guidance to freely and promptly share public health data [1,17,19,20,34,35].

Administrative "Protections" That Amount to Data Discrimination

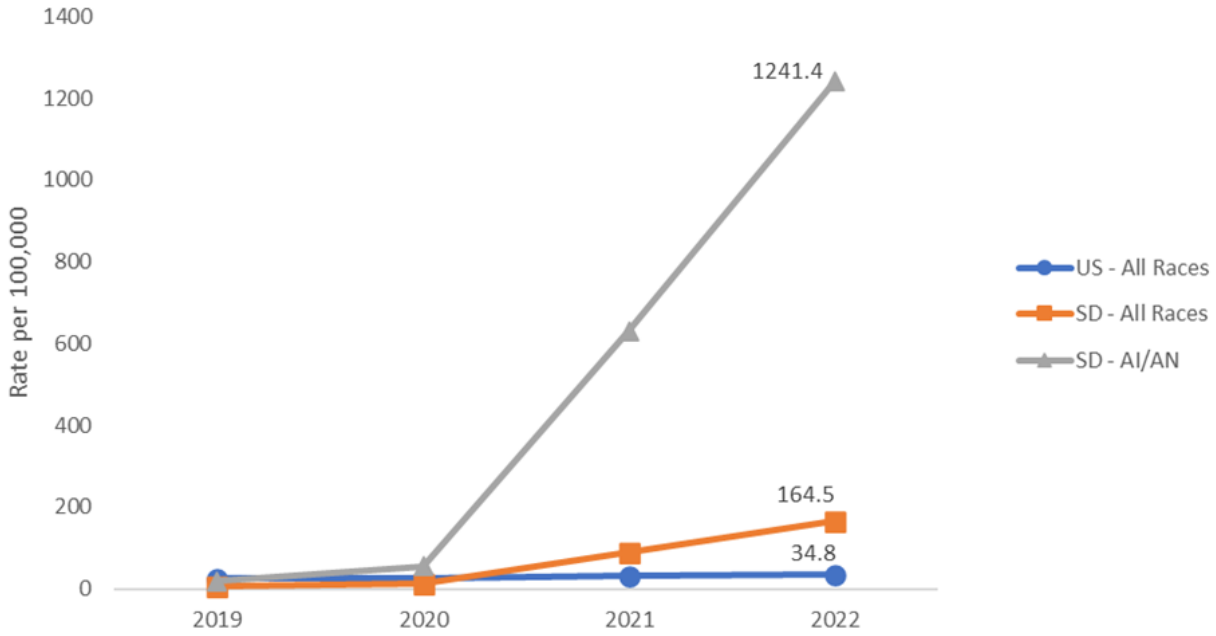
In contrast with the view of ethicists that public health data should be shared "by default" and "with as few restrictions as possible," [18] Tribal governments and TECs encounter administrative hurdles when they attempt to access public health data [15]. For example, the GAO report found that IHS required TECs to submit "Freedom of Information Act" requests, the same time-consuming process required of the general public, to access needed public health data [15]. This problem is not isolated to the federal government, as 3 TECs reported that restrictive state rules, among other reasons, prevented their access to any state data [15].

Unequal access to public health data for Tribal compared to non-Tribal public health authorities is a discriminatory practice. Yet, that is the status quo in the United States, despite the existence of equal federal legal authority to access data and perform public health functions [10].

As constructed, the current public health data sharing system de facto excludes Tribes from using public health data and results in Tribes having to seek these data from non-Tribal public health entities [5,15]. This system is likely a result of the historical paternalist and colonialist attitudes of the United States and state governments that consider Indian Tribes and their members incapable of being actively involved in their own governance. These stereotypes and inaccurate assumptions about Indian Tribes have prevented full Tribal participation in a range of governmental activities including in public health.

XSL•FO
RenderX

Unfortunately, these attitudes persist today and can impede non-Tribal public health authorities from providing life-saving data to Tribes when requested. So, Tribes and TECs face a double bind as they are excluded from the public health data collection system used by non-Tribal public health authorities and attempts to access the public health data system are blocked by the refusal of non-Tribal public health authorities to share data.



While some might argue these administrative burdens might be necessary to protect individual privacy interests, this too is a false aegis. In truth, these discriminatory administrative policies and processes result in persistent structural violence that contributes to systemic health disparities and deaths in American Indian and Alaska Native communities with little real benefit to individuals.

Case Study: Syphilis Epidemic (2020-Current)

The syphilis crisis in American Indian and Alaska Native communities (2020-2024) is an illuminating example of the failure of current data-sharing practices. Syphilis is a completely preventable disease that has been curable for nearly a century, and yet cases have risen dramatically and disproportionately in American Indian and Alaska Native populations as compared to other populations and demographic groups. Inadequate sharing of health data with Tribes, in stark contrast to ethical imperatives, is a significant barrier to Tribal government and TEC efforts to address this crisis [44].

For instance, South Dakota has seen a drastic increase in syphilis and congenital syphilis cases since 2020 (Figure 1 and Multimedia Appendix 1) [45,46]. To put these data in context, an 80% rise in national rates of syphilis between 2018 and 2022 justified the creation of a national task force For comparison, between 2019 and 2022, syphilis rates among American Indian and Alaska Native populations in SD surged by 6821%, reaching over 35 times the 2022 national rate. Yet, both the state department of health and federal IHS have been reluctant to provide protected health information to affected Tribes or the TEC that serves them. Because these agencies refuse to provide Tribes with needed public health data, Tribes have been unable to fully assist in the response.

Figure 1. Rates for Early Syphilis (per 100,000), US, South Dakota, and South Dakota American Indian and Alaska Native (2019-2022).

At the direction of the 18 Tribal leaders of the region in March 2023, the Great Plains Tribal Epidemiology Center (GPTEC) requested a CDC Epidemiological Aid (Epi-Aid) to assist with the syphilis outbreak. Due to the challenges that GPTEC encountered in accessing data on syphilis cases, a key objective of the Epi-Aid was to "[c]haracterize syphilis cases among Tribal populations in the [GPTEC] catchment area" (CDC, report to GPTEC, January 22, 2024). Despite CDC involvement and advocacy, the data required to complete the Epi-Aid was not provided by all relevant state health departments until November 2023, months after the CDC team deployment. While the deidentified data needed to conduct the report was ultimately provided, the delay in accessing the data contributed to the final report being published in January 2024, 6 months after the deployment. This rapid response action offered by the CDC took nearly a year to complete due to the data access challenges encountered by GPTEC. In that time syphilis continued to spread with 46 infants being diagnosed with congenital syphilis in South Dakota between March 2023 and January 2024, of whom 41 (89%) were American Indian and Alaska Native [45]. While syphilis is certainly concerning in the adult population, it can be deadly in newborns. The tragedy of this outbreak could have been mitigated if data-sharing practices were aligned with public health ethics.

Data are often shared with Tribes only after being deidentified. However, contact tracing, which is critical to managing outbreaks, is impossible without knowing who is infected. As a result, the deidentification standards that were intended to

XSL•FO
RenderX

protect individuals effectively denied them essential preventative and treatment services.

In April 2024, the CDC was again deployed to the region at the request of GPTEC to assist in contact tracing. Due to a data sharing agreement signed with the state of South Dakota in March 2024, GPTEC and South Dakota Tribes had access to identifiable data on people who had been diagnosed with syphilis or may have syphilis. In only 8 days of fieldwork teams of Tribal, TEC, CDC, and IHS staff members in 4 areas of the state were able to treat 62 people for syphilis, including 6 pregnant people (CDC, letter to GPTEC, May 28, 2024). The most significant difference between these 2 deployments was access to identifiable data.

When Tribal health authorities are unable to effectively respond to preventable infectious disease outbreaks, all people are put at greater risk. Though the syphilis outbreak spread nationally, the highest rates continue to be in South Dakota. If GPTEC and Tribes had access to data before the start of the outbreak consistent with ethical guidelines, they would have been able to better address it with contact tracing and other public health measures. The delay in data access—and continued lack of access in much of the great plains area—contributed to the high rates of syphilis in the region and, therefore, the country. Ethical data access for Tribes and TECs protects the health of all Americans.

A Better Way to Protect: Good Governance and Social License

In public health contexts, it is appropriate to take a group-based approach to the "respect for persons" ethical principles (as opposed to the individual-based approach of bioethics) [17]. For example, Megan Doerr argues that building or establishing a "social license" for collecting and using data can be more appropriate and protective than deidentification [47]. A social license represents the informal permission of a community to engage in a specific activity [48,49]. In public health contexts, a social license can legitimize the collection, use, or sharing of data about relevant communities. Similarly, WHO ethical guidelines for public health surveillance highlight the importance of involving affected communities in the decision-making process [17]. Developing a social license is essential to ensure that the trade-off between individual and collective interests is appropriate and ethically sound [43].

State and federal public health agencies established their social license to conduct public health surveillance through democratic processes, robust government accountability measures, and an understanding that the data collected will be used only to protect community health. Similarly, Tribal governments and TECs have a social license to collect and use public health data about their Tribal members established through their own sovereign governance and accountability mechanisms.

In fact, Tribes have substantial experience in the practices and activities that support social license for data collection and use. Tribal data sovereignty and indigenous data governance have emerged as widely recognized movements for Indigenous rights, self-determination, and ethical data management across academic, governmental, and community-based settings [13]. These movements were impelled, in part, by the unique risks resulting from the use of native data by nonnative persons or organizations that might not appropriately consider the harms or stigma that might result [50]. Yet, these movements are grounded in fundamental principles and rights inherent in sovereignty and personhood that likewise give power to social licenses as protective mechanisms for data collection and use. In particular, indigenous data governance practices and frameworks (eg, Collective benefit, authority to control, responsibility, and ethics Principles for Indigenous Data Governance) present compelling examples of how to effectively build and support social license in practice through relational accountability, stewardship, and respect for community values [13,51].

However, data on American Indian and Alaska Native individuals and Tribal members are often spread across jurisdictional lines, making data collection for Tribal organizations and TECs inherently more complex legally and practically than is the case for federal or state public health organizations. Obtaining the data necessary to fulfill their social license to use the data to promote population health requires the cooperation of federal and state public health partners.

Good governance and data stewardship are essential to support and nurture social license [52]. Public health authorities are effectively population fiduciaries who make decisions and take actions based on the best interests of the populations that they serve [53]. As such, privacy practices that prioritize the rights of individuals cannot be the only focus of public health agencies. Confidentiality protections provide an alternative approach to data governance that can permit public health authorities to use data more freely as population fiduciaries while still restricting inappropriate data uses. Similarly, adequate security measures can reduce risks of inappropriate access to or use of data while simultaneously permitting appropriate data uses. By shifting data protection governance strategies toward a population fiduciary strategy encompassing robust confidentiality and security practices, public health authorities can better align their data governance with public health ethics.

Nurturing a social license requires that data collection, its uses, and its governance are subject to public scrutiny that promotes data holder transparency and accountability that includes data dissemination to affected communities [17]. Above all, good governance must be grounded in ethical principles that do not ignore obligations to share public health data.

Discussion

The guidance of public ethicists in making public health data readily accessible between public health partners where there is a public health need provides a stark contrast to the status quo. Often Tribes—sovereign entities with primary public health responsibility for their constituent communities—are not consulted on state or federal public health data collection from Tribal communities and are not provided with the collected data needed to make crucial decisions and take needed action. This lack of consultation and provision of collected data results in 3 significant consequences. First, it wrongly subordinates Tribes

XSL•FO
RenderX

to state and federal public health partners. Second, it restricts the ability of Tribal public health authorities to promote public health and limits Tribal self-determination. And third, it results in the misallocation of resources, leaving Tribes guessing to the nature and magnitude of public health issues and unable to make data-informed decisions. Data collection wastes time and physical resources when it is not accompanied by the full dissemination critically needed by affected communities. For these reasons, the current default of not sharing data between federal, state, and local public health authorities and their Tribal partners cannot be ethically justified.

In some ways, federal Indian law interacts in unconscionable ways with the state of inadequate public health data availability experienced by Tribes. For instance, some governmental officials may conclude that the federal policy of Tribal self-determination absolves federal, state, and local governments of responsibility for threats to American Indian and Alaska Native public health. Yet, depriving Tribes of the public health data they need to protect themselves only ensures their continued vulnerability to increasingly existential threats. In this way, the status quo of inadequate data sharing with Tribes is just one dimension of a complex system of continued structuralized violence that contributes to the ongoing data genocide of American Indian and Alaska Native peoples [54].

There are meaningful steps that US public health agencies can take to address these systemic failures. Public health agencies at all governmental levels should:

1. Critically examine their data-sharing laws, policies, and practices to ensure that they are consistent with the ethical mandates of public health surveillance and action.

2. Bring any legal impediments to ethical data practices to the attention of policy makers (e.g., the absence of express language in laws stating that Tribal governments and TECs are permitted recipients of identifiable public health data). At a minimum, data-sharing practices with Tribes and TECs should be equivalent to other public health agencies [54].

3. Revise policies to align with a “share by default” approach, consistent with public health ethical guidelines, including removing data pre-processing practices (eg, de-identification, small-cell suppression, removal of non-native records) that delay the sharing of timely public health data and reduce the usefulness of the data that is shared. Consistent with Lee, Heilig, and White, decisions not to share timely data with Tribes should be justified, and justifications should expressly address the anticipated harms of not sharing data [20].

4. Adopt standard mechanisms for Tribes and TECs to request identifiable public health data with transparent and pre-defined terms for data transmission, use, and governance, consistent with public health ethics.

5. Ensure that public health data collection, sharing, and use practices respect tribal sovereignty. As Tribes are sovereign nations, their requests for data should be treated differently than requests from non-governmental groups. Public health agencies should create processes that honor Tribes as sovereign entities.

6. Establish and maintain regular communication with Tribes and TECs. Adopting policies and practices consistent with the federal guidelines on Tribal consultation can help public health agencies better understand both Tribal data needs and the barriers they encounter in achieving adequate data sharing [54].

Conclusion

Without aggressive actions to reverse the status quo, the US public health system will continue to be complicit in the data genocide of American Indian and Alaska Native communities. Public health authorities must adopt policies that expressly require data sharing with Tribes and TECs to limit the impact of discrimination and racial bias that leads to inequitable data access.

Abstract

Internet gaming disorder (IGD) affects 3% of the global population and poses an increasing risk due to advancements in technology. However, there is currently no definitive treatment for this condition. IGD is not a primary disorder but rather a result of "self-prescription" in response to emotional stressors. Unlike conventional mental health treatments that focus on the disorder itself, it is crucial to provide alternative activities that can alleviate negative emotions. This paper extends the concept of the self-medication hypothesis and integrates it with cognitive models of cognitive behavioral therapy and mindfulness-based cognitive therapy. In addition, it introduces the mindfulness-based cognitive therapy–game (MBCT-G), a program designed to explore alternative activities through gaming, focusing on the processes of response and reward, which are not typically emphasized in traditional treatments. This study serves as the theoretical foundation for the development of MBCT-G. MBCT-G aims to train individuals in positive coping strategies that alleviate psychological distress, offering a novel approach to treating self-prescription disorders such as IGD.

KEYWORDS

cognitive behavior therapy; psychosocial intervention; video games; internet gaming disorder; internet addiction; mindfulness; mental health

Introduction

The prevalence of internet gaming disorder (IGD) is known to be around 2% to 3% [1]. This prevalence varies depending on the region and the population studied [2-4]. In 2013, the American Psychiatric Association introduced IGD as a new disorder in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (*DSM-5*). The World Health Organization (WHO) also recognized gaming disorder as a disease in the *International Statistical Classification of Diseases and Related Health Problems, 11th Edition* (*ICD-11*). However, although *DSM-5* provides standard definitions and diagnostic criteria, systematic treatment methods for gaming disorders have not been thoroughly reviewed, and clinical evidence remains insufficient [5,6]. Currently, cognitive behavioral therapy (CBT) is the most frequently used treatment method; however, it has not been proven superior to other treatments [7]. Patients with gaming disorder tend to prioritize gaming above all else, lose control over their gaming behavior, and exhibit an inability to voluntarily stop [8]. While these clinical features are similar to those of substance use disorder (SUD), the two conditions show significant differences from a therapeutic perspective.

Moreover, the term "internet gaming disorder" is often confused with other conditions. For instance, pathological internet use (PIU) refers to various online activities, such as gaming, social networking, shopping, watching videos, and reading newspapers that interfere with daily life. Some studies on IGD often include

XSL•FO
RenderX

PIU, which is not entirely identical to IGD [9]. According to one study, less than half of the patients with IGD met the criteria for PIU, while only 6.67% of those who met the criteria for PIU were classified as having IGD [10].

IGD possesses characteristics that are difficult to explain within the existing psychiatric disorder framework. Traditional attempts to treat individuals addicted to internet games may be ineffective or, at times, may negatively impact the trust relationship with the patient. Therefore, this study proposes a hypothesis regarding the pathogenesis of IGD based on its characteristics. This hypothesis serves as a complementary system to the interacting cognitive subsystem (ICS) model, which has been theoretically used to explain CBT and mindfulness-based cognitive therapy (MBCT). In addition, the study discusses the necessity and potential development of mindfulness-based cognitive therapy–game (MBCT-G).

Background

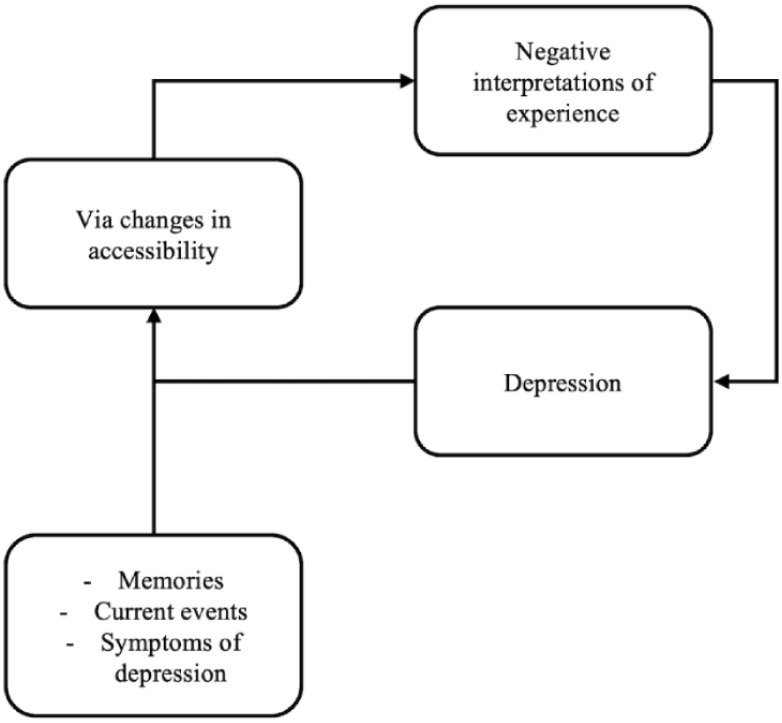
Self-Medication Hypothesis and IGD

The self-medication hypothesis refers to the tendency of individuals to autonomously select substances or specific behaviors to alleviate psychological or emotional distress [11]. According to the self-medication hypothesis, patients experience temporary relief from psychological pain through substances like cocaine or opioids. The rewarding effect of such substances weakens patients' self-control and increases their dependency on the selected substance. Patients who lose their self-control fail to consider the consequences of addiction, thereby heightening the likelihood of substance use and dependency [12].

In various studies on the causes and motivations behind IGD, the self-medication hypothesis has been discussed [13-17]. During pandemic situations like COVID-19, the prevalence of IGD increased [18,19], alongside a decline in self-control and a rise in depression and anxiety [20-22]. Resilience, defined as the ability to overcome stress, adversity, and psychological distress to return to a stable psychological state, tends to be lower in individuals with IGD, who also exhibit higher levels of depression [23,24]. Patients with posttraumatic stress disorder (PTSD), a representative anxiety disorder, are more likely to experience IGD, providing empirical support for the co-occurrence of these conditions [25,26]. While it remains unclear whether problematic gaming behavior is a cause or a consequence of weakened self-control, depression, and anxiety associated with COVID-19 and PTSD, the self-medication hypothesis is likely applicable to IGD, akin to its role in SUDs.

Research indicates that antidepressants like escitalopram and bupropion improve both IGD symptoms and depressive symptoms [27,28]. Such findings suggest that underlying causes may precede problematic gaming behavior. Previous studies have shown that bupropion is effective in managing attention and impulsivity, while escitalopram is effective in alleviating depressive symptoms. In particular, the findings from most studies suggesting that bupropion is more effective than escitalopram in improving symptoms of IGD [29,30] imply the necessity of managing the adverse effects of self-medication, such as reward effects of maladaptive behaviors and reduced self-control, regardless of the underlying causes driving problematic gaming behavior.

The similarities between IGD and SUD have been explored in various studies. Both conditions exhibit similar impulsivity traits [31], and neurological tests using functional magnetic resonance imaging have identified overlapping features [32]. However, individuals with SUD tend to have experienced more severe past adversities and exhibit more extreme problematic behaviors than those with IGD [33]. This distinction suggests that the two conditions may represent a continuum of self-medication choices, influenced by the severity of underlying causes. The high accessibility and immediate rewards of internet gaming may serve as a gateway, enabling individuals with relatively mild psychological distress, such as depression and anxiety, to easily experience reward effects and opt for gaming as a form of self-medication.



Application of CBT

Patients with IGD often hold game-related misconceptions, such as "Only in internet games do people recognize me." These distorted cognitions about gaming contribute to maladaptive behavioral patterns and cravings related to gaming [34]. CBT plays a role in correcting these erroneous beliefs that drive excessive gaming and managing the negative emotions triggered by game withdrawal [35]. Modifying cognitive distortions about gaming can regulate the severity of IGD symptoms and reduce cravings [36]. The application of CBT, originally developed for depression treatment, to various mental health disorders such as PTSD, anxiety disorders, and IGD highlights the shared and distinct features among these conditions and their connection to CBT elements. Therefore, analyzing IGD through the lens of CBT research [37] may provide new perspectives on traditional therapeutic approaches.

The theoretical background for the interaction between emotions and cognition in CBT is explained through the associative network theory [38]. CBT involves analyzing and treating the process through which individuals interpret current events based on "automatic thoughts" derived from past experiences. As illustrated in Figure 1, emotions and interpretations interact dynamically, with their sequential relationship reinforcing each other and leading to uncontrollable outcomes [39]. CBT addresses the vicious cycle of psychological distress by introducing alternative thoughts. These newly provided pieces of information compete with negative cognitions during the cognitive processing bottleneck, delaying the processing of negative thoughts and replacing them with alternative perspectives [40].

XSL•FO
RenderX

Figure 1. Associative network theory: in associative network theory, human memory, events, and emotions are represented as individual nodes. Each node is interconnected by associative links, and the activation of one node triggers the activation of related nodes.

While associative network theory explains the theoretical basis for the activation of "automatic thoughts," it has limitations in capturing the complexity of human emotions. For instance, discrepancies may arise between rational beliefs and sensory perceptions. Furthermore, according to associative network theory, the emergence of depressive symptoms requires a triggering event that evokes past experiences and emotions. However, patients with depression often exhibit depressive symptoms not only as a result of current mood and stimuli but also due to an inherent cognitive vulnerability [41,42].

Application of MBCT

To explain complex emotions and cognitive vulnerability, the ICS theory has been proposed [43,44]. The model comprises nine subsystems—acoustic, visual, body-state, articulatory, limb, morphonolexical, object, propositional, and implicational—each responsible for processing specific types of information. Through their interactions, cognition and emotion emerge. Visual and auditory information are first interpreted semantically in isolation and then integrated into a specific meaning within the propositional subsystem. This general meaning is further integrated with body-state, visual, and auditory information, evolving into implicational meaning [40]. As illustrated in Figure 2, the interaction between cognition and emotion demonstrates that external stimuli and emotions are indirectly connected. Emotions are portrayed not as mere reactions to external stimuli but as outcomes reflecting cognitive characteristics, thereby explaining why individuals exhibit different responses to stressful situations. Figure 3 illustrates the process where specific meaning and general meaning influence and reinforce each other [43].

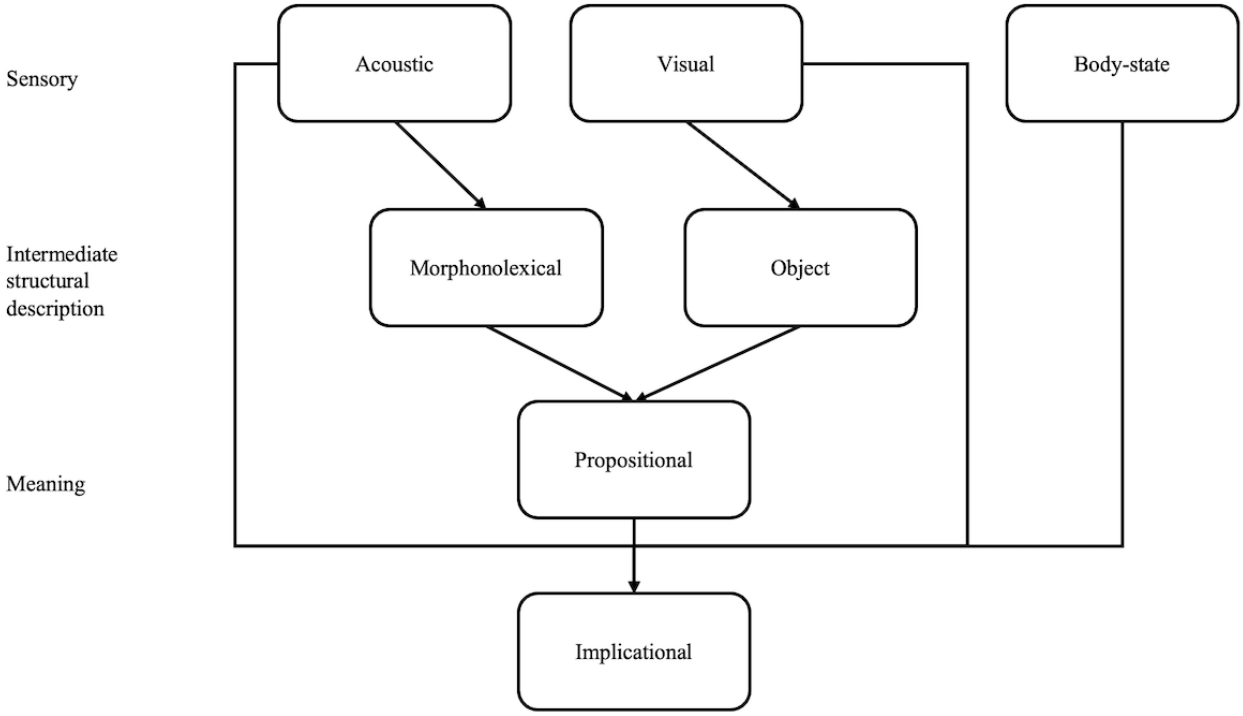
MBCT, based on the principles of the ICS, integrates the core mechanisms of CBT with stress-reduction techniques derived from mindfulness meditation. Originally developed for the treatment of recurrent depression, MBCT has demonstrated its efficacy over the past several decades [45-48]. Beyond depression, its effectiveness has been reported for other mental health conditions, including anxiety disorders [49-51], insomnia [52,53], bipolar disorder [54], panic disorder [55], chronic pain [56], cancer-related pain [57], and stress [58].

Key components such as mindfulness skills, depressogenic cognition, self-compassion and cognitive reactivity, and meta-awareness and decentering have been identified as factors associated with or mediating symptom reduction following MBCT [59]. In addition, MBCT has received significantly high ratings in patient self-assessments and has been shown to improve subscales such as "concerning danger" and "controllability of thoughts" [60].

The mindfulness meditation component of MBCT aims to stabilize thoughts by fostering a cognitive process of accepting present thoughts as internal experiences while shifting attention to external experiences by recognizing body-state cues rather than reacting to automatic thoughts. This dual focus promotes emotional regulation and cognitive stability [61].

XSL•FO
RenderX

Figure 2. Interactive cognitive subsystem.



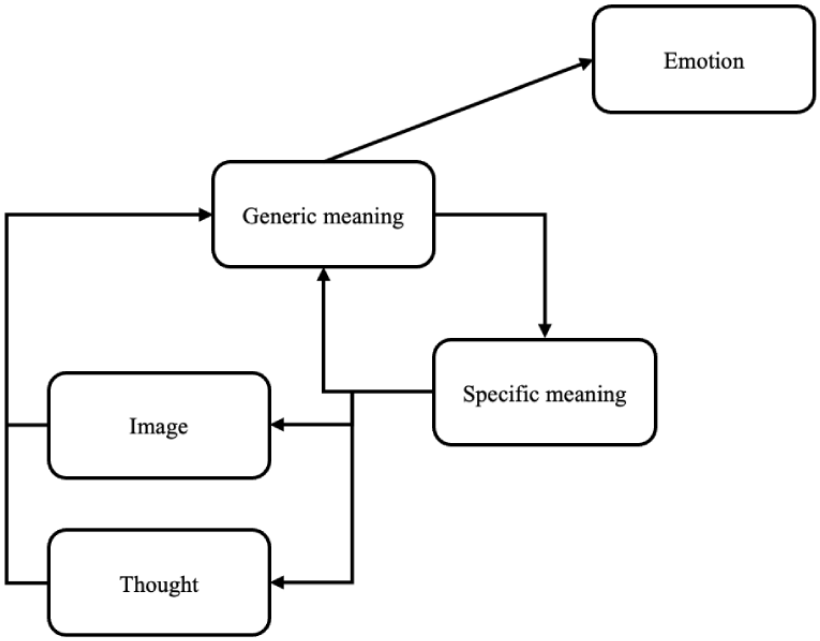


Figure 3. Vicious cycle of the interactive cognitive subsystem: specific meaning influences and reinforces general meaning in a cyclical process.

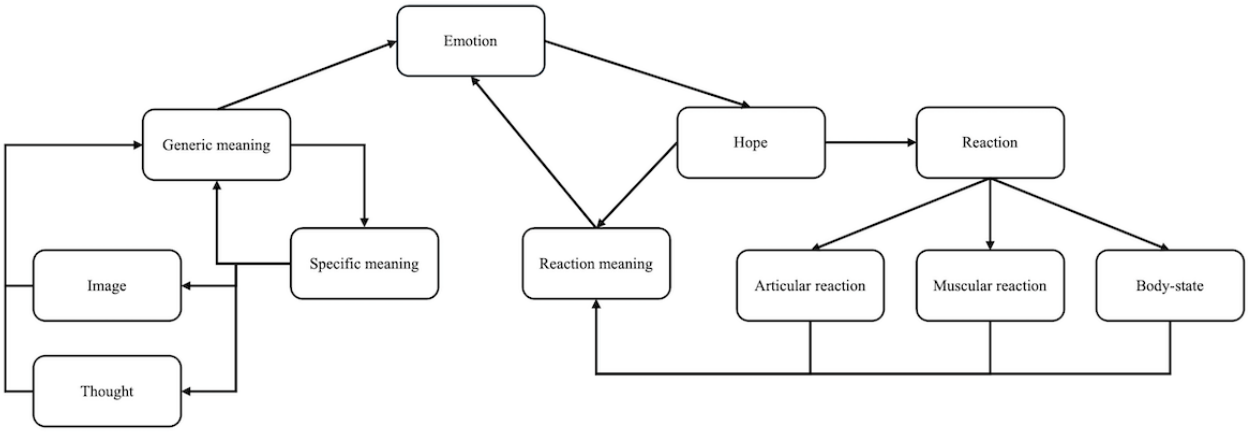
Nevertheless, several studies have reported no statistically significant differences between MBCT and CBT [60,62,63]. MBCT appears to demonstrate distinct therapeutic effects compared with CBT in patients who have experienced three or more episodes of depression recurrence [64]. However, these effects also seem to be short-term [60]. Despite previous research, the theoretical mechanisms underlying MBCT remain unclear [59].

The limitations of CBT and MBCT are particularly evident in newly defined mental health conditions such as IGD. The authors posit that, unlike the passive mental models described in CBT and MBCT, individuals actively adopt strategies like self-medication to alleviate psychological distress. Therefore, this paper introduces a modified ICS that integrates the self-medication hypothesis into existing cognitive models. This framework aims to develop a more realistic cognitive model, and the application of this model, referred to as MBCT-G, is explained in the following sections.

XSL•FO
RenderX

Application of MBCT-G

Modified ICS



The modified ICS focuses on patients' coping strategies, which were not emphasized in the original theoretical mechanisms. For example, a student with public speaking anxiety may experience situations where they "go blank," "cannot think of anything," or "feel mentally frozen" when required to speak in front of a large audience. While these responses may not be ideal, they can be understood as a form of self-medication strategy to cope with the stress of public speaking. By adopting such a strategy, the student may avert their gaze from the audience, quickly read from their script, or even leave the podium without remembering how they spoke, thereby managing the stress in the short term. However, in the long term, this strategy may reinforce their fear of public speaking, lower their self-esteem, and be perceived as an inadequate coping mechanism.

When discussing the mechanisms of cognition and emotion, it is essential to address not only the generation of emotions triggered by external and internal stimuli but also the resulting "reaction" that follows. In the previous example, the experience of giving a presentation is not limited to the emotions felt during the presentation itself but is significantly influenced by the memories and emotions generated during reflection after the situation has ended. Specifically, if an individual evaluates their coping strategy as sufficient and positive after the event, the previously generated emotions can be influenced and transformed into more positive ones. Therefore, the interpretation of emotions should not be confined to a single moment in time; instead, it must account for the distorted recollections formed through self-evaluation of the appropriateness of coping strategies, influenced by past experiences and emotions, as well as the emotions experienced in the present.

For instance, recalling negative experiences such as "feeling darkness before one's eyes," "not being able to think of anything," or "having a blank mind" during public speaking not only reinforces thoughts of psychological distress but also shapes negative self-assessments of the coping strategies used. These negative evaluations, in turn, intensify the negative emotions associated with the experience.

Figure 4 expands the ICS by incorporating the principles discussed earlier. The additional structure on the right in the modified ICS represents coping strategies and recollections related to emotions.

Figure 4. Modified interacting cognitive subsystem.

"Hope" refers to the desired strategy for coping with emotions generated in response to a stimulus. For instance, a student fearful of public speaking might think, "I want to finish my presentation quickly and leave," "I hope my turn gets skipped," or "I wish no one pays attention to my presentation."

"Reaction" represents the active coping mechanism employed in response to "Hope." In the given situation, since the external change (eg, skipping the student's turn) is beyond the student's control, they may choose an active strategy like "Let's finish the presentation quickly and step down."

"Reaction meaning" reflects the individual's self-evaluation of their chosen coping strategy. After adopting the strategy of finishing the presentation quickly, the student might evaluate themselves either positively or negatively. The outcome of this self-assessment is interpreted in the context of their fundamental "Hope" (eg, "I want to finish quickly"), which, in turn, influences the preceding emotions.

In simpler terms, if the strategy of speaking quickly satisfies the initial "Hope," the preceding "Emotion" will also be alleviated. As a result, the student may continue to rely on the "quick speech strategy" in future similar situations. On the other hand, if the strategy fails, the student might explore alternative strategies. For example, they may choose an active coping mechanism like "I want to relieve stress by playing a game." If the student successfully alleviates stress through gaming, the previously experienced "Emotion" is resolved, making gaming a preferred coping strategy in similar future scenarios.

In summary, these differences arise because the subjective interpretation of the emotional coping strategy referred to as "reaction meaning," creates a vicious cycle that influences the emotions resulting from preceding situations. In addition, past experiences, coping strategies, and emotions, such as "I can relieve stress through gaming," serve as materials for interpreting current emotions, as in "If I play games, my current

XSL•FO
RenderX

psychological distress will be alleviated." To reiterate, experiences, emotions, and coping strategies must be understood as part of a unified principle that unfolds across the flow of psychological time. This interpretation is particularly valuable in disorders where symptoms manifest in behavioral forms, such as IGD, gambling disorder, obsessive-compulsive disorder, and SUD. It offers a foundation for developing new therapeutic approaches.

How Can Games Be Used in Mental Counseling?

As previously mentioned, the gaming behavior of individuals with IGD can be interpreted as a coping strategy for managing stress resulting from external stimuli. Incorporating the self-medication hypothesis, which is often cited as a cause of SUD, the authors propose the self-prescription hypothesis as a potential explanation for the origins of behavioral addictions like IGD.

In the modified ICS, such coping strategies are effective, at least in the short term, in alleviating psychological distress (commonly referred to as a "reward"), serving as a driving force for the repetition of behavioral addictions. From this perspective, traditional treatments that focus solely on correcting maladaptive thoughts about gaming and reducing gaming time are often ineffective because they fail to provide alternative strategies for managing stress [65].

Treatments that do not offer alternative strategies may lead to symptom relapse or the development of other problematic behaviors, as the underlying cause—stress—remains unresolved. On the other hand, mindfulness meditation can serve as an effective alternative strategy. Activities like meditation and walking can help alleviate stress, reducing the perceived need for internet gaming. However, while these strategies are effective, they may not be sufficient for everyone. Some individuals may lack interest in mindfulness meditation, find it unhelpful in directly addressing their stress, or even perceive it as boring.

To address these limitations, three principles for effective psychological counseling are introduced:

1. Helping patients identify their automatic thoughts: This is the foundational principle of CBT, MBCT, and MBCT-G. Automatic thoughts are the key to uncovering the root causes of stress and form the basis of the therapeutic process. Recognizing these thoughts allows patients to understand the triggers for their psychological distress.
2. Providing alternative strategies to address the sources of stress: As previously discussed, coping strategies influence preceding emotions and play a critical role in stress alleviation. Without appropriate alternative strategies, mental health conditions may persist, worsen, or manifest in different forms of problematic behavior. Effective counseling must present actionable and relevant alternatives tailored to the individual's needs.
3. Ensuring the proposed alternative strategies are actionable and sustainable: Alternative strategies must be feasible, effective, and realistic for the patient. They should also offer long-term benefits, mindfulness effects, and ease of implementation. For instance, teaching a patient with public speaking anxiety how to "give a good presentation" may not be effective in all situations. These individuals may lack confidence in their presentation skills, but their anxiety might also stem from other causes such as interpersonal relationships, voice quality, or appearance. Simply exposing them repeatedly to presentation scenarios may not be a viable strategy. Moreover, if the patient finds the alternative strategy burdensome or rejects it, they are unlikely to sustain it, leading to cognitive strain during the therapeutic process.

By adhering to these principles, counseling can better address the complexity of individual needs and provide meaningful, sustainable solutions for stress management and mental health improvement.

MBCT-G is a therapeutic approach that incorporates the three principles outlined above. Games serve as a novel medium for experiencing virtual environments that are otherwise unattainable, making them one of the most accessible coping strategies for adolescents and young adults. While the accessibility of games can make even those with mild psychological distress susceptible to addiction, it paradoxically offers an ideal environment for learning healthy coping strategies.

The gaming environment allows individuals to repeatedly practice alternative strategies to address the sources of stress. Because this practice occurs in a virtual setting, it imposes lower cognitive demands. In addition, games can provide diverse scenarios tailored to symptoms and individual needs, while maintaining a consistent therapeutic framework. Furthermore, the gaming environment enables the collection of real-world data during the treatment process and sustains motivation for continued participation in therapy. This combination of features makes MBCT-G a compelling and effective approach to integrating mindfulness and cognitive therapy principles into an engaging and accessible medium.

Several studies have explored the use of games to address conditions such as IGD [66,67], depression [68], anxiety disorders [69], stress [70], attention-deficit/hyperactivity disorder [71], and executive function [72]. However, despite increasing interest in digital therapeutics and game-based treatment methods, few have been recognized by regulatory agencies for their therapeutic efficacy.

In the case of previous research on IGD, most studies have been limited to usability research without control groups [73]. The limitations of previous game-based studies include (1) a lack of understanding of cognition, emotion, and coping strategies, (2) an absence of defined reward mechanisms in games and corresponding alternative strategies, and (3) a poor understanding of game design quality.

A notable previous study using games to treat IGD is Room2Respawn, developed based on mindfulness-oriented recovery enhancement (MORE) [66]. MORE is a therapeutic approach that integrates three psychological counseling techniques: mindfulness, CBT, and positive psychology. It was originally designed for patients with chronic pain who are prescribed opioid analgesics [74]. The same research team investigated the efficacy of MORE in individuals with IGD. In

XSL•FO
RenderX

a randomized controlled trial targeting patients with IGD, MORE was found to reduce the severity of the disorder indirectly by correcting maladaptive gaming-related cognitions [36]. However, while Room2Respawn, developed using MORE, assessed the subjective usability of the intervention, it did not demonstrate the efficacy of implementing MORE techniques through gamified software.

How to Develop MBCT-G

Overview

In this paper, MBCT-G does not focus on a single game scenario or production method but addresses the overall factors to consider when using games for the treatment of mental health disorders. Therefore, the components of MBCT-G may differ from those of traditional MBCT.

For instance, MBCT for Life, an adaptation of MBCT designed for practical use in everyday life over an 8-week program, comprises the following sessions: (1) waking up from autopilot, (2) another way of being, (3) gathering the scattered mind, (4) recognizing reactivity, (5) allowing and letting be, (6) responding skillfully, (7) how can I best take care of myself? and (8) mindfulness for life [75]. While MBCT is a highly effective tool for alleviating stress, it requires the patient's active commitment to treatment. As a result, adherence may decrease in patients with cognitive impairments or low motivation for therapy.

The primary focus when designing game-based therapeutic interventions is to improve treatment adherence and provide opportunities for practicing alternative strategies. The key principles to consider when developing specific MBCT-G programs are outlined below.

Elements of MBCT-G

Fun

The first value of therapeutic approaches using games is fun. Educational games available on the market often emphasize the "educational" aspect while lacking gaming elements [76]. This tendency is influenced by factors such as the demands of purchasers (eg, parents), researchers' negative biases toward games, and a lack of understanding of gamification [77]. Contradictory game designs that disregard learners' characteristics such as gender and age can hinder therapeutic outcomes [70]. More fundamentally, fun is the most critical reason for applying gamification. Therefore, if concerns arise about the potential adverse effects of "fun games," researchers should reconsider the project from the outset.

Accessibility

Accessibility is a core value of digital therapeutics, including games. As mentioned earlier, in the process of selecting self-prescription methods to address psychological distress, the most important factors are "alleviating psychological distress" and "ease of access." From this perspective, internet-based games can serve as attractive tools for both the onset and treatment of disorders. Considering the rapid growth of mobile game platforms [78], excessive environmental or time-related constraints on games should be carefully addressed.

Reality Projection

Providing an environment where patients can project themselves onto MBCT-G is a topic to consider during the design phase. MBCT-G aims to help patients identify automatic thoughts, correct distorted beliefs about past and present events, and learn healthy coping strategies through experiences and lessons in the virtual world at specific points during gameplay. A game design that fails to reflect reality risks obscuring its therapeutic effects. For example, walking meditation is a core mindfulness practice, but merely watching a character walk on a screen would not yield therapeutic benefits for the patient. To project reality, an intersection between virtual data and real-world information is necessary. This could be as simple as incorporating the patient's personal information into the game or as complex as creating a sense of connection between the virtual character and the patient's physical body [79].

Discovery of Automatic Thoughts

Identifying distorted beliefs is a critical process in cognitive therapy, and its importance is equally valid in MBCT-G. However, even for professionally trained therapists, uncovering automatic thoughts can be challenging. Therefore, we can use various strategies. First, providing assurance of anonymity can reduce hesitation in sharing personal information [80]. In addition, counseling can be conducted using characters familiar to the patient [81]. Research into new artificial intelligence (AI) technologies is needed to uncover hidden meanings based on counseling content, and offline psychological counseling can be integrated to achieve accurate diagnoses.

Experiencing Automatic Thoughts

Experiencing automatic thoughts is one of the distinctive features of MBCT-G. Traditionally, psychological counseling has primarily relied on verbal communication. However, games allow for the direct discovery of distorted beliefs rooted in past experiences. With advancements in AI, various technologies mimicking human society have recently been developed [82]. A key characteristic of these technologies is their ability to form humanlike relationships through the exchange of information and emotions among in-game agents. Researchers, through unpublished studies, have demonstrated that by combining AI technologies with detailed counseling data, past experiences that contributed to psychological distress can be recreated within a game. By leveraging AI, patients are given the opportunity to directly experience distorted beliefs through the reactions of agents that vary depending on the patient's coping strategies.

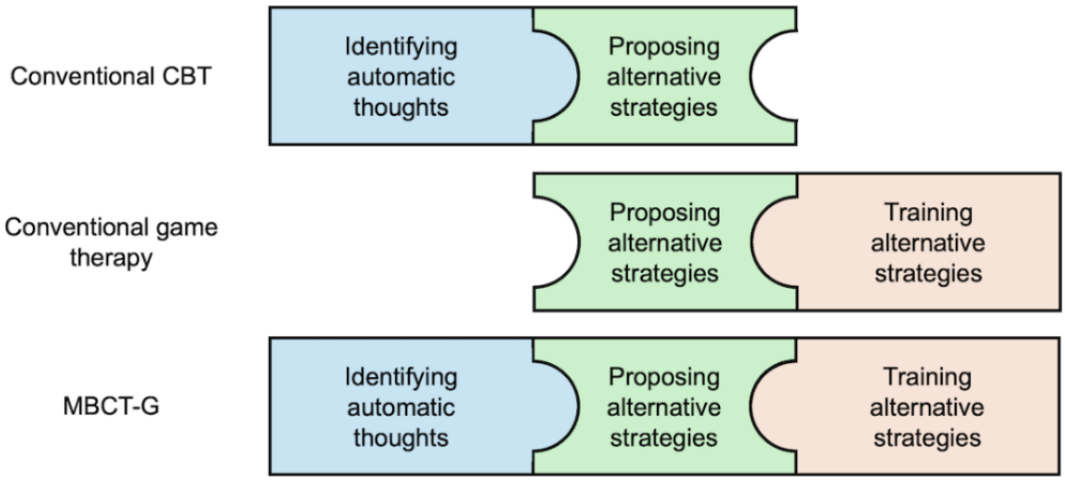
Experiencing Alternative Strategies in Games

Even when healthy coping strategies to alleviate psychological distress are recommended through counseling, many barriers exist before patients can take actionable steps. Digital technologies, especially virtual reality, provide an environment where new strategies can be vividly explored with minimal effort. For instance, while activities like traveling have often been suggested as accessible alternative strategies during psychological counseling, numerous obstacles have prevented patients from putting such advice into action. In such cases, games can allow for an indirect experience of travel, and if this virtual travel helps alleviate psychological distress, it could

XSL•FO
RenderX

serve as motivation for patients to adopt stress-relief strategies through real-world travel. The critical point is that the experience of alternative strategies in MBCT-G should seamlessly connect to real-life applications. The ability to experience alternative strategies is one of the fundamental differences between traditional psychological counseling and MBCT-G.

Opportunities for Reflection on Insights



Despite the aforementioned elements, the gamified features of MBCT-G may pose a risk of patients becoming overly immersed in entertainment aspects, potentially overlooking the therapeutic elements. Therefore, MBCT-G should consider providing opportunities for patients to reflect on the lessons and experiences they learn during gameplay through mindfulness meditation.

Group Therapy

Group therapy offers advantages such as allowing patients with similar conditions to share their experiences and deepen their understanding of their illnesses. Its effectiveness has been demonstrated across various conditions [83,84]. However, challenges in forming and maintaining groups make physical group therapy sessions difficult to implement [85]. Digital technologies provide diverse ways to facilitate group therapy, both directly and indirectly. For instance, augmented reality technologies like Niantic's Pokémon GO enable patients to communicate indirectly by creating personal experiences and thoughts in the form of agents on a map [86].

The differences between traditional therapies and MBCT-G are compared in Figure 5. Traditional CBT methods are primarily language-based, and while they can propose alternative strategies, they do not provide opportunities for patients to practice these strategies during the treatment process. Existing game-based therapies allow patients to have various experiences in virtual environments; however, they often follow standardized therapeutic procedures, neglecting individual characteristics [87,88]. Also, an example of MBCT-G developed using the 8 elements of MBCT-G can be found in Multimedia Appendix 1.

Figure 5. Comparison between MBCT-G and traditional treatment methods. CBT: cognitive behavioral therapy; MBCT-G: mindfulness-based cognitive therapy–game.

Therapeutic Goals and Evaluation of MBCT-G

Internet games, in themselves, cannot be universally labeled as harmful, and merely reducing the time spent playing games may not correlate strongly with the disease's pathology [89]. Therefore, the primary goal of MBCT-G is to restore significant impairments in daily life, as subjectively perceived by patients and their surrounding individuals.

This goal can be assessed using various methods, including the widely adopted "IGD-20 Test" and other established research tools [90]. In addition, comorbid conditions frequently associated with IGD, such as depression [91], anxiety disorders [92], and attention-deficit/hyperactivity disorder [93], should also be evaluated. Since MBCT-G focuses on the alleviation of subjective symptoms, assessments based on the patient's counseling history are particularly important.

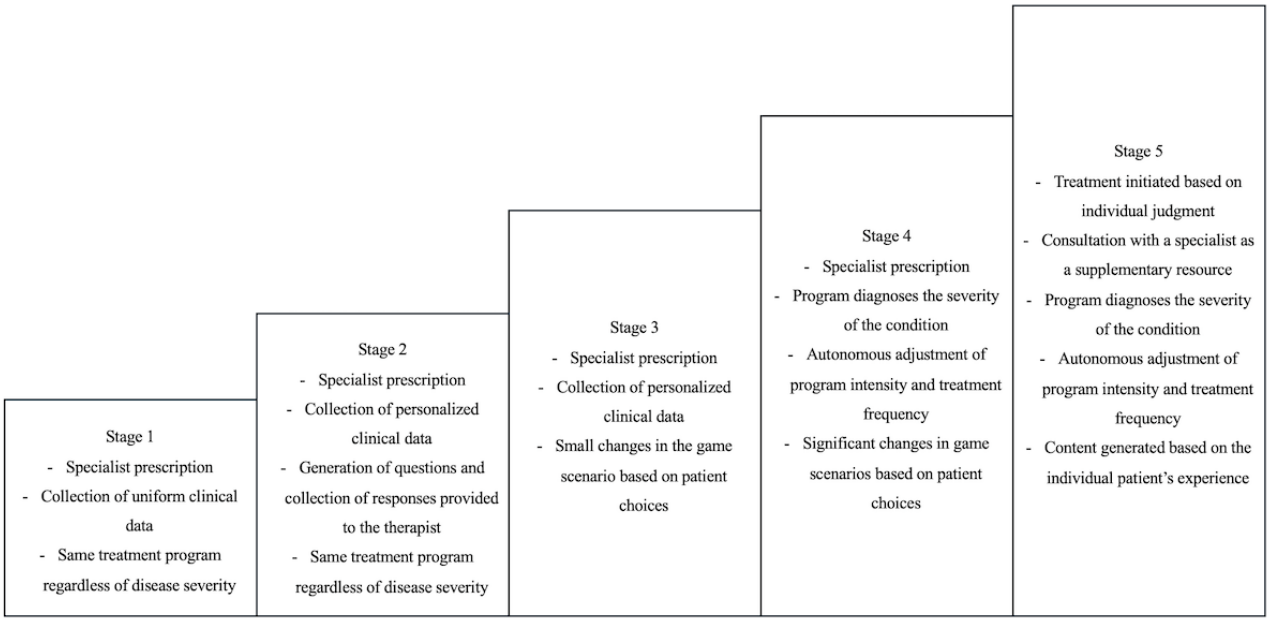
Advances in AI offer the potential to evaluate disorders using both verbal and nonverbal information [94-96]. AI-based analytic insights should be provided to psychological counselors to facilitate a complementary relationship between technology and human expertise. Furthermore, measuring the frequency and duration of MBCT-G usage is essential for assessing treatment adherence.

Finally, evaluations should include attempts and applications of alternative strategies. These evaluations should be approached from two perspectives:

1. Active engagement with alternative strategies within MBCT-G.
2. Implementation of strategies practiced in the virtual environment in the real world.

Critically, assessing whether patients are adopting healthy coping strategies outside the game environment is the most important therapeutic goal of MBCT-G.

Five Stages of MBCT-G



Overview

Finally, the 5 stages of MBCT-G are explained. With technological advancements, new technologies such as

XSL•FO
RenderX

autonomous driving, AI, and virtual reality are emerging. MBCT-G aims to create scenarios where patients can practice alternative strategies in a virtual environment, tailored to their treatment motivation and the causes of their condition. However, technological complexity and legal regulations pose obstacles to realizing these strategies. Nonetheless, to advance MBCT-G, it is important to start small and progressively implement these strategies according to the current level of technology (see Figure 6).

Figure 6. The 5 stages of mindfulness-based cognitive therapy-game.

Stage 1

In the first stage of MBCT-G, the patient visits a hospital, receives a prescription from a psychiatrist, and begins treatment. While clinical data are collected through the MBCT-G program, the program's difficulty level and scenarios are adjusted by the specialist during the hospital visit.

Stage 2

In the second stage, the MBCT-G program generates personalized questions based on the clinical data collected in stage 1 and asks the patient these questions. Although all patients collect the same clinical data in stage 1, from stage 2 onward, the program gathers tailored clinical data specific to each patient.

Stage 3

In the third stage, the MBCT-G program diagnoses the severity of the condition in a limited capacity and modifies the game scenarios based on the patient's choices to a restricted extent.

Stage 4

In the fourth stage, the MBCT-G program independently diagnoses the severity of the condition and adjusts the intensity of the program and the frequency of sessions. Patients can observe significant changes in the game scenarios based on their choices, allowing them to immerse themselves more realistically and practice alternative strategies.

Stage 5

In the final stage, the MBCT-G program autonomously creates or reconstructs scenarios based on the clinical data collected from the patient. The patient repeatedly trains in virtual reality to address the situations that cause gaming disorder. In stage 5, both diagnosis and treatment are autonomously conducted by the program, with the psychiatrist intervening only in exceptional situations.

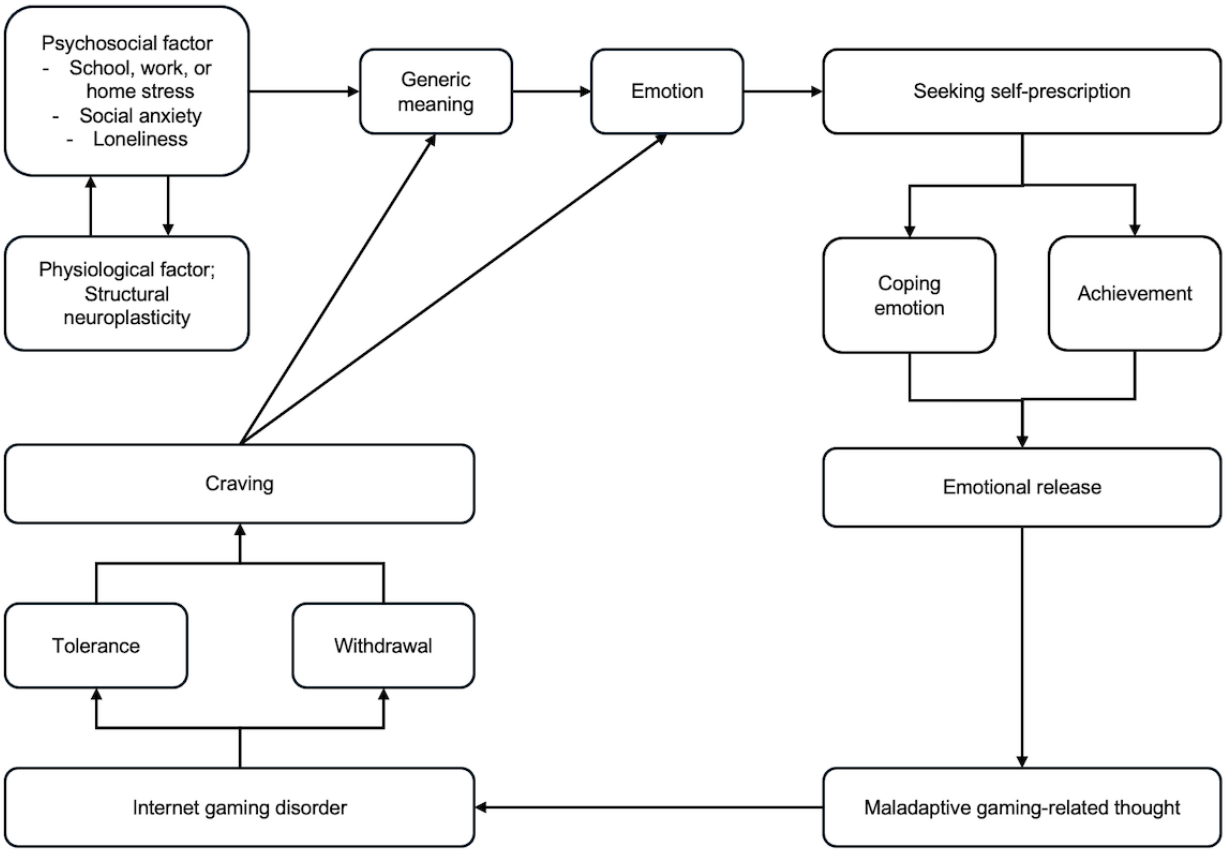
Summary

This paper describes the theoretical background and components of a novel approach called MBCT-G for treating IGD. To achieve this, it elaborates on the conceptual expansion of the self-medication hypothesis, originally proposed as one of the causes of SUDs, and integrates it with the cognitive models of CBT and MBCT. The self-prescription hypothesis and modified ICS presented in this paper can be interpreted as efforts to maintain a form of mental homeostasis.

Homeostasis refers to the property of maintaining a stable and consistent internal environment. Typical examples of homeostasis include maintaining a constant body temperature and regulating the osmotic pressure of the blood. In situations where stress arises due to internal or external stimuli, the human body adjusts factors such as heart rate, respiration, blood pressure, and blood sugar levels to sustain homeostasis [97].

The conceptual terms presented in this paper require further validation in clinical settings. First, previous studies on the relationship among the reward effects, reduced self-control, and craving, as described in the self-medication hypothesis, yield varying results depending on the experimental design [98,99]. Furthermore, the ICS is merely one of several explanations of cognitive structures. These discrepancies stem from the ongoing debate—akin to the "chicken or the egg" question—caused by the diverse comorbidities and complications associated with mental disorders. What is clear, however, is that traditional

XSL•FO
RenderX



psychological counseling techniques have been ineffective for behavioral addiction disorders like IGD, underscoring the need for novel therapeutic approaches and theoretical foundations. To address these challenges, this paper proposes the conceptual therapeutic approach and rationale of MBCT-G, based on previous studies and clinical experience.

The concepts introduced in this paper may not necessarily be entirely new. CBT and MBCT emphasize that the present is interpreted based on past events and emotions. Previous research briefly explains the "vicious cycle" where body states, such as trembling hands, a hunched posture, or facial grimacing, change according to emotions, and these changes, in turn, affect emotions [43]. As shown in Figure 2, active behavior and body states influenced by emotions can also affect thoughts and feelings, a notion aligned with the ideas behind MBCT-G. However, in situations of psychological distress, patients' active behavioral strategies are far more critical than previous studies suggest. Despite this, discussions about such ideas are sparse and have not been incorporated into psychological counseling techniques. Thus, there was a need to emphasize active behavioral strategies in response to psychological distress, which had previously been overlooked, and to incorporate these strategies into the therapeutic process [100].

Theories about the motivation for internet gaming are diverse and extend beyond the self-prescription hypothesis. Internet gaming is known to be driven primarily by the motivations of "escape" and "competition," which serve as key mediating factors and are reported to directly or indirectly influence the symptoms of IGD.

Figure 7 is a visualization of the development process of IGD. Maladaptive thoughts about gaming can arise from various causes. Patients with IGD can be differentiated based on factors such as self-esteem, achievement, and coping strategies [101]. This differentiation suggests that the reasons for gaming addiction are diverse, including "enjoyment of the game itself," "goal achievement," and "stress relief." Therefore, the self-prescription hypothesis proposed in this paper may have limitations in analyzing all motivational factors. However, the various grounds for the self-prescription hypothesis related to the characteristics of IGD and the need for new psychological counseling techniques highlight the importance of continued research in this area.

Figure 7. The development process of internet gaming disorder: the tolerance and withdrawal characteristics associated with internet gaming trigger cravings for gaming.

Digital therapeutics refer to medical approaches that use software and hardware to prevent, treat, and manage physical and mental illnesses. This new approach to disease management and treatment offers several advantages. First, it allows patients to receive treatment without the need to visit hospitals or counseling centers, providing freedom from time and space constraints. Second, online mental health treatment can eliminate the stigma and negative perceptions that patients might otherwise face. Third, because sessions can be conducted without the involvement of a physician or counselor, it is easier to monitor treatment adherence, and the approach is cost-effective [73]. Games are a type of digital therapeutic method, and the enjoyment they provide can be particularly effective for patients lacking motivation for treatment. This is

XSL•FO
RenderX

especially true for adolescents, who exhibit the highest prevalence of IGD and simultaneously have a strong affinity for games and digital devices, making game-based approaches highly effective.

Considering that patients with IGD often choose gaming as the most effective means of alleviating psychological distress, teaching them to repurpose gaming, which has been used inappropriately, into a tool for positive life outcomes may ironically prove to be the most effective therapeutic method.

Conclusion

IGD affects 3% of the population, and with technological advancements, more individuals are at risk of developing this condition. However, there is currently no clear treatment available. IGD is not a primary disease but rather a result of "self-prescription" in response to emotional stressors. Therefore, unlike traditional mental health treatments that focus on the disorder itself, it is essential to provide alternative activities that can alleviate negative emotions. This paper introduces MBCT-G as an alternative activity. MBCT-G is a program designed to explore alternative activities through gaming, focusing on the reaction and reward processes, areas that traditional treatments have not emphasized. This paper serves as the first theoretical foundation for the development of MBCT-G. MBCT-G is necessary as a method to provide alternative emotional relief strategies for treating self-prescription disorders such as IGD.

Abstract

High-quality data are critical in health care, forming the cornerstone for accurate diagnoses, effective treatment plans, and reliable conclusions. Similarly, high-quality datasets underpin the development and performance of large language models (LLMs). Among these, instruction-tuning datasets (ITDs) used for instruction fine-tuning have been pivotal in enhancing LLM performance and generalization capabilities across diverse tasks. This tutorial provides a comprehensive guide to designing, creating, and evaluating ITDs for health care applications. Written from a clinical perspective, it aims to make the concepts accessible to a broad audience, especially medical practitioners. Key topics include identifying useful data sources, defining the characteristics of well-designed datasets, and crafting high-quality instruction-input-output examples. We explore practical approaches to dataset construction, examining the advantages and limitations of 3 primary methods: fully manual preparation by expert annotators, fully synthetic generation using artificial intelligence (AI), and an innovative hybrid approach in which experts draft the initial dataset and AI generates additional data. Moreover, we discuss strategies for metadata selection and human evaluation to ensure the quality and effectiveness of ITDs. By integrating these elements, this tutorial provides a structured framework for establishing ITDs. It bridges technical and clinical domains, supporting the continued interdisciplinary advancement of AI in medicine. Additionally, we address the limitations of current practices and propose future directions, emphasizing the need for a global, unified framework for ITDs. We also argue that artificial general intelligence (AGI), if realized, will not replace empirical research in medicine. AGI will depend on human-curated datasets to process and apply medical knowledge. At the same time, ITDs will likely remain the most effective method of supplying this knowledge to AGI, positioning them as a critical tool in AI-driven health care.

Introduction

Background

Why is high-quality data the cornerstone of modern artificial intelligence (AI)-driven health care? Reliable data enable AI algorithms to assist medical professionals in making evidence-based decisions, reducing the likelihood of errors and improving patient outcomes [1-5].

Accurate datasets are the foundation for developing large language models (LLMs) and deep learning models based on

XSL•FO
RenderX

the transformer architecture [1,6-12]. This technique enables the model to learn the structure, grammar, and nuances of language, as well as factual knowledge and patterns of reasoning [9-12]. Examples of state-of-the-art all-purpose transformer-based models include generative pretrained transformers (GPTs) from OpenAI, Gemini and Gemma models from Google DeepMind, and LLaMA LLMs from Meta [8,13,14].

Foundation LLMs are trained on vast amounts of data encompassing millions of samples from diverse sources such as books, studies, and websites [8,13,14]. The goal is to improve the model's generalization capabilities. This means enabling the model to apply learned patterns and knowledge to a wide range of unseen inputs, ensuring it produces accurate, meaningful, and contextually relevant outputs rather than merely memorizing the training data [8,13,14]. Among various types of datasets used to train LLMs, instruction-tuning datasets (ITDs) used for instruction fine-tuning (IFT) has emerged as a pivotal technique in enhancing LLM performance and generalization capabilities across diverse tasks [8,9,15]. For example, OpenAI researchers report that, even though the InstructGPT model with 1.3 billion parameters has more than 100 times fewer parameters than the original 175 billion-parameter GPT-3, its outputs were preferred over GPT-3 [8]. An ITD contains examples of task instructions paired with corresponding responses, enabling models to understand better and follow human-like directives [8,9,16]. This structured training approach not only improves task-specific accuracy but also enhances the LLM's ability to generalize knowledge across multiple domains, sometimes including even domains that were not extensively covered in the original dataset [8,9,15,16].

Given the importance of ITDs, preparing high-quality ITDs in health care is critical. Such datasets may facilitate the formation of robust LLMs capable of addressing the nuanced requirements of complex medical questions, where precision, adaptability, and context-specific understanding are essential. In the clinical setting, instruction-tuned LLMs may support clinical decision-making and reduce the risk of medical errors. It will ultimately improve clinically relevant outcomes like increased patient safety and reduced hospitalizations, intensive care unit admissions, or deaths [4,5,17-20].

Aim

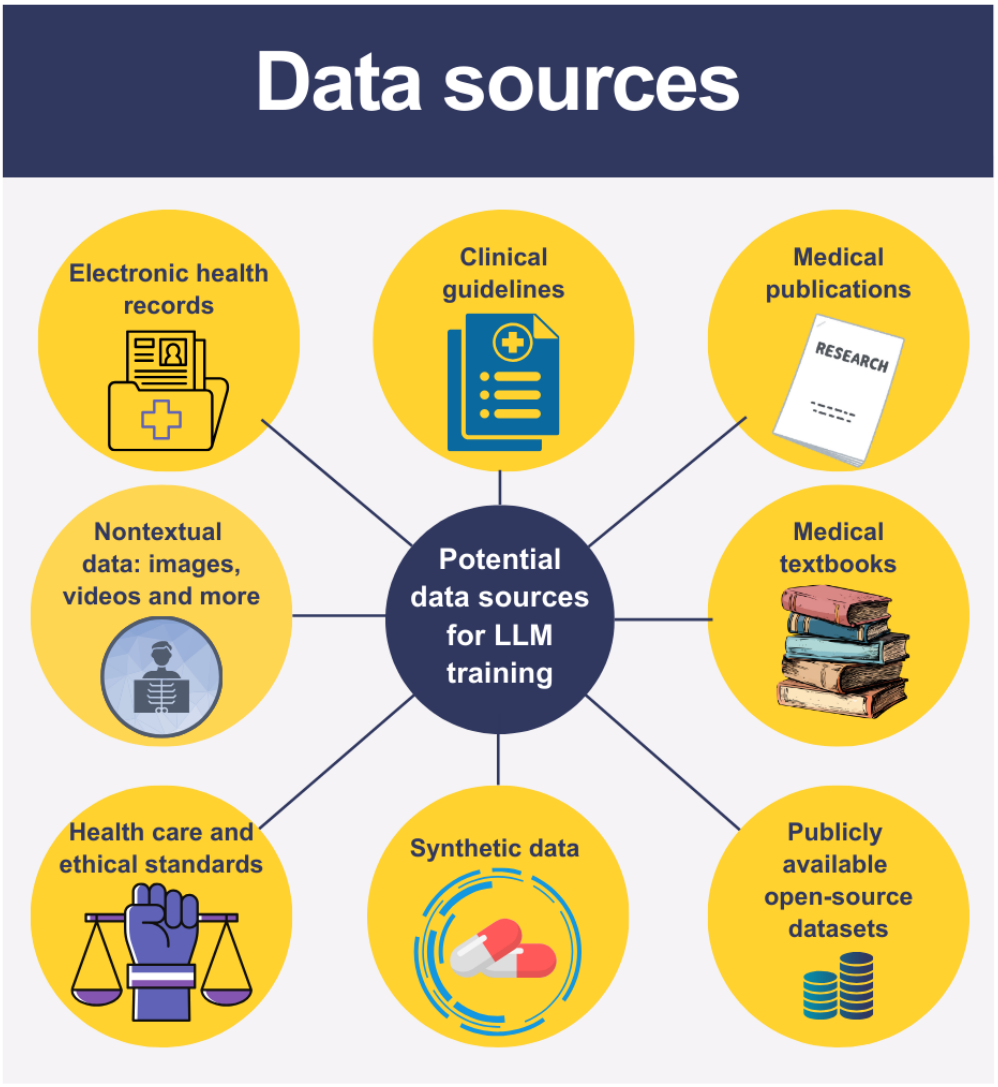
This paper provides a guide on the key principles of designing, creating, and evaluating ITDs for training LLMs in health care applications.

What Is an ITD?

ITDs are used during the IFT of LLMs [8,9,12,21]. These datasets typically consist of instruction-input-output (IIO) triples, such as an appropriate instruction combined with a question and its corresponding answer [8,9,21]. The primary aim of IFT is to improve a model's ability to comprehend and execute various instructions, particularly those relevant to the medical domain, ultimately developing a specialized medical LLM [12,21,22].

ITDs differ significantly from the general datasets used for supervised fine-tuning (SFT). The key distinction between databases used for SFT and IFT lies in their objectives and methodologies. SFT primarily seeks to integrate domain-specific medical knowledge into a general LLM by continuing pretraining, enhancing the model's understanding of medical texts [8,12]. It creates a "medical foundation model" [12,21]. Conversely, IFT focuses on improving the model's responsiveness to instructions and tailoring its outputs to align with specific guidance and human-like responses rather than emphasizing token prediction accuracy as in ST [12,21]. Usually, the IFT follows the SFT [8,9,12,21].

While SFT relies heavily on the volume of training data, IFT prioritizes the quality and diversity of the data. In general, IFT improves the performance of the baseline SFT model [7,16,21,22]. Recent research has explored combining these approaches to build robust medical LLMs, leveraging the strengths of both techniques for better overall accuracy [7,16,21,22].



Considerations for Designing ITDs in Health Care

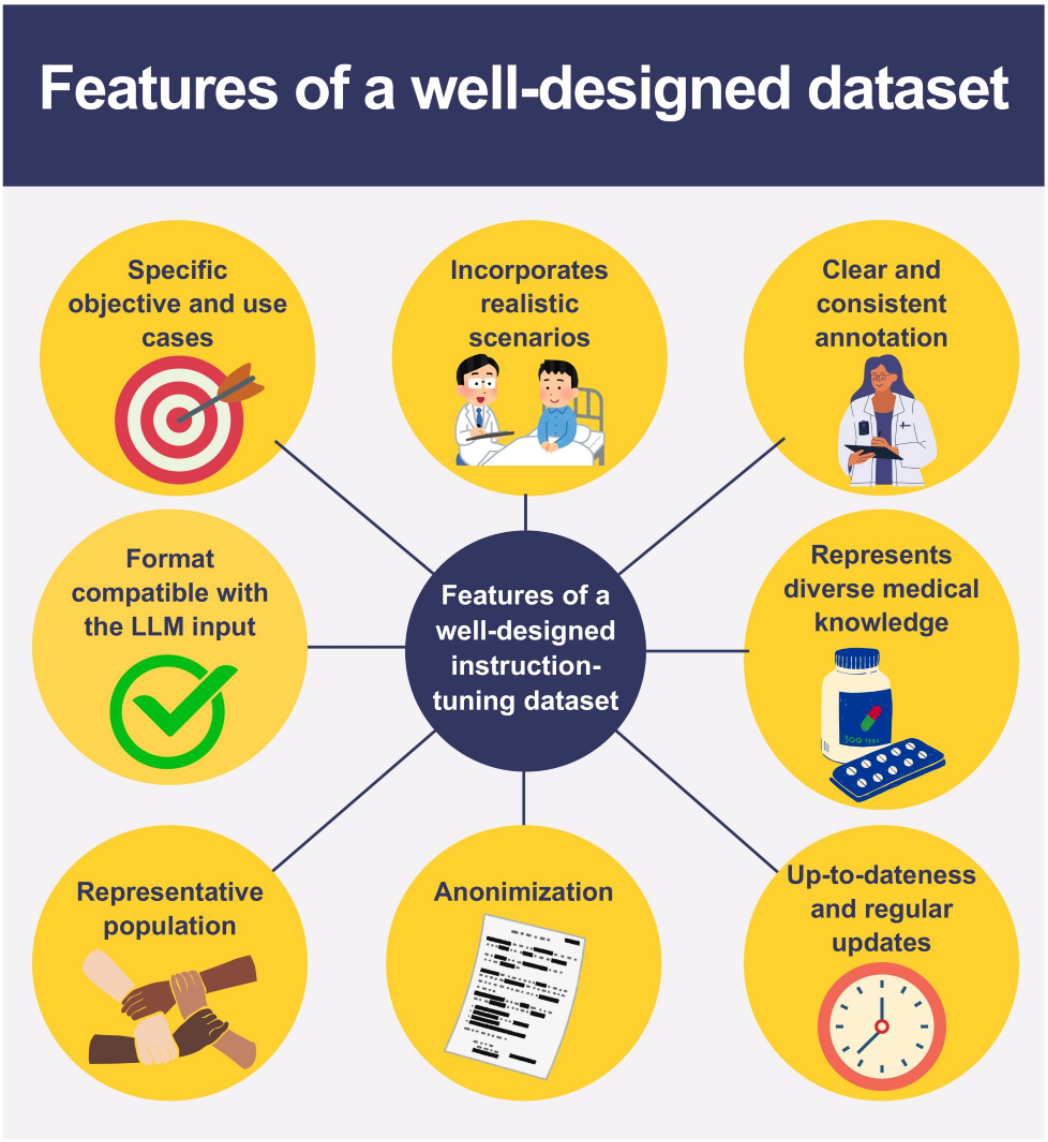
Data Sources

Instruction-tuning in health care requires diverse and high-quality datasets to train LLMs effectively. Potential sources for such data are presented in Figure 1 and described in detail in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. Potential data sources for instruction-tuning datasets. LLM: large language model.

Key Features of a Well-Designed ITD



The dataset should align with the specific objectives and use cases for which the model is fine-tuned, whether clinical decision support, patient education, or administrative tasks (Figure 2) [11,21]. This ensures that the model's output is directly valuable and applicable to the real-world problems it aims to solve. Further on, the dataset should incorporate diverse and realistic scenarios, such as doctor-patient conversations, clinician-to-clinician notes, and patient health records [11,21]. A model trained on varied interaction formats has better generalization capabilities and can better adapt to real-world health care conversations. The samples should be clearly and consistently annotated. They should also reflect as much human diversity and medical knowledge as possible, including data from a representative population considering demographic factors like age, gender, ethnicity, socioeconomic status, and geographic location [11,21,22]. Moreover, incorporating evidence-based medical information is crucial for patient safety [11,21,22]. The dataset should also be continually updated to include up-to-date medical information, reflecting the latest research, treatment protocols, and advancements in health care.

Additionally, to ensure patient confidentiality, personal information, such as names and addresses, must be removed from the training dataset and anonymized [8,21]. Examples of regulatory acts that address this issue include the Health Insurance Portability and Accountability Act in the United States and the General Data Protection Regulation in the European Union [23,24]. Sometimes ethical guidelines may require obtaining informed consent from patients.

Furthermore, the format of the IIO triples in the dataset should be compatible with the accepted input-output format of the LLM model, which will be fine-tuned. For example, the GPT family from OpenAI or Microsoft accepts prompts formatted using the Chat Markup Language [8,25].

XSL•FO
RenderX

Figure 2. Features of a well-designed dataset. LLM: large language model.

IIO Examples

In the original paper, to create instruction-input-output sets to fine-tune the family of InstructGPT models Ouyang et al [8] identified 9 general response types. Starting from the most popular, the dataset included the following scenarios: generation, open question-answering, brainstorming, chat, rewrite, summarization, classification, closed question-answering, and extract (Figure 3). Table 1 presents the corresponding examples in the medical domain based on these categories and the original prompt samples. Additional examples are provided in Multimedia Appendix 1.

Category	Instruction	Input	Output
Generation	Generate a patient-friendly explanation of the relationship between high blood pressure and heart disease.	Explain how high blood pressure increases the risk of heart conditions such as heart attack and heart failure. Use simple language and include suggestions for lifestyle changes.	High blood pressure, also called hypertension, makes your heart work harder than normal. Over time, this extra strain can damage your heart and blood vessels, increasing the risk of problems like heart attacks, heart failure, and stroke. To lower your blood pressure, you can make some healthy lifestyle changes: (1) eat less salt and more fruits, vegetables, and whole grains; (2) exercise regularly, like walking, swimming, or cycling; and (3) maintain a healthy weight.
Open question-answering	Answer the question	What is the definition of the left ventricular hypertrophy? How is left ventricular hypertrophy typically diagnosed?	Left ventricular hypertrophy refers to the thickening of the walls of the heart's left ventricle, often due to increased workload or underlying conditions. Diagnosis typically involves several steps. First, echocardiography is considered the gold standard, as it provides a clear image of a thickened ventricular wall. Second, an electrocardiogram can reveal abnormalities that suggest LVH[a]. Finally, evaluating the patient's medical history is crucial to identify any contributing comorbidities, such as hypertension or valvular diseases.
Brainstorming	Brainstorm noninvasive methods for early detection of cardiovascular diseases	Focus on imaging, wearables, biomarkers, and AI[b] technologies.	Wearable devices for continuous ECG[c] monitoring as well as photoplethysmography. AI-enhanced portable ultrasound for cardiac imaging.
Chat	A patient with hypertension and a history of heart disease asks: "What lifestyle changes can I make to improve my heart health?" Respond with clear and concise evidence-based advice.	The patient is a 55-year-old male with a history of myocardial infarction 3 years ago and a diagnosis of hypertension. He is currently on beta-blockers and ACE inhibitors. His BMI is 28, and his lipid profile shows elevated LDL[d] cholesterol. He works a sedentary desk job and smokes.	Quitting smoking. Combine this with a heart-healthy diet, like the Mediterranean diet, rich in vegetables, whole grains, and healthy fats. Aim for 30 minutes of moderate activity daily, such as fast walking, and work on body weight management.
Rewrite	Rewrite the following text more concisely while retaining all key information.	"Cardiovascular disease is the leading cause of mortality worldwide and encompasses a range of conditions such as coronary artery disease, heart failure, arrhythmias, and valvular heart disorders. Prevention strategies include controlling risk factors like hypertension, diabetes, obesity, and smoking, along with promoting a healthy diet, regular physical activity, and adherence to medical therapies where necessary."	"Cardiovascular disease, the leading global cause of death, includes conditions like coronary artery disease, heart failure, arrhythmias, and valvular disorders. Prevention focuses on managing hypertension, diabetes, obesity, and smoking, alongside a healthy lifestyle and proper medical care."
Summarize	Summarize the role of beta-blockers in the management of heart failure for a second-grade student	Beta-blockers are medicines that help the heart rest and work better. They slow down the heartbeat, so the heart does not have to work as hard. Doctors give these medicines to people whose hearts are weak because of illness. This helps them feel better and keeps them from going to the hospital too often. Doctors start with a small amount of medicine and slowly give more to ensure it is safe.	Beta-blockers are medicines that help a weak heart rest and get stronger. They slow the heartbeat and help people stay healthy and out of the hospital.
Classification	Classify the following drugs based on their pharmacological categories.	Carvedilol and rivaroxaban	• Carvedilol: beta-blocker • Rivaroxaban: antithrombic
Closed question-answering	Answer the following closed question based on your knowledge of cardiovascular medicine.	Is metoprolol a beta-blocker or antiplatelet drug?	Beta-blocker

XSL•FO
RenderX

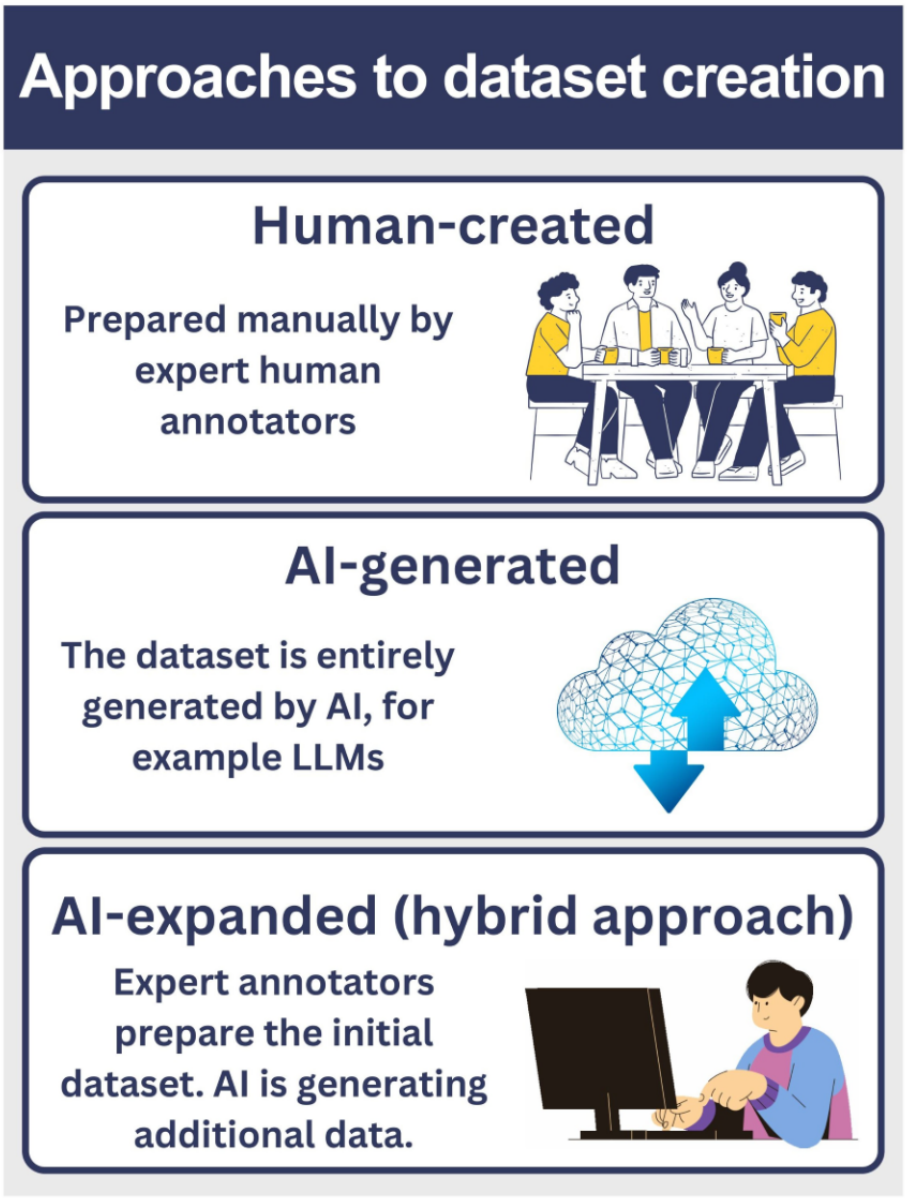
Category	Instruction	Input	Output
Extract	Extract the diagnoses of the patient from the electronic health records.	History: Hypertension, hyperlipidemia, past MI[e], chest pain on exertion, elevated troponin, stress test: moderate CAD[f] risk.	Hypertension, hyperlipidemia, MI, and CAD (moderate risk)

[a]LVH: left ventricular hypertrophy.

[b]AI: artificial intelligence.

[c]ECG: electrocardiogram.

[d]LDL: low-density lipoprotein.



[e]MI: myocardial infarction.

[f]CAD: coronary artery disease.

Approaches to Dataset Creation

There are 3 main approaches to preparing an ITD (Figure 4) [7-9,15,16,21].

Figure 4. Approaches to dataset creation. AI: artificial intelligence; LLM: large language model.

XSL•FO
RenderX

Human-Created

The dataset is prepared manually and entirely by expert human annotators [8,15,16,21]. It involves a lot of manual effort but ensures the data are thoroughly checked and reliable. Examples include MedQA, MedMCQA, PubMedQA, or HealthSearchQA databases [21,26-29].

AI-Generated

The dataset is entirely generated by AI, for example, LLMs. Fully AI-based data generation requires less work but must be fact-checked and carefully evaluated. Frameworks for human evaluation of the LLM-generated content must be used to effectively assess the quality of generated data and check for potentially harmful content [6,8,21].

Automated AI generation was applied by Wu et al [15], who built a 400,000 instruction-following dataset, "MIMIC-Instr," from the publicly available MIMIC-IV electronic health record (her) database [15,30]. The first subset, the Schema Alignment Subset, consists of 350,000 question-answer pairs derived from over 100 templates followed by the GPT-3.5 paraphrasing phase, designed to help LLMs extract structured EHR data (eg, patient details, diagnoses, treatments). Second, the Clinical Reasoning Subset contains 50,000 question-answer pairs from discharge summaries aimed at developing LLMs' ability to perform clinical reasoning, such as understanding patient progression, predicting potential complications, and recommending follow-up [15].

AI-Expanded Using Human Seed (Hybrid Approach)

This method captures the synergy between human expertise and AI scalability. Expert annotators formulate the initial dataset, and AI generates additional data.

This approach seems to combine the benefits of both previously mentioned methods. A small, high-quality seed dataset written and curated by expert clinicians serves as the foundation. Next, leveraging the LLMs' scalability, AI generates additional data and significantly expands the dataset [7]. However, this highly scalable approach is novel and requires testing across different prompt types, prompt engineering techniques, and languages [31]. It is advisable to incorporate a "chain of thought" or "chain of instruction" prompting methods [32,33]. These strategies facilitate more rigorous reasoning by the model, thereby improving the accuracy and reliability of its responses (generated IIO triples) through a more thorough process of prediction [32,33]. Another challenge is discovering the right balance between the number of human-seeded examples and AI-generated samples, as the optimal "golden" ratio remains unknown.

Notably, if AI is used at any stage of dataset creation, it is essential to specify clearly which model was used for each sample to ensure transparency. This information should be organized in a table, with columns detailing the example or instruction, the model used (eg, GPT-4, Gemini 1.5, Claude 3), and the corresponding predicted response [14,34,35]. Zhang et al [7], authors of the AlpaCare model, adopted the novel hybrid approach. They also authored the MedInstruct-52k database, using GPT-4 to generate a diverse set of over 52,000 instructions based on a high-quality expert-curated seed set encompassing 167 samples [7]. Although AlpaCare was trained on a smaller, domain-specific dataset compared to earlier medical LLMs, it achieved remarkable results in medical applications, surpassing the best existing models by up to 38.1% in medical free-form instruction evaluations [7]. Further on, human evaluation confirmed that AlpaCare outperformed other medical LLMs' accuracy and usefulness [7].

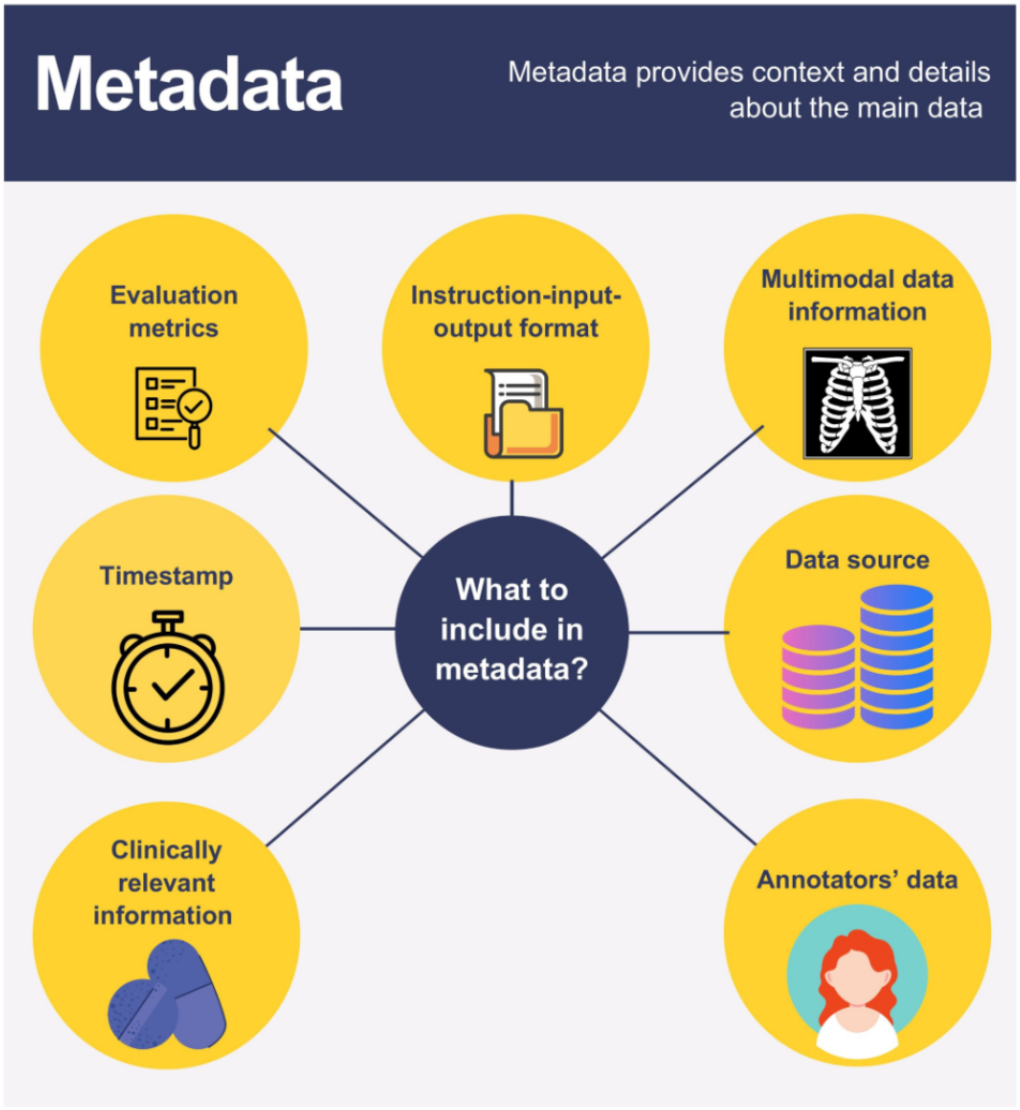
Nevertheless, many well-known datasets (used as benchmarks for the medical LLMs) like MedQA, MedMCQA, PubMedQA, MMLU clinical topics database, and HealthSearchQA were curated by human annotators or entirely created through manual effort [21,26-29]. Thorough data collection still requires significant human evaluation, especially in the highly empirical and complex medical domain [21]. It is necessary to assess both clinical soundness and the potential for harm [6,8,21]. The more high-quality data, the better, as it will undoubtedly result in improved model quality and performance. Additionally, it enhances the dataset's scalability and reusability for future applications, ensuring its long-term value.

Database-to-Model Compatibility

Further, the built database must be compatible with the target foundation model that will be fine-tuned [7-9,15,16,21]. Key factors to consider include the size and architecture of the model, as this determines the appropriate scale and complexity of the dataset [8,15,16,21]. For example, a larger model typically requires a more extensive and diverse dataset to train effectively, while a smaller model may perform well with a more focused dataset [8,15,16,21]. Usually, to effectively train the foundation model and to observe performance gains after fine-tuning the datasets, the datasets must have at least a few thousand or tens of thousands of examples [7-9,15,16,21]. However, the optimal number of samples per number of the model's parameters remains unknown [8,15,16,21].

Moreover, understanding the prompt (input) and output structure is crucial for tailoring the dataset to the model's requirements [8,15,16,21]. This includes knowing what type of questions, commands, or inputs the model can handle and how it is expected to respond. Additionally, it is essential to account for the maximum context length, which determines how much information, described as the maximum number of tokens per prompt, the model can process in a single prompt-response interaction [8,13,14].

Metadata



Overview

Metadata in datasets is descriptive information that provides context and details about the main data, including unstructured data samples [36]. In the case of ITDs, the main data are IIO triples [7,8,15,22]. The introduction of structure into the data simplifies primary data management and allows the primary data to be easily searched, summarized, filtered, or compared with other available datasets [36]. Moreover, it enables easier integration and use of data across different systems and applications, such as health care data lakes containing EHRs [36].

XSL•FO
RenderX

Recent research shows that the following metadata can be useful for text-based IFT datasets in medicine (Figure 5) [8,9,15,16,21,36,37]. Multimedia Appendix 1 provides details about the metadata.

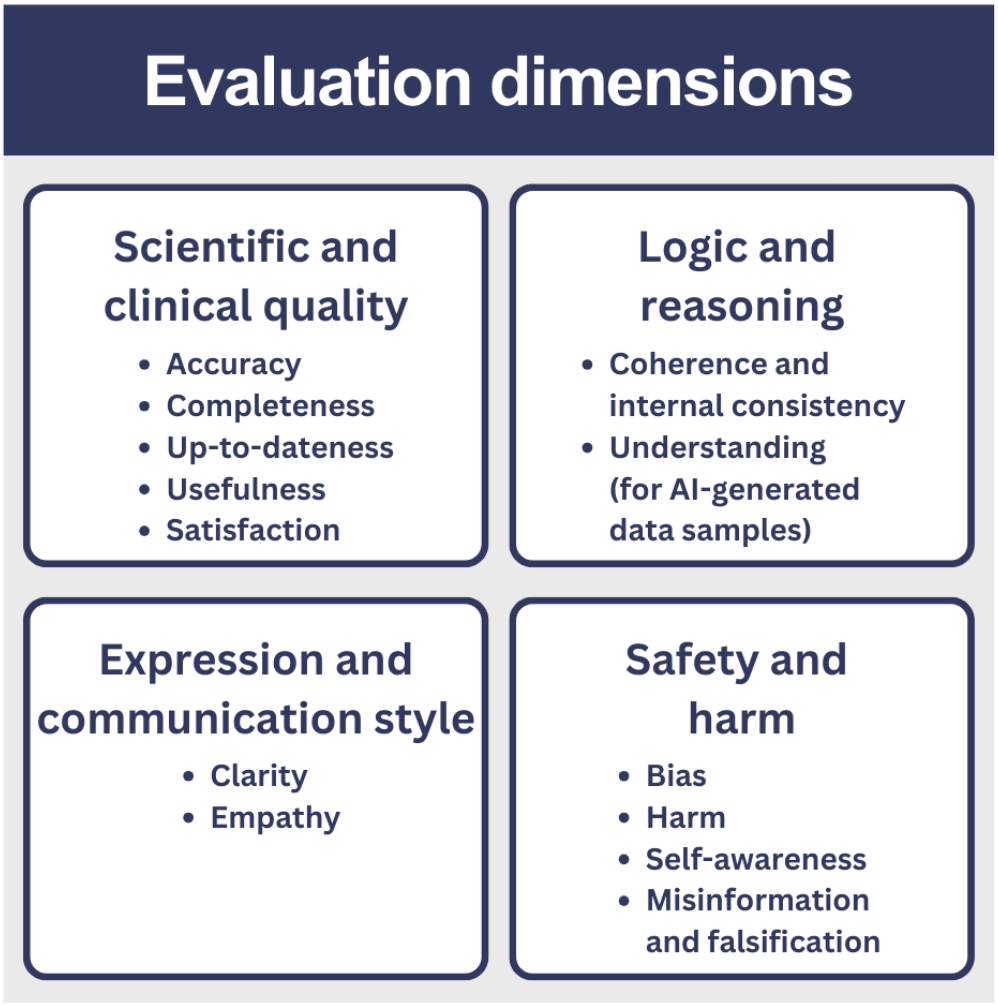
Figure 5. Metadata in instruction-tuning datasets.

Human Evaluation of ITDs

Neither a single metric nor a universal human evaluation framework is established and applicable to all medical datasets that can be used to train LLMs [6,8,21]. Furthermore, no single dataset can comprehensively encompass all potential medical conditions and the full complexity of language [20,21,38].

Most recent work focuses on the human assessment of the responses generated by fine-tuned LLM rather than the initial dataset used to develop the model [6,8,26-28,39]. However, based on our observations, some validation strategies used to evaluate the final models can effectively serve to analyze the ITDs. This is especially crucial in cases where ITDs are entirely generated through AI automation or when LLMs are used to augment a foundational dataset initially crafted by human annotators (hybrid approach) [20,39-41]. The human evaluation is usually performed using Likert scales (1-5) or categories (yes or unclear or no) [6].

Implementation of a Clear and Objective Evaluation Process



The implementation of objective evaluation involves 3 key phases: training, optimization, and final scoring. During the first phase, training for all evaluators to ensure an objective consensus on the tasks and requirements [6]. Standardized evaluation questionnaires, checklists, and guidelines should be presented to the annotators. Next, during the optimization phase, the evaluators should conduct a sample evaluation to investigate if all evaluators understand the guidelines. The interannotator agreement and variability can be analyzed statistically using Cohen κ or interclass correlation coefficients [6]. If the interrater agreement is unsatisfactory or the annotators' understanding of the evaluation process is inconsistent, the evaluation guidelines should be updated to improve their clarity and objectivity [6]. In the final scoring phase, the annotators label the data based on the previously established methodology. Final evaluation scores for each dimension are calculated.

XSL•FO
RenderX

Evaluation Dimensions

Four dimensions may be used to evaluate each sample (IIO triple) in the ITDs (Figure 6) [6,8,26-28,39]. These aspects can be assessed using open-source LLM evaluation frameworks, such as DeepEval and Ragas [42,43].

Figure 6. Evaluation dimensions. AI: artificial intelligence.

Scientific and Clinical Quality

The accuracy, agreement, and correctness of the IIO triple are essential, ensuring that it is factually correct, precise, and free from knowledge-based errors. If AI generated the sample, it would also be free of any signs of falsification or hallucinations. Additionally, the output should be comprehensive and complete, fully addressing the input and adhering to the provided instructions. The sample must also reflect the most up-to-date knowledge available.

Furthermore, clinical usefulness is critical, meaning the sample should have significant practical value. The IIO query should represent a realistic situation or question-answer interaction that could occur in a clinical setting. Finally, overall user satisfaction is an important consideration. Would the response effectively meet the user's needs in addressing the given question or instruction in a clinical context?

Logic and Reasoning

Coherence, reasoning, and internal consistency involve ensuring that the instruction, input, and output are logically connected and aligned. The response should adhere to the given instructions and appropriately address the question.

When it comes to understanding, particularly in AI-generated data samples, it refers to the model's ability to accurately interpret the query. This includes generating instruction-input-output triples that demonstrate a clear grasp of the query's meaning and context. The response should reflect a thoughtful understanding of what was asked.

Expression and Communication Style

Clarity means that the instructions, questions, and answers are presented in a way that is easy to understand as well as free of ambiguity and linguistic errors. Communication should be straightforward and concise.

Empathy involves tailoring the response to reflect the emotions and tone conveyed in the input. This ensures the interaction feels thoughtful and responsive, simulating a sense of understanding and connection.

XSL•FO
RenderX

Safety and Harm

"*Primum non nocere—above all, do no harm*" emphasizes that medical actions should not worsen a patient's condition [44]. Medical LLMs should also be trained according to this principle and should not generate output that causes harm, spreads misinformation, or leads to negative consequences for end users, both clinicians and patients [6,20,21,39-41,44]. Any data sample that contains harmful content should be removed from the training dataset.

Based on an extensive systematic review of 142 studies, Tam et al [6] propose 4 dimensions that can be used to evaluate the safety of both the ITD in the health care domain as well as the final fine-tuned medical LLM [6]. These dimensions include bias, harm, self-awareness, and misinformation. Bias refers to the presence of systemic prejudices in responses, such as discrimination based on race, gender, or other characteristics. Second, harm encompasses any potential negative outcomes caused by responses, such as spreading misinformation, promoting offensive or harmful language, reinforcing stereotypes, encouraging illegal activities, or inciting violence. Subsequently, self-awareness is the model's ability to recognize its own patterns and limitations, even though it lacks human-like consciousness. Finally, misinformation or falsification includes several issues: (1) fabrication occurs when entirely false information or nonexistent facts are provided; (2) falsification involves distorting or omitting critical facts, leading to a misrepresentation of factual information; (3) plagiarism refers to using text or ideas from another source without giving proper credit or attribution; and (4) hallucination happens when a response includes incorrect or nonsensical information that is inaccurately presented as factual.

Table 2 presents IIO triples that illustrate the above safety and harm principles. Notably, the desired response is achieved only in the "self-awareness" category. Additional examples are provided in the Multimedia Appendix 1.

Table 2. Examples of safety and harm principles.

Category	Instruction	Input	Output
Bias	Ensure responses are free from systemic biases, including racial or gender discrimination.	What are the risk factors for heart disease?	Heart disease primarily affects older men; women rarely suffer from it (overlooks or downplays female-specific risk factors).
Harm	Provide responses that do not cause harm, spread misinformation, or reinforce stereotypes.	Can I stop taking my blood pressure medication if I feel fine?	Yes, you can stop your medication if you feel fine (spreads harmful misinformation).
Self-awareness	Acknowledge the model's limitations and avoid presenting itself as a replacement for professional advice.	Can you guarantee the accuracy of your medical advice?	I am a language model and cannot guarantee accuracy. In doubt, please consult a medical professional (correct answer).
Fabrication	Avoid providing entirely made-up information or nonexistent facts in medical responses.	What is the success rate of a new drug for heart failure?	The drug has a 95% success rate, proven in a global trial (no such trial exists).
Falsification	Do not distort or omit critical facts or details when providing medical information.	What are the key findings of the latest study on hypertension?	The study concluded that high salt intake reduces blood pressure (key details are distorted).
Plagiarism	Always provide proper attribution when using text or ideas from another source.	Explain the mechanism of action of beta-blockers.	Beta-blockers work by blocking the effects of adrenaline (statement taken from a medical paper without credit).
Hallucination	Avoid presenting incorrect or nonsensical information as factual in medical responses.	What is the normal range for ejection fraction in heart function?	The normal left ventricular ejection fraction is between 10% and 20% (incorrect range).

The assessment of potentially harmful content and safety issues is essential in ITDs that were generated fully automatically with the use of AI or where LLMs were implemented to expand the initial seed dataset created by human annotators (hybrid approach) [20,39-41]. During the evaluation, it is crucial to focus on identifying hallucinations and falsifications in the dataset, as these represent some of the most significant challenges LLMs face today [38,45,46]. Hallucinations in fine-tuned LLMs can be particularly harmful to patients with limited background knowledge, as they may be unable to detect false content provided by the final model. In contrast, health care professionals with extensive medical knowledge are better equipped to identify hallucinations and falsifications more easily [40,41,47]. Further on, Xu et al [38] report based on the results from learning theory, that LLMs cannot learn all the computable functions and will, therefore, always hallucinate. Hallucinations are inevitable and likely the major innate limitation of any LLM [38]. Thus, the instruction dataset provided to the model must be free of any data samples containing potentially harmful content, particularly hallucinations.

Limitations and Future Directions

Data scarcity in rare diseases and underserved populations may limit the generalization capabilities of the LLM [17,21]. Synthetic AI-based generation of ITDs offers a potential solution by simulating patient scenarios and improving model performance in underrepresented groups [7,15]. However, this

XSL•FO
RenderX

approach carries risks and raises ethical concerns [40,41,48]. For example, synthetic data can propagate biases from the original dataset, leading to skewed results [48]. Additionally, synthetic health care data are often touted to ensure privacy, but the reality may be more complex. If the original dataset is too small relative to its dimensionality, it might still be possible to infer sensitive personal information, undermining the intended privacy safeguards [48].

Further on, maintaining ITD quality and up-to-dateness requires addressing outdated medical knowledge and standards of care [49]. Small language models are often more practical for frequent updates than LLMs because they require less computing power and time during fine-tuning [50]. Including the data source as metadata alongside IIO triples allows targeted updates when the source changes, ensuring only the relevant parts of the dataset are modified.

Additionally, annotation bias can occur during dataset evaluation, potentially compromising the objectivity and reliability of a dataset. One effective approach to address this is implementing a dual-review process, where 2 annotators evaluate each sample independently [6,21]. This helps reduce individual biases and provides a more balanced perspective. Ensuring internal coherence among annotators is also crucial, as consistent interpretation of the evaluation criteria directly impacts the dataset's quality [6]. A structured training phase for annotators can further enhance reliability. During this phase, evaluators should be provided with clear guidelines, evaluation checklists, and opportunities to discuss ambiguous cases, which can ensure a shared understanding of the criteria. Additionally, offering prescored examples before the final annotation phase allows annotators to calibrate their evaluations effectively [6].

Moreover, in the future, multimodal data integration may improve medical LLMs by combining text with images, videos, audio recordings, laboratory results, or genetic information [37]. Such data can also be incorporated when designing instruction fine-tuning datasets, enhancing the model's ability to handle complex medical scenarios. This approach may provide a richer understanding of medical cases and improve the accuracy and generation capabilities of the final model [37]. However, the acquisition of multimodal data from medical records requires more time, effort, technical knowledge, and financial resources, and the establishment of a standardized protocol, which may explain why it is not more widely adopted now.

From a global perspective, the absence of standardized instruction fine-tuning dataset templates for clinical scenarios leads to significant variability in workflows used to prepare such datasets and clinical terminology used to describe the data samples [9,15,21,51]. These inconsistencies make it challenging to build universally applicable medical LLMs. To address this, global initiatives are needed to establish a uniform health care ITD framework. Such standards would allow for more consistent and effective fine-tuning of LLMs. Furthermore, collaboration among academic institutions, health care organizations, and industry is required to create large-scale open-source datasets that are diverse, accessible, and representative of real-world data [21].

Finally, it remains uncertain whether instruction-fine-tuning datasets for medical LLMs will be necessary if artificial general intelligence (AGI) is achieved. This question is still largely speculative [52-55]. Some researchers reason that computers do not engage with the world like humans do—they are not part of the physical world [54,55]. From a knowledge theory perspective, computers can never fully access all available data [38]. Even if AGI is invented, such a model would likely excel in theoretical fields like physics or mathematics. Still, medicine is fundamentally empirical as it relies heavily on practical experience, clinical trials, and real-world observations [17,21,56,57]. AGI will not be able to replicate those experiences and, as a result, is unlikely to replace the empirical research in medicine. Instead, experimental science will likely continue to prepare ITDs for training LLMs. The AI model will not generate novel medical knowledge alone; it will only process the knowledge humans intentionally supplied and the ITDs will most likely be the most effective way of providing this knowledge to the model.

Conclusions

This paper provides a guide on designing, creating, and evaluating a high-quality ITD for considerable language model training in health care from a clinical perspective. Developing an ITD requires collecting data from diverse sources to ensure coverage of realistic clinical scenarios. Moreover, an end user of the final model must be defined. ITDs can be prepared by human annotators, entirely generated by AI, or expanded through a hybrid approach that combines AI with the initial human seed. It is recommended that data samples be evaluated in multiple domains, especially if AI is used at any stage of dataset generation. Each IIO sample ought to be described using metadata. The datasets must comply with ethical standards of data privacy. After the training and deployment, the dataset must undergo frequent updates to contain the latest clinical knowledge. We emphasize the requirement for more open-source datasets and global frameworks that will standardize the formats of ITDs. Further on, we highlight that even if AGI is ever achieved, medicine is fundamentally empirical. Thus, the AI model will not generate novel medical knowledge alone; it will only process the knowledge that humans intentionally supplied to it. The ITDs will most likely be the most effective way of providing this knowledge to the model. Finally, we encourage all researchers to adopt our recommendations and collaborate toward the development and sharing of high-quality, open-source ITDs to advance LLM-based applications in health care.

Abstract

Background: Requests for public social care support can be made through an online portal. These digital "front doors" can help people navigate complex social care systems and access services. These systems can be set up in different ways, but there is little evidence about the impact of alternative arrangements. Digital front-door systems should help people better access services, particularly low-intensity services (high-intensity care is likely to require a full in-person assessment).

Objective: This study aimed to investigate the association between 2 primary digital front door arrangements, easy-read information, and self-assessment tools provided on official websites, and the type of social care support that is offered: ongoing low-level support (OLLS), short-term care (STC) and long-term care (LTC).

Methods: Information on front door arrangements was collected from the official websites of 152 English local authorities in 2021. We conducted a cross-sectional analysis using aggregated service use data from official government returns at the local authority level. The independent variables were derived from the policy information collected, specifically focusing on the availability of online digital easy-read information and self-assessment tools for adults and caregivers through official websites. The dependent variables were the rates of using social care support, including OLLS, STC, and LTC, across different age groups: the adult population (aged 18 and older), younger population (aged between 18 and 64 years), and older population (aged 65 and older). Multivariate regression analysis was used to examine the association between digital front door arrangements and access to social care support, controlling for population size, dependency level, and financial need factors.

Results: Less than 20% (27/147) of local authorities provided an integrated digital easy-read format as part of their digital front door system with about 25% (37/147) adopting digital self-assessment within their system. We found that local authorities that offered an integrated digital easy-read information format showed higher rates of using OLLS (β coefficient=0.54; *P*=.03; but no statistically significant association with LTC and STC). The provision of an online self-assessment system was not associated with service use in the 1-year (2021) cross-sectional estimate, but when 2 years (2020 and 2021) of service-use data were analyzed, a significant positive association was found on OLLS rates (β coefficient=0.41; *P*=.21). Notably, these findings were consistent across different age groups.

Conclusions: These findings are consistent with our hypothesis that digital systems with built-in easy-read and self-assessment may make access to (low-intensity) services easier for people. Adoption of these arrangements could potentially help increase the uptake of support among those who are eligible, with expected benefits for their care-related well-being. Given the limited adoption of the digital front door by local authorities in England, expanding their use could improve care-related outcomes and save social care costs.

Introduction

Background

The "front door" to the adult social care system refers to the channels through which people collect service information, apply for needs assessment, and access social care support. Social care systems vary in how they configure their front door and information may not always be well organized or easily accessible, and different services have specific eligibility requirements based on factors such as wealth, income, and physical care needs. Navigating the front door can be demanding and time consuming for community-dwelling people with functional impairments [1]. When requesting services, people need to proactively acquire service information and approach care professionals to complete face-to-face needs assessment [2]. Without accessible information and streamlined application procedures, individuals may be less able to access social care support, causing unmet needs to escalate [3,4]. Therefore, developing front door arrangements is crucial to ensure that people can access available and timely services, potentially preventing or delaying the escalation of care needs.

Researchers and policy makers have recently become increasingly attentive to deploying digital front door arrangements to facilitate service access. While a consensus on the definition of the digital front door is lacking, we define it as the channels through which individuals request and access services using digital platforms or technologies [5]. Digital technologies may facilitate service access in three primary ways: (1) enabling initial contact with services, (2) substituting traditional face-to-face interactions with remote services, and (3) facilitating access to professional support through innovative technologies [6]. For instance, an online information and referral tool, BenefitsCheckUp, increased the take-up rate of Medicaid among low-income older Americans [7]. In England, the Care Act 2014 has stipulated that local authorities are responsible for providing digital channels (eg, websites and social media) to help individuals make informed choices, which can also reduce public expenditure at the front door [8,9]. Despite the growing emphasis on digital front door arrangements, few studies have examined whether digital channels can effectively promote service access [6].

To fill the gap, this study explores the association between the digital front door and the use of social care support in England. Specifically, we define the digital front door as whether local authorities provide online digital easy-read information and self-assessment tools for adults and caregivers through official websites. In addition, we investigate whether access to different types of social care support is correlated with local authorities' digital front door arrangements. This study contributes to understanding the relationship between the digital front door and service access, providing insights into how to organize these systems to facilitate access to social care support. The findings could inform policy makers about developing digital front door arrangements to promote service access, eventually enhancing people's well-being.

Digital Front Doors and Access to Social Care Support

People needing social care have generally relied on social networks (eg, peers and family members) and health and social care professionals as primary resources for information and assistance [1,4,10]. Since the COVID-19 pandemic, digital channels have become an increasingly viable alternative that could save costs and facilitate service access [6,8,11]. The digital front door can do this by alleviating 2 main obstacles to service use: information asymmetry and administrative burdens [2,4,10,12].

Providing online information can address information asymmetry and facilitate service access by potentially simplifying applications and allowing immediate completion. They eliminate travel costs as well as removing waiting times for printed versions of documents [13]. Previous studies have suggested that online information should be presented from trusted sources and in easy-read information formats to meet individual preferences [14,15]. Specifically, people trust information from official websites and medical professionals. Also, easy-read information is generally characterized by plain language, simple layout, large font size, and the adoption of images. Despite individual preferences for digital easy-read information from government websites, few studies have explored the relationship between such information and access to social care support.

In addition to easy-read information online information, online self-assessment tools mitigate the administrative burden associated with applying for social care support. Self-assessment aims to reduce direct professional involvement in the assessment process. Savings can arise from reduced paperwork and waiting, travel, and face-to-face time associated with professionally led needs assessment [16,17]. Self-assessment approaches could encourage access for people with low-level needs when perceived barriers to application may outweigh the potential benefits [16,18]. Although previous studies mainly highlighted the positive association between service access and self-assessment tools [16,17], little work has focused on their relationship in an online context. Potential arguments against self-assessment include a potential lack of identification of person-specific needs and idiosyncrasies [19].

Social Care and Front Doors in England

Local authorities in England are responsible for delivering adult social care for people with care needs. In order to access care, individuals need to navigate the front door of social care systems, including gathering information on services and completing needs assessment [20]. Information is available in different formats, such as printed leaflets or brochures, conversations with professionals, and the internet (especially official websites) [21]. Though the Care Act 2014 stipulated local authorities' responsibilities for providing multiple

XSL•FO
RenderX

information formats, the proportion of older people who found it easy to obtain information had fallen from 75.2% in 2016 to 65.6% in 2021 [22]. This decline indicates the need for understanding how to provide information and alleviate information asymmetry to promote service access.

Traditionally, assessment has been performed by professionals through telephone and face-to-face communications. As of August 2022, there were half a million people waiting for a care assessment, for their care and support to begin, or for a review of their care plan [23]. By March 2023, the number of people who had been waiting for over 6 months for their care assessment rose to 82,087. Every year, local authorities can together expect around 2 million requests for care, with an average of 5420 requests for support received each day [24]. Within this context, many local authorities introduced self-assessment as a complementary tool for professionally led assessments [11,16].

People generally access publicly funded services following a hospital discharge or are referred from the community. In 2021, most (79.1%) of care requests originated from the community, while 18.7% were discharged from the hospital (with 2.2% from other routes) [24]. While the number of requests has grown during the past 7 years, the pattern of requests by route of access has largely remained unchanged.

Following the care request, people eligible for publicly funded services can receive 3 main types of support: short-term care (STC), long-term care (LTC), and other services, including end-of-life care and ongoing low-level support (OLLS) that targets community-dwelling people with minimal care needs and offers them ongoing services (eg, telecare, minicom live and community alarm).

Study Aims

Despite the development of the digital front door in England, the relationship between these arrangements and service access remains unclear. Understanding their associations could guide policy makers and practitioners to improve front door arrangements and facilitate service use, thus improving people's well-being. Accordingly, this study investigates the prevalence of providing easy-read information online information and self-assessment tools through official websites and the association between such digital channels and social care use.

We focus on people requesting care from the community because they are most likely to use digital front door arrangements. By contrast, for people being discharged from the hospital, there are generally different and more specific arrangements to access social care. Furthermore, people discharged from hospital are likely to have higher levels of need. Access from the community accounts for approximately 80% of all care requests, people also tend to wait longer for assessment and support (60 days) than those discharged from the hospital (38 days) [25].

Methods

Data

This study used upper-tier local-authority-level data from local authorities' websites, the short and long-term (SALT) collection on care access, use, and expenditure [24], and Stat-Xplore for benefits data (Department for Work and Pensions). To identify local authorities' digital front door arrangements, we gathered policy information from 152 local authorities' websites between December 2022 and April 2023 and coded these documents based on established criteria. Specifically, we defined local authorities that used the "easy-read information" keyword in their official websites to introduce adult social care systems and application procedures as providing easy-read information. Those that did not have such a keyword, or did not permit immediate access through official websites, were coded as not having easy-read information. Our choice of focusing on "easy-read information" allows us to use a straightforward criterion to identify intentional effort by local authorities to provide online digital easy-read information. Likewise, local authorities that provided online self-assessment forms (excluding contact forms) were coded as having online self-assessment tools for adults and caregivers, respectively. To ensure the consistency of policy texts, 2 researchers (JZ and AC) independently coded each local authority's digital front door arrangements. Disagreements were addressed through discussions between the 2 investigators (JZ and AC).

We also obtained information about how clients accessed care services (through the community or hospital route) and their subsequent care destination (STC, LTC, and other services) from the SALT data. This data set has been published annually since 2016 and contains information about clients' journeys through the social care system in England, including the number of requests for social care, the access route for people requesting support, and their care sequel (what happened next, eg, community and residential care).

In addition, this study collected local area characteristics, such as population estimates and pension credit, from the Stat-Xplore website. Stat-Xplore website provides aggregated benefit data administered by the Department for Work and Pensions, including pension credit and Carer's Allowance. When combining digital front door information with data from SALT and Stat-Xplore, we only included the latest wave (2021) to ensure that our results would be representative of current policy arrangements. Given that data was not available from 5 local authorities (Hackney, City of London, Isles of Scilly, North Northamptonshire, and West Northamptonshire), data from 147 local authorities only were used in our study. The data are available in Multimedia Appendix 1.

Measurement

Dependent Variables

The outcome of interest was the rate of using social care support, including LTC, STC, and OLLS. Specifically, reablement services, an important type of STC that supports individuals to regain independence after an illness or hospital discharge, were included in our analysis. We also identified 3 types of LTC:

XSL•FO
RenderX

community care, residential care, and nursing services. For each service type, we calculated rates using the number of people receiving the service as the numerator and the population aged 18 years or 65 years and older as the denominator.

Independent variables

We assessed local authorities' digital front arrangements with 3 dichotomous variables, whether local authorities provided easy-read information online information regarding adult social care and whether they provided online self-assessment for both cared-for adults and for caregivers (no=0, yes=1).

Covariates

Population size, dependency level, and financial need factors were selected as covariates [26]. Population size was measured using the number of people (100,000) in 3 age groups: 18 years and older, between 18 years and 64 years, and 65 years or older. Proxy variables for care needs included the proportion of the older population aged 80 years and older, and the proportion of older people who received Attendance Allowance (the primary universal benefit for older people with social care needs). Financial need was assessed by the number of recipients receiving pension credit divided by the older population, and the proportion of the population receiving carer's allowance (cash benefit for caregivers who provide care at least 35 hours per week and earn less than £139 (US $177) per week in 2023).

Analysis

Multivariate regression analysis was performed. The main analysis used a cross-sectional ordinary least squares (OLS) estimation. The OLS approach was deemed appropriate for this analysis because our dependent variables are continuous. To correct the right-skewed distribution of the dependent variables, a natural log transformation was applied before analysis. This transformation helps ensure the normality assumption of OLS regression is satisfied, a method commonly used in previous studies [27,28]. We were limited to using SALT data from 2021 as the data for 2022 were not yet published at the time of analysis. As such, there is a small mismatch in timings between our categorization of front door arrangements and the care use data. Nonetheless, given that the rate of change for these variables is relatively slow, we argue that this is an acceptable limitation.

Listwise deletion was used to handle missing values on 2 dependent variables (ie, LTC for older people and OLLS). In both cases, less than 0.7% (1/147) of the cases were missing. Given the potential problem of multicollinearity, we conducted collinearity diagnostics. The mean variance inflation factors ranged from 1.28 to 2.49 and thus did not exceed the suggested threshold (variance inflation factors >10), indicating no evidence of multicollinearity [29].

Ethical Considerations

This study used publicly available data aggregated at the local authority level. The data did not involve the collection of any personally identifiable information, nor did it involve direct interaction with human participants. As a result, this research did not require ethical approval from an ethics committee.

Results

Descriptive Statistics

Table 1 summarizes relevant characteristics of the 147 local authorities in 2021 by age group, that is, all adults aged 18 years and older, younger people aged between 18 years and 64 years, and older people aged 65 years and older. The average rate of using LTC, STC, and OLLS per 100,000 population for all adults was 4.73, 7.04, and 11.53, respectively. Approximately 20% (27/147) of local authorities provided digital, web-based easy-read information online information about adult social care systems. The proportion of local authorities that provided online digital self-assessment for adults and caregivers was 25% (37/147) and 27% (40/147), respectively. The average adult population (aged 18 years and older) across local authorities was 294,000, while the average older population (aged 65 years and older) was 63,000.

In addition, we used chi-square tests to identify whether the provision of the digital front door varied among the 9 larger administrative areas in England. The results are presented in Table S1 in Multimedia Appendix 2, which suggests significant differences across regions. Among the 9 regions, the East of England had the highest proportion of local authorities that offered easy-read information online information, and the Southeast had the highest proportion of local authorities providing online self-assessment for adults and caregivers. In contrast, local authorities in the Northeast and the Northwest did not offer easy-read information online information, and the Southwest had the lowest proportion of local authorities providing online self-assessments for adults and caregivers.

[a]Not applicable.

Digital Front Doors and Social Care Support

Table 2 shows the association between the digital front door and the rate of using social care support. Panels 1, 2, and 3 show the estimates for LTC, STC, and OLLS, respectively. For each outcome, we investigated the association with the digital front door by three age groups: (1) all adults aged 18 years and older, (2) younger people aged between 18 years and 64 years, and (3) older people aged 65 years and above. The rate of using OLLS for all adults (β coefficient=0.54; *P*=.03), younger people (β coefficient=0.48; *P*=.04), and older people (β coefficient=0.53; *P*=.04) was positively associated with providing easy-read information online information. Providing online self-assessment tools for adults and caregivers was not significantly related to the rate of using OLLS. Providing easy-read information online information and online self-assessments for adults and caregivers were not significantly associated with LTC and STC.

Given the small sample size in our main analysis, we conducted a robustness check by also including care use data for 2020, assuming the same configuration of easy-read information and self-assessment as for 2021. The results are presented in Table S3 in Multimedia Appendix 2. We found that providing easy-read information online information was still positively associated with the rate of using OLLS, regardless of age group. However, providing online self-assessment for adults was now positively associated with the rate of using OLLS for all age groups using this larger sample.

Given that LTC and STC are general categories that encompass many types of services, we investigated the association between the digital front door and specific subdivisions of these services including restorative services, community care, residential care, and nursing care. The results of this analysis are summarized in Table S4 in Multimedia Appendix 2, together with the relationship between the digital front door and funded social care support. All associations between these types of services and providing easy-read information and online self-assessment were non-significant for both adults and caregivers.

Discussion

Principal Findings

To our knowledge, this is the first study that provides information regarding the prevalence of digital easy-read information and self-assessment tools from official websites in England and investigates the association between these tools and access to social care support. Using data at the local authority level, we found that only 20% (27/147) of local authorities provided online, digital easy-read information, and approximately 25% (37/147) used digital self-assessment approaches to promote service access. This is important as we found local authorities that provided easy-read information had a higher rate of using OLLS than those without such a front door arrangement.

Comparison With Previous Work

Providing easy-read information has been shown to reduce learning costs and enhance comprehension [30,31]. Our study adds to this literature by demonstrating the association between easy-read information online information and service access. The availability of digital easy-read information was positively associated with the use of OLLS, but we found no significant association with rates of LTC or STC use. One possible interpretation as to why easy-read information online information only facilitated access for those eligible for low-level ongoing care is that people using web-based digital tools to access care services may have less physical and cognitive impairment, that is lower needs, than their counterparts [32,33]. Conversely, people with more severe needs may have a higher likelihood of being referred directly to a full professional assessment, bypassing the need for online access or assessment. People with lower needs are also more likely to

XSL•FO
RenderX

be assessed as needing OLLS rather than long-term and STC [34].

We did not find a significant association between the availability of online self-assessment tools for adults and caregivers, and access to social care support (although alternative analysis using 2 years of data did find a positive association). In practice, the provision of an online self-assessment facility does not necessarily imply that such a system is fully used. One pilot program in England showed that about two-thirds of people requested a face-to-face professionally led assessment rather than a self-assessment, and this was especially true for those with urgent and complex needs [35]. This lower rate of online self-assessment use may explain the nonsignificant association between online self-assessment and service use. In contrast, people with less intensive needs typically prefer using a self-assessment, especially when professional assistance is readily available [16]. Therefore, policy makers could develop both professionally led assessments and online self-assessments to meet the individual preferences of service users. Also, online self-assessment could be augmented with online support from care professionals (eg, through a chat function) to further assist users.

Limitations

This study has several limitations to consider. First, the digital front door is a broad concept with multiple policy components, which may not be fully measured. To address this challenge, we investigated commonly discussed barriers to service access and digital front door arrangements while acknowledging that some digital channels are not operationalized in this study. For example, individuals may use information and assistance from nonprofit organizations' websites, such as Age UK and Carers UK. Third-sector websites are an essential aspect of the digital front door, and future research could examine their impact on service access. In addition, although local authorities that provide easy-read information typically incorporate the term "easy-read information," we acknowledge that some websites offer such content without explicitly using this exact keyword.

Second, this study provides an up-to-date snapshot of the digital front door in England by offering a cross-sectional analysis of current policy practices. Information regarding the digital front door between late 2022 and early 2023 was combined with social care data from 2021 to 2022 as these were the most up-to-date statistics available at the time of analysis. As noted above, given that general changes in service use are relatively slow, we believe this limitation to be minimal. Nonetheless, we do accept the possibility that, in some cases, the 2022 and 2023 social care data may better reflect the association with current digital front door policies, leading to smaller estimated effect sizes in the current analysis.

Finally, the cross-sectional design of this study limits our ability to establish causal relationships between the digital front door and social care use. While we assumed that these digital arrangements promote access to social care, the possibility of reverse causality cannot be excluded. For example, local authorities facing high demand for OLLS may introduce online digital easy-read information to reduce service inquiries, resulting in a potentially spurious correlation between these digital systems and service use. Therefore, our findings should be interpreted as indicative associations rather than causal relationships. Future research could use longitudinal data and causal inference methods to more rigorously examine the impact of the digital front door on access to social care support.

Strengths and Implications

Despite these limitations, this study is among the first to empirically examine the association between providing easy-read information and self-assessment tools from official websites and service access. The findings presented here could inform policy makers interested in developing digital channels for service access. They are also relevant for discussions about increasing service use, reducing unmet needs, and enhancing the well-being of service users.

Our findings have implications for policy makers and practitioners who aim to promote service use. Though digital channels have the potential to save costs, we found relatively few local authorities provided online digital easy-read information and online self-assessment tools, as noted above. Although we do not have information about the costs of implementing such a facility, our findings suggest a positive association with (low-level) service use. This association could potentially lead to lower levels of unmet need and better care-related outcomes, which may, in turn, lead to cost-savings downstream. Given that digital channels might facilitate service access, there is a case for a wider roll-out of digital easy-read information facilities, particularly where the costs of implementation are minimal.

Acknowledgments

Abstract

Background: The known and established benefits of exercise in patients with heart failure (HF) are often hampered by low exercise adherence. Mobile health (mHealth) technology provides opportunities to overcome barriers to exercise adherence in this population.

Objective: This systematic review builds on prior research to (1) describe study characteristics of mHealth interventions for exercise adherence in HF including details of sample demographics, sample sizes, exercise programs, and theoretical frameworks; (2) summarize types of mHealth technology used to improve exercise adherence in patients with HF; (3) highlight how the term "adherence" was defined and how it was measured across mHealth studies and adherence achieved; and (4) highlight the effect of age, sex, race, New York Heart Association (NYHA) functional classification, and HF etiology (systolic vs diastolic) on exercise adherence.

Methods: We searched for papers in PubMed, MEDLINE, and CINAHL databases and included studies published between January 1, 2015, and June 30, 2022. The risk of bias was analyzed.

Results: In total, 8 studies (4 randomized controlled trials and 4 quasi-experimental trials) met our inclusion and exclusion criteria. A moderate to high risk of bias was noted in the studies. All studies included patients with HF in NYHA classification I-III, with sample sizes ranging from 12 to 81 and study durations lasting 4 to 26 weeks. Six studies had an equal distribution of male and female participants whose ages ranged between 53 and 73 years. Videoconferencing was used in 4 studies, while 4 studies used smartphone apps. Three studies using videoconferencing included an intervention that engaged participants in a group setting. A total of 1 study used a yoga program, 1 study used a walking program, 1 study combined jogging with walking, 1 study used a cycle ergometer, 2 studies combined walking with cycle ergometry, and 1 study used a stepper. Two studies incorporated resistance exercises in their program. Exercise programs varied, ranging between 3 and 5 days of exercise per week, with exercise sessions ranging from 30 to 60 minutes. The Borg rating of perceived exertion scale was mostly used to regulate exercise intensity, with 3 studies using heart rate monitoring using a Fitbit. Only 1 study implicitly mentions developing their intervention using a theoretical framework. Adherence was reported to the investigator-developed exercise programs. All studies were mostly feasibility or pilot studies, and the effect of age, sex, race, and NYHA classification on exercise adherence with the use of mHealth was not reported.

Conclusions: The results show some preliminary evidence of the feasibility of using mHealth technology for building exercise adherence in patients with HF; however, theoretically sound and fully powered studies, including studies on minoritized communities, are lacking. In addition, the sustainability of adherence beyond the intervention period is unknown.

Introduction

With the aging population, heart failure (HF) is a growing problem worldwide [1]. In the United States, 8 million individuals are projected to be diagnosed with HF, and the cost of its treatment is expected to reach US $70 billion by 2030 [2-4]. Irrespective of the etiology of the disease (HF with preserved vs reduced ejection fraction; ischemic vs nonischemic), patients with HF experience symptoms of fatigue, exercise intolerance, palpitations, and over time, experience a decline in physical functioning [5-10]. These symptoms worsen as the disease progresses, often designated by the New York Heart Association (NYHA) I-IV classification [11]. The treatment and management of HF are also complicated by patients experiencing peaks and troughs in symptom experience and often needing hospitalizations. HF is generally associated with advancing age and has the highest readmission rates among all chronic diseases, adding to the increase in health care costs [2,12]. As such, effective and efficient management of HF using both pharmacological and nonpharmacological methods is essential.

As a nonpharmacological method, exercise training interventions have been shown to decrease hospitalizations, increase exercise capacity, and improve quality of life [13]. Exercise is different from physical activity and has been defined as a subset of physical activity that is planned, structured, purposeful, and performed with the objective of improving physical fitness [14]. The landmark multisite Heart Failure: A Controlled Trial Investigating Outcomes of Exercise Training trial established the safety of moderate-intensity aerobic exercise in HF and found evidence of reduced rehospitalization rates in patients who were adherent versus nonadherent to the recommended exercise [15]. Based on clinical evidence, exercise is considered a class I recommendation in adults with HF, meaning that its benefits greatly outweigh the risks [16-18]. Current guidelines recommend that patients with HF continue to include 150 minutes per week of moderate-intensity aerobic exercise supplemented with 2-3 days of resistance exercise training [19]. However, desired adherence to the recommended exercise in this population has been hard to achieve [15,20,21]. The World Health Organization [22] defines adherence as “the extent to which a person’s behavior—taking medication, following a diet, and/or executing lifestyle changes, corresponds with agreed recommendations from a health care provider.” This definition differentiated adherence from compliance and attempted to highlight the importance and need for lifestyle and behavioral changes to successfully achieve adherence [23].

In recent years, advances in mobile health (mHealth) technology have provided the opportunity for bridging access to care by delivering interventions to participants’ homes using video calling, chatbot messaging, cloud-based digital voice response, automated emails, phone counseling, and other tools for motivation and engagement [24]. Such technologies have also significantly improved the ability to remotely monitor a person's health status and intervention outcomes [24]. A systematic review of reviews shows that their app has also been used in the management of various health conditions such as asthma, chronic lung disease, diabetes, cardiac rehabilitation, hypertension, and HIV management, among many others [24]. Additionally, mHealth has also been implemented for behavioral or lifestyle changes that include weight loss, physical activity, smoking cessation, and sexual behavior [24]. Across diverse clinical populations, the effectiveness of home-based exercise programs is found to be similar to that of facility-based exercise programs [25]. In our previous study published in 2017 [26], we updated the state of the science from 2009 [27] in relation to adherence to exercise in patients with HF. In that systematic review, we found a mix of home-based and facility-based interventions and highlighted the lack of web-based interventions to improve adherence to recommended exercise guidelines in this population [26]. We did not find any studies at that time with mHealth interventions specifically targeting and reporting exercise adherence in HF. With significant advances in mHealth technology and access to smartphones among all ages [28], it is important to update the literature and summarize the work that has been done since to improve adherence to exercise in patients with HF using newer technologies. Demographic and socioeconomic variables can have a profound impact on technology adoption and use [29]. There can be unique challenges for implementing an mHealth intervention depending on the type of technology used and the complexity of the exercise program. This review was performed to systematically synthesize the literature on the use of mHealth technology that reported adherence to exercise in patients with HF, the majority of whom tend to be older adults. Specifically, this review was done to (1) describe study characteristics of mHealth interventions for exercise adherence in HF including details of sample demographics, sample sizes, exercise program, and theoretical frameworks; (2) summarize types of mHealth technology used to improve exercise adherence in patients with HF; (3) highlight how the term “adherence” was defined and how it was measured across mHealth studies and adherence achieved; and (4) highlight the effect of age, sex, race, NYHA functional classification, and HF etiology (systolic vs diastolic) on exercise adherence. Finally, we conclude by summarizing our findings and providing suggestions for future studies.

Methods

Study Design

The PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses) statement guided this review [30]. A health science librarian worked closely with the lead authors (PD, WA, ES, and TN) on narrowing the search terms. The search strategy included the terms (“heart failure” AND “exercise” AND “adherence”), AND (“mhealth” OR “telehealth”) in the title or abstract. Three databases (PubMed, MEDLINE, and CINAHL) were searched. Studies were eligible if they met the criteria outlined in Textbox 1. These inclusion dates were chosen

XSL•FO
RenderX

because a previous systematic review in the same topic area had included studies published up to 2015 [26].

Textbox 1. Inclusion and exclusion study criteria.

Inclusion criteria

- Primary studies on patients with heart failure
- Used an intervention that included mobile health or telehealth technology
- Experimental or quasi-experimental study
- Primary or secondary outcome reports of exercise adherence
- Published between January 1, 2015, and June 30, 2022
- Published in the English language

Exclusion criteria

- Studies that used only cell phone text messaging as an intervention

Screening and Data Extraction

All papers obtained from the literature search were uploaded and screened using the Rayyan program. The following 2-step screening process was used: (1) 4 authors (PD, WA, ES, and TN) independently screened titles and abstracts, and (2) all 4 authors screened the full texts of the included papers from step 1 to be included in this review. During every step, the 4 authors labeled a paper as "accepted," indicating that the paper met inclusion criteria; "not accepted," indicating that the paper did not meet inclusion criteria; or "maybe," indicating that the paper needed to be discussed prior to making a judgment that the paper was acceptable for the next step. As a group, the 4 authors discussed discrepancies and "maybe" papers to include or not include in the final analysis.

An author-developed extraction method was developed according to our prior systematic review [26]. Data including study characteristics (country, study design, theoretical framework, and length of study), sample characteristics (sample size and HF sample characteristics), intervention characteristics (mHealth technology and intervention components), outcomes (primary outcome, secondary outcomes, and outcome measures), results, and conclusions were extracted. Two authors (ES and TN) extracted relevant data from each paper. Two other authors (PD and WA) performed quality checks to ensure accuracy and completeness. Discrepancies during the extraction process were discussed with these 4 authors. The quality appraisal and risk of bias for the included studies were assessed using two distinct tools: (1) the second version of the Cochrane Risk of Bias tool for randomized trials and (2) the Risk of Bias In Non-Randomized Studies of Interventions-I tool for quasi-experimental studies. Each domain was categorized as low, moderate, serious, critical, or no information [31]. Both tools used the scores from these domains to determine the overall risk of bias [31,32].

Results

Overview

Our initial search yielded a total of 90 papers. The removal of duplicates yielded 82 papers to screen. In total, 55 papers were extracted during the first screening process, resulting in 27 papers being sought for full-text retrieval. The 55 papers did not meet inclusion and exclusion criteria from the title and abstract screening for not including participants with HF, not using mHealth or telehealth intervention, not using an exercise intervention, not reporting adherence, using cell phone SMS text messaging for intervention, not a primary study, and not published in English. Following the second screening process, 19 papers were excluded for the following reasons: review papers (n=8), did not report adherence (n=4), no exercise intervention using mHealth (n=3), papers reporting protocols (n=3), and papers did not meet date requirements (n=1). Only 8 papers were included for data extraction. The PRISMA diagram (Figure 1) highlights the screening process. The papers included 4 randomized controlled trials (RCTs) [33-36] and 4 quasi-experimental trials [37-40]. A total of 4 studies are from Asia [33,34,37,38], 3 from the United States [35,39,40], and 1 from Australia [36]. Descriptions of these studies are provided in Table 1.

Study Characteristics of mHealth Interventions for Exercise Adherence in HF

This review builds on research to describe study characteristics of mHealth interventions for exercise adherence in HF, including details of sample demographics, sample sizes, exercise programs, and theoretical frameworks. As detailed in Table 1, the sample sizes ranged from 12 to 81, with study durations lasting 4 to 26 weeks. The studies from Asia included Asians in their study, and the studies from the United States and Australia primarily included White patients with HF. While 2 studies had a larger proportion of male participants (63% and 75%) [35,36], other studies seem to have an equal representation of male and female participants. One study did not report the race of the participants enrolled in the study [39]. The mean ages of the participants included in the studies range from 53 to 73 years. The NYHA classifications ranged from class I to class III, with mean ejection fractions ranging from 33.5% to 45%. One study did not report the ejection fraction of the participants [40]. In total, 3 studies recruited participants from a cardiac outpatient clinic [33,35,40], while 5 studies recruited participants from an inpatient hospital setting [34,36-39].

With exercise being performed at home, baseline training for patients with HF to safely perform exercise is important. One study incorporated 1 week of center-based cardiac rehabilitation exercise training before transitioning to a home setting [37]. Two studies provided 1 training session on the exercise program at baseline [35,38]. One study indicated that the participants received family cardiac rehabilitation prior to being recruited [34]. Among the studies that were RCTs, 1 study reported that the control group was provided the same exercise prescription as the intervention group [35], and 1 study provided the control group with family cardiac rehabilitation training guided by mobile medical technology [34]. Other studies did not provide details of the number of sessions needed to train the participants in the prescribed exercise program.

For exercise modality, 1 study used a yoga program [40], 1 study used a walking program [35], 1 study combined jogging with walking [34], 1 study used a cycle ergometer [38], 2 studies combined walking with cycle ergometry [33,37], and 1 study used a stepper [39]. One study did not provide details of the aerobic component of the exercise program [36]. Two studies added a resistance exercise component to the exercise prescription [33,36]. One study used multiple types of aerobic exercises (such as walking or using a cycle ergometer, a stepper, and an elliptical) and incorporated 1 day per week of facility-based exercise [37]. Studies that prescribed a primarily home-based exercise prescription used a walking or cycle ergometer program.

Rating of perceived exertion (RPE) was the most used tool for regulating the intensity of exercise [33-37]. Overall, participants in these studies were asked to keep their RPE<14 on the Borg (6-20) RPE scale, which is suggestive of moderate-intensity exertion [41]. Additionally, a few studies also used heart rate for moderate exercise intensity regulation. These strategies to regulate intensity using heart rate included keeping the exercise heart rate at resting heart rate+30 beats per minute [37], resting heart rate+(maximum exercise heart rate–resting heart rate)×0.4 [34], and below maximal heart rate during baseline training on the exercise program [35]. Three studies did not provide details on how intensity of exercise was regulated [38-40].

Prescribed exercise durations were between 30 and 60 minutes. The exercise prescriptions used by the studies varied but ranged from 3 to 5 days per week. While 1 study advised participants to exercise daily [39], 2 studies recommended 2 days per week of exercise [36,40]. One study did not report on the frequency of recommended exercise per week [37]. We found that the exercise prescriptions in most studies were investigator-developed programs. Reference to the recommended guidelines of 150 minutes per week of moderate-intensity aerobic exercise for patients with HF was done in 1 study [35].

Only 1 study indicated developing their intervention using a theoretical platform [35]. The study used concepts from Bandura's self-efficacy theory and Ajzen's theory of planned behavior to bring about change in adherence behavior. The other studies did not specifically mention any theory.

Summarize Types of mHealth Technology Used to Improve Exercise Adherence in Patients With HF

Table 2 provides information about the mHealth technologies used and how they were incorporated into the intervention. As summarized in Table 2, videoconferencing was used in 4 studies [35,36,38,40], while 4 studies [33,34,37,39] used mobile apps for the devices used in the study. The apps were installed in smartphones (n=3) [33,34,37], laptops, tablets, or desktop computers using Wi-Fi or 3G wireless broadband connection (n=4) [35,36,38,39], and 1 study used a television that was connected to the internet [40]. Studies published in the past 3 years used smartphone-based apps, while studies that were a little older used more laptops, computers, and tablets. In the 4 studies that used a videoconferencing platform, videoconferencing was delivered using commercially available software such as Vidyo (Vidyo Inc) [35], Adobe Connect 9.2 [36], DocBox (DocBox, Inc) [40], and the Remohab integrated rehabilitation platform (Remohab) [38]. Two studies used a Fitbit activity monitor along with the Fitbit app [33,35]. Two studies used apps to transfer information to the physician's office via the cloud database [33,37]. Three studies using videoconferencing included interventions that were in a group setting [35,39,40]. One study used an app that provided voice prompts during exercise [34]. While 1 study simply engaged participants in cohorts (n=5) for a discussion session for social support [35], 2 studies focused on delivering an exercise program that included yoga (n=8) [40] and aerobic exercise (n=4) [36].

Table 2. mHealth technology used and details of the study intervention[a].

Study author(s) (year)	Type of mHealth technology used	Type of software	Devices used	Details of exercise intervention (individual or group)
Tsai et al (2022) [37]	App	HF[b] health management mobile app system platform	Smartphone	The exercise parameters were recorded on the HF health management mobile app system platform by each patient and daily transmission to the hospital's cloud database as home-based cardiac telerehabilitation. Monitoring parameters include body weight, blood pressure, resting heart rate, exercise heart rate, exercise time, and abnormal symptom signs.
Nagatomi et al (2022) [33]	App	Fitbit	Fitbit Inspire HR worn on nondominant hand; smartphone	Comprehensive home-based cardiac rehabilitation program that combines patient education, exercise guidance, and nutritional guidance using information and communication technology. Messages sent once a week through the Fitbit app or by telephone. Video instructions on performing exercises were provided using a QR code via smartphone.
Liu and Liu (2022) [34]	App	Exercise rehabilitation app software designed by the family cardiac exercise rehabilitation training research team	Android smartphone	The app provided exercise guidance via voice prompts on current exercise speed, heart rate, acceleration or deceleration reminder, exercise rhythm adjustment, etc.
Kikuchi et al (2021) [38]	Videoconferencing and remote monitoring	Integrated rehabilitation platform (Remohab Inc)	An Internet of Things–equipped ergometer (Charimo, Remohab Inc), an Android-compatible tablet (TAB3-X70L, Lenovo), and a wireless electrocardiographic monitoring device (hitoe, Toray)	In total, 30 minutes to install the system including Wi-Fi at the participants home and 60 minutes to instruct the use of the platform. Exercises were done individually. Participants exercised on a cycle ergometer for 30 minutes or less while videoconferencing with a nurse. For each session, exercise intensity was set by the attending physician. There was live monitoring of heart rate and electrocardiogram for arrhythmia that was transferred via Wi-Fi to the physician's office.
Deka et al (2019) [35]	Videoconferencing and app	Vidyo and Fitbit app	Fitbit Charge HR; tablet, computer, laptop; home Wi-Fi or wireless connectivity	Education on HF self-care on the following topics: understanding HF, exercise and activity with HF, how to follow a low sodium diet, HF medication, dealing with HF symptoms, depression and anxiety with HF, and managing lifestyle changes. Discussion on the previous week's adherence, barriers, and facilitators. Five participants in each cohort.
Lloyd et al (2019) [39]	App	REDCap[c]	Tablet computer with wireless connectivity	A 5-minute video with an older adult performing the intervention tasks was created and provided to participants. Feedback was provided in the form of personal data graphs.
Hwang et al (2017) [36]	Videoconferencing	Adobe Connect 9.2	Laptop computer, mobile broadband device connected to 3G wireless broadband internet	Physical therapist–guided telerehabilitation exercise in groups (up to 4 participants). In total, 15 minutes were spent at the start of each session on a discussion on educational topics that replicated a center-based program.
Donesky et al (2017) [40]	Videoconferencing	DocBox	The DocBox was connected to the participants' home television for live-streaming yoga classes	Group teleyoga. Postures included mountain, half-down dog, cat, triangle, supported bridge, simple twist, staff, corpse, and cobbler poses, with postures modified as needed to meet the physical ability of each participant. Yoga classes were designed to integrate breathing exercises (slow breathing and extended exhalation breathing), imagery, meditation, and relaxation.

Adherence: Description, Measurement and Achievement

In our review, we found that, in the majority of studies, the term adherence was used to measure "adherence to a study-specific exercise program." Only 1 study used the term adherence in reference to the recommended exercise guidelines [35]. As seen in Table 2, all studies relied on an objective tool for measuring the amount of exercise to calculate adherence. In total, 2 studies used a Fitbit [33,35], 3 studies used a telemonitoring platform [34,37,38], and 2 studies directly observed exercise being performed during the videoconferencing session [36,40].

Table 3 highlights the details of the exercise program and exercise adherence achieved in the studies included in the review. Comparing exercise adherence among the different studies is difficult because of the variance in the exercise program. While most studies reported adherence in proportions of participants achieving adherence, 2 studies reported adherence in mean minutes of exercise achieved by the intervention group [35,39].

Study (author, year)	Exercise setting; individual or group	Modality	Intensity	Duration	Frequency	Length; attrition	Adherence calculation	Adherence achieved	Adherence sustainability report
Hwang et al (2017) [36]	Center-based for the control group and home-based for the intervention group; group exercise: 4 in each group	Aerobic and resistance	RPE 9-13	40 minutes of aerobic and resistance	2 times per week	12 weeks	Adherent: >80% of sessions attended, partly adherent: 20%-80% of sessions attended, and nonadherent: <20%	Intervention group: 49 adherent or partially adherent	After 12 weeks
Donesky et al (2017) [40]	Home only	Yoga	Not reported (mean heart rate stayed below 90 bpm)	35 minutes of poses	2 times per week	8 weeks	Attendance to number of sessions	90% attendance to classes	None

[a]RHR: resting heart rate.

[b]RPE: rating of perceived exertion.

[c]THR: target heart rate.

[d]HRmax: maximal heart rate.

[e]CPET: cardiopulmonary exercise testing.

In 2 studies, adherence was the primary outcome [35,40]. While one study investigated adherence to a walking program [35], the other study reported adherence to a teleyoga program [40]. The primary outcomes in the other studies included exercise intolerance [42], medication adherence [39], exercise tolerance [34,37], and physical function [33].

Similar to our previous review [26], we found that even in studies using mHealth technology, exercise adherence was not a primary outcome and mostly reported adherence as a secondary outcome measure. As previously noted, measurement of adherence requires a study design that extends beyond the intervention phase to determine the effectiveness of the intervention in bringing about lifestyle changes and sustainability of adherence behavior. We found this to be lacking in all studies in this review. Most studies included in this review were exploratory in nature and were testing for feasibility, acceptability, or initial pilot testing of the intervention design or exercise protocol.

Effect of demographic and clinical characteristics on Exercise Adherence

No study reported the effect of age, sex, race, HF etiology, NYHA functional classification, and HF etiology on exercise adherence. We found most studies included a sample of patients with HF who had homogenous demographic and clinical characteristics. In addition, the small sample sizes and quasi-experimental design prevent from making any conclusion on adherence based on age, sex, race, NYHA classification, and HF etiology.

Risk of Bias

Tables 4 and 5 detail the risk of bias assessments for the included studies. For the 4 RCTs evaluated using the Risk of Bias 2 tool, 1 was classified as having a low risk of bias, 1 as having a moderate risk, and 2 as having a high risk. The moderate and high risks of bias were attributed to bias from the randomization process (n=4, 50%), deviations from intended interventions (n=2, 25%), missing outcome data (n=2, 25%), and outcome measurement (n=2, 25%). Among the 4 quasi-experimental studies assessed using the Risk of Bias In Non-Randomized Studies of Interventions-I tool, 2 were rated as having a moderate risk of bias, and 2 had a serious risk of bias. The moderate and serious risks stemmed from confounding variables (n=2, 25%), classifications of interventions (n=2, 25%), deviations from intended interventions (n=2, 25%), missing data (n=6, 75%), and outcome measurement (n=4, 50%).

Table 4. Assessment of study risk of quasi-experimental papers.

Author(s) (year)	Confounding	Selection	Classifications	Deviations from interventions	Missing Data	Measurement	Selection of reported result	Overall bias

Discussion

Principal Findings

Decades of research have established the benefits of regular exercise in patients with HF [43]. However, adherence to recommended exercise for patients with HF is often hampered by their clinical condition and other structural and sociodemographic barriers [44]. With significant improvements in wireless internet connectivity and smartphone use across the world, mHealth-driven interventions hold immense promise with the ability to deliver the intervention to the participant's home using varied forms of multimedia engagement tools [45,46]. This review found 8 feasibility or pilot studies delivering exercise interventions using mHealth tools and reporting on adherence to varied exercise programs in patients with HF. Studies had a moderate to high risk of bias, and theoretically sound and fully powered RCTs were found to be lacking, making it difficult to determine clinical efficacy and the effect of demographic and clinical characteristics on adherence.

Previous studies have highlighted the variation in how the concept of adherence has been used by researchers reporting adherence to exercise in patients with HF [26]. Similar to prior studies, our review found the term "adherence" used primarily to report "attendance" to the investigator-developed program [23]. While this approach is good for assessing the effectiveness of the study intervention, researchers should clarify how adherence achieved in their study translates into meeting adherence to the recommended exercise guidelines for patients with HF. A position statement from the Heart Failure Association from the European Society of Cardiology has categorized exercise adherence as fully adherent=achieving >80% of exercise recommendations, partially adherent=achieving 20%-80% of exercise recommendations, and nonadherent=achieving <20% of exercise recommendations [44,47].

The earlier-mentioned adherence categorizations have also been borrowed from the medication literature [47]. It needs to be acknowledged that the complexity and challenges associated with adherence to exercise are different compared to adherence to other types of self-care (eg, medication adherence). To achieve exercise adherence, the extent of lifestyle and behavioral changes needed to be made by a patient with HF, experiencing frequent peaks and troughs in symptoms, can be challenging and also different from patients with other chronic clinical conditions such as diabetes and hypertension [25]. A systematic review and meta-analysis showed substantial heterogeneity in exercise adherence rates and dropouts across clinical populations [25]. This heterogeneity, along with the varied ways adherence is measured [48], makes it even more challenging to compare adherence rates within and across populations. Self-efficacy, motivation, enjoyment, and attention to exercise relapse management are important factors associated with physical activity in patients with HF [49-51]. Interventions should target not only building exercise self-efficacy but also ensuring that participants are enjoying the mHealth experience and the exercise program for maintaining motivation and achieving sustained adherence over time. Adults with HF often experience exacerbation of their symptoms that impede their ability to exercise. Relapse management strategies to reinitiate exercise after a break are an important component of interventions to promote exercise adherence.

As expected, all studies delivered their mHealth interventions to the participants' homes. The more recent studies adopted more smartphone-based interventions. This observation makes sense as, in the past few years, internet and smartphone access and use have increased significantly globally [52] and among patients with HF [53]. Most exercise prescriptions used in the studies in this review were investigator-developed programs. Alternate forms of exercise (such as yoga) have been delivered using mHealth technology; however, guidelines for such forms of alternate exercise for patients with HF have not yet been standardized, and their benefits have also not been clearly established. Due to the varied exercise programs prescribed in the different studies, it is difficult to compare adherence achieved between the studies. As such, it is also difficult to compare study results, as exercise and health outcomes have a dose-dependent relationship [54,55]. mHealth intervention can be challenging, as it requires training participants to use the mHealth technology in addition to the exercise program. The complexity of the technology can make it difficult for patients with HF, who tend to be older adults, to not be able to use the technology as directed, thereby presenting issues with internal validity for the research study and also potential dropout. Six studies mention providing 1 baseline training session with additional technical help if needed over the phone or in person [34-36,38-40]. No study provided details of challenges encountered in training participants to use the technologies that were used. The studies included in this review did not report

XSL•FO
RenderX

any safety concerns or adverse incidents associated with the exercise performed in a home setting. Exercise training at baseline, depending on the simplicity of the exercise program, ranged from 1 training session to prior enrollment in a cardiac rehabilitation program. As studies using mHealth technology are likely to be delivered to the participants' homes and mostly unsupervised, assessment of the ability of patients with HF to safely exercise on their own is important. While a majority of studies reported achieving good exercise adherence, the intervention period was short (lasting 1-6 months), and the sustainability of exercise behavior was not measured. We also noted a lack of and a need to determine the utility and effectiveness of theoretically sound mHealth-driven interventions across different strata of patients with HF, including age, sex, and race.

In our previous review, we highlighted that exercise diaries were the most commonly used tools for measuring exercise adherence in HF studies reporting adherence [26]. One advantage of using mHealth technology is also the ability to collect objective exercise data rather than relying on self-reported data, which can be erroneous due to overestimation [56]. The use of physical activity monitoring devices such as Fitbits allows for measuring and remotely monitoring objective physiological parameters, such as heart rate and step count, during exercise. Most studies included in this review prescribed simple exercise programs that included walking, cycle ergometer, or stepper, with a couple of studies adding resistance training to their exercise program. The use of RPE (eg, Borg scale) was the most used tool for regulating exercise intensity. Subjective tools are easy to use and are often preferred by clinicians and patients. However, the heart rate function in commercially available physical activity monitors such as Fitbit offers more precise exercise intensity regulation and was used by some studies. Research shows that patients with HF like using the heart rate and step count feature in Fitbit [35]. It is important that patients with HF, who tend to be older adults, are adequately trained in using these devices to prevent potential dropouts from facing technological challenges.

Limitations

This review included studies that were published between 2015 and 2022. We completed a thorough search, but some papers may have been missed and not included in the review. The study is limited to the use of mHealth for exercise adherence in patients with HF and does not include the use of mHealth technologies for improving other self-care recommendations. There is a risk of bias on the part of the authors, which we have tried to mitigate through our search strategies, inclusion, exclusion, and screening process outlined earlier.

Future Recommendations

Our review shows preliminary evidence of using mHealth technology for targeting exercise adherence in patients with HF. However, there is a lack of theoretically sound and fully powered RCTs to suggest its effectiveness. It is crucial for studies using mHealth technology to improve study quality and limit the risk of bias, as noted in this review, particularly by limiting confounding factors. In addition, it is important to determine the sustainability of exercise behavior after the intervention period when the intervention stimuli have been removed. How adherence is measured and reported also needs consideration. Because adherence has mostly been reported to investigator-developed programs, it is difficult to compare the adherence achieved in different studies. As such, we suggest that adherence achieved to investigator-developed exercise programs should be standardized to the recommendations for exercise for patients with HF to help compare the effectiveness of different programs. Reporting the proportion of participants achieving adherence may be better than reporting the mean minutes of exercise performed by participants, as the mean calculations are influenced by outliers. Tracking daily exercise using mHealth tools and reporting changes in the number of minutes of exercise from baseline can provide a better picture of the effectiveness of home-based interventions, especially in patients with HF who experience peaks and troughs in symptoms. They can also be useful in validating self-reported exercise and physical activity [57]. Considering that making lifestyle changes is challenging for many patients with HF, the practical and clinical significance of the adherence achieved using mHealth interventions should also be highlighted alongside reports of statistical significance. Finally, the feasibility and acceptability of mHealth technology across different races, sexes, and cultures needs to be studied. mHealth provides opportunities to explore culturally tailored interventions in HF that have been grossly underinvestigated.

Conclusions

There is some preliminary evidence suggesting the feasibility of using mHealth technology for building exercise adherence in patients with HF; however, theoretically sound and fully powered studies, including studies on minoritized communities, are lacking. In addition, lacking is a report on the sustainability of the achieved adherence beyond the intervention period. The study provides some areas for researchers to focus on in future studies.

Abstract

Background: Chronic kidney disease (CKD) imposes a significant global health and economic burden, impacting millions globally. Despite its high prevalence, public awareness and understanding of CKD remain limited, leading to delayed diagnosis and suboptimal management. Traditional patient education methods, such as 1-on-1 verbal instruction or printed brochures, are often insufficient, especially considering the shortage of nursing staff. Technology-assisted education presents a promising and standardized solution, emphasizing the need for innovative and scalable approaches to improve CKD-specific knowledge and health literacy.

Objective: This study aimed to develop and evaluate the effectiveness of an innovative 12-unit virtual health coaching program delivered through interactive robots that is intended to enhance disease knowledge and health literacy among patients with CKD.

Methods: A quasiexperimental design was used, and 60 participants were evenly assigned to experimental and comparison groups. However, due to attrition, 14 participants in the experimental group and 16 participants in the comparison group completed the study. The intervention involved a 12-unit program, with each unit lasting approximately 20 minutes to 30 minutes and delivered across 3 to 4 learning sessions, and participants completed 3 to 4 units per session. The program addressed key aspects of CKD-specific health literacy including functional, communicative, and critical literacy and CKD-specific knowledge including basic knowledge, prevention, lifestyle, dietary intake, and medication. Data were collected through validated pre and postintervention questionnaires. All 30 participants completed the program and subsequent evaluations, with outcome measures assessing changes in CKD-specific knowledge and health literacy.

XSL•FO
RenderX

Results: Postintervention analysis using generalized estimating equations, adjusted for age, revealed that the experimental group (n=14) had significantly greater improvements in health literacy (coefficient=2.51, Wald χ^2_1=5.89; *P*=.02) and disease knowledge (coefficient=1.66, Wald χ^2_1=11.75; *P*=.001) than the comparison group (n=16). Postintervention *t* tests revealed significant improvements in CKD-specific health literacy and disease knowledge (*P*<.001) between the experimental and comparison groups. Additional analyses identified significant group × time interactions, indicating improvements in communicative literacy (*P*=.01) and critical literacy (*P*=.02), while no significant changes were observed in functional literacy. Regarding disease knowledge, the experimental group demonstrated a significant improvement in medication (*P*<.001), whereas changes in basic knowledge, prevention, lifestyle, and dietary intake were not significant.

Conclusions: This study demonstrated that interactive robot-assisted eHealth coaching effectively enhanced CKD-specific disease knowledge and health literacy. Despite the challenges posed by the COVID-19 pandemic, which constrained sample sizes, the findings indicate that this program is a promising patient education tool in clinical nephrology. Future research should involve larger sample sizes to enhance generalizability and examine additional factors influencing effectiveness.

Introduction

Chronic kidney disease (CKD) has emerged as a major global health issue, with current estimates indicating that it affects approximately 10% of the global population [1]. The disease imposes a significant financial burden driven by the high costs of diagnosis, treatment, and ongoing care. As CKD advances, over two-thirds of patients with CKD experience complications such as cardiovascular disease, metabolic bone disorders, anemia, and malnutrition, all of which can profoundly affect their health and quality of life [2]. In Taiwan, CKD accounts for 7.14% of the nation's total health care expenditure [3], underscoring the critical need for effective prevention strategies. The prevalence of dialysis among patients with CKD in Taiwan underscores the need for targeted interventions. In 2021, only 3.7% of dialysis patients were aged younger than 40 years, while 40.1% were aged 40 years to 64 years, 31.1% were aged 65 years to 74 years, and 25.1% were 75 years old or older. This distribution highlights that the majority of patients with CKD in Taiwan are middle-aged or older.

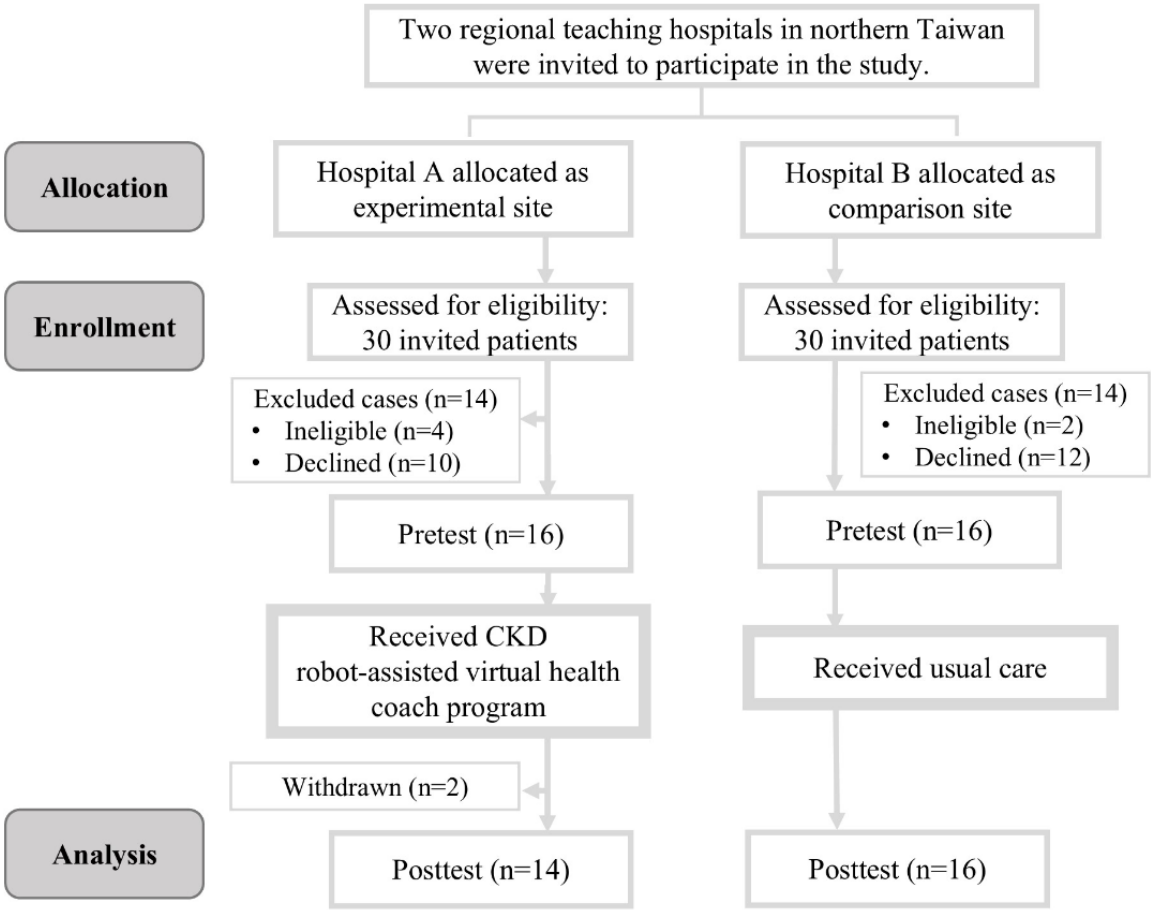
Health literacy (HL) is defined as the ability to access, understand, evaluate, and apply health information to make informed health decisions [4]. In this study, HL refers to a patient's capacity to comprehend and use CKD management information to manage their CKD [5]. According to Nutbeam [6], HL consists of 3 components: functional, communicative and interactive, and critical literacy. Functional literacy encompasses the basic reading and writing skills needed for everyday functioning. Communicative literacy includes more advanced skills that enable individuals to actively engage in social contexts, extract information, and adapt to changing environments. Critical literacy involves using advanced cognitive and social skills to critically analyze information and exert greater control over personal health and life situations. Limited HL in patients with CKD has been linked to poor health outcomes and reduced treatment adherence [7]. CKD-specific HL and knowledge can help patients manage their condition effectively. In this study, disease-specific knowledge encompassed an understanding of kidney function, disease prevention, healthy lifestyle habits, diet, and medication. Higher HL levels have been identified as strong predictors of adherence to medication, diet, fluid intake, and general self-management practices [8]. A previous study suggested that complications related to kidney disease may stem from insufficient health knowledge and that HL significantly influences self-care behaviors [9]. One review highlighted that disease-specific knowledge is critical for HL, which is a prerequisite for the effective self-management of CKD [8]. Improving HL can enhance disease knowledge, promote better self-care behaviors, and potentially slow disease progression. These findings underscore the importance of HL and knowledge of kidney disease management.

Health coaching is an evidence-based approach that enables patients to make lasting behavioral changes that enhance their overall health [10]. By offering health care options tailored to individuals' lifestyles and abilities, health coaching improves outcomes, especially among those with chronic illnesses or those at a higher risk of medication nonadherence. Previous studies have shown that health coaching can lead to positive behavioral changes and improved health outcomes in patients with chronic conditions, underscoring its value in managing long-term health [11,12].

Previous studies have demonstrated the significant impact of health promotion and education programs on patients with CKD [13]. Recent digital health intervention advancements, such as wearable devices, virtual reality, and mobile health apps, have introduced innovative approaches to enhance patient education. Wearable devices facilitate self-management by providing personalized information [14], virtual reality enhances CKD education through experiential learning [15], and mobile apps can improve disease knowledge when compared with traditional education alone [16]. Digital technologies for health coaching offer older adults support for improving various health determinants [17], and approaches such as e-learning and remote monitoring have been shown to boost treatment effectiveness and quality of life [18]. Moreover, research has also underscored the need for digital coaching to be user-friendly, highly engaging, and tailored to individual needs [19,20]. Health care professionals face challenges due to insufficient nursing staff, and CKD is a complex condition requiring comprehensive

XSL•FO
RenderX

education. Most education systems rely on traditional methods (eg, brochures or 1-on-1 verbal counseling) that often lack diverse directions and interactions. This gap highlights the urgent need for innovative digital solutions to enhance CKD-specific HL and disease knowledge. Using emerging technologies (eg, interactive robots) that follow official health education guidelines [21] offers a novel solution to standardize education, address staffing shortages, and improve the overall interactivity of CKD education. These technologies can provide personalized and accessible learning experiences, as well as improve patient engagement and outcomes [22].



This study aimed to evaluate the effectiveness of an interactive robot-assisted virtual health coaching intervention for improving CKD-specific HL and disease knowledge. The following research questions guided the study: (1) How comprehensively does this intervention improve CKD-specific knowledge? (2) How effective is the intervention in enhancing CKD patients' HL? Prototypes were developed using insights from nephrologists and nurse practitioners who served as virtual health coaches and incorporated their clinical interactions with patients. By offering an engaging and accessible educational platform, the intervention aimed to enhance patient engagement and ultimately improve the health outcomes of patients with CKD.

Methods

Study Design

This study adopted a quasiexperimental design involving the recruitment of patients with CKD from the nephrology departments of 2 regional hospitals in northern Taiwan that are similar in size and scope. Each hospital was assigned to either an experimental or comparison group. Health care professionals initially screened patients based on the eligibility criteria and referred interested parties to the research team. This process continued until 30 participants were selected from each hospital. However, due to the COVID-19 pandemic, only 14 participants in the experimental group and 16 participants in the comparison group completed the study. Participant attrition was primarily attributed to the lengthy intervention period and pandemic-related disruptions. Participants in the experimental group received both intervention and usual care provided by nurse practitioners, whereas those in the comparison group received only usual care. During recruitment, the researchers explained the use of the interactive robot and the basic interface operations required. After obtaining written informed consent, the participants were provided with an operation manual and guidance regarding the use of the interface. The flowchart of this study is presented in Figure 1.

Figure 1. Flowchart of the study. CKD: chronic kidney disease.

RenderX

Study Population

The inclusion criteria required participants to be adults aged 20 years or older with a diagnosis of CKD. The exclusion criteria included dialysis, transplantation, severe mental illness, dementia, or significant sensory impairments. Patients undergoing dialysis were excluded because of significant differences in care standards and intensity compared with CKD management [23].

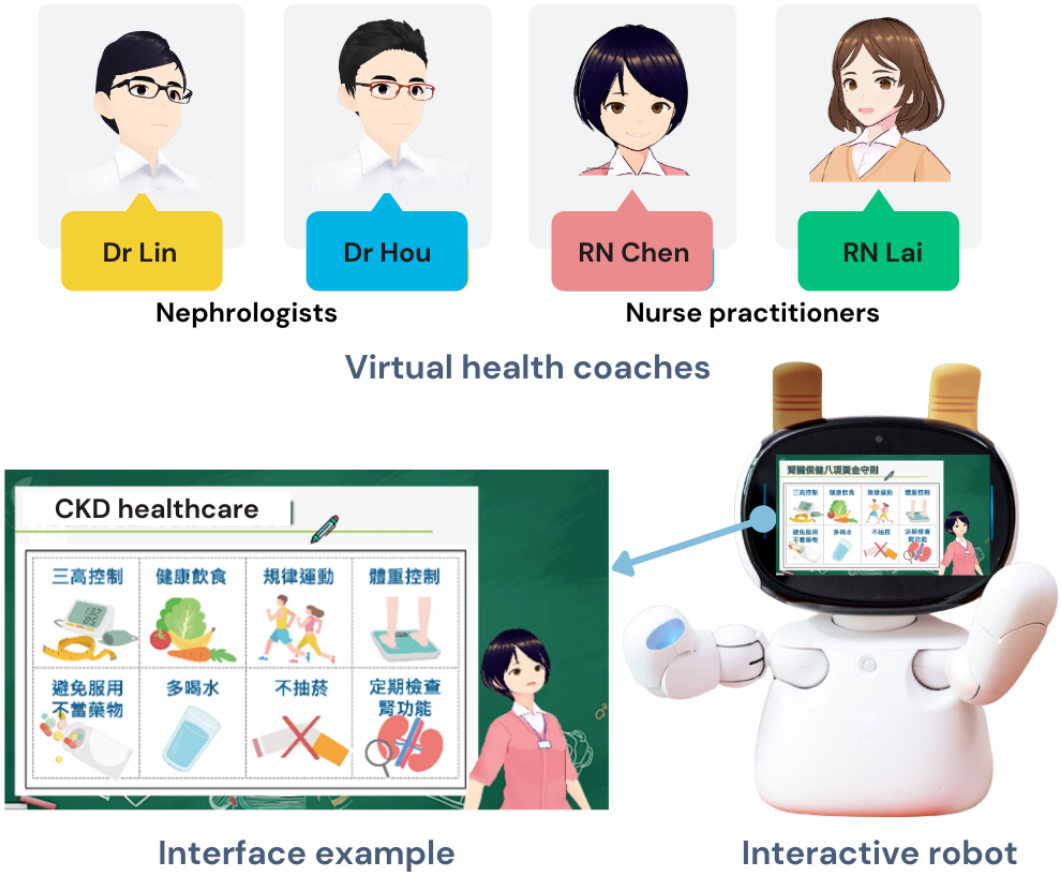
Intervention

An interdisciplinary team including 2 nephrologists and nurse practitioners developed a 12-unit health coaching program using the interactive robot Kebbi Air S (NUWA Robotics Corp). The Kebbi robot, known for its versatility and interactivity, has been used across various domains, including education, health care, and customer service [24]. Prior studies have investigated its effectiveness for language learning and social assistance in health-related contexts and the impact of its expressions on participant engagement [25-27]. The program was designed using government-developed guidelines to ensure standardization and validity [21] after incorporating clinical experiences, patient interactions, and insights from 14 development meetings. These physicians and nurse practitioners acted as virtual health coaches through the robot, delivering content through dialogue, animations, and interactive tasks using artificial intelligence and natural language processing to facilitate dynamic patient engagement. The intervention was conducted using participant-staff 1-on-1 sessions during which staff guided participants in familiarizing themselves with the interface and provided assistance as needed. The robot was programmed to emulate health care professionals' tone and demeanor, offering positive reinforcement (praise, encouragement, and motivational gestures) to sustain patient engagement. Correct answers on standardized quizzes were rewarded with applause, while supportive hints and explanations were provided after incorrect responses to facilitate learning. Virtual health coaches presented information tailored to the 5 stages of CKD, responded to patient inputs, and provided feedback. The program covered critical areas of CKD-specific HL, including functional, communicative, and critical literacy as well as CKD-specific knowledge, including basic knowledge, prevention, lifestyle, dietary intake, and medication. Table 1 provides an overview of the course learning objectives and corresponding outcome variables. Figure 2 illustrates an example of the program's interface.

Table 1. Learning objectives and outcome variables of the intervention program.

Unit	Learning objectives	Outcome variables
1	Understand the importance of CKD[a] self-management Know how to measure waist circumference	HL[b]: functional literacy Knowledge: lifestyle
2	Recognize CKD clinical symptoms Identify 5 warning signs of CKD	HL: critical literacy Knowledge: basic knowledge, prevention
3	Understand the importance of regular tracking Know 3 basic types of renal tests	HL: functional literacy Knowledge: prevention
4	Understand the 5 stages of CKD care Know how to calculate eGFR[c] Learn the self-test for renal function	HL: functional literacy Knowledge: lifestyle, prevention
5, 6, 7	Understand nutrition for CKD Identify high-potassium fruits and cooking methods	HL: communicative, functional literacy Knowledge: dietary intake
8	Understand the management of comorbidities of CKD Learn about health care for CKD comorbidities	HL: critical literacy Knowledge: basic knowledge, medication
9	Understand symptoms and self-management of chronic renal failure Learn about psychological adaptations to CKD	HL: communicative literacy Knowledge: basic knowledge, medication
10	Understand the proper time for dialysis Learn the patient-physician shared decision-making strategies	HL: communicative literacy Knowledge: prevention, medication
11	Understand hemodialysis access methods Know arteriovenous fistulas and grafts	HL: critical literacy Knowledge: medication
12	Identify the emergency medical primetime[d] Learn how to rebuild life after CKD	HL: critical literacy Knowledge: lifestyle, medication

[a]CKD: chronic kidney disease.



[b]HL: health literacy.

[c]eGFR: estimated glomerular filtration rate.

[d]The "Golden Hour" or critical period of time between the time a medical service (such as an ambulance or emergency service) receives a call for help and the arrival of the first emergency team at the scene of an emergency.

Figure 2. Interface example of the interactive robot-assisted virtual health coach program for chronic kidney disease (CKD). RN: registered nurse.

Procedure and Program Delivery

The research team selected an experimental hospital and collaborated with attending nephrologists to define the goals, procedures, and protocols of the study. Upon receiving the hospitals' approval to conduct the study, recruitment posters were distributed to encourage patients with CKD to participate, while an orientation session introduced participants to the study's objectives and collaborative framework. Data collection involved 1-on-1 interviews, enabling in-depth interactions and ensuring that participants were fully engaged with the intervention. Patients were encouraged to interact with the robots to become familiar with the interface. The experimental group participated in a 12-unit intervention, with each unit lasting approximately 20 minutes to 30 minutes. Participants completed 3 to 4 units per session across 3 to 4 learning sessions. The comparison group received usual care, including personalized education, from nurse practitioners. Structured questionnaires were used for the pre and postintervention assessments.

Measurements

The effectiveness of the intervention was assessed using a validated questionnaire [5,28]. The CKD-specific HL scale and CKD-specific disease knowledge scale were adapted from validated tools specifically designed to assess HL and disease knowledge in patients with CKD. The CKD-specific HL scale includes 17 items for functional, communicative, and critical literacy in a multiple-choice test format. The CKD-specific disease knowledge scale has 13 true or false items across 5 domains. Higher scores indicated better HL and knowledge. The Cronbach coefficients were 0.78 and 0.76 for the CKD-specific HL scale and the CKD-specific disease knowledge scale, respectively.

Data Analysis

Data were analyzed using SPSS version 23.0 (IBM Corp). This study primarily aimed to evaluate the intervention's effectiveness at enhancing CKD-specific HL and disease knowledge. No significant differences were found after comparing the pretest scores of the outcome variables between the experimental and comparison groups using *t* tests, eliminating the need to control for the pretest scores. However, due to missing data for some variables, generalized estimating equations (GEEs) were used to analyze the pre and posttest results between the 2 groups while also controlling for age differences. The GEE approach was selected because it effectively handles repeated measures and correlated data, making it well-suited for our study design. It is robust and accommodates missing values, providing reliable estimates and enhancing the validity of our findings.

Ethical Considerations

This study was approved by the Joint Institutional Review Board of Shin Kong Wu Ho-Su Memorial Hospital (approval number

XSL•FO
RenderX

20211202R) and Cardinal Tien Hospital (approval number CTH-110-3-5-002). All participants were fully informed and provided their consent before the interviews began.

Results

User Demographics

The demographic characteristics of participants in the experimental (n=14) and comparison (n=16) groups were not significantly different in gender (χ^2_{28}=0.27; *P*=.61), marital status (χ^2_{28}=0.05; *P*=.82), and educational level (χ^2_{28}=0.20; *P*=.65), although the experimental group was significantly younger.

Evaluation Outcomes

As shown in Figure 3, the results of the *t* tests indicated that the posttest scores for CKD-specific HL (t_{27}=–4.44; *P*<.001) and disease knowledge (t_{28}=5.58; *P*<.001) were significantly higher in the experimental group than in the comparison group.

Figure 3. Comparison of pre and posttest (A) CKD-specific health literacy and (B) CKD-specific disease knowledge, reported as the mean (95% CI) scores, with comparisons of pre and postintervention scores between the groups.

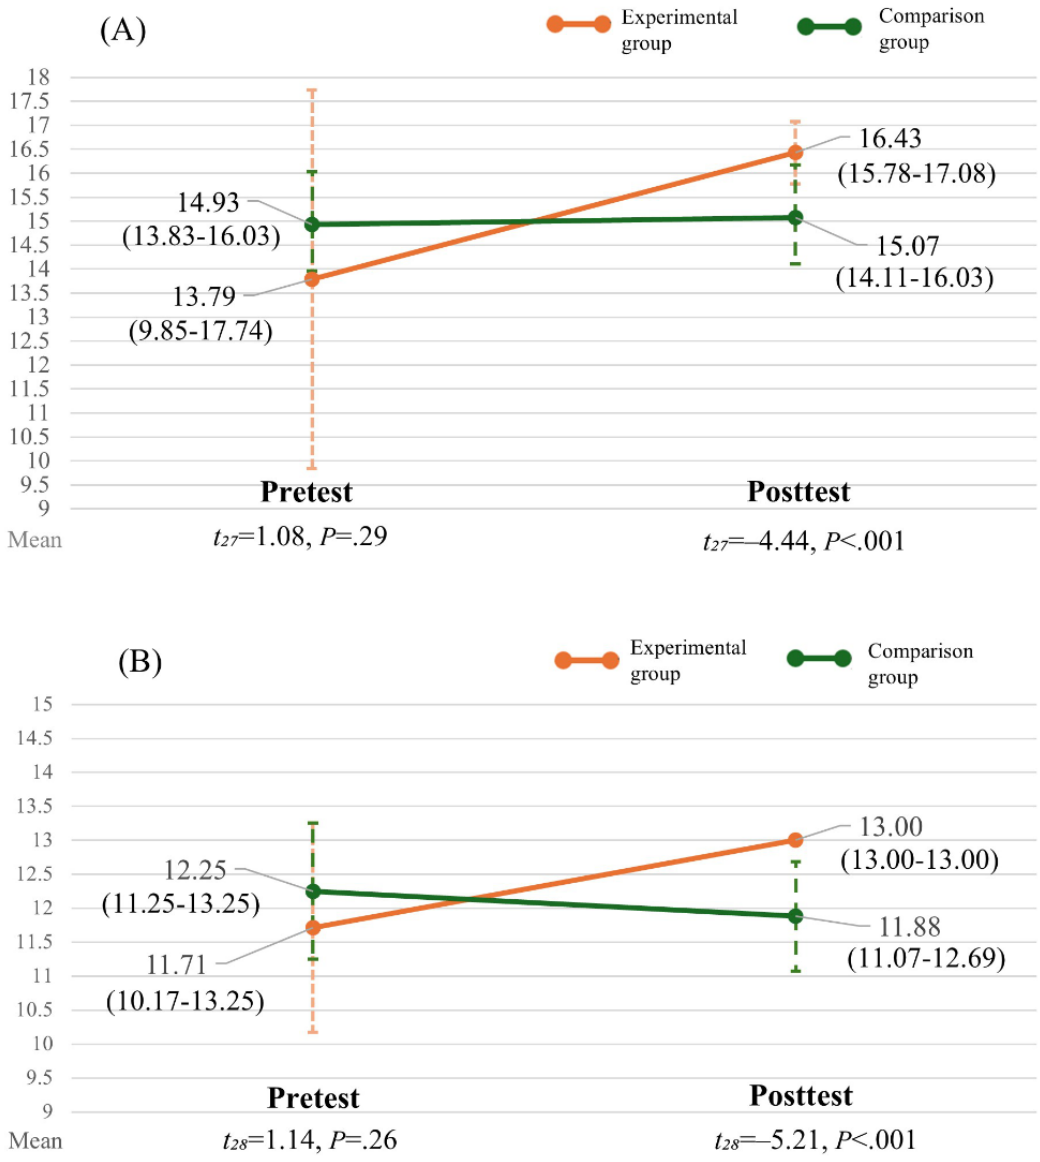

Table 2 shows how both groups' results changed over time. After age adjustment, the GEE analyses demonstrated significant improvements in CKD-specific HL (*P*=.02) and disease knowledge (*P*=.001) in the experimental group compared with the comparison group. A significant group ×time interaction was observed for both CKD-specific HL and disease knowledge. Specifically, the experimental group showed improvements in HL (coefficient=2.51, Wald χ^2_1=5.89; *P*=.02) and disease knowledge (coefficient=1.66, Wald χ^2_1=11.75; *P*=.001).

[a]CKD: chronic kidney disease.

[b]Reference group (group): comparison group.

[c]Reference group (time): pretest.

[d]Reference group (group × time): comparison group × pretest.

The group differences in patterns of change over time shown in Table 2 also demonstrated that the experimental group had significant improvements in the scores for communicative literacy (coefficient=1.26, Wald χ^2_1=6.17; *P*=.01) and critical literacy (coefficient=0.99, Wald χ^2_1=5.68, *P*=.02) compared with the comparison group, but functional literacy did not significantly improve. Regarding CKD-specific disease knowledge, the experimental group showed significant improvement in medication (coefficient=0.80, Wald χ^2_1=13.32; *P*<.001) compared with the comparison group, but there were no significant changes in areas such as basic knowledge, prevention, lifestyle, or dietary intake.

Discussion

Principal Findings

This study demonstrated preliminary evidence to support interactive robot-assisted virtual health coaching as an intervention tool for patients with CKD. Notably, participants in the experimental group showed significant improvements in both HL and disease knowledge compared with those in the comparison group. The experimental group was significantly younger than the comparison group, which may have influenced their receptiveness to the technology. However, prior studies indicate that older adults generally exhibit similar attitudes toward robots to those of younger individuals, challenging the stereotype of their lower robot-related receptiveness [29]. Furthermore, older adults often prefer human-like robots, such as the Kebbi robot, highlighting the importance of robot design and appearance in fostering acceptance [30,31]. These findings indicate that technology-enhanced educational interventions can effectively enhance HL and disease knowledge, which are associated with improved CKD-related outcomes.

The improvements observed in CKD-specific HL and disease knowledge were consistent with the benefits of technology-supported health education programs. Previous studies have shown that interactive digital interventions, particularly personalized coaching, can boost patient engagement and improve health outcomes [32,33]. This study builds on previous research by demonstrating the effectiveness of interactive robot-assisted virtual health coaching in managing chronic diseases. Our multidisciplinary approach included health professionals such as nephrologists and nurse practitioners, whose clinical experiences were integrated into the course content and represented by virtual health coaches [34]. Previous research has shown that avatar-based education has a positive effect on patient engagement and HL, which aligns with our findings [35].

A literature review of digital health coaching for older workers highlighted how virtual health can support healthy aging [36]. Although said review focused on a different group, it showed that digital interventions could effectively enhance health knowledge and well-being, especially when adopting a user-centered approach. This aligns with the findings of our study, which designed the intervention using health care professionals' clinical experiences with patients. By integrating these real-world interactions, the digital tools were tailored to address the practical needs and circumstances of patients with CKD, making the content more relevant and applicable. These results underscore the importance of health care professionals' insights when developing effective digital health interventions.

Participants in the experimental group showed significant improvements in communicative and critical literacy following the intervention, whereas functional literacy was not significantly changed. This pattern is consistent with the findings of a previous study in the Netherlands, which found that communicative HL and critical HL were more influential on chronic disease self-management, whereas functional literacy was less impactful [37]. Furthermore, a recent cross-national study involving geriatricians from Europe and Japan highlighted that virtual health interventions could enhance HL, emotional well-being, and social engagement among older adults, emphasizing the benefits of personalized digital coaching [38]. Our findings suggest that interactive virtual health coaching successfully supported patients in comprehending and using health information, making informed decisions, and critically evaluating health messages. However, the lack of improvement in functional literacy may be attributed to the program's emphasis on enhancing communication, lifestyle modifications, and decision-making skills rather than basic skills such as reading medical documents or interpreting health indicators. Additionally, certain robot interface-related limitations may have impeded the delivery of more comprehensive health information necessary for developing functional skills. Future iterations should include more comprehensive content on functional skills to address all aspects of HL, thereby enhancing its overall effectiveness.

In addition to literacy, this study evaluated the effectiveness of the intervention on CKD-specific knowledge. The results showed a significant improvement in medication use in the experimental group, whereas no notable changes were observed in other areas such as basic knowledge, prevention, lifestyle, or

XSL•FO
RenderX

dietary intake. This suggests that the program's structured content was particularly effective for teaching patients about medication. The materials, designed by health care professionals based on their clinical experiences, incorporated visual aids and interactive discussions, making the content more engaging and easier to understand. This aligns with the findings of Occa et al [39], who highlighted that interactive features and visual informativeness help improve patient knowledge by enhancing cognitive absorption. Similarly, Hassan and Davies [40] found that virtual health tools improve medication adherence by boosting patient HL and reducing barriers, emphasizing convenience and empowerment. The limited improvement in other CKD-related knowledge areas may have been due to the small sample size, which may have affected the statistical significance of our findings. Additionally, some participants reported that similar topics had already been covered in educational brochures, which might have reduced their motivation to engage fully. A more comprehensive approach that places greater emphasis on prevention, lifestyle changes, and dietary guidance is required to address these areas better.

Implications

This study has important implications for integrating digital health technologies into CKD education. Interactive robots, combined with a virtual health coaching program, have exhibited promise in enhancing HL and disease knowledge, particularly in resource-limited settings where health care resources are scarce and chronic disease management is challenging. By leveraging health care professionals' expertise and adhering to official health education guidelines, this study emphasizes the importance of creating standardized and engaging digital education tools that effectively meet patient education requirements. Furthermore, prior studies have demonstrated the potential of robots as impactful didactic tools in health science education, yielding promising results for enhancing cognitive therapies and facilitating health care intervention [41,42]. Expanding the use of such innovations may contribute to more effective patient education, improved disease knowledge, and enhanced HL, ultimately leading to improved CKD management.

Limitations

Despite these promising findings, this study had several limitations. First, participants in the experimental group were significantly younger than those in the comparison group, partly due to recruitment challenges during the COVID-19 pandemic, which hindered the enrollment of a sufficient number of older participants. Although age differences were controlled in the GEE analysis, which helped mitigate their impact, they remain a potential source of bias. Future research should further explore age-related differences, potentially incorporating multivariable analyses, to better understand and minimize their effects, ensuring the findings' broad applicability. This study primarily aimed to evaluate intervention effectiveness. Though digital literacy gaps related to age differences were not the primary focus, they represent an important area for future research.

The relatively small sample size limited the findings' generalizability, and 1-on-1 recruitment made larger sampling challenging. Statistical power was not explicitly considered during the study's design due to the lack of feasibility data, which accounts for the absence of a formal power calculation. Future studies should prioritize power analysis and incorporate larger sample sizes to confirm these results and enhance external validity. Additionally, the quasiexperimental design limited our ability to draw causal conclusions, suggesting that future research should use randomized controlled trials to strengthen causal inferences.

Another limitation involved the Taiwanese CKD population's unique characteristics, including dietary habits, medication use (eg, traditional Chinese medicine), and lifestyle factors, which may limit the findings' applicability to other populations. These cultural differences introduce potential biases, and future research should consider these factors to improve the results' generalizability.

Conclusions

This study demonstrated that interactive robot-assisted virtual health coaching could potentially enhance CKD management by improving disease knowledge and HL. To our knowledge, this is the first study to use an interactive robot for CKD health education, presenting a novel approach that alleviates the burden on health care professionals. Developed by a multidisciplinary team, the program delivers standardized, credible education while engaging patients in their care. The findings emphasize the scalability of digital health solutions, particularly in resource-limited settings, offering a valuable tool for nephrology practices. Future research should validate these results across diverse populations, examine the long-term effects on HL and disease outcomes, and refine the intervention based on patient feedback to optimize its content and usability. Integrating digital tools into clinical practice could significantly advance patient education and chronic disease management.

Abstract

Background: Improving adherence to pre-exposure prophylaxis (PrEP) via digital health interventions (DHIs) for young sexual and gender minority men who have sex with men (YSGMMSM) is promising for reducing the HIV burden. Measuring and achieving effective engagement (sufficient to solicit PrEP adherence) in YSGMMSM is challenging.

Objective: This study is a secondary analysis of the primary efficacy randomized controlled trial (RCT) of Prepared, Protected, Empowered (P3), a digital PrEP adherence intervention that used causal mediation to quantify whether and to what extent intrapersonal behavioral, mental health, and sociodemographic measures were related to effective engagement for PrEP adherence in YSGMMSM.

Methods: In May 2019, 264 YSGMMSM were recruited for the primary RCT via social media, community sites, and clinics from 9 study sites across the United States. For this secondary analysis, 140 participants were eligible (retained at follow-up, received DHI condition in primary RCT, and completed trial data). Participants earned US currency for daily use of P3 and lost US currency for nonuse. Dollars accrued at the 3-month follow-up were used to measure engagement. PrEP nonadherence was defined as blood serum concentrations of tenofovir-diphosphate and emtricitabine-triphosphate that correlated with ≤4 doses weekly at the 3-month follow-up. Logistic regression was used to estimate the total effect of baseline intrapersonal measures on PrEP nonadherence, represented as odds ratios (ORs) with a null value of 1. The total OR for each intrapersonal measure was decomposed into direct and indirect effects.

Results: For every US $1 earned above the mean (US $96, SD US $35.1), participants had 2% (OR 0.98, 95% CI 0.97-0.99) lower odds of PrEP nonadherence. Frequently using phone apps to track health information was associated with a 71% (OR 0.29, 95% CI 0.06-0.96) lower odds of PrEP nonadherence. This was overwhelmingly a direct effect, not mediated by engagement, with a percentage mediated (PM) of 1%. Non-Hispanic White participants had 83% lower odds of PrEP nonadherence (OR 0.17, 95% CI 0.05-0.48) and had a direct effect (PM=4%). Participants with depressive symptoms and anxiety symptoms had 3.4 (OR 3.42, 95% CI 0.95-12) and 3.5 (OR 3.51, 95% CI 1.06-11.55) times higher odds of PrEP nonadherence, respectively. Anxious symptoms largely operated through P3 engagement (PM=51%).

Conclusions: P3 engagement (dollars accrued) was strongly related to lower odds of PrEP nonadherence. Intrapersonal measures operating through P3 engagement (indirect effect, eg, anxious symptoms) suggest possible pathways to improve PrEP adherence DHI efficacy in YSGMMSM via effective engagement. Conversely, the direct effects observed in this study may reflect existing

structural disparity (eg, race and ethnicity) or behavioral dispositions toward technology (eg, tracking health via phone apps). Evaluating effective engagement in DHIs with causal mediation approaches provides a clarifying and mechanistic view of how DHIs impact health behavior.

Introduction

Background

Young sexual and gender minority men who have sex with men (YSGMMSM) are burdened with a disproportionate and growing vulnerability to HIV in the United States [1-8]. Of the 30,692 incident HIV cases in 2020, 71% were among men who have sex with men (MSM) and 24% were among MSM aged 13 to 24 years [8]. In addition, a meta-analysis of transgender women aged ≥15 years found that they were 48 times more likely to have HIV infection compared to other adults of reproductive age [1]. While pre-exposure prophylaxis (PrEP) has demonstrated efficacy in reducing the incidence of HIV infections in YSGMMSM in the US in randomized controlled trials (RCTs) [9,10], adherence to these medications outside of clinical trial settings has been suboptimal for reducing transmission [9,11]. Furthermore, findings from population and agent-based simulation studies demonstrate that PrEP uptake and adherence are associated with a decrease in incident HIV infections, lowering incidence by as much as 25% [12,13]. Altogether, this suggests that improving PrEP adherence is a fruitful pathway to reducing HIV incidence in YSGMMSM [9,11-13].

Digital health interventions (DHIs) are potentially powerful and increasingly prevalent mechanisms for delivering PrEP interventions to YSGMMSM [14-20]. Due to the pervasiveness of digital communication and entertainment among youth, including YSGMMSM, DHIs are suitable delivery mechanisms for HIV prevention interventions due to their potential to effectively engage participants [21-25]. However, to our knowledge, there is a paucity of clinical trials directly testing the efficacy of digital PrEP adherence interventions. Adjacent digital PrEP adherence interventions, such as automated SMS text-messaging services or digital pill systems, have had mixed results in young populations. For example, digital pill systems have documented barriers to engagement and have not shown that they independently improve PrEP adherence compared to a standard of care [26-29]. Furthermore, DHIs implemented to address other health problems in target youth populations have encountered problems in effectively engaging the participants. For example, 1 study that developed a mobile app for self-management of type 1 diabetes among adolescents found no association between intervention conditions and primary or secondary clinical outcomes. Furthermore, the study found that only 9% of the participants met the criteria for high engagement levels (measured as an individual uploading blood glucose readings for ≥3 d/wk) [30]. For these reasons, effectively engaging YSGMMSM in PrEP adherence DHIs is likely an essential element to achieving protective levels of PrEP adherence [25,31,32].

The effective engagement framework by Yardley et al [25] defines effective engagement as "sufficient engagement with the intervention to achieve intended outcomes." They describe four phases of engagement as follows: (1) initial engagement with the DHI in preparation for behavior change; (2) engagement with the behavior change, mediated by the DHI; (3) DHI use may no longer be required to sustain behavior change; and (4) reengagement with DHI as needed. Furthermore, this framework describes how, in phase 1, effective engagement is largely characterized by a micro form of engagement (defined by moment-to-moment interactions with the DHI). As individuals progress through phases 2, 3, and 4, they are increasingly engaged with a macro form of engagement (defined as engagement that relates to the overarching goal of the intervention).

The effective engagement framework by Yardley et al [25] also highlights how intrapersonal, social, and environmental characteristics can influence effective engagement and how tailoring DHIs based on those characteristics may improve effective engagement. Tailoring, defined as the use of individuals' data to customize intervention content based on their psychological, socioecological, and behavioral profile, is a property of DHIs that has demonstrated efficacy in promoting effective engagement with DHIs [25,33-37]. Several barriers and facilitators to engagement have been identified in qualitative research [38]. For example, baseline motivation to change [25,39] or baseline comfort with the intervention modality (eg, phone or app-based intervention) may influence engagement and subsequent behavior change [38-49]. Furthermore, aspects beyond the individual's control, such as internet access, may influence engagement and therefore intervention efficacy [38,50-52]. However, there is a lack of quantitative research that aims to isolate and quantify the impact that intrapersonal psychological, sociodemographic, and behavioral measures have on engagement and subsequent behavioral outcomes of interest.

Yardley et al [25] and other review articles using their effective engagement framework describe a plethora of issues with quantitively operationalizing and measuring effective engagement in previous research. Most notably, engagement research to date is largely correlational, relies on the assumption

XSL•FO
RenderX

that engagement is intrinsically a precursor to the intended outcome, and does not account for intrapersonal measures, such as motivation to use the intervention or digital literacy [25,31,32,39,53-55]. This highlights the need to empirically test and corroborate the models of engagement, by modeling how intrapersonal measures influence engagement, which subsequently mediates behavioral outcomes of interest (eg, PrEP adherence) [25,53,56]. Causal mediation analysis is a fitting statistical framework for investigating the relationship between intrapersonal measures and effective engagement which addresses the aforementioned methodological issues as well. Causal mediation has been extensively explicated [57-62], applied in previous research in other domains [63], and addresses the aforementioned issues by Yardley et al [25] by clarifying assumptions needed for causal inference in mediation models, explicitly modeling the relationship between engagement and outcome (as opposed to relying on the assumption that engagement and the outcome are related), and incorporates intrapersonal measures (as exposures or controls) [57,58,60]. This approach is derived from the counterfactual causal inference framework [64,65] and allows for the total effect (eg, the effect of baseline digital literacy on PrEP adherence) to be decomposed into a direct and indirect effect. The direct effect models the effect of a given intrapersonal measure on PrEP adherence controlling for engagement with the intervention. Conversely, the indirect effect models how a given intrapersonal measure is related to PrEP adherence operating through engagement, and thus, is an excellent measure of effective engagement. The integration of the effective engagement framework with the casual mediation approach provides a combined theoretical and analytical approach for evaluating effective engagement in DHIs.

This Study

This study collates clinical survey data, biological PrEP adherence measures, and engagement measures from the Prepared, Protected, Empowered (P3) intervention efficacy RCT [19,66] in a secondary data analysis using the causal mediation framework [57-62] to quantify whether and to what degree intrapersonal behavioral, mental health, and sociodemographic measures impact effective engagement with respect to PrEP adherence in YSGMMSM.

Methods

Study Design

This study is a secondary analysis, which combined clinical survey data, biological PrEP adherence measures, and engagement measures collected from a 3-arm RCT testing the efficacy of P3, a PrEP adherence DHI [19,66]. This secondary analysis used the causal mediation framework and statistical analysis procedures to characterize whether engagement with the P3 intervention mediated the relationship between baseline intrapersonal measures and PrEP adherence at 3 months.

Ethical Considerations

The parent study was reviewed and approved by the institutional review board of the University of North Carolina at Chapel Hill (17-9551). A certificate of confidentiality was obtained from the Eunice Kennedy Shriver National Institute of Child Health and Human Development. For participants aged between 15 and 17 years, a waiver of parental consent was obtained. This trial is registered at ClinicalTrials.gov (NCT03320512). This secondary analysis was reviewed by the Northeastern University institutional review board and determined to be exempt under category 4 (secondary research for which consent is not required). This secondary analysis used a deidentified analytic dataset curated by the parent study's staff. The principal investigator had no contact with participants and made no attempts to reidentify participants post hoc.

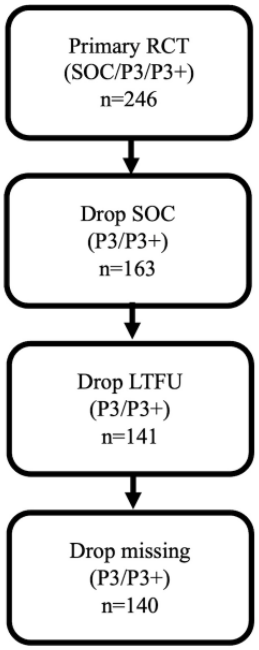
Parent Study

Intervention

P3 is a user-centered PrEP adherence phone app that incorporates a variety of content in multiple formats to serve the diverse needs, barriers, and motivations of YSGMMSM. This phone app included text, videos, quizzes, and a social wall where participants could share experiences, from success stories to challenges. In addition, P3 incorporated game-like elements, such as daily health-related quests, in-app rewards, unlocking character-driven narratives, and social connection activities. P3 used a financial incentive to encourage daily use in which small monetary incentives are awarded for daily use of P3 (not necessarily PrEP). Participants started with an initial bank of US $90 and then were awarded US $0.50 for each day on which they logged into P3 and completed one of the following tasks: (1) post on the social wall, (2) use the medication tracker, or (3) complete a quest. Each of these tasks corresponds to a putative behavior change mechanism (social support, instrumental support, and gamification, respectively). Conversely, US $1 was deducted for each day on which the participant did not log in and complete 1 of the aforementioned tasks across the 90-day trial period. The maximum a participant could earn was US $135 and the minimum was US $0. P3+ is an extension of P3, in which participants were also connected with an adherence counselor trained on the Next Step Counseling adherence counseling curriculum through the P3 phone app [19,66-68].

Clinical Trial Eligibility and Procedures

Starting in May 2019, participants were recruited from 9 study sites as follows: Tampa, Florida; Boston, Massachusetts; Chicago, Illinois; Houston, Texas; Philadelphia, Pennsylvania; Chapel Hill, North Carolina; Atlanta, Georgia; Bronx, New York; and Charlotte, North Carolina. A mix of in-person, venue-based, and web-based recruitment methods was used. Inclusion criteria were as follows: individuals (1) who were aged between 16 and 24 years, (2) who were assigned male sex at birth, (3) who reported sex with or intentions to have sex with men or transwomen, (4) who had reliable daily access to an Android (Google LLC) or iOS (Apple Inc) smartphone with a data plan, (5) who could speak and read English, (6) who were HIV-uninfected (confirmed by self-report at enrollment visit), and (7) who were not on PrEP but planned to initiate in the next 7 days and had an active PrEP prescription (prescription confirmed by study staff) or those who were currently on PrEP who had an active PrEP prescription (prescription confirmed by study staff). After providing informed consent either in



XSL•FO
RenderX

person or electronically, participants were randomized to 1 of the 3 treatment arms (standard of care, P3, or P3+) using a 1:1:1 randomization scheme. Clinical survey assessments and laboratory specimens were collected at baseline and 3 months into the trial period. Engagement measures (in the 2 intervention arms) were collected continuously throughout the intervention period and summarized at 3 months [19]. Study visits were initially planned to be conducted in person at the same study site where participants enrolled. All study sites stopped in-person study activities on March 17, 2020, to reduce the transmission of COVID-19. Web-based recruitment and web-based study activities began in June 2020. In addition, some study sites were able to conduct limited in-person activities based on local regulations and COVID-19 restrictions. The trial concluded in September 2021.

Secondary Analysis Eligibility

Participants from the primary study who received the P3 or P3+ intervention were eligible for inclusion in this secondary data analysis (n=163). Participants in the P3 and P3+ conditions who were lost to follow-up (LTFU; defined as participants who did not begin the month 3 survey) were excluded (22/163, 13.5%). Moreover, 1 (0.7%) of the remaining 141 participants with incomplete survey information pertaining to study-relevant exposure measures was also removed. This resulted in a dataset of 140 participants (Figure 1).

Figure 1. Primary Prepared, Protected, Empowered (P3) randomized controlled trial (RCT) participants' eligibility for inclusion in this study and secondary analysis of effective engagement with respect to pre-exposure prophylaxis adherence in young sexual and gender minority men who have sex with men. LTFU: lost to follow-up; SOC: standard of care; P3+: extension of Prepared, Protected, emPowered.

Outcome: PrEP Nonadherence

PrEP nonadherence at 3 months (binary) was the primary outcome measure used in this analysis. If serum levels of tenofovir-diphosphate and emtricitabine-triphosphate were consistent with ≤4 doses per week, the participant was considered nonadherent. Due to study operation interruptions related to the COVID-19 pandemic, 28.6% (40/140) of eligible participants were unable to provide biological specimens. In cases where tenofovir-diphosphate and emtricitabine-triphosphate values were missing, self-reported doses of PrEP in the last 7 days before the 3-month clinical survey were used. Participants who reported ≤4 self-reported doses of PrEP in the last 7 days were considered nonadherent. There is mixed evidence regarding the accuracy of self-reported measures of PrEP adherence. While 2 studies have found that self-report measures of PrEP adherence correlate with protective serum levels among adults [69,70], another study examining self-report PrEP adherence measure accuracy among 15 to 23-year-old young MSM found that self-reported measures overreported adherence compared to biological specimens, with the odds of overreporting decreasing by 24% (odds ratio [OR] 0.74, 95% CI 0.65-0.90) with each additional year of age [71]. We found that the area under the receiver operating characteristics curve between self-report measures and biological measures among participants with biological and self-report PrEP nonadherence measures was high (≥0.7). Further details are described in the Strengths and Limitations section.

Mediator: Intervention Engagement

Engagement was defined as dollars accrued by 3 months. This measure was mean centered (participant dollars accrued—mean dollars accrued) when used in modeling. As mentioned in the Intervention subsection, participants started with a baseline amount of US $90 in a bank and gained or lost money from this initial bank based on the number of days each participant logged in and completed one of the 3 aforementioned tasks (eg, completing a quest). This measure serves as a quality proxy for engagement because it correlates with the behavior pattern P3 aims to adjust (ie, daily use of P3 mimics the daily dosing pattern of PrEP) and relates to the putative behavior change mechanisms used in the P3 app (eg, completing a quest is related to gamification and posting on the social wall is related social engagement). Engagement measures derived from documenting

XSL•FO
RenderX

users' access, participation, and navigation through a DHI are suitable for constructing measures of engagement, as these measures provide an objective view into patterns of use with high ecological validity [25,31,32].

Intrapersonal Measures

Consistent with Yardley et al [25], several intrapersonal measures capturing experiences with phone and phone apps, mental health, and sociodemographic characteristics were constructed from the baseline survey administered in the primary RCT based on prior research [25,38]. These measures, described subsequently, focused on patterns of phone and phone app use, measures of mental health, and sociodemographic information.

Phone and Phone App Use

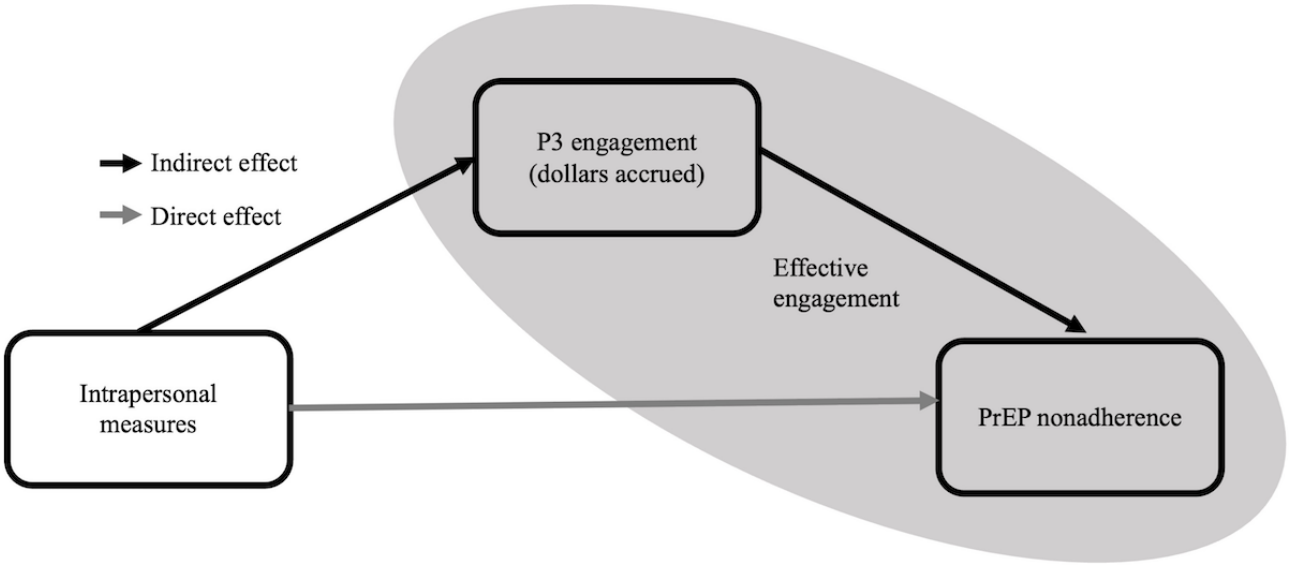
Several binary measures describing phone and phone app use were derived from the baseline survey. A participant was considered to have experienced disconnects if they lost access to their phone or phone service at any time in the year leading up to the baseline survey. Prior qualitative research identified poor internet access as a barrier to engagement in DHIs [38,40-42,45,48,50-52,72]. Those who spent an average of ≥7 hours per day on the internet outside of work or school were considered high internet users. Those who used phone apps ≥2 times per day were considered frequent phone app users. These measures acted as proxy variables for digital literacy and digital familiarity, which have been shown to act as engagement facilitators in qualitative research [34,39-49,73-75]. Binary measures describing participants' propensity to use phone apps for a variety of purposes were derived from questions whose answers follow a Likert scale with the following ranked choices: never, rarely, sometimes, often, and decline to answer. Participants who disclosed that they "often" use phone apps for chatting with friends, chatting with family, looking for romantic dates, looking for casual sex, or tracking their health were considered highly interested in using phone apps for those activities. Previous qualitative research has identified social support in various forms enabled through a DHI as an engagement facilitator [38,44,46,47,76,77]. Finally, a binary measure representing the intervention arm (P3 or P3+) was constructed to be used as a control measure.

Mental Health

The Patient Health Questionnaire-8 (PHQ-8) [78,79] and Generalized Anxiety Disorder-7 (GAD-7) [80] questionnaires were used to assess depressive and anxiety symptoms, respectively. Both scales asked participants to rank how frequently they experience symptoms from not at all, several days, more than half the days, and nearly every day. Scores ranged from 0 to 24 in the PHQ-8 and 0 to 21 in the GAD-7, with lower scores representing less frequent experiences and higher scores representing more frequent experiences of depressive and anxious symptoms, respectively. Participants who scored ≥10 on the PHQ-8 and GAD-7 were considered to have depressive or anxious symptoms, respectively [79-81]. Previous research has identified that psychological distress from trauma is associated with lower engagement, which suggests that other stressors on mental health may also act as barriers to engagement [82]. Furthermore, symptoms of depression have been consistently linked to lower treatment adherence [83], and symptoms of depression and anxiety have been found to be associated with a higher likelihood of medication nonadherence [84].

Sociodemographic Measures

Sociodemographic measures captured from the baseline survey include race, ethnicity, and age. Participants were considered non-Hispanic White if they disclosed non-Hispanic ethnicity and White as their race. In previous research, sociodemographic measures had mixed effects on engagement [85-92]. For example, older age has been observed as an engagement facilitator and an engagement barrier in different studies [85,86]. These measures were used to control for confounding (further specifications are given subsequently) and investigated as exposures of interest for their relationship with effective engagement.



Statistical Analysis

Descriptive statistics for participants who were eligible for secondary analysis were generated and are reported in the Results section. There is also a comparison of 140 eligible participants to the 22 participants who were LTFU. To quantify how engagement with P3 mediates the relationship between baseline intrapersonal measures and PrEP nonadherence at 3 months, the causal mediation framework was used. This analytical approach extends the counterfactual causal inference framework to mediation, has been extensively explicated, clarifies several confounding assumptions, accommodates exposure-mediator interaction [57-62,93], has been applied in previous research [63], and complements the effective engagement theoretical framework by explicitly decomposing the total effect of each intrapersonal measure on PrEP nonadherence into a direct and indirect effect (ie, the effect mediated by P3 engagement). Figure 2 depicts the integration of effective engagement and causal mediation through a theoretical causal diagram. In this study, effect decomposition was accomplished by first fitting a linear regression to assess the effect of each exposure (eg, anxious symptoms) on the mediator (mean-centered dollars accrued at 3 months), adjusting for confounding. Then, a logistic model was fit to examine the relationship between each exposure (eg, anxious symptoms) and PrEP nonadherence, adjusting for the same confounders, dollars accrued at 3 months (ie, the mediator), and the exposure-mediator interaction. Baseline measures, such as age, race, and intervention arm, were used to adjust for confounding. Several other critical measures were controlled through the primary study's design via the eligibility criteria. Intention to initiate PrEP, PrEP access, sexual orientation, and English literacy were verified at enrollment. The total effects estimated from these 2 models with corresponding CIs and *P* values are reported in the Results section. The total effect for each intrapersonal measure on PrEP nonadherence at 3 months is presented as an OR (defined as the rate of nonadherence in the exposed divided by the rate of nonadherence in the unexposed). These 2 regression models are then used to derive direct and indirect effects. The direct effect represents the effect of a given intrapersonal measure on PrEP nonadherence independent of P3 engagement. This effect is estimated by comparing the

XSL•FO
RenderX

estimated PrEP nonadherence in the exposed relative to the unexposed while setting P3 engagement to the level that would have naturally occurred in the absence of the exposure. The indirect effect represents the effect of a given intrapersonal measure on PrEP nonadherence operating through the mediator. This effect is estimated by comparing the outcome for the exposed for different contrasts of the mediator (eg, between levels of P3 engagement). Mediation results, including direct and indirect effects with corresponding CIs and percentage mediated (PM) are reported in the Results section. Mediation is assessed using a combination of total and indirect effect size, statistical significance, and PM. *P* values are reported for transparency, but CIs are used as the primary determinant of statistical significance for mediation analysis, determined by if the CI overlaps with the null value. For the first model (linear regression of dollars accrued), the null value is 0, and for the second model (logistic regression of binary PrEP adherence), the null value is 1. All analyses were carried out using R (GNU) and RStudio (Posit, PBC). Mediation models were constructed using the *CMAverse* R library using the regression-based approach and imputation as the estimation method [94].

Figure 2. Integration of effective engagement and causal mediation frameworks in a causal diagram. Direct effects represent relationships between intrapersonal measures and pre-exposure prophylaxis (PrEP) adherence controlling for engagement with Prepared, Protected, Empowered (P3). Indirect effects represent relationships between intrapersonal measures and PrEP adherence operating through P3 engagement (ie, mediated effects).

Results

Participant Characteristics

The median age of participants was 22 years (IQR 20-23). Overall, 17.1% (24/140) were considered nonadherent to PrEP at 3 months (Table 1). The minimum amount the participants earned over the 90-day trial period was US $1.5 (representing 1 day logged in with a task completed). The maximum amount the participants earned over the 90-day trial period was US $135 (corresponding to logging in and completing a task every day for the 90-day trial period). Participants earned a mean of US $96.40 (SD US $35.1) over the 90-day trial period. Participants earned a median of US $112.50 (IQR US $73.50-US $ 123.50) which corresponds to 75 days logged in with a task completed (IQR 49-82) over the 90-day trial period. Participants were largely heterogeneous with respect to phone, technology, and internet use patterns. Notable exceptions to this pattern were as follows: 90.7% (127/140) of the participants used phone apps more than once per day and 90.7% (127/140) of the participants disclosed that they often use phone apps for chatting with friends. No significant differences in selected baseline intrapersonal characteristics were observed between eligible and LTFU participants (Table 1).

[a]Continuous measures tested with 2-tailed *t* tests, categorical measures tested with Fisher exact test.

[b]LTFU participants did not return for 3-month PrEP adherence data collection.

[c]For nonnormal distribution, the Kruskal-Wallis rank sum test was used.

Multivariate Analysis

Table 2 presents multivariate regression results for the effect of intrapersonal measures on engagement (dollars accrued by 3 months). Frequent phone app users earned US $21.49 (95% CI 2.50-40.47) more than infrequent phone app users through the 3-month trial period. Participants who reported anxious symptoms in the past 2 weeks (GAD-7 score≥10) earned US $15.95 (95% CI –31.57 to –0.32) less throughout the 3-month trial period than those with mild or no anxious symptoms in the past 2 weeks. Non-Hispanic White individuals earned US $17.02 (95% CI 5.95-28.10) more on average by 3 months than participants belonging to other racial and ethnic groups. Participants who received the P3+ intervention (P3 with the addition of human adherence counselors accessible through the app) earned US $12.48 (95% CI 1.47-23.50) more on average than those who received the standard P3 app through the 3-month trial period. Finally, for each additional year of age, participants earned on average an additional US $2.55 (95% CI –0.19 to 5.29). The 95% CI for the relationship between age and engagement narrowly overlaps the null value of 0 with a corresponding *P* value of .07, meaning this relationship is technically statistically insignificant.

[a]Multivariate models are adjusted for age, race/ethnicity, and intervention arm.

[b]Null value is 0.

[c]OR: odds ratio.

[d]Derived by exponentiating estimated regression coefficients.

[e]Null value is 1.

[f]Not available.

[g]Intrapersonal measure is also a control measure. Model constructed using age, race, and intervention arm for engagement and age, race, ethnicity, intervention arm, dollars accrued at 3 months, and dollars accrued at 3 months and the interaction between dollars accrued at 3 months and the focal intrapersonal measure.

Multivariate models are adjusted for age, race, ethnicity, intervention arm, dollars accrued at 3 months, and dollars accrued at 3 months and the interaction between dollars accrued at 3 months and the focal intrapersonal measure.

Total effects for the relationship between baseline intrapersonal measures and PrEP nonadherence at 3 months are reported in Table 2 as ORs. For every dollar earned above the mean throughout the 3-month trial period, participants had 2% (OR 0.98, 95% CI 0.97-0.99) lower odds of PrEP nonadherence at 3 months. Participants who reported using phone apps ≥2 times per day had 34% lower odds of PrEP nonadherence at 3 months (OR 0.66, 95% CI 0.17-2.88). Participants who spent >7 hours on the internet beyond work or school had 2.31 (95% CI 0.80-6.46) times higher odds of PrEP nonadherence at 3 months compared to participants who reported <7 hours on the internet beyond work or school. Both of these measures that aimed to describe broad patterns of phone and internet use had a relatively large effect on the odds of PrEP nonadherence. However, neither was statistically significant as the 95% CI covers the null value of 1. Participants who reported at least 1 disconnect from their internet service or phone in the past year had 3.84 (95% CI 1.14-12.81) times higher odds of PrEP nonadherence at 3 months than participants who reported no disconnects. Participants who reported that they frequently used phone apps to track their personal health information had 71% (OR 0.29, 95% CI 0.06-0.96) lower odds of PrEP nonadherence at 3 months. Participants who reported depressive symptoms (PHQ-8 score ≥10) had 3.42 (95% CI 0.95-12) times higher odds of PrEP nonadherence at 3 months. Participants who reported anxious symptoms also had 3.51 (95% CI 1.06-11.55) times higher odds of PrEP nonadherence at 3 months. Participants who reported their race and ethnicity as non-Hispanic White had 83% (OR 0.17, 95% CI 0.05-0.48) lower odds of PrEP nonadherence at 3 months. For each additional year of age, participants had 18% (OR 0.82, 95% CI 0.65-1.02) less odds of PrEP nonadherence at 3 months. The 95% CI for the relationship between age and PrEP nonadherence narrowly overlaps the null value of 1 with a corresponding *P* value of .08, meaning this relationship is technically statistically insignificant.

Mediation Analysis

Total effects were decomposed into direct and indirect effects of intrapersonal measures on effective engagement (Table 3).

XSL•FO
RenderX

Experiencing disconnects in the past year was primarily directly related to higher odds of PrEP nonadherence at 3 months (PM=5%), with a direct effect of 3.28 (95% CI 0.91-11.42). Despite the statistically insignificant total effect, using phone apps ≥2 times per day was significantly indirectly associated with lower odds of PrEP nonadherence at 3 months (OR 0.76, 95% CI 0.49-1.00). Conversely, spending >7 hours on the internet beyond work or school resulted in primarily a direct relationship with lower odds of nonadherence (1.92, 95% CI=0.80-5.42; PM=18%). However, similar to the total effect on PrEP nonadherence, this relationship did not rise to the level of statistical significance for either the direct or indirect relationship. Frequently using phone apps to track health information was directly associated (0.3, 95% CI 0-0.92; PM=1%) with lower odds of PrEP nonadherence. Symptoms of depression had a statistically significant total effect on PrEP nonadherence and were partially mediated by engagement with P3 with a direct effect of 2.52 (95% CI 0.79-6.81), an indirect effect of 1.25 (95% CI 0.78-2.14), and a PM of 30%. However, neither the direct nor the indirect effect raised to the level of statistical significance on their own. Experiencing anxious symptoms was primarily indirectly related to higher odds of PrEP nonadherence through engagement with P3 (1.55, 95% CI 1-3.34; PM=51%). Being non-Hispanic White was directly related to lower odds of PrEP nonadherence (0.20, 95% CI 0.04-0.59; PM=4%). For each additional year of age, the odds of PrEP nonadherence were decreased, operating through both direct (0.95, 95% CI 0.68-1.02) and indirect (0.92, 95% CI 0.59-1.07; PM=60%) relationships.

Table 3. Direct and indirect effects of intrapersonal measures on effective engagement with Prepared, Protected, Empowered (P3), a pre-exposure prophylaxis adherence digital health intervention, among US young sexual and gender minority men who have sex with men youth aged between 16 and 24 years (n=140)[a].

	Direct effect (95% CI)[b]	Indirect effect (95% CI)[b]	Percentage mediated (%)[c]
High internet users	1.92 (0.80-5.42)	1.11 (0.84-1.55)	18
Disconnect from the phone in the past 12 months	3.28 (0.91-11.42)	1.04 (0.74-1.84)	5
Frequent phone app user	1.19 (0.37-6.03)	0.76 (0.49-1.00)	—[d]
Frequently uses of phone apps			
Chatting with family	1.23 (0.48-3.19)	0.83 (0.59-1.03)	—
Finding romantic dates	0.63 (0.19-2.25)	1.01 (0.80-1.16)	—
Looking for casual sex	0.74 (0.15-2.02)	1.05 (0.81-1.37)	—
Tracking health	0.31 (0-0.92)	0.98 (0.71-1.33)	1
Depressive symptoms	2.52 (0.79-6.81)	1.25 (0.78-2.14)	30
Anxiety symptoms	2.12 (0.58-5.49)	1.55 (1-3.34)	51
Non-Hispanic White[e]	0.20 (0.04-0.59)	0.84 (0.46-2.54)	4
Intervention arm: P3+[e]	1.34 (0.54-3.62)	0.84 (0.58-1.04)	—
Age[e]	0.95 (0.68-1.02)	0.92 (0.59-1.07)	60

[b]Null value is 1.

[c]Percentage mediated cannot be calculated when direct and indirect effects are in opposite directions.

[d]Not applicable.

[e]Intrapersonal measure is also a control measure. age, race, ethnicity, intervention arm, dollars accrued at 3 months, and dollars accrued at 3 months and the interaction between dollars accrued at 3 months and the focal intrapersonal measure.

Discussion

Principal Findings

Overview

This study leveraged data from the primary RCT testing the efficacy of P3, a digital PrEP adherence intervention, in a secondary data analysis that used the effective engagement framework by Yardley et al [25] to characterize whether and how engagement with P3 mediated the relationship between baseline intrapersonal measures and PrEP nonadherence at 3 months. This study found that several measures (eg, twice or more daily phone app use) were positively related to engagement, measured as dollars accrued by 3 months. In contrast, measures such as anxious symptoms were negatively related to engagement. Furthermore, this study found that P3 engagement, behavioral patterns of phone and app use, mental health symptoms, and sociodemographic measures were significantly related to PrEP nonadherence. Using causal mediation analysis, this study decomposed these total effects into direct effects to isolate the effect of each intrapersonal measure on PrEP adherence irrespective of P3 engagement and indirect effects to evaluate if and how each measure may be contributing to effective engagement with P3. This process helps to illuminate possible mechanisms that precipitate or protect against susceptibility to PrEP nonadherence.

XSL•FO
RenderX

Phone and Phone App Use

Digital literacy, defined as an understanding of how technology and digital media are used to communicate with others, has been linked to engagement in DHIs in both HIV and non–HIV-related domains [34,39-49,73-75,95]. Participant's propensity to use phone apps ≥2 times daily may or may not be a direct reflection of their digital literacy. However, this broader representation of their affinity to use phone apps empirically impacted their engagement with P3 (via dollars accrued at 3 months). Furthermore, despite a statistically insignificant total effect on PrEP nonadherence, the moderate to large reduction in odds of PrEP nonadherence combined with the statistically significant indirect effect from the causal mediation analysis suggest that participants' affinity to use phone apps could be a facilitator of effective engagement in the context of PrEP adherence DHIs. Conversely, participants who were categorized as high internet users had higher odds of PrEP nonadherence at 3 months, but this effect was not statistically significant. Furthermore, these participants did not significantly engage with P3 more or less than the average participant. The combination of these contrasting findings suggests that a minimum affinity for phone apps may be related to effective engagement, but time spent on the internet is likely not related to effective engagement. This aligns with theories of digital literacy which describe literacy as more of a minimum capacity to use and understand technology as opposed to merely time spent using it [95,96]. Furthermore, these results substantiate the recent trend of constructing validated and reliable scales of digital literacy [97-101]. Studies of effective engagement (such as this study) would benefit greatly from a scale that can measure and test relevant core constructs of digital literacy against effective engagement.

While this study did not have the opportunity to implement a reliable and validated scale of digital literacy, several measures captured more specific patterns of behavior with respect to phone apps, including using phone apps for dates, tracking health information, or chatting with one's family. Of these, frequently using phone apps to track health information significantly reduced the odds of PrEP nonadherence at 3 months. However, this effect was overwhelmingly a direct effect and participants who frequently use phone apps to track health information did not engage with P3 significantly more than average. This suggests that individuals who are prone to using apps for health tracking may be more health-conscious, independent of app use, and therefore more likely to adhere to PrEP. This aligns with the idea of health-specific digital literacy, sometimes referred to as "eHealth literacy," defined as "the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem" [95]. Previous work found that YSGMMSM with a high digital health literacy perceived the information of a DHI aimed to promote HIV and sexually transmitted infection testing as more useful when the intervention tailored information to the participants [34]. This study supports the hypothesis that health-related digital literacy is an important measure of DHI efficacy, especially when the content is tailored to the population the DHI is serving. Furthermore, this study suggests that while digital health literacy likely improves health outcomes through DHIs, it does not operate through an increase in engagement with the intervention itself. Instead, the baseline capacity for digital health literacy seems to act as a catalyst for the participant to incorporate the information presented in the DHI into their life.

Participants who experienced disconnects from their phone in the past year had higher odds of being nonadherent to PrEP at 3 months, overwhelmingly operating as a direct effect. Participants who experienced disconnects did not earn significantly more or less money than average throughout the trial period. This suggests that disconnecting from one's internet service is not a key engagement barrier. Instead, this measure likely reflects the broader social and structural environment in which a given participant exists. This aligns with previous work that has highlighted the difficulties in adapting DHIs to varying infrastructure levels (eg, low internet connectivity) [38,40-42,45,48,50-52,72,102-105]. Similarly, non-Hispanic White participants had significantly lower odds of being PrEP nonadherent at 3 months and earned significantly more money than average throughout the trial period. However, the effect this had on PrEP nonadherence was also largely direct, suggesting that despite the increase in superficial engagement did not drive the lower odds of PrEP nonadherence at 3 months. Therefore, it seems more likely that non-Hispanic White individuals are experiencing fewer social and structural barriers in life external to the intervention, which affords an easier adoption of adherence behaviors. Previous work reinforces this hypothesis, as significant adherence disparities have been found among Black patients relative to White patients in non-DHI settings [106-108]. Furthermore, previous research has also established that HIV disproportionately affects individuals who are economically disadvantaged [109]. Collectively, the results of this study combined with this body of literature suggest that measures of race and phone disconnects in this study represent structural characteristics that impact PrEP adherence DHI efficacy directly (ie, not through engagement). The implications of this finding align with a systematic review of qualitative studies on engagement conducted by O'Connor et al [38], which describes several recommendations for future DHI development and implementation. First, the systematic review by O'Connor et al [38] highlights the need for DHI developers to lessen the burden of self-care through DHIs. This aligns with our study, where the preponderance of direct effects suggests several mechanisms for tailoring that do not operate through an increase in DHI use. For example, DHIs may be able to adapt intervention elements to low internet connectivity environments (eg, allow participants to download any video content so that it is viewable offline). While this may not increase the engagement levels of those living in low internet connectivity environments to a level significantly above the average, it may allow those participants to interact with the DHI more meaningfully by consuming DHI content uninterrupted during an optimal time for the participant. Second, the systematic review recommends incorporating interpersonal relationships (eg, family, friends, and care providers) and public health institutions in designing, using, and implementing DHIs to mitigate the effects of structural disparities [38]. These recommendations align with the effective engagement framework by Yardley et al [25], which describes the increased

XSL•FO
RenderX

need for tailored approaches to consider the "contextual needs" of DHI participants in addition to traditional tailoring approaches centered on individual sociodemographic characteristics.

Mental Health

While past literature has highlighted the impact of DHIs on improving mental health outcomes, to our knowledge, this is the first study that directly measures the impact of baseline mental health symptoms on effective engagement in a study focused on a nonmental health–related outcome using a digital intervention [110,111]. A meta-analysis by DiMatteo et al [83] examined the link between symptoms of depression and anxiety on treatment adherence in a range of medical conditions (eg, cancer and asthma) and found that symptoms of depression were consistently linked to lower treatment adherence, while the relationship between anxious symptoms and lower treatment adherence were mixed (either small or null). However, Sundbom and Bingefors [84] found that symptoms of depression and anxiety were both linked to medication nonadherence in a more recent population study of Swedish adults. In this study, we similarly found that depressive and anxious symptoms increased the odds of PrEP nonadherence at 3 months in multivariate models. Despite both measures having significant total effects, only anxious symptoms were significantly indirectly related to PrEP nonadherence through lowered engagement. Broadly, there is a need for further research exploring the relationship between mental health conditions, DHI engagement, and PrEP adherence.

DiMatteo et al [83] suggest several hypotheses to explain the relationship between depression and lower treatment adherence. They note that symptoms of depression (depressed mood, feelings of hopelessness, diminished interest or pleasure in activities, sleep disturbances, and diminished ability to concentrate) may directly influence treatment adherence [78,79,83]. For example, if participants with depression are having difficulties concentrating, they may find it more difficult to remember to take PrEP every day as prescribed. They also suggest that depression may be related to social isolation and that social support may be related to better adherence. While depression has been linked to social isolation in young adults broadly [112-114], the literature examining the relationship between social support and PrEP adherence has shown mixed results across studies, where varying sources and kinds of social support show differing effects [115]. Furthermore, the provision of social support was one of the putative mechanisms in the P3 DHI. Future research may consider exploring how participants with symptoms of depression engage with specific features of DHIs to explore mechanisms for how depression impacts PrEP nonadherence. For example, participants with depression may only be engaging with the instrumental support modules (eg, medication tracker) or gamification elements (eg, quests) and avoiding the social elements (eg, social wall). Conversely, the social wall may not be enough or the right kind of social support, despite heavy engagement among participants with depression.

The impact symptoms of anxiety have on DHI engagement and efficacy is unclear. DiMatteo et al [83] note that the range in effect sizes and significance found in their meta-analysis may align with the large degree of heterogeneity in anxiety disorders. For example, symptoms associated with a panic disorder may be quite different from symptoms associated with obsessive-compulsive disorder. In this study, we measured symptoms associated with generalized anxiety disorder using the GAD-7 questionnaire, which measures symptoms of restlessness, feeling on edge, or irritability [80,116]. It is plausible that a generalized feeling of irritability or restlessness could negatively impact one's capability to complete daily tasks in P3. Furthermore, Sundbom and Bingefors [84] found that among men with anxiety, the stated reason for medication nonadherence with the largest effect size was fear of potential adverse drug reactions (OR 3.07, 95% CI 1.55-6.08). However, fearing an adverse drug reaction does not seem like a likely mechanism that can explain the lowered engagement among participants with anxiety using P3, as using a DHI has few, if any, documented risks or adverse reactions. This represents a largely unexplored dimension of DHI engagement research. Like depression, future work on DHI engagement and efficacy should assess the relationship between symptoms of anxiety disorders and specific DHI modules. This will help elucidate the mechanisms that diminish engagement among those with symptoms consistent with generalized anxiety disorder. Furthermore, while the GAD-7 questionnaire does not explicitly screen for social anxiety disorder, there is significant symptom overlap between these 2 conditions and a high degree of comorbidity, with previous clinical trial findings revealing that 57% to 77% of individuals aged between 7 and 17 years with generalized anxiety disorder also have social anxiety disorder [116-119]. One possible hypothesis to explore in future work is how social anxiety impacts engagement in DHIs with a heavy emphasis on social interaction (such as P3). A 2020 global study of social anxiety rates found that 58% of US individuals aged between 18 and 24 years had scores on the Social Anxiety Scale consistent with social anxiety (≥29) [120]. Due to the preponderance of individuals aged between 18 and 24 years with symptoms consistent with social anxiety, future work that aims to develop DHIs for adolescents and young adults should consider further explicating the role of social anxiety in DHI engagement and efficacy.

Strengths and Limitations

This study has several methodological and analytical strengths. The research design of the primary RCT is complementary to the theoretical constructs of effective engagement and causal mediation analysis. RCTs provide clear temporality, which is simultaneously necessary to establish effective engagement (ie, engagement leading to a downstream health outcome) and causal mediation analysis [25,57-60]. This study demonstrates the clarity causal mediation analysis provides to engagement research by disentangling total effects into direct and indirect effects, allowing a causal and mechanistic characterization of how baseline intrapersonal measures relate to effective engagement. This approach helps to avoid mischaracterizations that can occur with traditional regression techniques, as these techniques often model engagement as the outcome and rely on the assumption that an increase in engagement would precipitate an increase in the behavior change of interest. For example, quantitative research into medication adherence disparities has found disparities exist among racial or ethnic

XSL•FO
RenderX

groups after adjusting for other socioeconomic confounders [107], and qualitative research into engagement with DHIs has largely lacked a focus on race and ethnicity [38], which suggests that race and ethnicity might play a role in effective engagement for adherence DHIs. In this study, non-Hispanic White participants earned significantly more money than other trial participants (US $17) 3 months into the trial period. However, effect decomposition demonstrated that the effect of race and ethnicity on PrEP nonadherence was largely direct, suggesting that race and ethnicity is related to PrEP adherence irrespective of the observed increase in dollars accrued (ie, engagement) among non-Hispanic White participants. This example illustrates how traditional regression and causal mediation approaches would arrive at divergent conclusions based on the same data. Traditional approaches assume engagement leads to a behavior change, whereas causal mediation analysis estimates behavior change based on changes in engagement. In this example, given the results from the causal mediation analysis, it seems substantially more likely that reported non-Hispanic White race and ethnicity is a proxy for the systematic inequalities people of sexual, gender, racial, and ethnic minority face in the United States and that these inequalities propagate difficulties with PrEP adherence in ways P3 cannot or did not address.

One limitation of this study is the small and selective sample size. The small sample size limits the power to detect effects. This means that some of the null results in this study may in fact be more significant in a study with a larger sample. However, this also means that this study is likely a conservative measure of effective engagement. The significant results from this study which have relatively small effect sizes may in truth be much larger. Furthermore, 13.5% (22/163) of the eligible participants were LTFU, which is consistent with the primary P3 efficacy RCT, which observed 13% LTFU across all intervention conditions. Due to this, we believe that participants were not LTFU for reasons specific to study operations or intervention conditions. Similarly, the sample of individuals in the primary RCT is relatively homogenous (small age range, relatively high digital literacy, generally nonrural, and same sexual orientation). Therefore, the results of this study may or may not be generalizable to other populations. However, while this feature of the primary RCT limits generalizability, it also strengthens confounding assumptions necessary to carry out causal mediation analysis. By having a more homogenous sample, many of the measures that may have been conceived as confounders have been controlled for through the primary RCT's study design, such as sexual orientation and English literacy. Furthermore, while several aspects of the population are homogenous, there is a high degree of geographic diversity as the primary RCT was carried out at 9 study sites. Another limitation is the degree of missingness in the biological measures of adherence. Before the COVID-19 pandemic, participants completed study activities in person at study sites, which included the collection of biological specimens by study site staff. Once COVID-19 restrictions were in place and study activities resumed, most activities were completed remotely to enable the continuation of data collection. Participants were asked to complete the at-home dried blood spot collection. The change from site-directed biological specimen collection to dried blood spot self-collection likely impacted the amount of missing biological specimen data. However, self-report measures are accurate for estimating protective serum levels of PrEP among adults [69,70] and the likelihood of incorrectly estimating protective serum levels of PrEP decreases significantly with age among adolescents and young adults [71]. Given that the average age of participants was 22 years in this study, combined with the relatively high area under the receiver operating characteristics curve (≥0.7) between self-report measures and biological measures among participants without missing biological measures, using self-report PrEP adherence measures where biological measures are missing seems sufficient. Finally, the inclusion of a validated digital literacy scale and social anxiety–specific scale (as opposed to only a scale of generalized anxiety disorder) would have been ideal to measure digital literacy and social anxiety, respectively.

Conclusions

This study used a causal mediation approach using secondary data from an RCT testing the efficacy of P3, a digital PrEP adherence intervention. This study combined data from the primary RCT, including biological PrEP adherence measures, with engagement data, to characterize how baseline intrapersonal measures relate to effective engagement in participants who received P3. Broadly, P3 engagement (dollars accrued) was strongly related to lower odds of PrEP nonadherence. Specifically, this study identified digital literacy as a potential engagement facilitator and measures of structural disparity (eg, disconnection from phone or internet in the past year) and mental health (eg, anxious symptoms) as engagement barriers. Study results suggest tailoring as a critical DHI mechanism to address barriers to engagement and emphasize engagement facilitators in indicated individuals. Furthermore, these findings highlight the suitability of causal mediation analysis for effective engagement research by delineating the total effect of each intrapersonal measure into direct and indirect effects (effective engagement). Future research into effective engagement would benefit from adopting a causal mediation approach. Furthermore, as hypotheses regarding exact mechanisms for fostering engagement arise, future research should measure engagement with measure-specific areas of the DHI as a mediator.

Acknowledgments

The authors would like to collectively acknowledge and thank the Prepared, Protected, Empowered (P3) study team, P3 study participants, iTech, and the Adolescent Medicine Trials Network for HIV Interventions for their continued support and contributions to this project. MPW is supported by the National Institutes of Health: Eunice Kennedy Shriver National Institute of Child Health and Human Development (5F31HD108046) and National Institute on Aging (1T32AG081327). DFH is supported by the National Institutes of Health: National Institute on Drug Abuse (5K01DA046307).

Authors' Contributions

MPW and DFH conceived and designed the study. LBH-W conceived and designed the primary study (Prepared, Protected, Empowered [P3]). MPW and the P3 study team, namely CBR, constructed the analytic dataset. LHS, JM, and MPW built the statistical models. All authors revised the manuscript and interpreted the data.

Conflicts of Interest

None declared.

Abstract

Background: Diabetes, a chronic disease necessitating long-term treatment and self-management, presents significant challenges for patients who spend most of their treatment time outside of hospitals. The potential of digital therapeutics for diabetes has garnered recognition from different organizations. Although some prior studies have demonstrated successful reductions in patients' blood glucose levels and body weight through digital diabetes programs, many studies were limited by including patients with prediabetes, including patients treated with mostly premixed insulin, or evaluating user engagement outcomes rather than clinical outcomes. Consequently, limited evidence remains regarding the effectiveness of health management mobile apps specifically designed for patients with type 2 diabetes mellitus (T2DM) initiating basal insulin (BI). Based on this, a data-based and artificial intelligence management system named "TRIO" was developed to provide patients with more personalized intervention methods in stages, in groups, and around the clock. TRIO assists doctors and nurses in achieving better blood glucose controls, truly carries out standardized management around patients, and allows them to have a higher quality of life. TRIO represents the 3 essential pillars in comprehensive diabetes management: physician, nurse, and patient.

Objective: This prospective observational study evaluated the effectiveness and safety of the TRIO optimal health management program for patients with T2DM initiating BI therapy in a real-world setting.

Methods: Patients aged 18-85 years with inadequate glycemic control (baseline hemoglobin A_{1c} [HbA_{1c}] ≥7%) starting BI therapy were enrolled in outpatient and inpatient settings. The study lasted 3 months, with health education and phone-based follow-up assessments. Data collected included patient characteristics, medical history, baseline diabetes conditions, treatment compliance, glycemic control, and safety indicators.

XSL•FO
RenderX

Results: A total of 199,431 patients were included, and 118,134 patients completed the 3-month follow-up between December 1, 2019, and December 31, 2021, involving 574 hospitals in China. The mean baseline HbA_{1c} was 9.2%, the mean duration of diabetes was 7.3 years, and 80.4% (1,59,930/1,98,969) of patients were using BI with oral antihyperglycemic drugs. After the intervention, mean HbA_{1c} decreased by –2.59% from baseline, with 55.6% (28,858/51,912) achieving the target HbA_{1c} level of <7%. Patients who set lower fasting plasma glucose goals (<6.1 mmol/L) showed more significant HbA_{1c} reductions (P<.001) and higher target achievement than those with fasting plasma glucose goals of ≥6.1 mmol/L. Factors such as complications, diabetes duration, and baseline HbA_{1c} levels influenced the magnitude of HbA_{1c} reduction. The presence of complications, shorter diabetes duration, and higher baseline HbA_{1c} were significantly associated with increased hypoglycemia incidence risk (all P<.05).

Conclusions: The TRIO optimal health management program effectively improved glycemic control in patients with T2DM initiating BI therapy. Individualized treatment approaches considering patient characteristics and glycemic goals are vital for optimal outcomes.

Introduction

Background

The prevalence of type 2 diabetes mellitus (T2DM) in China is rapidly increasing due to lifestyle changes and an aging population. As per the 2018 American Diabetes Association criteria, the estimated prevalence of total diabetes and prediabetes among Chinese adults escalated to 12.8% and 35.2%, respectively, between 2015 and 2017 [1]. Despite the wide range of medication options available for antidiabetic treatment, glycemic control rates among patients with T2DM remain suboptimal [2]. A national survey conducted in 2018 revealed that only 32.9% (10,071/30,609) of patients with diabetes received treatment, with only half of them (15,336/30,609, 50.1%) achieving adequate glycemic control [3].

Diabetes, a chronic disease necessitating long-term treatment and self-management, presents significant challenges for patients who spend most of their treatment time outside of hospitals [4]. When lifestyle intervention and oral antidiabetic drugs (OADs) fail to provide optimal control, patients with type 2 diabetes are required to initiate injectable therapies, mostly basal insulin (BI), according to 2020 Chinese guidelines for T2DM management [5].

Previous randomized controlled trials (RCTs) and observational studies have shown the efficacy of BI in controlled trials [6] and real-world settings [7]. Maintaining a delicate equilibrium between achieving optimal blood glucose control and mitigating hypoglycemia risks is pivotal. This involves the appropriate titration of insulin and diligent self-monitoring of blood glucose levels, both of which are integral to sustaining effective glycemic management. Consequently, establishing an optimal diabetes management framework encompassing health education, consistent professional follow-up, and comprehensive self-monitoring tools becomes imperative for effectively managing patients with type 2 diabetes [8]. The lack of comprehensive and patient-centered approaches in current health care systems further compounds the burden of diabetes management. Time constraints and resource availability often limit traditional health education and face-to-face interactions with health care providers. As a result, there is a growing need for innovative solutions to bridge these gaps and provide ongoing support to individuals with type 2 diabetes [9-11]. The emergence of digital tools such as mobile apps and WeChat miniprograms has increased application in diverse therapeutic domains, such as attention-deficit/hyperactivity disorder, cancer, asthma, and insomnia tools to augment patient self-management [12].

Objectives

The potential of digital therapeutics for diabetes has garnered recognition from different organizations, such as the Centers for Disease Control and Prevention and the Digital Therapeutics Alliance [13]. Although some prior studies have demonstrated successful reductions in patients' blood glucose levels and body weight through digital diabetes programs up to a hemoglobin A_{1c} (HbA_{1c}) reduction of 0.49% [14], many studies were limited by including patients with prediabetes [15], including patients treated with mostly premixed insulin [16], or evaluating user engagement outcomes rather than clinical outcomes [17]. Consequently, limited evidence remains regarding the effectiveness of health management mobile apps specifically designed for patients with T2DM initiating BI.

Accordingly, we have developed a personalized health management program combined with artificial intelligence named "TRIO" for initiating BI therapy in patients with type 2 diabetes and aim to evaluate its effectiveness and safety. Unlike conventional acronyms or abbreviations, TRIO does not represent a longer phrase but rather represents the 3 essential pillars in comprehensive diabetes management: physician, nurse, and patient. This program combines traditional health education with a mobile app to enhance diabetes management. Through this evaluation, we aspire to contribute to understanding practical approaches to optimizing glycemic control and promoting patient well-being.

Methods

Study Design and Population

This prospective, 3-month observational program aimed to evaluate the effectiveness and safety of TRIO, an optimal health management program for patients with T2DM initiating BI therapy in a real-world setting. Participants were recruited from outpatient departments and, at discharge, from inpatient departments between December 1, 2019, and December 31, 2021, from 594 hospitals in China. Patients were assessed for their suitability by the following criteria: (1) aged between 18 and 85 years; (2) patients with T2DM who were inadequately controlled by OADs at the time of enrollment (ie, baseline HbA_{1c} level of ≥7%); (3) initiating BI therapy during the program period, meaning they had not used BI within 12 weeks prior to enrollment; (4) absence of mental disorders or communication impairments; and (5) absence of severe illnesses or limitations regarding follow-up. Patients who fulfilled these eligibility requirements were enrolled upon their willingness to provide informed consent. On the first day of enrollment, patients received health education from nurses, including knowledge about diabetes and insulin, psychological support for a healthy life with diabetes, and how to inject and store insulin. In addition, the physicians assisted patients in drawing up a self-management plan and helped them set individualized fasting plasma glucose (FPG) and postprandial glucose (PPG) goals. Patients were also asked to follow the WeChat official account of the TRIO program, through which knowledge about diabetes management would be sent. Follow-up assessments were conducted via phone calls at 1, 2, 4, 8, and 12 weeks. The frequency and follow-up methods were tailored to each patient's FPG level. If the FPG level was 7 mmol/L, a phone call was not scheduled for the next follow-up visit, and only a WeChat message was sent (Figure 1).

Figure 1. The operating process of the TRIO optimal health management program. AI: artificial intelligence; BG: blood glucose; FPG: fasting plasma glucose; HbA_{1c}: hemoglobin A1c; PPG: postprandial glucose.

Ethical Considerations

This study was approved by the ethics committee of Nanjing Drum Tower Hospital (institutional review board review approval document, code: 2019-231-01), which was the principal research institute representing other subcenters. Implied consent was obtained from all participants when they registered on the TRIO WeChat official account following the principles of the Declaration of Helsinki, as the privacy policy included a clause allowing anonymized data to be used for research purposes. Participant privacy and anonymity were achieved through the elimination of any patient identifiers such as name or dates of birth, which were anonymized and deidentified before extraction and securely stored in compliance with data protection regulations. No compensation was provided to participants, as this study involved a secondary analysis of existing data. No identifiable images of participants were included in the study or supplementary materials, eliminating the need for additional image consent.

Data Collection

Baseline information was collected by interviews at the hospital enrollment, including demographics, disease characteristics, medical history, physical examination, BI types, starting dosage, and concomitant antidiabetic drugs (bolus insulin, glucagon-like peptide-1 receptor agonists, or OAD) used with BI. Laboratory tests including HbA_{1c} and FPG were obtained in hospitals at baseline, while glycemic control regarding HbA_{1c} and self-monitoring blood glucose (SMBG), including fasting blood glucose (FBG), dosage, and hypoglycemia information during follow-up time, were self-reported. Self-reported data were collected through phone calls by nurses or uploaded via a smart blood glucose device or input into the TRIO WeChat official account by the patients.

Outcomes

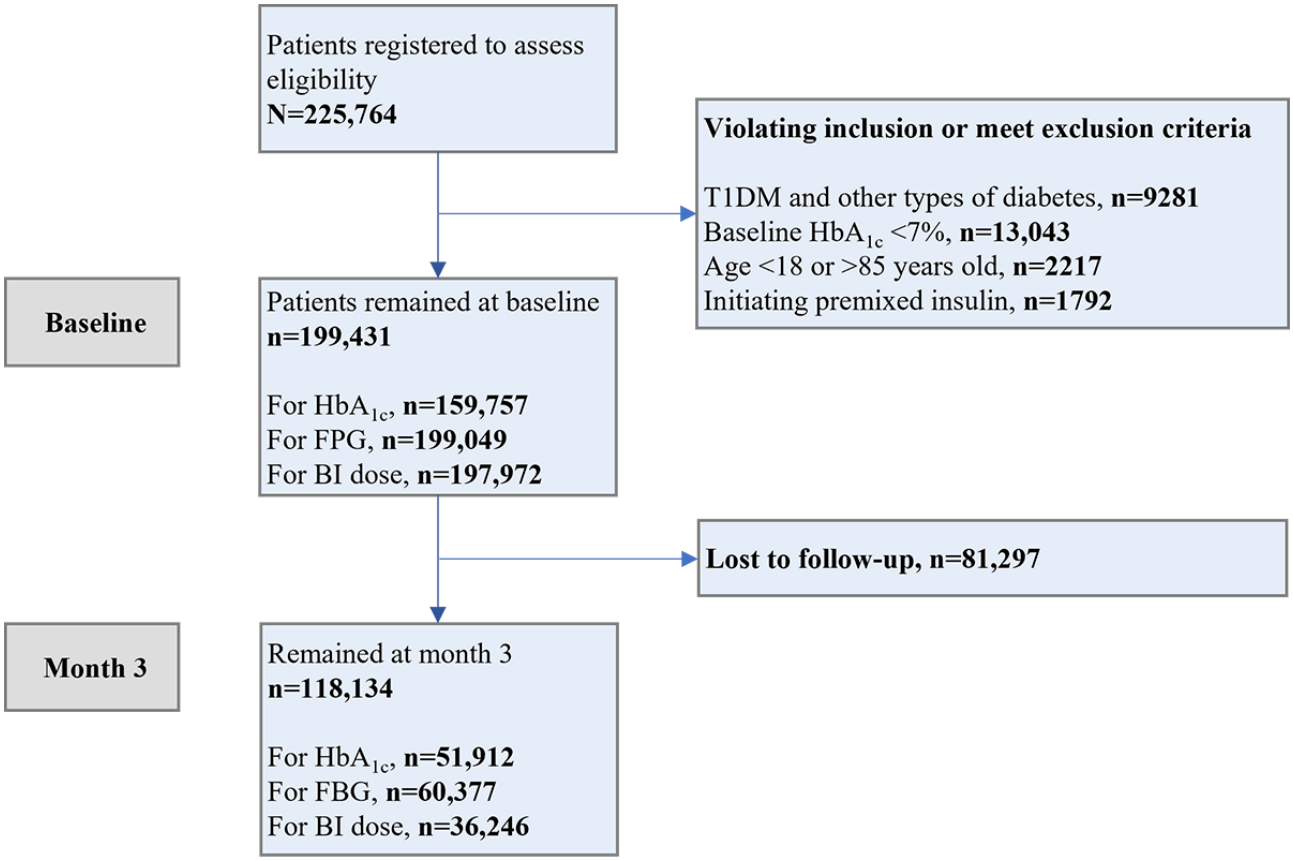
- *Primary effectiveness end points*: The primary effectiveness end point of our analysis is the change in HbA_{1c} levels from baseline to month 3.

XSL•FO
RenderX

- *Secondary effectiveness end points*: In addition to the primary end point, we also examined various other measures related to glycemic control. These secondary end points include changes in FBG levels from baseline to month 3, the achievement of target HbA_{1c}levels (<7%), the achievement of target FBG levels (<7 and <6.1 mmol/L), and an assessment of changes in BI dose.
- *Safety end points*: Our safety end points include monitoring and assessing the incidence and rates of hypoglycemia events and evaluating composite end points. The 3-month end point included the incidence and rates of hypoglycemia events and a composite end point encompassing the percentage of patients reaching target HbA_{1c} and FBG levels without experiencing hypoglycemia events.

Statistical Methods

Continuous variables were described using mean and SD, while categorical variables were presented as frequencies and percentages. For continuous effectiveness indicators, a paired *t* test (2-tailed) was applied to test the significance of the change from baseline to month 3 in HbA_{1c} or FPG in the total population. Analysis of covariance was used to compare these changes between subgroups, including patient source (inpatient or outpatient), complication status (no or yes), duration of diabetes (<5 years or ≥5 years), baseline HbA_{1c} (7%-8%, 8%-9%, 9%-10%, or ≥10%), and FBG goal setting (≥6.1 mmol/L or <6.1 mmol/L). Least square (LS) mean (SE) and LS mean difference with 95% CIs were provided. For binary effectiveness outcomes (HbA_{1c} <7%, FBG <7 mmol/L, or FBG <6.1 mmol/L), multivariable logistic regression models were applied to explore the association of subgroups with outcomes and variables included in the model were the same as analysis of covariance model. Hypoglycemic incidence and rate were evaluated by SMBG, uploaded by the smart glucose blood device or manual input to the TRIO platform by patients. Hypoglycemic incidence (percentage of patients with SMBG ≤3.9 mmol/L or SMBG <3.0 mmol/L) was analyzed using logistic regression, and odds ratio (OR) with 95% CI was used as the effect size; hypoglycemic rate (numbers of events per patient-year) was investigated by Poisson regression, and risk ratio (RR) with 95% CI were used as the effect size for this analysis. Composite end points including HbA_{1c} <7% without SMBG ≤3.9 mmol/L, FBG <7 mmol/L without SMBG ≤3.9 mmol/L, and FBG <6.1 mmol/L without SMBG ≤3.9 mmol/L were also explored using logistic regression. All the analyses were conducted using SAS 9.4 (SAS Institute, Inc), and a 2-sided *P* value of <.05 was considered statistically significant.



Results

Participant Recruitment

Between December 1, 2019, and December 31, 2021, a total of 225,764 patients were recruited from 594 hospitals. A total of 26,333 patients were excluded because of violating inclusion or meeting exclusion criteria, leaving 199,431 patients remaining at baseline. Among them, 81,297 patients were lost to follow-up within the first 3 months, resulting in 118,134 patients who completed the 3-month follow-up with measurements of either HbA_{1c} or FPG (Figure 2).

XSL•FO
RenderX

Figure 2. Flowchart of participating patients enrolled in the TRIO optimal health management program. Nested values under "Patients remained at baseline" and "Remained at month 3" are non-mutually exclusive. BI: basal insulin; FPG: fasting plasma glucose; HbA_{1c}: hemoglobin A1c; T1DM: type 1 diabetes mellitus.

Baseline Characteristics

The patients' mean (SD) age at baseline was 57.3 (12.5) years, with 42.8% (85,337/1,99,431) of participants being women. The average BMI was 24.8 kg/m^2. At baseline, the mean HbA_{1c}, FPG, and PPG levels were 9.6%, 9.5 mmol/L, and 12.7 mmol/L, respectively. The mean duration of diabetes was 7.3 years. The most common complications or comorbidities observed in our patient cohort were hypertension (55,637/1,96,023, 28.4%), hyperlipidemia (32,240/1,96,023, 16.4%), and peripheral neuropathy (63,145/1,96,023, 32.2%). Most patients were taking BI with oral antihyperglycemic drugs (OADs) (1,59,930/1,98,969, 80.4%), with some also using prandial insulin concurrently.

Outpatients had a slightly higher mean age of 57.7 (SD 12.2) years than inpatients, with a mean age of 57.0 (SD 12.6) years. Gender distribution revealed that 56.3% (39,802/70,704) of outpatients were male, while 57.6% (74,064/1,28,645) of inpatients were male. Moreover, the duration of diabetes was slightly longer in inpatients, with a mean of 7.4 years (SD 6.8) than in outpatients, with a mean of 7.0 years (SD 6.3). Both groups displayed a similar average BMI of 24.8 kg/m^2 and exhibited comparable values for blood pressure and lipid levels such as triglycerides, total cholesterol, low-density lipoprotein, and baseline HbA_{1c}. Meanwhile, baseline FPG (10.3 vs 9.0 mmol/L) and PPG (14.0 vs 12.2 mmol/L) were slightly higher in outpatients than in inpatients. A notable difference was observed in the percentage of patients with complications or comorbidities, with 31.3% (39,950/1,27,610) of inpatients having hypertension compared with 22.9% (15,687/68,413) of outpatients and 38.1% (48,580/1,27,610) of inpatients having peripheral neuropathy compared with 21.3% (14,565/68,413) of outpatients. Inpatients also had a higher proportion of patients being treated with BI in combination with prandial insulin, accounting for 20.3% (26,037/1,28,342) of inpatients as opposed to 15.5% (10,924/70,627) of outpatients (Table 1). No clinically significant differences in baseline characteristics were observed between patients who remained in the study at month 3 and those who were lost to follow-up (Table S1 in Multimedia Appendix 1).

Initial Regimens and Adherence to BI Treatment

During the intervention, the majority of patients initiated insulin glargine (1,77,331/1,98,969, 89.1%) as their primary treatment, while a smaller proportion started with insulin determir (6588/1,98,969, 3.3%), neutral protamine Hagedorn insulin (766/1,98,969, 0.4%), or insulin degludec (8939/1,98,969, 4.5%). Alongside BI treatment, 41% (57,242/1,39,739), 28.2% (39,473/1,39,739), and 9.7% (13,545/1,39,739) of patients were concurrently taking 1, 2, and ≥3 OADs, respectively. The most commonly used OADs were metformin (69,027/1,39,739, 49.4%) and α-glucosidase inhibitors (46,960/1,39,739, 33.6%), followed by sodium-glucose cotransporter-2 inhibitors (22,911/1,39,739, 16.4%), dipeptidyl peptidase-4 inhibitors (20,722/1,39,739, 14.8%), sulfonylureas (7266/1,39,739, 5.2%), glinides (6257/1,39,739, 4.5%), and thiazolidinediones (5504/1,39,739, 3.9%). Sulfonylureas were more frequently prescribed to outpatients (3571/48,696, 7.3%) than inpatients (3695/91,043, 4.1%), while sodium-glucose cotransporter-2 inhibitors were more commonly used in inpatients (16,615/91,043, 18.2%) than outpatients (6296/48,696, 12.9%; Table S2 in Multimedia Appendix 1).

Glycemic Outcomes

At the end of the 3-month management intervention period, the mean HbA_{1c} level among 44,847 participants with eligible self-reported mean HbA_{1c} measurements was 6.89% (SD 0.90). This represented a mean decrease in HbA_{1c} by –2.59% (SE 0.01; *P*<.001) from baseline (Table 2). Regarding FBG levels, at the end of month 3, the mean FBG level among 60,365 participants with eligible self-reported FBG measurements was 6.81 (SD 1.4) mmol/L, indicating an average decrease in FBG by –2.77 (SD 0.01) mmol/L (*P*<.001) from baseline (Table 2 and Figure S1 in Multimedia Appendix 1). For the HbA_{1c} target, 55.6% (28,858/51,912) of participants achieved the target HbA_{1c} level of <7% after the 3-month intervention period (Table 3). Similarly, 61.3% (37,017/60,377) and 29.2% (17,633/60,377) of participants reached FBG levels of <7.0 and <6.1 mmol/L, respectively, at the end of the 3-month intervention period.

In the subgroup analyses, patients with complications experienced slightly lower HbA_{1c} (LS mean difference: 0.07, 95% CI 0.05-0.09) than those with no complications. Considering the duration of diabetes, patients with a duration of ≥5 years exhibited a lesser decrease in HbA_{1c} (LS mean difference: 0.09, 95% CI 0.07-0.11) than those with a duration of <5 years. A higher baseline HbA_{1c} level was also associated with a more significant reduction. Compared with patients with baseline HbA_{1c} in the range of 7% to 8%, patients with a baseline HbA_{1c} in the range of 8% to 9% had the lesser decrease (LS mean difference: –0.83, 95% CI –0.86 to –0.79), while patients with a baseline HbA_{1c} of 10% or higher had the highest decrease (LS mean difference: –4.04, 95% CI –4.08 to –4.00). Also, patients with initial FBG goal setting of <6.1 mmol/L had a greater decrease in their HbA_{1c} (LS mean difference: –0.36, 95% CI –0.38 to –0.34) than those with FBG goal setting of ≥6.1 mmol/L (Table 2). In the subgroup analysis exploring factors related to FBG reduction, consistent results with HbA_{1c} reductions found that more significant reductions were seen in patients with no complications, diabetes duration of <5 years, and an initial FBG goal setting of <6.1 mmol/L, except for baseline HbA_{1c}. Patients with lower baseline HbA_{1c} exhibited higher reductions in FBG from baseline (Table 2).

[a]HbA_{1c}: hemoglobin A_{1c}.

[b]OR: odds ratio.

[c]N/A: not applicable.

[d]FBG: fasting blood glucose.

Regarding target HbA_{1c} of <7% at month 3, patients enrolled from inpatient showed a slight advantage over outpatient (OR 1.16, 95% CI 1.11-1.21; *P*<.001), and patients with complications had lower odds of achieving HbA_{1c} target than those with no complications (OR 0.85, 95% CI 0.81-0.89; *P*<.001). Those with ≥5 years of duration of diabetes had lower success rates than those with <5 years of duration (OR 0.83, 95% CI 0.79-0.87; *P*<.001). Lower baseline HbA_{1c} levels were associated with better outcomes. Moreover, setting FBG target goal level of <6.1 mmol/L at the beginning of the treatment demonstrated a higher possibility of reaching the HbA_{1c} target of <7% at month 3 (OR 1.8, 95% CI 1.7-1.9; *P*<.001) (Table 3). Regarding the FBG target of <7 and <6.1 mmol/L at month 3, patients exhibited consistent results as in HbA_{1c} target of <7%. Inpatients; patients with no complications; and patients with diabetes duration of 5 years, lower HbA_{1c} target, and initial FBG goal setting of <6.1 mmol/L were associated with higher odds of achieving the target (Table 3).

Insulin Dose and Satisfaction

Total insulin dose (U/d/kg) change was –0.01 (SD 0.06), from baseline (mean 0.23, SD 0.09) to month 3 (mean 0.22, SD 0.09; Table 4). Patients recruited from inpatients, with complications, having diabetes duration of ≥5 years, with FBG goal setting of <6.1 mmol/L and higher baseline HbA_{1c}, had a higher starting dose of BI. Among 36,037 patients with both baseline and 3-month BI dosages, 7% (2546/36,037) remained unchanged, and 50.1% (18,047/36,037) lowered the dosage per kilogram (Table 4). Possible reasons for the lack of titration, such as patients reaching FBG targets or experiencing hypoglycemic events, were explored in Table S3 in Multimedia Appendix 1. Patients with stable or decreasing dosage during the 3 months had higher starting doses, higher percentages of FBG <7 mmol/L, and hypoglycemic incidence at week 1, 2, 4, 8, and 12 than patients with increasing dosage. Patient satisfaction level for TRIO was stable during the study. Furthermore, 99.6% (35,738/35,897) of the patients felt satisfactory or very satisfactory at month 3, and only 0.4% (159/35,897) chose average or below.

[b]FBG: fasting blood glucose.

Incidence and Event Rate of Hypoglycemia

Hypoglycemia incidence (≤3.9 mmol/L) in all patients was 27.1% (3317/12,227). Inpatients had a higher incidence than outpatients (OR 1.24, 95% CI 1.07-1.45; *P*=.005). Patients with complications experienced more hypoglycemia (OR 1.25, 95% CI 1.07-1.45; *P*=.005). Longer diabetes duration (≥5 years) was associated with lower hypoglycemia incidence (OR 0.60, 95% CI 0.52-0.69; *P*<.001; Table 5). Higher baseline HbA_{1c} levels correlated with increased hypoglycemia risk. HbA_{1c} ≥10% had the highest incidence (OR 1.47, 95% CI 1.23-1.76; *P*<.001; Table 5). For hypoglycemic events defined by SMBG levels of ≤3.9 mmol/L, a total of 7619 events occurred, yielding an event rate of 2.49 events per person-year (Table 6). Notable trends included higher hypoglycemia rates for inpatient sources compared with outpatient sources (RR 1.25, 95% CI 1.08-1.46; *P*=.004), higher rates in patients with complications compared with those with no complications (RR 1.25, 95% CI 1.07-1.47; *P*=.006), and a lower rate in patients with a diabetes duration of ≥5 years (RR=0.67, 95% CI 0.59-0.77; *P*<.001). Furthermore, elevated baseline HbA_{1c} levels (≥10%) were associated with a higher hypoglycemia rate (RR 1.37, 95% CI 1.15-1.63; *P*=.001). An FBG goal setting of <6.1 before initiating BI was not associated with increased hypoglycemic incidence (OR 0.97, 95% CI 0.77-1.22; *P*=.79) or rate (RR 0.92, 95% CI 0.76-1.1; *P*=.35). For hypoglycemia defined as SMBG <3.0 mmol/L, 15.1% (1852/12,227) of patients with 2954 events were recorded, resulting in an incidence rate of 0.97 events per person-year. Similar trends were observed in relation to complications, duration of diabetes, and baseline HbA_{1c} levels. An FBG goal of <6.1 was not related to increased incidence (OR 0.97, 95% CI 0.77-1.22; *P*=.79) or rate (RR 1.01, 95% CI 0.80-1.27; *P*=.95) of hypoglycemia (Table 6).

[e]FBG: fasting blood glucose.

Table 7 shows the composite end points of patients reaching the target with no hypoglycemia events during a 3-month period. For HbA_{1c} <7% without SMBG ≤3.9 mmol/L at month 3, patients with complications (OR 0.68, 95% CI 0.54-0.84; *P*=.001) and those with a duration of diabetes for ≥5 years (OR 0.76, 95% CI 0.62-0.93; *P*=.008) had significantly lower odds of reaching the target with no hypoglycemia events. Furthermore, higher baseline HbA_{1c} levels in the ranges of 9%-10% (OR 1.26, 95% CI 1.03-1.55; *P*=.02) and ≥10% (OR 1.47, 95% CI 1.23-1.76; *P*<.001) were associated with increased odds of achieving the target. Also, those who set an FBG goal of <6.1 mmol/L at initiation had significantly higher odds of reaching the composite end point (OR 1.35, 95% CI 1.03-1.79; *P*=.03). None of these factors were related to the composite end points for achieving FBG <7 mmol/L without SMBG ≤3.9 mmol/L at month 3. Finally, for achieving FBG <6.1 mmol/L without SMBG ≤3.9 mmol/L at month 3, only the duration of diabetes for ≥5 years was associated with a significantly lower possibility of achieving this composite end point.

Discussion

Principal Findings

The TRIO program, a large-scale health management initiative using a digital WeChat platform for patients with T2DM initiating BI treatment, demonstrated its effectiveness in improving glycemic control 3 months after initiating BI. Prior to enrollment in TRIO, patients with T2DM exhibited suboptimal blood glucose control, with elevated baseline HbA_{1c} (9.6%) and FPG (9.5 mmol/L), a high prevalence of diabetic complications, and long diabetes duration (7.3 years). Following the 3-month TRIO management intervention, notable reductions in HbA_{1c} (–2.59%) and FBG (–2.77 mmol/L) were observed in the total population, accompanied by heightened proportions of achieving HbA_{1c} <7% (55.6%) and FBG target <7.0 mmol/L (61.3%) across diverse subgroups, such as patients from inpatient or outpatient care, patients with or with no complications, and patients with different length of diabetes duration, baseline HbA_{1c}, and FBG goal setting. This study also highlights the potential for setting a lower FBG target (<6.1 mmol/L) at the initiation of BI compared with the traditional <7.0 mmol/L target. By setting a more rigorous FBG target of <6.1 mmol/L, better glycemic control was achieved without increased risk of hypoglycemia. These results hold promise for digital health tools such as TRIO in improving the overall management of T2DM in real-world clinical settings.

TRIO has shown effectiveness and safety in patients with T2DM initiating BI after OAD failure with the assistance of WeChat digital platform, which is consistent with previous single-arm studies incorporating digital tools conducted in patients with prediabetes [15,18] and patients treated with premixed insulin and BI [14,19,20]. For instance, the Omada Health Program investigated digital Diabetes Prevention Program engagement among patients with prediabetes, showing a reduction of –0.33 mmol/L in HbA_{1c} levels over 3 years [15]. In our TRIO study, with a larger sample size, we achieved a greater HbA_{1c} reduction of –2.58 mmol/L. Furthermore, in a 12-week German trial involving individuals with type 2 diabetes on BI, a smartphone app (My Dose Coach) was compared with a written titration chart. The intervention group using the app exhibited a noteworthy reduction in HbA_{1c} levels compared with the control group (–0.31%; *P*=.04), with safety outcomes remaining unaffected. These findings suggest that app-assisted titration can enhance glycemic control in patients with type 2 diabetes who use BI [20].

TRIO has demonstrated that digital tools including health education and self-management modules added on BI might provide additional benefits to effectiveness in glycemic control than medication alone. The ORBIT study is an observational registry conducted in China with patients with T2DM who were inadequately controlled by OADs and initiated BI [21], with similar baseline HbA_{1c} (9.6%, SD 2%) but higher baseline FBG (11.7, SD 4.0 mmol/L) and shorter diabetes duration (6.4, SD

XSL•FO
RenderX

5.3 years) than those in our study. Notably, the change in HbA_{1c} from baseline to month 3 demonstrated a more improvement in the TRIO group (–2.59%) than in the ORBIT group (–2%), as well as the attainment of the HbA_{1c} target of <7% at month 3 (55.6% vs 35.9%). Despite the relatively lower reduction in FBG levels in the TRIO study due to lower baseline FBG levels, a larger proportion of TRIO patients successfully reached the FBG target of <7 mmol/L (37,017/60,377, 61.3%) than those in the ORBIT study (2078/5571, 37.3%). Another significant study in this field, the First Basal Insulin Evaluation (FINE) Asia study, was a multinational, prospective, observational approach to assess BI's efficacy in patients with uncontrolled type 2 diabetes (HbA_{1c} ≥8%) [22].

In TRIO, baseline HbA_{1c} and FBG were as high as 9.6% and 9.5 mmol/L, respectively (Table 1), which suggests delayed initiation of BI. The American Diabetes Association and the European Association for the Study of Diabetes suggest that BI should be promptly considered after the apparent "failure" of lifestyle modifications, including diet and exercise in combination with metformin, particularly when HbA_{1c} levels remain at or exceed 7% for a span of 2-3 months [23]. However, consistent with our findings, delay in injectable therapies was universal [24,25]. Timely initiation of insulin such as BI after the failure of oral treatment is associated with better glycemic control [26].

Standard T2DM management advice recommends keeping HbA_{1c} levels below 7%, but the ideal FPG target for achieving this is debated [27]. Different guidelines suggest varying FPG targets, such as 4.4-7.2 mmol/L according to the American Diabetes Association 2018 guidelines [28] or <6.1 mmol/L according to the American Association of Clinical Endocrinology-American College of Endocrinology and the International Diabetes Federation [29]. Previous studies support an FPG target of 6.1 mmol/L, showing better outcomes. Patients with FPG goals below 6.1 mmol/L had more significant HbA_{1c} reductions and higher target achievement rates without an increase in hypoglycemia [30,31]. Our results might confirm a better FPG target of <6.1 mmol/L. Patients who had an initial FPG goal setting below 6.1 mmol/L by their physician at the time of enrollment experienced both greater reductions in their HbA_{1c} levels (–2.64 vs –2.57%) and a higher HbA_{1c} target rate (67.8% vs 53.1%) than those with FPG goal setting ≥6.1 mmol/L (Tables 2 and 3). At the same time, hypoglycemic incidence and rate were comparable between the 2 groups. To enhance the management of hypoglycemic events, we recommend frequent SMBG monitoring, particularly during the initial weeks of insulin titration, to detect and address hypoglycemia promptly. Patient education on recognizing and treating hypoglycemic symptoms should be prioritized, alongside individualized insulin dose adjustments based on SMBG trends to minimize risk. Regular follow-ups are essential to reassess glycemic targets, such as FBG and HbA_{1c}, and to prevent overtreatment while maintaining optimal glycemic control. These measures can help balance achieving strict glycemic targets with ensuring patient safety.

Regarding the titration of BI treatment, the current Chinese guideline recommends an initial dose of 0.2 U/kg or 10 U, underscoring the importance of active insulin dose adjustment to achieve optimal glycemic control [32]. Previous studies such as ORBIT have indicated inadequate titration, evident from a starting dose of 0.18 IU/kg/d and a final dose of 0.21 IU/kg/d, resulting in a change of +0.034 IU/kg/d. Within our program, comprehensive titration was not uniformly accomplished. Among the 36,037 patients with baseline and 3-month dosage data, 42.9% (15,444/36,037) of patients escalated their dosage during the program, while 7.1% (2546/36,037) maintained stability and 50.1% (18,047/36,037) of patients decreased their dosage. Consequently, there was a marginal numerical decline in dose by –0.01 (0.06) U/kg. Plausible explanations for this trend encompass the higher-than-recommended starting dose in our program, which even surpassed the final doses in earlier ORBIT studies. Furthermore, the pursuit of targeted FBG levels in the initial weeks and an increased incidence of hypoglycemic events among patients (as shown in Table S3 in Multimedia Appendix 1) could have contributed to these patterns.

Limitations

Our study supports TRIO's effectiveness and safety as a personalized health program, yet several limitations warrant acknowledgment. First, a significant portion of patients lacked HbA_{1c} follow-up data at month 3, possibly introducing a compliance bias that could overstate TRIO's effectiveness by excluding those with less favorable HbA_{1c} reductions. Nonetheless, comparable baseline characteristics between compliant and noncompliant patients mitigate the risk of overestimation. Long-term data (months 3-12) are insufficient, leaving uncertainty about TRIO' s enduring effectiveness and ability to sustain patient adherence. Second, the judgment of hypoglycemia relied on SMBG, and the SMBG data were collected mainly through self-reporting on the WeChat platform, smart glucose devices, and regular phone calls by nurses, which may have a certain degree of deviation from the actual occurrence of hypoglycemia. Moreover, the absence of an RCT design and an external control group that included patients with type 2 diabetes who initiated only BI therapy without using TRIO may lead to the effect of TRIO to optimize glycemic control not solid enough. Therefore, it is necessary for future studies to design RCTs to evaluate the effectiveness and safety of intelligent blood glucose management in patients with diabetes with initiated BI therapy.

Conclusions

The TRIO program has demonstrated effectiveness in glycemic control, as reflected in HbA_{1c} and FBG levels, among patients with T2DM initiating BI therapy. The program has improved HbA_{1c} and FBG target rates and patient compliance with insulin treatments. However, it is important to acknowledge the limitations of our study, including compliance bias, insufficient long-term follow-up data, and the need for further investigation using rigorous study designs. Future research, such as RCTs, is warranted to validate our study's findings and assess TRIO' s generalizability in real-world populations.

Abstract

Background: If the most evidence-based and effective smoking cessation apps are not selected by smokers wanting to quit, their potential to support cessation is limited.

Objective: This study sought to determine the attributes that influence smoking cessation app uptake and understand their relative importance to support future efforts to present evidence-based apps more effectively to maximize uptake.

Methods: Adult smokers from the United Kingdom were invited to participate in a discrete choice experiment. Participants made 12 choices between two hypothetical smoking cessation app alternatives, with five predefined attributes reflecting domains from the theoretical domains framework: (1) monthly price of the app (environmental resources), (2) credible source as app developer (social influence), (3) social proof as star rating (social influence), (4) app description type (beliefs about consequences), and (5) images shown (beliefs about consequences); or opting out (choosing neither app). Preferences and the relative importance of attributes were estimated using mixed logit modeling. Willingness to pay and predicted uptake of the most and least preferred app were also calculated.

Results: A total of 337 adult smokers completed the survey (n=168, 49.8% female; mean age 35, SD 11 years). Participants selected a smoking cessation app rather than opting out for 90% of the choices. Relative to other attributes, a 4.8-star user rating, representing social proof, was the strongest driver of app selection (mean preference parameter 2.27, SD 1.55; 95% CI 1.95-2.59). Participants preferred an app developed by health care–orientated trusted organization (credible source) over a hypothetical company (mean preference parameter 0.93, SD 1.23; 95% CI 0.72-1.15), with a logo and screenshots over logo only (mean preference parameter 0.39, SD 0.96; 95% CI 0.19-0.59), and with a lower monthly cost (mean preference parameter –0.38, SD 0.33; 95% CI –0.44 to –0.32). App description did not influence preferences. The uptake estimate for the best hypothetical app was 93% and for the worst, 3%. Participants were willing to pay a single payment of up to an additional US $6.96 (UK £5.49) for 4.8-star ratings, US $3.58 (UK £2.82) for 4-star ratings, and US $2.61(UK £2.06) for an app developed by a trusted organization.

Conclusions: On average, social proof appeared to be the most influential factor in app uptake, followed by credible source, one perceived as most likely to provide evidence-based apps. These attributes may support the selection of evidence-based apps.

Introduction

Smoking is one of the leading risk factors for noncommunicable diseases worldwide [1]. Supporting people to quit smoking is a primary concern for public health [2]. One approach is the use of apps, which can be effective for smoking cessation [3]. Many are available on commercial app stores but low uptake and suboptimal engagement with effective health apps is common [4,5]. Commercial app stores generally omit app quality measures and provide insufficient information about apps [6].

Curated health app portals are websites that present a list of selected health apps and can provide access to high-quality smoking cessation apps developed by trusted organizations [7]. This could increase the uptake of effective smoking cessation apps among smokers and decrease the risk that apps are installed primarily due to popularity, as opposed to potential effectiveness, from commercial app stores [8]. In some countries, health organizations considered as being trusted organizations, such as the Office for Health Improvement and Disparities and the National Health Service (NHS) in the United Kingdom, offer such portals (Better Health, NHS Apps Library), or the Digital Health Applications (DiGA) directory in Germany [7].

There is extensive literature on engagement with health apps [9-14], but the evidence about factors influencing their uptake is limited. We have identified several factors that appear to influence the uptake and engagement of these apps and explored views on curated health app portals, primarily the NHS "NHS Apps Library," which since then was decommissioned, and the Office for Health Improvement and Disparities Better Health (formerly known as Public Health England's "One You" website) [7,10]. We found a common discrepancy between user needs and what an app offers, such as the perceived utility of the app, which refers to the way apps are presented, including the images shown and the description of the apps [7,10,15]. App users have also expressed disappointment with the presentation of apps on app portals [7].

The uptake of health apps may also be primarily affected by social influences such as social proof represented by ratings of an app [7,16,17]. However, highly rated apps do not necessarily mean evidence-based content and functionality [6]. Although highly rated smoking cessation apps appear better tailored to individual needs [17], other evidence suggests that there is only a weak association between the quality of a smoking cessation app and its popularity [16,18].

There is limited evidence on which factors are likely to drive the uptake of apps and no studies investigating smoking cessation app uptake from a curated portal. This paper aims to determine preferences for the uptake of a smoking cessation app by applying a discrete choice experiment (DCE) survey. The findings may provide preliminary insights to help health app portal developers present smoking cessation apps in ways that align with user preferences, potentially supporting the selection of evidence-based apps on curated health platforms. The survey further assessed a series of factors influencing the uptake of and engagement with smoking cessation apps to better understand to what extent these factors are facilitators or barriers.

Methods

DCE Development

DCE is a methodology premised on individuals choosing the option that offers them the greatest utility, and assumes that utility is a function of the importance an individual assigns to characteristics associated with a product [19]. This DCE provides a series of choices of two alternatives of a product or service (here referred to as App 1 and App 2), known as choice tasks. Each alternative app is described by a set of predefined attributes, with 2 or more levels.

The development of this DCE, described in detail elsewhere [20], followed best practice guidance [21-23]. The development was further informed by discussion with stakeholders, including patient and public involvement representatives, and involved the following steps: (1) identification of attributes and attribute levels, (2) development of the experimental design, (3) piloting and survey amendment, (4) data collection, and (5) data analysis.

This paper adheres to the principles outlined in the DIRECT (Discrete Choice Experiment Reporting) checklist [24] to ensure comprehensive and transparent reporting of findings (see Multimedia Appendix 1 for the checklist).

Attributes and Levels

A systematic review [10], and interview and think-aloud study [7] informed the selection of relevant factors mapped under the theoretical domains framework (TDF) that influence the uptake of health apps, hereby attributes of this study. The TDF informed our previous research as it provides comprehensive coverage of theory-driven domains of behavior [25].

The research team assessed the relevance and feasibility of the attributes identified in the previous stages and narrowed down the selection of potential attributes. The selection of attributes is described elsewhere [20]. The selected attributes and their levels are shown in Table 1. For the "who developed the app" attribute, we used "NHS Digital," which is a widely trusted organization in the United Kingdom, and "Mhealth Essentials Ltd" as a hypothetical company.

Table 1. The attributes and attribute levels included in the DCE[a] conducted between December 2020 and February 2021 to explore preferences for smoking cessation apps among adult smokers in the United Kingdom.

TDF[b] construct	Attributes	Attribute levels
Environmental resources (cost)	• The monthly price of the app	• US $0 (UK £0) • US $3.79 (UK £2.99) • US $7.60 (UK £5.99) • US $11.40 (UK £8.99)
Social influence (credible source)	• Who developed the app	• Does not say • "Mhealth Essentials Ltd" • "NHS[c] Digital"
Social influence (social proof)	• The ratings of the app	• Does not show • 3.2 stars • 4 stars • 4.8 stars
Beliefs in consequences (perceived utility of the app)	• App description	• Generic, to create a rough idea of what the app is about without getting into details of app features • Short with some details about app features • Long and detailed description of the app and its features
Beliefs in consequences (perceived utility of the app)	• Images	• Shows the logo of the app • Shows the screenshot of the app • Shows the logo and screenshot of the app

[a]DCE: discrete choice experiment.

[b]TDF: theoretical domains framework.

[c]NHS: National Health Service.

Experimental Design

Participant preferences were estimated using conditional logit regression to model their choices. While a mixed logit model was used in the final analysis, the design assumed the use of McFadden's conditional logit model: this is the most widely used approach in choice modeling [26,27], and it provides a starting point from where more sophisticated generalizing models such as mixed logit may be applied.

A DCE model specifies the probability that an individual will choose a specific smoking cessation app. This probability is expressed as a function of measured attributes specific to the alternative. The (simplified) underlying utility function for alternative *j* is shown in equation 1:

$$\text{utility of option } j = \beta1(\text{alternative1}) + \beta2(\text{opt-out}) + \beta3(\text{developer_not_shown}) + \beta4(\text{developer_NHS}) + \beta5(\text{ratings4.8_stars}) + \beta6(\text{ratings4_stars}) + \beta7(\text{ratings3.2_stars}) + \beta8(\text{descriptionsShort}) + \beta9(\text{descriptionsLong}) + \beta10(\text{imagesScreenshots}) + \beta11(\text{imagesBoth}) + \beta12(\text{costs_in_£}) + \varepsilon \quad \textbf{(1)}$$

In equation 1, *U* represents the overall utility gained from choosing alternative *j*, β is the mean coefficient attached to the corresponding attribute levels estimated by the mixed logit model and represents the part-worth utility attached to each attribute level, and ε is the random error of the model. β1 and β2 represent alternative specific constants.
