The practicality and efficacy of VR for older patients may be limited by difficulty using the technology, cost, and limited accessibility in medical settings [66]. For example, an approximately 1- to 2-pound VR headset may be relatively heavy, which is challenging for patients with frailty, as well as those with a serious illness [67]. In many cases, older patients may tend to be unfamiliar with new technologies and, therefore, may require supervision and assistance. This role can be fulfilled with caregivers, friends, or clinicians. In addition, immersive VR can cause motion sickness, which is a concern for older adults with serious illnesses, and are costlier than nonimmersive therapies [68]. Unfortunately, 5 (21%) of the 24 assessed studies lacked descriptions of supervision, training, or assistance provided, which may limit the ability of other researchers or providers to translate the results to their settings [45,48,50,51,56]. Therefore, VR assessments in older adults should include whether and how users were trained and supported, how their clinical condition impacted their ability to use the system, and how their ability to independently use VR was verified.

The extent to which VR treatment efficacy is reliant on media content remains unclear. This is particularly important because VR audio and visual media content varies generally within and between different VR systems. Furthermore, different clinical conditions and intervention goals may lead to the use of specific VR resources, interactive functionality, interactivity, and content. As a result, there are fundamental limitations for researchers and clinicians in understanding the mechanisms and efficacy of VR due to the opaqueness or lack of content descriptions in many publications [69]. In addition, subtleties in achieving high presence or in how perceived reality is portrayed may significantly impact the clinical impact and patient satisfaction. Therefore, better-published specifications of VR media, such as soundscapes, public accessibility, and other features, are required to better evaluate and clinically apply VR to patients [11].

XSL•FO
RenderX

This evaluation is limited by the sparse availability of specific VR content that was used in the previous studies. In addition, the outcomes related to patients' quality of life in the different studies were heterogeneous, and therefore, a quantitative synthesis was not possible. These factors, combined, limited the ability to characterize the effects of specific VR features on patient outcomes. However, this may be a representation of an evolving field with limited reporting guidelines. In addition, this study focused specifically on immersive VR, and future research can further examine the effectiveness of different types of VR. One of the original aims of this study was to compare individual differences in VR effectiveness (eg, by gender, race, and ethnicity); however, this was not possible due to a lack of sufficient detail in included studies. Nonetheless, this systematic review provides researchers and clinicians with a detailed overview of the current state of the literature for older adults with serious illness, as well as an awareness and emphasis on the need to follow standard best practices to enhance VR research rigor. Future directions to build upon this systematic review include evaluating different types of VR media and frequency and duration to target improvements in specific outcomes in patients with serious illness. Future studies may also consider more structured supervision and training for VR use for older adults and determine whether this leads to increased compliance and efficacy of VR to improve outcomes in serious illness. Finally, future research can focus on making VR more accessible to everyone, including older adults [70].

Conclusions

Our systematic review identified a growing body of research evaluating VR apps for older adults with serious illness through RCTs. The literature review illustrates the potential of VR in this population and finds promising but limited extant evidence. These limitations also highlight an important gap in the development and understanding of using VR to improve health and wellness, which are crucial to address for rapidly aging populations.

Acknowledgments

This study would not have been possible without the support of Stanford University School of Medicine and the VA Center for Innovation to Implementation.

Data Availability

The datasets analyzed during this study are publicly available, as detailed in the Methods section.

Authors' Contributions

BM contributed to the project ideation, data collection, data analysis, manuscript writing, and manuscript editing. AK contributed to the project ideation, data collection, data analysis, and manuscript editing. NI contributed to the data collection, data analysis, and manuscript writing. SF, JB, BB, and KG contributed to the project ideation, data analysis, and manuscript editing. CK and TO contributed to manuscript editing. KL contributed to the project ideation, data collection, data analysis, manuscript editing, and overall project oversight. All authors read and approved the final version of this manuscript.

Conflicts of Interest

Author TO contributed to the project while working at the VA, however, is now employed at Microsoft. After his participation in the project, he also recently became an advisor for the VR enabled company RadiusXR.

Abstract

Background: Patients with type 2 diabetes mellitus (T2DM) face elevated morbidity, mortality, and care costs. Digital self-monitoring of blood glucose (SMBG) can automatically upload data to apps, share the data with health care providers, reduce errors, and aid long-term diabetes management.

Objective: This study aimed to assess the effectiveness of digital diabetes management techniques based on digital SMBG on blood glucose in patients with T2DM at home.

Methods: A systematic search was conducted in PubMed, Embase, Web of Science, China National Knowledge Infrastructure, Wanfang, China Biomedical Literature Database, and Cochrane Library for articles published from the establishment of each database to December 25, 2023. Data were extracted independently by 2 researchers (YX and NX), and the risk of bias in individual trials was rated using the Cochrane risk-of-bias tool. A meta-analysis was conducted using RevMan 5.3 (Cochrane).

Results: Twelve studies were included, involving 1669 participants. The meta-analysis found that in the digital diabetes management group, hemoglobin A_{1c} (mean difference [MD] –0.52%, 95% CI –0.63% to –0.42%; *P*<.001), fasting blood sugar (MD –0.42, 95% CI –0.65 to –0.19 mmol/L; *P*<.001), 2-hour postprandial blood sugar (MD –0.64, 95% CI –0.97 to –0.32 mmol/L; *P*<.001), and BMI (MD –1.55, 95% CI –2.92 to –0.17 kg/m^2; *P*=.03) were each improved compared to the control group.

Conclusions: Digital diabetes management has been shown to effectively improve blood glucose levels and BMI in individuals with T2DM in home settings. A key feature of successful digital health interventions is the frequent SMBG by patients, supported by dedicated health care professionals who provide timely, personalized, and responsive guidance.

Introduction

Type 2 diabetes mellitus (T2DM) is a chronic metabolic disorder primarily characterized by persistent hyperglycemia due to insulin resistance or inadequate insulin secretion [1]. The International Diabetes Federation [2] reported that the global prevalence of diabetes reached 533 million cases in 2022, with projections indicating a surge to 783 million by 2045, of which over 90% are expected to be T2DM cases [3]. This condition often manifests insidiously, progressing over an extended period, with chronic hyperglycemia as its hallmark clinical feature [4]. Poorly controlled blood glucose levels over time can inflict severe damage on vital organs and tissues, including the heart, brain, and kidneys [5], leading to debilitating complications that significantly compromise patients' health and quality of life [6].

T2DM is a lifelong condition, and short-term treatment is insufficient to achieve effective blood sugar control. Patients require lifelong management and a long-term, standardized approach to home care [7,8]. International scholars universally agree on the importance of home management for individuals with T2DM [9]. Research by Yan et al [10] has highlighted the high demand among patients with diabetes for home blood glucose monitoring, a finding consistent with the observations by Simsek et al [11] regarding chronic disease management in older adult populations. An increasing number of patients now seek personalized, home-based guidance from health care professionals (HCPs), underscoring the pivotal role of the home environment in diabetes rehabilitation [12,13]. Moreover, studies demonstrate that home blood glucose self-monitoring effectively improves glycemic control and reduces the risk of long-term complications [14].

Traditionally, home blood glucose management has relied on clinician-led, face-to-face consultations. However, such offline consultations are time-consuming for HCPs and impose economic burdens on patients. In addition, these short-term interactions often fail to adequately support patients' long-term self-management efforts, rendering them less effective [15].

Mobile internet technology has brought about a revolution in diabetes management by introducing digital platforms designed for home-based patients with T2DM. Digital diabetes management entails using advanced tools to gather self-monitoring of blood glucose (SMBG) data, which is subsequently sent to HCPs for analysis and feedback. This technology simplifies blood glucose monitoring and boosts patient-provider communication [16]. Research indicates that it allows HCPs to assess data in real time, reducing the necessity for outpatient visits and easing the burden on both health care facilities and patients [17].

Despite its benefits, the manual entry of SMBG data during home care remains time-intensive, particularly for older adult patients, and is prone to errors, including transcription inaccuracies or intentional misreporting [18,19]. In addition, HCPs often face challenges in interpreting SMBG data to identify lifestyle or treatment issues. Recent advancements in SMBG devices now allow automatic uploads of blood glucose measurements to secure digital health applications accessible to HCPs [20-22]. Real-time monitoring of this data enables timely interventions when abnormal readings are detected, thereby facilitating more accurate management of hypoglycemia or hyperglycemia. Furthermore, this technology supports long-term diabetes care by informing adjustments to insulin, diet, and exercise regimens [23].

Currently, no meta-analysis has systematically assessed the effectiveness of digital SMBG-based diabetes management technologies. Evaluating the impact of these technologies on blood glucose control in home settings is essential for understanding their utility in managing T2DM. This study aims to synthesize global research findings through meta-analysis, examining the effects of digital SMBG-based diabetes management on glycemic control in home-based patients with T2DM. The results are intended to provide evidence to support the broader application of digital SMBG technologies in home care environments.

Methods

Overview

This review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines published in 2020 [24], and a search protocol retrospectively registered on July 5, 2024 on PROSPERO (CRD42024560431) formed the basis of the review process.

Search Strategy

We searched PubMed, Web of Science, Embase, Cochrane Library, China National Knowledge Infrastructure, Wanfang, and the Chinese Biomedical Literature Database using the terms "Diabetes Mellitus, Type 2," "Internet," and "RCT" from inception until December 25, 2023. The search strategy used Boolean logic to combine medical subject headings and text word searches. We also screened references from relevant previous systematic reviews as additional sources, and the languages were limited to Chinese and English. The complete search strategy can be found in Multimedia Appendix 1.

Eligibility Criteria

Inclusion criteria were formulated based on the populations, interventions, comparisons, outcomes, and study design (PICOS) framework:

1. Populations: Participants with T2DM
2. Interventions: Patients used a digital blood glucose management system that allowed for the automatic upload of SMBG data from home to a secure platform via Bluetooth or other wireless technologies, and HCPs provided timely and responsive personalized guidance
3. Comparisons: Traditional home blood glucose monitoring methods (including routine outpatient follow-up, blood glucose monitoring logs, etc)
4. Outcomes: Hemoglobin A_{1c} (HbA_{1c}), fasting blood glucose (FBG), 2-hour postprandial blood glucose (PBG), and BMI. HbA_{1c} is the gold standard for long-term blood glucose control, reflecting the average blood glucose levels over the past 2 to 3 months. FBG can present information on blood glucose in the fasting state, which helps to understand

XSL•FO
RenderX

basic glucose metabolism. Measuring the PBG can evaluate the body's ability to handle the glucose load after a meal and provide insights into the PBG regulation. BMI is a practical tool for assessing overall body fat, which is associated with health risks caused by obesity and metabolic disorders, and the included studies reported at least one of these findings.

5. Study design: Randomized controlled trials

Exclusion criteria included (1) studies involving patients with gestational diabetes or type 1 diabetes, (2) review or discussion papers, and (3) studies with insufficient data.

Study Selection

Two reviewers (YX and NX) independently performed the screening and selection of studies. Disagreements were resolved through discussion or consultation with a third reviewer (ZW). First, we imported the retrieved literature into the NoteExpress software (Beijing Aiqinhai Software Company) and used it to identify and remove duplicate literature. Then, we evaluated whether the titles and abstracts were eligible. In addition, clearly incompatible studies were excluded after screening the titles and abstracts. Finally, full texts of qualified studies that strictly adhered to the inclusion and exclusion criteria [25] were screened to determine their final eligibility for the review.

Data Extraction

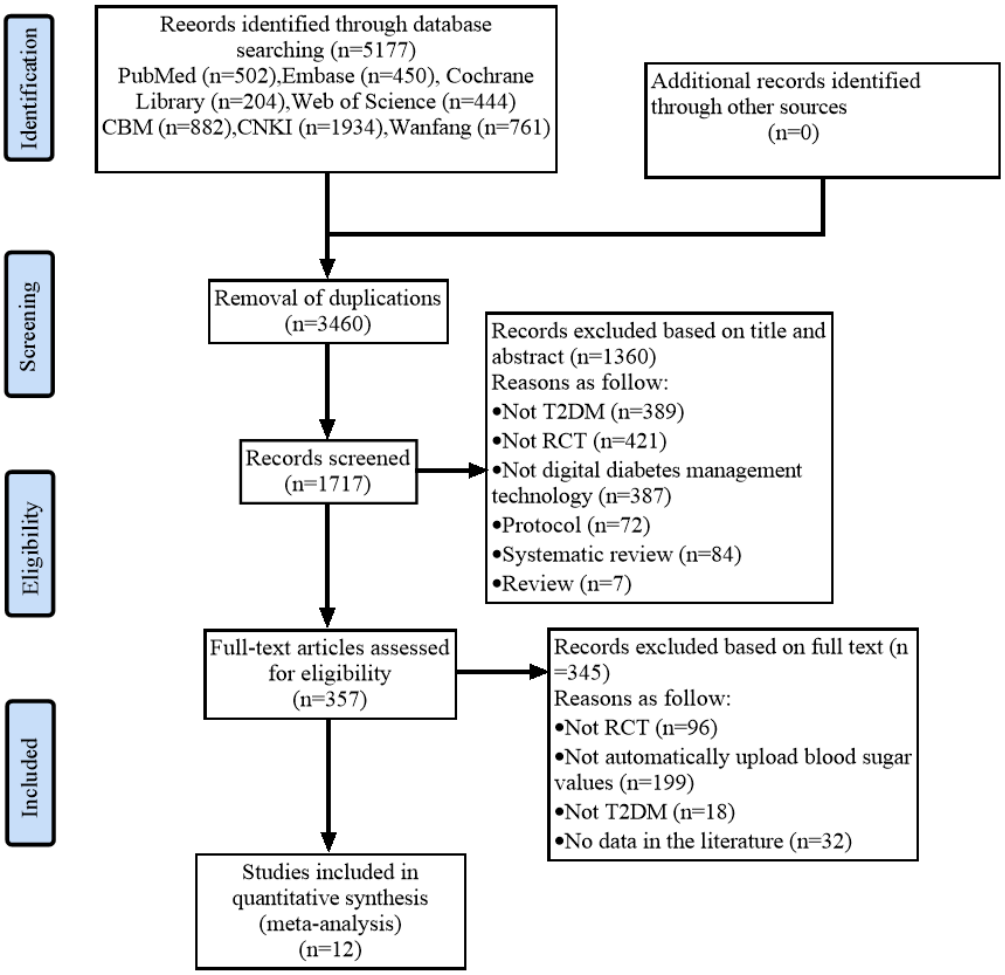
Data extraction from the studies included was performed by 2 independent reviewers. Characteristics of the studies (author, year, country, and sample size) and intervention characteristics (equipment used by the intervention, intervening measures, control measures, duration, and outcomes) were included.

Risk-of-Bias Assessment

The quality of the included studies was assessed using the Cochrane risk-of-bias tool, administered by 2 independent assessors. This tool evaluates the quality of study methodology across seven core dimensions: (1) the process of randomization sequence generation, (2) the concealment of allocation, (3) blinding of participants and researchers, (4) blinding during outcome assessment, (5) completeness of outcome data and handling of missing data, (6) selective reporting of study results, and (7) the potential for other sources of bias. The risk of bias for each domain was categorized into 3 levels: low, unclear, or high. Disagreements between the assessors were resolved through discussion, or, if necessary, consultation with a senior reviewer (ZW).

Data Analysis

The meta-analysis was conducted using RevMan 5.3 [26], a desktop version of Review Manager software used for Cochrane intervention and flexible reviews. For continuous outcomes, we calculated the mean difference (MD) as a metric; while for dichotomous variables, the risk ratio was used and visualized by forest plots. In each analysis, I^2 was used to measure statistical heterogeneity among studies. According to the values of P and I^2, the fixed-effect model ($P>.10$, $I^2<50\%$) or random-effects model ($0<P<.10$, $I^2\geq50\%$) were selected [27].



Results

Results of Literature Search

A total of 5177 papers were retrieved from 7 databases. After removing 3460 duplicate records, 1360 articles were deleted due to unqualified titles and abstracts. A more detailed full-text screening was conducted on the remaining 357 articles, and 345 of them were excluded for not meeting the established criteria. As a result, the final systematic review included 12 meta-analysis studies [28-39]. The detailed research screening process and results are shown in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram: papers included and excluded in this review. RCT: randomized controlled trial; T2DM: type 2 diabetes mellitus.

Study Characteristics

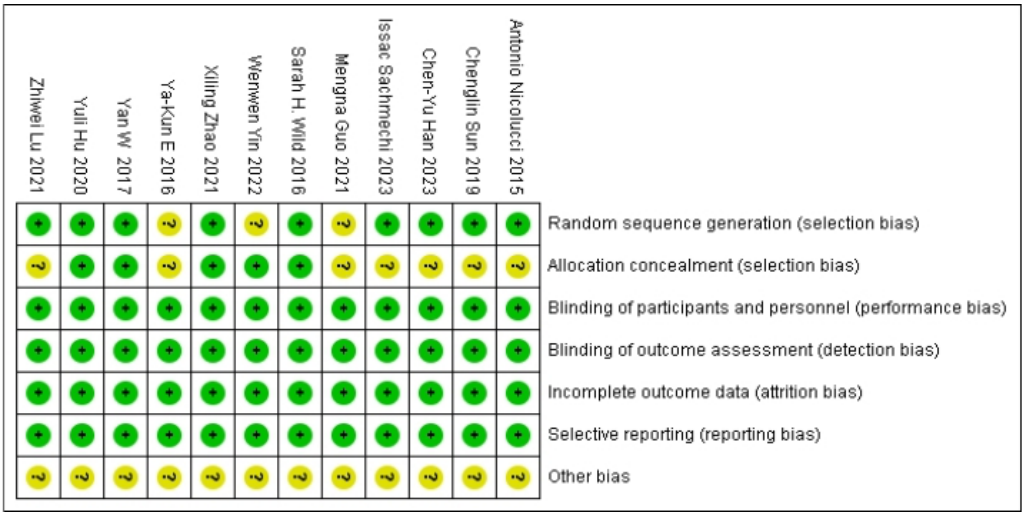
The research includes trials conducted in 5 countries: China [28-34,36], the United States [35], India [37], the United Kingdom [38], and Italy [39]. These trials were published between 2015 and 2023. The sample size ranged from 64 to 285 participants, and the intervention duration varied from 1 to 12 months. Among the 12 studies, 6 used Bluetooth technology to achieve automatic upload of blood glucose values [28,29,32,34,38,39], one study adopted an implantable blood glucose sensor for automatic data transmission [33], and another 5 studies used local area network technology to automatically upload blood glucose measurement values [30,31,35-37]. Multimedia Appendix 2 [28-39] presents the author, year, country, sample size, equipment used by the intervention, intervening measure, control measure, duration, and outcomes.

Risk of Bias

Based on the Cochrane criteria, a risk-of-bias assessment is presented in Figures 2 and 3 [28-39]. A total of 12 studies were included, all of which were assigned a literature quality grade of B [28-39]. Randomized methods were reported in detail in 9 (75%) of the 12 studies [28-30,34-39]. The remaining 3 studies did not provide detailed randomization methods. In terms of allocation concealment, 5 studies explicitly mentioned the methods used [30,32,35-37]. In all studies, participants were not blinded due to the specificity of the intervention method.

XSL•FO
RenderX

Figure 2. Risk-of-bias analysis of each included study.



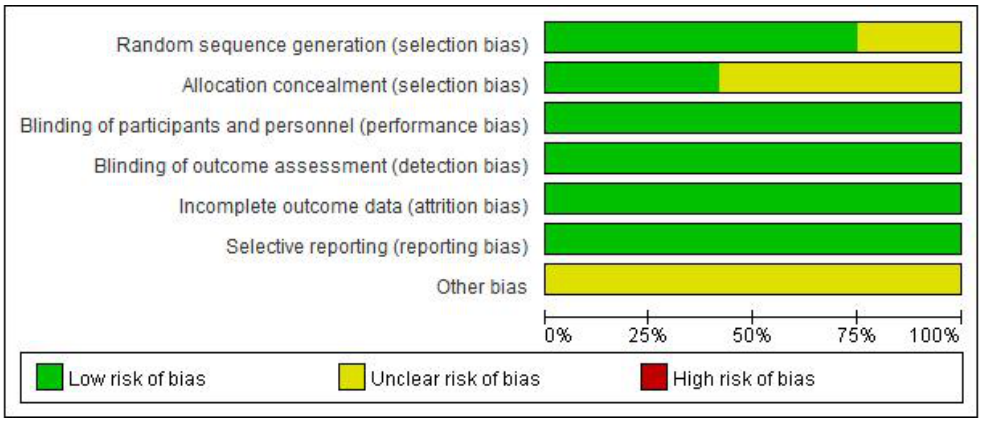


Figure 3. Overall risk-of-bias analysis of included studies.

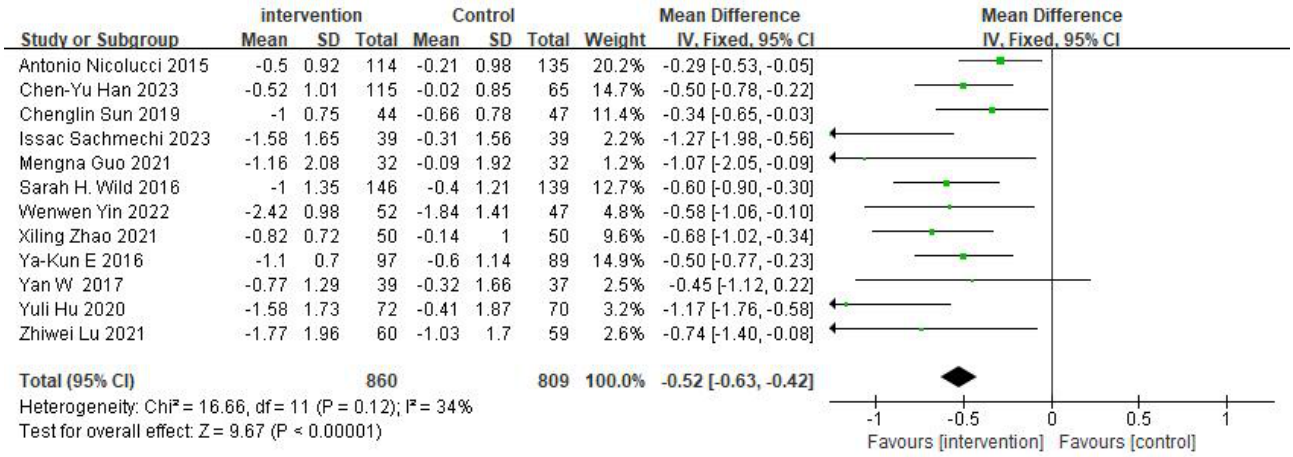
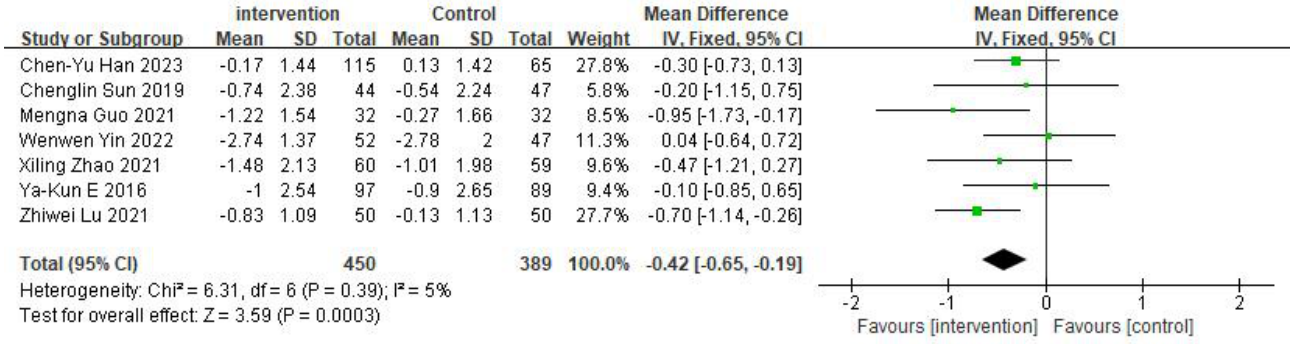


Results of the Meta-Analysis

Effects on HbA_{1c}

Twelve studies reported the effectiveness of digital diabetes management in improving HbA_{1c} [28-39]. The meta-analysis results showed a significant improvement in HbA_{1c} (n=1669; MD −0.52%, 95% CI −0.63 to −0.42; *z* value 9.67, *P*<.001; I^2=34%; fixed-effects model) compared to the control group (refer to Figure 4 [28-39]).

Figure 4. Forest plot of hemoglobin A_{1c} (HbA_{1c}).



Effects on FBG

Seven studies were reported on FBG [28-34]. The results indicated that participants in the intervention group experienced a significantly greater reduction in FBG compared to the control group (n=839; MD −0.42, 95% CI −0.65 to −0.19 mmol/L; *z* value 3.59; *P*<.001; I^2=5%; fixed-effects model; refer to Figure 5 [28-34]).

XSL•FO
RenderX

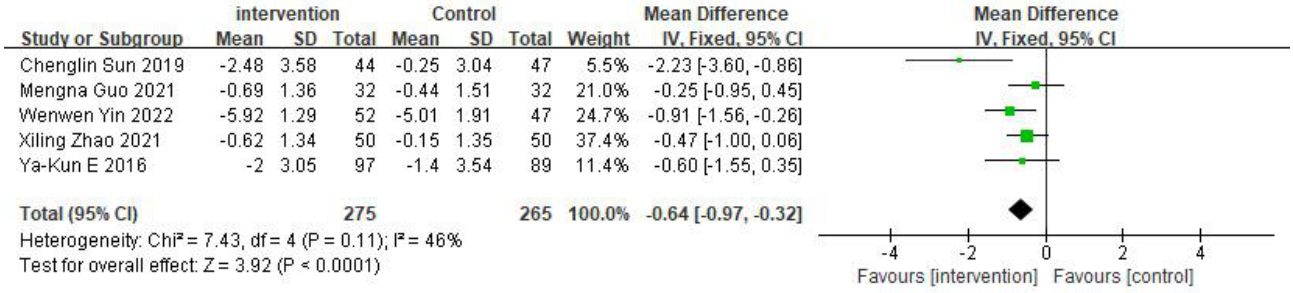


Figure 5. Forest plot of fasting blood sugar.

Effects on PBG

Five studies reported on PBG [29-33]. The results showed that participants in the intervention group had a significantly greater reduction in PBG compared to the control group (n=540; MD −0.64, 95% CI −0.97 to −0.32 mmol/L; *z* value=3.92; *P*<.001; I^2=46%; fixed-effects model; refer to Figure 6 [29-33]).

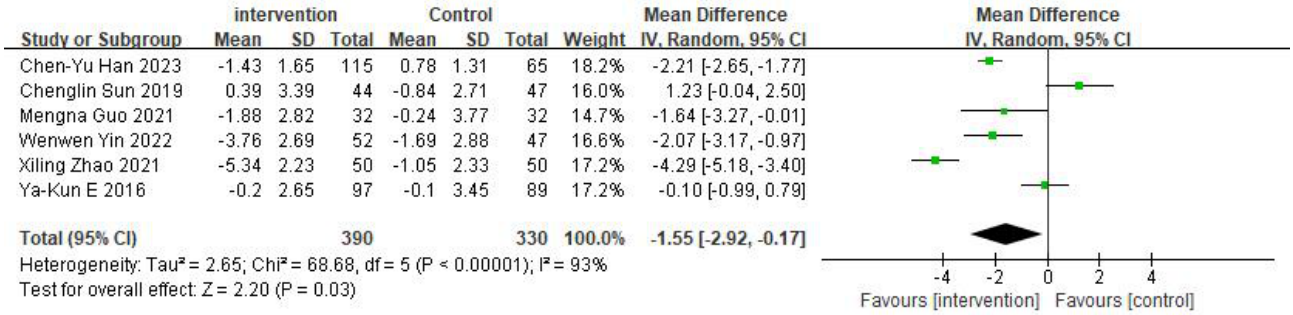

Figure 6. Forest plot of 2-hour postprandial blood glucose.

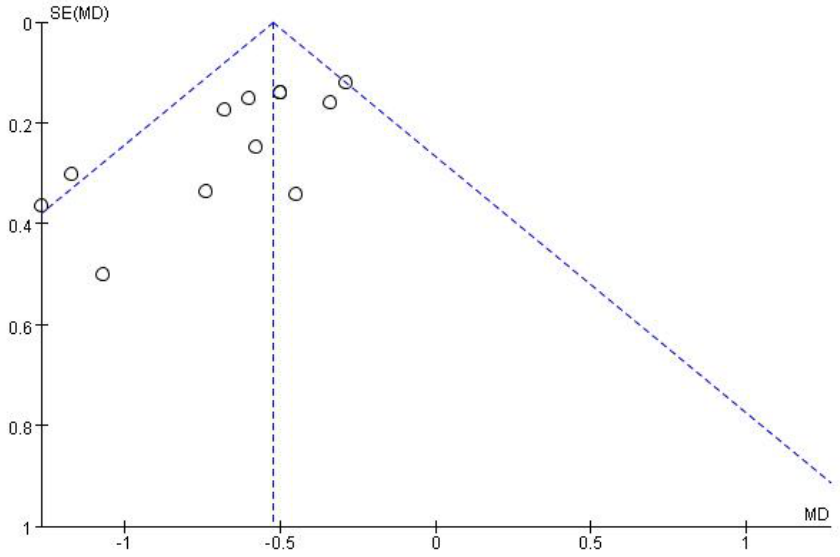
Effects on BMI

Six studies reported on the effectiveness of digital diabetes management in improving BMI [28-33]. The meta-analysis results showed a significant improvement in BMI (n=720; MD −1.55, 95% CI −2.92 to −0.17 kg/m^2; *z* value=2.20; *P*=.03, I^2=93%; random-effects model) compared to the control group (refer to Figure 7 [28-33]). Due to high heterogeneity, 3 studies were identified as contributing to the variability, as revealed by sensitivity analysis [29-31]. After removing these 3 studies, the heterogeneity was reduced to 0% (MD −2.16, 95% CI −2.55 to −1.76 kg/m^2; *z* value=10.70; *P*<.001).

Figure 7. Forest plot of BMI.



Publication Bias and Sensitivity Analyses

Most of the points in the distribution of HbA_{1c}, an outcome measure, were clustered within the funnel plot; however, the distribution was not entirely symmetrical, suggesting the possibility of publication bias in the results for HbA_{1c} in digital diabetes management (refer to Figure 8). We also performed a sensitivity analysis to assess how the results varied when individual studies were excluded and to evaluate the stability of the findings. When we removed a study from the model and recalculated the pooled estimates for the remaining studies, heterogeneity either disappeared or decreased, and the pooled results remained consistent, indicating the robustness of our findings.

XSL•FO
RenderX

Figure 8. Funnel plot. MD: mean difference.

Subgroup Analysis

Subgroup analysis of BMI based on the length of the intervention revealed that digital diabetes management for 3 months or less resulted in more significant improvements in BMI (refer to Table 1).

Table 1. Subgroup analysis.

Outcomes	Studies, n	Participants, n	Heterogeneity		Effect model	Meta-Analysis	
			P value	I^2 value (%)		Effect size (95% CI)	*P* value
BMI	6	720	<.001	93	Random	–1.55 (–2.92 to –0.17)	.03
≤3 months	2	164	.005	87	Random	–3.06 (–5.65 to –0.47)	.02
6 months	4	556	<.001	92	Random	–0.84 (–2.37 to 0.69)	.28

Discussion

Principal Findings

This meta-analysis evaluated the effectiveness of digital diabetes management technology based on digital SMBG for home-based patients with T2DM. The findings demonstrated significant improvements in HbA_{1c}, FBG, PBG, and BMI. Key features of effective digital health interventions include frequent patient engagement in SMBG and timely, personalized guidance provided by specialized HCPs.

Studies have shown that while the compliance rate for blood glucose control among patients with T2DM during hospitalization can reach as high as 80%, this rate significantly decreases by 25% to 30% once they are discharged and transition to home self-management [40,41]. Consequently, there is an urgent need to support home-based patients with T2DM in managing blood glucose fluctuations [42]. This study demonstrates that compared with traditional home blood glucose management, digital diabetes management technologies can significantly improve blood glucose levels in home-based patients with T2DM. Twelve studies [28-39] reported improvements in HbA_{1c} levels among home-based patients with T2DM following the use of digital diabetes management technologies, 7 studies reported that digital diabetes management technologies effectively improve FBG levels [28-34], and 5 studies examined the impact on PBG levels [29-33]. In conclusion, digital diabetes management technologies play a pivotal role in blood glucose management for home-based patients with T2DM and should be widely implemented in clinical practice. Ongoing focus on blood glucose monitoring is essential for maintaining stable blood sugar levels in these patients [43].

At the same time, the meta-analysis results of this study suggest that digital diabetes management technologies can reduce the BMI of home-based patients with T2DM, consistent with the findings of a systematic review by Marcolino et al [44]. However, the heterogeneity in this study is relatively high. Sensitivity analysis, conducted by excluding studies one at a time, indicated that the variability may be due to differences in intervention durations. Subgroup analysis based on intervention duration showed that when the intervention lasted less than 3 months, it effectively improved BMI. In contrast, when the intervention duration exceeded 6 months, no similar improvement was observed. Given the relatively small sample size, future large-scale, double-blind randomized controlled trials are needed to further validate the impact of digital diabetes management technologies on BMI.

With continuous innovation in sensor, microelectronics, and data analysis technologies, researchers have been actively investing in research and development. Meanwhile, the market's

XSL•FO
RenderX

strong demand for convenient and efficient blood glucose monitoring has spurred the rapid development of continuous glucose monitoring (CGM) technology. Medical staff assist patients in accessing blood glucose data via supporting mobile apps to formulate treatment plans. CGM technology offers continuous, dynamic blood glucose data, enabling a comprehensive grasp of blood glucose fluctuations, allowing timely detection of asymptomatic hypoglycemia and hyperglycemia, and contributing to optimized treatment plans and prevention of diabetes complications.

Nonetheless, CGM technology has limitations. Its equipment is costly, making long-term use unaffordable for some patients. In addition, frequent blood glucose checks may cause psychological stress in some, negatively affecting blood glucose control. Therefore, SMBG continues to play an indispensable role in diabetes management. SMBG offers patients immediate blood glucose readings at specific time points, enabling prompt adjustments to diet, exercise, or insulin dosage to maintain glucose levels within a safe range and prevent hypoglycemia or hyperglycemia. Furthermore, compared to CGM, SMBG devices are simpler, more affordable, and thus more accessible to a broader patient population, especially those with limited financial resources or relatively stable glucose fluctuations. SMBG also promotes active patient participation, increasing their awareness of disease management and enabling them to better understand the impact of daily factors on blood glucose levels. This process fosters improved lifestyle adjustments, enhances confidence in glucose control, and strengthens compliance with self-management regimens.

Among the 12 included randomized controlled trials, only 2 studies evaluated the impact of SMBG frequency on blood glucose levels [28,36], so a meta-analysis was not conducted. Both studies demonstrated that more frequent home blood glucose monitoring improved blood glucose control in home-based patients with T2DM. We observed that the frequency of SMBG in the intervention group was significantly higher than in the control group, and the digital diabetes management technology notably enhanced blood glucose control. Tomah et al [45] reported that higher SMBG frequency correlated with greater improvements in HbA_{1c}, suggesting that the frequency of measurements may directly influence clinically relevant outcomes, with 4 to 8 measurements per day being the most effective. Similarly, Mannucci et al [46] found that SMBG was more effective when a structured monitoring plan was implemented, and HCPs used the collected data. None of the 12 randomized controlled trials included in this study considered the frequency of contact with HCPs as an outcome measure to assess improvements in blood glucose levels. As a result, a meta-analysis could not be conducted. However, an analysis of the intervention strategies in these studies revealed that the frequency of contact with HCPs was higher in the intervention group than in the control group. In addition, a systematic review found that SMBG without support from HCPs did not yield significant clinical benefits [47]. This lack of benefit may be attributed to treatment inertia, where poor adherence to lifestyle changes and prescribed medications is common among patients with T2DM [48,49]. When feedback from HCPs is minimal, patients may feel anxious and uncertain when faced with poor SMBG control. In conclusion, digital diabetes management technologies, along with SMBG supported by HCPs, can significantly improve blood glucose control in home-based patients with T2DM.

This study advocates for the promotion of digital diabetes management technologies based on digital SMBG for home-based patients with T2DM. Such technologies can help eliminate transcription errors associated with manual data entry and offer increased convenience for patients, especially older adult individuals with T2DM, who may struggle with inputting blood glucose values due to poor vision or limited dexterity. This technology provides an age-friendly solution for blood glucose management. In addition, for older adult patients who live alone or have limited mobility, HCPs can remotely monitor blood glucose data, offer timely care, and quickly detect and address hypoglycemia or hyperglycemia. This improves the continuity and responsiveness of diabetes management. Furthermore, the use of digital devices in clinical practice can reduce the workload of clinical nurses and enhance overall work efficiency. Thus, it is recommended that this technology be widely implemented in both home and clinical settings to improve the safety and efficiency of diabetes management.

Comparison to Previous Work

The results of this meta-analysis align with those of previous studies on the effectiveness of digital diabetes management technology for improving blood glucose levels in home-based patients with T2DM. However, in many previous studies, SMBG devices required manual data entry for glucose measurements, whereas this study focuses on digital SMBG technologies capable of automatic data uploading [50-56]. To date, no other meta-analysis has specifically evaluated the application of digital diabetes management technology based on automatic SMBG for home-based patients with T2DM.

In addition, the results of this study revealed that digital diabetes management technology can significantly reduce BMI levels in home-based patients with T2DM, consistent with the findings of a systematic review by Marcolino et al [44]. However, several other systematic reviews suggest that digital diabetes management technology has no significant effect on BMI improvement [57-59]. This discrepancy highlights the need for future high-quality, large-sample studies to further investigate the impact of digital diabetes management technology on BMI. Such studies should explore potential differences in results due to variations in patient populations, intervention measures, and follow-up durations. Moreover, standardizing research methodologies and evaluation criteria will enhance the comparability and reliability of findings, providing a stronger evidence base for determining whether this technology can effectively improve BMI in patients with T2DM.

Strengths and Limitations

This systematic review and meta-analysis has several notable strengths. First, to the best of our knowledge, it is the first meta-analysis to evaluate digital diabetes management techniques based on digital SMBG for improving blood glucose levels and BMI in home-based patients with T2DM. Second, a comprehensive search of multiple databases was conducted,

XSL•FO
RenderX

with strict adherence to established methodological tools to ensure the reliability and transparency of the research process. Third, this study included a detailed subgroup analysis of BMI outcomes, confirming that the duration of intervention significantly influences the effectiveness of digital diabetes management technologies in home-based patients with T2DM. Finally, by analyzing multiple outcome indicators, this review provides a more comprehensive understanding of the role of digital health in diabetes management, offering valuable references for clinical practice.

We also acknowledge that this meta-analysis has some limitations. First, confined to Chinese and English literature, it excluded non–English and Chinese materials, failing to reflect global research. Future reviews should cover more languages. Second, most selected studies lack blinding details, risking measurement biases. Future research must focus on blinded outcome evaluation to minimize performance biases. Third, the HbA_{1c} funnel plot asymmetry indicates publication bias. Future studies should use multicenter, large-sample, randomized controlled trials for reliable results. Fourth, done over a year ago, the study may miss recent research due to the field's rapid development, and lacking timeliness. Future research needs constant updates. Fifth, 8 (67%) of the 12 studies were from China, with regional limitations as China's medical resources and telemedicine acceptance differ from elsewhere. Future studies should include more diverse regions to boost conclusion generality.

Future Directions

Overall, future digital health research can fill the existing gaps and improve the approach in 5 key areas. First, for the diabetes management technology based on SMBG, continuous exploration should be carried out on its advantages in blood glucose control. In particular, the impact of SMBG supported by HCPs on blood glucose should be assessed to tap more potential. Second, the intervention measures should be elaborated in detail so as to achieve the maximum degree of reproducibility and universality in different clinical contexts. Third, a comprehensive evaluation system will be constructed, covering aspects such as cost-effectiveness, patient satisfaction, and technology availability. This system is used to measure the value of intervention measures for the sustainable development of digital health in diabetes management. Fourth, researchers should be encouraged to study the differences in the efficacy of different population subgroups or provide patient-level data, enabling future reviews to identify the patient characteristics related to treatment outcomes. Fifth, researchers should actively collect and report patients' views on the intervention measures to improve the design basis.

Conclusion

This meta-analysis demonstrates that digital diabetes management technologies can effectively regulate blood glucose levels, improve glucose metabolism, and reduce BMI in patients with T2DM. However, due to the variation in intervention strategies, frequencies, and content across the included studies, future research should prioritize multicenter, large-sample, high-quality randomized controlled trials to refine and standardize these interventions. Notably, effective digital health interventions share a common characteristic: frequent patient engagement in SMBG, supported by HCPs who provide timely and personalized guidance.

Acknowledgments

This research was funded by the Innovation Training Project of College Students' Innovation and Entrepreneurship Training Program (S202210716065), the Project of Shaanxi Sports Bureau (20240063), and the Key Discipline Construction Project of High-level Traditional Chinese Medicine in Nursing of Shaanxi University of Chinese Medicine (2024XKZD16). In addition, we declare that we did not use generative artificial intelligence in any part of writing the manuscript.

Data Availability

All data generated or analyzed during this study are included in this published paper and its supplementary information files.

Authors' Contributions

YX contributed to conceptualization, data curation, formal analysis, methodology, software, and writing the original draft. LZ performed formal analysis, software, and writing the original draft. NX handled conceptualization, methodology, writing review, and editing. FC managed methodology, project administration, writing review, and editing. ZS contributed to conceptualization, methodology, and project administration. SZ handled project administration, writing, review, and editing. ZW managed conceptualization, funding acquisition, methodology, project administration, writing review, and editing.

Abstract

Background: Stroke is one of the most common cerebral vascular diseases, usually affecting people aged 60 years and older. It leads to a variety of disabilities requiring motor and cognitive rehabilitation. Poststroke rehabilitation is critical for recovery, particularly for upper limb impairments, which affect approximately 80% of stroke survivors. Conventional rehabilitation often faces barriers such as cost, accessibility, and patient adherence. In contrast, eHealth technologies offer a promising alternative by providing accessible, cost-effective, and engaging rehabilitation solutions.

Objective: While numerous systematic reviews have explored various aspects of technology-based rehabilitation for poststroke upper limb recovery, there is a notable lack of comprehensive synthesis of these findings. This gap presents challenges, primarily due to the focus on specific technologies, which complicates understanding the overall effectiveness of these interventions. Consequently, clinicians and researchers may find it difficult to assess the field holistically, potentially hindering informed decision-making in clinical practice. This review synthesizes evidence from systematic reviews evaluating the effectiveness of eHealth technology–based interventions for upper limb recovery in poststroke individuals. Two main questions are examined: (1) Are eHealth technology–based therapies more or equally effective than conventional therapies for stroke rehabilitation? (2) What are the main clinical considerations for low-cost eHealth technology–based rehabilitation?

Methods: Comprehensive literature searches were conducted in PubMed, Web of Science, Scopus, Embase, and Google Scholar using predefined inclusion criteria based on the Population, Intervention, Comparison, Outcome, and Study Design (PICOS) framework. Systematic reviews published in English without date restrictions were included. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) flowchart guided study selection. Methodological quality was assessed using the Assessment of Multiple Systematic Reviews (AMSTAR 2) criteria.

Results: A total of 1792 records were screened, resulting in 7 systematic reviews published between 2019 and 2023 being included. These reviews encompassed 95 studies involving 2995 participants with a mean age of 58.8 years across acute, subacute, and chronic stroke phases. Interventions included telerehabilitation, mobile health (mHealth) apps, augmented reality (AR), virtual reality (VR), wearable devices, and exergames. While AR and VR demonstrated potential benefits when combined with conventional therapies (eg, AR showing significant improvements in upper limb function with a standardized mean difference 0.657; $P<.001$), evidence for stand-alone effectiveness remained inconclusive due to heterogeneity in study designs, intervention protocols, and outcome measures. Most reviews were rated as critically low quality due to methodological limitations.

Conclusions: eHealth technologies hold promise for enhancing upper limb rehabilitation post stroke by addressing barriers such as cost and accessibility while providing engaging interventions. However, the field remains fragmented with insufficient evidence to establish clear efficacy. Future research should focus on standardizing protocols, optimizing neurorehabilitation principles such as dosage and task specificity, and improving methodological rigor to evaluate these interventions' long-term impact better.

Introduction

Background

A stroke event refers to the alteration in brain functions after a sudden disruption of brain blood flow. It has an incidence of 15 million people a year. Stroke is one of the most common cerebral vascular diseases, usually affecting the population aged 60 years and older, leading to a variety of disabilities for about 5 million surviving patients who require motor and cognitive rehabilitation [1,2].

This massive incidence puts tremendous pressure on health care systems to satisfy the need for effective and sustainable solutions for rehabilitation poststroke after hospital discharge. Indeed, the consequences of stroke encompass a spectrum of disabilities, spanning physical impairments to cognitive challenges, including issues with language, social interactions, and emotional well-being [3]. In about 80% of cases, patients with stroke experience motor impairments of the upper limbs [4], which are functionally complex and difficult to recover, making activities of daily living very difficult for the patients. Poststroke disability negatively impacts the quality of life and health, and only 25% of patients recover with only minor impairments [5].

Poststroke rehabilitation has a lead role in the recovery of the patients, and it is never too late to start [6]. The level of recovery varies from person to person, but with time, effort, and support, many patients with stroke can significantly improve their function and quality of life [7]. For this, stroke rehabilitation should be planned and implemented in a structured and coordinated approach to help patients regain their physical, cognitive, and functional abilities. For instance, the increasing understanding of brain plasticity is relevant to the rehabilitation strategy and outcome after brain damage, and the principles of experience-dependent plasticity are valuable for treatment [8,9]. Indeed, rehabilitation requires multiple and varied therapeutic approaches at any stage of disease (acute and chronic phases) [10]. In addition, the quantity and quality of treatment are important for an effective recovery: rehabilitation after a stroke should be task-oriented, offered in large doses, and with an active learning component for providing intentional and more effective training [11]. Training several times daily is necessary to exploit the neuronal plasticity that ensures effective neurorehabilitation.

Nevertheless, high-intensity treatments are very expensive for the health care system, and hospital stays often must be reduced. This could mean that patients could still have functional deficits on the day of hospital discharge [4], especially in the upper limb [11,12].

In addition, outpatient therapy is not feasible for many patients because of the high costs of individual specialized therapies and the logistical difficulties of transportation from or to the hospital.

Home rehabilitation is a good option to continue recovery from chronic diseases such as stroke and a good alternative to manage long-term rehabilitation problems. Therefore, home rehabilitation is necessary to provide such a large amount of training [13] because traditional rehabilitation programs do not usually comply with all the abovementioned requisites. Thus, to maintain progress in the recovery process, the conventional rehabilitation pathway must include self-administered home exercises, a home rehabilitation solution, and outpatient therapy.

However, even within these strategies, certain limitations exist. Patients often lack motivation or lose interest in performing exercises independently, for example, they may consider them too difficult or too easy or monotonous. Here, technology can play a crucial role. The absence of external feedback can be overcome with interactive systems that provide real-time guidance and encouragement, stimulating patients to continue their rehabilitation [14].

Technology plays a crucial role in bridging the gap between home rehabilitation and remote therapy. By providing tools and platforms, it enables patients with stroke to receive therapy, guidance, and support without the need for a physical presence in a health care facility. This not only improves long-term recovery but also allows hospitals to reduce the length of outpatient treatment and its associated costs, while maximizing the treatment capacity of therapists.

Technology That Impacts Poststroke Rehabilitation

Attempting to reduce and overcome all the mentioned logistical and economic barriers of long-term rehabilitation, technological solutions offer a beneficial and effective alternative to conventional therapy, making rehabilitation more accessible to everyone. Rehabilitation technologies can significantly enhance the effectiveness and accessibility of stroke rehabilitation programs when incorporating principles of experience-dependent plasticity [8,9,15]. These advanced and simple technologies are more commonly explored and used in developed countries, mainly due to their readiness and availability, but their potential for accessibility is universal, making them a promising solution for poststroke rehabilitation worldwide [16].

Advanced technological interventions for poststroke rehabilitation include robotics, transcranial magnetic stimulation, transcranial direct current stimulation, brain-computer interface, and functional electrical stimulation. These therapies, while effective, require a certain level of expertise and resources that may not be readily available in a home setting. Therefore, they are typically conducted in a clinical or rehabilitation center under the supervision of trained professionals. Other current less invasive technologies are virtual reality (VR), augmented reality (AR), and activity trackers (such as accelerometers, gyroscopes, pedometers, breath sensing, heart rate monitors, and calorie trackers) [17]. As a cutting-edge and computer-generated simulation technology, VR can create an enriched environment, facilitate task-specific training, and provide multimodal feedback to augment functional recovery

XSL•FO
RenderX

[18]. Users can use their hands or movement sensors, such as gloves or joystick, to interact with virtual objects. The development of low-cost sensors has allowed this technology to spread at the consumer level: the Sony PlayStation 3, Microsoft Xbox 360, and Nintendo Wii are examples of VR-based consoles [15]. AR technology combines real and virtual objects to provide an interactive real-time experience in a common environment [19]. Users can interact with AR through devices such as smartphones, visors, display, or active mirrors. These devices use cameras, sensors, and software to overlay digital information onto the real world. In contrast, functional electrical stimulation or neuromuscular electrical stimulators have been used predominantly for stimulating lower and upper extremity functions [20].

Telerehabilitation (TR), mobile health (mHealth) apps, assistive technologies, and electromechanical gait training (with variable automated speed and sensing treadmill) are simple technological interventions for poststroke rehabilitation [17]. Home-based TR is a branch of telemedicine that consists of the use of a variety of telecommunication platforms (such as telephone visits, mobile apps, serious games, web-based self-care programs, web-based videoconferencing, and sensor-based telemonitoring) by health care professionals to provide necessary patient care and remote evaluation, supervision, and support for persons with disabilities living at home [11,21]. Home-based TR allows to meet the rehabilitation needs of stroke survivors living in rural areas with limited health services, especially in westernized countries, where the stroke burden is rapidly increasing [22]. Home-based TR implies access at any time and from any place to rehabilitation services to address stroke aspects: (1) *motor function*: upper and lower extremities, balance, and gait; (2) *cognitive function*: spatial neglect, cognition, and memory; and (3) *language*: aphasia [23]. TR can be delivered synchronously or asynchronously, depending on patients' needs, medical conditions, and treatment plans [24]. The choice between synchronous and asynchronous TR depends on various factors, including the patient's needs, the nature of the therapy, and the available technology. Synchronous sessions are often used for live consultations, real-time feedback, and interactive exercises. Asynchronous sessions are more flexible and beneficial when patients need rehabilitation in their daily routines. Some TR programs use a combination of both approaches to offer a well-rounded service that combines real-time interaction with flexibility and convenience.

Also, mHealth apps are defined as health and well-being mobile services for medical care delivered using a mobile app or other wireless technology. These are interesting for their mobility, multifunctional skills such as reminders and videos, and ability to support specific rehabilitation goals and promote self-management [25]. mHealth apps for stroke rehabilitation can target different aspects of the disease, and there are mobile apps designed as games to improve finger dexterity and programs to increase adherence to home rehabilitation exercises, for example, for upper limb rehabilitation [26,27].

Objectives

This study identifies and appraises published systematic reviews. The aim is to describe the quality, summarize and compare the conclusions, and discuss the strengths and weaknesses in the effectiveness of low-cost eHealth technology–based rehabilitation for the recovery of the upper limb in poststroke individuals.

While numerous systematic reviews have examined various aspects of technology-based rehabilitation for poststroke upper limb recovery, there is a lack of comprehensive synthesis of these findings. This gap presents several challenges. The first challenge concerns the focus on specific technologies, which makes it difficult for clinicians and researchers to understand the overall effectiveness of technology-based interventions and the field holistically. Without this comprehensive understanding, health care providers may struggle to make informed decisions about implementing these interventions in clinical practice. We aim to address these gaps by reviewing systematic reviews and providing a comprehensive, high-level synthesis of the current evidence.

This systematic review focuses on technology-based rehabilitation with interventions supported by synchronous (real-time care) or asynchronous (not real-time care) TR, mHealth apps, or eHealth portable devices equipped with VR or AR apps. Hence, in this systematic review, we assessed the low-cost eHealth systems to determine their impact on improving upper limb functional recovery among patients with stroke by examining 2 main questions: (1) Are eHealth technology-based therapies more or equally effective than conventional therapies for stroke rehabilitation? (2) What are the main clinical considerations for low-cost eHealth technology–based rehabilitation?

Methods

Databases, Criteria, and Search Strategy

Separate literature searches were conducted in PubMed, Web of Science, Scopus and Embase databases, and Google Scholar. The Population, Intervention, Comparison, Outcome, and Study Design (PICOS) framework was used to define the following inclusion criteria: (P) the target population was composed of persons with poststroke, (I) we considered technological interventions for upper limb rehabilitation in stroke survivors (ie, eHealth rehabilitation, at home TR, and smartphone-based rehabilitation), (C) studies were selected with or with no control group comparison, (O) we considered upper limb function recovery outcomes, and (S) we search for systematic reviews written in English that evaluated the effectiveness of technology-based intervention for the rehabilitation of the upper limb in poststroke patients. There was no restriction on publication dates. The combination of key terms reported in Multimedia Appendix 1 was used for the search in each database. The searches were finalized in May 2023. Papers were excluded if they were not systematic review papers or were not written in English.

According to the predefined criteria, the screening phase was based on analyzing titles and then abstracts. Later, full-paper articles of those titles or abstracts of screened publications were reviewed independently by MR and SL. VS was involved in reaching a consensus in cases of disagreement. Studies that met

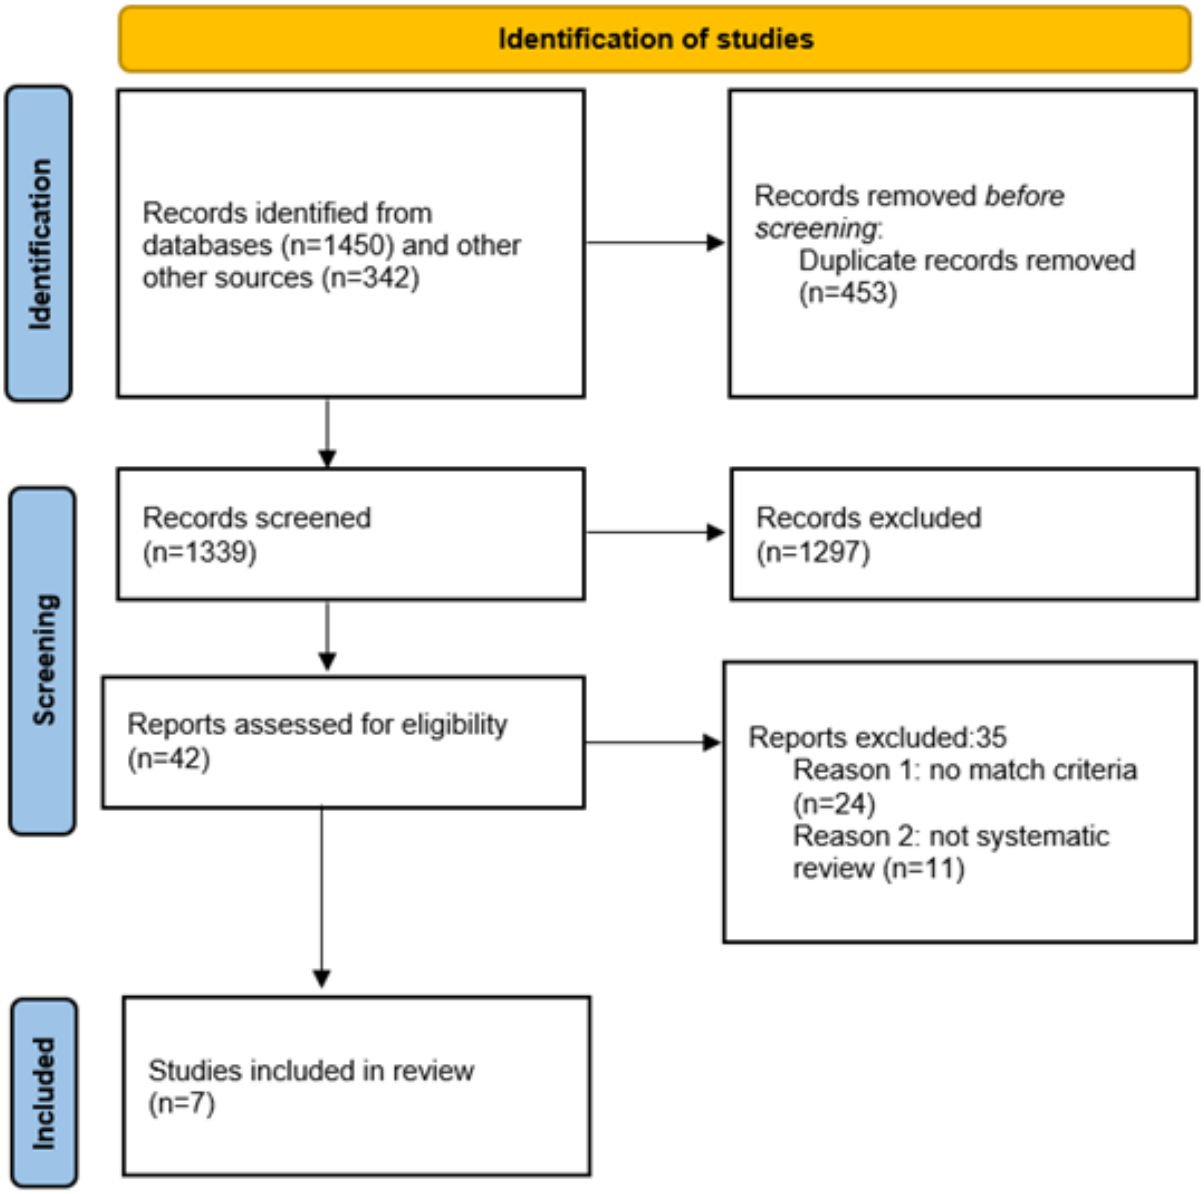
XSL•FO
RenderX

the inclusion criteria were included, and the results of the searches were summarized. We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) [28] flowchart in the retrieval and selection process. Each included systematic review was summarized by extracting essential data to answer the 2 research questions. The themes analyzed are (1) types of interventions and technology used, (2) effectiveness of eHealth technology–based interventions for recovering the upper limb, and (3) methodological quality assessments using the Assessment of Multiple Systematic Reviews (AMSTAR 2) criteria. The summaries were synthesized to provide a cohesive narrative highlighting similarities and differences across studies. This process involved comparing intervention types (eg, VR, AR, and mHealth apps), their reported effectiveness, and any noted limitations or gaps in evidence.

Study Quality Assessment

Three authors independently and anonymously appraised the final papers' methodological quality using the AMSTAR 2 [29]. AMSTAR 2 is designed to appraise systematic reviews of health care interventions and rate their overall confidence. The tool can appraise various aspects of systematic reviews of randomized controlled trials (RCTs), nonrandomized studies of interventions, or both.

It is composed of 16 items evaluated either with "yes" or "no" (items 1, 3, 5, 6, 10, 13, 14, and 16); with "yes," "partial yes," or "no" (items 2, 4, 7, 8, and 9); or with "yes," "no," or "no meta-analysis conducted" (items 11, 12, and 15). This tool evaluates the overall quality based on performance in critical and noncritical domains, which are assigned different weights in the rating rules. A "yes" answer means the item is fulfilled and is considered a positive result. Based on the performance in these 16 domains with different weights, overall ratings were generated, and the quality was determined to be "high," "moderate," "low," or "critically low." Namely, high confidence was defined as no or 1 noncritical weakness. Moderate confidence was defined as more than 1 noncritical weakness. Low confidence was defined as 1 critical flaw with or with no noncritical weaknesses. Critically low confidence was defined as more than 1 critical flaw with or with no noncritical weaknesses. Each review was appraised by 3 authors (MR, SL, and VR). In case of disagreement, it was planned that a fourth author (LA) would have solved them, but this was not the case. The analysis is reported in Multimedia Appendix 2.



Results

Characteristics of the Selected Reviews

As reported in the PRISMA flowchart (Figure 1), 7 systematic reviews were included. A summary of the studies and their findings is reported in Multimedia Appendix 3. Initially**,** the search process identified 1450 records from the databases and an additional 342 by Google Scholar. After duplicates (n=453) were removed, 1339 papers remained for initial screening by title. From this process, other 1297 papers were excluded because (1) studies involved patients for general rehabilitation (n=18), (2) the intervention was not specific for upper limb recovery functions (n=195), (3) the intervention was performed using other technologies (n=402), and (4) studies dealt with other topics or disorders (n=682). This process resulted in 42 potentially eligible abstracts. The authors analyzed the retained abstracts to obtain the final list of full-text papers to be reviewed. After examining the abstracts, 24 were excluded, as they did not fit the established criteria of the target population and the specific technology-based intervention. A second screening step was performed for those full-text papers that matched all the criteria (n=18). The other 11 were excluded from this process because the type of studies were not systematic reviews. The 7 studies included were published between 2019 and 2023.

XSL•FO
RenderX

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) flowchart.

Five of the selected reviews defined the study's design using the PICOS framework [30-34] whereas the other 2 defined the inclusion criteria [35,36]. Four reviews [30,31,35,36] were registered in the research protocol on the international database of prospectively registered systematic reviews in health and social care (PROSPERO). A total of 95 studies were included in the 7 reviews that overall mapped not only RCTs [30,32,33,35,36] and RCTs and non-RCT studies [31,34] but also observational studies [32] and uncontrolled clinical trials [34]. A total of 2995 patients were enrolled with a mean age of 58.78 years (SD 0.15 years). The average duration of stroke onset among the participants ranged from 7 days to more than 5 years, as each of the 7 reviews included patients in the acute (7 days to 3 months), subacute (3-6 months), and chronic (>6 months) phases. Only 1 paper also included patients without specifying stroke duration [35].

The chronic patients enrolled have had a stroke from 6 months or more [33,36], 21 months [35], 3 years [30,34] to 5 years [31], and more than 5 years [32].

Four of the selected reviews [30-32,34] investigated the effectiveness of technology-based rehabilitation interventions on physical functioning compared with a combination of traditional treatments in patients with stroke [30], upper limb wearable technology for improving physical activity and social participation in adult stroke survivors [31], AR for the upper and lower limb functional recovery after stroke [32], and mHealth apps containing a physical training in stroke rehabilitation [34]. Two reviews [33,35] examined the effects of home-based exergaming interventions on upper limb activity after stroke, compared with conventional therapy, in postintervention and follow-up [33]; the use of mobile apps for stroke rehabilitation on stroke-related impairments (motor paresis, aphasia, and neglect); and functional outcomes

XSL•FO
RenderX

(adherence to exercise, activities of daily living, quality of life, secondary stroke prevention, and depression and anxiety) [35]. Only 1 review [36] gathered evidence on VR-based TR for patients after stroke and compared it with conventional in-person rehabilitation.

As reported in Table 1, all 7 reviews analyzed the upper limb function as an outcome. The categorization of the most used outcome measures of upper limb is reported in Multimedia Appendix 4.

Table 1. Outcomes.

Outcomes (upper limb function)	Authors (years)						
	Rintala et al (2019) [30]	Parker et al (2020) [31]	Phan et al (2022) [32]	Gelineau et al (2022) [33]	Rintala et al (2023) [34]	Szeto et al (2023) [35]	Hao et al (2023) [36]

[a]N/A: not applicable.

Five reviews also assessed lower limb function and walking [30,32,34-36], balance [30,32,34,36] and physical activity, and function [30,34]. Participation was included as an outcome in 3 of the selected reviews [30-32], while the other 3 [34-36] evaluated the quality of life. Three studies assessed the activity of upper limb function [31-33], lower limb function [32], and participation [31,32] after stroke, according to the World Health Organization's International Classification of Functioning, Disability and Health framework [37].

Types of Interventions and Technology Used

Different low-cost eHealth technology–based interventions were reported in the 7 reviews analyzed. Web-based video monitoring and physical home exercises use smartphones, tablets, and web-based programs for real-time therapist-patient interaction and feedback. mHealth apps aim to improve limb movement and dexterity through user interaction with the app, allowing therapists to preselect exercises and assist caregivers in monitoring patient progress. Wearable technologies such as sensors and accelerometers capture actions or measurements and relay information for analysis and are connected to video games that require active body movements. AR projects virtual objects in real environments, allowing patients to interact with them and receive feedback. VR creates immersive simulations that require patient interaction, often with remote or in-person therapist supervision.

Web-Based Video

Web-based video monitoring and techniques for monitoring physical home exercises, goal settings or overall treatment, gamification, and accelerometers are mapped in 4 of the selected reviews [30,33-35]. The tools used varied from smartphones, phones, tablets, DVDs and programs via the web [30], and video game environments that required active body movements to control the game [33], to mHealth apps [34,35].

Looking at the details of the selected reviews, web-based video monitoring, phone calls, and messaging are the most common technologies used till now, as mentioned by Rintala et al [30]. They normally ensure a real-time therapist-patient interaction, with a "call" frequency ranging from 3 to 5 times per week to 1 per month. The therapist can also provide feedback through the web and, when necessary, by scheduling virtual training (eg, exercise videos) in advance [30].

Another option for remote technology–based rehabilitation, analyzed by Gelineau et al [33], is to provide exergames requiring a physical interaction (active body movements) to play the game. In that case, nonspecific video game systems (eg, Nintendo Wii, Xbox Kinect, etc) need to be combined with specific rehabilitation systems (eg, Rehabilitation Gaming System, virtual gloves, etc) or specific rehabilitation devices (eg, Hand Mentor Pro, Polhemus 3, etc). Patients with a prescription, usually ranging from 3 to 7 days per week, can use exergames systems independently, producing self-reported or observational measures (eg, technological sensors and therapist telehealth visits) [33].

mHealth Apps

Leveraging everyday technologies, such as smartphones and tablets or PCs, has become increasingly prominent in rehabilitation. This is made possible through implementing mHealth apps well investigated in the study by Gelineau et al [33]. These apps incorporate physical training components and offer a customizable approach tailored to individual patient requirements. This customization encompasses specific goals, desired difficulty levels, and the duration of app usage.

Moreover, these apps serve various purposes, including interactive gaming (eg, FINDEX and ARMStrokes), prescription of exercise routines (eg, CARE4STROKE), and progress monitoring (eg, STARFISH). They can also be integrated with

XSL•FO
RenderX

devices such as inertial measurement unit sensors and pedometers to enhance their effectiveness. This innovative use of technology complements traditional physiotherapy and widens the spectrum of rehabilitation possibilities.

Generally, the "gaming apps" require limb movement and interaction, aiming, for example, to improve upper limb and finger dexterity. In the "exercise prescription" app a therapist preselects a set of standardized exercises shown in the app, allowing the caregiver assistance, if necessary. "Monitoring apps" supervise and check patients' physical behavior (eg, number of steps per day, walking or sitting time, walking distance or speed, etc).

For all the types of apps, the prescription is maximally 30 minutes per session, from 1 to 7 times per week. The therapist's constant presence is not necessary, thanks to auditory and vibration feedback provided directly by the apps [34].

The mobile apps can be on any operating system (iOS, Android, and Windows) and on any aspect of stroke impairment rehabilitation (motor paresis, aphasia, and neglect). Focusing more on their possible goals, we could have therapy apps (with users' active device interaction to complete activities) or rehabilitation videos (exercises mobile guide), education apps (to learn about stroke), reminders (messaging to encourage compliance), or even a combination of them [35].

Wearable Technologies

Parker et al [31] described 2 types of wearable devices worn by patients. The first device operated independently and functioned as a central connector for other devices, whereas the second one captured specific action or executed a measurement and then sent the information to a primary wearable device for analysis.

The "wearable technologies" are something portable to wear externally on the body and to be used independently of a therapist. They can be used in both clinical and nonclinical settings to facilitate recovery, provide formative and real-time feedback, and measure intervention outcomes over long periods of time. They span from microelectromechanical systems (with accelerometers, gyroscopes, etc) to electromyographic biofeedback to robotics. This type of intervention can last 3-12 weeks, with various intensities [31].

AR- and VR-Based Rehabilitation

AR- and VR-based rehabilitation systems providing games were reviewed by Phan et al [32] and Hao et al [36]. Such systems included using head-mounted displays, Leap Motion, HD webcam, Microsoft Kinect v2 sensors connected to a laptop, or AR mirrors with visual tracking methods. AR technology is a real-time projection of virtual objects or scenarios in a common and real environment or place. During the game, the patients will interact with these virtual objects and receive automatic instructions, score, and visual and audio feedback via tracking devices (mouse, arm skate, HD Webcam, etc). The AR systems usually allow the creation of a personal training program with various training intensities, and the treatment duration is between 30 minutes and 1 hour per session [32]. VR is a computer-generated simulation technology that requires patient interaction, providing multimodal feedback. VR systems are often installed at patients' houses and may include the remote supervision of a therapist (eg, virtual-based TR group, interfaces for patient, and therapist remote communications). It is also used at hospitals or clinics, with a therapist's in-person supervision or instruction [36].

Effectiveness of eHealth Technology–Based Interventions for Recovering the Upper Limb

The selected reviews were analyzed regarding the effectiveness of the low-cost eHealth interventions. An effective intervention is based on statistically significant differences in 1 or more outcomes from the baseline, compared with the control, or if there is no control comparator, compared with another SD. Although all technology-based interventions included in these studies are economically favorable rehabilitation delivery models, no clear or direct evidence of impact on function recovery has been underlined.

Parker et al [31] highlighted little evidence to support the use of wearable technologies to improve activity and participation in the recovery of the upper limb.

Even if all the other reviews [30,32-36] reported similar effectiveness to conventional treatments, results are interpreted and discussed cautiously. For example, Rintala et al [30,34], Gelineau et al [33], and Szeto et al [35] discussed that rehabilitation technology, including mHealth apps, may have benefits as an additional treatment, but a lack of robust evidence does not consent authors to determine apparent effects.

Also, in the case of AR-based [32] and VR-based [36] TR, patients might still have a similar subjective experience of rehabilitation with therapists' supervision as in-person rehabilitation. According to Phan et al [32], the use of AR significantly influenced the upper limb function (standardized mean difference 0.657, 95% CI 0.287-1.026; $P<.001$). AR-based applications could offer options for increasing treatment intensity and promoting motor recovery after a stroke used with conventional rehabilitation methods. Also, for Hao et al [36], VR-based TR is a promising avenue for patients with stroke that can potentially overcome the barriers of traditional in-person rehabilitation. VR-based TR achieved comparable outcomes in the upper extremity function and equivalent effects on balance ability compared with in-person rehabilitation.

One aspect that holds significant clinical relevance is the duration of the intervention, which is measured in terms of both the quantity and the intensity of the dosage. Studies suggested a positive correlation between the time allocated for therapy and the therapy outcomes [38]. In the 7 reviews, the duration of the trials primarily ranged from 2 to 12 weeks.

According to Parker et al [31], improvements were observed across some studies for the control and intervention groups. The increase in the amount of rehabilitation has led to improvements in all the studies analyzed. This observation could suggest that a fundamental mechanism for improvement is the augmentation of the amount of rehabilitation administered. This concept has been acknowledged and incorporated into the national clinical guidelines for stroke. Szeto et al [35] concluded that the dosage and duration should be customized to address individual problems.

XSL•FO
RenderX

Some studies included in the study by Gelineau et al [33] reported follow-ups. However, in most of these cases, the duration of the follow-up is too short (4-24 weeks), leading to inconsistent results.

The selected reviews did not mention or report rigorous application of the experience-dependent plasticity principles, which are not always made explicit or clear [8,9].

In conclusion, further research is necessary to differentiate between the mechanisms of dosage and intensity. This will aid in understanding the impact of the volume of rehabilitation activity and how it compares with the intensity, which is the amount of rehabilitation administered over a specific time of period.

Quality Assessment

Among the 7 reviews assessed, 6 were rated as critically low quality [31-36], and 1 as low quality according to AMSTAR-2 criteria (Multimedia Appendix 2). Key issues affecting the validity of these reviews included inadequate protocol registration, inconsistent risk of bias assessments due to poor reporting on blinding and allocation concealment, and substantial heterogeneity across studies.

Only 1 review [36] lacked an explicit statement about protocol registration before the study began. All reviews demonstrated partial adequacy in their literature searches, with written protocols or guides that included review questions, search strategies, inclusion or exclusion criteria, and risk of bias assessments. None justified the exclusion of individual studies.

For risk of bias assessment, only 1 review [36] failed to use a satisfactory technique, while another [35] partially excluded nonrandomized studies of interventions. Three reviews [31,34,35] did not conduct a meta-analysis and 1 omitted it [32]. Five reviews [30,31,33-35] considered the risk of bias in their discussions. Only 2 reviews [30,32] adequately investigated publication bias and its potential impact.

In noncritical domains, 2 reviews [35,36] did not include all PICO components. All reviews explained their study design selections and performed study selection in duplicate; however, only 3 [30,31,33] duplicated data extraction. All reviews adequately described included studies; 4 [30,33,34,36] met all required criteria. Only 1 review reported funding sources for included studies. While 3 reviews [31,34,35] did not conduct a meta-analysis, only 2 [30,33] assessed the impact of bias on meta-analysis results. Five reviews [30,32-34,36] satisfactorily explained observed heterogeneity. Only 1 review failed to report potential conflicts of interest [30].

Overall, the critically low and low-quality assessments of the 7 reviews reflect the methodological shortcomings reported across these studies as low to moderate due to methodological limitations such as small sample sizes, lack of blinding, and heterogeneity in interventions.

Discussion

Principal Findings

Low-cost eHealth technology–based interventions should provide affordable and scalable science-based TR to cope with the pressure on health care systems to satisfy the need for effective and sustainable solutions for rehabilitation post stroke after hospital discharge.

In this study, 7 systematic reviews were selected to map the actual scenario of the use of low-cost eHealth technology–based interventions by examining two main questions: (1) Are eHealth technology–based therapies more or equally effective than conventional therapies for stroke rehabilitation? (2) What are the main clinical considerations for low-cost eHealth technology–based rehabilitation?

Most of these studies used advanced technologies with AR- and VR-based technologies and simple technologies with TR, mHealth apps, assistive technologies, and gait training.

Despite the differences among the reviews, all reached a unanimous conclusion, highlighting a cautious interpretation of data due to unclear evidence of the effectiveness of the examined technologies in restoring lost upper limb function [30-36]. Indeed, the variability in interventions, study designs, participant demographics, and measured outcomes contributed to heterogeneity across the studies, underscoring the need for future research to establish rehabilitation intervention principles that can inform the development of targeted innovative technologies [30-36]. Studies indicated that AR, VR, wearable devices, and exergames can improve upper limb motor function when combined with conventional rehabilitation methods, but their effectiveness alone is often comparable with traditional therapy [30,32-34,36].

Different clinical considerations favoring low-cost eHealth technology–based rehabilitation can be derived from the analyzed reviews. A central consideration is the potential of technology-driven interventions to enhance at-home poststroke rehabilitation for motivating survivors through interactive, user-friendly, engaging, and cost-effective tools. Indeed, eHealth systems could be seen as a way to reduce and overcome logistical and economic barriers of long-term conventional rehabilitation approaches by providing engaging and motivating rehabilitation interventions at home. Even if cognitive impairments or a lack of familiarity with technology can hinder the adoption of eHealth solutions, systems must be user-friendly to accommodate stroke survivors with varying levels of ability [30]. Continued research into the usability and effectiveness of this kind of system can guide the designers in developing a more user-friendly and engaging virtual ambient. Moreover, health care institutions should invest in patient education and engagement by introducing innovative systems into clinical practice.

Recent literature suggests that stroke affects the entire brain and its network properties, making it a network disease. Therefore, stroke-related neurological deficits and their recovery depend on neural network interaction patterns and follow principles of network plasticity [39]. In addition, the observation that network

interactions are correlated with current and future neurological function directly leads to whether their modulation through therapy might be feasible and clinically useful [40]. This evidence could open new frontiers for developing technology-based rehabilitation in poststroke individuals.

The feasibility of modulating brain networks through technology-based therapy may depend on several factors inherently linked to neurorehabilitation principles. According to these principles, exposure to specific training experiences in a recovery pathway improves impairment precisely because of the activation of these mechanisms of neuronal plasticity and remodeling [8]. The following neurorehabilitation principles should guide the selection of training experiences and rehabilitation technologies to optimize effectiveness [15]: massed practice, spaced practice, dosage, task-specific practice, goal-oriented practice, variable practice, increasing difficulty, multisensory stimulation, rhythmic cueing, explicit feedback or knowledge of results, implicit feedback or knowledge of performance, modulate effector selection, action observation or embodied practice, motor imagery, and social interaction. On the contrary, the selected reviews did not consistently adhere to all the principles of experience-dependent plasticity [8]. For example, interventions involving web-based video monitoring and phone calls often lack clear dosage specifications [30]. The AR system analyzed by Phan et al [32] used specific sensors [41] and viewers [42] to deliver exercises through games in both clinical and home settings. This system incorporated the neurorehabilitation principles of feedback (eg, game scores and social interaction), variable practice, and training intensity. However, AR systems face limitations: they are not always user-friendly, portable, or low-cost. While they offer a viable rehabilitation option, they may not be the most convenient solution for home-based upper limb rehabilitation.

Gelineau et al [33] highlighted the heterogeneity in exergame-based rehabilitation regarding the supervision and treatment dosage. Exergames are promising technologies that support stroke recovery and TR but still need to be explored more from clinical and neurorehabilitative perspectives. mHealth apps studies [34,35] often did not specify dosage prescriptions, indicating a limited application of neuroscience principles.

In VR-based TR [31,36], some systems offer synchronous patient supervision, while others provide only asynchronous settings; both ensure activity feedback and patient supervision. Nevertheless, the dosage prescriptions for these TR systems require further exploration. Low-cost eHealth technologies offer a promising avenue for stroke rehabilitation. They reduce barriers to rehabilitation by enabling remote monitoring and therapy delivery. This is particularly beneficial for patients in rural or underserved areas who face challenges accessing traditional in-person care [30,36]. Technologies such as wearable sensors and off-the-shelf gaming systems (eg, Wii) require poor infrastructure, making them suitable for home use [31,33]. Moreover, wearable devices and sensors allow continuous monitoring of movement quality, intensity, and frequency, providing valuable data for therapists to refine treatment plans remotely [31].

In conclusion, the integration of low-cost eHealth technology–based rehabilitation into clinical practice requires addressing usability challenges, standardizing protocols, rigorous adherence to all the principles of experience-dependent plasticity [8], and ensuring long-term effectiveness through further research. Combining these technologies with conventional therapies appears to yield the most beneficial outcomes for patients with stroke [43,44].

Limitations

Data sources were drawn only from PubMed, Web of Science, Scopus and Embase databases, and Google Scholar, excluding other data sources. Moreover, it is possible to miss relevant studies, especially if they are published in nonindexed journals, unavailable in electronic databases, or written in languages not included in the search criteria. Even if the PICOS framework was used to define the inclusion criteria, the combination of key terms to target the population and the specific technology-based intervention could have omitted some results from the search. Another significant limitation is the search strategy, which relied on a simple keyword search in titles and abstracts across databases. This approach may have inadvertently excluded relevant studies due to the lack of use of MeSH (Medical Subject Headings) and other controlled vocabulary terms that could have enhanced the comprehensiveness of the search. Medical Subject Headings terms are designed to capture all relevant papers on a topic, regardless of variations in terminology used by different authors. Future reviews should consider incorporating comprehensive search strategies, including keywords and controlled vocabulary terms across multiple fields within each database, to enhance the validity and reliability of conclusions drawn.

The heterogeneity and the different quality levels of the included studies are the significant limitations claimed by almost all the selected reviews [30,31,33-36]. Even if each review assessed quality using Physiotherapy Evidence Database Scale [30,33,34,36], Cochrane Risk of Bias for RCTs [31,35], Downs and Black Instrument for non-RCTs [31,34], and QualSyst [32], given the differences in assessment quality, our reviews' results should be interpreted and generalized with caution.

Moreover, we restricted the search strategy to only low-cost eHealth technology–based interventions for the upper limb recovery. This decision could have been the reason for excluding other relevant studies [45,46].

Implications for Clinical Practice and Future Research

This review indicated that the field of technology-based rehabilitation is still fragmented due to poor evidence achieved in terms of efficacy. This is probably due to the high heterogeneity of the experimental studies. We mapped various study designs, outcomes, and quality levels that demonstrate only the potential to assist with stroke recovery and augment face-to-face rehabilitation. Future research is called to frame a more robust methodology with a larger sample size [31-36] and valid measurement tools [31,34], deeper investigation on different gender and age groups [31,32], and other impacts depending on the stroke stage [33,35]. Also, the trial length and the study follow-up time were mentioned [35,36]. Regarding

XSL•FO
RenderX

technology readiness level, different issues were underlined to overcome the drawbacks of the reported technology-based rehabilitation interventions, for example, the integration and interoperability with intelligent infrastructure and the design of an attractive, user-friendly, portable, and low-cost system [32,34,35]. So, when developing a technology-based rehabilitation program, it is crucial to carefully plan and link all the relevant actors, user-driven design guidelines, and principles of neuroscience.

With this potential, the preferred option is to better understand the impact of technology interventions on varying types of stroke deficits and related outcomes, both alone and in combination with traditional rehabilitation. As Gelineau et al [33] have already highlighted the need for a gold standard, this field of research could benefit from standardized protocols provided to patients, enabling comparison and interpretation to discover evidence currently missing [15].

Conclusions

This review pooled the findings of 7 systematic reviews to map the actual scenario of the use of low-cost eHealth technology–based interventions and determine whether (1) eHealth technology–based therapies are more or equally effective than conventional therapies for stroke rehabilitation and (2) what the main clinical considerations for low-cost eHealth technology-based rehabilitation are. It found heterogeneity among interventions and measures, but the commonality of no clear or direct evidence of impact on recovery of function has been underlined. Advanced and simple technologies used for stroke rehabilitation allow overcoming financial, physical, and attitudinal barriers while providing engaging, specific, and low-cost exercises with constant feedback and supervision. These technologies serve as a valuable enhancement to traditional rehabilitation methods, particularly for the upper limb [47]. Unfortunately, demonstrating the efficacy of such interventions for restoring function after a stroke is still a challenge. Combining these technologies with interventions that follow neurorehabilitation principles may be more effective in promoting the recovery and retention of motor and cognitive functions after a stroke. Indeed, the integration of low-cost eHealth technology–based rehabilitation into clinical practice requires addressing usability challenges, standardizing protocols, rigorous adherence to all the principles of experience-dependent plasticity [8], and ensuring long-term effectiveness through further research. Combining these technologies with conventional therapies appears to yield the most beneficial outcomes for patients with stroke [48,49].

Acknowledgments

All authors provided intellectual contributions and critical feedback and reviewed the final manuscript. This study is cofunded by the EU Active and Assisted Living Program (AAL-2020-7-227-CP) and partially supported by Ricerca Corrente funding from the Italian Ministry of Health.

Authors' Contributions

VS designed the study; VS, SL, and MR conceptualized and drafted the manuscript and analyzed the data; and AM and LA reviewed the manuscript.

Abstract

Background: Telemedicine is a strategy for providing health care services remotely that improves service accessibility. Telemedicine has attracted growing research interest in the past 10 years, including systematic reviews that synthesize evidence to share experiences and enhance knowledge. However, most of the published systematic reviews have focused on synthesizing evidence from studies on telemedicine at the organizational level. A collected understanding of factors on the system level that influence the successful implementation and adoption of telemedicine needs to be developed, especially in regional and rural areas.

Objective: This scoping review aims to explore key success factors and challenges that influence the implementation and adoption of telemedicine at the system level, particularly in regional and rural areas.

Methods: This scoping review was conducted in accordance with the framework by Arksey and O'Malley and reported using the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews). A total of 5 databases (CINAHL, Cochrane, Medline, Ovid, and Scopus) were searched for research articles published in English between January 2010 and 2023, using the established inclusion criteria.

Results: Of the 10,691 papers identified, 89 were included in this review, including 16 (17.98%) studies conducted in regional and rural areas and 13 (14.61%) in metropolitan areas. Another 13 (14.61%) studies were conducted in both metropolitan areas and regional and rural areas. Overall, 6 categories with more than 70 key success factors, including system-level requirements (n=13, 18.40%), economic considerations and funding (n=6, 8.70%), technological requirements (n=6, 8.70%), organizational requirements (n=19, 27.54%), understanding and supporting clinicians (n=12, 17.39%), and understanding and improving patients' perceptions (n=13, 18.84%), were identified. Additionally, 5 categories containing over 50 challenges, including those related to system levels (n=11, 23.91%), technological requirements (n=6, 13.04%), organizational requirements (n=13, 28.26%), clinicians (n=10, 21.74%), and patients (n=6, 13.04%), were identified. Among the identified factors, 11 (9.57%) were specific to regional and rural areas.

Conclusions: This scoping review confirms that the successful implementation of telemedicine requires collective efforts at both the system and organizational levels, including coordination and collaboration across different regions and organizations. It underscores the importance of establishing a national network that enhances public awareness of telemedicine and clarity in payment and benefit distribution models and strengthens data security protection measures. The review also highlights the necessity of addressing infrastructural deficiencies, including internet connectivity in regional and rural areas, and suggests the implementation of targeted incentives and support measures. The required collective efforts are detailed in the proposed framework that promotes popularizing telemedicine, enhancing the overall quality and efficiency of health care services, and achieving broader health equity.

KEYWORDS

telemedicine; telehealth; digital health; success factors; challenges

Introduction

Background

Telemedicine enables medical professionals to provide diagnosis and treatment to patients from different locations by using phone or video calls. It is regarded as a strategy for addressing many challenges facing health care service provision, particularly for improving the accessibility of services provided remotely [1]. The World Health Organization defines telemedicine as "the delivery of health care services, where distance is a critical factor, by all health care professionals using information and communication technologies for the exchange of valid information for diagnosis, treatment and prevention of disease and injuries, research and evaluation, and for the continuing education of health care providers, all in the interests of advancing the health of individuals and their communities" [2]. This definition has been commonly applied in the 10 years since it was first published [3-6]. Telemedicine is one of the main tools in the current development of health systems, with significant potential for diagnosing, treating, and preventing diseases [7]. Different from the broad definition of telehealth, which covers both clinical and nonclinical services including training and continuing medical education for practitioners, telemedicine solely refers to remote clinical services [8]. However, both telemedicine and telehealth are core components of eHealth, a concept that includes all health care practices supported by electronic processes such as information and communication technologies (ICTs) [9,10].

Telemedicine can be implemented in the following 3 models: televisit, telemonitoring, and tele-expertise [11]. Televisits occur between doctors and patients through phone calls, video conferencing software, or secure email systems [11]. Telemonitoring involves using personal health technologies to collect, transmit, evaluate, and communicate patients' personal health data from outside hospitals or clinical departments (eg, patients' homes) and relay them to health care providers [12]. Tele-expertise allows health care professionals to seek medical opinions and guidance from, and share patient data with, experts via phone, video conferencing software, or secure email [13]. According to the care delivery modalities, telemedicine can be divided into synchronous and asynchronous telemedicine [14]. Synchronous telemedicine requires a real-time 2-way interaction between the doctor and patient [1] or between doctors [15]. In asynchronous telemedicine, clinical data elements, such as medical reports, images, and video recordings, are stored and transmitted for later evaluation [16]. Patients send photos of lesions, radiological scans, and lab results to doctors, who respond later in the same manner [17]. Based on these implementation and delivery methods, telemedicine is widely used in medical consultations, patient follow-ups, specialist consultations, drug prescription and delivery, teletriage and screening, and telerehabilitation, among other services [18].

The existing evidence indicates that telemedicine can bring multiple benefits. For patients, the use of telemedicine increases access to care [19], improves care outcomes [20], reduces costs [21], and leads to high patient satisfaction [22,23]. For health care providers, telemedicine saves a significant amount of time and costs [24] and reduces travel time [25]. Health care providers also show high satisfaction with telemedicine [26]. Given the numerous benefits of telemedicine, it is important to understand and identify its key enabling factors and the specific challenges in implementing it.

Key Success Factors

The existing research has focused on factors that enable the implementation and adoption of telemedicine services, including individual, organizational, technological, and economic factors. One individual enabling factor is doctor training and skill-building, which can mitigate the knowledge and skill gaps among health care personnel, enabling them to use telemedicine more easily [27]. Additionally, patients' satisfaction with telemedicine [28] and their positive opinion of digital devices [29] are also key individual factors for effective telemedicine implementation. At the organizational level, coordination between different health care levels and integrating telemedicine into clinicians' workflows [27] can enable the successful implementation of telemedicine services. At the technological level, the availability of technical support, good network coverage, user-friendly applications, and privacy protection are important [30]. Furthermore, in low- and middle-income countries, economic factors may include funding telemedicine projects to purchase equipment and software and pay for mobile services [30]. In high-income countries and regions, establishing a financial framework for telemedicine, financial benefits, and cost savings is a key economic factor [27].

Challenges Facing Telemedicine Implementation and Adoption

On the other hand, barriers to the adoption and implementation of telemedicine have been identified in the literature, including technology and equipment, patient privacy, user attitudes, and reimbursement policies. Common technology and equipment–related barriers include the lack of telemedicine equipment, inability to connect to the internet [31], and lack of access to or comfort with the necessary technology for a video visit [32]. User attitudes toward telemedicine could result in resistance to using telemedicine among both health care providers [33] and patients [34]. Evidence also indicates that the lack of reimbursement for telemedicine services [35] hinders the adoption and implementation of telemedicine.

Efforts in Synthesizing Evidence on Telemedicine

To further understand the current state of the research on telemedicine, we systematically retrieved 305 scoping reviews, systematic reviews, and meta-analysis papers on telemedicine published between 2010 and 2023 from the Scopus database. The search and review of the 305 review articles confirmed that existing studies mainly focused on the following four aspects: (1) the application of telemedicine before and after COVID-19 (n=63, 20.66%), particularly in specific diseases or populations;

XSL•FO
RenderX

(2) evaluating the effectiveness of telemedicine use (n=72, 23.61%), such as reducing patient mortality and improving patient quality of life; (3) the economic evaluation of telemedicine (n=109, 35.74%), such as cost-effectiveness and cost-utility analyses; and (4) examining factors influencing the implementation and adoption of telemedicine (n=43, 14.10%).

Among these scoping reviews, systematic reviews, and meta-analysis papers, the majority focused on synthesizing evidence from studies on telemedicine at the organizational level. Only a few papers synthesized information from studies focusing on understanding factors on the societal level or funding, policy, and regulation (system-level) factors influencing the successful implementation and adoption of telemedicine. System-level factors, beyond the boundaries of individual organizations, specifically refer to the national structures and policy environments, funding, and investment in infrastructure required to deliver telemedicine services, a process that involves collaborative efforts across multiple organizations [36]. Furthermore, a thorough understanding of the challenges facing telemedicine implementation and adoption in regional and rural areas is limited. Therefore, a scoping review was conducted to answer the following questions:

(1) What are the key factors that can influence the implementation and adoption of telemedicine at the system level, particularly in regional and rural areas?

(2) What are the key challenges facing the implementation and adoption of telemedicine at the system level, particularly in regional and rural areas?

Methods

Overview

The systematic review was conducted following the 5-step process described by Arksey and O'Malley [37], chosen for the exploratory and descriptive nature of our study objectives. The keywords and abstract screening, conducted by the authors XL and LH, only included studies in the health context. Authors XL and LH worked on the full-text review and data extraction together, in consideration of their lack of experience in conducting the systematic literature review and data extraction. Author ZL reviewed abstracts that received contradictory assessment outcomes from XL and LH. ZL also performed full-text reviews on the articles when required. A thematic analysis of the factors that influence the implementation of telemedicine was performed by contracted research officer LK. The Covidence systematic literature review platform [38] was used to perform both the abstract and full-text screening.

On December 16, 2023, a literature search was performed in the following 5 databases: CINAHL, Cochrane, Medline, Ovid, and Scopus. Table 1 details the 4 key concepts with associating keywords that were used to conduct the keyword search. Each search strategy includes keywords from concept 1 and either concept 2, 3, or 4. The key concepts were connected using the conjunction "AND," and the keywords under the same key concept were connected using the logical operator "OR." Search terms used were not restricted to the title only. They were found within the title, abstract, or keywords.

Table 1. Keywords and key concepts.

Concept 1	Concept 2	Concept 3	Concept 4
Telemedicine	Factors	Design	Location
• Telehealth • Tele-health • Tele-care • Telemedicine • Tele-medicine • Remote clinical service • Tele-critical care • (same concept use OR)	• Barriers • Challenge • Difficulty • Facilitator • Factors • Failure • Obstacles • Success	• Application • Execution • Financing • Funding • Implementation • Model • Operation • Regulation • Strategy	• District • Nonmetropolitan • Regional • Remote • Rural

Inclusion and Exclusion Criteria

Papers that met all the following criteria were included in the data extraction: (1) published in English in or after 2010; (2) published in a peer-reviewed journal; and (3) research findings that are relevant to 1 or 2 of the research questions for the review. Papers that did not meet all the aforementioned criteria were excluded from the final data extraction.

Data extraction

An Excel (Microsoft Corp) spreadsheet was set up for data extraction with the following categories: (1) year of publication; (2) country where the study was conducted; (3) purpose of the paper; (4) study design; (5) methods for data collection; (6) study population and sector; (7) target population; (8) sample size; (9) response rate; (10) metro or regional/rural location; and (11) factors that influence the adoption or implementation of telemedicine.

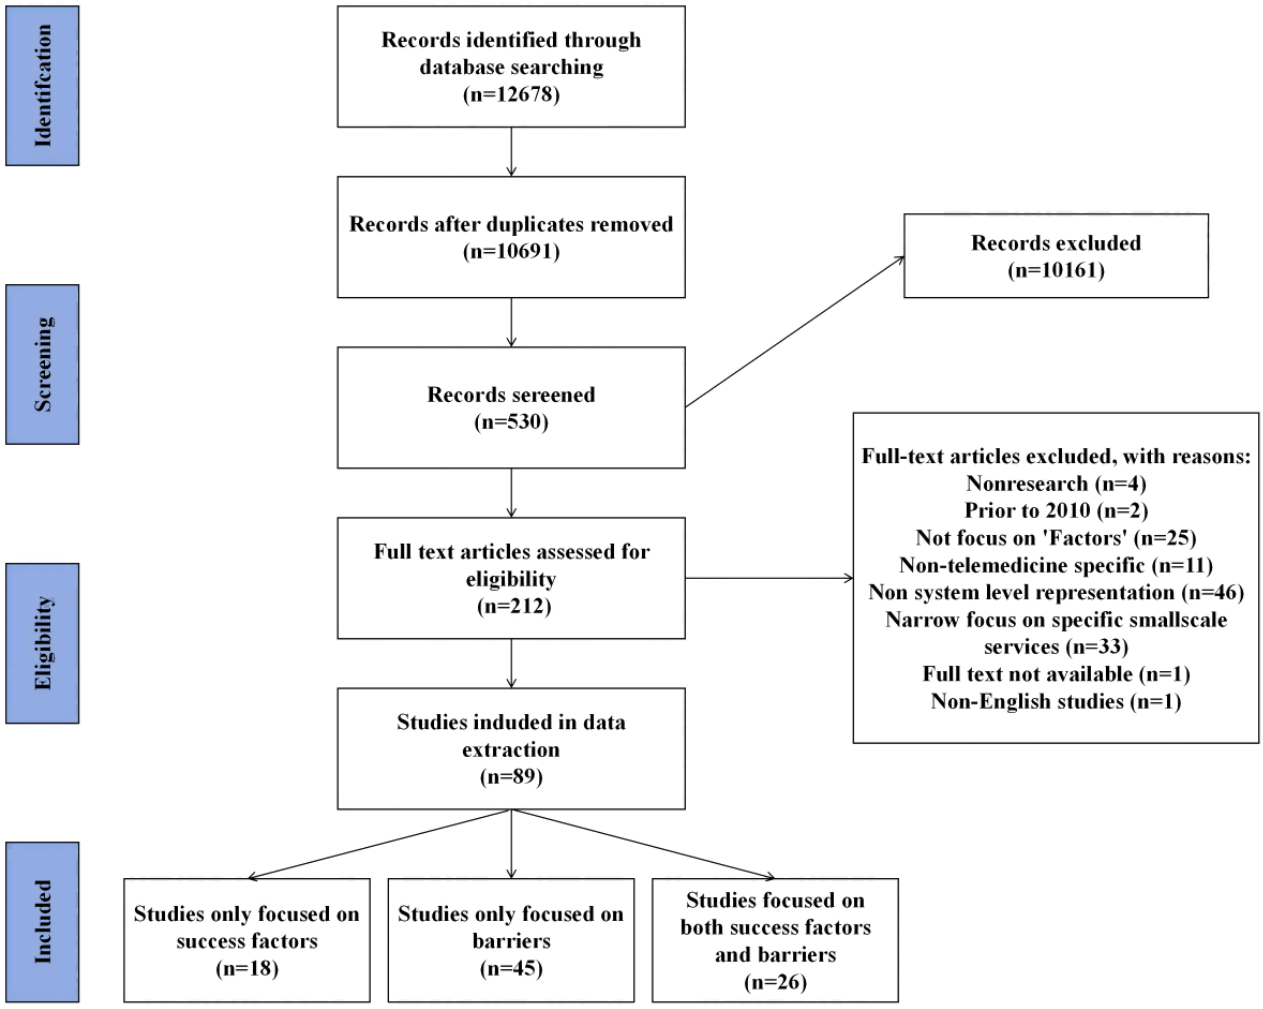
Data Synthesis

The data synthesis focused on key factors and challenges and involved a descriptive summary of the included studies. Guided by Braun and Clarke's thematic analysis [39], key themes were identified by examining data patterns and grouping similar concepts. A comparative analysis was performed to explore differences in findings between regional/rural and metropolitan areas. The results were synthesized to identify commonalities and discrepancies in the literature, addressing identified challenges that guided the development of a framework for implementing and adopting telemedicine. To ensure the accuracy of the analytical process, a codebook with descriptive meanings

XSL•FO
RenderX

of each theme was generated and discussed between the authors to refine codes and enhance the depth of the analysis.

Critical Appraisal



In line with the scoping review framework, we did not conduct a critical appraisal of the papers [37].

Results

Study Selection

This study was reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [40]. The completed PRISMA-ScR checklist is available in Multimedia Appendix 1. The PRISMA flowchart (Figure 1) details the review process and search results. The initial key concept and keyword search found 10,691 potentially relevant articles from the 4 databases. Title screening reduced the number to 530 papers, which were uploaded to Covidence [38] for abstract screening. After the abstract screening, 212 articles were included in the full-text review. The full-text review confirmed the inclusion of 89 articles for data extraction. Multimedia Appendix 2 contains a description of the 89 articles.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart.

Study Location and Year of Publication

Publication dates ranged from 2010 to 2023 (Multimedia Appendix 3). A total of 66 (74.16%) studies were published between 2020 and 2023. Among them, 4 (4.49%) studies were conducted in multiple countries in the following continents: the Middle East, South America and Europe, Sub-Saharan Africa, and North America. A total of 28 (31.46%) studies were conducted in the United States, 10 (11.24%) in Australia, 5 (5.62%) in China, 3 (3.37%) in Canada, 3 (3.37%) in Ethiopia, 3 (3.37%) in Germany, 3 (3.37%) in the United Kingdom, 2 (2.25%) in Egypt, and 2 (2.25%) in Uganda. Only 1 (1.12%) study was conducted on a global scale, which included 75 countries. Another 25 (28.10%) studies were conducted in 25 different countries. Of the 89 studies, 13 (14.61%) were conducted in metropolitan areas and 16 (17.98%) in regional and rural areas. Another 13 (14.61%) studies were conducted in both metropolitan areas and regional and rural areas.

Sectors and Target Population

A total of 21 (23.60%) studies were conducted in multiple sectors (hospitals, primary health care, nursing homes, aged

XSL•FO
RenderX

care, health authorities, and so on). On the other hand, 55 (61.80%) studies were single-sector studies, including 37 (41.57%) studies in hospitals, 14 (15.73) in primary health care, 2 (2.25%) in community health services, and 2 (2.25%) in mental health. Another 13 (14.61%) studies did not specify the sectors in which they were conducted.

Of the 89 studies, 31 (34.83%) focused on multiple target groups including patients, clinicians, managers, and service providers. The other 58 (65.17%) studies focused on single target groups, including 27 (30.34%) on clinicians, 18 (20.22%) on service providers, 6 (6.74%) on other users (eg, technicians, decision-makers, and medical students), 5 (5.62%) on patients, and 2 (2.25%) on managers.

Methods Used to Identify Factors

A total of 46 (51.69%) and 35 (39.33%) studies adopted quantitative and qualitative approaches, respectively. Among the studies, 10 (11.24%) adopted a mixed methods approach combining both quantitative and qualitative methods. The most common methods for data collection were surveys (n=43, 48.31%), interviews (n=24, 26.97%), and focus group discussions (n=7, 7.87%).

Key Success Factors

Among the identified articles, 44 (49.44%) discussed factors important to the implementation and adoption of telemedicine. More than 70 factors were mentioned in different papers. Based on the similarities and differences, these factors were organized into 6 different categories, as detailed in Textbox 1. The factors were placed into 4 categories—individual, organizational, technological, and economic. Individual factors were subcategorized based on their relevance to clinicians and patients. A category of system-level requirements was also created to accommodate the health system–level factors identified in this review. In total, the review identified 16 (17.98%) studies that focused on regional, rural, and/or remote areas. Factors identified in these studies were compared with the factors associated with metropolitan areas. For each included source of evidence, the detailed data that were charted are displayed in Multimedia Appendix 4.

XSL•FO
RenderX

Textbox 1. Factors important for the success of telemedicine (listed in alphabetical order). The * symbol indicates factors that are common to both metropolitan and nonmetropolitan areas. Factors that are specific to nonmetropolitan areas are italicized. ICT: information and communications technology

System-level requirements

- Established performance requirements and monitoring mechanism
- Improved security and reliability*
- Improvement of digital and health literacy
- National Health ICT index
- Policy and guidelines for the use of telemedicine
- Promotion of telemedicine (to both the workforce and the community)
- Provision of incentives
- Remuneration for service providers
- Robust telehealth program design*
- Telehealth equipment and software applications
- Workforce development
- Additional support and infrastructure investment in rural and remote areas
- Addressing unmet health care needs

Economic considerations and funding

- Cost and benefits sharing between providers and stakeholders
- Financial support and remuneration
- Health insurance coverage and arrangements
- Prior consideration of economic feasibility
- Provision of equipment grants
- Sustained funding allocation (beyond the grant period)

Technological requirements

- Data security and protection
- Efficient and functional network and information-sharing
- Improved ICT infrastructure and support
- Telehealth equipment and software applications
- Up-to-date computers, software, and telecommunication devices
- User friend software and system

Organizational requirements

- Engaging staff in designing the telemedicine goals and processes
- Established performance indicators that measure the benefits of telemedicine to patients, clinicians, and organizations
- Governance and policy
- ICT infrastructure and support
- Improved awareness of the benefits of telemedicine across organizations
- Leadership and management support
- Needs assessment and preparation
- Ongoing monitoring and modification of staff workload
- Patient education and support
- Promotion of telemedicine to both patients and key stakeholders
- Provision of incentives
- Provision of technical support

XSL•FO
RenderX

- Resources and support
- Simplified, standardized, and transparent processes
- Staff capability and competence
- Stakeholder engagement support
- Utilization of existing expertise
- Well-established quality improvement and monitoring processes
- Visible staff champions

Understanding and supporting clinicians

- Being flexible and adaptive to change*
- Digital skills*
- Feeling empowered and efforts are recognized
- Manageable workload and appropriate transition
- Perceived benefits of telemedicine for themselves, patients, and the organization *
- Positive perception and attitudes toward telemedicine*
- Positive teamwork*
- Receiving regular information and updates*
- After-hours staff support
- Encouraged safer clinical practices
- Increased access to relevant resources
- Perceived patient benefits and quality of care

Understanding and improving patients' perceptions

- Access to required telecommunication devices*
- Established confidence and trust in clinicians and the organization
- Increased awareness of telemedicine and its benefits to themselves
- Positive perception and attitudes
- Preexisting relationship with clinicians and organization
- Prior exposure to telemedicine
- Support in improving digital and health literacy
- Timely and accessible support and troubleshooting
- Transparent feedback system*
- Good internet access
- Improved patient-provider communication
- Improved patient experiences and outcomes
- Previous positive experience with telemedicine

Major Challenges Facing Telemedicine Implementation and Adoption

A total of 71 (79.78%) articles identified articles discussed challenges facing the implementation and adoption of telemedicine. More than 50 challenges were mentioned in different papers. These challenges (Textbox 2) were placed into the same categories as those created for the success factors.

XSL•FO
RenderX

Textbox 2. Challenges facing telemedicine (listed in alphabetical order). ICT: information and communications technology.

System-level

- Absence of nationwide integrated telemedicine framework
- Absence of regulatory framework
- Absence of coordination of telemedicine at the national level
- Inadequate efforts in addressing network and data security concerns
- Lack of funding to support organization readiness
- Lack of insurance coverage
- Lack of performance monitoring
- Lack of standardized and specific guidelines for the protection of patient privacy and confidentiality
- Social and cultural concerns
- Unclear reimbursement mechanism
- Unclear or confusing financial arrangements and funding and insurance model

Technological requirements

- High cost of equipment
- Lack of ICT infrastructure
- Lack of integration with other digital/online platforms
- Not user-friendly
- Poor internet access
- Unclear data processing procedure and techniques

Organizational requirements

- Concerns about meeting legal requirements
- High staff turnover and burnout
- Human resources issues, such as high staff turnover and increased training demands
- Inadequate information and data sharing
- Inadequate budgeting and funding to meet increased costs, such as investment in technology upgrades
- Increased administration and human resource support requirements
- Lack of investment in training and upskilling prior to the implementation of telemedicine
- Legal concerns (eg, potential lawsuits because of patient complaints)
- Negative effects on quality of care (eg, long wait time, poor clinician-patient interaction, reduction of patient safety, and lack of physical examination)
- Patient scheduling
- Staff workload issues
- Unclear governance and policy direction
- Unclear performance and outcome measures

Clinicians

- Concerns about patient confidentiality
- Inadequate digital literacy
- Lack of confidence and trust from patients
- Lack of confidence in patient consent and choices
- Lack of familiarity with new equipment, software, and devices
- Patient scheduling
- Resistance from patients

XSL•FO
RenderX

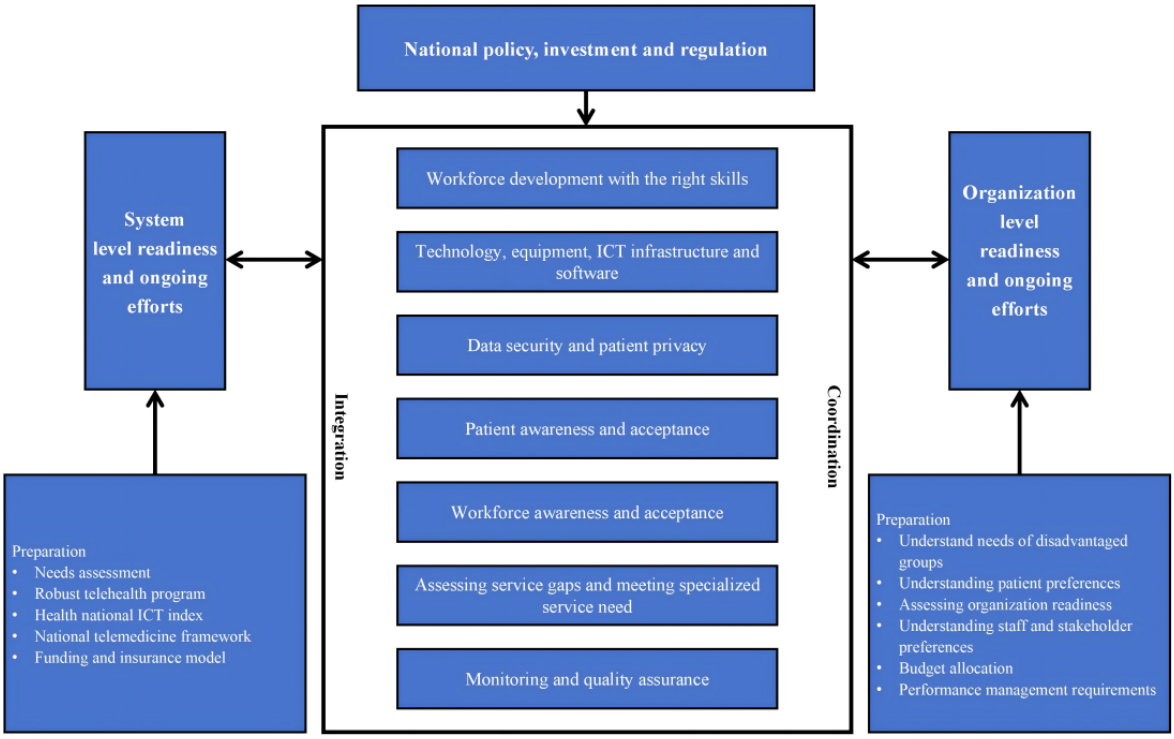
- Resistance from team members
- Responsibility for data security and protection
- Unmanageable workload

Patients

- Affordability of digital devices
- Increased isolation due to the reduced interaction with clinicians and health care organizations
- Language barriers
- Patient resistance due to various factors that were not addressed, such as reduced contact time with clinicians and unclear consultation mechanisms and feedback systems
- Perceived decreased access to care
- Poor internet access

Discussion

Principal Findings



This study fills a knowledge gap by confirming key system-level factors that are critical to the successful implementation and adoption of telemedicine, as well as factors specific to nonmetropolitan areas. Particularly, the study reinforced the importance of 4 success factors that have not been discussed in published systematic review papers. The first factor is the development of a national health ICT index, a comprehensive measure of a country's ICT capabilities, which is crucial for the large-scale implementation of telemedicine [41]. The index includes national ICT infrastructure and access, ICT usage levels, and ICT skills [41]. The second factor is the provision of additional support and investment in building necessary infrastructure in rural and remote areas to enhance telemedicine adoption in these regions [42-44]. The third factor is the need for targeted efforts to raise awareness and promote the benefits of telemedicine among both health care professionals and patients, addressing misconceptions and facilitating adoption [45,46]. The fourth factor is investment in innovation and robust design in telemedicine programs, which can enhance efficiency and sustainability [47-50]. This study also suggests the necessity of developing a nationwide integrated telemedicine framework to improve coordination across national, regional, and local telemedicine initiatives and ensure that national and local policies and strategies are aligned [51]. The factors identified in this scoping review are common to health care organizations, rather than problems specific to individual organizations, and hence may need to be addressed at the system level.

Framework for the Implementation and Adoption of Telemedicine

This scoping review confirms that a successful implementation of telemedicine requires collective efforts at both the system and organizational levels. At the national level, policies and regulations to set the direction, quality expectation, and boundary of telemedicine service provision are necessary. Additionally, investments in improving infrastructure and system-level readiness and addressing potential barriers that may undermine the benefits of telemedicine are required [41]. These efforts can be categorized into 7 core areas, as illustrated in Figure 2—a framework that guides the implementation and adoption of telemedicine proposed by our study. The framework highlights the changes and ongoing efforts required within health systems and health care organizations to help realize the benefits of telemedicine. Continuous improvements to enhance the maturity of health care organizations provide a foundation for innovation and future system and organizational transformations. It is also critical to achieve strategic alignment across the system, between the system and organizations, and across the individual organization internally. The success of telemedicine is a system matter rather than a silo organization business [51].

XSL•FO
RenderX

Figure 2. Framework for the successful implementation of telemedicine. ICT: information and communication technology.

Specifically, the successful implementation of telemedicine necessitates assessment at both system and organizational levels of their respective readiness, as well as the efforts required [36,52]. For a system as complex as health care, different sectors and organizations are interconnected; hence, the implementation of telemedicine is a system-level matter rather than an individual health care organization's sole business [53]. Therefore, the successful implementation of telemedicine requires the adoption of a system integration approach. Organizational requirements; directions; and system-side funding, policy, and regulation must be aligned to enable cooperation and coordination across organizations [36]. Coordination implies the necessity for intraorganizational and interorganizational collaboration and coordination to ensure that key factors that facilitate the successful implementation of telemedicine are addressed or attended to [54].

Furthermore, common factors that impact the implementation of telemedicine cannot be considered in isolation due to the dynamic, bidirectional relationship between factors at the system and organizational levels. Enhancing common factors may influence the readiness and maturity of systems and organizations, providing a foundation for innovation and thereby altering the preparation and effort required for future system-level and organization-level transformations.

As mentioned in the Introduction, there are factors localized to health care organizations that impact the implementation of telemedicine, such as ICT infrastructure, internet connectivity, technical support systems [55], reimbursement, and data security [56]. This scoping review confirms that we must consider these factors at the system level, as they cannot be resolved by a single organization. Hence, support and efforts at both the organization and system level are required. The successful implementation of telemedicine typically requires strong team leadership, suitable training, flexibility, the use of cost-effective and straightforward systems, and implementation within a defined legal and regulatory framework [57]. Addressing organization-level barriers at the system level enables organizations to implement telemedicine successfully.

Improving Awareness, Understanding, and Readiness

One of the key factors emerging in recent studies is resistance to the utilization of telemedicine by both health care professionals and patients, which is common across health care organizations and countries [58-61]. This is partly attributed to health professionals and patients' lack of understanding of telemedicine's benefits [62], patients' fear of losing face-to-face interaction with doctors [63], and the difficulties encountered in utilizing telemedicine [64]. Efforts are required to improve the health workforce and patients' and carers' understanding of the important role and inevitable trend of telemedicine in improving the quality of care. It requires broader government actions to raise public awareness [45] and improve health and digital literacy [44]. Evaluating health systems and organizations' readiness for implementing telemedicine is a critical step that requires adequate preparation, planning, support, and coordination across the health system. This may include developing policies that broadly guide telemedicine design, implementation, and utilization [45,65,66]. Studies also suggest the necessity of offering incentives and financial support to health care organizations in improving infrastructure and enhancing training for health care workers and patients [47,67].

XSL•FO
RenderX

This systemic approach ensures that the unique circumstances of each organization are considered, facilitating a more effective and widespread adoption of telemedicine.

Financial Arrangements, Funding, and Insurance Model

Health insurance coverage, financial arrangements, funding mechanisms, and health insurance models were discussed in 23 (25.84%) identified papers. Additionally, concerns about lower reimbursement rates provided for telemedicine services compared to face-to-face visits, and inappropriate reimbursement strategies were raised [68]. Although some of the factors were discussed in a previous review paper that focused on the organizational level [69], this scoping review explores these factors from a system-level perspective. Unclear or confusing financial arrangements and payment models were identified as key obstacles to the successful adoption of telemedicine [59], as the development of payment models has not kept pace with the rapid expansion of telemedicine.

Internationally, the traditional fee-for-service payment system is still predominantly used to reimburse or pay for telemedicine services [11]. As a result, clinical providers may alter the way services are provided to ensure they receive adequate reimbursement. For instance, some previously free medical services offered by health professionals were modified for new names such as audio-only telemedicine visits or e-visits, to be billed [70]. This non–user-friendly service model discourages patients from accessing services, hindering the development and expansion of telemedicine. Systematically designed payment policies and payment models that support and adequately reimburse service providers are crucial for the continuous development and adoption of telemedicine [71]. The examined studies suggested exploring hybrid models that combine capitation payment and fee-for-service payment [11], bundled payment models [72,73], and other models that are superior to the traditional fee-for-service model to promote telemedicine adoption.

To design a feasible and equitable funding model for telemedicine, mechanisms that support cost and benefit sharing among stakeholders must first be established. For example, a study in Norway [51] shows that telemedicine is primarily supported by internal organizational funds or funded through national or regional research and innovation projects, lacking sustainable long-term financing channels, which affects the continuous development and scaling of telemedicine projects. A feasible and equitable cost-sharing mechanism requires partnership between governments, health care institutions, and other stakeholders, making telemedicine broadly accessible and sustainable. Additionally, mechanisms that enable fair benefit distribution and provide incentives to stakeholders are critical. For example, in the United States, specialized services are often provided by more advanced and well-equipped medical centers or hospitals to patients initially treated and referred by primary care providers. Under the current funding model, the primary care advanced medical centers or hospitals may receive greater economic returns. Medicare only pays a fixed telemedicine service facility fee to the initiating party—primary care institutions—while paying the providing party 100% of the equivalent offline service fees [74]. Additionally, general practitioners may experience increased workloads without proportional financial gain due to inadequate compensation mechanisms [75]. Ultimately, primary care providers, being the least favorable party for benefit distribution, lack the motivation to support telemedicine. The distribution of benefits in telemedicine is thus a complex issue that requires comprehensive consideration and the gradual development of mechanisms to promote equitable redistribution among all stakeholders [51].

Network and Data Security

Previously published systematic reviews confirmed that the stability and security of the telemedicine network, as well as patient and service data, are among the key concerns of telemedicine adoption at health care organizations [56,57]. This review, based on 16 (17.98%) identified papers, confirmed that it is a key systemic factor that hinders the success of telemedicine and must be promptly addressed in and across health care organizations and the health system. Network concerns are related to not only problems of internet availability and connectivity [43,76,77] but also the absence of an integrated nationwide telemedicine network that supports the adoption of telemedicine [51]. Internet availability and connectivity concerns refer to internet availability [43], network latency [76], and poor network connections [77]. These issues pose significant technical challenges to the adoption of telemedicine. On the other hand, the lack of coordination of telemedicine initiatives at the national, regional, and local levels has resulted in the fragmentation of the health care sector, hindering the construction of a nationwide integrated telemedicine network [51].

To build a nationwide integrated telemedicine network, institutions must coordinate and align their strategic plans to national strategies and policies, while ensuring patient quality and safety [51]. Concerns about data security were identified among both health professionals and patients [78]. These concerns are related to low digital literacy levels, measures adapted to enable the secure use of information, and adopted communication technologies [79]. Patient concerns about data security can lead to resistance to using telemedicine, highlighting the need for clinical standards, certifications for service providers and institutions offering telemedicine services, and robust legal frameworks to protect user and institutional data security [7].

Telemedicine in Regional and Rural Areas

Considering health disparities, geographical constraints, and limitations on infrastructure in regional and rural areas, telemedicine is an important initiative that should address the health care needs of the local population and improve service provision by clinicians, including addressing the challenges of workforce shortages [80,81]. Telemedicine presents an opportunity to alleviate the imbalance between health care demand and supply in nonmetropolitan areas by meeting patients' urgent needs for high-quality health care services and addressing disparities in health care resource allocation, diagnostic and treatment capabilities, and quality between urban and rural areas [82]. For patients living in rural and remote areas, telemedicine is becoming critical to enhancing access to

XSL•FO
RenderX

health care specialists [83] and high-quality health care services, such as timely e-consultations and tailored treatment plans [84] from their homes, through telemedicine platforms. On the other hand, telemedicine allows health care providers to receive support and expert advice online, thus directly improving the capacity of health professionals to deliver quality patient care [81]. To fully leverage the potential of telemedicine, comprehensive strategies and substantial investments in infrastructure, along with training for health professionals who provide or receive services via telemedicine platforms, are required [85].

One significant challenge in regional and rural areas is the lack of infrastructure enabling the smooth adoption and implementation of telemedicine. Poor access and unstable internet service have limited the coverage and effectiveness of telemedicine initiatives. Therefore, prioritizing functional broadband access with a sufficient download speed that meets the requirements of telemedicine in rural areas is an essential government/system-level investment [85,86]. Creating a community broadband network may be a good example [86]. It is worth noting that even when broadband is available, the affordability of broadband usage can be a barrier for rural populations [86]. Therefore, government/system-level investments must include relevant policy support and incentives that enable affordable broadband service provision, such as subsidies for broadband deployment and usage, in underserved rural areas [87].

Telemedicine is a core strategy for improving health service availability and accessibility in regional, rural, and remote areas. To maximize its intended benefits, telemedicine must be designed to address the specific health care needs of the servicing areas [43,81] and enhance the support to clinical staff for safer and more effective clinical practices [42], such as remote expert consultation and after-hours staff support [80]. Studies also confirmed the importance of addressing the skepticism and fear of how losing face-to-face interactions between patients and clinicians may affect the quality of care received [88]. Hence, specific strategies should be developed to enhance patient-provider communication in the process of telemedicine implementation and adoption [81].

Limitations

First, this study only searched for English articles, and studies in other languages were excluded, which may be a potential limitation. Second, due to the inability to access and analyze unpublished articles, some important factors might not have been included. Third, only studies about telemedicine related to clinical services were included in this review, and some studies may have been overlooked.

Conclusions

This study reveals the key system-level factors for the successful implementation of telemedicine in health care systems and provides an in-depth insight into factors specific to regional and rural areas. The results show that the widespread implementation of telemedicine is constrained by multifaceted factors, including economy, technology, organization, and individual factors. This study underscores the importance of establishing a national network enhancing public awareness of telemedicine, ensuring clarity in payment and benefit distribution models, and strengthening data security protection measures. In addition, for regional and rural areas, this study highlights the necessity for addressing infrastructural deficiencies, particularly in terms of internet connectivity, and suggests the implementation of targeted incentives and support measures. In summary, this study provides valuable insights for policy makers, health care administrators, and health care providers by highlighting the importance of coordination and collaboration across different regions and organizations. Through these efforts as detailed in the proposed framework, it is possible to promote the popularization of telemedicine, enhance the overall quality and efficiency of health care services, and achieve broader health equity.

Abstract

Background: Natural language processing (NLP) has the potential to promote public health. However, applying these technologies in African health systems faces challenges, including limited digital and computational resources to support the continent's diverse languages and needs.

Objective: This scoping review maps the evidence on NLP technologies for public health in Africa, addressing the following research questions: (1) What public health needs are being addressed by NLP technologies in Africa, and what unmet needs remain? (2) What factors influence the availability of public health NLP technologies across African countries and languages? (3) What stages of deployment have these technologies reached, and to what extent have they been integrated into health systems? (4) What measurable impact has these technologies had on public health outcomes, where such data are available? (5) What recommendations have been proposed to enhance the quality, cost, and accessibility of health-related NLP technologies in Africa?

Methods: This scoping review includes academic studies published between January 1, 2013, and October 3, 2024. A systematic search was conducted across databases, including MEDLINE via PubMed, ACL Anthology, Scopus, IEEE Xplore, and ACM Digital Library, supplemented by gray literature searches. Data were extracted and the NLP technology functions were mapped to the World Health Organization's list of essential public health functions and the United Nations' sustainable development goals (SDGs). The extracted data were analyzed to identify trends, gaps, and areas for future research. This scoping review follows the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) reporting guidelines, and its protocol is publicly available.

Results: Of 2186 citations screened, 54 studies were included. While existing NLP technologies support a subset of essential public health functions and SDGs, language coverage remains uneven, with limited support for widely spoken African languages, such as Kiswahili, Yoruba, Igbo, and Zulu, and no support for most of Africa's >2000 languages. Most technologies are in prototyping phases, with only one fully deployed chatbot addressing vaccine hesitancy. Evidence of measurable impact is limited, with 15% (8/54) studies attempting health-related evaluations and 4% (2/54) demonstrating positive public health outcomes, including improved participants' mood and increased vaccine intentions. Recommendations include expanding language coverage, targeting local health needs, enhancing trust, integrating solutions into health systems, and adopting participatory design approaches. The gray literature reveals industry- and nongovernmental organizations–led projects focused on deployable NLP applications. However, these projects tend to support only a few major languages and specific use cases, indicating a narrower scope than academic research.

XSL•FO
RenderX

Conclusions: Despite growth in NLP research for public health, major gaps remain in deployment, linguistic inclusivity, and health outcome evaluation. Future research should prioritize cross-sectoral and needs-based approaches that engage local communities, align with African health systems, and incorporate rigorous evaluations to enhance public health outcomes.

Introduction

Public Health Needs in Africa

Most African countries face major challenges in meeting the sustainable development goal (SDG) 3 targets for good health and well-being [1-3]. Key public health challenges include high rates of infectious diseases, maternal and child health inequities, and a growing burden of noncommunicable diseases, alongside the critical need for resilient emergency response systems [4,5].

Some of these challenges stem from acute shortages in the health workforce and weak public health surveillance systems, among other weaknesses in public health systems [6,7]. For instance, Africa has only 1400 epidemiologists, despite an estimated need for 6000 [4]. These issues are further amplified by structural weaknesses in health systems and insufficient multisectoral coordination for health [5,8], which are particularly exposed by public health emergencies [9], such as the COVID-19 pandemic and the mpox outbreaks. During the COVID-19 pandemic, while several African countries were able to rapidly leverage their past experiences with outbreaks to respond to COVID-19, they also faced challenges, such as inadequate adherence to infection control, insufficient personal protective equipment, poor contact tracing, supply chain shortages, and a lack of training for key personnel [10].

To systematically strengthen public health capacities, the World Health Organization (WHO) has outlined 12 essential public health functions (EPHFs) [11]. These functions include a broad range of activities, from disease surveillance and health promotion to emergency preparedness and equitable access to health care services. However, many countries across the region, especially those with lower income levels (note that in 2024, Africa comprises upper-middle–income, lower-middle–income, and low-income countries [12]), face substantial challenges in fully implementing these functions, mainly because of limited financial, infrastructural, and health care workforce resources [5]. In resource-constrained settings, innovative technologies, such as artificial intelligence (AI) technologies, could play a crucial role in supporting the implementation of EPHFs [5,13], thereby improving public health outcomes and advancing progress toward achieving health-related SDGs.

Natural Language Processing Technologies for Public Health

Natural language processing (NLP) is a vibrant interdisciplinary field within AI research, known by various terms in different disciplines, such as NLP in computer science, computational linguistics in linguistics, speech recognition in engineering, computational psycholinguistics in psychology, and language technologies in public discourse [14]. Despite the diversity in terminologies and research focuses within these disciplines, they share the common goal of enabling computers to interpret, understand, and generate human language [14,15]. NLP allows computers to perform a wide range of language-based tasks, including facilitating human-machine communication; improving human-to-human interactions; and processing text and speech data for practical NLP applications across different sectors, including public health.

NLP holds significant potential for advancing public health in Africa by addressing the ongoing challenges faced by many countries. By appropriately leveraging NLP, countries can improve health communication, enhance disease surveillance, support workforce training, and optimize limited resources [2,16,17], all of which are crucial for achieving SDG 3 targets. NLP technologies can be used to process and analyze large volumes of health data from diverse sources, including social media, medical records, and public health reports, to identify emerging health threats and track disease patterns in real time. This capability is especially valuable in regions with limited health workforce and surveillance infrastructure, as it enables faster, data-driven responses to public health emergencies.

In practice, NLP-driven tools have already shown promise in Africa. For instance, during the COVID-19 pandemic, WhatsApp chatbots in South Africa, Rwanda, and Senegal were used to disseminate reliable information and facilitate rapid COVID-19 testing, while a Telegram-based chatbot in Ghana was developed to combat misinformation and provide accurate data to the public [18]. Such tools can bridge communication gaps by delivering health information in local languages, empowering communities to recognize symptoms, prevent disease transmission, and respond more effectively. These innovations could play a transformative role in strengthening health systems across the continent, making them more resilient and responsive to both everyday health needs and unexpected crises.

Africa has made progress toward achieving some of its innovation and technology targets [19]. Specifically, the continent is making strides in mobile network coverage, with approximately 89% of the total African population now having access to mobile networks. Countries like Mali, Namibia, and Guinea-Bissau have achieved 100% 2G mobile network coverage [20]. This expanding network coverage creates new opportunities for cloud-based NLP applications in public health.

XSL•FO
RenderX

Cloud computing, which uses remote servers to store, manage, and process data, allows African countries to access computing power that was previously unattainable [13]. This scalability is crucial for deploying NLP-based health solutions in resource-constrained settings where local infrastructure may be insufficient or absent. The synergy of cloud technology and increasing network accessibility opens the door to the expansion of NLP technologies in Africa, providing promising opportunities to improve public health outcomes across the continent.

However, a primary obstacle to the development of NLP applications is a lack of essential digital datasets for the >2000 languages spoken on the continent [21,22]. The development of modern NLP-based health applications for African language communities requires large-scale datasets to fully unlock the capabilities of deep learning models; however, there is a scarcity of digitized, in-language (ie, datasets collected in the specific languages spoken by the target user of the NLP technology), and in-domain (ie, datasets tailored to a specific use case or application, such as health education or disease surveillance, rather than general-purpose language) data. This scarcity is particularly profound in the health sector, where data tailored to specific African languages and contexts are often completely absent. This conjunction of linguistic diversity and data scarcity creates significant obstacles to developing effective NLP technologies tailored to Africa's specific public health needs. Moreover, even when NLP technologies are developed, their successful deployment, validation, and integration into existing health systems are critical for achieving a meaningful positive impact. In resource-constrained environments, lessons learned from previous experience suggest that NLP technologies should be integrated into existing systems and institutions, rather than aiming to replace them [23]. This requires overcoming various obstacles, including the development of a nuanced understanding of local public health needs, the creation of sustainable and scalable solutions, and ensuring equitable access for all users [13,23-25].

Research Gaps

Most previous reviews related to NLP technologies in public health have focused on global health [2,16,26] or low- and middle-income countries [13] as a whole, examined AI applications without focusing specifically on NLP [2,13,16,27], or focused on a single type of NLP application, such as chatbots [18]. Unlike other AI technologies, NLP applications are heavily influenced by the languages and cultures they are designed to serve [28,29]. Given Africa's vast linguistic diversity and the complex spectrum of public health challenges faced by countries in the region, an Africa-focused review is critical for a more nuanced understanding of how NLP can be tailored to meet the diverse health needs across the continent. This approach aligns with pan-African initiatives, such as the African Union's Agenda 2063 [30], which seeks to address health challenges and promote collaboration across borders. At the same time, modern NLP technologies often share similar development paradigms, meaning that advancements in one type of application can provide valuable insights and sometimes resources to others. These benefits extend beyond the experience gained during application development and include the shared use of digital resources across applications, often improving performance through NLP's *transfer learning* techniques [31]. Therefore, a broader review of NLP technologies, compared to one focused on a specific application, provides researchers and developers with a more comprehensive set of evidence to guide future development.

To the best of our knowledge, this is the first scoping review to comprehensively examine the application of NLP technologies to public health in Africa. By mapping the current evidence, this review aims to provide insights into the key barriers and opportunities for the development and deployment of these technologies. Specifically, the review aims to answer five main research questions: (1) *Needs and availability:* What public health needs are being addressed by NLP technologies in Africa, and what unmet needs remain? (2) *Prevalence and distribution:* What factors influence the availability of public health NLP technologies across African countries and languages? (3) *Deployment and integration:* What stages of deployment have these technologies reached, and to what extent have they been integrated into health systems? (4) *Public health impact:* What measurable impact has these technologies had on public health outcomes, where such data are available? (5) *Outlook:* What recommendations have been proposed to enhance the quality, cost, and accessibility of health-related NLP technologies in Africa? By answering these questions, the review aims to provide actionable recommendations for future research and development.

Methods

Overview

The paradigms of developing NLP technologies have evolved significantly since the origin of NLP in the 1940s. The early rule-based systems, such as ELIZA [32], were followed by a shift toward machine learning–based methods in the 1990s. This new approach leveraged large datasets, reducing reliance on manually crafted rules. In 2013, the introduction of Word2Vec marked a major milestone for NLP [33], by representing words as vectors. This approach formed the foundation for neural language models. Subsequently, pretrained language models, such as BERT (Bidirectional Encoder Representations from Transformers) [34] and GPT-2 (Generative Pre-trained Transformer 2) [31], have become the backbone for NLP development, allowing systems to be fine-tuned and developed using datasets of thousands of examples.

Recent advances in large language models [35,36] have further simplified NLP development, allowing systems to achieve optimal performance after learning on just a handful of task-specific examples.

In the context of public health in Africa, the development of NLP technologies will likely use a mixture of paradigms, depending on the availability of task-specific datasets and computational resources. For the purposes of this scoping review, we define *NLP technologies* broadly to include *any computational systems that process natural language, either as input or output*. This inclusive definition ensures that the review captures a wide range of applications in public health across

XSL•FO
RenderX

Africa. In Multimedia Appendix 1 [18,37-108], we provide examples of technologies that fall within or outside the scope of this review. The scoping review maps the current evidence on NLP technologies within the framework of EPHFs. The review follows the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) reporting guidelines [109] (see the PRISMA-ScR checklist in Multimedia Appendix 2), and its review protocol is available on *medRxiv* [110].

Search Strategy

A systematic search of *academic literature* was conducted on May 13, 2024, and updated on October 3, 2024, using the following five electronic bibliographic databases:

1. *MEDLINE via PubMed:* Medical and public health literature
2. *ACL Anthology:* NLP and language science literature
3. *Scopus:* Broad interdisciplinary scope, including medical research
4. *IEEE Xplore:* Engineering literature, particularly in NLP and health informatics
5. *ACM Digital Library:* Computing literature, including NLP and health informatics

The search included studies published from January 1, 2013, to October 3, 2024, with the aim being to capture recent developments in NLP, particularly after the introduction of neural language models in 2013 [33]. No language restrictions were applied, although the search terms were in English.

Search terms were developed around three key areas:

1. *Africa:* The names of all 55 African Union member countries and African languages with >1 million native speakers
2. *Public health:* On the basis of the 12 EPHFs outlined by the WHO
3. *NLP:* As suggested by a team of experts in the field

These terms were combined with general phrases and Medical Subject Headings. The search strategy for each database was tailored with database-specific features to enhance the retrieval of relevant studies. The complete search strategy for MEDLINE (PubMed) and the full list of search terms are detailed in Multimedia Appendix 1. Reference chaining of relevant articles was also conducted.

Discussion of NLP technologies for public health in Africa occurs beyond the academic literature, spanning a diverse array of contributors, formats, and outlets. As such, sparse academic literature on this topic does not necessarily indicate a lack of progress [13]. Many promising technologies addressing public health challenges in Africa are introduced through media outlets, as well as by the individuals, companies, governments, and nongovernmental organizations (NGOs) that develop and use them. These contributions are often presented on the web or shared at events, such as conferences. Therefore, this scoping review also mapped evidence from a broad gray literature. In addition to structured academic databases, the following gray literature sources were included: (1) preprints, non–peer-reviewed studies, and reports; (2) media articles and blog posts; (3) commercial products from startups and established companies; (4) initiatives led by NGOs; and (5) proceedings and presentations from events and conferences. The complete search strategy for gray literature is available in Multimedia Appendix 1.

Screening and NLP Technology Selection Criteria

This review includes NLP technologies designed to support public health in Africa. In addition, we consider digital and computational resources essential for the development and deployment of these technologies, such as digital datasets, hardware, and software toolkits.

The selection of sources for this scoping review followed a systematic 2-step screening process. Initially, titles and abstracts were reviewed by one reviewer (AO) to exclude studies meeting any of the predefined exclusion criteria (Textbox 1), such as those not involving NLP technologies, unrelated to public health, or lacking a focus on Africa. Studies that passed this initial screening were then subjected to full-text screening, where studies meeting all the inclusion criteria (Textbox 1) were included. The full-text screening was conducted by the same reviewer (AO), and the reasons for exclusion at this stage were documented.

Before the formal screening process, pilot screenings were conducted to refine our screening guidelines (Multimedia Appendix 1) and to ensure consistency and accuracy in study selection. In these pilots, 10% (179/1791 for title and abstract screening and 36/361 for full-text screening) of candidate papers were randomly selected and independently reviewed by 2 trained reviewers (AO and CC) following the predefined screening guidelines. Interreviewer agreement was assessed using exact match rate and Cohen κ to ensure reliability. The screening process and guidelines were iteratively refined by a review coordinator (SH), and the pilot screening was repeated until both an exact match rate of 0.9 and a Cohen κ score of 0.8, indicating almost perfect agreement, were achieved. Following the pilot, formal screening was conducted by a single reviewer (AO), with any concerns resolved by a review coordinator (SH), a subject matter expert in NLP.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- All types of scientific publications aimed at an academic audience (eg, peer-reviewed articles, conference proceedings, and book chapters); for gray literature search, other web-based publications (eg, blog posts and media outlets)
- Studies focusing on the development, evaluation, or adaptation of natural language processing (NLP) technologies specifically promoting public health
- Studies demonstrating direct or indirect relevance to the population in the continent of Africa
- Studies published between January 1, 2013, and October 3, 2024
- Studies published in any language

Exclusion criteria

- Articles without full-text availability; for articles not available through Cambridge University libraries, full text was requested by emailing the authors
- Studies unrelated to NLP technologies or their application to public health; for example, non-NLP applications, where no language technologies were involved, and the technology was used to perform tasks, such as predicting outcomes solely from structured datasets or images
- Studies focused on non-African contexts, except where such studies offer comparative insights relevant to African NLP technologies
- Studies published before January 1, 2013, or after October 3, 2024
- No language requirement specified

Data Extraction and Synthesis

Data were extracted for each included study based on a predefined data extraction template (Multimedia Appendix 1), capturing key information on study descriptions, the characterization of NLP technologies (Textbox 2), and their contributions to EPHFs, SDGs, and SDG 3 targets specifically. In addition, where such data were available, any public health outcomes measured and recommendations for future development were documented. One reviewer (AO) completed the data extraction for all included studies, with any concerns resolved through team discussions. Due to the heterogeneity of study goals, methodologies, evaluation methods, and outcomes, a formal meta-analysis was not attempted. Instead, a narrative synthesis of the results was conducted, with introduced NLP technologies characterized according to the categories outlined in the data extraction template. The extracted data were analyzed to identify trends, gaps, and areas for future research. In addition, the authors' recommendations for future development were documented and summarized to provide guidance for advancing NLP technologies in public health.

A similar pipelined approach of screening, data extraction, and synthesis was applied to the gray literature. Given that our gray literature search covered sources beyond academic publications, we omitted undisclosed data extraction items, as commercial products often lack full disclosure of their design and implementation. A detailed description of our approach to identifying and synthesizing the gray literature is available in Multimedia Appendix 1.

XSL•FO

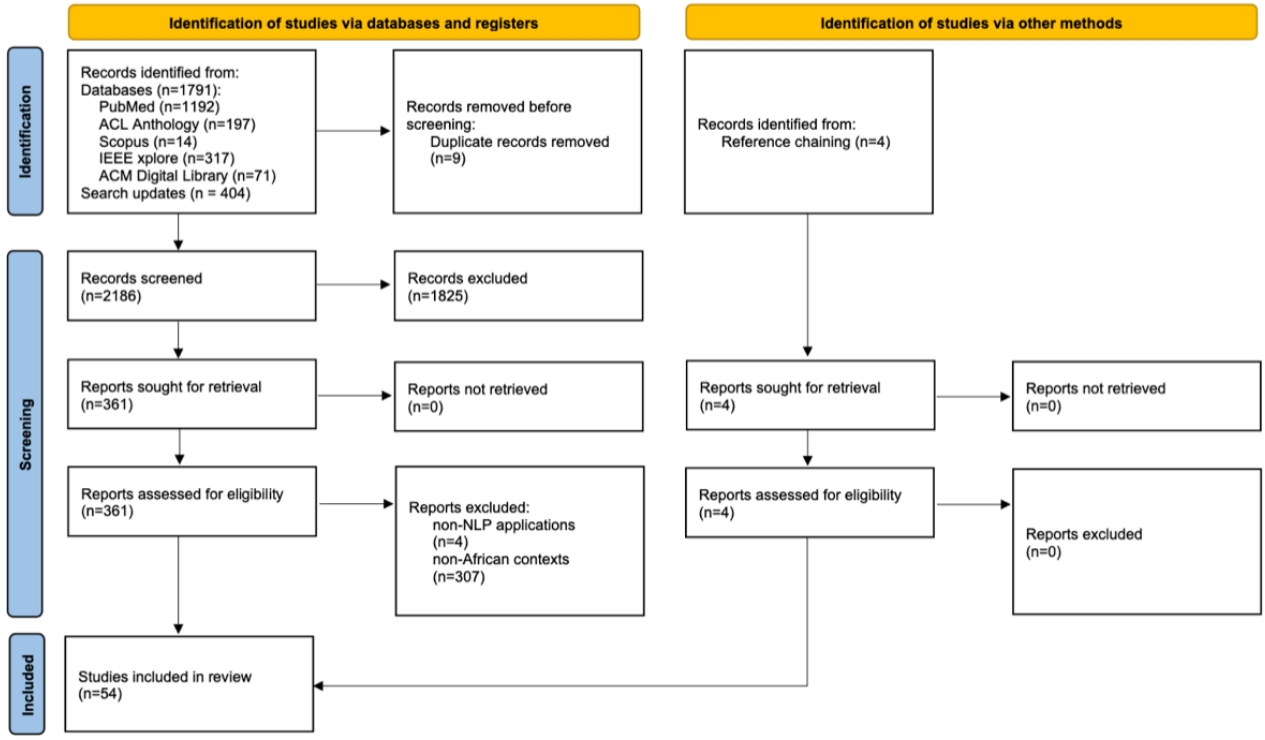
Textbox 2. Selected characterization of natural language processing technologies in public health.

- Natural language processing (NLP) applications: The NLP application each system performs, such as conversational assistant, language translation, or automated diagnosis
- Modality: Type of data processed by the NLP application (eg, text, audio, and image)
- Supported languages: The set of languages supported by the NLP technology; languages are documented using ISO (International Organization for Standardization) 639-2 codes
- Target countries: Countries or regions where the introduced NLP technology is applied or intended to be used; countries are documented using the Alpha-3 code from the ISO 3166 standard
- Evaluation method (Adapted from Laranjo et al [111])
  - Technical performance: Intrinsic evaluation measures such as accuracy, precision, recall, and F1 score
  - User experience: Results on usability testing, user satisfaction surveys, and qualitative feedback from health care providers
  - Health-related measure: Extrinsic evaluation measures such as patient engagement rates, reduction in diagnostic errors, or improvements in treatment outcomes
- Domain coverage
  - General domain: Data concerning general language processing outside specialized contexts
  - Research domain: Research articles and professional materials for expert audiences
  - Clinical domain: Clinical notes, patient interactions, and other health care–specific communications
- Target users
  - Health care providers: Direct care providers including physicians, nurses, practitioners, community health workers, and other health care professionals
  - Public health officials and policy makers: Individuals involved in public health policy, administration, and epidemiology
  - Researchers and data scientists: Academics and professionals focused on public health research and data analysis
  - Specific equity-seeking groups: Populations grouped by protected demographic characteristics, such as people with disabilities, children, LGBTQ+ (lesbian, gay, bisexual, trans, queer) individuals, and older adults, who advocate for health equity within and beyond their group
  - General public: The broader community, especially those at higher risk or in need of specific health interventions
  - Others: Any target users that do not fit into the above categories
- Deployment stage
  - Conceptualization: This initial stage is when the need for an NLP application is identified, and its feasibility is considered
  - Design and prototyping: Development of initial prototypes; these prototypes are usually evaluated based on their technical performance
  - Validation: Rigorous testing of the system with public health outcomes to validate its effectiveness and efficiency in real-world settings
  - Deployment and operational: Deployment of the NLP technology in actual public health settings, where it is actively used
  - Not applicable: The study does not introduce or use any new NLP technologies
- Level of accessibility
  - Open-source: Publicly accessible datasets and tools that are open-source for future research and analysis
  - Publicly available: Datasets and NLP applications that are accessible to the general public via web or mobile but not necessarily open-source
  - Limited access: Datasets and NLP applications available only to certain users or under specific conditions
  - Closed access: Datasets and applications that are not openly accessible outside the group of authors but may be available upon request or through collaboration
- Available platform
  - Mobile apps: Technologies accessible via mobile apps
  - Web-based applications: Technologies accessible via web applications or web-based platforms
  - Web service: Technologies accessible via web-based application programming interfaces without user interfaces
  - Dataset: Specific datasets published in the study
  - NLP tool and library: Specific NLP tools and libraries; these tools usually require installations on each deployed computer, which require expertise in computer science



XSL•FO

Results

Overview

The initial database search on May 13, 2024, retrieved 1791 citations, and the final updated search on October 3, 2024, retrieved an additional 404 citations (Figure 1). The updated search retrieved 289 additional articles from PubMed, 70 from ACL Anthology, 2 from Scopus, 36 from IEEE Xplore, and 7 from ACM Digital Library, resulting in 6 additional papers being identified for full-text eligibility assessment. After removing 9 duplicate citations, 2186 unique records were screened. During the title and abstract screening, 1825 articles were excluded. Full-text reviews were conducted for the remaining 361 articles, which included 6 articles identified through the final updated search. Following the full-text screening, 311 articles were excluded, resulting in the inclusion of 2.29% (50/2186) studies. An additional 4 studies were identified through reference chaining of the included studies. Before the formal screening process, 3 rounds of pilot screenings, covering 10% (179/1791 for title and abstract screening and 36/361 for full-text screening) of the citations, were conducted to ensure consistency and reliability. The final round achieved interreviewer agreement scores of 0.97 for accuracy and 0.89 for Cohen κ in title and abstract screening, and perfect agreement (ie, 1.0 for both measures) in full-text screening.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram showing the search and study selection process for 54 included studies. NLP: natural language processing.

In this section, we provide an overview of the academic literature on NLP technologies for public health in Africa and present our findings in response to the 5 aforementioned research questions. In addition, we separately summarize relevant gray literature, which provides complementary perspectives to the academic literature. By combining these 2 sources of evidence, we aim to provide a comprehensive and up-to-date analysis of the landscape, while adhering to the rigorous methodological standards of this scoping review.

Description of Academic Literature

Over the past decade, there has been a rapid increase in the number of publications on NLP for public health in Africa, with a notable spike in 2022, where 6 (43%) out of the 14 papers published that year were in response to the COVID-19 pandemic (Textbox 3). The number of academic papers from authors affiliated with African and non-African institutions has been similar (Textbox 3). Of the 54 included citations, 38 (70%) papers were contributed by authors affiliated with African institutions [18,37-73], while 35 (65%) papers [38,40-44,46,48,50-52,59,61,62,64,66,69,71,73-89] were authored by researchers affiliated with institutions outside Africa. For readability, we do not provide a full list of in-text citations for all our categorizations throughout this review, instead highlighting specific papers where necessary. A complete table with all the categorizations and their corresponding references is available in Multimedia Appendix 1. Notably, 19 (35%) papers [38,40-44,46,48,50-52,59,61,62,64,66,69,71,73] stem from collaborations between African and non-African institutions, highlighting the prevalence and importance of cross-border and cross-continental collaborations at the intersection of NLP and public health research. Among these 19 papers, 16 (84%) involved coauthorship between researchers from North America and Africa, 6 (32%) involved coauthorship between Asia and Africa, 4 (21%) involved coauthorship between Europe and

XSL•FO
RenderX

Africa, and 1 (5%) involved coauthorship between Oceania and Africa. Researchers affiliated with institutions in the United States and South Africa (18/54, 33% papers each) emerged as the leading contributors to NLP research for public health in Africa.

Textbox 3. Number of papers by publication years, author institutional affiliations by country, languages supported, and African countries and regions supported in the 54 included studies.

Publication years

- 2015: n=1; 2016: n=2; 2017: n=2; 2018; n=1; 2019: n=5; 2020: n=9; 2021: n=8; 2022: n=14; 2023: n=9; 2024: n=3
- Note that data gathering ended on October 3, 2024, providing only 9 months of data for 2024, which means the 2024 data are not directly comparable to the other years.

Author institutional affiliations by country

- South Africa: n=18; the United States: n=18; Kenya: n=8; Canada: n=6; India: n=5; Germany: n=3; Iran: n=3; Rwanda: n=3; Saudi Arabia: n=3; the United Kingdom: n=3; others: n=23
- Countries with fewer than 2 papers are grouped under others, including Belgium, Brazil, Cameroon, Egypt, Eswatini, Ethiopia, France, Hungary, Indonesia, Italy, Lebanon, Lesotho, Morocco, Netherlands, New Zealand, Nigeria, Qatar, Senegal, Sierra Leone, Spain, Switzerland, Tanzania, and Uganda.
- Note that a single paper can have authors from multiple countries, so the total number of country affiliations exceeds the total number of papers reviewed.

Language supported

- English: n=40; Arabic: n=8; Kiswahili: n=7; French: n=4; Zulu: n=4; Amharic: n=3; Hausa: n=3; Hindi: n=3; Northern Sotho: n=3; Xhosa: n=3; others: n=64
- Languages supported by <3 technologies are grouped under others, which includes Afrikaans (n=2), Bengali (n=2), Chinese (n=2), Gujarati (n=2), Igbo (n=2), Indonesian (n=2), Japanese (n=2), Korean (n=2), Marathi (n=2), North Ndebele (n=2), Portuguese (n=2), Sinhala (n=2), Sotho (n=2), Spanish (n=2), Urdu (n=2), Assamese (n=1), Central Atlas Tamazight (n=1), Czech (n=1), Dutch (n=1), German (n=1), Iloko (n=1), Italian (n=1), Kannada (n=1), Kikuyu (n=1), Kinyarwanda (n=1), Luo (n=1), Malay (n=1), Malayalam (n=1), Nepali (n=1), Nyankole (n=1), Panjabi (n=1), Persian (n=1), Polish (n=1), Pushto (n=1), Russian (n=1), Shona (n=1), Somali (n=1), Swati (n=1), Tagalog (n=1), Tamil (n=1), Telugu (n=1), Thai (n=1), Tigrinya (n=1), Tsonga (n=1), Tswana (n=1), Turkish (n=1), Uighur (n=1), Venda (n=1), and Yoruba (n=1).
- Languages are identified using the ISO 639-2 code, and different dialectal variants of a language (eg, Arabic) are not distinguished.
- A single technology may support multiple languages.

African countries and regions supported

- South Africa: n=25; Kenya: n=14; Nigeria: n=9; Rwanda: n=7; Egypt: n=5; Ethiopia: n=5; Uganda: n=5; Zimbabwe: n=4; Cameroon: n=3; Eritrea: n=3; Morocco: n=3; Somalia: n=3; Tunisia: n=3; others: n=55
- Countries and regions supported by <3 technologies are grouped under others, which includes Algeria (n=2), Botswana (n=2), Democratic Republic of the Congo (n=2), Eswatini (n=2), Lesotho (n=2), Malawi (n=2), Mozambique (n=2), Namibia (n=2), Niger (n=2), Senegal (n=2), South Sudan (n=2), Sudan (n=2), Tanzania (n=2), Angola (n=1), Benin (n=1), Burkina Faso (n=1), Burundi (n=1), Cabo Verde (n=1), Central African Republic (n=1), Chad (n=1), Comoros (n=1), Congo (n=1), Côte d'Ivoire (n=1), Djibouti (n=1), Equatorial Guinea (n=1), Gabon (n=1), Gambia (n=1), Ghana (n=1), Guinea (n=1), Guinea-Bissau (n=1), Liberia (n=1), Libya (n=1), Madagascar (n=1), Mali (n=1), Mauritania (n=1), Mauritius (n=1), Sao Tome and Principe (n=1), Seychelles (n=1), Sierra Leone (n=1), Togo (n=1), Western Sahara (n=1), and Zambia (n=1).
- Countries and regions are identified using the ISO 3166 code.

Approximately 48% (26/54) of the papers included in this review did not disclose their source of funding. Of the 28 (52%) papers that did report funding, some of them received funding from more than one source, with the vast majority of papers (26/28, 93%) supported by public entities. This included government grants, NGOs, and research councils. Only 2 (4%) papers were funded by industry actors [38,88]. Geographically, with international funding sources determined by their headquarters' location, most of the papers that disclosed funding were financially supported by institutions in North America (14/54, 26%) and Europe (9/54, 17%). Reflecting the global nature of these research contributions, funding was also sourced from other continents, including Africa and Asia, demonstrating the wide range of financial support for these studies. Notably, no funding was recorded from Oceania and South America.

The data used to develop NLP technologies for public health in Africa is generally up-to-date. Among the 36 (67%) papers that reported the year of data collection, most studies (30/54, 56%) used data collected either in the same year or within 1 year before publication. Specifically, 13 (24%) papers used data collected in the same year, while 17 (31%) used data with a 1-year delay. In this review, for papers introducing a dataset, unless otherwise specified, assume the year of data collection is the same as the year of publication. For papers that introduce NLP applications or perform an analysis using a data set from other sources, the year of data collection is the year when the data was originally published.

XSL•FO
RenderX

Most of the data (36/54, 67% papers) fall within the general domain, primarily produced and consumed by the general public, such as social media data. In addition, 15 (28%) studies covered clinical domains, including clinical notes, patient interactions, and other health care–specific communications, while 8 (15%) papers focused on the research domain, covering research articles and professional materials aimed at expert audiences. It should be noted that one study can cover multiple domains simultaneously, as seen in 5 (9%) studies. Regarding data modality, most of the data (53/54, 98% studies) used to develop these technologies were text-based, with minimal use of other modalities. Only 4 (7%) papers used audio [47,63] or image [44,48] data, highlighting a limited exploration of non–text-based data in NLP applications for public health in Africa.

Needs and Availability

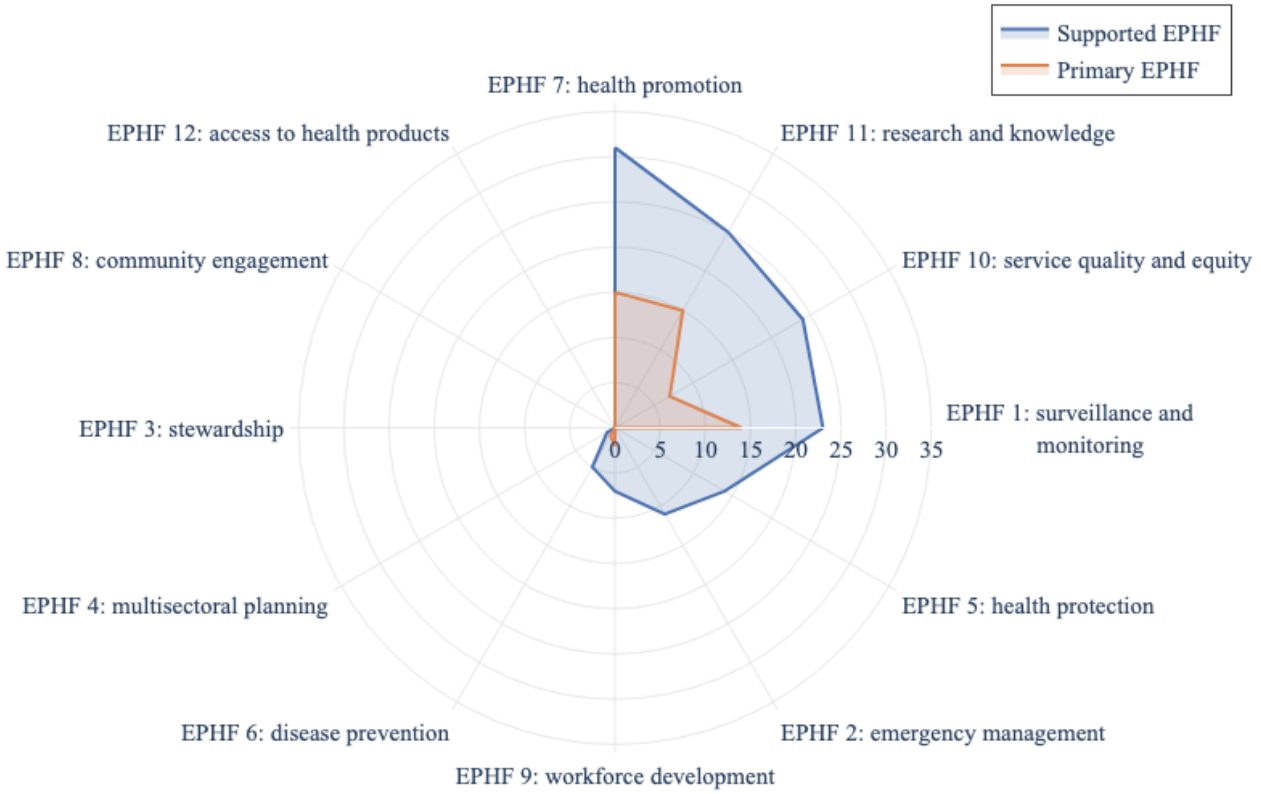
Most of the reviewed papers focused on conversational assistants (17/54, 31%) and sentiment analysis (15/54, 28%). Additional applications included machine translation (3/54, 6%), thematic analysis (3/54, 6%), information extraction (3/54, 6%), and outbreak detection (2/54, 4%). Fewer papers addressed tasks, such as infection detection, misinformation detection, disease prediction, optical character recognition, question-answering, hate speech detection, medical report generation, and speech recognition, with each of these applications covered by only 1 study. A smaller subset of studies focused on fundamental NLP challenges in the context of public health, such as syntax parsing (1/54, 2%), word embedding (1/54, 2%), and lexical processing (1/54, 2%), rather than user-facing applications.

Most available NLP technologies for public health in Africa were designed to serve expert users, such as researchers (45/54, 83%), policy makers (38/54, 70%), and health care providers (30/54, 56%). Fewer than half of the systems were public-facing (25/54, 46%) and targeted toward equity-seeking groups (8/54, 15%). This focus on expert-driven systems suggests an opportunity to develop more public-facing NLP technologies that engage and empower communities to proactively manage their health. After mapping the currently available NLP technologies into the WHO's EPHF framework, Figure 2 shows that 9 (75%) out of 12 EPHFs were addressed by existing NLP technologies in Africa, with EPHF 3 (ie, public health stewardship), EPHF 8 (ie, community engagement and social participation), and EPHF 12 (ie, access to and utilization of health products, supplies, equipment, and technologies) remaining unaddressed. Most studies predominantly focused on 4 EPHFs: EPHF 7 (ie, health promotion; 31/54, 57%), EPHF 11 (ie, public health research, evaluation, and knowledge; 25/54, 46%), EPHF 10 (ie, health service quality and equity; 24/54, 44%), and EPHF 1 (ie, public health surveillance and monitoring; 23/54, 43%). Work on other EPHFs remains relatively sparse, with only a handful of papers addressing them. When each paper was assigned one primary EPHF, only 6 EPHFs were the main focus of these studies, leaving 6 EPHFs unaddressed, including EPHF 2 (ie, public health emergency management), EPHF 3, EPHF 4 (ie, multisectoral planning, financing, and management for public health), EPHF 5 (ie, health protection), EPHF 8, and EPHF 12.

When mapping the included NLP technologies to the United Nations' SDGs, all the reviewed NLP technologies contributed to SDG 3 (good health and well-being). The interconnected nature of the SDGs means that contributing to one SDG often supports progress in others. For example, 15/54 (28%) studies contributed to SDG 10 (reduced inequality), 10/54 (19%) studies to SDG 9 (industry, innovation, and infrastructure), 6/54 (11%) studies to SDG 8 (decent work and economic growth), 5/54 (9%) studies to SDG 4 (quality education), 4/54 (7%) studies to SDG 5 (gender equality), 1 (2%) study to SDG 15 (life on land), and 1 (2%) study to SDG 16 (peace, justice, and strong institutions). Thus, even with a primary focus on health, these projects may have a far-reaching impact on other SDGs [112]. When zooming in on the targets of SDG 3, currently available NLP technologies in Africa only cover 6 of the 13 specific targets (Figure 3). Of the 4 means of implementation listed for SDG 3, available technologies engage 3 (ie, tobacco control, access to vaccines and medicines, and health financing).

XSL•FO
RenderX

Figure 2. Distribution of all the essential public health functions (EPHFs) to which the 54 included papers contribute. The blue line represents EPHF coverage, where each paper may contribute to multiple EPHFs. The orange line indicates the primary EPHF, where each paper is assigned a single, most relevant EPHF focus.



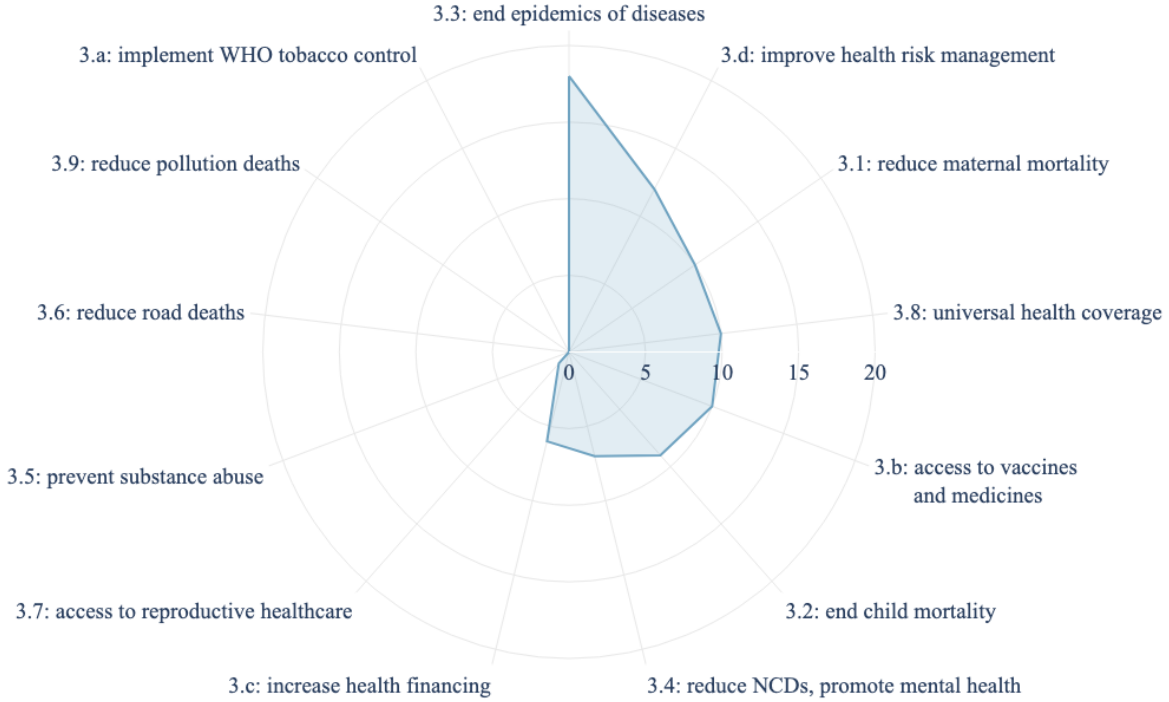


Figure 3. Distribution of specific targets (3.1-3.9) and means of implementation (3.a-3.d) under Sustainable Development Goal 3 (good health and well-being) to which the 54 included papers contribute. NCD: noncommunicable disease; WHO: World Health Organization.

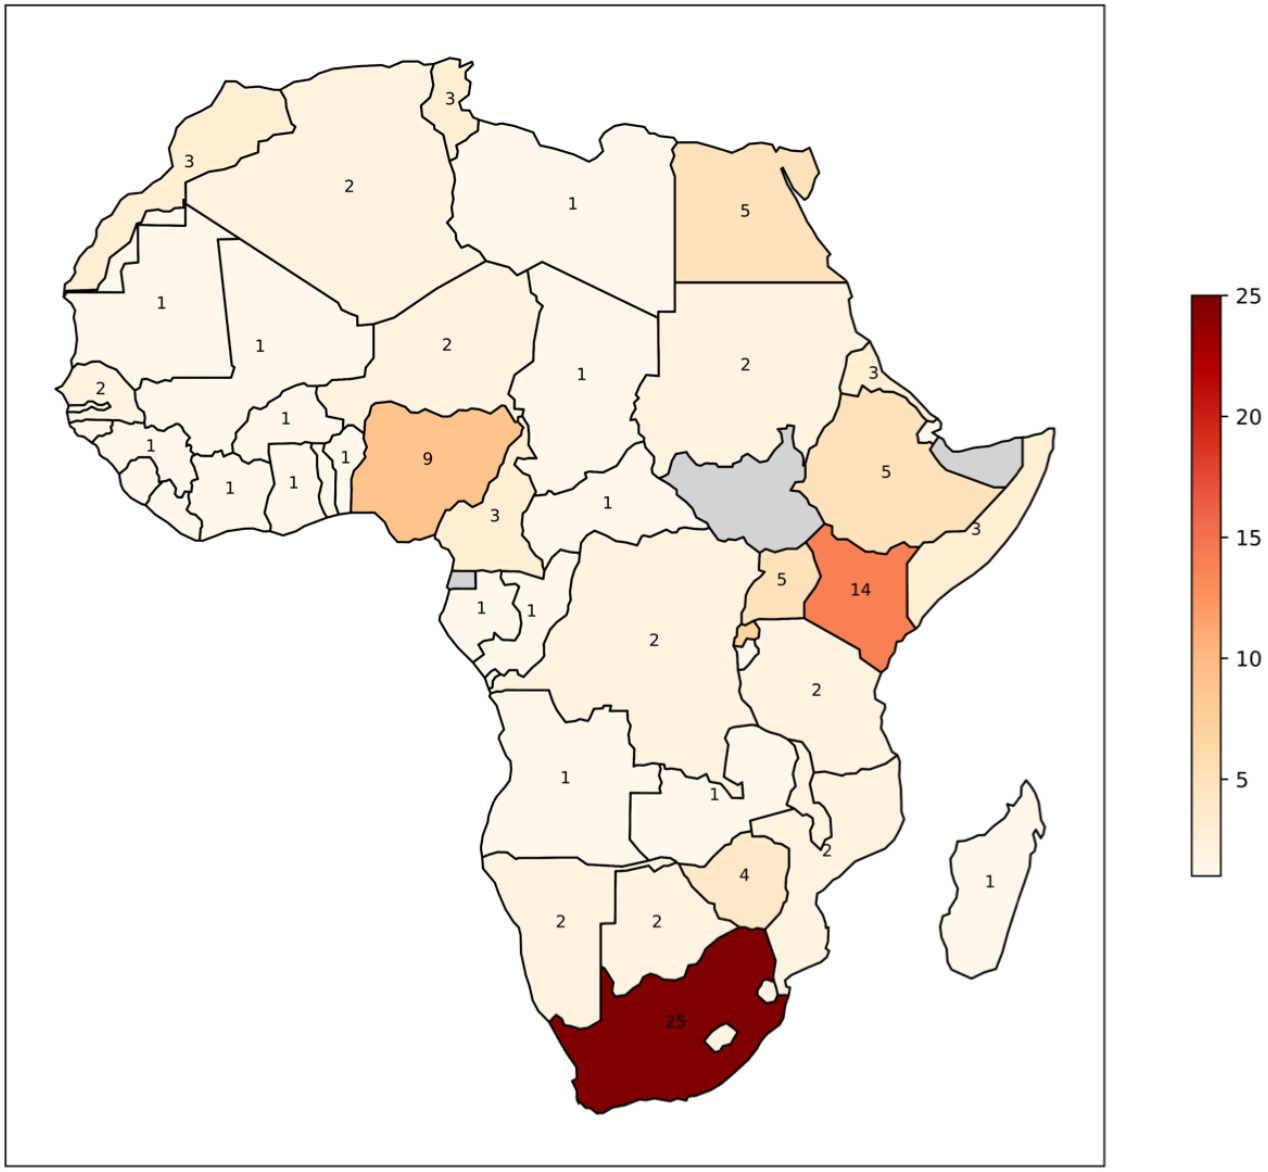
Prevalence and Distribution

The availability of NLP technologies for public health in Africa is strongly influenced by the languages these technologies support. Most NLP technologies predominantly serve widely spoken high-resource languages (Textbox 3), such as English (40/54, 74%), Arabic (8/54, 15%), and French (4/54, 7%), reflecting their status as official languages in academic, governmental, and professional sectors across the continent. In contrast, support for indigenous African languages is



XSL•FO
RenderX

significantly limited. While some widely spoken African languages, such as Kiswahili (7/54, 13%) and Zulu (4/54, 7%), are represented, many other indigenous languages remain underrepresented or entirely absent from these technologies. Overall, 59 languages were supported by the 54 studies included in this review, a number that falls far short of covering Africa's linguistic diversity.

The availability of NLP technologies for public health in Africa varies significantly across countries and regions. As shown in Textbox 3, South Africa is the primary target country for these technologies, with 25 (46%) out of 54 studies targeting this country, followed by Kenya (14/54, 26%) and Nigeria (9/54, 17%). In contrast, 29 African countries and regions, including Angola, Benin, and Burkina Faso, are supported by only 1 technology each, highlighting uneven distributions of NLP technologies across the continent.

Our review reveals a geographic concentration of available NLP technologies in certain countries, especially South Africa, Kenya, and Nigeria, suggesting a need for future efforts to expand NLP technology development to underserved regions (Figure 4). The results further highlight a major gap in linguistic inclusivity within the existing NLP technologies across the continent, where languages spoken in these better-supported regions receive more attention compared to those in other areas (Figure 5).

Figure 4. A map illustrating the distribution of target countries across Africa based on the 54 studies included in this review. Darker shades indicate a higher number of studies per country, as outlined in Textbox 3. Note that small African island states are missing from this map.

XSL•FO
RenderX

Figure 5. A map illustrating the distribution of supported languages across Africa based on the 54 studies included in this review. Each name is positioned near the geographic center of its primary speaking population, with a larger font size indicating a greater number of studies available. The data on supported languages is based on Textbox 3. Note that our study used English language search terms and small African island states are missing from this map.

Deployment and Integration

Among the 54 included studies, 4 (7%) were reviews of existing NLP technologies related to health chatbots [18], HIV prevention in Africa [84], HIV prevention in Malawi specifically [85], and chatbots for HIV prevention [59]. These reviews do not introduce new NLP technologies but rather summarize findings from other research that has introduced new technologies and reported primary results. As such, the concept of deployment is less relevant to these review studies. Therefore, this subsection focuses on the 50 studies that directly introduce new NLP applications.

Most NLP applications for public health in Africa are still in the early stages of development, with only 1 (2%) out of the 50 studies fully deployed and operational. This deployed system is a Facebook messenger chatbot designed to address vaccine hesitancy in Kenya and Nigeria, collecting real-time data on vaccine hesitancy trends from user interactions [89]. Most studies (44/50, 88%) are in the *design and prototyping* phase, where they are evaluated only based on their technical performance in controlled, lab-based environments. Meanwhile, 5 (10%) studies have reached the *validation* stage, where their effectiveness has been tested in real-world settings through methods, such as expert reviews [37,74] and user testing [39,44,45]. Specifically, 2 (4%) studies [37,74] involved health

XSL•FO
RenderX

care professionals who reviewed system performance in practical scenarios. The remaining 3 (6%) studies [39,44,45] conducted evaluations with small samples of target users to test the developed NLP technologies. However, these systems were accessible only to a limited number of users and have not yet achieved full deployment.

Regarding accessibility (as defined in Textbox 2), >half (29/50, 58%) of the NLP applications are publicly accessible, allowing general use without significant restrictions. Of these, 12 (24%) are *open-source*, enabling researchers and developers to build new NLP applications based on their published systems. By contrast, a significant number of systems are categorized as having *limited access* (18/50, 36%) or are *closed access* (3), likely due to the sensitive nature of health-related data, raising concerns around privacy and data security.

In terms of platform support, most NLP technologies for public health in Africa are offered as tools and libraries (29/50, 58%), datasets (5/50, 10%), or web services (4/50, 8%), all of which require a certain level of technical expertise in computer science to exploit effectively. A smaller proportion of technologies are provided as mobile apps (11/50, 22%) and web-based applications (9/50, 18%), offering more user-friendly interfaces that can be accessed by a broader range of users, including public health practitioners and the general public. This distribution suggests an opportunity to develop NLP technologies with more accessible interfaces to promote wider adoption and usability of these technologies for public health across Africa.

Of the 50 reviewed NLP technologies, 40 (80%) indicated an intent to integrate their solutions into existing public health systems, and 41 (82%) were designed to be interoperable with various health infrastructures. This reflects a clear recognition among researchers and developers of the importance of ensuring that these technologies function seamlessly within current health frameworks. However, despite this intent, only 1 (2%) study has reached the stage of deployment, highlighting the need to move these technologies from development into operational use.

Scope and Public Health Impact

Out of the 54 studies reviewed, 30 (56%) aimed to develop NLP applications or inform public policies to improve public health outcomes in Africa. Of these, 22 (41%) specifically focused on addressing public health challenges within African countries, directly targeting the health issues faced by local communities. The remaining 8 (15%) studies adopted a broader global health perspective. While they do not exclusively tailor their approaches to Africa, these studies aim to promote public health on a global scale, with intended outcomes that also benefit Africa. The other 24 (44%) studies were divided into 18 (33%) studies that advance NLP technologies for public health using African data (eg, social media, health records, or public health data) without directly targeting specific health challenges, and 6 (11%) studies that contribute to global health discussions, with Africa serving as a case study or example.

In terms of evaluation, nearly all studies (51/54, 94%) reported technical performance using a variety of automatic evaluation metrics. Classification metrics were the most commonly used, such as accuracy (used in 22/54, 41% studies), precision (13/54, 24%), F_1-score (15/54, 28%), and recall (11/54, 20%), making these the 4 most frequently applied automatic metrics. However, because of the wide variation in evaluation approaches, direct comparisons between the studies were impractical and not attempted. In contrast, only 11 (20%) studies reported evaluation results based on user experiences, such as usability testing, user satisfaction surveys, or qualitative feedback from health care providers. Furthermore, only 8 (15%) studies attempted to evaluate these technologies using health-related measures. Among these, 2 (4%) studies confirmed a positive impact on public health outcomes, with NLP-based interventions shown to improve participants' mood [71] and increase vaccine intentions and willingness [89].

Outlook and Ethical Consideration

Among the 54 included papers, 20 (37%) provided recommendations for the future development of NLP technologies for public health in Africa. A thematic analysis of these recommendations identified 6 key areas for future research: addressing specific public health challenges with NLP (11/54, 20%), expanding data coverage for underrepresented languages (8/54, 15% studies), contextualizing solutions to local health needs (6/54, 11% studies), enhancing trust and ethical standards (5/54, 9% studies), integrating NLP technologies with existing health systems (5/54, 9% studies), and incorporating participatory design with domain expert input (3/54, 6% studies).

In terms of ethical considerations, 46 (85%) out of 54 studies attempted to engage stakeholders during the study design and implementation, while 38 (70%) studies explicitly addressed data privacy compliance. Approximately half of the studies (26/54, 48%) involved the local community in their research. However, only 16 (30%) studies reported receiving explicit ethics approval from an independent review board, and 10 (19%) studies mentioned obtaining informed consent from human participants. It is important to note that not all types of studies involved human participants or required explicit ethics approval in advance. In addition to these considerations, 45 (83%) papers highlighted other ethical concerns, including bias and fairness (11/54, 20%), cultural relevance and appropriateness (11/54, 20%), avoiding miscommunication by NLP technologies (9/54, 17%), preventing misuse of NLP technologies (9/54, 17%), data sharing and accessibility (7/54, 13%), adherence to regulatory standards (2/54, 4%), data representativeness (1/54, 2%), and fair compensation for participants (1/54, 2%).

Description of Gray Literature

Our gray literature review covered two types of sources: (1) academic literature, including unpublished preprints and peer-reviewed articles not indexed in the 5 structured databases, and (2) nonacademic sources, such as online articles, blog posts, products from startups and established companies, initiatives from NGOs, and proceedings from events and conferences. Full results of the gray literature search are detailed in Multimedia Appendix 1, with key findings highlighted below.

Within the academic gray literature, we identified 11 relevant articles from the first 100 Google Scholar results, with 9 (9%)

XSL•FO
RenderX

peer-reviewed articles and 2 (2%) preprints. These studies generally aligned with the patterns observed in the aforementioned structured database search. Each study involved researchers affiliated with at least one African institution, with contributions from South Africa (6/11, 55% studies) [90-95], Nigeria (4/11, 36%) [95-98], Guinea (1/11, 9%) [99], and Rwanda (1/11, 9%) [100]. In addition, 4 (36%) studies involved collaborations with international researchers from institutions based in the United States (3/11, 27% studies), Canada (3/11, 27%), Germany (1/11, 9%), and Mexico (1/11, 9%). Funding was disclosed in 6 (55%) of the 11 studies, all supported by public entities.

The primary NLP applications developed in these studies were conversational assistants (4/11, 36% studies) and sentiment analysis tools (3/11, 27% studies). These studies primarily supported EPHF 7 (ie, health promotion, 8/11, 73% studies). Regarding language coverage, nearly all studies (11/11, 100%) reported support for English. A smaller number addressed African languages, including Ndebele (2/11, 18% studies), Sotho (2/11, 18%), Kiswahili (2/11, 18%), Swati (2/11, 18%), Venda (2/11, 18%), Xhosa (2/11, 18%), Zulu (2/11 18%), with one study each for Afrikaans, Hausa, Kinyarwanda, Northern Sotho, Shona, Tsonga, and Tswana. For target countries, Nigeria and South Africa were the primary focus, each covered in 5 (45%) studies. Notably, none of the studies provided performance evaluations based on health-related measures or reported reaching the stage of actual deployment.

Outside academia, commercial products and NGO-led initiatives have focused on creating practical NLP solutions aimed at real-world public health impact. On the basis of our search results, 4 NLP technologies were developed as commercial products by companies [101-104], and another 4 were created as part of initiatives led by NGOs [105-108]. These projects were often in partnership with charitable organizations like the Bill and Melinda Gates Foundation, international bodies, such as the WHO, and industry partners like Google or Meta, frequently collaborating with telecom providers to reach populations with lower literacy levels and limited access to public health resources. The primary focus of these NLP technologies was on disseminating public health information through conversational assistants, with applications supporting EPHF 7 (ie, health promotion) and SDG 3 (good health and well-being). Most tools were designed in English with the limited inclusion of widely spoken African languages like Hausa, Kiswahili, and Zulu. In contrast to academic literature, NLP technologies from these nonacademic sources typically disclosed only limited details about their design and implementation.

Furthermore, our review of events and conferences did not introduce additional evidence of NLP technologies tailored to African public health challenges. A lack of standardized protocols for reporting NLP technologies, such as established reporting standards or controlled vocabularies for indexing, may explain why no relevant NLP technologies were retrieved during our search, likely due to limited keyword overlap.

Discussion

Principal Findings

Research into NLP technologies for public health in Africa is an emerging field, with significant growth since 2019. Current studies primarily focus on 2 applications: conversational agents for public health information dissemination and sentiment analysis tools that track public health attitudes on social media. Most studies target high-resource languages like English, Arabic, and French, with limited support for widely spoken African languages, such as Kiswahili and Zulu, and no support for most of Africa's >2000 languages.

Most NLP applications remain in the prototype stage, with evaluations often limited to technical performance metrics in controlled settings. Only a handful of studies have validated their systems in real-world contexts, and just 1 has reached full deployment. Until now, most systems have been developed as technical NLP tools rather than targeted health interventions, with limited evaluation of their impact on public health outcomes through rigorous study designs and implementation research approaches.

While current research highlights the potential of NLP to address public health needs in Africa, this potential remains largely unrealized in terms of measurable public health outcomes. The following discussion explores pathways for public health and NLP researchers to contribute to the development and deployment of NLP technologies toward achieving positive health impacts in Africa. In addition, we reviewed the strengths and limitations of our review approach, providing context for readers to critically evaluate the subsequent discussion.

Bridging Technical NLP Performance With Health-Related Outcomes

The review of 54 studies highlights the growing effort to leverage NLP technology for health improvement in Africa. However, it identifies a significant gap in evaluating real-world health outcomes or the behavioral antecedents of these outcomes. Most studies (51/54, 94%) emphasized technical performance, using metrics, such as accuracy, precision, F_1-score, and recall. In comparison, only 11 (20%) studies incorporated user-centered evaluations, such as usability testing or health care provider feedback. While some studies [45,47,54] assessed user outcomes like the accuracy of health communications and improvements in health care interactions, only 2 (4%) studies [71,89] measured explicit health-related impacts. Specifically, 1 (2%) paper [71] demonstrated improvements in participants' mood through an automated intervention targeting maternal mental health in Kenya, while another paper [89] showed increased vaccine willingness via a chatbot addressing individual concerns. These examples illustrate the potential of NLP interventions to influence public health, while their rarity highlights the need for more research focused on evaluating health impacts.

An overreliance on technical NLP metrics limits our understanding of whether these technologies effectively address real-world health challenges. To ensure NLP solutions meet their intended public health goals, future research should

XSL•FO
RenderX

incorporate tools to evaluate health-related measures and behavioral outcomes of NLP solutions alongside technical performance. Tools and frameworks already exist to guide the evaluation of health interventions, such as the WHO's "Monitoring and Evaluating Digital Health Interventions" framework [113], which provides standardized guidelines for assessing the impact of digital health technologies on health outcomes and behaviors. Despite the availability of such resources, they remain underutilized in the evaluation of NLP technologies. To fully realize the potential of NLP for public health, it is essential that future studies adopt these established frameworks to rigorously measure both health outcomes and behavioral changes. Integrating these tools will strengthen evidence on the real-world effectiveness of NLP interventions and support more impactful, data-driven public health strategies.

Deployment, Integration, and Cross-Sectoral Development

For NLP technologies to be deployed in an impactful way, they must be integrated into African health systems and broader public health infrastructure, ensuring accessibility to diverse groups of users. The results of our review of the academic literature have shown the nascent nature of NLP deployment in Africa, with only 1 technology, a Facebook messenger chatbot collecting data on vaccine hesitancy [89], having reached full deployment. Other described technologies (40/50, 80%) were designed with the potential for integration into public health systems, and most apps under development are available without significant restrictions (ie, either open-source or publicly available). However, many of these apps require substantial expertise in computer science for installation and use, limiting their accessibility. For effective integration, these technologies need to be accessible to their intended users, such as health care workers, patients, and nonspecialists. Approximately 20 apps in this review were designed to be delivered via mobile- or web-based interfaces, increasing their potential usability.

In contrast, industry-led commercial products and NGO-driven initiatives have generally progressed further, often yielding immediate, tangible impacts for African communities. These initiatives commonly partner with organizations [114] like the Bill and Melinda Gates Foundation [115], the WHO, and companies [116], such as Google or Meta, and frequently collaborate with telecom providers to enhance accessibility for populations with limited resources and lower literacy levels. Unlike academic studies, which typically prioritize proof-of-concept and feasibility testing, these projects aim for direct public health impact, real-world validation, and, at times, profitability. However, as highlighted in this review, nonacademic projects tend to focus on narrower applications, primarily conversational assistants, offer limited language support, serve smaller populations, and address a more focused range of public health challenges compared to the diverse objectives often seen in academic research.

Moving forward, bridging the gap between NLP research and accessible, real-world applications will be essential for delivering positive public health impacts. The narrower focus of nonacademic projects highlights a need for extended collaboration between academic and nonacademic researchers, combining priorities, expertise, and resources to enhance NLP's potential in addressing Africa's public health needs. Cross-sectoral partnerships offer a promising model for advancing academic NLP technologies from proof-of-concept to impactful public health solutions across the continent.

Toward Needs-Based Approaches

As we move toward the SDGs' 2030 deadline, it is sobering to note that "current progress falls far short of what is required to meet the SDGs" [117]. Within this, the world is off track to achieve SDG 3 [117]. The SDG dashboard map offers a country-by-country breakdown of each of the SDG 3 indicators [118]. Progress toward SDG 3 in all but one mainland African country (ie, Tunisia) is described as "major challenges remain" (ie, the most concerning category), while Tunisia and the island nations of Cabo Verde, Mauritius, and the Seychelles are in the less severe category of "significant challenges remain." In terms of progress, no African countries are currently considered to be "on track" or "decreasing" their progress; instead, they are all described as having major challenges in their progress toward the SDG 3 (ie, good health and well-being) targets [3].

In response to this somewhat bleak outlook, the United Nations prescribes that "changing course requires prioritizing the achievement of universal health coverage, strengthening health systems, investing in disease prevention and treatment, and addressing disparities in access to care and services, especially for vulnerable populations" [117]. Furthermore, it should be recognized that poverty and inequality constrain the possibilities for health gains [119], highlighting the need for a paradigm focused not only on treatment but on prevention, equity, and intersectional, multisectoral approaches to health promotion.

There is also a need to address technological and infrastructural limitations which still exist. Globally, a third of people remain offline—that is 30% of men and 35% of women [117]. In 2015, 15.6% of people in sub-Saharan Africa had internet access, rising to 37% by 2023 (*ibid*). Furthermore, a study of 15 countries (of which 7 were African countries) demonstrated how access to this technology often varies, with lower phone ownership in rural compared to urban areas, and varied ownership levels between poorer and wealthier income groups [120].

A review of the successes and limitations of telemedicine deployment in Africa during the COVID-19 pandemic [121] demonstrates what this means in practice. The study found the following technologies were used "videos, telephones, smart wearable digital devices, messaging mobile apps, virtual programs, online health education modules, SMSs, live audio–visual communication, and other digital platforms." Among these, phones were the most widely used. Some of the difficulties faced included an array of digital challenges ranging from low connectivity and high data costs to the inaccessibility of smartphones, nondelivery of messages, and insufficient digital skills. This was in a broader context characterized by a lack of telemedicine frameworks and policies to support a roll out; some patients and health care personnel preferred not to use these technologies, and there was an underlying shortage of health care personnel [121].

XSL•FO
RenderX

For NLP technologies to address real-world health challenges, they should be viewed not just as technical solutions but as tools shaped by and responsive to the local context. Developing effective NLP applications will require a community-centered approach [122,123], grounded in local needs, ethical principles, infrastructures, and capacities to ensure these tools are truly accessible and impactful. Engaging people in research, including coresearchers, can facilitate a closer understanding of local needs and suitable ways to address these [124].

The Need for Culturally and Linguistically Inclusive NLP Applications in Africa

Africa has exceptional linguistic diversity, with >2000 languages spoken across the continent [21,22]. This includes widely used official languages, such as Arabic, English, and French, alongside popular indigenous languages, such as Zulu, as well as a large majority of underrepresented languages spoken by smaller communities. Kiswahili spans several African countries, uniting East Africa as the shared language of politics, trade, music, literary tradition, and religion (both Islam and Christianity) [125]. Nigeria is the most linguistically diverse, with >500 indigenous languages [126]. While official languages tend to have relatively sufficient digital data to support NLP development, most indigenous African languages fall into the category of being low-resource, extremely low-resource, or even no-resource, often lacking any digital data essential for NLP technologies. The scarcity of digital language resources forms significant performance disparities in NLP systems [127]. These disparities, including higher error rates for underrepresented languages (ie, error rate disparities [128]), contribute to broader inequities, limiting access to advancements in NLP technology and impeding speakers of underrepresented languages from fully benefiting from progress in NLP technology.

To develop inclusive NLP applications that equitably serve African populations, strategically expanding digital datasets for underserved languages is essential. This is particularly the case for languages with limited online representation [129]. Concurrently, advancements in multilingual NLP and cross-lingual transfer learning provide promising opportunities [130-132]. These approaches allow neural language models, the backbones of most modern NLP applications, to leverage knowledge from high-resource languages to perform well in low-resource contexts, even with minimal in-language data. By combining efforts in data collection with advancements in NLP research, these technologies can better support Africa's linguistic diversity, contributing to public health solutions that promote, rather than hinder, health equity.

In addition to linguistic inclusivity, cultural relevance is essential for NLP technologies [29,133] to meet the diverse needs of African communities effectively. Distinct cultural practices, health beliefs, and communication styles influence how groups perceive and interact with technology.

Embedding cultural practices into the design and implementation of NLP technologies is essential for ensuring their relevance and successful integration into Africa's health systems and institutions. For example, a health education dialogue system advising users to visit a *general practitioner*, a term commonly associated with primary care doctors in the United Kingdom's National Health Service, may be irrelevant or confusing to many users in Africa. Furthermore, Loveys et al [134] highlighted how expressions of depression in text, such as the ratio of positive to negative emotions, vary across cultures. Similarly, the extensive use of traditional medicine in many African countries [135] highlights the need for NLP technologies to incorporate culturally recognized terms and references to these practices. Another good example is the recent work by Olatunji et al [136], which introduces a geo-culturally diverse dataset of clinically diverse questions and answers annotated by health experts. This dataset enables the development of question-answering systems serving African patients.

Respecting and integrating these cultural nuances into NLP design and implementation can enhance trust, ensure alignment with the expectations and needs of each community, and ultimately promote equitable public health outcomes.

Integrative Development for NLP in Public Health

Our analysis shows that NLP technologies focusing on health in Africa intersect most frequently with SDG 10 (ie, reduced inequality) and SDG 9 (ie, industry, innovation, and infrastructure). This study did not identify any intersections with other SDGs, even those that are particularly relevant to public health, such as SDG 1 (ie, end poverty), SDG 2 (ie, zero hunger), SDG 6 (ie, clean water and sanitation), SDG 7 (ie, affordable and clean energy), SDG 11 (ie, sustainable cities and communities), SDG 12 (ie, responsible consumption and production), SDG 13 (ie, climate action), and SDG 17 (ie, partnership for the goals) are absent. This highlights an opportunity for more cross-cutting intersections between NLP applications for health and broader sustainable economic development efforts, as well as the importance of a more integrated approach to achieving the SDGs [112,137].

The current coverage of the SDG 3 targets and means of implementation by existing NLP technologies (Figure 3) highlights the need for more investment in the WHO framework convention on tobacco control (SDG 3.a), substance abuse (SDG 3.5), road traffic (SDG 3.6), and environmental health (SDG 3.9) for sustained and long-term health impacts. While the goals of ending epidemics (SDG 3.3), reducing maternal mortality (SDG 3.1), and achieving universal health coverage (SDG 3.8) are strongly represented in the literature, there remains significant potential to invest more in cross-cutting activities that have long-term impacts on health systems.

The limited attention given to 6 key EPHFs (ie, highlighted by the orange line in Figure 2) also highlights a significant gap in the research landscape, with critical public health functions, such as emergency management, stewardship, and multisectoral planning being overlooked. These underaddressed EPHFs and SDG 3 targets play a fundamental role in building resilient health systems, especially in low-resource settings. Therefore, there is a need for more balanced research efforts to ensure all aspects of public health are adequately supported.

Developing NLP technologies to address these underresearched EPHFs and SDG 3 targets requires a deep understanding of local contexts and the integration of NLP technologies within

XSL•FO
RenderX

them. For instance, addressing EPHF 12 (ie, access to health products) requires integrating NLP technologies into existing logistics and supply chain systems, which often vary significantly between countries. Such highly specialized and localized contexts introduce additional challenges and requirements for system development.

Future studies should aim to bridge these gaps by aligning NLP development with more integrative, cross-disciplinary collaborative approaches that promote system-wide impact. By embedding NLP technologies within broader health system goals and leveraging collaborative input across fields, these solutions can become more effective, resilient, and responsive to public health challenges. Such an approach will help guide interventions and inform policy development, ensuring that public health improvements are enduring and responsive to Africa's evolving health needs.

Strengths and Limitations of the Review

This review has several strengths. We developed and followed a protocol guided by the PRISMA-P (Preferred Reporting Items for Systematic Review and Meta-Analyses—Protocols) guidelines [138], ensuring a transparent and systematic approach throughout the study. Our literature search was comprehensive and multidisciplinary, integrating both academic and gray literature sources to capture a broad range of perspectives and to provide a current reflection of the scope of research. The inclusion of gray literature, such as reports from industry and NGOs, enabled a wider view of NLP applications in public health that extends beyond the academic literature. Screening and data extraction were conducted following predefined guidelines created by a team of domain experts, enhancing both the consistency and relevance of the data collected. The extracted data is publicly available in a machine-readable format to facilitate future research (Multimedia Appendix 3).

However, there are some limitations to consider. Our review relied primarily on English search terms, which may have inadvertently excluded studies published in other languages without English annotations. Although we included 5 representative databases spanning public health, NLP, computing, and engineering, some relevant studies may have been missed because of the highly interdisciplinary nature of the field. In addition, NLP research is frequently disseminated as preprints, blog posts (eg, OpenAI's introduction of ChatGPT), and in peer-reviewed machine learning conference proceedings (such as International Conference on Learning Representations and Conference on Neural Information Processing Systems) not indexed by our selected databases. Consequently, certain emerging studies may not have been captured, especially given the rapid development of NLP applications in public health. However, the results of our gray literature search indicate that most academic papers, including preprints and conference proceedings, have been covered in this review.

Although this review included a broad range of gray literature, the search for nonacademic sources was far from exhaustive, and some relevant NLP technologies may have been overlooked. The primary focus of this review was on peer-reviewed academic literature, with gray literature providing supplementary insights. This work could be further expanded through a series of expert interviews, such as with representatives from the WHO or the SDG by 2030 committees, to interrogate the factors shaping the development, or lack thereof, of NLP applications for public health in Africa [139,140]. In addition, the heterogeneity of NLP methodologies, applications, and evaluation metrics hindered our ability to conduct a formal meta-analysis, resulting in a reliance on narrative synthesis. Despite efforts to maintain consistency during data extraction, inconsistencies in reporting approaches for included studies presented challenges, particularly in evaluating public health focus and outcomes, which impacts comparability across different technologies.

These challenges reveal a broader misalignment between the rigorous methodological standards of systematic reviews and the agile, fast-evolving, and highly interdisciplinary nature of NLP research. Future research should explore methodological adaptations that better align with the field of NLP, especially for applications in health contexts.

Conclusions

The application of NLP technologies to public health in Africa is a promising and rapidly evolving field, with the potential to enhance health care accessibility, equity, and efficiency across the continent. However, significant gaps persist in real-world deployment, language inclusivity, and the rigorous evaluation of health outcomes. The identification of, and responses to, such gaps would be greatly enabled by the establishment of reporting standards for NLP technologies.

Future research should adopt a needs-based and cross-sectoral approach, engaging expertise from diverse fields, including the expertise of local communities on their own needs and possible solutions, and using existing frameworks for evaluating their public health impacts and outcomes. This approach will help build a deeper understanding of needs and support the tailored design of NLP technologies to effectively address public health challenges where this technology can be useful and is wanted. Furthermore, qualitative research, such as expert interviews, can contribute to better understand the dynamics and demand for progress in this area. By bridging existing gaps in meaningful local engagement, NLP research can better support resilient, culturally relevant, and equitable public health systems in Africa.

Authors' Contributions

EM and AK conceived the idea for this scoping review and provided project supervision. SH developed the research protocol and conducted the academic literature search. AO, CC, and SH participated in the screening of papers, with AO as the primary reviewer, CC as the secondary reviewer, and SH as the coordinator. SH designed the data extraction template, while AO carried out the data extraction. Data analysis and visualization were conducted by SH, AO, and GO. SH led the drafting of the manuscript, with substantial contributions from SH, AO, EM, CC, GO, AB, and AK in writing and refining the paper. All authors engaged in discussions throughout the project. SH and AO contributed equally as shared first authors. ChatGPT was used exclusively for editorial assistance, such as improving language clarity and identifying grammatical errors, alongside editing by the authors. The authors have reviewed all content carefully and assume full responsibility for the manuscript's final form.

Abstract

Background: Although the implementation process of digital health technologies (DHTs) has been extensively documented in high-income countries, the factors that facilitate and prevent their implementation in lower- and middle-income countries (LMICs) may differ for various reasons.

Objective: To address this gap in research, this scoping review aims to determine the facilitators and barriers to implementing DHTs in LMIC hospital settings following the onset of the COVID-19 pandemic. Additionally, the review outlined the types of DHTs that have been implemented in LMICs' hospitals during this pandemic and finally developed a classification framework to categorize the landscape of DHTs.

Methods: Systematic searches were conducted on PubMed, Scopus, Web of Science, and Google Scholar for studies published from March 2020 to December 2023. We extracted data on authors, publication years, study objectives, study countries, disease conditions, types of DHTs, fields of clinical medicine where the DHTs are applied, study designs, sample sizes, characteristics of the study population, study location, and data collection methods of the included studies. Both quantitative and qualitative data were utilized to conduct a thematic analysis, using a deductive method based on the Practical, Robust Implementation and Sustainability Model (PRISM), to identify facilitators and barriers to DHT implementation. Finally, all accessible DHTs were identified and organized to create a novel classification framework.

Results: Twelve studies were included from 292 retrieved articles. Telemedicine (n=5) was the most commonly used DHT in LMICs' hospitals, followed by hospital information systems (n=4), electronic medical records (n=2), and mobile health (n=1). These 4 DHTs, among the other existing DHTs, allowed us to develop a novel classification framework for DHTs. The included studies used qualitative methods (n=4), which included interviews and focus groups, quantitative methods (n=5), or a combination of both (n=2). Among the 64 facilitators of DHT implementation, the availability of continuous on-the-job training (n=3), the ability of DHTs to prevent cross-infection (n=2), and positive previous experiences using DHTs (n=2) were the top 3 reported facilitators. However, of the 44 barriers to DHT implementation, patients with poor digital literacy and skills in DHTs (n=3), inadequate awareness regarding DHTs among health care professionals and stakeholders (n=2), and concerns regarding the accuracy of disease diagnosis and treatment through DHTs (n=2) were commonly reported.

Conclusions: In the postpandemic era, telemedicine, along with other DHTs, has seen increased implementation in hospitals within LMICs. All facilitators and barriers can be categorized into 6 themes, namely, (1) Aspects of the Health Care System; (2)

XSL•FO
RenderX

Perspectives of Patients; (3) External Environment; (4) Implementation of Sustainable Infrastructure; (5) Characteristics of Health Care Organization; and (6) Characteristics of Patients.

(J Med Internet Res 2025;27:e63482) doi:10.2196/63482

KEYWORDS

digital health implementation; facilitators; barriers; digital health classification framework; lower- and middle-income countries

Introduction

Populations residing in lower- and middle-income countries (LMICs) face numerous unmet health care needs due to various factors [1], including an aging population [2], escalating health care costs [3], widening income disparities [4], increased child morbidity and mortality [5], the emergence of new epidemics and pandemics [6], and growing racial discrimination in health care access [7]. The COVID-19 pandemic has further exacerbated the existing disparities and limitations of health care systems in LMICs, further exposing the issues of understaffing, underfunding, inadequate infrastructure, limited access to testing and treatment, and vulnerability to health emergencies [8]. In response to this unprecedented pandemic, many hospitals in LMICs have attempted to leverage digital health technologies (DHTs) as an innovative approach to curb the spread of the SARS-CoV-2, improve health care provision, and strengthen pandemic response efforts [9].

Generally, DHTs are defined as a set of information and communications technologies utilized in medicine and health care to manage illnesses and promote wellness [10]. These technologies have expanded as a transformative force in health care since the onset of the COVID-19 pandemic era, thereby offering a myriad of benefits that revolutionize health care delivery and improve patient outcomes. These technologies encompass a wide range of digital tools, including mobile health (mHealth) [11], telemedicine [12], wearable technologies [13], electronic medical records [14], big data analytics [15], Internet of Medical Things [16], blockchain in health care [17], metaverse [18], software as a medical device [19], augmented reality [20], and virtual reality [21]. With increasing computing power and appreciation of artificial intelligence [22] and machine learning [23] in health and medicine, many such smart tools are an making appearance in different aspects of hospital care [24,25].

Despite the benefits of DHTs, such as improved access to health care, enhanced patient engagement and empowerment, efficient health care delivery, timely and personalized care, remote monitoring, and data-driven decision-making, the implementation process of DHTs in the hospital settings, including its facilitators and barriers, is mostly described in the context of high-income countries [26,27]. Given the differences in resources, infrastructure, health care systems, socioeconomic status, level of digital divide, and regulatory frameworks in the LMICs compared with the high-income countries, the evidence on facilitators and barriers to implementing DHTs reported in previous literature may not apply to the LMICs [28]. To address these research gaps, this scoping review aimed to:

- Provide an overview of the facilitators and barriers in implementing DHTs within hospital settings in LMICs since the onset of the COVID-19 pandemic.
- Identify and describe the types of DHTs that have been put into practice in hospitals within LMICs since the onset of the COVID-19 pandemic.
- Develop a classification framework to better define the landscape of DHTs, providing a more comprehensive and practical understanding.

Methods

Design

The scoping review was conducted using the methodological framework developed by Arksey and O'Malley [29]. The protocol has been registered in the Open Science Framework and has been previously published [30]. The PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [27,31] was used to conduct and report our findings.

Identifying Relevant Literature

To comprehensively identify the literature relevant to DHTs, a broad, sensitive, and specific search strategy was applied to capture all DHT-related literature. With the assistance of an information technologist, a comprehensive list of literature relevant to DHTs was identified according to the criteria below. Textboxes 1 and 2 describe the inclusion and exclusion criteria adopted for this scoping review. The focus was on the period between March 2020 and December 2023, as the World Health Organization (WHO) officially declared COVID-19 as a pandemic in March 2020.

XSL•FO
RenderX

Textbox 1. Inclusion criteria.

- Studies that were conducted in lower- and middle-income countries (LMICs). (The World Bank classifies countries by income each year, covering all nations with a population over 30,000. In 2023, countries are divided into 4 income categories based on their gross national income (GNI) per capita. Low-income countries are defined as those with a GNI per capita of US $1145 or less. LMICs have a GNI per capita between US $1146 and US $4515, while upper-middle-income countries fall between US $4516 and US $14,005. High-income countries are those with a GNI per capita exceeding US $14,005. Based on this classification, LMICs in the current review are defined as countries with GNI below US $14,005 per capita.)
- Studies that reported the implementation of digital health technologies in hospital settings (for both acute and chronic conditions).
- Studies that were reported between March 2020 and December 2023.
- Studies that were reported in the English language.
- Qualitative studies (phenomenology, ethnography, grounded theory, case study, etc), quantitative studies (case-control, cohort study, cross-sectional, randomized controlled trials, etc), mixed methods studies, and reviews (narrative review, scoping review, systematic review, meta-analysis, etc).
- Relevant gray literature (eg, Google Scholar).

Textbox 2. Exclusion criteria.

- Studies that were nondigital-based (ie, studies that did not investigate the effectiveness of digital interventions, such as paper-based studies and postage surveys).
- Studies that implemented digital health technologies (DHTs) in primary care or community settings alone. However, studies that concurrently reported on the implementation of DHTs in hospital settings will still be included.
- Studies that used DHTs in dentistry and nonclinical medicine area (eg, dentistry, basic sciences, medical education, medical engineering, nutrition, dietetics, veterinary science, laboratory experimentations, and medical anthropology).

Systematic searches were conducted in PubMed, Scopus, and Web of Science databases. Potentially relevant gray literature was searched through targeted searches of Google Scholar. Lateral searching included screening reference lists in identified studies or reviews for relevant publications. Articles published in English between March 2020 and December 2023 were retrieved. Two investigators (SQY and NIHA) independently performed literature searches in the aforementioned electronic databases.

The search strategy was developed based on the "Population-Concept-Context" (PCC) framework as recommended by the Joanna Briggs Institute for Scoping Reviews [32] (Table 1). It aimed to identify the intersection between the "Population," "Concept," and "Context." Based on the PCC framework, the search strategy was "Population combined" AND "Concept" AND "Context." The details of the search strategy and search terms are tabulated in Multimedia Appendix 1.

Table 1. The PCC[a] framework used to generate search terms.

Framework	Search terms
Population	• Population 1: hospital settings (search terms as in Multimedia Appendix 1). • Population 2: LMICsb (search terms as in Multimedia Appendix 1). • Population combined: Population 1 AND Population 2.
*C*oncept	• Digital health technologies (search terms as in Multimedia Appendix 1).
*C*ontext	• Facilitators, barriers, and implementation.

[a]PCC: Population-Concept-Context.

[b]LMICs: lower- and middle-income countries

Study Selection

Records were downloaded in Rayyan software (an artificial intelligence–assisted article screening software) [24] and after deduplication, all titles and abstracts were screened independently against the inclusion criteria by 2 reviewers (SQY and NIHA). Among all titles and abstracts found, 70 out of 279 (25%) were randomly selected and screened to establish interreviewer reliability. The interreviewer reliability (κ) was 0.63, indicating good reliability. Full-text articles of potentially relevant papers identified were screened independently by SQY and NIHA. Disagreements were resolved via discussion, with consultation from a third reviewer (BHC) if needed to reach a consensus. We included studies that met the review criteria and reported on barriers and facilitators of DHT implementation. For this review, DHTs were defined as a set of information and communications technologies used in medicine and health care to manage illnesses and to promote wellness [10].

XSL•FO
RenderX

Charting the Data

Two authors (SQY and NIHA) independently extracted the following data from the included papers: authors, publication years, study objectives, study countries, disease conditions, types of DHTs, fields of clinical medicine where the DHTs are applied, study designs, sample sizes, characteristics of the study population, study location, and data collection methods of the intervention or program. We categorized the DHTs according to the types of equipment and method of operation. Any disagreements were resolved by discussion and consultation with a third author (BHC).

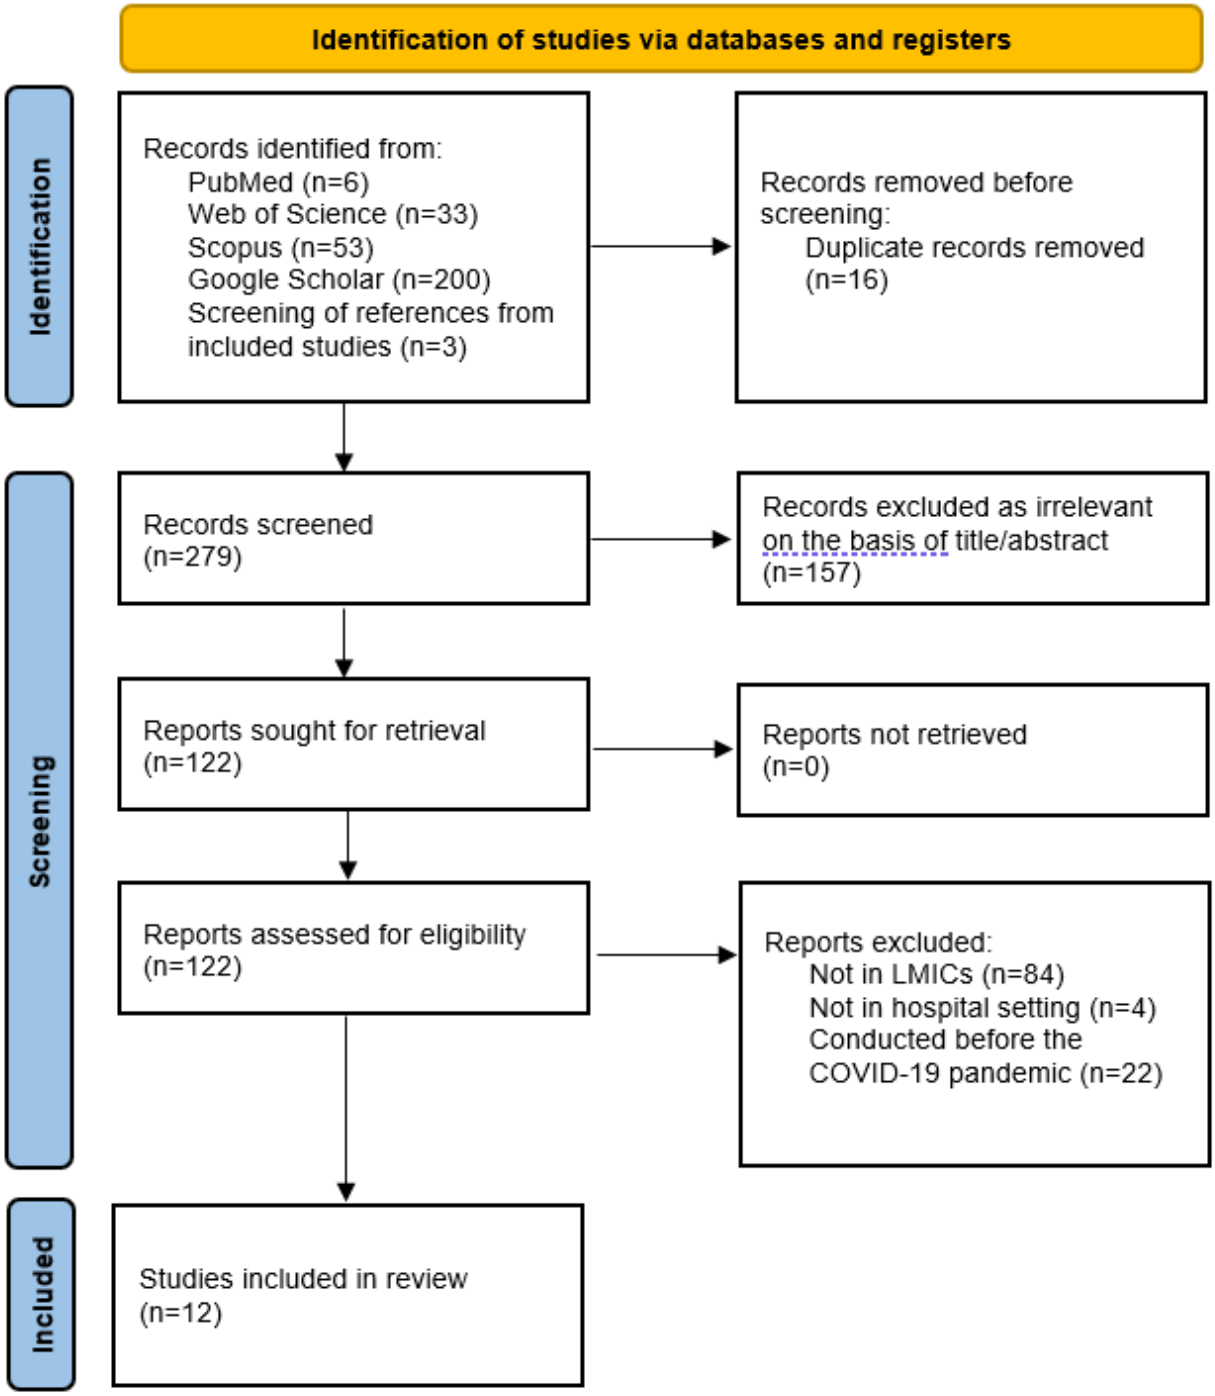
Collating, Summarizing, and Reporting the Results

Descriptions of the included studies, such as study countries, types of DHTs, fields of clinical medicine where the DHTs are applied, and study designs were reported using descriptive statistics (eg, frequency distribution). Facilitators and barriers to DHT implementation, which were in the form of quantitative and qualitative data, were thematically analyzed using a deductive approach. To guide the thematic analysis, facilitators and barriers to DHT implementation were organized using the Practical, Robust Implementation, and Sustainability Model (PRISM) [33].

During the coding process, 2 authors (SQY and NIHA) identified the key components of the PRISM relevant to DHT implementation. They mapped the facilitators and barriers reported in the included studies to the predefined categories and subsequently grouped similar categories under overarching themes. By organizing the facilitators and barriers into themes and categories, patterns, trends, and relationships among the factors influencing DHT implementation can be identified, providing a structured framework for understanding the complexities of implementing DHTs in LMICs' hospital settings [34].

Consultation With Stakeholders

Clinicians and information technology (IT) experts from a local teaching hospital were invited to help interpret and contextualize the findings. Through interactive discussions and collaborative sessions, stakeholders provided valuable input on the categorization of facilitators and barriers as well as the implications of implementation of DHTs in their respective contexts. Moving forward, the authors plan to continue engagement with these stakeholders to disseminate the findings of the scoping review through presentations, policy briefs, and peer-reviewed publications.



Results

Literature Search

A systematic search yielded 295 titles and abstracts. After removing 16 duplicates, 279 unique articles remained. Among these, 157 were excluded based on title or abstract review. We thoroughly evaluated 122 full-text articles, and ultimately, 12 met the eligibility criteria. The PRISMA flow diagram was used to illustrate the search decision process of the scoping review [35] (Figure 1 and Multimedia Appendix 2).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart. LMIC: lower- and middle-income country.

Characteristics of the Included Studies

Of the 12 articles, 6 (50%) were conducted in Asia [36-41], 4 (33%) in Africa [42-45], 1 (8%) in the Middle East [46], and 1 (8%) in South America [47]. Most of the studies (10/12, 83%) [36,37,40-47] did not specify the specific field of clinical medicine where DHTs were applied. However, some reported implementation in respiratory medicine (1/12, 8%) [38] and cancer (1/12, 8%) [39]. Telemedicine (5/12, 42%) [37,38,40,41,46] was the most commonly reported technology, followed by hospital information systems (4/12, 33%) [36,42,45,47], electronic medical records (2/12, 17%) [43,44], and mHealth (1/12, 8%) [39]. In terms of study design, there were 5 (42%) cross-sectional studies [37,41,42,44,46], 4 (33%) qualitative studies [38-40,43], 2 (17%) mixed method studies [45,47], and 1 (8%) case study [36]. The participant numbers ranged from 12 to 3386 individuals (Table 2).

Facilitators and Barriers to DHT Implementation

Among the 12 studies, 9 explored both the facilitators and barriers to implementing DHTs in hospital settings in LMICs since the onset of COVID-19 [36-40,43-45,47]. Two studies focused solely on facilitators [41,42], while 1 solely addressed barriers [46]. A total of 63 facilitators and 44 barriers were identified. Subsequently, these facilitators and barriers were systematically organized into 6 themes according to the PRISM, which include the following: (1) Aspects of the Health Care System; (2) Perspectives of Patients; (3) External Environment; (4) Implementation of Sustainable Infrastructure; (5) Characteristics of Health Care Organization; and (6) Characteristics of Patients. These are outlined in Table 3.

XSL•FO
RenderX

Table 3. Facilitators and barriers to DHT[a] implementation in hospital settings in lower- and middle-income countries after the COVID-19 pandemic.

Themes and categories	Codes for facilitators	Codes for barriers
Aspects of the Health Care System (n^b=11)		
Readiness (n_f[c]=4; n_b[d]=3)	• Understand the basics of information technology [37] • Knowledge in protecting data confidentiality [37] • High level of self-efficacy [42] • Good attitude toward DHTs [42] • High awareness about the implementation of DHTs [47] • High personal interest and motivation [47] • The high willingness of health care providers to provide DHTs for patients [41]	• Inadequate awareness regarding DHTs [40,44] • Feeling that DHTs are only complementary to traditional health care [38] • Preference of some health care providers for printed materials [44]
Strength of the evidence base (n_f=1; n_b=2)	• The ability of DHTs to offer statistical analysis and reports for decision-making [36] • The ability of DHTs to offer timely and up-to-date patient information [36]	• Concerns regarding accuracy in disease diagnosis and treatment [40,46]
Addresses barriers to frontline staff (n_f=1; n_b=2)	• Easy access to computers in the working area [44]	• Fear of inappropriate data protection might breach patient's privacy [37] • Inadequate computers at the workplace and service point local area network at the workplace [43]
Coordination across departments and specialties (n_f=1; n_b=1)	• Use of single information technology policy and standard hospital information system [47]	• Lack of interoperability standards between systems [47]
Burden (complexity and cost; n_f=4; n_b=1)	• Perceive that operations of DHTs are not complex [42] • The availability of information technology budget [47] • Regular upgrades on DHT hardware [43] • Funding support focusing on research and learning opportunities on DHTs [45]	• The need for retrospective data entry into systems [43]
Usability and adaptability (n_f=4; n_b=3)	• The ability of DHTs to prevent cross-infection [38,40] • Ability to provide health care in remote areas [40] • The functionalities of DHTs align with hospital's practices [47] • User-friendliness of DHTs [43]	• Difficulty in performing physical examination with DHTs [40] • Lack of compliance among health care professionals and patients [40] • DHTs might reduce the quality of medical services by increasing the probability of medical mistakes [37] • Perceive DHTs as research agenda only [45] • Some DHTs are not user-friendly [36]
Trialability and reversibility (n_f=1; n_b=0)	• Conduct beta tests and pilot tests before implementation of DHTs [47]	• N/Ae
Ability to observe results (n_f=3; n_b=0)	• Positive previous experiences using DHTs [41,47] • The ability of DHTs to increase administrative and health care efficiency [36] • The ability of DHTs to reduce medication errors [36]	• N/A
Perspectives of Patients (n=5)		

XSL•FO
RenderX

Themes and categories	Codes for facilitators	Codes for barriers
Patient centeredness (n_f=1; n_b=1)	• Using technology gives a superior feeling [38] • Repeated motivational or praising words increase patients' usage of DHTs [38]	• The feeling of the distance between the patient and health care providers during remote interaction [38] • The feeling of being forced to use DHTs [38]
Addresses patient barriers (n_f=1; n_b=1)	• Involvement of patients' children could improve the efficiency and effectiveness of DHTs [38]	• Patients' resistance to change practice [46]
Seamlessness of transition between program elements (n_f=1; n_b=0)	• Unification of hospitals in a single network and centralized management [47]	• N/A
Service and access (n_f=1; n_b=0)	• Easy access to online health information and applying the knowledge [38]	• N/A
Burden (complexity and cost; n_f=2; n_b=0)	• The ability of DHTs to reduce stress among patients [40] • DHTs are cost-effective [38]	• N/A
Feedback of results (n_f=2; n_b=0)	• DHTs are easy and convenient to use [38,39] • DHTs are able to improve the comfort level of patients [39]	• N/A
External Environment (n=3)		
Competition (n_f=0; n_b=2)	• N/A	• Competition for resources between information technology equipment and other health care equipment [45,47]
Regulatory environment (n_f=1; n_b=2)	• Good communication process between the regulatory authority and the hospitals [47]	• Political and economic instabilities [45,47]
Community resources (n_f=1; n_b=0)	• Good internet access among users of DHTs [44]	• N/A
Implementation of Sustainable Infrastructure (n=5)		
Adopter training and support (n_f=1; n_b=0)	• Familiarity with handling DHT tools [40]	• N/A
Relationship and communication with adopters (n_f=0; n_b=1)	• N/A	• The communication gap between supervisors and supervisees [45]
Adaptable protocols and procedures (n_f=1; n_b=0)	• Remote health service can be carried out easily among clinicians [37]	• N/A
Facilitation of sharing of best practices (n_f=1; n_b=0)	• Experience sharing between advanced and beginner hospitals [47]	• N/A
Plan for sustainability (n_f=1; n_b=1)	• Health care facilities prioritize the implementation and sustainability of DHTs [47]	• The end of the COVID-19 pandemic reduced the demand for DHTs [46]
Characteristics of the Health Care Organization (n=11)		

XSL•FO
RenderX

Themes and categories	Codes for facilitators	Codes for barriers
Organizational health and culture (n_f=3; n_b=1)	• The availability of fair-to-good organizational support [42] • Commitment from the top management or managers [47] • Top management mandates the adoption of DHTs [47] • Promote experience and knowledge sharing among hospital networks [47] • A workplace culture that is receptive to change [47] • Understand the policies made by the government [41]	• Frequent changes in the hospital management team [47] • Lack of medium- and long-term information technology policy planning [47]
Management support and communication (n_f=2; n_b=1)	• Presence of supervision at the workplace [42] • The availability of fair-to-good technical support [42] • Provision of support to groups with little knowledge of technology [47]	• Lack of planning and implementation of system design [47]
Shared goals and cooperation (n_f=2; n_b=1)	• The information technology department of the hospital is directly linked to local information technology sectors [47] • Create a multidisciplinary management committee [47] • Partnership with universities to develop DHTs [45]	• Health care providers' resistance to change practice [46]
Clinical leadership (n_f=1; n_b=1)	• High level of decision-making autonomy in the workplace [42]	• Weak leadership and poor commitment at the hospital level [45]
Systems and training (n_f=3; n_b=5)	• The workplace has sufficient facilities [37] • The availability of continuous on-the-job training [37,43,47] • Regular system upgrades [43] • The availability of prompt technical assistance from desk support [43]	• Lack of training in advanced technologies [36,40] • Delays in system development, implementation, and updates [43,47] • Frequent power blackouts [43] • Poor electrical power and backup facilities [36] • Lack of skill among health care providers in accessing and using DHTs [44]
Data and decision support (n_f=2; n_b=2)	• The availability of 24-hour technical support services at the workplace [37] • Centralization of system development and technical support [47]	• Lack of contingency plan for DHTs [47] • Delayed information technology support [43]
Staffing and incentives (n_f=3; n_b=3)	• Workplace has sufficient trained personnel in DHTs [37] • Improved financing of human and material resources [47] • Sufficient human resource allocation [41]	• Lack of incentives for health care providers to use DHTs [38] • High staff turnover rate, work overload, and reduced staffing [43,47] • Health care providers who are old aged [43]
Expectation of sustainability(n_f=0; n_b=3)	• N/A	• Health care providers do not have sufficient time and energy to participate and offer timely feedback while using DHTs [38,44] • Unrealistic expectations toward DHTs [47]
Characteristics of patients (n=4)		

XSL•FO
RenderX

Themes and categories	Codes for facilitators	Codes for barriers
Demographics (n_f=0; n_b=2)	• N/A	• Older patients contemplated using and have low confidence in DHTs [38] • Personal inertia and the conservative mentality of the older generation [38] • Costs of accessing the internet beyond affordability for patients from lower socioeconomic status [39] • Poor cellular network connectivity and internet access in some geographical areas [39]
Knowledge and beliefs (n_f=2; n_b=4)	• Confidence to learn, engage, and sustainably participate in DHTs [38] • High eHealth and computer literacy among patients [38,44] • High information-searching skills among patients [44]	• Patients have poor digital literacy and skills in DHTs [36,38,39] • Patients have skepticism about the accuracy of remote diagnosis [38] • Social prejudice against DHTs [38]

[a]DHT: digital health technology.

[b]n: number of studies in general.

[c]n_f: number of studies that reported on facilitators.

[d]n_b: number of studies that reported on barriers.

[e]N/A: not applicable.

Specifically, the theme of Aspects of the Health Care System included 23 facilitators and 13 barriers (n=11 studies). Among the prominent facilitators were the ability of DHTs to prevent cross-infection (n=2) and positive previous experiences using DHTs (n=2). By contrast, inadequate awareness regarding DHTs (n=2) and concerns regarding accuracy in disease diagnosis and treatment (n=2) were the leading barriers highlighted.

Regarding the theme of Perspectives of Patients, 9 facilitators and 3 barriers were reported (n=5 studies). Among these, the convenience and easiness of using DHTs (n=2) were noted as the primary facilitator. However, the feeling of distance between the patient and health care providers during remote interaction (n=1), the feeling of being forced to use DHTs (n=1), and patients' resistance to change practice could pose challenges to the implementation of DHTs in hospital settings within LMICs.

The successfulness of implementing DHTs also relies on the theme of External Environment (n=3 studies). Within this context, 2 facilitators are aiding the implementation, which include a good communication process between the regulatory authority and the hospitals (n=1) and good internet access among users of DHTs (n=1). Among the 2 barriers identified in this context, competition for resources between IT equipment and other health care equipment (n=2) stands out as the more prevalent barrier.

The theme of Implementation of Sustainable Infrastructure comprises 4 facilitators and 2 barriers (n=5 studies). Notably, familiarity with handling DHTs tools (n=1), the ease of conducting remote health service among clinicians (n=1), and experience sharing between advanced and beginner hospitals (n=1) emerge as facilitators for DHT implementation. Conversely, barriers in this theme include the communication gap between stakeholders (n=1) and the end of the COVID-19 pandemic reducing the demand for DHTs (n=1).

The Characteristics of Health Care Organization theme consists of 22 facilitators and 17 barriers to DHT implementation (n=11 studies). Previous studies have highlighted the availability of continuous on-the-job training (n=3) as the most frequent facilitator of DHT implementation in the health care organization. Conversely, barriers such as lack of trainings in advanced technologies (n=2); delays in system development, implementation, and updates (n=2); high staff turnover rate, work overload, and reduced staffing (n=2); as well as insufficient time and energy among health care providers to participate and offer timely feedback while using DHTs (n=2) prevent the implementation of DHTs.

The Characteristics of Patients was the final theme that could influence the successfulness of DHT implementation in LMICs' hospital settings. It comprised 3 facilitators and 7 barriers (n=4 studies). Notably, the most frequently mentioned facilitator in this theme is the high eHealth and computer literacy among patients (n=2). Not surprisingly, the exact opposite, that is, patients with poor digital literacy and skills in DHTs (n=3), is reported as the commonest barrier.

The relationship between codes, categories, and themes of facilitators and barriers to DHT implementation is summarized in Figure 2, in which the codes and categories are arranged from the most frequent (top) to the least frequent (bottom).

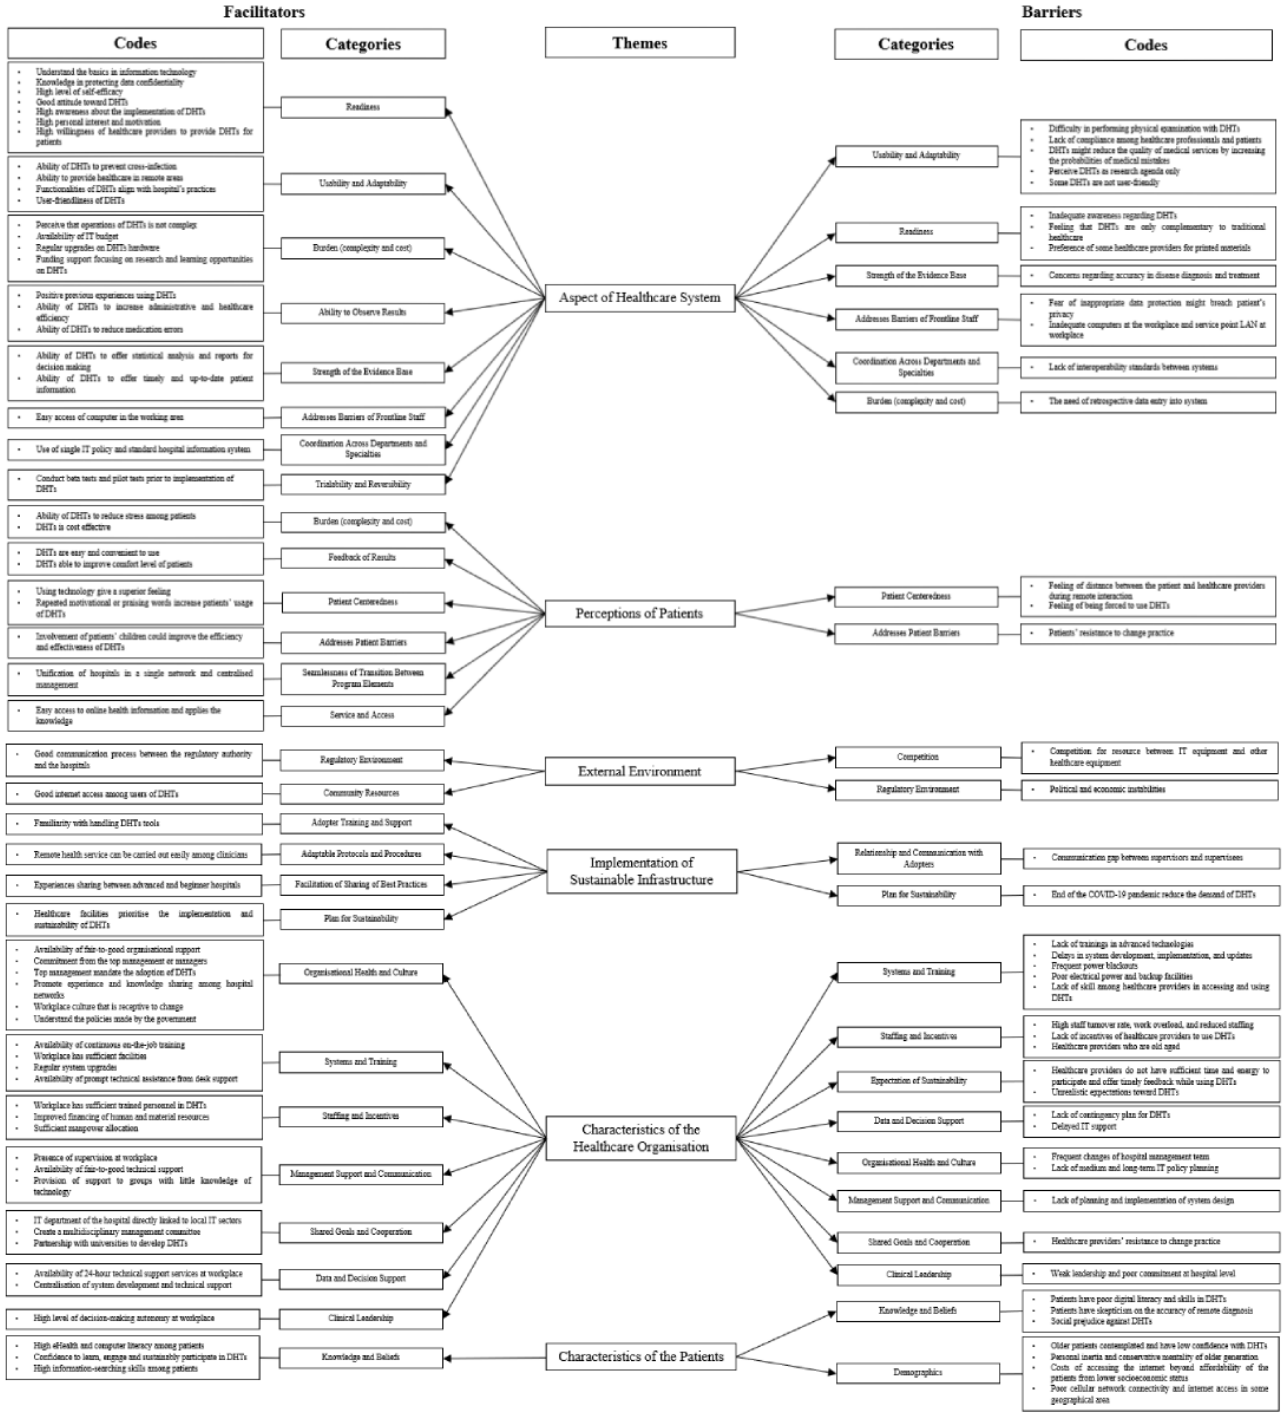

Figure 3 illustrates the network analysis of the facilitators of DHT implementation. Of note, facilitators such as "Perspectives of Patients" and "Aspect of the Health Care System" are central to the network. This suggests their broad impact across multiple domains, making them key intervention points for DHT implementation. Although no obvious clusters were observed, the interconnectedness suggests that addressing certain facilitators (eg, "Perspectives of Patients," "Aspect of the Health Care System," and "Characteristics of the Health Care Organization") can have ripple effects on others. Figure 4 illustrates the network analysis of the barriers to DHT

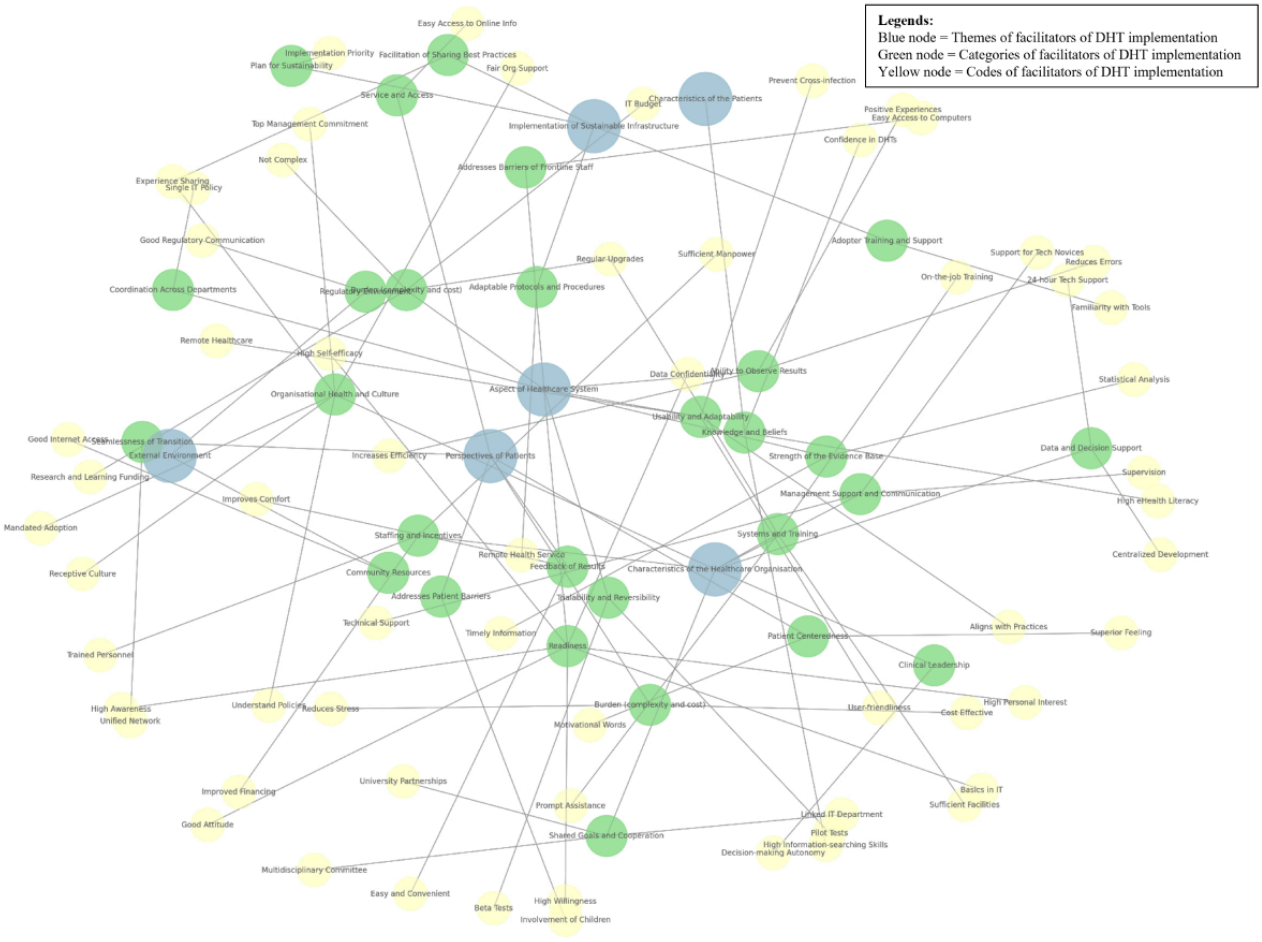
XSL•FO
RenderX

implementation. It was noted that some barriers are more central, such as the "Characteristics of Health Care Organizations," "Aspect of the Health Care System," "Implementation of Sustainable Infrastructure," and "Characteristics of Patients" barriers, highlighting their pivotal roles in the network. These central barriers act as key influencers and bridge multiple barriers. Meanwhile, the "External Environment" and "Perspectives of Patients" barriers are more toward the periphery and, hence, have less impact on the network. A cluster was observable in the network analysis, involving the "Characteristics of Health Care Organization" and "Aspect of the Health Care System" barriers. Many barriers are interconnected, which indicate that addressing one (eg, "Characteristics of Health Care Organizations") may alleviate others. However, it should be noted that some nodes, such as "Readiness" and "Usability and Adaptability," can be both facilitators of and barriers to DHT implementation, and hence, can appear in both network analyses.



Since the onset of the COVID-19 pandemic, the most commonly utilized DHTs in LMICs' hospitals were telemedicine, followed by health information systems, electronic medical records, and mHealth, as depicted in Figure 5.

Figure 2. Summary of the codes, categories, and themes of facilitators and barriers of digital health technology (DHT) implementation. IT: information technology; LAN: local area network.

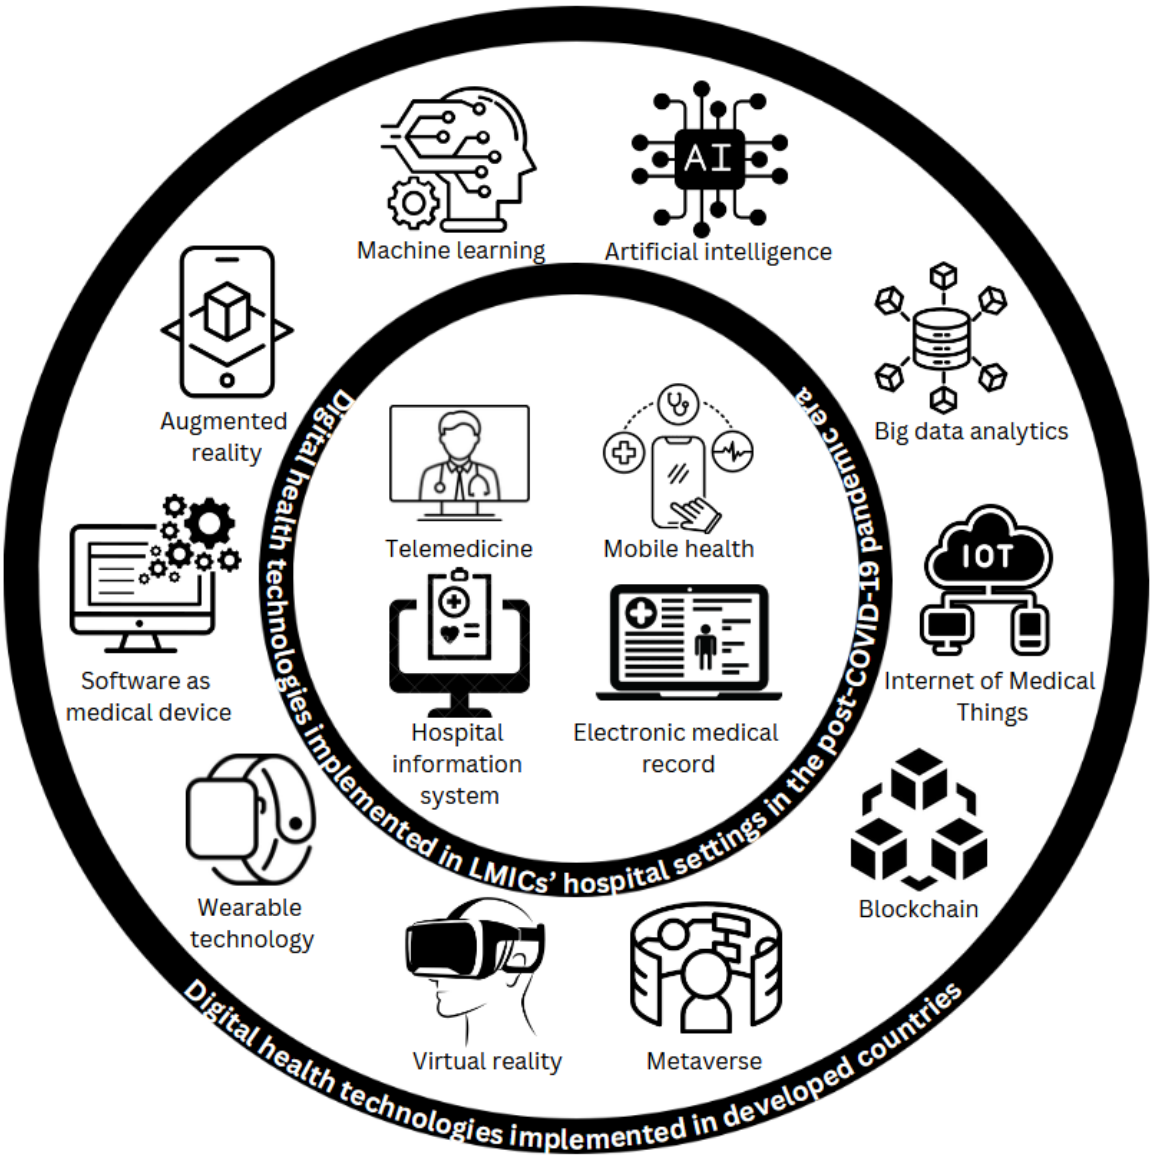
Discussion

Facilitators of and Barriers to DHT Implementation in LMICs

The most common facilitators of DHT implementation include the convenience and easiness of using DHTs, the ability of DHTs to prevent cross-infection, positive previous experiences using DHTs, the availability of continuous on-the-job training, and high eHealth and computer literacy among patients. By contrast, we identified that the most frequently reported barriers are inadequate awareness regarding DHTs; concerns regarding accuracy in disease diagnosis and treatment; competition for resources between IT equipment and other health care equipment; lack of trainings in advanced technologies; delays in system development, implementation, and updates; high staff turnover rate, work overload, and reduced staffing; insufficient time and energy among health care providers to use DHTs; and patients with poor digital literacy and skills in DHTs.

To our knowledge, this scoping review is the first to examine the facilitators and barriers to implementing DHTs in hospitals within LMICs since the onset of the COVID-19 pandemic. It is important to note the scarcity of published literature on this topic in LMICs. Even existing reviews often focused on studies from high-income countries or concentrated on specific diseases [27,48,49]. For example, a systematic review by Whitelaw et al [27], comprising 29 studies, investigated DHT implementation in cardiovascular diseases predominantly in high-income countries. As expected, the facilitators and barriers identified in this review significantly differed from our findings. Whitelaw et al highlighted facilitators such as enhanced communication with clinicians, personalized DHT components, user-friendly interfaces, institutional and organizational support, increased efficiency, and perceived usefulness of DHTs. The reported barriers were complex technology, technological apprehension, increased workload, unreliable technology, and lack of integration with electronic medical records. These discrepancies may stem from various factors such as differences in health care infrastructure [50], socioeconomic contexts [51], health care financing [52], as well as costs of DHT development and implementation [53] between high-income and LMIC settings. Additionally, the focus on specific diseases in previous literature might not fully capture the diverse facilitators and barriers relevant to DHT implementation across various health care contexts.

DHTs That Have Been Implemented



To our surprise, telemedicine was the most commonly reported technology implemented in hospital settings since the onset of the COVID-19 pandemic, exceeding other DHTs such as hospital information systems, electronic medical records, and mHealth. This can be understood by the fact that telemedicine is well-suited for health care providers and patients who are self-isolating, as it effectively reduces the risk of COVID-19 transmission. It eliminates the need for direct physical contact, ensures ongoing care for the community, and ultimately lowers the rates of illness and death during the COVID-19 pandemic [54].

Classification Framework for DHT Implementation in LMICs

Despite the emergence of various innovative technologies such as wearable technologies, metaverse, Internet of Medical Things, blockchain in health care, big data analytics, artificial intelligence, machine learning, software as medical devices, augmented reality, and virtual reality, the implementation of DHTs in hospitals within LMICs remains rudimentary compared with high-income countries. The current utilization of DHTs in LMICs, such as telemedicine, hospital information systems, electronic medical records, and mHealth, has informed the key components of a new classification framework that emphasizes LMICs. Based on recent literature [13,15,17-23,55] and the specific facilitators and barriers to utilizing these DHTs in LMICs, we propose a classification framework of DHTs, as illustrated in Figure 6.

XSL•FO
RenderX

Figure 6. Classification framework of digital health technologies (DHTs). LMIC: lower- and middle-income country.

This classification framework is justified by the fact that simpler DHTs, such as telemedicine, hospital information systems, electronic medical records, and mHealth, are easier to implement in LMICs due to lower costs and infrastructure requirements, adaptability to limited resources, and minimal training needs. These technologies rely mainly on basic internet connectivity, mobile devices, and computers, making them more accessible and feasible given the broader availability of mobile networks in LMICs. They also integrate easily into existing health care workflows, requiring only short training sessions and basic digital literacy. Furthermore, because LMICs prioritize addressing immediate health care needs such as infectious diseases, these accessible technologies receive more support and funding. By contrast, advanced technologies such as artificial intelligence, virtual reality, and blockchain demand specialized infrastructure, technical expertise, and substantial financial resources, which are often scarce in LMICs.

This proposed classification framework also consists of other DHTs that were implemented in high-income countries. This, hopefully, will aid health care stakeholders in LMICs to delineate the scope of DHTs in LMICs and help them to prioritize the right DHTs that could be implemented in the scarcity of resources. Consequently, policy makers can allocate health care funding (eg, the Ministry of Health can determine the DHT classes that are eligible for subsidies), and insurers can reimburse patients who utilized DHTs (ie, identifying which DHT classes can be covered by insurance policies) [56,57]. Moreover, clear and effective communication among the public, health care providers, and technology experts can be facilitated [57,58]. Legally, a defined classification framework enables authorities to regulate and govern DHT usage [58,59]. Finally, a clearly outlined classification framework for DHTs may streamline implementation, especially in resource-scarce environments, as stakeholders can prioritize which DHT classes should be implemented [56].

Strengths and Limitations

This scoping review possesses several notable strengths. Initially, we comprehensively gathered data from a diverse array of databases, including gray literature sources such as Google

XSL•FO
RenderX

Scholar. This deliberate choice was made to ensure the inclusivity and robustness of the studies included. Additionally, during the planning phase of the review, we actively engaged relevant stakeholders, including information technologists, seeking and incorporating their feedback into the review protocol. Furthermore, in structuring and categorizing the identified barriers and facilitators, we utilized a conceptual model developed by Feldstein and Glasgow [33], thereby enhancing the analytical rigor of the review. Moreover, our review offers a wealth of qualitative and quantitative insights into the implementation of DHTs, providing comprehensive guidance for stakeholders interested in implementing DHTs within their respective settings.

Despite its strengths, our review does have certain limitations. Specifically, in focusing on identifying barriers and facilitators of DHT implementation in hospital settings within LMICs, we restricted our inclusion criteria to studies conducted solely within hospitals. Consequently, many studies providing insights from primary care and community perspectives were excluded. Additionally, studies that did not explicitly address facilitators and barriers were omitted, potentially overlooking valuable information on other beneficial DHTs for patient care. Furthermore, as our primary aim was to offer an overview of existing literature on DHTs, we did not apply any quality control measures to the included studies. The variation in analytical methods, interview questions, and study populations across the included papers presents a potential inconsistency in the findings and makes quality assessment difficult. Additionally, with 128 LMICs at the time of the literature search, listing each country by name in the search string was impractical, which could result in some LMICs not being captured in the search results.

Implications and Recommendations

Understanding the facilitators and barriers to DHTs in hospital settings of LMICs has profound implications for both clinical practice and research. Identifying facilitators of DHT implementation enables the effective integration of DHTs in hospitals, leading to improved diagnostic accuracy, better patient monitoring, improved patient records management, and the availability of remote health care services. Conversely, recognizing the barriers to DHT implementation can prompt various stakeholders in LMICs to devise strategies that address issues in terms of financial resources, technological infrastructure, and knowledge among health care providers. In terms of research, this review is hoped to promote international collaborations, governmental support, and investment in digital infrastructure, which in turn boost the capacity for data collection, analysis, and sharing. These advancements can enhance research capabilities, allowing for more comprehensive epidemiological studies, real-time disease monitoring, and the development of context-specific health interventions.

To maximize the benefits of DHTs in hospital settings in LMICs, several recommendations can be made to leverage facilitators and mitigate barriers. First, the convenience and ease of using DHTs should be emphasized through user-friendly interfaces and intuitive designs, ensuring that health care providers can quickly and efficiently adopt these technologies in their daily routines. Second, the role of DHTs in preventing cross-infection should be highlighted in training programs and awareness campaigns, particularly in regions where infectious diseases are prevalent. Positive previous experiences with DHTs should be shared widely to build trust and demonstrate the tangible benefits of these technologies. Continuous on-the-job training must be provided to keep health care workers up-to-date with the latest advancements and best practices, while also enhancing their technical proficiency. Promoting high eHealth and computer literacy among patients through community outreach and education programs will further support the effective use of DHTs.

Addressing barriers requires a multifaceted approach. To tackle inadequate awareness and concerns regarding the accuracy of DHTs, it is crucial to implement comprehensive educational initiatives that highlight the reliability and clinical efficacy of these technologies. Clear, evidence-based information should be disseminated to health care providers and patients to build confidence in DHTs. Competition for resources between IT equipment and other health care tools can be mitigated by advocating for balanced budget allocations and seeking external funding or partnerships to supplement resources. Training programs in advanced technologies must be expanded to equip health care providers with the necessary skills to use DHTs effectively. To address delays in system development and implementation, streamlined processes and timelines should be established, with dedicated project management teams overseeing these initiatives. High staff turnover rates and work overload can be managed by improving working conditions, offering competitive salaries, and providing career development opportunities. Finally, enhancing digital literacy among patients through targeted educational programs will ensure that they can engage with DHTs effectively, ultimately leading to better health outcomes. By implementing these recommendations, LMICs can overcome barriers and fully harness the potential of DHTs to improve clinical practice and advance health care research.

Conclusions

The scoping review on DHT implementation in LMICs since the onset of the COVID-19 pandemic underscores significant policy, clinical, and research implications. Policy makers can utilize the insights to craft targeted strategies for DHT adoption, while the developed classification framework aids in prioritizing DHTs. In clinical settings, understanding DHT types, facilitators, and barriers enhances decision-making for improved patient care and resource optimization. Additionally, investing in capacity building and training programs for health care professionals is crucial, with a focus on enhancing digital literacy and technical skills. Moreover, identifying research priorities and aligning funding with key challenges such as improving digital literacy and addressing concerns about DHT accuracy will drive advancements in DHT implementation and health care delivery in LMICs.

In the postpandemic era, telemedicine has been widely used in hospital settings in LMICs, among other DHTs. Our findings also reveal numerous facilitators and barriers to DHT implementation in LMIC hospital settings. These factors can be organized into 6 themes, namely, (1) Aspects of the Health Care System; (2) Perspectives of Patients; (3) External

XSL•FO
RenderX

Environment; (4) Implementation of Sustainable Infrastructure; (5) Characteristics of Health Care Organization; and (6) Characteristics of Patients.

Acknowledgments

We acknowledge the contributions of the information technologist at the library of Universiti Putra Malaysia for the provision of technical and intellectual assistance during the literature search.

Data Availability

All data retrieved and analyzed are included in this scoping review.

Authors' Contributions

SQY and BHC developed the concept for the scoping review. SQY and DT were involved in designing the research methodology. NIHA and SQY carried out an extensive literature review to identify relevant frameworks and methodological approaches for the scoping review. SQY prepared the initial draft of the review.

Abstract

Background: Tuberculosis (TB) remains a significant health concern, contributing to the highest mortality among infectious diseases worldwide. However, none of the various TB diagnostic tools introduced is deemed sufficient on its own for the diagnostic pathway, so various artificial intelligence (AI)–based methods have been developed to address this issue.

Objective: We aimed to provide a comprehensive evaluation of AI-based algorithms for TB detection across various data modalities.

Methods: Following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analysis) 2020 guidelines, we conducted a systematic review to synthesize current knowledge on this topic. Our search across 3 major databases (Scopus, PubMed, Association for Computing Machinery [ACM] Digital Library) yielded 1146 records, of which we included 152 (13.3%) studies in our analysis. QUADAS-2 (Quality Assessment of Diagnostic Accuracy Studies version 2) was performed for the risk-of-bias assessment of all included studies.

Results: Radiographic biomarkers (n=129, 84.9%) and deep learning (DL; n=122, 80.3%) approaches were predominantly used, with convolutional neural networks (CNNs) using Visual Geometry Group (VGG)-16 (n=37, 24.3%), ResNet-50 (n=33, 21.7%), and DenseNet-121 (n=19, 12.5%) architectures being the most common DL approach. The majority of studies focused on model development (n=143, 94.1%) and used a single modality approach (n=141, 92.8%). AI methods demonstrated good performance in all studies: mean accuracy=91.93% (SD 8.10%, 95% CI 90.52%-93.33%; median 93.59%, IQR 88.33%-98.32%), mean area under the curve (AUC)=93.48% (SD 7.51%, 95% CI 91.90%-95.06%; median 95.28%, IQR 91%-99%), mean sensitivity=92.77% (SD 7.48%, 95% CI 91.38%-94.15%; median 94.05% IQR 89%-98.87%), and mean specificity=92.39% (SD 9.4%, 95% CI 90.30%-94.49%; median 95.38%, IQR 89.42%-99.19%). AI performance across different biomarker types showed mean accuracies of 92.45% (SD 7.83%), 89.03% (SD 8.49%), and 84.21% (SD 0%); mean AUCs of 94.47% (SD 7.32%), 88.45% (SD 8.33%), and 88.61% (SD 5.9%); mean sensitivities of 93.8% (SD 6.27%), 88.41% (SD 10.24%), and 93% (SD 0%); and

XSL•FO
RenderX

mean specificities of 94.2% (SD 6.63%), 85.89% (SD 14.66%), and 95% (SD 0%) for radiographic, molecular/biochemical, and physiological types, respectively. AI performance across various reference standards showed mean accuracies of 91.44% (SD 7.3%), 93.16% (SD 6.44%), and 88.98% (SD 9.77%); mean AUCs of 90.95% (SD 7.58%), 94.89% (SD 5.18%), and 92.61% (SD 6.01%); mean sensitivities of 91.76% (SD 7.02%), 93.73% (SD 6.67%), and 91.34% (SD 7.71%); and mean specificities of 86.56% (SD 12.8%), 93.69% (SD 8.45%), and 92.7% (SD 6.54%) for bacteriological, human reader, and combined reference standards, respectively. The transfer learning (TL) approach showed increasing popularity (n=89, 58.6%). Notably, only 1 (0.7%) study conducted domain-shift analysis for TB detection.

Conclusions: Findings from this review underscore the considerable promise of AI-based methods in the realm of TB detection. Future research endeavors should prioritize conducting domain-shift analyses to better simulate real-world scenarios in TB detection.

Introduction

Tuberculosis (TB) stood as the dominant infectious disease threat worldwide, affecting over 10.5 million individuals and claiming the lives of 1.3 million people in 2022 [1]. A pivotal strategy in halting this worldwide epidemic revolves around breaking the transmission chain by identifying and treating all individuals with infectious forms of TB [2]. Various diagnostic tools have been introduced, including chest radiography, tuberculin skin tests, interferon-gamma release assays, sputum smear microscopy, sputum mycobacterial culture, and an array of nucleic acid amplification tests [3]. Nonetheless, each of these diagnostic modalities faces significant implementation challenges, and none alone is deemed adequate for the diagnostic pathway. Consequently, researchers have endeavored to integrate artificial intelligence (AI)–based algorithms to augment the detection of TB.

AI encompasses a spectrum of techniques enabling computer programs to tackle intricate problems by emulating human cognitive processes [4]. Presently, 2 widely used terms denote AI techniques that necessitate minimal-to-no human intervention: machine learning (ML) and deep learning (DL). ML possesses the capability to discern meaningful patterns within datasets autonomously, without explicit programming [5]. Conversely, DL emerges as a subdomain within ML, leveraging deep and intricate neural networks to extract features or patterns from datasets for subsequent analysis [5,6].

In this study, we aimed to comprehensively evaluate the performance of AI-based algorithms, particularly ML and DL, for TB detection. This aligns closely with the first pillar of the World Health Organization (WHO) End TB Strategy, which includes systematic screening for TB in high-risk groups [7]. In fact, a novel recommendation was issued by WHO in 2021: the approval of AI tools to analyze chest X-rays (CXRs) for TB detection in place of human readers [8].

Several notable review papers have emerged. Jimmy et al [9] conducted a meticulous systematic review, delving into various DL methods for TB detection based on CXR. Similarly, Sharma et al [10] contributed a narrative survey spotlighting DL-based convolutional neural networks (CNNs) tailored for TB diagnosis from CXR. Zeyu et al [11] embarked on a narrative review aimed at dissecting diverse DL-based approaches for TB diagnosis. Oloko-Oba and Viriri [12] scrutinized DL techniques for TB detection via chest radiographs. Santosh et al [13] conducted a systematic review, albeit with a narrower time frame spanning 5 years (2016-2021), focusing on DL for TB screening using CXR. Carvalho et al [14] contributed a systematic review on DL techniques used for classifying TB bacilli in microscopic Ziehl-Neelsen (ZN) sputum smear images. Da Silva Barros et al [15] conducted a systematic review on ML models geared toward predicting TB treatment outcomes. Distinguished from these endeavors, our current review took a broader perspective, encompassing not only DL but also ML as integral components of AI-based methods for TB detection.

Siddiqui and Garg [16] examined recent studies of intelligent techniques (ML and DL) for diagnosing pulmonary TB. Singh et al [17] scrutinized the drawbacks of conventional TB diagnostics, while exploring the utility of ML and DL methods for TB diagnosis. Additionally, they highlighted several commercial computer-aided detection (CAD) tools as promising AI-driven instruments. Notably, both reviews were reported as narrative reviews, rather than using the systematic review methodology we adopted here.

Harris et al [18] meticulously conducted a systematic review focusing on the diagnostic accuracy of AI-based tools in TB detection using CXR. Hansun et al [19] recently published a systematic review examining the effectiveness of ML and DL methods for TB detection using CXR. Both studies aligned closely with our review but were limited to CXR. In contrast, our review encompassed a broader spectrum of diagnostic data, including radiographic, biochemical, physiological, and other clinical data. This broader scope enabled a more comprehensive evaluation of AI-based methods across diverse data modalities for TB detection.

Methods

Design, Registration, and Information Sources

In conducting this systematic review, we adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Multimedia Appendix 1) [20]. Our review protocol, in accordance with the PRISMA-Protocol 2015 statement [21,22], was registered on PROSPERO (Prospective Register of Systematic Reviews; ID CRD42023453611) [23,24].

The systematic review drew upon 3 primary academic search systems and online databases: Scopus, PubMed, and the Association for Computing Machinery (ACM) Digital Library. These platforms are widely recognized as pivotal sources for comprehensive literature reviews [25]. The searches encompassed all published literature up to July 25, 2023.

Ethical Considerations

As this systematic literature review focused on retrospective studies, no ethical approval was required.

Search Strategy

For our search strategy, we used 3 primary keywords: "artificial intelligence," "tuberculosis," and "detect*." Additionally, we incorporated several alternative terms for each main keyword to ensure comprehensive coverage during the search process, resulting in the findings outlined in Table 1. Initially, we identified a total of 1146 records; however, certain records were not available from the respective databases (n=58, 5.1%). The full search queries can be seen in Multimedia Appendix 2.

Table 1. Sample search queries and results.

Search query	Scopus, n/N (%)	PubMed, n/N (%)	ACM[a], n/N (%)
(TITLE-ABS-KEY ("Machine Learning" OR "Predictive Analytics" OR "Statistical Learning" OR "Deep Learning" OR "Artificial Intelligence" OR "AI") AND TITLE-ABS-KEY ("Tuberculosis" OR "TB") AND TITLE-ABS-KEY ("Early detection" OR "detect*" OR "Early diagnosis" OR "diagnosis")) AND DOCTYPE (ar OR cp) AND (LIMIT-TO (LANGUAGE , "English")) AND (LIMIT-TO (SRCTYPE , "j") OR LIMIT-TO (SRCTYPE , "p"))	857/1146 (74.8)	284/1146 (24.8)	5/1146 (0.4)
Not available for download (n=58)	53/58 (91.4)	5/58 (8.6)	0
Available for download (n=1088)	804/1088 (73.9)	279/1088 (25.6)	5/1088 (0.5)

[a]ACM: Association for Computing Machinery.

Inclusion and Exclusion Criteria, Data Extraction, and Storage

All downloaded records underwent scrutiny against the inclusion and exclusion criteria outlined for this review study. There were 4 criteria that all included studies had to meet: (1) full-text papers reporting original data published in peer-reviewed journals or proceedings, (2) cross-sectional diagnostic test evaluations, (3) papers focused on TB detection using AI, and (4) papers written in English.

The information extracted from each included study comprised the title, authors, publication year, journal title, objectives, and outcome measures. Dataset characteristics, including their source and total number of data items, were documented, along with details regarding the modality and type of data used. The AI methods applied, evaluation techniques used, performance metrics, best results obtained, and any comparisons with other studies were recorded. Additionally, outcome types, citation counts, and information regarding sponsors or funding sources, were also gathered as part of the comprehensive extraction process.

Each review author was actively engaged in the conceptualization and execution of all phases outlined in the PRISMA 2020 guidelines. At least 2 review authors were involved in each phase, including identification, screening, and assessment of eligibility for inclusion. To ensure accuracy and transparency, we documented the results of each phase using a standardized spreadsheet.

Outcomes Assessed

The first outcome from this review was the compilation of diverse AI methods used for TB detection. The second outcome encompassed diagnostic performance exhibited by various AI methods in TB detection. This summary encompassed key metrics, such as accuracy, area under the receiver operating characteristic (ROC) curve (AUROC), sensitivity, and specificity, providing valuable insights into the efficacy and reliability of these methods in clinical practice.

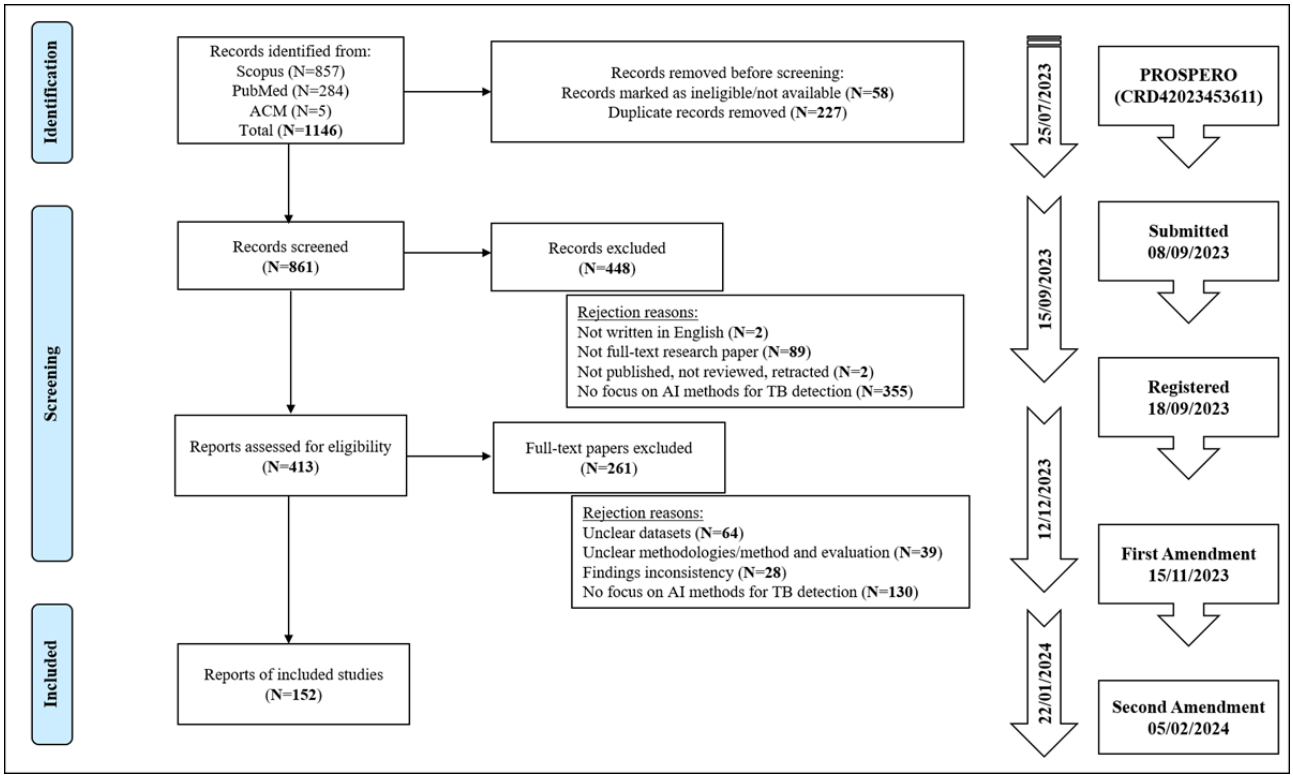
Strategy for Data Analysis and Synthesis

We adopted a narrative synthesis approach, integrating information extracted from the included studies within the text. The narrative synthesis method facilitated an in-depth exploration of the relationships and insights both within and across included studies, stratified by various attributes, such as modality, biomarker types, and AI methods. Descriptive statistics, primarily using box-whisker and violin plots, alongside tables and figures, presented the quantitative outcomes of this systematic review. Given the pronounced heterogeneity observed in study designs, comparators, biomarker types, evaluation techniques, and AI methods encompassed in this review study, a meta-analysis was deemed impractical.

Risk-of-Bias Assessment

In assessing the risk of bias within the included studies, we used the QUADAS-2 (Quality Assessment of Diagnostic Accuracy Studies version 2) tool. This tool is widely recommended for systematic reviews as it enables the evaluation of bias and applicability in diagnostic accuracy studies [26]. It comprises

XSL•FO
RenderX



4 key domains: (1) patient selection, (2) index test, (3) reference standard, and (4) flow and timing. To tailor the assessment to the specific focus of this review on evaluating AI-based methods' performance in TB detection, adjustments were made to the questions in the QUADAS-2 tool. Two review authors (SH and AW) assessed each included study, and a third opinion was sought from the author AA or the author GBM in the case of disagreements.

Results

Overview

Figure 1 delineates all the processes conducted throughout the systematic review. We adhered to the PRISMA 2020 flowchart, including the incorporation of a process timeline and the inclusion of a registered protocol status in PROSPERO.

Figure 1. PRISMA 2020 flowchart with timeline and PROSPERO information. ACM: Association for Computing Machinery; AI: artificial intelligence; PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analysis; TB: tuberculosis.

Of the 1146 records initially identified from Scopus (n=857, 74.8%), PubMed (n=284, 24.8%), and ACM Digital Library (n=5, 0.4%), 58 (5.1%) were found to be unavailable. Upon checking and removing duplicates (n=227, 20.9%), we were left with 861 (79.1%) unique titles to be passed to the screening phase. Subsequently, titles, abstracts, and keywords underwent examination based on 4 primary selection criteria, where 413 (48%) records remained for eligibility assessment.

All 413 records underwent thorough assessment by examining their full-text content. From this pool, 261 (63.2%) papers were excluded, leaving us with a total of 152 (36.8%) papers being included as part of this systematic review. Subsequently, the data extraction process was carried out for all included studies.

The entirety of the review process spanned approximately 6 months (July 2023-January 2024).

General Characteristics of Included Studies

A summary of the general characteristics of the 152 studies included in this systematic review is included in Tables 2 and 3. The majority of the included studies opted for a single modality (n=141, 92.8%), with a smaller subset using a multimodal approach (n=11, 7.2%). Among the various data types used, radiographic data emerged as the most prevalent data type (n=129, 84.9%), followed by biochemical (n=21, 13.8%) and physiological (n=16, 10.5%) data types. Several studies using a multimodal approach integrated more than 1 data type, such as a combination of radiographic and physiological data types.

[a]AI: artificial intelligence.

[b]ML: machine learning.

[c]DL: deep learning.

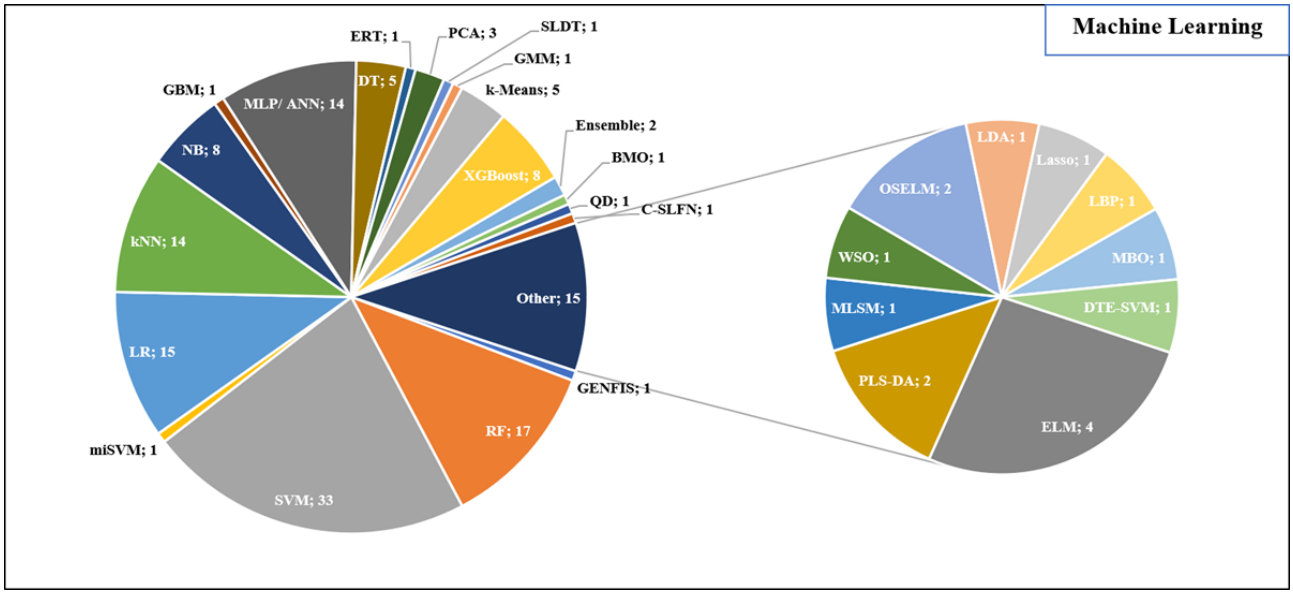
In terms of evaluation techniques, the majority of studies (n=95, 62.5%) used the holdout evaluation technique, which involves dividing the entire dataset into training and test sets. In total, 48 (31.6%) studies used the k-fold cross-validation (CV) technique, dividing the dataset into k partitions and conducting the evaluation k times. Only 9 (5.9%) studies incorporated external datasets during the evaluation phase. Of the 152 included studies, 143 (94.1%) focused on AI model development, while 8 (5.3%) studies concentrated on application or prototype creation, and 1 (0.7%) study examined the clinical evaluation of AI-based CAD tools.

Regarding the AI approaches, a large number of studies (n=122, 80.3%) used various DL methods, while 49 (32.2%) studies used ML methods. We also collected information regarding various reference standards used in the included studies. We classified them into 2 groups, namely the human reader and bacteriological standards. Of the 152 included studies, 103 (67.8%) used human reader reference standards, 43 (28.3%) used bacteriological reference standards, and 24 (15.8%) did not report any reference standard. Similar to the data-types group, both AI-type and reference standard groups were not mutually exclusive.

XSL•FO
RenderX

In addition, 89 (58.6%) studies used the TL approach, a relatively recent and validated strategy for addressing domain-specific challenges [27], especially prevalent in studies using DL methods. Moreover, 68 (44.7%) studies conducted comparisons with multiple prior studies. Notably, an equal proportion of studies received funding or sponsorship from various entities (n=78, 51.3%) compared to those that did not receive any funding (n=74, 48.7%). All included studies were published between 2011 and 2023.

A total of 141 distinct data sources were identified across the included studies, comprising 2,072,457 records. Among these, the most frequently used data sources were Shenzhen (SZ; n=51, 36.2%), Montgomery County (MC; n=46, 32.6%), Kaggle TB CXR (n=6, 4.3%), and TBX11K (n=5, 3.5%), all of which provided radiographic data. MC and SZ were the predominant data sources, both publicly available CXR datasets from the US National Library of Medicine. MC contains 138 images, while SZ offers 662 images [28]. The Kaggle TB CXR dataset contains 7000 images, although only 4200 (60%) are publicly accessible [29]. Conversely, TBX11K, introduced in 2020, stands out as a newer and more extensive CXR dataset for TB-related research, featuring a total of 11,200 images [30]. For further insights into the extracted data from all included studies, detailed information is available in Multimedia Appendix 3.



AI Techniques for TB Detection

Among the 152 included studies, the majority were published within the past 8 years, with only 3 (2%) studies predating 2016 [31-33]. As of January 18, 2024, these studies collectively garnered 6070 citations on Google Scholar. Remarkably, the top 3 (2%) cited publications were identified as Lakhani and Sundaram [34] with 1695 citations, Pasa et al [35] with 312 citations, and Lopes and Valiati [36] with 260 citations. This underscored the burgeoning interest among researchers in integrating AI-based methods into TB detection studies.

The included studies implemented various AI-based algorithms, which could be broadly categorized into 2 major approaches: ML and DL. Specifically, 102 (67.1%) studies used DL methods [30,34,35,37-135], while 30 (19.7%) studies used ML techniques [31-33,136-162]. Additionally, 19 (12.5%) studies used a combination of both ML and DL approaches [36,163-180]. Furthermore, 1 (0.7%) study [181] focused on the implementation of a DL-based CAD tool, namely Lunit INSIGHT v4.7.2, specifically designed for systematic TB screening in a low-prevalence setting.

Figure 2 illustrates the diverse array of ML methods used in the included studies. Notably, support vector machines (SVMs; n=33, 21.7%), random forests (RFs; n=17, 11.2%), and logistic regression (LR; n=15, 9.9%) emerged as the 3 most prevalent ML techniques.

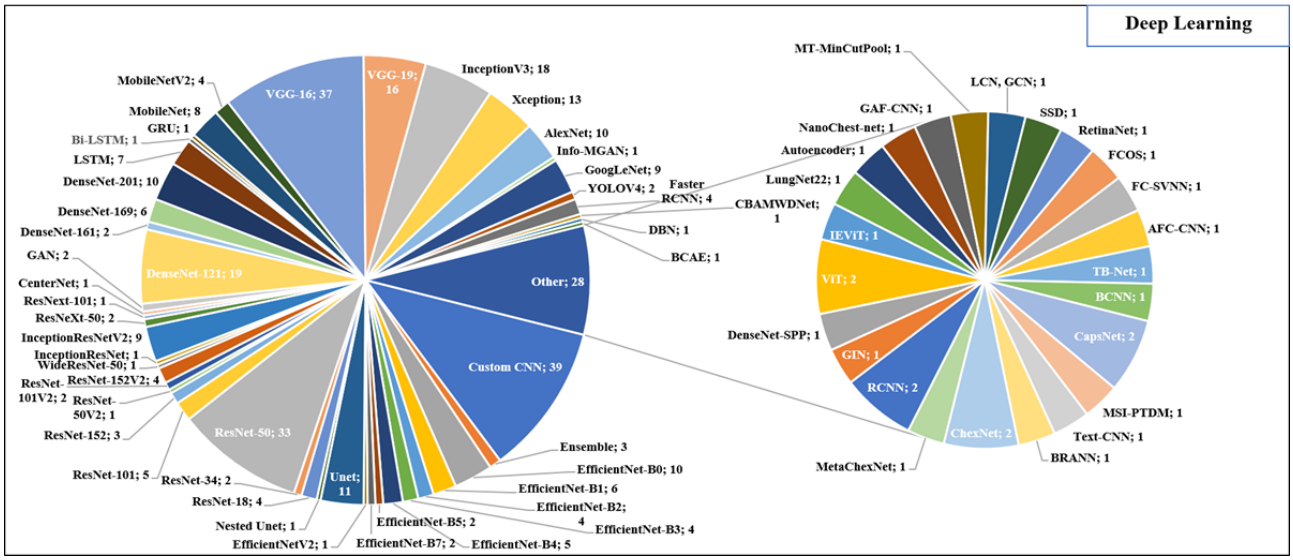


Figure 2. Different ML methods identified from the included studies. ANN: artificial neural network; BMO: bird mating optimizer; DT: decision tree; DTE-SVM: deep transferred EfficientNet with support vector machine; ELM: extreme learning machine; ERT: extremely randomized tree; GBM: Generalized Boosting Machine; GENFIS: genetic-neuro-fuzzy inferential system; GMM: Gaussian mixture model; kNN: k nearest neighbor; Lasso: least absolute shrinkage and selection operator; LBP: local binary pattern; LDA: linear discriminant analysis; LR: logistic regression; MBO: monarch butterfly optimization; ML: machine learning; MLP: multilayer perceptron; MLSM: multilevel similarity measure; NB: naïve Bayes; OSELM: online sequential extreme learning machine. PLS-DA: partial least squares–discriminant analysis; PCA: principal component analysis; QD: quadratic discriminant; RF: random forest; SLDT: stacked loopy decision tree; SLFN: single hidden layer feedforward neural network; SVM: support vector machine; WSO: water strider optimization; XGBoost: extreme gradient boosting.

CNNs were the predominant DL method among the included studies. Alongside custom CNNs (n=39, 25.7%), many researchers have leveraged established DL architectures, notably including Visual Geometry Group (VGG)-16 (n=37, 24.3%), ResNet-50 (n=33, 21.7%), and DenseNet-121 (n=19, 12.5%). Figure 3 provides an overview of the various DL methods identified in the included studies.

Figure 3. DL methods identified from the included studies. AFC-CNN: adaptive fractional crow convolutional neural network; BCNN: Bayesian-based convolutional neural network; bi-LSTM: bidirectional long short-term memory; BRANN: Bayesian regularization artificial neural network; CBAM: convolutional block attention module; CNN: convolutional neural network; DenseNet-SPP: DenseNet with spatial pyramid pooling; DL: deep learning; FC-SVNN: fractional crow search–based deep convolutional neural network; FCOS: fully convolutional one stage; GAF-CNN: Gramian angular field convolutional neural network; GAN: generative adversarial network; GCN: global complex network; GIN: graph isomorphism network; GRU: gated recurrent unit; IEViT: image enhanced vision transformer; LCN: local complex network; LSTM: long short-term memory; MSI-PTDM: multistream integration–pulmonary tuberculosis diagnosis model; MT-MinCutPool: multivariate time series with MinCutPool; RCNN: region-based convolutional neural network; SSD: single-shot multibox detector; VGG: Visual Geometry Group; ViT: vision transformer; YOLO: you only look once.

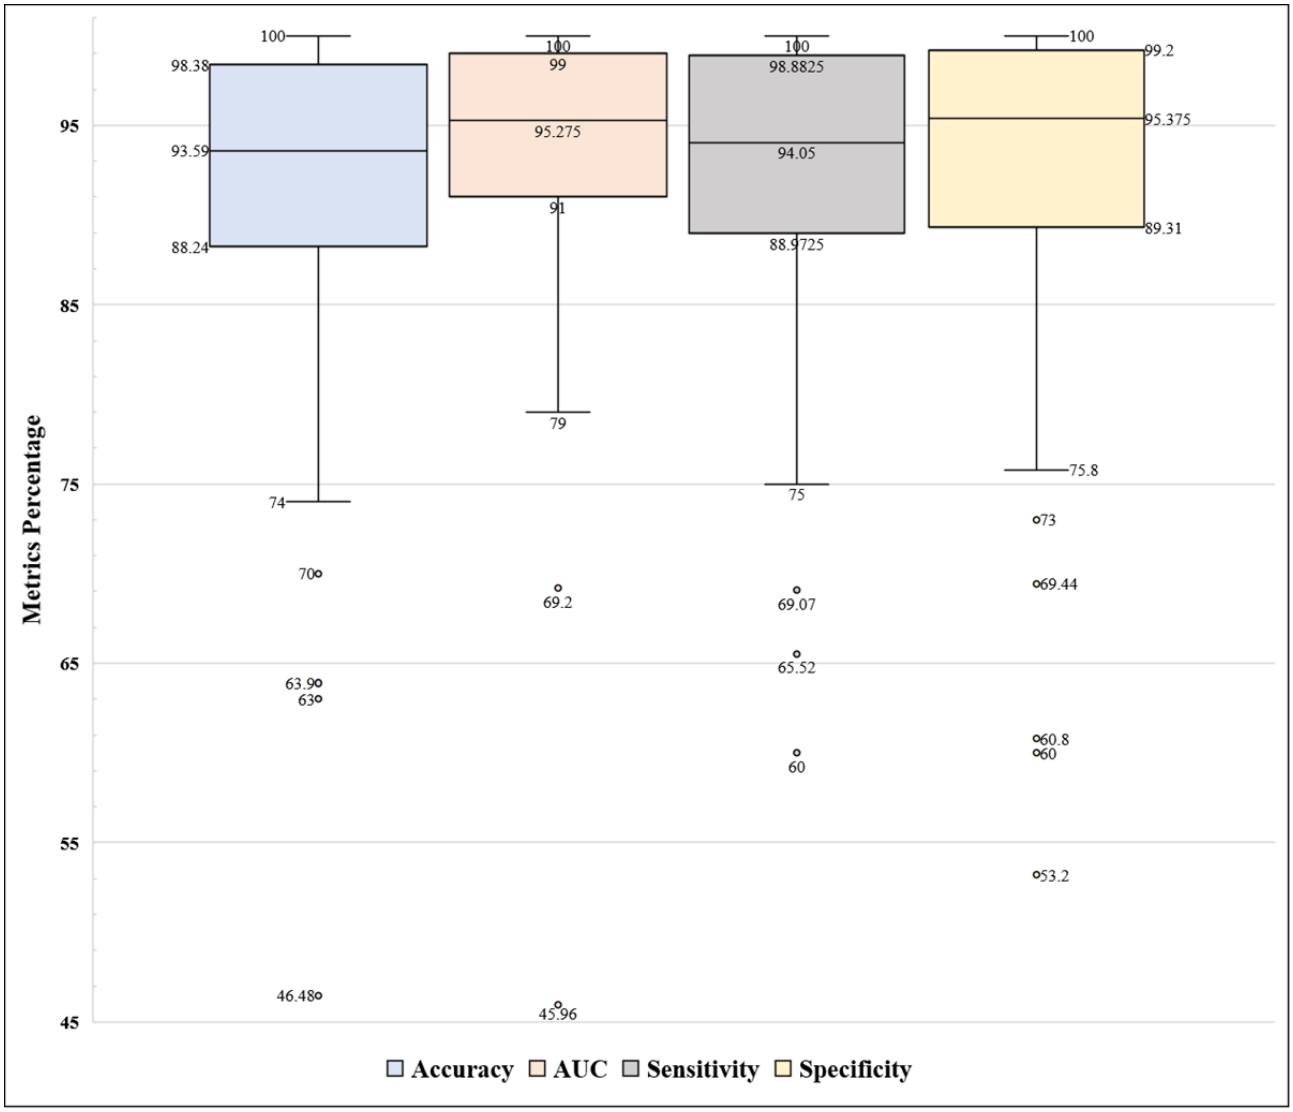
Regarding the diagnostic performance of AI methods used in the literature, the most frequently used evaluation metrics encompassed accuracy (n=128, 84.2%), sensitivity (n=112, 73.7%), the AUC (n=87, 57.2%), and specificity (n=77, 50.7%). Accuracy denotes the proportion of correctly predicted cases, encompassing true positives and true negatives among all cases [182]. Sensitivity measures a model's ability to accurately identify individuals with a condition [183,184]. The AUC, derived from the ROC curve, quantitatively assesses a model's performance [182]. Specificity gauges a model's accuracy in identifying individuals without a condition [183,184]. Table 4 presents the distribution of various performance metrics identified in the included studies. For an in-depth exploration of the performance metrics used across the included studies, refer to the detailed description provided in Multimedia Appendix 4.

XSL•FO
RenderX

Table 4. Different performance evaluation metrics in the included studies (N=152).

Metric	Studies, n (%)
Accuracy	128 (84.2)
AUROC[a]	87 (57.2)
Sensitivity/recall/true-positive rate	112 (73.7)
Specificity/true-negative rate	77 (50.7)
Precision/positive predictive value	56 (36.8)
Negative predictive value	9 (5.9)
F_1-score	55 (36.2)
Average recall	1 (0.7)
Mean average precision	2 (1.3)
Matthews correlation coefficient	7 (4.6)
True detection rate	1 (0.7)
Area under the alternative free-response ROC[b] curve	1 (0.7)
Error loss	1 (0.7)
Cohen kappa	3 (2.0)
Root mean square error	2 (1.3)
False positive rate	4 (2.6)
False negative rate	1 (0.7)
Squared error	1 (0.7)
Balanced accuracy	1 (0.7)
Fowlkes-Mallows index	1 (0.7)

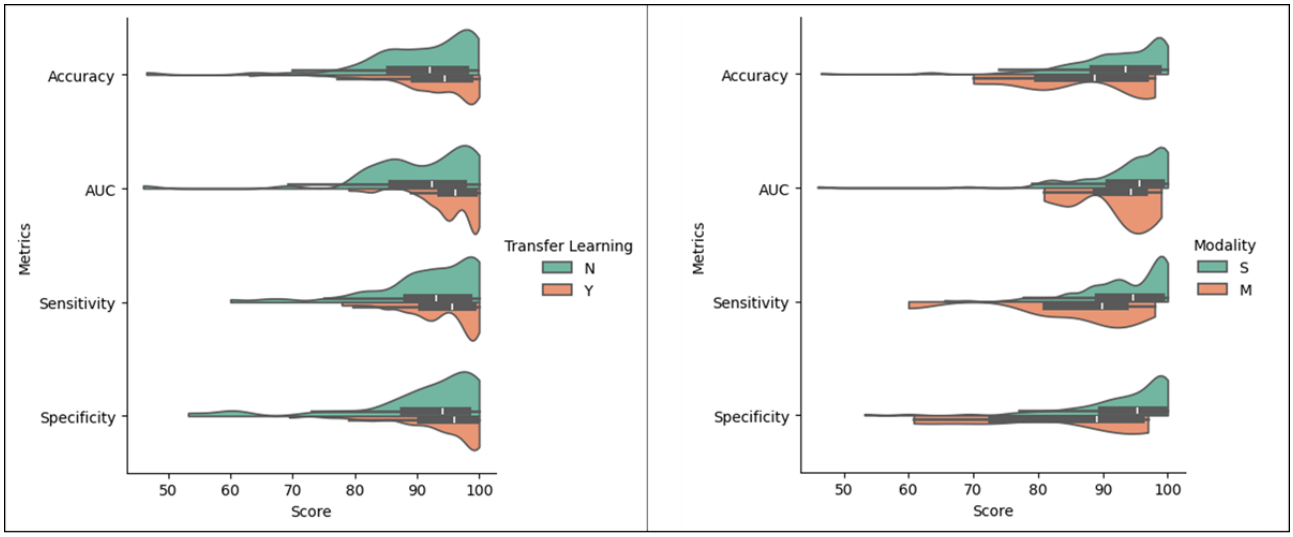
[a]AUROC: area under the receiver operating characteristic curve.



[b]ROC: receiver operating characteristic.

AI Diagnostic Performance

Figure 4 provides a comprehensive overview of the overall performance results across all included studies. From the depicted box plot, it is evident that accuracy ranged from 46.48% [59] to 100% [118], with a mean value of 91.93% (SD 8.10%, 95% CI 90.52%-93.33%) and a median of 93.59% (IQR 88.33%-98.32%). Similarly, the AUC ranged from 45.96% [59] to 100% [72,78,96,178], with a mean value of 93.48% (SD 7.51%, 95% CI 91.90%-95.06%) and a median of 95.28% (IQR 91%-99%). Sensitivity spanned from 60% [156] to 100% [85,92,100,118,128,132,141,146,163,178,181], with a mean value of 92.77% (SD 7.48%, 95% CI 91.38%-94.15%) and a median of 94.05% (IQR 89%-98.87%). Meanwhile, specificity ranged from 53.2% [129] to 100% [113,162,174,177], with a mean value of 92.39% (SD 9.4%, 95% CI 90.30%-94.49%) and a median of 95.38% (IQR 89.42%-99.19%). Several outliers were detected for each metric, including 4 for accuracy, at 46.48% [59], 63% [126], 63.9% [129], and 70% [156]; 2 for the AUC, at 45.96% [59] and 69.2% [129]; 3 for sensitivity, at 60% [156], 65.52% [155], and 69.07% [143]; and 5 for specificity, at 53.2% [129], 60% [146], 60.8% [168], 69.44% [67], and 73% [152].



XSL•FO
RenderX

Figure 4. Overall accuracy, AUC, sensitivity, and specificity of the included studies. AUC: area under the curve.

We conducted further performance comparisons based on several criteria, including whether a study used the TL method and whether it adopted a single (S) or multimodal (M) approach. Figure 5 presents split-grouped violin plots illustrating the comparative performance results of the included studies based on TL (yes [Y], no [N]) and the modality used.

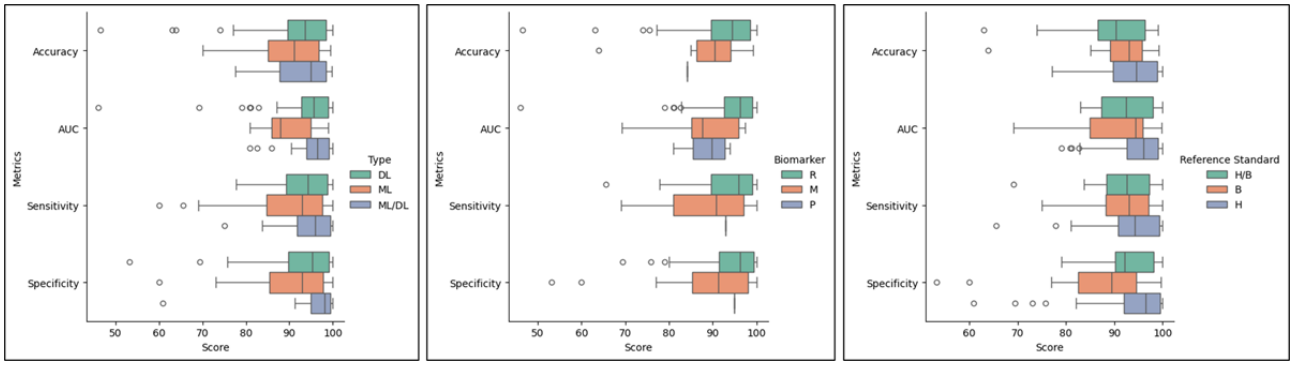


Figure 5. Comparative performance based on TL (left) and modality (right). AUC: area under the curve; M: multimodal; N: no; S: single; TL: transfer learning; Y: yes.

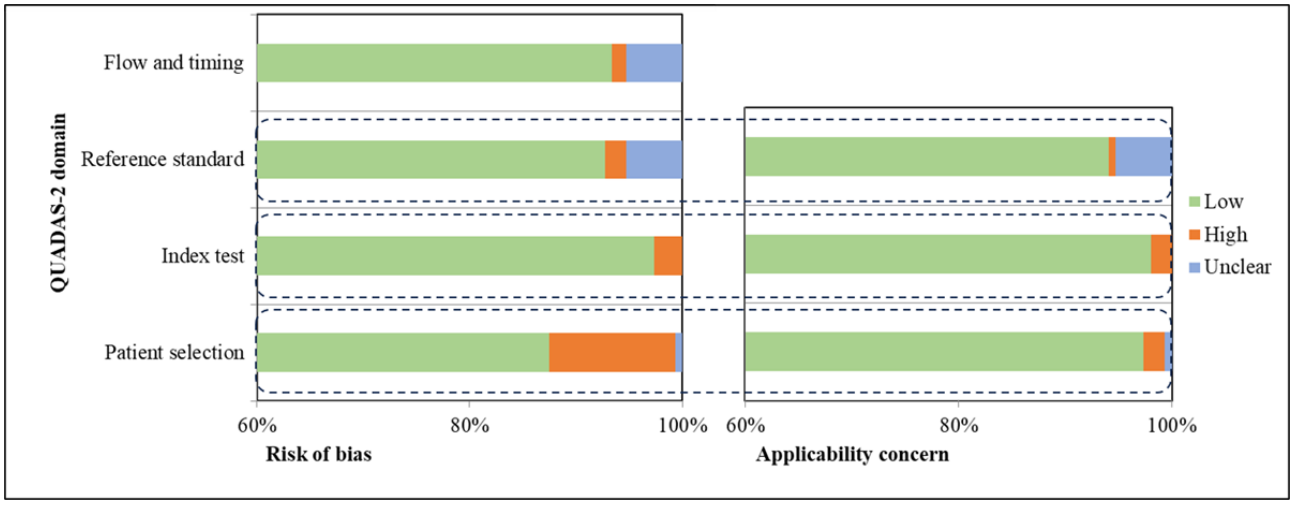
XSL•FO
RenderX

We also examined the performance of AI methods used in all the included studies based on the AI techniques applied (ML, DL, or both [ML/DL]), the types of data or biomarkers used (radiographic [R], molecular [M], physiological [P]), and the reference standard used (human [H], bacteriological [B], or both [H/B]). Figure 6 showcases the box plots, offering a comparative analysis of the performance results of the included studies based on AI methods, biomarker types, and reference standards.

Figure 6. Comparative performance based on AI methods (left), biomarker types (middle), and reference standards (right). AI: artificial intelligence; AUC: area under the curve; B: bacteriological; DL: deep learning; H: human; H/B: both human and bacteriological; M: molecular; ML: machine learning; ML/DL: both machine learning and deep learning; P: physiological; R: radiographic.



Specifically, the AI performance across different biomarker types showed mean accuracies of 92.45% (SD 7.83%), 89.03% (SD 8.49%), and 84.21% (SD 0%); mean AUCs of 94.47% (SD 7.32%), 88.45% (SD 8.33%), and 88.61% (SD 5.9%); mean sensitivities of 93.8% (SD 6.27%), 88.41% (SD 10.24%), and 93% (SD 0%); and mean specificities of 94.2% (SD 6.63%), 85.89% (SD 14.66%), and 95% (SD 0%) for radiographic, molecular/biochemical, and physiological biomarkers, respectively. Meanwhile, AI performance across various reference standards show mean accuracies of (SD 7.3%), 93.16% (SD 6.44%), 88.98% (SD 9.77%); mean AUCs of 90.95% (SD 7.58%), 94.89% (SD 5.18%), 92.61% (SD 6.01%); mean sensitivities of 91.76% (SD 7.02%), 93.73% (SD 6.67%), 91.34% (SD 7.71%); and mean specificities of 86.56% (SD 12.8%), 93.69% (SD 8.45%), 92.7% (SD 6.54%) for bacteriological, human reader, and combined bacteriological and human reader reference standards, respectively.

Risk-of-Bias Assessment Result

Figure 7 presents the QUADAS-2 outcomes across all included studies. Among the assessed studies, 18 (11.8%) [32,46-48,57,70,95,97,111,124,127,136,140,144,153,169,170,178] were flagged for a high risk of bias, with 1 (0.7%) study [141] marked as having an unclear risk concerning patient selection, largely attributable to incomplete or absent information in the data selection process. Moreover, 4 (2.6%) studies [41,101,108,174] were identified as having a high risk regarding the index test, attributed to the absence of crucial details on model architecture and parameters. Additionally, 3 (2%) studies [57,156,158] were classified as having a high risk and 8 (5.3%) studies [32,63,64,97,98,111,140,161] as having an unclear risk concerning reference standards, due to incomplete or missing information regarding the reference standards used. Concerning flow and timing, 2 (1.3%) studies [88,95] were deemed to have a high risk of bias, while 8 (5.3%) studies [53,65,67,87,102,141,156,179] were assigned an unclear risk, primarily due to unclear or absent information regarding the time interval and intervention provided in those studies.

Figure 7. Summary of QUADAS-2 results of the included studies. QUADAS-2: Quality Assessment of Diagnostic Accuracy Studies version 2.

The majority of the included studies exhibited a low level of concern about applicability. Only 3 (2%) studies [48,88,144] were identified with a high risk and 1 (0.7%) study [141] with an unclear risk in terms of patient selection. Additionally, 3

XSL•FO
RenderX

(2%) studies [41,108,151] were flagged with a high risk concerning the index test, while 1 (0.7%) study [158] showed a high risk, and 8 (5.3%) studies [32,63,64,97,98,111,140,161] had an unclear risk concerning reference standards. For comprehensive QUADAS-2 results, please refer to Multimedia Appendix 5.

Discussion

Principal Findings

This review study examined the diagnostic performance of various AI-based algorithms, including both ML and DL, for TB detection across different techniques, data modalities, and reference standards used in the included studies. Approximately 84.9% (n=129) of the included studies used radiographic data types, particularly CXRs. Notably, the SZ and MC datasets emerged as the most frequently used, with 51 and 46 studies, respectively, making use of them. However, it is noteworthy that the availability of data in SZ and MC, totaling 800 images, is relatively limited, posing challenges, especially for studies using DL methods where larger datasets are often required for optimal performance. Consequently, numerous techniques have been introduced to augment data quantity [185,186], including conventional methods, as well as DL-based augmentation techniques.

Few recent studies have used other data types, such as exhaled breath particles [146,150] and cough sounds [63,64,175]. Although not recommended as a standard tool for TB detection, results from these noninvasive approaches could be a supplement to the standard TB detection tool using CXRs. Hence, further studies that analyze CXRs together with other data types are encouraged.

Concerning modality, the majority of the included studies adopted a single modality (n=141, 92.8%) rather than using a multimodal approach (n=11, 7.2%). Studies using a single modality tended to exhibit higher median values and narrower distribution ranges compared to those using a multimodal approach (Figure 5, right). This suggests that the single-modality approach may outperform the multimodal approach. However, more outliers were observed in all performance metrics for the single modality compared to the multimodal approach. Additionally, these outcomes were not obtained under identical scenario settings. When applied under similar scenario settings, the multimodal approach has demonstrated the potential to enhance performance results compared to the single modality [9,187]. This is supported by findings from several included studies that have directly compared single-modality and multimodal approaches [79,86,95].

DL emerged as a cornerstone in the majority of the included studies (n=122, 80.3%), with CNNs taking the forefront. Among these, architectures such as VGG-16 [188], ResNet-50 [189,190], and DenseNet-121 [191] have gained notable traction. More recent DL architectures, including EfficientNets [192], Vision Transformer (ViT) [193], and ConvNeXts [194], have gained increasing attention. These emerging models, with more efficient architectures that require fewer computational resources, show potential for application in medical image processing, particularly in TB detection tasks.

Some of the included studies explored various explainable AI (XAI) methods to bolster the interpretability and trustworthiness of their AI models' outcomes. Originating from the need to strike a balance between interpretability and accuracy in ML and DL models [195], XAI has garnered considerable attention. Among the XAI techniques used in the included studies were gradient-weighted class activation mapping (Grad-CAM), local interpretable model-agnostic explanation (LIME), and Shapley additive explanations (SHAP).

TL is a powerful technique that capitalizes on knowledge acquired from a source dataset and adapts it to a target domain, relaxing the assumption that training data must be independent and identically distributed with test data [196]. TL proves especially beneficial in scenarios with a limited data volume. Indeed, TL has been extensively used in the studies encompassed in this systematic review (n=89, 58.6%), particularly those using DL methods. Notably, as illustrated in Figure 5 (left), investigations integrating TL tend to exhibit a higher median accuracy compared to counterparts. Additionally, they showcase a narrower distribution range, suggesting that TL-based approaches consistently deliver superior and more consistent results.

The majority of the included studies (n=143, 94.1%) focused primarily on the development of AI models for TB detection. Only 8 studies [44,73,92,106,111,137,153,176] progressed beyond model development to build prototypes or systems aimed at supporting real-world applications. Among these, 3 studies implemented their proposed models in real-world settings: eRx, a mobile health system for TB diagnosis deployed in Lima, Peru [111]; the multistream integration–pulmonary tuberculosis diagnosis model (MSI-PTDM), multistream integration for a TB diagnosis model implemented in China [176]; and AIChest4All, an automated CXR-screening system used in Thailand [44]. We excluded studies evaluating commercial TB detection tools, such as Lunit INSIGHT, CAD4TB, and qXR, as they typically do not provide detailed discussions of the underlying AI models. For further insights into commercial TB detection tools, interested readers are referred to the narrative review by Singh et al [17].

In terms of overall performance metrics, the AI methods displayed remarkable achievements. Further analysis based on the AI methods used in the included studies revealed interesting insights. As illustrated in Figure 6 (left), DL exhibits higher accuracy with less variation compared to ML and ML/DL. However, regarding the AUC, sensitivity, and specificity, studies integrating ML/DL tend to yield superior results, followed by DL and then ML. This suggests that the fusion of ML and DL methods may enhance model performance, albeit few studies have explored this avenue.

We also examined the performance results concerning the types of data used. Radiographic data-type studies showcased superior median scores across all performance metrics (Figure 6, middle). Notably, they demonstrated a higher level of consistency, evidenced by their shorter IQRs in all performance metrics. Regarding the reference standards used in the included studies,

XSL•FO
RenderX

studies that used the human reader exceled compared to those that used bacteriological and both reference standards, as indicated by the higher median and mean scores on all performance metrics in Figure 6 (right). Despite accuracy, the IQRs were also shorter for the AUC, sensitivity, and specificity. This finding might be rooted in the large number of included studies that used DL methods on radiographic data types with human reader reference standards.

Finally, it is worth noting that the majority of the included studies overlooked the evaluation of proposed solutions regarding the domain-shift problem. Remarkably, only 1 study [126] addressed domain-shift analysis in the context of TB detection, as highlighted by Hansun et al [197]. Although our review confirmed the high performance of AI-based methods across various data types in TB detection tasks, these evaluations were predominantly conducted on in-domain datasets. In other words, the datasets used for validation and testing shared the same distribution and characteristics as the training data. However, many AI methods, particularly DL, struggle when applied to real-world settings [198]. This discrepancy often arises due to differences in data distribution between the training data and real-world datasets. As such, it is imperative to broaden our focus to include not only in-domain evaluations but also domain-shift analysis in future research endeavors.

Limitations and Strengths

This systematic review has several limitations that warrant acknowledgment. First, our search was limited to the literature published in English from 3 primary academic databases: Scopus, PubMed, and ACM Digital Library. Although these sources are comprehensive, it is possible that relevant studies might exist in other databases, potentially leading to a partial representation of the literature.

Second, we did not conduct further investigations into aspects with high or unclear risks from the bias assessment. Given the prevalence of radiographic datasets across most included studies, we assumed uniformity across these aspects. However, this assumption may overlook potential variations that could impact the overall assessment.

Lastly, in this review study, we opted not to perform a meta-analysis. Although a meta-analysis could provide valuable insights, the diverse nature of the included studies made it challenging to ensure meaningful comparability across studies, potentially affecting the validity and reliability of the synthesized findings. It is also important to note that the variations in data distribution and experimental settings across studies may lead to different results. Although the descriptive statistics reported in this study have been grouped based on several approaches, they should be seen as general performance results of AI for TB detection.

Despite the aforementioned limitations, our review study is among the few to systematically review the evidence available in the literature regarding the efficacy of AI-based methods for TB detection. Although most review studies focus only on a specific biomarker type for TB detection, we performed a more comprehensive review of AI-based methods across diverse biomarker types. We further assessed the AI methods' performance based on several dominant approaches used in the included studies, including TL, multimodalities, reference standards, and ML/DL fusion methods for TB detection, which have never been explored before.

Key Takeaways

AI-based approaches, particularly DL, have been extensively used for TB detection with high-accuracy results. A single-modality approach with chest radiographs has been dominantly used. Further studies that analyze chest radiographs together with other data types (multimodality) are encouraged. AI models trained and tested on radiographic data tend to achieve higher performance compared to other data types. Emerging DL models, such as EfficientNets, ViT, and ConvNeXts, show the potential to enhance TB detection results. TL has shown a great advantage in handling a limited data volume and consistently delivering superior results. Most of the included studies evaluated their proposed solutions using in-domain datasets. Future research endeavors should prioritize conducting domain-shift analyses to better simulate real-world scenarios in TB detection.

Conclusion

This systematic review underscores the considerable promise of AI-based approaches in TB detection. Among the array of AI methods, DL emerges as the predominant choice. This preference for DL is attributed to its consistently robust performance, likely bolstered by the prevalence of studies using radiographic data. A notable observation across many studies is the use of relatively small datasets. Despite achieving commendable results, the potential of DL models could be further enhanced with larger and more diverse datasets.

Finally, although AI models demonstrate impressive performance on in-domain datasets, there is a notable gap in evaluating their robustness to domain shifts. Future research endeavors should prioritize conducting domain-shift analyses to better simulate real-world scenarios in TB detection. This approach would provide invaluable insights into the generalizability and applicability of AI-based methods beyond controlled settings.

Abstract

Background: Currently, there is a lack of effective early assessment tools for predicting the onset and development of cardiac arrest (CA). With the increasing attention of clinical researchers on machine learning (ML), some researchers have developed ML models for predicting the occurrence and prognosis of CA, with certain models appearing to outperform traditional scoring tools. However, these models still lack systematic evidence to substantiate their efficacy.

Objective: This systematic review and meta-analysis was conducted to evaluate the prediction value of ML in CA for occurrence, good neurological prognosis, mortality, and the return of spontaneous circulation (ROSC), thereby providing evidence-based support for the development and refinement of applicable clinical tools.

Methods: PubMed, Embase, the Cochrane Library, and Web of Science were systematically searched from their establishment until May 17, 2024. The risk of bias in all prediction models was assessed using the Prediction Model Risk of Bias Assessment Tool.

Results: In total, 93 studies were selected, encompassing 5,729,721 in-hospital and out-of-hospital patients. The meta-analysis revealed that, for predicting CA, the pooled C-index, sensitivity, and specificity derived from the imbalanced validation dataset were 0.90 (95% CI 0.87-0.93), 0.83 (95% CI 0.79-0.87), and 0.93 (95% CI 0.88-0.96), respectively. On the basis of the balanced validation dataset, the pooled C-index, sensitivity, and specificity were 0.88 (95% CI 0.86-0.90), 0.72 (95% CI 0.49-0.95), and 0.79 (95% CI 0.68-0.91), respectively. For predicting the good cerebral performance category score 1 to 2, the pooled C-index, sensitivity, and specificity based on the validation dataset were 0.86 (95% CI 0.85-0.87), 0.72 (95% CI 0.61-0.81), and 0.79 (95% CI 0.66-0.88), respectively. For predicting CA mortality, the pooled C-index, sensitivity, and specificity based on the validation dataset were 0.85 (95% CI 0.82-0.87), 0.83 (95% CI 0.79-0.87), and 0.79 (95% CI 0.74-0.83), respectively. For predicting ROSC, the pooled C-index, sensitivity, and specificity based on the validation dataset were 0.77 (95% CI 0.74-0.80), 0.53 (95% CI 0.31-0.74), and 0.88 (95% CI 0.71-0.96), respectively. In predicting CA, the most significant modeling variables were respiratory rate, blood pressure, age, and temperature. In predicting a good cerebral performance category score 1 to 2, the most significant modeling variables in the in-hospital CA group were rhythm (shockable or nonshockable), age, medication use, and gender; the most significant modeling variables in the out-of-hospital CA group were age, rhythm (shockable or nonshockable), medication use, and ROSC.

Conclusions: ML represents a currently promising approach for predicting the occurrence and outcomes of CA. Therefore, in future research on CA, we may attempt to systematically update traditional scoring tools based on the superior performance of ML in specific outcomes, achieving artificial intelligence–driven enhancements.

Introduction

Background

Cardiac arrest (CA) remains a critical challenge in contemporary medicine, characterized by a dismally low survival rate and poor prognosis, and, therefore, has garnered global attention [1]. CA can be classified by the occurrence location into in-hospital CA (IHCA) and out-of-hospital CA (OHCA). Despite advancements in cardiopulmonary resuscitation techniques, global registry data indicate that the incidence and survival rates of CA have not significantly improved. The incidence of IHCA in the United States increased to 900 to 1000 per 100,000 hospitalized patients between 2008 and 2017, compared to 160 per 100,000 in the United Kingdom from 2011 to 2013 and 840 per 100,000 in China as of 2020 [2-4]. Meanwhile, the estimated averages of incidence of OHCA under emergency medical services (EMS) in North America, Asia, and Europe from 2010 to 2020 were 47.3, 45.9, and 40.6 per 100,000 people, respectively. The estimated averages of the survival rates of IHCA from 2010 to 2020 were 25% in the United States, 18% in the United Kingdom, and only 9.4% in China. For OHCA, the estimated averages of the survival rates during this same period were 10% to 12% in the United States, 8% in Europe, and just 3.6% in Asia [2,5]. These low survival rates also impose significant economic burdens on nations. According to relevant reviews, the cost-effectiveness threshold for CA ranged from US $20,000 to US $150,000 per quality-adjusted life year, with each life saved potentially reducing costs by US $19,000 to US $71,000 per case [6].

Although efforts to establish CA centers independently began in various regions of the United States as early as 2000 to 2010 [7] and Germany initiated CA center certification throughout the country [8] in August 2019 aiming to provide evidence-based, bundled care to improve CA survival rates, CA remains a formidable clinical challenge. If resuscitation is not timely, the patient may lose consciousness within approximately 10 seconds, with irreversible hypoxic-ischemic brain injury occurring within 4 minutes [9], and if resuscitation is delayed beyond 10 minutes, survival is practically impossible [10,11]. Thus, early prediction and identification of CA are critical factors in preventing death and poor outcomes and represent a major challenge that requires urgent clinical attention.

Objectives

However, there is a scarcity of efficient, internationally recognized, and universally accepted assessment tools for early prediction and identification of CA risk and adverse outcomes. In recent years, with the rapid advancement of artificial intelligence (AI), many researchers have used machine learning (ML) to address clinical challenges. Commonly used ML approaches can be broadly categorized into supervised and unsupervised learning. In the context of supervised ML, clinical predictors can be incorporated into various models. In these models, their parameters are adjusted based on outcome variables to generate predictions regarding the probability of positive event occurrence [12]. It is now common to see ML being used to predict disease progression and even to diagnose and treat complex diseases effectively. For instance, in 2019, several authors, including Hatib et al [13] and Wijnberge et al [14], successfully predicted intraoperative hypotensive events using ML, leading to the clinical translation of these models into products that significantly enhanced patient safety during surgical anesthesia [15]. By 2023, some researchers had similarly affirmed the substantial potential of ML models in cancer detection, prognosis, and treatment, recognizing their exciting discoveries and contributions to advancing medical practice [16]. The aforementioned studies were based on supervised ML and the extensive use of interpretable clinical features to construct predictive models and simultaneously demonstrate the promising predictive performance of ML in clinical events across various fields. In this context, some researchers have also developed different ML models for risk prediction in CA. Recent reviews by Sem et al [17] and Chen et al [18] indicate that ML appears to exhibit high accuracy in both the management and risk prediction of CA. However, these reviews do not quantitatively synthesize the results of ML models, which significantly limits our ability to interpret the specific value of various ML models in CA applications and the selection of appropriate models. Therefore, we conducted this systematic review and meta-analysis to review the predictive performance of ML for the occurrence of CA, good neurological prognosis after CA, mortality, and the return of spontaneous circulation (ROSC) after CA to provide evidence-based guidance for the development and updating of simple prediction tools with high accuracy and direct access to results.

Methods

Study Registration

This study was conducted in adherence to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines and prospectively registered with PROSPERO (International Prospective Register of Systematic Reviews; ID CRD42024518949). The detailed PRISMA checklist is presented in Multimedia Appendix 1.

Eligibility Criteria

Detailed inclusion and exclusion criteria were defined to screen the original studies relevant to our systematic review from the retrieved literature (Textbox 1).

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria for original studies.

Inclusion criteria

- Study type: the included studies must be case-control, cohort, nested case-control, case-cohort, or cross-sectional studies.
- Model construction: although some studies, due to limited sample sizes, lacked independent external validation, we could not dismiss their contributions. In our analysis, it was necessary to synthesize results from the training and validation sets to assess the presence of severe overfitting. Therefore, those with no external validation were also included.
- Outcomes: studies that comprehensively constructed machine learning (ML) models for cardiac arrest (CA) occurrence prediction or clinical outcomes following CA were selected.
- Language: we included original studies in English.

Exclusion criteria

- Study type: studies categorized as meta-analyses, reviews, guidelines, expert opinions, or conference abstracts and not fully peer reviewed and published were removed.
- Model construction: studies with only risk factor analysis but no construction of a complete ML model were excluded, those with a limited number of samples (<20) were not included, and those only focusing on the accuracy of univariate predictors were removed.
- Outcomes: in existing ML studies, model performance was assessed using the receiver operating characteristic curve, C-statistic, sensitivity, specificity, accuracy, recall, precision, confusion matrix, or F_1-score. However, a few original studies that lacked at least one of these metrics and, therefore, did not evaluate model performance adequately were excluded.
- Language: non–English-language original studies were excluded.

Data Sources and Search Strategy

A systematic search of the PubMed, Embase, Cochrane Library, and Web of Science databases was carried out from their inception to May 17, 2024. The search strategy involved controlled vocabulary and free-text terms, with no restrictions on geographical location or publication year. The detailed search strategy is presented in Multimedia Appendices 2-5.

Study Selection and Data Extraction

The retrieved studies were imported into EndNote X9 (Clarivate Analytics). Their titles and abstracts were reviewed. After the exclusion of duplicates, the preliminary eligible original studies were selected and their full texts downloaded for determining the final inclusion. An electronic spreadsheet was prepared to extract the following information: first author, publication year, author's country, study type, patient source, prediction events, data balance, location of CA occurrence, number of cases with study events, total number of cases, number of cases in the training and validation sets, method of validation set generation, missing data–handling methods, and types of models used. Study selection and data extraction were independently conducted by 2 researchers. Disagreements were discussed and resolved with a third author.

Risk of Bias in the Studies

The Prediction Model Risk of Bias Assessment Tool (PROBAST) was used to assess the risk of bias in all the included original studies. PROBAST comprises several questions across 4 domains—participant, predictor, outcome, and statistical analysis—which reflect the overall risk of bias and applicability. These domains consist of 2, 3, 6, and 9 questions, respectively, each with 3 possible answers (*Yes* or *Probablyyes*, *No* or *Probably no*, and *No information*). A domain was classified as high risk if any question was answered with *No* or *Probably no*. Conversely, a domain was regarded as low risk only if every question was answered with *Yes* or *Probably yes*. The overall risk of bias was assessed as low when all domains were deemed to be low risk. When at least one domain was high risk, the overall risk of bias was rated as high. In total, 2 authors independently assessed the risk of bias using PROBAST and cross-checked their findings. Any discrepancies were addressed by consulting with a third author to reach agreement.

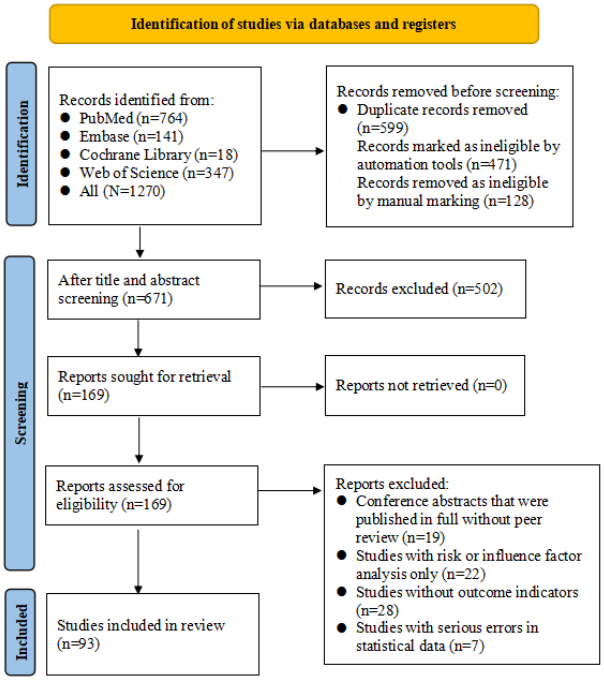
Outcomes

The primary outcome measure was the C-index, which reflects the predictive ability of ML models for IHCA and OHCA. However, we found that the C-index might not have accurately described the predictive performance of ML for positive events, particularly in models built on severely imbalanced data, as these original studies often suffered from such imbalance. This limitation was evident in predicting the occurrence of IHCA and OHCA, the good cerebral performance category score 1 to 2 (CPC 1-2), mortality, and ROSC. Therefore, in addition to the C-index, our primary outcome measures encompassed sensitivity and specificity. Our secondary outcome was the frequency of variables used in the ML models.

Synthesis Methods

A meta-analysis of the C-index, a measure of the general accuracy of ML models, was carried out. When the 95% CI and SE for the C-index were missing in some studies, the SE was estimated based on the study by Debray et al [19]. Due to the differences in the included variables and inconsistent parameters among the ML models, random-effects models were prioritized in the meta-analysis of the C-index. In addition, a meta-analysis on sensitivity and specificity was conducted through a bivariate mixed-effects model based on diagnostic 2 × 2 tables. However, most original studies did not report these tables. In such cases, we used the following methods to calculate the 2 × 2 tables: (1) calculation based on sensitivity, specificity, precision, and case numbers; and (2) calculation based on the best Youden index to extract sensitivity and specificity, followed by case number

XSL•FO
RenderX



integration. Nevertheless, this method allowed for meta-analysis only when there were ≥4 models. For <4 models, we presented the range of sensitivity and specificity. Our meta-analysis was conducted in R (version 4.2.0; R Foundation for Statistical Computing).

Results

Study Selection

A total of 1270 articles were obtained from databases, with 599 (47.17%) being duplicates. Among these 599 duplicates, 471 (78.6%) were found to be duplicates via software, and 128 (21.4%) were manually identified as duplicates. After the elimination of duplicates, 671 articles were screened by title and abstract, with 169 (25.2%) being selected for full-text review. After the exclusion of conference abstracts published in full text without peer review (19/169, 11.2%), studies with risk factor analyses but no complete ML models (22/169, 13%), studies lacking outcome indicators (28/169, 16.6%), and studies with severe statistical errors (7/169, 4.1%), a total of 93 articles were included finally. The detailed process is illustrated in Figure 1.

Figure 1. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for study selection.

Study Characteristics

The 93 selected studies were published between 2011 and 2024, covering 14 countries, primarily South Korea, China, Japan, the United States, and Singapore. Among the 93 studies, there were 23 (25%) prospective cohort studies and 3 (3%) case-control studies, with the remainder (67/93, 72%) being retrospective cohort studies. Data for 26% (24/93) of the studies were sourced from multiple centers, whereas 37% (34/93) of the studies used data from registry databases and the rest (35/93, 38%) were single-center studies. In 30% (28/93) of the studies, the predicted outcome was the occurrence of CA. In 42 studies, the predicted outcome was the neurological prognosis of patients with CA, with 10 (24%) studies focused on patients with IHCA and the remainder (n=32, 76%) focused on patients with OHCA. In 27% (25/93) of the studies, the predicted outcome was CA mortality, and in 12% (11/93) of the studies, the predicted outcome was ROSC in patients with CA. The 93 studies collectively encompassed a total of 5,729,721 cases, including 1,737,085 OHCA cases and 3,992,636 IHCA cases. Regarding the predictive models constructed, 81% (75/93) of the studies had independent validation sets, but only 27% (25/93) used external validation, primarily using k-fold cross-validation and random-sampling internal validation methods. A total of 34% (32/93) of the studies described methods to prevent data overfitting, mainly through cross-validation. In total, 17 types of ML models were involved, with logistic regression (LR), random forest (RF), deep learning, and decision trees (DTs) being the most prominent. In addition, these studies validated several previously established scoring tools, including the Cardiac Arrest Neurological Prognosis score, distance scoring system, Emergency Department In-Hospital Cardiac Arrest Score, FACTOR score, Modified Early Warning Score, National Early Warning Score, National Early Warning Score 2, OHCA score, proposed scoring system, Rapid Emergency Medicine Score, Simplified Acute Physiology Score II, Cardiac Arrest Hospital Prognosis score, and ROSC after CA score. The details of the included studies are shown in Tables 1 and 2.

Table 2. Analytical characteristics of the included studies.

Study	Balance of data (balanced or unbalanced)	Location of CA[a]	Number of cases of studied events	Total number of cases	Number of cases in the training set	Generation of validation set	Number of cases in the validation set	Handling method for missing values	Model type
Wang et al [20]	Unbalanced	In hospital	474	224,413	182,716	External validation	41,697	Deletion	Logistic regression, National Early Warning Score, and Modified Early Warning Score
Raheem et al [21]	Unbalanced	In hospital	5483	97,353	77,886	Internal validation	19,467	Deletion	Artificial neural network, random forest, and logistic regression
Amacher et al [22]	Balanced	In hospital and out of hospital	IHM[b]: 309; CPC 3-5[c]: 309	713	—[d]	—	713	No processing	Out-of-hospital CA score, the Cardiac Arrest Hospital Prognosis score, and logistic regression
Cho et al [23]	Unbalanced	In hospital	228	95,607	—	External validation	95,607	Deletion	Deep learning, Modified Early Warning Score, and National Early Warning Score
Shin et al [24]	Unbalanced	In hospital	198	1995	970	External validation	1025	Deletion	Deep learning, logistic regression, random forest, and National Early Warning Score
Ding et al [25]	Balanced	In hospital	CPC 1-2[e]: 20; IHM: 30	53	—	Internal validation	53	Deletion	Logistic regression and Cox regression
Nishioka et al [26]	Balanced	Out of hospital	6486	7587	3337	External validation	4250	Supplement	Logistic regression
Kajino et al [27]	Unbalanced	Out of hospital	11,411	302,799	149,425	Internal validation	153,374	Deletion	Deep learning
Pham et al [28]	Balanced	Out of hospital	210	434	231	External validation (multicenter)	203	—	Logistic regression
Rahadian et al [29]	Unbalanced	Out of hospital	860	20,713	17,162	—	3551	Imputation	Logistic regression, LASSO[f], and random forest
Wang et al [30]	Unbalanced	Out of hospital	84	48,371	32,244	—	16,127	—	Logistic regression
Tsai et al [31]	Balanced	Out of hospital	CPC 1-2: 127	443	265	Internal validation	178	—	Logistic regression
Schweiger et al [32]	Balanced	Out of hospital	120	291	138	Internal validation	153	Supplement	FACTOR score
Caputo et al [33]	Unbalanced	Out of hospital	2719	12,577	—	Internal validation	12,577	—	Logistic regression

[a]CA: cardiac arrest.

[b]IHM: in-hospital mortality.

[c]CPC 3-5: poor cerebral performance category score 3 to 5.

[d]Not provided.

[e]CPC 1-2: good cerebral performance category score 1 to 2.

[f]LASSO: least absolute shrinkage and selection operator.

[g]XGBoost: Extreme Gradient Boosting.

[h]ICU: intensive care unit.

[i]NROSC: nonreturn of spontaneous circulation.

[j]ROSC: return of spontaneous circulation.

[k]STD: survival to discharge.

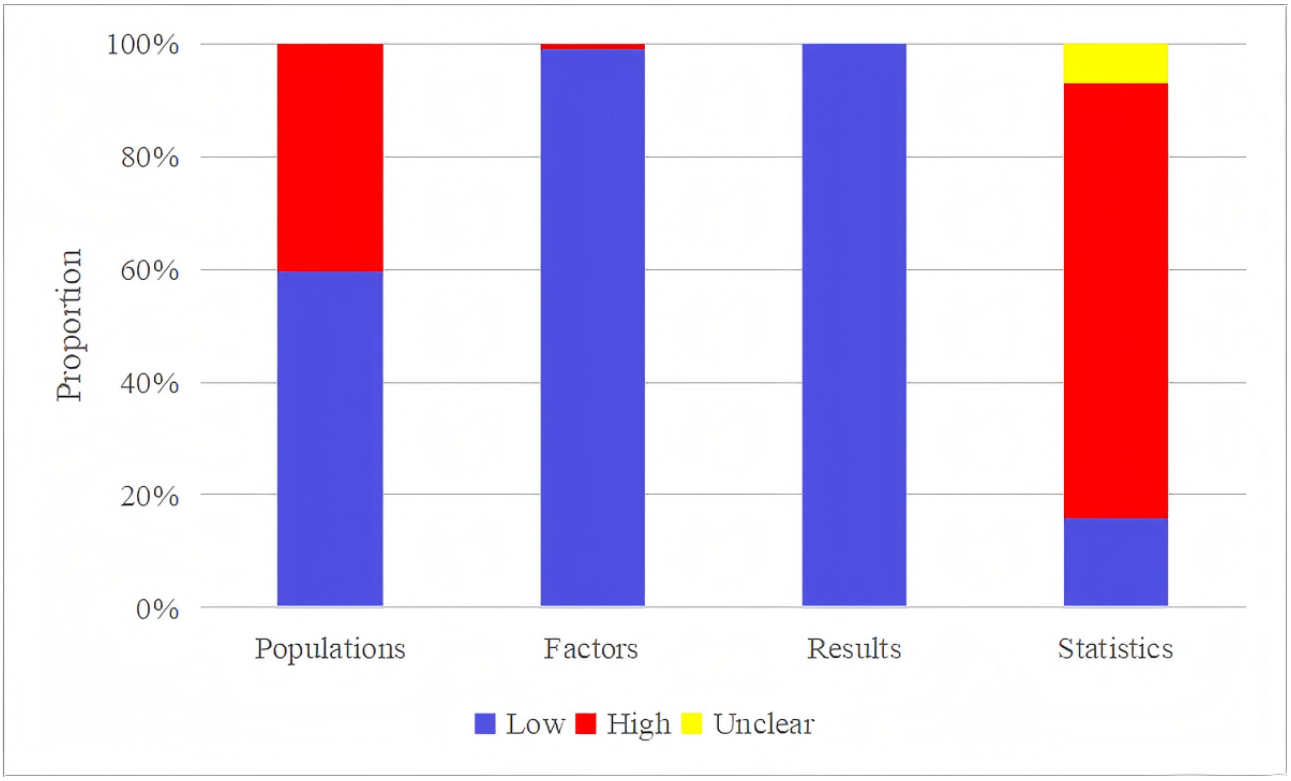
[l]LightGBM: Light Gradient-Boosting Machine.

[m]BD: brain death.

[n]HVec: hierarchical vectorizer.

[o]CANP: Cardiac Arrest Neurological Prognosis.

[p]AdaBoost: Adaptive Boosting.



Risk of Bias in the Studies

After our exclusion of previously established scoring tools, a quality assessment of 208 ML models, involving 17 types, was conducted. In total, 24% (50/208) of these models originated from case-control studies, which introduced a high risk of bias in study participant selection. Regarding predictive factors, 1% (2/208) of the models were linked to a high risk of bias owing to the use of outcome information. Regarding outcome assessment, as both CA and prognosis outcomes were clearly defined using standard definitions, no additional predictive factors were required, resulting in a low risk of bias in outcome assessment. The included ML models were primarily derived from large-sample statistical analyses; however, 9.1% (19/208)

XSL•FO
RenderX

of the models were based on a very small number of cases, with an event per variable value of <10. In addition, inappropriate deletion methods were applied to address missing data in 65.4% (136/208) of the models, and only univariate analysis was used to screen for predictive factors in 22.6% (47/208) of the models, ultimately resulting in a high risk of bias for 76.9% (160/208) of the models in the domain of statistical analysis, as detailed in Figure 2.

Figure 2. Assessment results for the risk of bias in the included models.

Meta-Analysis

CA Occurrence

A meta-analysis of ML models for predicting CA occurrence in the training set was conducted through a random-effects model. The analysis revealed a C-index of 0.84 (95% CI 0.82-0.86; 38/208, 18.3% of the models), sensitivity of 0.78 (95% CI 0.70-0.84; 34/208, 16.3% of the models), and specificity of 0.84 (95% CI 0.80-0.88; 34/208, 16.3% of the models). Similarly, a meta-analysis of ML models for predicting CA occurrence in the validation set was conducted, yielding a C-index of 0.89 (95% CI 0.87-0.91; 52/208, 25% of the models), sensitivity of 0.83 (95% CI 0.78-0.87; 43/208, 20.7% of the models), and specificity of 0.93 (95% CI 0.88-0.96; 43/208, 20.7% of the models; Multimedia Appendices 6-13).

Because of the diverse sources of modeling data from both balanced and imbalanced datasets and the variety of models, a subgroup analysis was conducted based on the data model type. The detailed results are presented in Multimedia Appendices 14-18.

Favorable Neurological Outcomes (CPC 1-2)

A meta-analysis of ML models for predicting CPC 1-2 in the training set was conducted using a random-effects model. The results indicated a C-index of 0.90 (95% CI 0.89-0.92; 21/208, 10.1% of the models), sensitivity of 0.72 (95% CI 0.47-0.98; 15/208, 7.2% of the models), and specificity of 0.85 (95% CI 0.79-0.90; 15/208, 7.2% of the models). Similarly, the meta-analysis of ML models for predicting CPC 1-2 in the validation set revealed a C-index of 0.86 (95% CI 0.85-0.87; 69/208, 33.2% of the models), sensitivity of 0.72 (95% CI 0.61-0.81; 44/208, 21.2% of the models), and specificity of 0.79 (95% CI 0.66-0.88; 44/208, 21.2% of the models; Multimedia Appendix 19, and Table S1 and Figures S1-S3 in Multimedia Appendix 20).

It was hypothesized that there might have been differences in CPC 1-2 between patients experiencing IHCA and OHCA. As the real-world data closely resembled balanced datasets, a subgroup analysis was conducted exclusively on the IHCA and OHCA populations. The detailed results are shown in Multimedia Appendix 19, and Table S1 and subgroup analysis report S1 in Multimedia Appendix 20.

CA Mortality

A random-effects model was used for the meta-analysis of ML models for predicting CA mortality in the training set. The analysis indicated a C-index of 0.80 (95% CI 0.76-0.84; 14/208, 6.7% of the models), sensitivity of 0.82 (95% CI 0.58-0.94; 7/208, 3.4% of the models), and specificity of 0.76 (95% CI 0.51-0.91; 7/208, 3.4% of the models). Similarly, a meta-analysis of ML models for predicting CA mortality in the validation set revealed a C-index of 0.85 (95% CI 0.82-0.87; 28/208, 13.5% of the models), sensitivity of 0.83 (95% CI 0.79-0.87; 23/208, 11.1% of the models), and specificity of 0.79 (95% CI 0.74-0.83; 23/208, 11.1% of the models; Tables S2-S3 and Figures S4-S6 in Multimedia Appendix 20).

XSL•FO
RenderX

It was thought that there might have been differences in mortality rates between patients experiencing IHCA and OHCA. Given that the real-world data closely resembled balanced datasets, a subgroup analysis was conducted exclusively on the IHCA and OHCA populations. The detailed analysis results are provided in Tables S2-S3 and subgroup analysis report S2 in Multimedia Appendix 20.

ROSC Analysis

A meta-analysis of ML models for predicting ROSC following CA in the training set was conducted using a random-effects model. The analysis yielded a C-index of 0.83 (95% CI 0.79-0.88; 10/208, 4.8% of the models), sensitivity of 0.52 (95% CI 0.31-0.73; 8/208, 3.8% of the models), and specificity of 0.91 (95% CI 0.88-0.93; 8/208, 3.8% of the models). Similarly, a meta-analysis of ML models for predicting ROSC in the validation set revealed a C-index of 0.77 (95% CI 0.74-0.80; 13/208, 6.3% of the models), sensitivity of 0.53 (95% CI 0.31-0.74; 6/208, 2.9% of the models), and specificity of 0.88 (95% CI 0.71-0.96; 6/208, 2.9% of the models; Tables S4-S5 and Figures S7-S9 in Multimedia Appendix 20).

It was postulated that there may have been differences in ROSC between patients who experienced IHCA and OHCA. As the real-world data closely resembled balanced datasets, a subgroup analysis was performed solely on the IHCA and OHCA populations. The comprehensive analysis results are provided in Tables S4-S5 and subgroup analysis report S3 in Multimedia Appendix 20.

Modeling Variables

Modeling variables were extracted and weighted for analysis from the 93 studies on ML models for predicting CA and CPC 1-2. Among the 28 studies on predicting CA, the variables with the highest weights were respiratory rate (n=22, 79%), blood pressure (n=20, 71%), age (n=19, 68%), temperature (n=19, 68%), oxygen saturation (n=15, 54%), and airway (n=9, 32%). Among the 42 studies on predicting CPC 1-2, the results showed that the modeling variables with the highest weights in the IHCA group were rhythm (shockable or nonshockable; 8/10, 80%), age (7/10, 70%), medication use (6/10, 60%), gender (5/10, 50%), and Glasgow Coma Scale (GCS; 5/10, 50%). The modeling variables with the highest weights in the OHCA group were age (25/32, 78%), rhythm (shockable or nonshockable; 24/32, 75%), medication use (18/32, 56%), ROSC (14/32, 44%), gender (12/32, 38%), no-flow time (resuscitation duration; 12/32, 38%), EMS transport (scene interval, arrival time, and response time; 12/32, 38%), defibrillation (11/32, 34%), and GCS (6/32, 19%). The detailed results of the modeling variables and weight analysis are presented in Tables S6 and S7 in Multimedia Appendix 20.

Discussion

Summary of the Principal Findings

It was observed that ML has garnered widespread attention among numerous researchers in the management of CA, particularly focusing on early CA risk prediction in both in-hospital and out-of-hospital populations. Our systematic review and meta-analysis demonstrated a relatively favorable predictive value of ML in the validation set for forecasting CA risk, with a C-index of 0.89. Similarly, ML also appeared to exhibit a relatively favorable predictive value for neurological outcomes (CPC 1-2) and mortality in patients who had already experienced CA, with pooled C-indexes of 0.86 and 0.85, respectively. However, in predicting ROSC following CA, ML seemed to display a predictive value comparable to that of traditional scoring tools, with a pooled C-index of 0.77.

Comparison With Previous Reviews

Currently, in clinical practice, classic early warning scoring tools, including the Cardiac Arrest Risk Triage (CART) score, Modified Early Warning Score, and VitalPAC Early Warning Score, are commonly used for predicting the occurrence of CA. A previous review by Churpek et al [112] found that, among these tools, the CART had the highest accuracy in predicting CA compared to the others. However, the CART had certain limitations, with an area under the curve of 0.83, sensitivity calculated at 0.61 based on the optimal Youden index, and a specificity of 0.84. Moreover, the CART has not been externally validated, and the included population is limited to ward inpatients. Therefore, whether the CART can dynamically monitor the occurrence of CA in real-time clinical events, improve rescue success rates, and enhance patient outcomes requires prospective validation using high-quality, large-sample external data. Our summarized results of the ML models reveal that ML has certain clinical predictive value in forecasting the occurrence of CA and demonstrates relatively favorable accuracy, with an overall C-index of 0.89, sensitivity of 0.83, and specificity of 0.93. Comparatively, this is superior to previous scoring tools, providing a certain clinical basis for the future establishment of more reliable early warning scoring systems for predicting CA.

In a recent review by Carrick et al [113], the accuracy of scoring tools for predicting survival or neurological outcomes following CA, such as the OHCA score, Cardiac Arrest Hospital Prognosis score, and Good Outcome Following Attempted Resuscitation score, was summarized. These 3 tools, which have undergone rigorous clinical validation, exhibited relatively high accuracy, with C-indexes of 0.79, 0.83, and 0.76, respectively. However, our summarized results of ML models suggested that ML seems to exhibit more favorable accuracy, with an overall C-index of 0.86, sensitivity of 0.72, and specificity of 0.79 for predicting favorable neurological outcomes. For predicting CA mortality, ML achieved an overall C-index of 0.85, sensitivity of 0.83, and specificity of 0.79.

Among various ROSC prediction models for CA that have been developed in the current clinical field, the ROSC after CA score developed by Gräsner et al [114] using data from 5471 patients with OHCA from the German Resuscitation Registry has attracted the most attention. It has been externally validated in several European and Asian countries, demonstrating relatively good accuracy, with an area under the curve of 0.736 in a recent large-scale external validation study [115]. However, our summarized results of ML models indicated that the overall C-index of ML was 0.77, with a sensitivity of 0.53 and specificity of 0.88. Comparatively, these ML models did not

XSL•FO
RenderX

seem to significantly outperform traditional scoring tools in predicting ROSC outcomes for patients with CA.

Modeling Variables in ML

In our review, the modeling variables of the discussed models primarily originated from common clinical features. It was found that variables such as respiratory rate, blood pressure, age, temperature, oxygen saturation, and airway were key predictors in existing ML models, and they also constitute critical variables in traditional scoring models [116,117]. Therefore, the impact of these variables on predicting the occurrence of CA is well established. However, these predictors differ to some extent from the findings of recent studies, such as the review by Andersen et al [3], which identified CA risk factors. The review by Andersen et al [3] suggested that age was more associated with post-CA prognosis and reduced survival rates, whereas a history of cardiac diseases such as myocardial infarction, arrhythmias, and heart failure was recognized as the most common risk factor for CA occurrence. Other potential risk factors included the use of certain medications, such as those that prolong the QT interval, opioids, and sedatives. Nonetheless, the review concurred that respiratory function and body temperature also had predictive significance for CA, with early interventions targeting these factors being crucial for achieving reversible outcomes [118].

In the models we reviewed that aimed to predict CPC 1-2 outcomes in patients with IHCA and OHCA, the modeling variables with the highest weight were age, rhythm (shockable or nonshockable), medication use, ROSC, gender, no-flow time (resuscitation duration), defibrillation, EMS transport (scene interval, arrival time, and response time), and GCS. When compared to the review by Sandroni et al [119], which highlighted the predictive value of GCS, biological markers (eg, neuron-specific enolase), and electrophysiological indicators (eg, somatosensory evoked potential) for favorable neurological outcomes, our findings show some differences. In addition, complex variables such as medical imaging might need consideration in clinical practice. In recent years, AI methods have been widely used in medical imaging for identifying disease progression and prognosis, demonstrating superior accuracy and cost-effectiveness compared to traditional clinical feature–based predictive models [120]. Therefore, in the prediction of CA occurrence and prognosis, the high-value variables identified in recent studies, such as electrocardiography [121] and ultrasound [122], are not reflected in traditional scoring tools. This raises the question of whether it is worth further validating these more complex variables and attempting to identify more efficient predictive factors to develop or update risk-scoring tools in the field of CA.

Clinical Applications of ML

Our study reveals that ML methods appear to outperform traditional scoring tools in predicting the occurrence and progression of CA. Therefore, the development of simple auxiliary tools based on ML theory is recommended to facilitate rapid risk screening of CA for both in-hospital and out-of-hospital patients, enabling timely formulation of appropriate treatment strategies. These ML-based CA prediction models would be particularly beneficial for emergency departments and out-of-hospital response teams. Under the current circumstances, in which emergency departments worldwide are facing challenges of overcrowding, resource limitations, and a high influx of patients who are critically ill [123-125], relying solely on human assessment of CA risk based on various clinical data could pose significant challenges to the efficiency of CA treatment. Furthermore, the complexity and volume of clinical data, including patient demographics, laboratory results, imaging data, and textual notes from health care providers, are continuously increasing. Thus, using ML to analyze large datasets and handle complex variables, such as clinical images, seems to be a more feasible approach [126]. The development of simplified ML prediction tools or intelligent reading systems has the potential to mitigate risks such as treatment delays and poor prognoses in patients with CA in emergency departments. These tools could also enhance health care service quality, reduce human resource costs, and support the formulation of targeted therapeutic strategies. Similarly, ML models that incorporate real-time input of variables such as vital signs, electrocardiograms, and response times for out-of-hospital rescue scenarios can accurately predict positive CA events. This capability aids response teams in avoiding repeated and frequent evaluations, enabling timely decisions on whether to implement preventive therapeutic interventions to avert CA or, in cases of CA occurrence, whether to initiate extracorporeal membrane oxygenation cardiopulmonary resuscitation to improve survival rates [127,128].

In addition, our findings indicate that the balance of data significantly impacts the outcomes of ML model construction in CA-related studies. This effect is particularly pronounced in scenarios in which the outcome metrics exhibit severe imbalance. For instance, in predicting the occurrence of CA in our study, the rationale for the selected predictive factors remained challenging, and the accuracy of the constructed model was often influenced by the overwhelming proportion of negative events [129]. In such cases, the C-index hardly represented the actual outcome prediction accuracy of the model. Therefore, in our study, the sensitivity and specificity of ML models were also summarized [130]. The data balance in the studies we included was primarily addressed using oversampling, but these studies rarely considered validating models constructed from balanced data against imbalanced data. This raises certain doubts regarding the accuracy of existing models constructed based on balanced data when applied to real-world cases of CA. Our study reveals that CA events in the real world are often inherently imbalanced. Therefore, we recommended prioritizing the use of models constructed from real-world data or validating models constructed from balanced data against real-world data to ascertain their true effectiveness [131].

Ethical Considerations and Model Selection

Although ML models demonstrated relatively satisfactory accuracy in predicting the occurrence and progression of CA in our study, several common challenges inherent to ML modeling should be acknowledged. For instance, compared to traditional scoring tools, ML models rely on general algorithms to generate desired outputs in response to specific input data, a process characterized by less explicit rules [132]. In addition,

XSL•FO
RenderX

algorithmic biases may result in unrepresentative datasets [133], and the reliability of model validation remains a concern [134]. These issues underscore the ethical challenges associated with the application of AI in medicine, including result interpretability, algorithmic transparency, predictive fairness, and data privacy [135,136]. These potential ethical concerns are specifically reflected in a patient survey study on the prevention of CA occurrence and development conducted by Maris et al [137]. The study results indicate that, while AI-driven CA treatment decisions offer objective data, the absence of patient involvement and informed consent, along with the interpretability of the model, suggest that the overuse of AI technology may ultimately undermine patient trust in physicians. This, in turn, poses challenges to the current high-quality health care goal of patient-centered care [138] in the field of cardiovascular disease treatment, which is built on shared decision-making [139], respect for patient autonomy, and mutual trust. Therefore, in the high-risk and critical treatment of CA, it seems that physicians should continue to make final decisions in collaboration with ML models based on evidence-based clinical experience and the values of the patients.

Therefore, based on ethical considerations, the choice of different models during research remains challenging as model interpretability and accuracy are factors that need to be considered comprehensively during model construction [140]. Selecting models with higher interpretability, such as LR, Cox regression, or DTs, can facilitate better communication, interaction, and trust between health care providers and patients. However, these models may have limited predictive value for certain outcome events [141]. On the other hand, models whose interpretability is poorer, including neural networks, support vector machines (SVMs), and Extreme Gradient Boosting, often perform exceptionally well in predicting outcomes [142]. At this point, it may become necessary to grant patients and their families greater rights to information and autonomy, enabling their active participation in medical decision-making. In our research, LR was the most frequently used model type as it facilitated the development of predictive nomograms, which are simple and easily applicable tools.

Among the 17 ML models that we included, artificial neural networks, RF, and LR appeared to demonstrate relatively ideal predictive value in forecasting the occurrence of CA and were more frequently used by clinical researchers. In predicting neurological outcomes, our study found that LR remained the model most commonly selected by clinicians, followed by DT, RF, SVM, and others. If we aim to develop a simplified predictive scoring scale to assist in clinical practice, priority may be given to using LR for its development and subsequent updates. This preference arises because, according to our research findings, LR demonstrates relatively satisfactory accuracy and facilitates the construction of straightforward and practical predictive nomograms [143,144]. Furthermore, considering the interpretability of models is essential in real-world clinical practice. However, if the objective is to develop auxiliary applications for disease surveillance and prediction in clinical settings, alternative, more complex models may be considered. For example, models such as neural networks, SVM, and Extreme Gradient Boosting, which demonstrated higher accuracy in our study, could be appropriate choices. On the other hand, when dealing with image-based features, such as medical imaging or electrocardiograms, it may be necessary to use models with lower interpretability, such as those based on deep learning [145], rather than confining the analysis to commonly used clinical features with stronger interpretability.

Prospects

In addition, we observed a minimal number of studies that constructed models based on artificial neural networks and ensemble learning, which exhibited highly favorable results, indicating that further validation of these models may be required in future research. Currently, in clinical practice, there is an increasing preference for using simple scoring tools based on interpretable clinical features. While opting for such tools may reduce the ethical dilemmas encountered in clinical settings, relying solely on traditional methods and highly interpretable clinical indicators, such as the Delphi method, during the development of these scoring tools seems to introduce significant bias into the constructed models. Therefore, we considered using multicenter real-world big data, using ML approaches, and incorporating a broader range of cases and clinical features to construct interpretable scoring tools and promote their application. Regarding the processing of clinical image features, our expectation lies in the development of intelligent reading tools based on deep learning methods. Nonetheless, in our study, there was limited research on deep learning based on medical imaging and ultrasounds, particularly in the field of CA, where such research remains relatively underexplored. Therefore, future research on CA should actively explore the integration of medical imaging and ultrasonography. In selecting datasets and algorithms for the development of AI prediction models, it is crucial to rigorously investigate and address the ethical shortcomings of AI applications in health care. Efforts should be made to minimize the influence of individual characteristics such as gender, race, skin color, and socioeconomic status, ensuring that population representation and sample size are carefully considered. Sufficient numbers and the quality of representative populations should be selected from diverse regions, ethnicities, and age groups to establish standardized big data models, thereby maximizing the potential of AI technologies [146,147]. It is essential to adopt a multifaceted, interdisciplinary approach; strengthen data protection systems to prevent the leakage of patient information; and conduct extensive reviews to avoid biases [148], ultimately preventing unfairness toward individuals or patient populations in the development of intelligent diagnostic or predictive tools for CA [149,150].

Advantages and Limitations of This Study

Our study has 3 strengths. First, it represents the first attempt to summarize evidence comparing ML models and scoring tools in predicting the occurrence and prognosis of CA, thereby providing an evidence-based foundation for the subsequent clinical update and development of new scoring tools or AI early warning systems in the field of CA. Second, our study encompassed 93 original studies with large sample sizes, covering 14 countries and involving 5,729,721 patients,

XSL•FO
RenderX

significantly enhancing the strength of our evidence. Third, we conducted a detailed discussion of the accuracy of different models on balanced and imbalanced data. However, this study also had the following limitations. First, most of the original studies on the prediction of CA occurrence (28/93, 30%) constructed models based solely on imbalanced data without validating them on balanced data. Second, many model validation processes primarily used internal validation through random sampling, lacking external multicenter validation to examine their generalizability. Third, due to potential differences in the predictive performance of different models for outcome events, despite our in-depth discussion of various ML models and datasets, the limited number of studies on certain ML models restricted our ability to interpret the results of ML applications in CA more comprehensively. Fourth, due to the small number of included studies, we did not strictly distinguish between IHCA and OHCA populations when summarizing the predictors of CA. Fifth, as this review only included English-language original studies, there may be potential language bias.

Conclusions

Current traditional scoring tools have demonstrated relatively ideal efficacy in predicting the occurrence and prognosis of CA. On the basis of this review, ML appeared to offer greater advantages in predicting the occurrence of CA, neurological functional prognosis, and mortality outcomes. However, for predicting outcomes associated with ROSC after CA, ML models did not seem to significantly outperform traditional models. Therefore, in future studies on CA, researchers may explore the systematic updating of traditional scoring tools based on the superior performance of ML in specific outcomes. This approach would enable the implementation of AI-driven enhancements within complex and diverse clinical data, thereby assisting clinicians in monitoring and providing early warnings for multiple predictive factors. For outcomes that are still unpredictable, multicenter large-sample studies are warranted.

Abstract

Background: eHealth literacy has increasingly emerged as a critical determinant of health, highlighting the importance of identifying its influencing factors; however, these factors remain unclear. Numerous studies have explored this concept across various populations, presenting an opportunity for a systematic review and synthesis of the existing evidence to better understand eHealth literacy and its key determinants.

Objective: This study aimed to provide a systematic review of factors influencing eHealth literacy and to examine their impact across different populations.

Methods: We conducted a comprehensive search of papers from PubMed, CNKI, Embase, Web of Science, Cochrane Library, CINAHL, and MEDLINE databases from inception to April 11, 2023. We included all those studies that reported the eHealth literacy status measured with the eHealth Literacy Scale (eHEALS). Methodological validity was assessed with the standardized Joanna Briggs Institute (JBI) critical appraisal tool prepared for cross-sectional studies. Meta-analytic techniques were used to calculate the pooled standardized β coefficient with 95% CIs, while heterogeneity was assessed using I2, the Q test, and τ2. Meta-regressions were used to explore the effect of potential moderators, including participants' characteristics, internet use measured by time or frequency, and country development status. Predictors of eHealth literacy were integrated according to the Literacy and Health Conceptual Framework and the Technology Acceptance Model (TAM).

Results: In total, 17 studies met the inclusion criteria for the meta-analysis. Key factors influencing higher eHealth literacy were identified and classified into 3 themes: (1) actions (internet usage: β=0.14, 95% CI 0.102-0.182, I2=80.4%), (2) determinants (age: β=–0.042, 95% CI –0.071 to –0.020, I2=80.3%; ethnicity: β=–2.613, 95% CI –4.114 to –1.112, I2=80.2%; income: β=0.206, 95% CI 0.059-0.354, I2=64.6%; employment status: β=–1.629, 95% CI –2.323 to –0.953, I2=99.7%; education: β=0.154, 95% CI 0.101-0.208, I2=58.2%; perceived usefulness: β=0.832, 95% CI 0.131-1.522, I2=68.3%; and self-efficacy: β=0.239, 95% CI 0.129-0.349, I2=0.0%), and (3) health status factor (disease: β=–0.177, 95% CI –0.298 to –0.055, I2=26.9%).

Conclusions: This systematic review, guided by the Literacy and Health Conceptual Framework model, identified key factors influencing eHealth literacy across 3 dimensions: actions (internet usage), determinants (age, ethnicity, income, employment status, education, perceived usefulness, and self-efficacy), and health status (disease). These findings provide valuable guidance for designing interventions to enhance eHealth literacy.

KEYWORDS

meta-analysis; eHealth literacy; eHealth; Technology Acceptance Model; Literacy and Health Conceptual Framework; social determinants of health; digital health; consumer

Introduction

The links between literacy and health have attracted increasing international attention over the past decade [1]. Numerous studies have demonstrated that health outcomes, such as health behaviors and disease risks, are influenced by various forms of literacy, including health literacy, eHealth literacy, and other related literacy [2]. Especially in an era characterized by advanced information technology, the importance of eHealth literacy cannot be more pronounced due to the widespread adoption of digital health applications. eHealth literacy is defined as the capacity to search for, access, and analyze health information from electronic resources to solve health problems [3]. According to the Lily model of eHealth literacy, the 6 core literacies of eHealth literacy encompass essential aspects of health literacy and digital information literacy, including traditional literacy, health literacy, information literacy, scientific literacy, media literacy, and computer literacy [3]. Therefore, eHealth literacy not only directly influences the adoption of eHealth by users [3] but also is founded as a new determinant of health [4].

Studies have also found that eHealth literacy is positively associated with different aspects of health promotion and care. It influences an individual's acquisition, judgment, and application of health knowledge [5]. It also shapes their perception and attitude toward health and disease [6,7], especially in an era of advanced social media. eHealth literacy also plays a facilitating role in promoting the positive adoption of health-promoting behaviors [8-10]. Ultimately, this has a positive impact on health-related physical, behavioral, psychosocial, and cognitive outcomes [2,11,12]. Thus, understanding the determinants of eHealth literacy to identify intervention targets is of significant research value. Such efforts can enhance patients' eHealth literacy levels, ultimately contributing to improved health outcomes.

It is crucial for health care professionals to assess an individual's eHealth literacy before developing and conducting target interventions. Some tools have been developed to measure eHealth literacy. These include the eHealth Literacy Scale (eHEALS), the eHealth Literacy Questionnaire (eHLQ) [13], and the Digital Health Literacy Instrument (DHLI) [14]. eHEALS, developed by Norman and Skinner [15], is the most widely used scale to assess eHealth literacy. It comprises 8 items and encompasses 3 dimensions (application, evaluation, and decision-making capabilities related to online health information and services). eHEALS has been translated into different languages and validated as exhibiting robust reliability and validity. Additionally, numerous studies have evaluated individuals' eHealth literacy. However, the findings have not been systematically summarized. Therefore, this review aimed to synthesize the findings of studies that have used eHEALS to assess eHealth literacy. Although many studies have explored eHealth literacy among various populations, such as students, older adults, and the general population, the results have been inconsistent. Additionally, the influencing factors of eHealth literacy are diverse, including sociodemographic factors (ie, age, gender, and educational level), health-related behaviors, and internet usage. Despite the large number of cross-sectional surveys conducted to explore these factors, complex influences from both micro and macro levels have been identified, with results varying significantly [16]. The Literacy and Health Conceptual Framework, developed by the Literacy and Health Research Program in Canada, outlines 4 key themes: actions, determinants, literacy, and effects of literacy. Actions (eg, policy, training) and determinants (eg, sociodemographic status) can influence literacy (eg, general, health, and eHealth literacy). The Technology Acceptance Model (TAM) is a widely used theoretical framework. TAM posits that perceived usefulness and perceived ease of use directly influence an individual's attitude toward using a technology, in turn, affecting their intention to use the technology. TAM has been widely used to explore the user acceptance of various information systems and technologies. Thus, the Literacy and Health Conceptual Framework [1] and TAM can serve as theoretical frameworks to summarize and integrate the influencing factors of eHealth literacy [17,18].

Consequently, we systematically reviewed studies on eHealth literacy among different populations and synthesized their findings through a meta-analysis to understand the eHealth literacy status and examine its influencing factors.

Methods

Overview

This systematic literature review was conducted in accordance with the Cochrane Collaboration [19] and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [20] (Multimedia Appendix 1). The study was registered in PROSPERO (International Prospective Register of Systematic Reviews; ID CRD42022383384).

Search Strategy

We searched PubMed, CNKI, Embase, Web of Science, Cochrane Library, CINAHL, and MEDLINE databases from inception to April 11, 2023, to obtain a preliminary list of relevant studies. To develop search strategies, we checked 2 main sets of keywords: (1) eHealth literacy and corresponding synonyms (digital health literacy, electronic health literacy, e-health literacy, online health literacy, etc) and (2) influencing factors and corresponding synonyms. For both sets of keywords, we also reviewed the thesaurus and Medical Subject Headings (MeSH) terms. Next, we developed a search strategy for each database. An expert in information retrieval was consulted during this process. After formulating the initial search strategy, we conducted a preliminary search for each database. The search terms and results for each database were then sent to the expert for confirmation and refinement, ensuring the accuracy and comprehensiveness of the search strategy across all databases.

XSL•FO
RenderX

The detailed strategies for the different databases are presented in Multimedia Appendix 2. These search terms were used to search titles and abstracts in all the selected databases without applying any filters or limits.

Eligibility Criteria and Study Selection

We included all studies that were written in English or Chinese and reported the eHealth literacy status measured with eHEALS. For influencing factor analysis, we excluded (1) studies that did not examine the relationship between influencing factors and eHealth literacy or included only univariate analysis; (2) studies that did not provide effect size indicator values in the results or values that could not be converted to β, SE, and 95% CI values; and (3) reviews, case studies, poster presentations, and conference presentations. However, we examined their references to identify additional relevant papers for inclusion. We also manually searched the reference lists of studies in the final sample for additional relevant papers.

Data Extraction and Management

Two reviewers (authors HZ and QL) independently screened each identified study in duplicate for inclusion, initially reviewing the title and abstract, followed by a full-text review, as necessary. All discrepancies were resolved through consensus. We extracted the following data from each study: country, year conducted, sample size, questionnaire used to measure eHealth literacy, status of eHealth literacy, influencing factors with details, and effect size values. Where relevant data were missing or incomplete, we contacted the authors for clarification and verification.

Critical Appraisal of Methodological Quality

The included studies were critically appraised for methodological quality using the standardized Joanna Briggs Institute (JBI) critical appraisal tool prepared for cross-sectional studies and cohort studies [21] (Multimedia Appendix 3). Each study was evaluated by 2 independent assessors.

Data Analysis

Descriptive Statistics and Narrative Synthesis of the Studies in the Final Sample

Descriptive statistics were used to summarize the characteristics of the included studies. Narrative synthesis was used to synthesize the findings related to eHealth literacy in the studies, for which means (SDs) were reported. The year, country, sample size, study population, mean age (SD) of the sample, funding, mean score (SD) of eHEALS, and influencing factors were examined.

Random-Effects Meta-Analyses and Fixed-Effects Meta-Analyses to Examine Factors Affecting eHealth Literacy

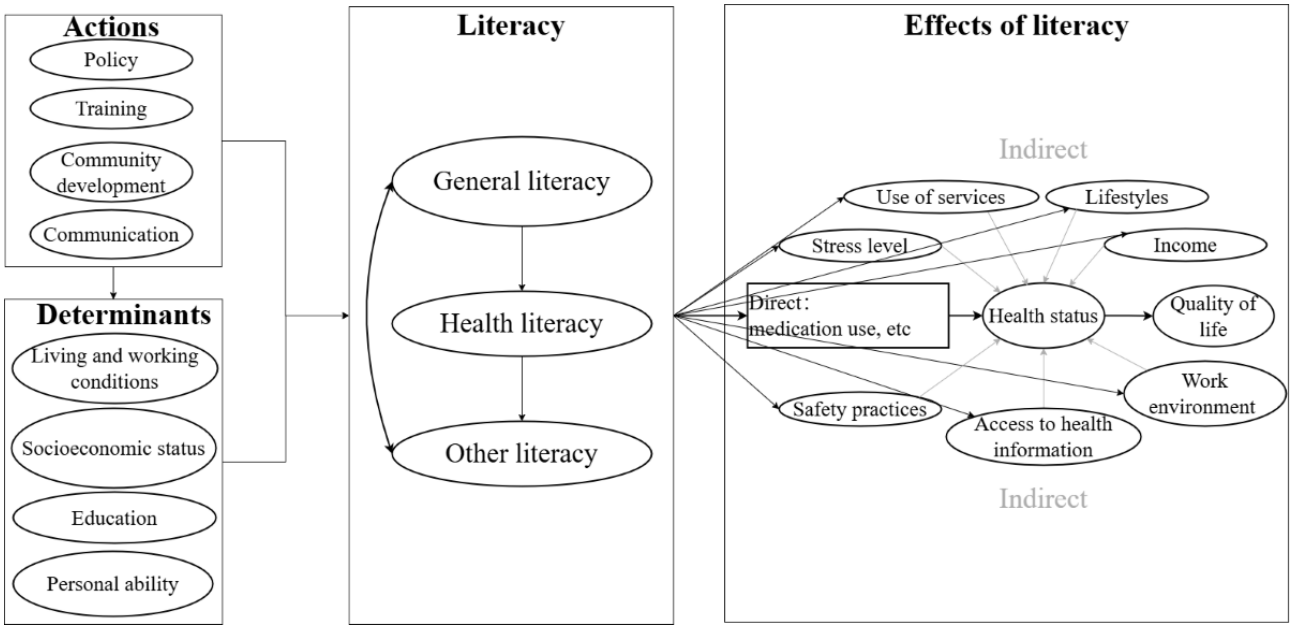
Meta-analyses were conducted separately for eHealth literacy and each influencing factor using StataMP 17 software. Pooling was considered when at least 2 studies assessed eHealth literacy and its influencing factors. Standardized β coefficient estimates and their 95% CIs were calculated using random- or fixed-effects meta-analysis based on I^2 and the number of studies [22,23]. If $I^2 \leq 50\%$, the study was considered homogeneous and a fixed-effects model was used for meta-analysis. If $I^2 > 50\%$, the random-effects model was selected. If $I^2 > 85\%$ and the source of heterogeneity could not be determined, meta-analysis was not performed and descriptive analysis was used. In addition, the fixed effects model was considered if the number of studies that reported eHealth literacy's influencing factors was small (<5) [23,24]. Forest plots were created to show the results, and all comparisons were 2-tailed using a threshold of $P \leq .05$.

The heterogeneity of effect sizes was determined using the following statistics: (1) Q test of heterogeneity, (2) τ^2 estimate of true between-study variance, and (3) I^2 statistic of the proportion of true variation in observed effects. The Egger test was used to assess the possibility of publication bias [25].

Meta-Regression Analysis to Examine the Cofounders Affecting eHealth Literacy

The effect of moderators (participants' characteristics, internet use measured by time or frequency, country development status) was measured via random-effects univariate meta-regressions using restricted maximum-likelihood estimation. For the analysis, participants were categorized into 3 groups: students (coded as 1), the general population (coded as 2), and older adults (coded as 3). Regarding the country variable, studies conducted in low- to middle-income countries were coded as 1, while those conducted in high-income countries were coded as 2. The development status of a country was queried on the United Nations Big Data Global Platform [26]. To conduct cofounder analyses and obtain robust coefficient estimates, we followed the recommendations of Fu et al [27] and conducted moderator analysis only when at least 4 studies per group were available.

Assessment of the Quality of Evidence



The quality of evidence for the results of the meta-analyses was evaluated by authors QL and HZ using the GRADE (Grading of Recommendations, Assessment, Development, and Evaluation) framework [28]. For each factor influencing eHealth literacy, the initial quality of evidence was considered high and was downgraded by 1 level for every significant concern identified within the domains of risk of bias, inconsistency, indirectness, imprecision, and publication bias. The risk of bias was evaluated by examining potential biases in participant selection, measurement instruments, data collection, and analysis. The inconsistency domain was assessed using I^2 values, and the GRADE quality was downgraded when I^2 was 50% or higher. Indirectness was evaluated based on whether the studies directly assessed the influence of various factors on eHealth literacy. Imprecision was determined by the width of the CIs of the estimates and the sample size. Publication bias was assessed using the Egger test, with GRADE quality being downgraded for statistically significant results ($P<.05$) in this test.

Theoretical Support for the Integration Framework of Influencing Factors

This study combined the Literacy and Health Conceptual Framework [1] and TAM [17,18] to synthesize and present factors that influence eHealth literacy, as identified in the literature review. The Literacy and Health Conceptual Framework (Figure 1), developed through the Literacy and Health Research Program sponsored by the Social Sciences and Humanities Research Council of Canada, comprises 4 key themes: actions, determinants, literacy, and effects of literacy. Actions and determinants can impact literacy and the effects of literacy. Each theme is further subdivided into various conceptual elements that have been delineated in greater detail. Arrows and line segments within the framework illustrate the interconnections and relationships among these elements. Actions include policy, training, community development, and communication. Determinants comprise sociodemographic status, living and working status, education, and personal ability. Literacy comprises health literacy, general literacy, and other literacy. In our study, we used the Literacy and Health Conceptual Framework as the primary structure to organize all influencing factors (Figure 2). We identified literacy as eHealth literacy and summarized its influencing factors into actions and determinants.

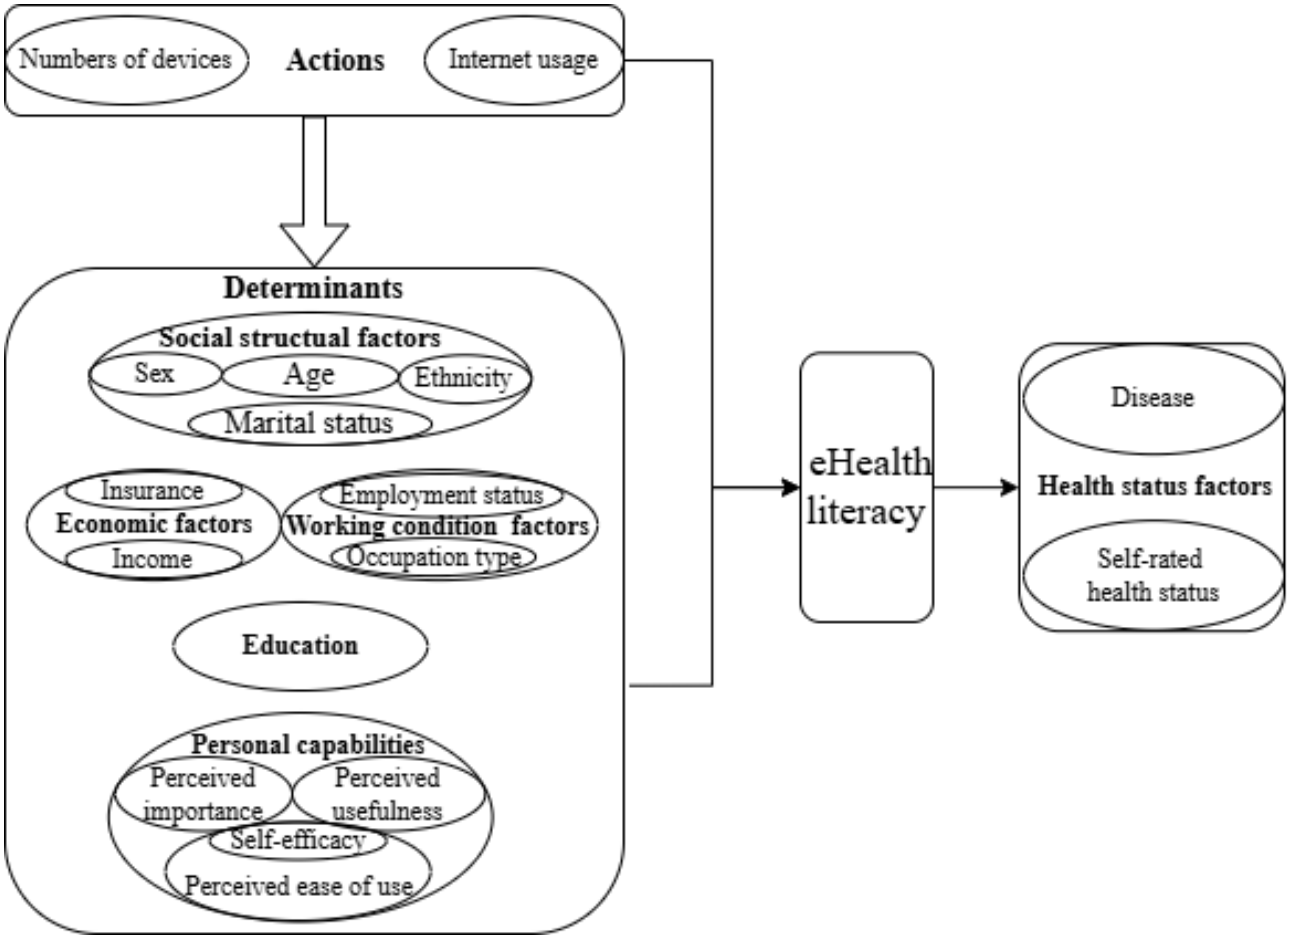

Figure 1. The Literacy and Health Conceptual Framework.

TAM, a theoretical framework developed by Venkatesh and coworkers [17,18], predicts individuals' adoption of new information technologies and has been extensively applied in eHealth domains. TAM posits that perceived usefulness and perceived ease of use mediate individuals' intention to use technology by shaping their attitudes toward it. The third iteration of this model, TAM3, expands on the original by integrating additional components, such as computer self-efficacy, which reflects an individual's confidence in their ability to perform tasks using a computer. Studies have found that perceived importance is strongly associated with both perceived usefulness and eHealth literacy [29-31]. In our study, we categorized key aspects of TAM3, including perceived usefulness, perceived importance, and self-efficacy, under personal capabilities. This emphasized that technology acceptance abilities are part of an individual's overall capabilities (Figure 1).

Results

Literature Selection Process and Characteristics of the Final Studies

The process of literature search and selection is shown in Figure 3. In total, 1295 potential papers were identified, but only 17 (1.3%) were identified as eligible and included in the final review to analyze the relationship between eHealth literacy and influencing factors (Figure 2). All the studies were cross-sectional in design (Table 1 and Table S1 in Multimedia Appendix 4). They were conducted in Turkey (n=1, 6%), China (n=1, 6%), Italy (n=1, 6%), South Korea (n=2, 12%), Serbia (n=1, 6%), Sweden (n=1, 6%), Australia (n=1, 6%), Vietnam (n=1, 6%), Kuwait (n=1, 6%), Saudi Arabia (n=1, 6%), Thailand (n=2, 12%), the United States (n=1, 6%), Malaysia (n=1, 6%), the United Kingdom (n=1, 6%), and Portugal (n=1, 6%). The study samples were the general population (n=3, 17.6%), older adults (n=3, 17.6%), nursing students (n=2, 12%), adult residents of urban and rural communities (n=1, 6%), undergraduate and postgraduate students (n=1, 6%), only undergraduate students (n=1, 6%), middle school students (n=1, 6%), adolescents (n=1, 6%), adults (n=1, 6%), medical students (n=2, 12%), and army personnel (n=1, 6%). Only 10 (59%) studies reported the age of participants. The mean age of students ranged from 20.13 (SD 2.16) to 24 (SD 1.48) years, and the mean age of adults ranged from 47 (SD not reported) to 78 (SD 2.4) years. All the studies were published in 2015 and later, and the majority (n=14, 82%) were published between 2018 and 2023. In addition, 15 (88%) studies had sample sizes greater than 100.

Table 1. Details of the 17 studies included in this meta-analysis.

Study	Country	Study population	Age (years), mean (SD)	eHealth literacy status[a], mean (SD)
Tennant et al [9]	United States	Older adults	67.46 (9.98)	29.05 (5.75)
Alhuwail and Abdulsalam [29]	Kuwait	General population	NR[b]	28.63 (5.6)
Sinan et al [31]	Turkey	Nursing students at nursing departments of 2 state universities in Ankara, Turkey	21.14 (1.62)	29.28 (4.73)
Zuo et al [32]	China	Adult residents of urban and rural communities	NR	32 (24.40)[c], 28 (21.34)[d]
Del Giudice et al [33]	Italy	Undergraduate and postgraduate students	NR	28.2 (6.2)
Park [34]	South Korea	Middle school students	NR	28.72 (5.68)
Gazibara et al [35]	Serbia	Adolescents (14-19 years)	NR	26.0 (10.0)
Ghazi et al [36]	Sweden	Older adult participants of the Swedish National Study on Aging and Care, Blekinge (SNAC-B)	78 (2.4)	27.5 (10.8)
Richtering et al [37]	Australia	Adults with moderate-to-high risk for a cardiovascular disease event	67 (8.0)	27.2 (6.59)
Hoang Nguyen and Bich Thi Le [38]	Vietnam	Medical students	NR	27.03 (3.54)
Almoajel et al [39]	Saudi Arabia	General population	24 (1.48)	28.79 (6.75)
Wongjinda and Taneepanichsakul [40]	Thailand	Royal Thai Army (RTA) personnel	NR	31.6 (NR)
Lee et al [41]	Malaysia	General population	47 (NR)	27.38 (6.59)
Kim and Jeon [42]	South Korea	Nursing students	21.69 (2.77)	29.68 (NR)
Holch and Marwood [43]	United Kingdom	Undergraduate students	20.13 (2.16)	29.46 (4.91)
Tanasombatkul et al [44]	Thailand	Medical students	22 (NR)	33.45 (3.28)
Martins et al [45]	Portugal	Older adults	67.36 (7.23)	NR

[a]Measured with the eHealth Literacy Scale (eHEALS).

[b]NR: not reported.

[c]Median (IQR) of eHEALS for rural community residents.

[d]Median (IQR) of eHEALS for urban community residents.

Quality of Included Studies

Based on the JBI critical appraisal tool, the overall quality of the included studies was high. Of the 17 studies, 6 (35%) achieved a perfect score of 100%, 7 (41%) scored 87.5%, 3 (18%) scored 75%, and only 1 (5%) scored 62.5% (Multimedia Appendix 3). This result demonstrated that the majority of the included studies (n=13, 76%) were rated as high-quality studies, with scores of 75% or higher [46].

Influencing Factors

According to the Literacy and Health Conceptual Framework [1], the factors influencing eHealth literacy were categorized into 3 themes: actions, determinants, and health status (Figure 2). Perceived importance, perceived usefulness, and self-efficacy, as defined by TAM3 [17], were integrated under the broader concept of personal capabilities. All the outcomes of the meta-analyses are presented in Table 2.

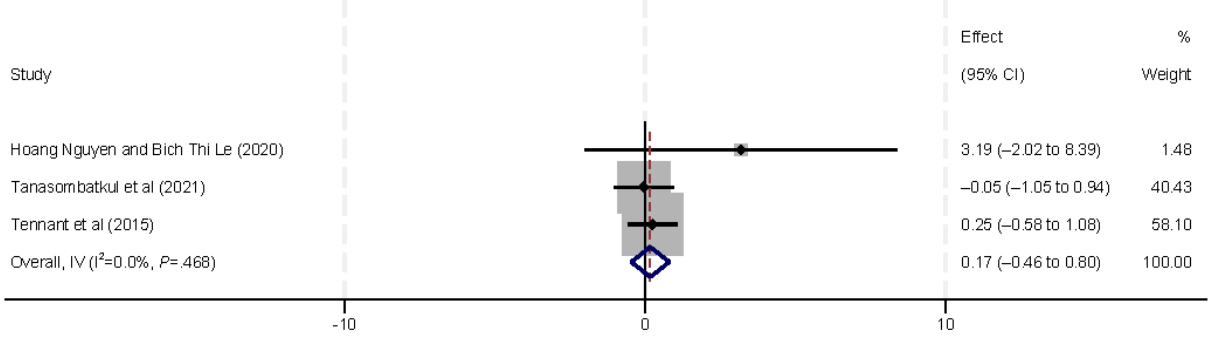
Health status					
Self-rated health status	3 (18); 1451	0.564 (–0.198 to 1.323)	17.3	.47	Moderate
Disease	7 (41); 2817	–0.177 (–0.298 to –0.055)[b]	26.9	.29	High

[a]GRADE: Grading of Recommendations, Assessment, Development, and Evaluation.



[b]The factor was significant in the meta-analysis.

[c]N/A: not applicable (as <3 experiments were analyzed).

Influencing Factors in the Actions Theme

The influencing factors in actions included the number of devices and internet usage. Three studies [9,38,44] identified an association between eHealth literacy and the number of devices (Figure 4). These studies examined whether the number of electronic devices an individual owns is correlated with their eHealth literacy. However, the results of our analysis did not yield any statistically significant findings. Eight studies [29,31,33,37,40,42,44,45] demonstrated a positive correlation between eHealth literacy and internet usage (β=0.14, 95% CI 0.10-0.18).

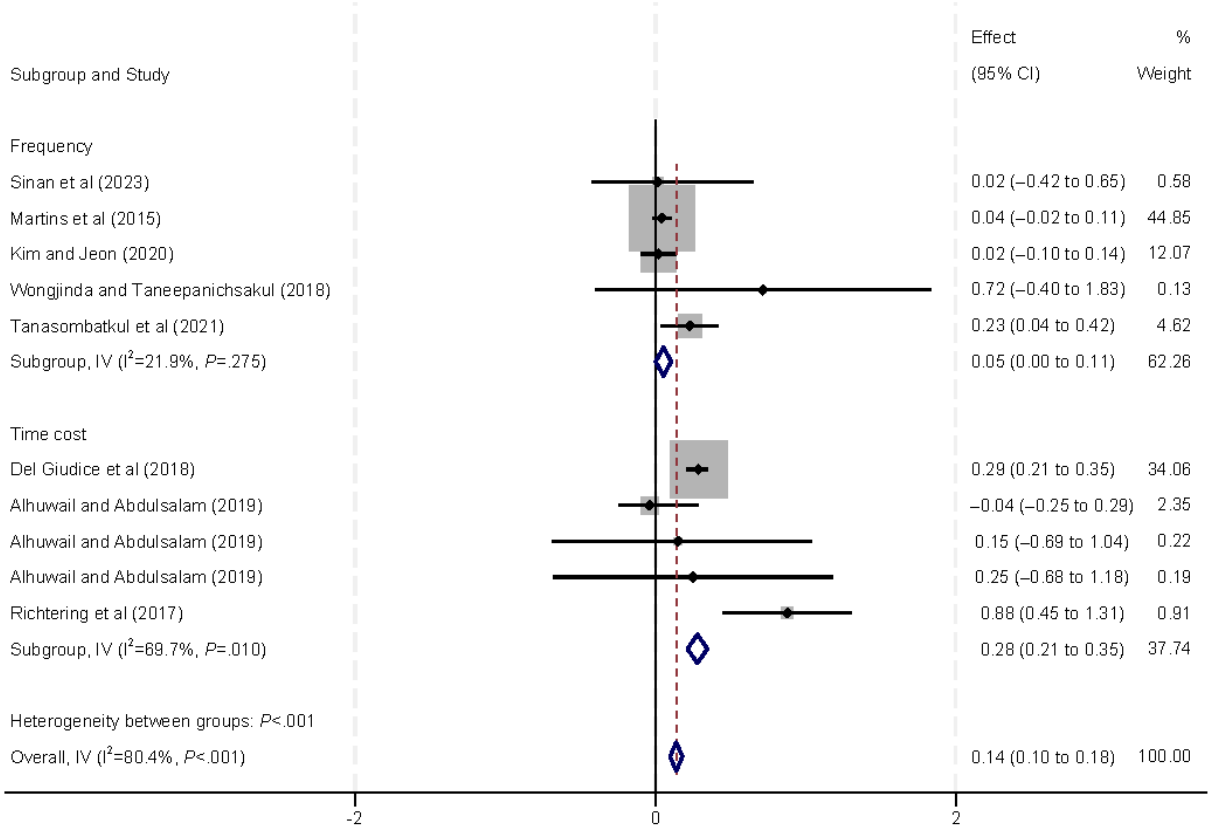


Figure 4. Forest plot of the meta-analytic association between the number of devices and eHealth literacy. IV: inverse variance weighted.

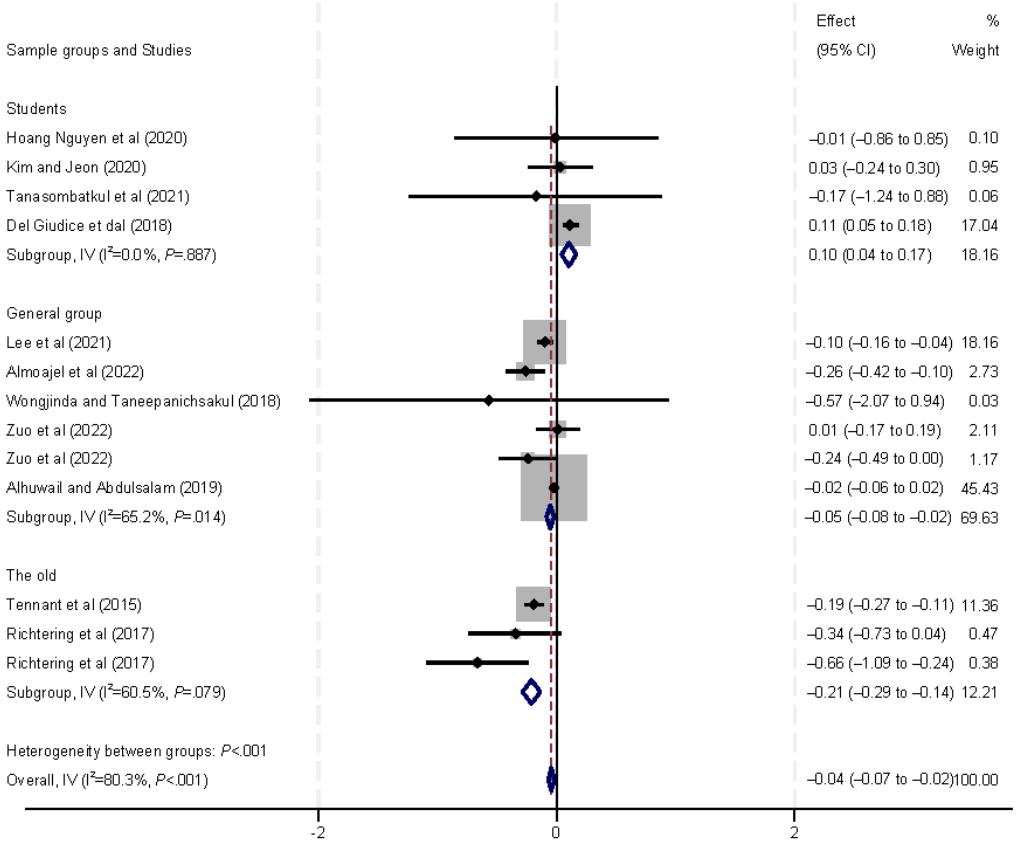
XSL•FO
RenderX

Furthermore, we conducted subgroup analyses to examine internet use measured by duration or frequency (Figure 5). The results from both subgroups showed a positive correlation between internet usage and eHealth literacy, indicating that higher levels of internet use are associated with increased eHealth literacy.

Figure 5. Forest plot of the meta-analytic association between internet usage and eHealth literacy. IV: inverse variance weighted.

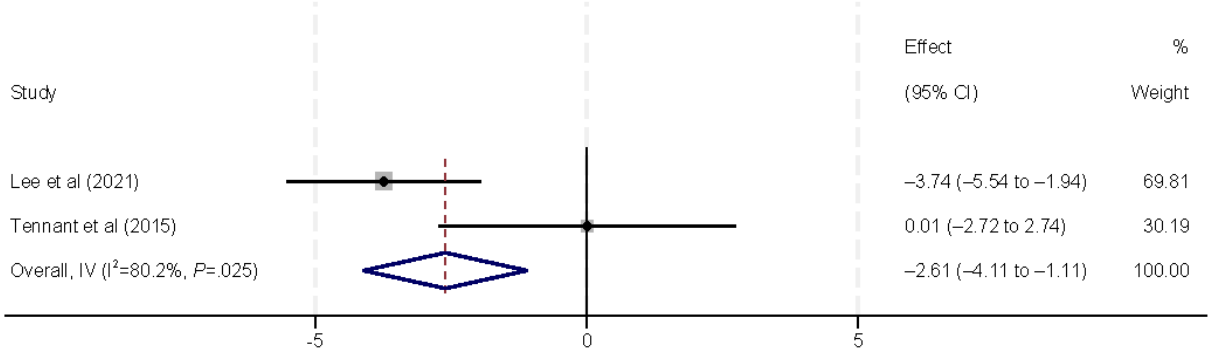
Influencing Factors in the Determinants Theme



Social determinants of health, economic and working conditions, education, and personal capabilities were included under the determinants theme.

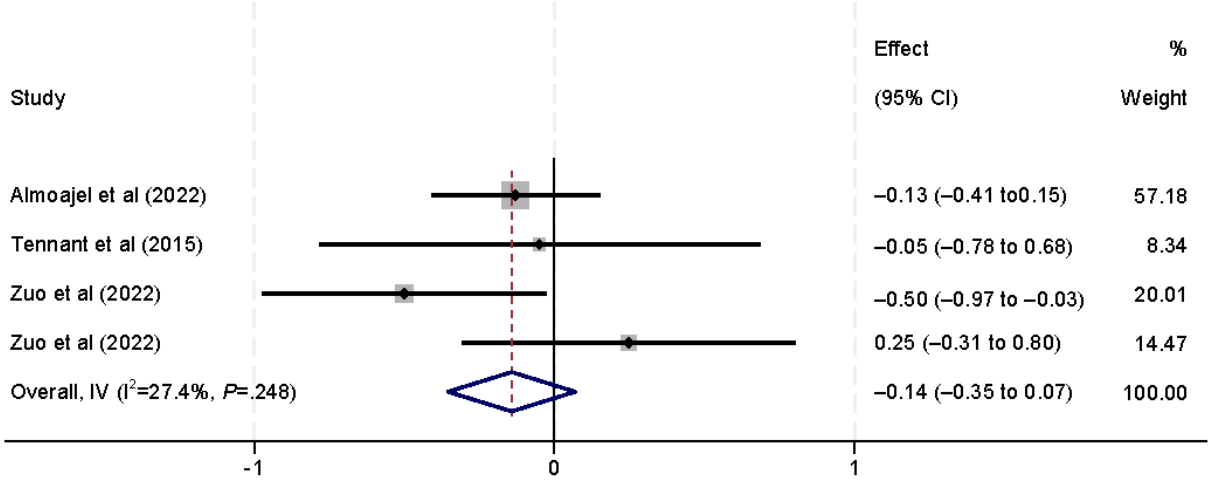
Social Determinants of Health

The following social determinants of health were analyzed to assess their relationship with eHealth literacy: age, ethnicity, marital status, and sex. The age of participants was significantly associated with eHealth literacy (Figure 6). Only 1 (13%) [33] of the 8 (47%) studies assessing eHealth literacy found a positive correlation with age, with the other 9 (53%) studies [9,29,37-42,44] reporting a negative correlation. Subgroup analyses based on age revealed that studies conducted among students showed a positive correlation between eHealth literacy and age (β=0.10, 95% CI 0.04 to –0.17). Conversely, in the general population (β=–0.05, 95% CI –0.08 to –0.02) and among older adults (β=–0.21, 95% CI –0.29 to –0.14), eHealth literacy was found to be negatively correlated with age.



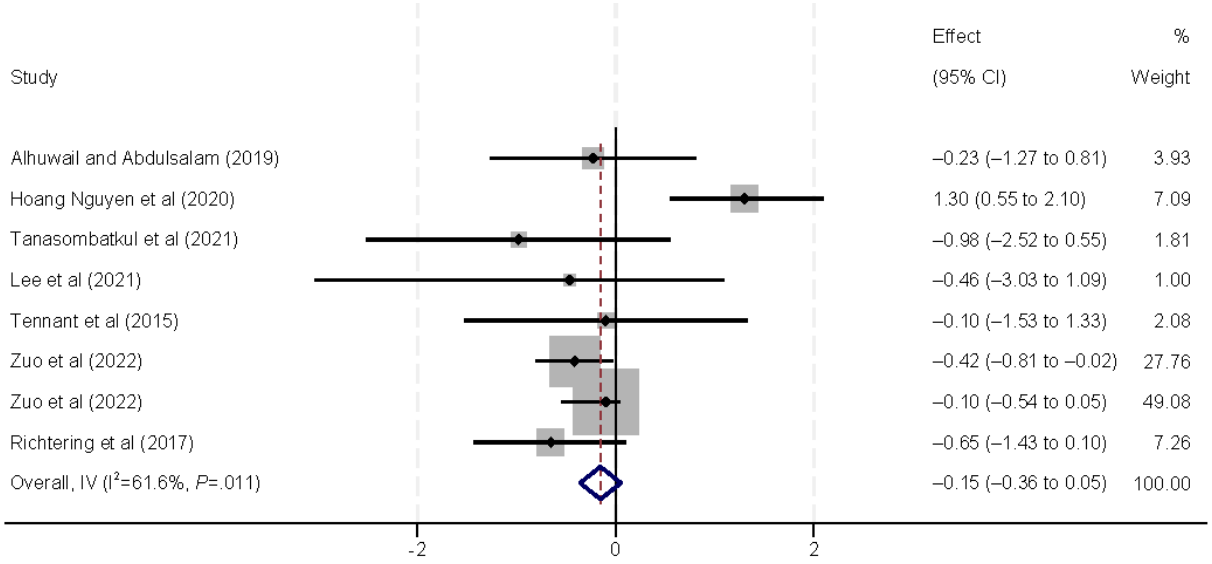
XSL•FO
RenderX

Figure 6. Forest plot of the meta-analytic association between age and eHealth literacy. IV: inverse variance weighted.



Ethnicity was also found to affect eHealth literacy (β=–2.61, 95% CI –4.11 to –1.11) [9,41]. Lee et al [41] found that lower eHealth literacy is associated with patients of minority ethnicity (Malaysian Chinese). However, Tennant et al [9] found that ethnicity is not significantly associated with eHealth literacy (Figure 7). Marital status was also included in the analysis (Figure 8). However, no statistically significant association was found, consistent with the results of the 3 (18%) studies [9,32,39].

Figure 7. Forest plot of the meta-analytic association between ethnicity and eHealth literacy. IV: inverse variance weighted.



XSL•FO
RenderX

Figure 8. Forest plot of the meta-analytic association between marital status and eHealth literacy. IV: inverse variance weighted.

Seven studies [9,29,32,37,38,41,44] assessed the relationship between sex and eHealth literacy using multivariate analysis (Figure 9). Of these, 6 (15%) studies [9,29,32,37,41,44] found that women are at a higher risk of low eHealth literacy than men. However, the final meta-analysis results showed no statistically significant association.

Figure 9. Forest plot of the meta-analytic association between sex and eHealth literacy. IV: inverse variance weighted.

Economic and Working Conditions

Regarding economic and working conditions, we analyzed eHealth literacy in relation to economic aspects (eg, income and insurance coverage), as well as working conditions (eg, employment status and occupation type). All 5 (29%) included studies [9,32,38,40,44] found a positive correlation between income and eHealth literacy (Figure 10), which was also confirmed by the final meta-analysis (β=0.21, 95% CI 0.06-0.35). However, in subgroup analyses, the correlation between income and eHealth literacy was only confirmed in the general population (β=0.63, 95% CI 0.36-0.91). Private insurance is also considered an economic factor. Neither of the 2 (12%) included studies [37,39] found a correlation between the presence or absence of private insurance and the level of eHealth literacy, which aligns with the findings of our meta-analysis (Figure 11). Unemployment status was identified as a risk factor for eHealth literacy levels by Almoajel et al [39] and Lee et al [41]. However, our meta-analysis revealed substantial heterogeneity, which prevented reliable statistical inferences (Figure 12). Zuo et al [32] observed variations in eHealth literacy according to occupation type, but these findings were not supported by the final results of our meta-analysis (Figure 13).

XSL•FO
RenderX

XSL•FO
RenderX

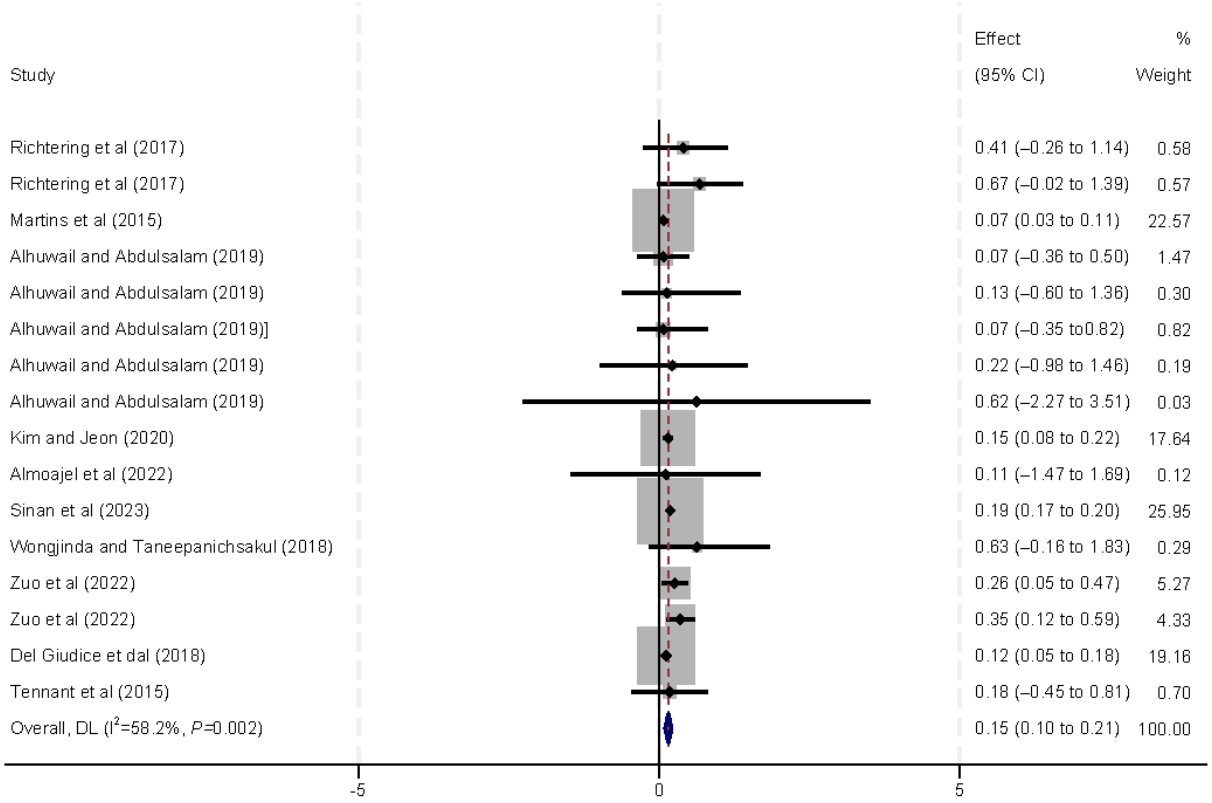

Figure 13. Forest plot of the meta-analytic association between occupation type and eHealth literacy. IV: inverse variance weighted.

Education

As shown in Figure 14, 10 (59%) studies [9,29,31-33,37,39,40,42,45] identified lower educational status or a lack of formal education as being associated with lower eHealth literacy (β=0.15, 95% CI 0.10-0.21).

Figure 14. Forest plot of the meta-analytic association between education and eHealth literacy. DL: DerSimonian and Laird.

Personal Capabilities

The personal capabilities of perceived importance, perceived usefulness, and self-efficacy were found to significantly influence eHealth literacy (Figures 15-17). Perceived importance [29,31,40], perceived usefulness (β=0.83, 95% CI 0.13-1.52) [29,40], and self-efficacy (β=0.24, 95% CI 0.13-0.35) [42,43] were positively correlated with eHealth literacy levels in all included studies.

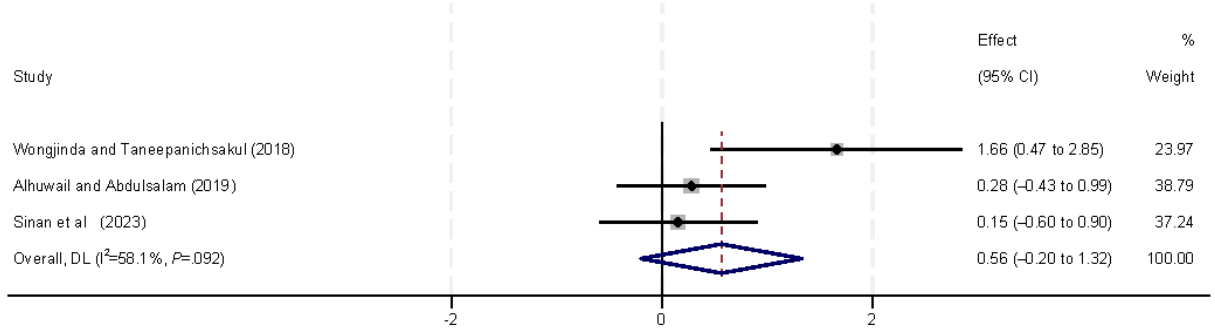

Figure 16. Forest plot of the meta-analytic association between perceived usefulness and eHealth literacy. IV: inverse variance weighted.

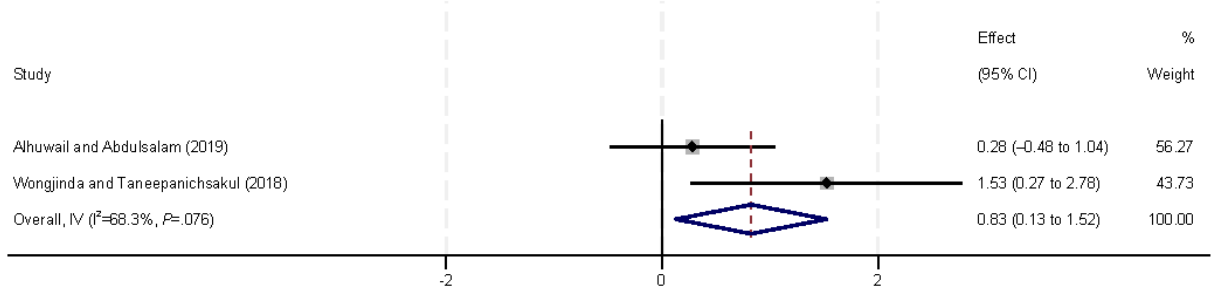

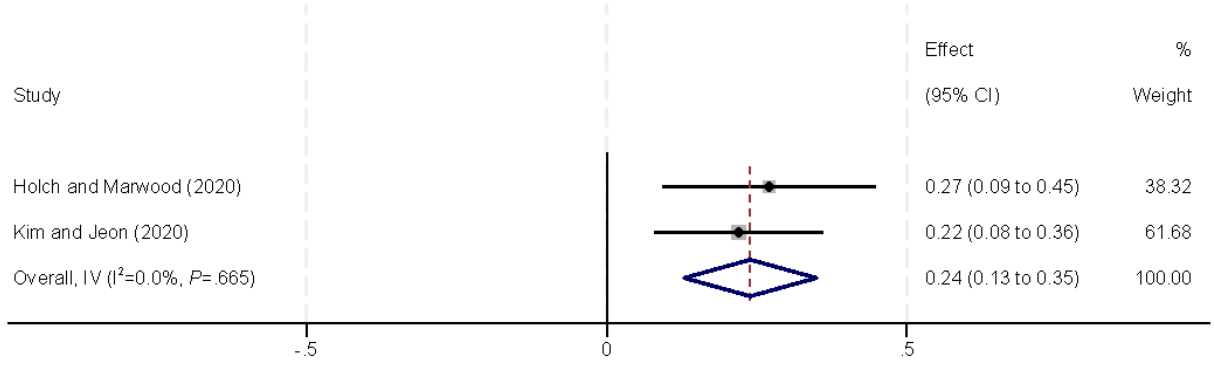

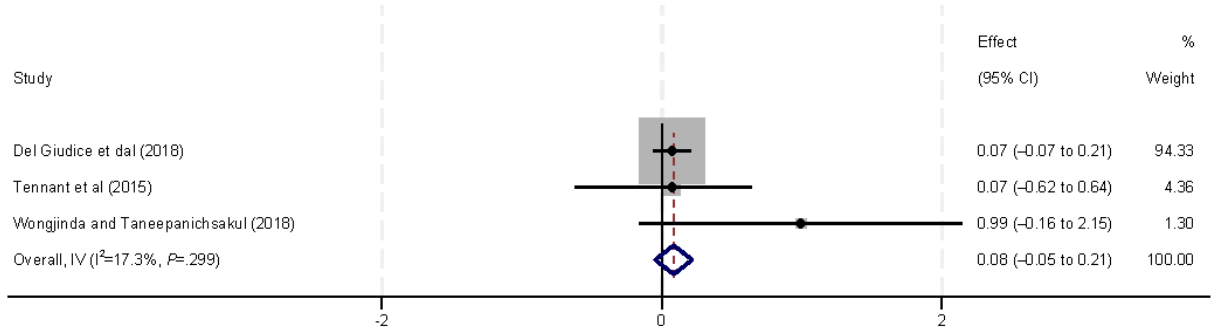

Figure 17. Forest plot of the meta-analytic association between self-efficacy and eHealth literacy. IV: inverse variance weighted.

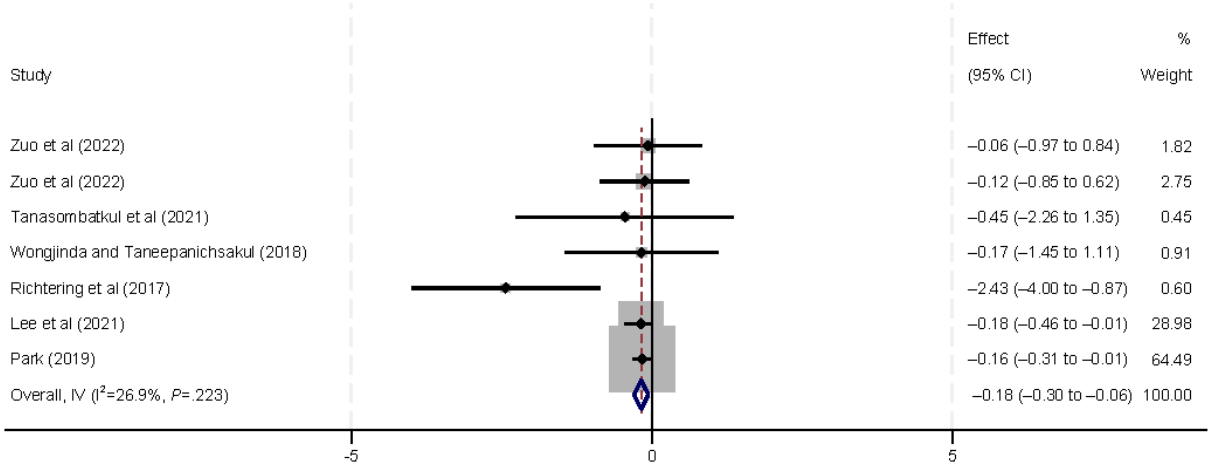
Influencing Factors in the Health Status Theme



Health status, specifically self-rated health and disease status, was found to significantly influence eHealth literacy (Figures 18 and 19). According to Del Giudice et al [33], Tennant et al [9], and Wongjinda and Taneepanichsakul [40], individuals with better self-rated health exhibit higher levels of eHealth literacy. The 6 (35%) included studies [32,34,37,40,41,44] found that participants with existing disease or at a higher risk for disease have lower levels of eHealth literacy (β=–0.15, 95% CI –0.8 to –0.16).

XSL•FO
RenderX

Figure 19. Forest plot of the meta-analytic association between disease and eHealth literacy. IV: inverse variance weighted.

Meta-Regression Analyses to Examine Cofounders Affecting eHealth Literacy

In the meta-regression analysis of confounding factors, only age grouping significantly moderated the relationship between income and eHealth literacy (Table 3). For other influencing factors, neither age nor the developmental level of the country where the study was conducted was identified as a significant confounding factor.

Table 3. Confounder analysis results.

Confounder and influencing factors	β coefficient (SE)	*t* test (*df*)	*P* value	I^2 (%)	τ^2

[a]Significant in meta-analyses.

[b]Significant *P* value.

Discussion

Principal Findings

We summarized and analyzed the findings from relevant scientific studies, highlighting significant variability in the reported factors influencing eHealth literacy across different study populations. Our meta-analysis indicated that the majority of influencing factors are demographic variables (eg, age, ethnicity) and social determinants of health (eg, income, education). Additionally, we identified factors amenable to clinical intervention, such as internet usage, self-efficacy, and the perceived usefulness of eHealth. However, most of these factors did not achieve a high-level grade according to the GRADE framework.

Influencing Factors of eHealth Literacy

Numerous cross-sectional studies have identified various influencing factors of eHealth literacy. This study categorized the influencing factors into 3 main themes based on the Literacy

XSL•FO
RenderX

and Health Conceptual Framework and TAM. In the *actions* theme, this study revealed that internet usage is positively associated with eHealth literacy. A possible explanation is that eHealth literacy encompasses an individual's comprehensive ability to seek, discover, understand, evaluate, and apply health information obtained through electronic channels to address health-related issues. According to the eHealth literacy Lily model, individuals who use the internet more frequently tend to exhibit higher levels of information literacy, media literacy, and computer literacy [15]. This enables them to find and access health information through electronic channels more easily, thereby enhancing their eHealth literacy. Furthermore, some studies have identified a significant negative correlation between computer use stress and eHealth literacy among users [47]. Additionally, users with higher internet usage frequency tend to exhibit stronger self-efficacy in using eHealth technologies, which may reduce their computer use stress and, consequently, enhance their ability to access and use internet health information and services [48]. Recent studies have also confirmed that eHealth literacy can be improved by internet use interventions [49]. Therefore, it is beneficial for health care professionals to provide health education that enhances internet skills, such as training in searching for and evaluating health information.

In the *determinants* theme, various social determinants of health and other complex demographic factors are included. Factors such as age, ethnicity, economic status, and education are closely associated with eHealth literacy [9,14]. The effect of age varies across different population subgroups. Among student groups, eHealth literacy is positively correlated with age, whereas in the general population and among older adults, the correlation is negative. According to socioemotional selectivity theory [50], individual needs change with age. Young people tend to engage in growth-related activities, such as accumulating knowledge and advancing their careers [51]. Consequently, students are typically more active in digital environments, due to both their educational settings and their personal interests, which increasingly leverage information technology for learning and communication [52]. This constant interaction likely enhances their eHealth literacy as they progress through their academic careers. As people grow older, their values shift toward meaning and social needs [51]. When users are not yet aware of their health-related needs, they are less likely to proactively seek health information, hindering actions that could enhance their eHealth literacy. Additionally, research has shown that with aging, especially in the older adult phase, cognitive and physiological decline makes it more challenging to perceive and manage eHealth-related technologies [53]. This reduced ease of use can result in lower adoption of eHealth technologies, making it challenging to improve eHealth literacy levels. Other social determinants of health, such as ethnicity, economic status, and education, contribute to this issue in complex and often unmodifiable ways, closely intertwined with the digital divide [9]. A survey conducted by Choi and Dinitto [6] revealed that low-income and older populations exhibit significantly lower levels of eHealth literacy and internet usage compared to the general population in the United States. This disparity can be attributed to factors such as limited access to computers and internet technologies, financial constraints that prevent the acquisition of personal devices, and limitations caused by medical conditions and disabilities [6]. Modifiable factors that can be targeted for intervention include self-efficacy [54] and the perceived usefulness of eHealth. Self-efficacy reflects an individual's confidence in the ability [55], and eHealth literacy is defined as an ability [3]. It is reasonable to hypothesize a positive correlation between self-efficacy and eHealth literacy. Moreover, self-efficacy explains the eHealth-adopting motivation, behaviors, and awareness of appraisal and application skills [56]. Perceived usefulness is significantly correlated with eHealth literacy, even as a supplemental question for eHEALS [29,30,37]. This relationship can be explained by TAM [18]. Perceived usefulness is one of the core beliefs that determines individuals' intention to use IT, defined as the extent to which a person believes that using IT will enhance their performance [17]. Some researchers have proved that individuals with high perceived usefulness may have a more active attitude toward eHealth use [57,58]. In summary, the association between eHealth literacy and background attributes is difficult to modify. However, meso- and macrolevel approaches can be used. At the macro level, these include the level of government support and policy direction [16], for instance, providing technology subsidies or allowances to low-income individuals. Government agencies and nongovernmental organizations (NGOs) can play a significant role in recycling and refurbishing unused or discarded computers for older adults and low-income individuals. These initiatives can be cost-effective, enabling individuals to live more independently, reducing their reliance on both formal and informal support systems, and enhancing their quality of life [6]. The meso level encompasses various characteristics related to the planning, design, and development of eHealth services [16]. Emphasizing user-friendliness is essential. For example, recommendations including simplifying operational interfaces and steps optimize workflows, create more visually prominent interfaces, provide clearer system prompts, and replace technical terms with plain language and illustrations in designs tailored for older adults [57]. From an individual's micro perspective, interventions can focus on enhancing self-efficacy and perceived usefulness. Older adults who are hesitant to use the internet due to low self-efficacy in technology can be encouraged through demonstrations and educational interventions. Younger individuals with strong computer and internet skills can assist by volunteering or being employed to teach older adults how to engage with social media, browse the web, and participate in health-related activities. Particularly for low-income, homebound older adults who have limited exposure to computers and internet technology but substantial needs, it is important to emphasize the multiple benefits of internet use and to provide resources, such as equipment and training [6].

In the *health status* theme, disease was identified as a negative influencing factor for eHealth literacy [37,40,41,44]. Previous research indicates that individuals with higher eHealth literacy often achieve better health outcomes [12,59]. However, the relationship between eHealth literacy and health outcomes is complex and not strictly linear. Our study suggests a substantial overlap between populations with low eHealth literacy and those experiencing poor health conditions. Both groups are influenced by social determinants of health and are more likely to be older,

XSL•FO
RenderX

less educated, and of a lower socioeconomic status. Additionally, various studies have identified mediating factors in the relationship between health outcomes and eHealth literacy. For example, a cross-sectional study by Li et al [60] involving 802 Chinese residents revealed that social media use mediates the relationship between eHealth literacy and health-promoting behaviors. Similarly, Rabenbauer and Mevenkamp's [61] study of 224 Australian patients with chronic back pain identified self-efficacy as a mediator in the relationship between eHealth literacy and healthy habits. Therefore, further research is needed to clarify the relationship between eHealth literacy and health outcomes, particularly by exploring this connection after controlling for confounding factors. Future research could also apply health- and literacy-related theories to investigate whether additional factors moderate this relationship.

Limitations

This study has several limitations that should be acknowledged. First, only studies using the eHEALS measurement tool were included in this review. Insufficient data from other research instruments, such as the eHLQ and the Digital Health Literacy Questionnaire (DHLQ), prevented a comprehensive synthesis of findings across different tools. Second, papers written in languages other than English and Chinese were excluded from this review, potentially introducing language and publication bias. Third, due to the limited number of randomized controlled trials (RCTs) and the inability to combine their effect sizes, RCTs were not included in the meta-analyses. This exclusion is a significant limitation, as RCTs are considered the gold standard for establishing causal relationships. Their exclusion means that the meta-analysis relied more heavily on observational studies, which are more susceptible to confounding factors and bias. This reliance can limit the ability to draw firm conclusions about the causal relationship between eHealth literacy and health outcomes. Fourth, the standardized beta coefficient (β) was used as the effect size measure for data integration in this study, allowing for the inference of correlation relationships but not supporting causal inference. Moreover, the majority of studies included in the meta-analysis focused on student and adolescent populations, which limits the generalizability of the findings to broader populations. Additionally, some of the results reported I^2 exceeding 50%, indicating substantial heterogeneity. This high level of heterogeneity is expected, as eHealth literacy is significantly influenced by social and demographic characteristics, as well as variability in the measurement of influencing factors. This heterogeneity limits the generalizability of the identified factors influencing eHealth literacy. Therefore, the results of the meta-analysis and meta-regression should be interpreted with caution. Finally, all studies included in this research categorized gender using binary terms. This approach overlooks the experiences and outcomes of nonbinary and transgender individuals, potentially leading to a less comprehensive understanding of how eHealth literacy impacts various gender identities. We encourage future research to explore whether differences exist.

Conclusion

Based on the Literacy and Health Conceptual Framework, we explored the impact of various factors on users' eHealth literacy across 3 dimensions: actions, determinants, and health status. We found that users' eHealth literacy is influenced by various factors, including internet usage, age, ethnicity, income, employment status, education, perceived usefulness, self-efficacy, and disease. These findings provide valuable guidance for designing interventions to enhance eHealth literacy.

Abstract

Background: Chronic obstructive pulmonary disease (COPD) is a common chronic incurable disease. Treatment of COPD often focuses on symptom management and progression prevention using pharmacological and nonpharmacological therapies (eg, medication, inhaler use, and smoking cessation). Self-management is an important aspect of managing COPD. Self-management interventions are increasingly delivered through eHealth, which may help people with COPD engage in self-management. However, little is known about the actual content of these eHealth interventions.

Objective: This literature review aimed to investigate the state-of-the-art eHealth self-management technologies for COPD. More specifically, we aimed to investigate the functionality, modality, technology readiness level, underlying theories of the technology, the positive health dimensions addressed, the target population characteristics (ie, the intended population, the included population, and the actual population), the self-management processes, and behavior change techniques.

Methods: A scoping review was performed to answer the proposed research questions. The databases PubMed, Scopus, PsycINFO (via EBSCO), and Wiley were searched for relevant articles. We identified articles published between January 1, 2012, and June 1, 2022, that described eHealth self-management interventions for COPD. Identified articles were screened for eligibility using the web-based software Rayyan.ai. Eligible articles were identified, assessed, and categorized by the reviewers, either directly or through a combination of methods, using Atlas.ti version 9.1.7.0. Thereafter, data were charted accordingly and presented with the purpose of giving an overview of currently available literature while highlighting existing gaps.

Results: A total of 101 eligible articles were included. This review found that most eHealth technologies (91/101, 90.1%) enable patients to self-monitor their symptoms using (smart) measuring devices (39/91, 43%), smartphones (27/91, 30%), or tablets (25/91, 27%). The self-management process of "taking ownership of health needs" (94/101, 93.1%), the behavior change technique of "feedback and monitoring" (88/101, 87%), and the positive health dimension of "bodily functioning" (101/101, 100%) were most often addressed. The inclusion criteria of studies and the actual populations reached show that a subset of people with COPD participate in eHealth studies.

Conclusions: The current body of literature related to eHealth interventions has a strong tendency toward managing the physical aspect of COPD self-management. The necessity to specify inclusion criteria to control variables, combined with the practical challenges of recruiting diverse participants, leads to people with COPD being included in eHealth studies that only represent a subgroup of the whole population. Therefore, future research should be aware of this unintentional blind spot, make efforts to reach the underrepresented population, and address multiple dimensions of the positive health paradigm.

Introduction

Background

Chronic obstructive pulmonary disease (COPD) is a common disabling lung condition characterized by chronic respiratory symptoms that cause persistent, mostly progressive airflow limitations [1]. It is one of the major issues of public health, and its prevalence, mortality, and morbidity are increasing [1-3]. COPD was listed as the third leading cause of death worldwide in 2019 [4], and it is estimated that by 2040, deaths from COPD will rise to 4.4 million per year [5]. In addition, people with a lower socioeconomic status are at increased risk of developing COPD [6]. Although COPD may, in some cases, be the result of a genetic risk factor, it is, in most cases, caused by exposure to tobacco smoking and the inhalation of toxic particles and gases from indoor and outdoor air pollution [7,8]. People with COPD often experience symptoms such as dyspnea, fatigue, chest tightness, activity limitation, and cough that may be accompanied by sputum production [7]. Furthermore, they may experience acute events, known as exacerbations, which can lead to hospitalization. Although COPD is chronic and thus not curable, it is, however, treatable, and disease progression is preventable [3,9]. Therefore, the treatment of COPD often focuses on reducing symptoms and future risks of exacerbation with the use of pharmacological and nonpharmacological therapies (eg, inhaler use, vaccinations, smoking cessation, and self-management) [7]. Given its chronic nature and the impact of the disease on all facets of one's life, an important aspect of treating COPD and secondary prevention is chronic disease management.

An essential component of chronic disease management is self-management [10]. Owing to the variation in the literature regarding the definition of self-management in COPD, this paper defines self-management as follows: "The ability of an individual to manage one's symptoms, treatment, physical, social, and emotional consequences, and lifestyle changes. It includes means of empowerment, educating oneself, being autonomous, learning and adapting to new behaviors, acceptance, and adapting to a new balance in life." It requires patients to take an involved and responsible role in their health, with the aim of becoming active participants [10,11]. Self-management interventions or programs are developed to help patients engage in self-management, and their effectiveness is investigated in research.

Self-management interventions or programs are shown to have positive effects, for example, in supporting patients to develop and improve their self-management skills and disease knowledge [12-14]. Camus-García et al [15] found that self-management interventions may improve clinical outcomes in COPD (eg, improvements in health-related quality of life) and lower the probability of hospital admissions. The actual content of such self-management intervention programs for COPD is diverse [12], and it remains unclear which specific elements are essential for designing a successful program. In the following sections, some elements that can be considered when designing an intervention program will be briefly described: content for COPD self-management, processes of self-management, and behavior change techniques (BCTs).

The diversity of content may be explained by the numerous objectives and end points of self-management intervention programs [16]. Interventions focus on acute exacerbation management and admission avoidance by incorporating exacerbation action plans [17] and often also include education, exercise training, and breathing strategies [18]. However, research suggests that intervention programs that only include education or action plans alone may not result in behavioral change, increased patient confidence, or the acquisition of new skills that patients learn or practice [16,19].

Besides the content of self-management intervention programs, the design of the intervention program should also reflect that self-management consists of different processes. Schulman-Green et al [20] identified different self-management processes for chronic illnesses, such as "learning,'" "taking ownership of health needs," and "performing health promotion activities." All processes are divided into specific self-management tasks (eg, "learning about condition and health needs" and "changing behavior to minimize health impact") and skills (eg, "acquiring information" and "reducing stress") [20]. Schulman-Green et al [20] concluded that the identification of such processes may help support and guide future self-management intervention programs. They also demonstrated that these various processes should be viewed within the broader context, as their significance to patients may vary depending on where they are in their patient journey [20]. Therefore, more knowledge about such self-management processes within self-management eHealth intervention programs is needed to support the development of such interventions.

Self-management interventions may also aim to change a certain behavior of the patient, so the incorporation of BCTs can be beneficial to designing a successful intervention program. A BCT is "a specific observable, replicable, and irreducible component of an intervention program designed to alter or redirect causal processes that regulate behavior" [21] and can be included in the design of any type of self-management intervention program. By adding these "active ingredients" (eg, "feedback" and "self-monitoring"), chances for achieving behavioral change may be increased [21]. Thus, combining self-management processes and BCTs in intervention programs may lead to positive results for one's self-management. However, to the best of our knowledge, no research is dedicated to investigating the presence of BCTs and self-management processes in current self-management interventions for COPD.

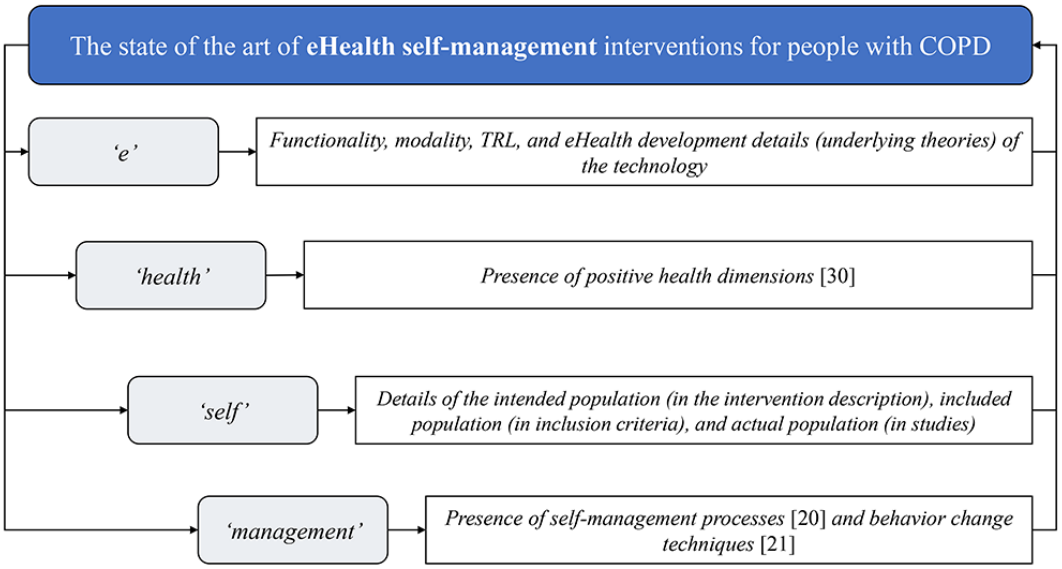
One way to support people with COPD in engaging in self-management is through the use of eHealth interventions. eHealth interventions can be defined as "An eHealth technology specifically focused on intervening in an existing context by changing behaviors and/or cognitions" [22]. eHealth interventions to support self-management may help people with chronic diseases become more independent and empowered by, for example, gaining knowledge about their disease, monitoring and reporting daily symptoms, and learning specific self-management skills [23-25]. Therefore, the use of eHealth interventions in COPD care represents a promising way of

XSL•FO
RenderX

delivering health services, such as support in self-management [26].

In the current literature, a diverse range of eHealth interventions aim to support patients in their self-management, and these are increasingly provided to support patients in health communication, self-monitoring, and their medical treatment [10,26]. Available literature revealed that current eHealth interventions for COPD mainly focused on COPD care, education, smoking cessation, medication adherence, exercise, diet, and symptom management [27,28]. This indicates a tendency toward managing the physical aspect of COPD in self-management eHealth interventions. However, the physical aspect of one's disease is only 1 dimension of the positive health paradigm. As conceptualized by Huber et al [29], "Health includes the ability to adapt, and self manage in the face of social, physical, and emotional challenges," also referred to as "positive health." Huber et al [30] stated that positive health as a concept has several important health indicators, categorized into 6 dimensions: "bodily functions," "mental well-being," "meaningfulness," "quality of life," "social participation," and "daily functioning" [30]. They stressed the fact that paying attention to these indicators could support shared decision-making and bridge the gap between health care and the social context. Therefore, these dimensions are all important to consider when self-managing one's disease. However, no research is available regarding the extent of positive health dimensions addressed in current self-management eHealth interventions for COPD.

Furthermore, using eHealth to support people with COPD might entail some challenges, as low health literacy is prevalent among people with COPD [31,32]. In addition, moderate levels of self-reported eHealth literacy are common among people with COPD [33]. Some studies revealed that people with COPD experienced technical barriers when using eHealth interventions for self-management [34]. However, Williams et al [35] indicated a few technical issues experienced by people with COPD when using eHealth to support self-management, leading to uncertainty about whether such eHealth technologies are suitable for the whole COPD population. Although some information about eHealth use for this population is available [27-28,33,35-36], little research is dedicated to investigating whether current eHealth interventions account for the wider population of people with COPD (such as those with eHealth literacy). Therefore, it should be investigated whether there is a difference between the intended population that eHealth interventions aim to target and the eventual included population in those studies. As knowledge and new insights derived from those studies often serve as a starting point for future work, it can be very valuable to look into the representation of the COPD population within studies.



Objectives

To summarize, little is known about the actual content and design of self-management eHealth interventions for people with COPD. Therefore, this scoping review aimed to investigate the current state-of-the-art eHealth interventions for COPD self-management and identify potential gaps in the literature, which may provide insight into or serve as inspiration for the development of future eHealth self-management interventions. "State of the art" within the context of this study can be defined as follows: "The collection of all underlying components that form the basis for the eHealth self-management interventions for people with COPD." Figure 1 shows how the different parts of this review contribute to an overall picture of the current literature and highlights the specific aspects explored in this review. More specifically, we aimed to unravel the state of the art of eHealth self-management interventions by using the following subquestions:

- What is the "e" in eHealth self-management?
- What is the "health" in eHealth self-management?
- Who is the "self" in self-management?
- What is the "management" in eHealth self-management?

Figure 1. Flowchart of the research questions. COPD: chronic obstructive pulmonary disease; TRL: technology readiness level.

Methods

Overview

A scoping review was performed to investigate the currently available literature. According to Munn et al [37], a scoping review is an ideal tool for providing, for example, an overview of existing literature, identifying key characteristics, and highlighting knowledge gaps, among others. Hence, this was deemed the most suitable method for answering the proposed research questions. Parts of the PRISMA-ScR (Preferred Reporting Items For Systematic Reviews and Meta-Analyses extension for Scoping Reviews) protocol (items 1-7, 9-11, and 13-21), as proposed by Tricco et al [38], were followed and tailored to this study to ensure a systematic approach for answering the research questions. The PRISMA-ScR checklist is provided in Multimedia Appendix 1 [38]. The protocol for this review was not published.

Search Strategy

The first reviewer (EtB) was responsible for identifying relevant articles in the databases PubMed, Scopus, PsycINFO, and Wiley. Combinations of the search terms "self-management," "COPD," and "eHealth" were used to generate the search string. The search string that was used for this review is provided in Multimedia Appendix 2.

Study Selection

Studies were considered eligible if they were original research and portrayed an eHealth intervention supporting the self-management of COPD. The eHealth self-management intervention should actively involve and engage individuals with COPD, ensuring they experience personal benefits from their self-management efforts, supported and encouraged by the intervention. Per definition, self-management aims for patients to become active participants in their care, which means that patient involvement within self-management eHealth interventions is essential to be able to fulfill an active role. Therefore, we did not consider that eHealth interventions actually support self-management when patients themselves are not involved (eg, if the interaction with the eHealth service is limited to collecting data). Furthermore, articles needed to be published between January 1, 2012, and June 1, 2022. As of 2012, eHealth technologies were upcoming, and their relevance for future health care appeared to be promising. For example, national efforts to implement eHealth in current care were presented in 2012 in the Netherlands (eg, [39]). The complete list of assessment and eligibility criteria is presented in Textbox 1.

XSL•FO
RenderX

Textbox 1. Assessment and eligibility criteria for studies.

Concept

- Studies describing an eHealth intervention supporting the self-management of chronic obstructive pulmonary disease (COPD) were included.
- Studies not fulfilling the inclusion criteria were excluded.

Population

- Studies involving adults aged ≥18 years diagnosed with COPD (and other chronic conditions provided that the eHealth technology has a dedicated part toward COPD) were included.
- Studies using general terms such as "older adults," "rural patients," or "communities" or referencing unspecified multimorbidity or chronic conditions without any clarification about the population were excluded.

eHealth technology

- Studies where eHealth technologies were used to support people with COPD in engaging in self-management, involving patients in their intervention were included if they used at least 1 self-management process, as defined by Schulman-Green et al [20], and in the case of sole monitoring, where patients were able to see their data.
- Studies collecting data solely for research purposes to train machine learning or artificial intelligence algorithms without any further patient engagement were excluded.

Study design

- Original research studies were included.
- Reviews, protocols, abstracts, letters, conference proceedings, commentaries, notes, short surveys, and erratum were excluded.

Language

- Studies in English were included.
- Studies not fulfilling the inclusion criteria were excluded.

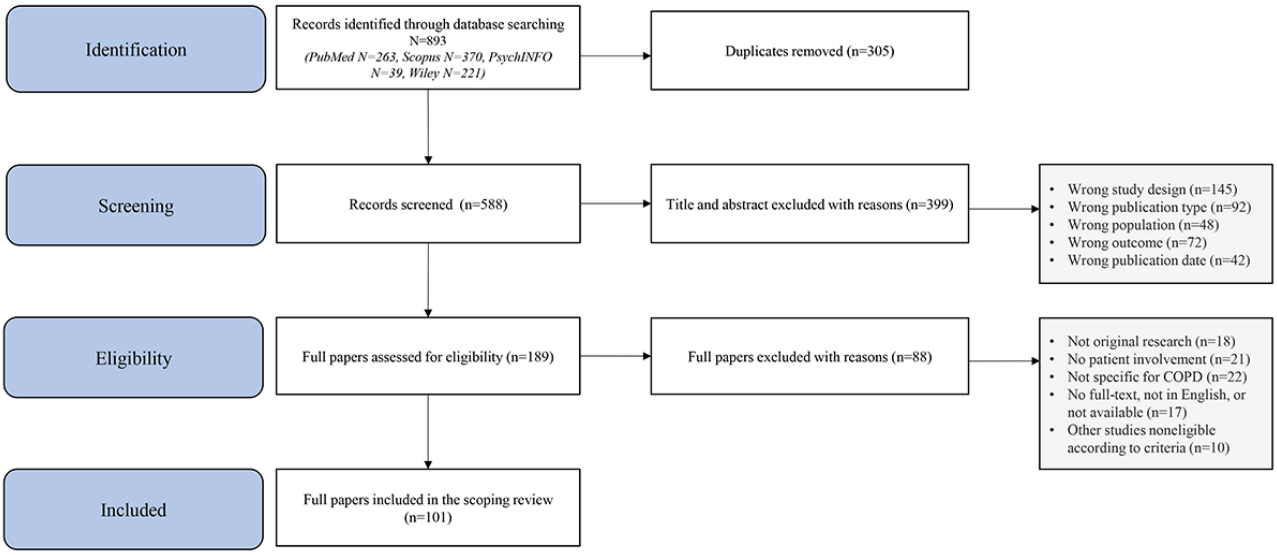
Year of publication

- Studies published between January 1, 2012, and June 1, 2022, were included.
- Studies not fulfilling the inclusion criteria were excluded.

Procedure

The screening was performed on June 3, 2022, with screening supported by the web-based software Rayyan.ai (Rayyan Systems Inc) [40]. To screen articles for title and abstract, both reviewers (EtB and RV) adhered to the eligibility criteria that were discussed before the start of the screening (Textbox 1). One reviewer (EtB) screened all articles for title and abstract. The second reviewer (RV) screened 20% (118/588) of the titles and abstracts of those studies. After this first screening, a discussion took place to compare discrepancies and come to a consensus between reviewers (EtB and RV). Both reviewers had previous experience with performing a systematic review. After this first screening, it was necessary to revise and clarify some of the inclusion criteria to arrive at a satisfactory level of agreement between reviewers. This means that with the use of the revised inclusion criteria, clear and substantiated decisions could be made on whether to include a certain article in this review. For the full-text screening, the same process was applied. In this screening, the level of agreement between reviewers was satisfactory. Reasons for excluding articles during the full-text screening were recorded. Before extracting the data, a data extraction form was developed, discussed, and agreed upon with 3 authors (EtB, CG, and MT). This form was piloted after the full-text screening to reduce errors during data extraction. Data extraction was performed by the first author (EtB) using Atlas.ti (version 9.1.7.0; Lumivero) [41], based on the data extraction form. Some of the data to answer the subquestions were directly extracted (eg, type of study and year of study), some data were the result of an assessment or categorization of the reviewers (eg, positive health dimensions), and some data were a combination of both (eg, BCTs). After the extraction, data were clustered and charted in various ways (eg, bar charts, tables, and descriptive presentations). Finally, charted data were scrutinized and synthesized by 1 reviewer (EtB) before discussing the results with 2 authors (CG and MT). Thereafter, results were written down to answer the proposed research questions. An overview of how the articles were extracted and charted is provided in Multimedia Appendix 3.

Results



Search Results

Figure 2 shows the detailed flowchart of the inclusion of studies. A total of 893 articles were identified during the initial search, of which 305 (35.1%) duplicates were removed, and the remaining 588 (%) articles were screened on title and abstract; this screening phase resulted in 189 (32.1%) articles that could be assessed for full text. After full-text screening of 189 articles,

XSL•FO
RenderX

88 articles (46.6%) were excluded, resulting in 101 articles (53.4%) being included in this scoping review.

Figure 2. Flowchart of the inclusion of studies. COPD: chronic obstructive pulmonary disease.

Study Characteristics

The included papers represented 101 unique studies. Most articles (18/101, 17.8%) were published in 2021, followed by 2020 (15/101, 14.8%) and 2017 (13/101, 12.9%). As shown in Table 1, the most common study types were either randomized controlled trials (18/101, 17.8%) or (prospective) pilot studies (16/101, 15.8%).

Table 1. Type of studies (n=101).

Type of studies	Frequency, n (%)
Randomized controlled trials	18 (17.8)
Prospective pilot study	17 (16.8)
Evaluation study	10 (9.9)
Feasibility study	9 (8.9)
Qualitative study	9 (8.9)
Retrospective or secondary analysis	7 (6.9)
Observational study	6 (5.9)
Design or development study	4 (4)
Implementation study	3 (3)
Mixed methods study	3 (3)
Exploratory study	3 (3)
Others	12 (11.9)

The e in eHealth

This section focuses on the functionality, modality, technology readiness level (TRL) [42], and eHealth development details of the used technologies. Details about the functionality and modality of the eHealth interventions are provided in Multimedia Appendix 4 [25-27,32,36,43-139]. Of the 101 included studies, 76 (75.2%) mentioned the name of their eHealth technologies. Some articles reported on studies using the same eHealth technologies (eg, “EDGE” [35,51-54], “It’s Life!” [43,55,56], “MasterYourBreath” [57-60], and “COMET” [61,62]). In some cases, studies using the same eHealth technology together portrayed the process of developing, testing, and evaluating an eHealth intervention. A total of 50 unique eHealth technologies were found in this review.

Most articles (91/101, 90.1%) included self-monitoring (eg, monitoring of symptoms) as a function of their technology. Of the 101 articles, 69 (68.3%) included the function of educating or informing (eg, education on COPD) and 27 (26.7%) supported communication (eg, eConsults with HCPs and peer-to-peer support chats). Most articles (68/101, 67.3%) included >1 function within their technology.

Table 2 shows that a (smart) measurement device (eg, wearable or monitoring system) was the most common (39/101, 38.6%) modality used in the studies, followed by a smartphone (27/101, 26.7%) and tablet (25/101, 24.7%). If studies used >1 device,

XSL•FO
RenderX

the most common combination was a (smart) measurement device with a tablet (19/101, 18.8%) or smartphone (8/101, 7.9%).

Table 2. Overview of modalities of the eHealth technologies. Some articles had used >1 device, resulting in 131 modalities within 101 articles.

Modalities of the eHealth technology	Frequency, n (%)
Smart measurement and monitoring devices	45 (34.4)
Smartphone	26 (19.8)
Normal phone or landline	16 (12.2)
Computer, laptop, or whiteboard	16 (12.2)
Tablet	15 (11.5)
Not mentioned	9 (6.9)
Television	3 (2.3)
Other	1 (0.8)

This review found no article that explicitly stated their TRL. According to our assessment and categorization, 47 eHealth technologies in the articles were assessed to be in the development phase (TRL 4 to TRL 6), 53 in the deployment phase (TRL 7 to TRL 9), and 0 in the research phase (TRL 1 to TRL 3).

Details about the eHealth development process showed that only 14 (13.9%) out of 101 studies explicitly mentioned using either a user-centered design, participatory design, scenario-based methods, reflective lifeworld research, or action research approach. Furthermore, of the 101 studies, 18 (17.8%) reported details about the theories on which their self-management intervention was based. Some of these were targeted toward BCTs independent of technology use, while others were technology related and more targeted toward technological adoption or persuasive design. Table 3 lists the various theories identified as underlying the eHealth interventions. Theories that were present could be divided into the following categories: behavioral change, technological adoption or persuasive design, and unspecified. This review found 11 different behavior change theories, 3 different technological adoption or persuasive design theories, and 3 unspecified theories. Of all the different theories within the different categories, the social cognitive theory was most often used (5/11, 45%).

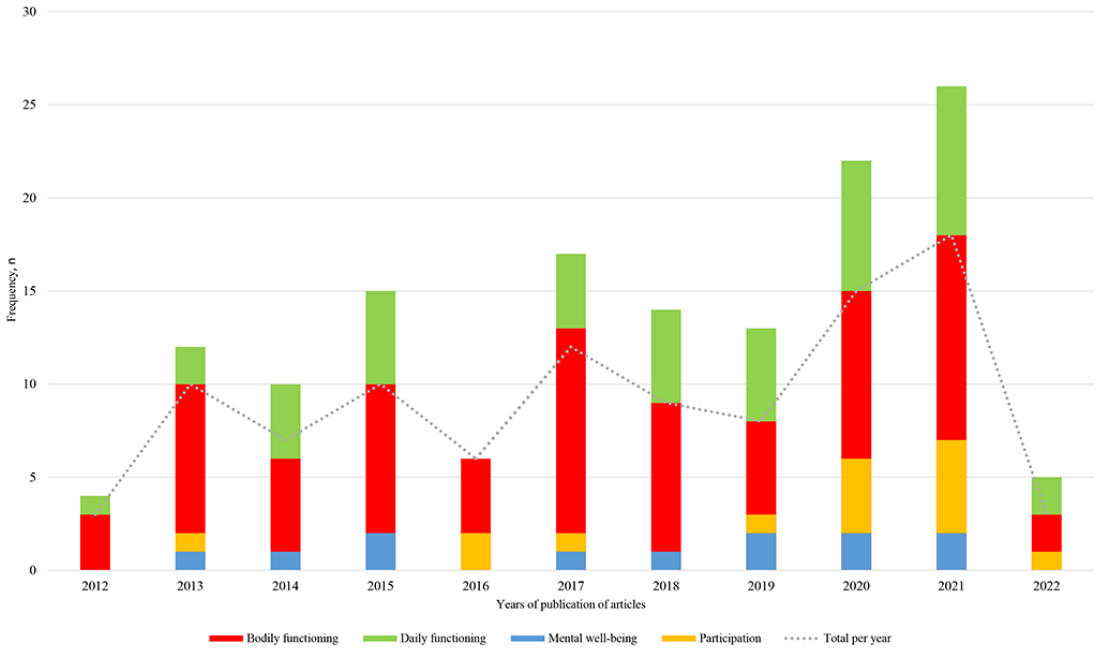
The Health in eHealth Technologies for Self-Management

Table 4 shows how many eHealth technologies used in the studies addressed the different positive health dimensions. All the included articles (N=101, 100%) addressed (at least) the dimension of bodily functioning, 45 (44.6%) addressed daily functioning, 13 (12.9%) addressed participation, and 12 (11.9%) addressed mental well-being. We were not able to identify any indications that the dimensions of meaningfulness and quality of life were explicitly addressed in any of the eHealth technologies supporting self-management. Details about the positive health dimensions are provided in Multimedia Appendix 5.

Most studies (48/101, 47.5%) focused on 1 specific dimension, namely, bodily functioning. Other articles (42/101, 41.6%) focused on 2 dimensions, 11 (10.9%) on 3 dimensions, and only 3 (3%) on 4 dimensions within their eHealth technology. The combination of the dimensions of bodily functioning and daily functioning was the most common (33/101, 32.7%), followed by the combinations of bodily functioning, daily functioning, and mental well-being (5/101, 5%); bodily functioning and participation (4/101, 4%); bodily functioning, daily functioning, and participation (3/101, 3%); bodily functioning, mental well-being, and participation (3/101, 3%); body functioning, mental well-being, participation, and daily functioning (3/101, 3%); and bodily functioning and mental well-being (1/101, 1%).



XSL•FO
RenderX

Table 4. Distribution of the positive health dimensions. Some technologies addressed >1 dimension, which are counted separately in this table, resulting in 172 dimensions found within 101 articles.

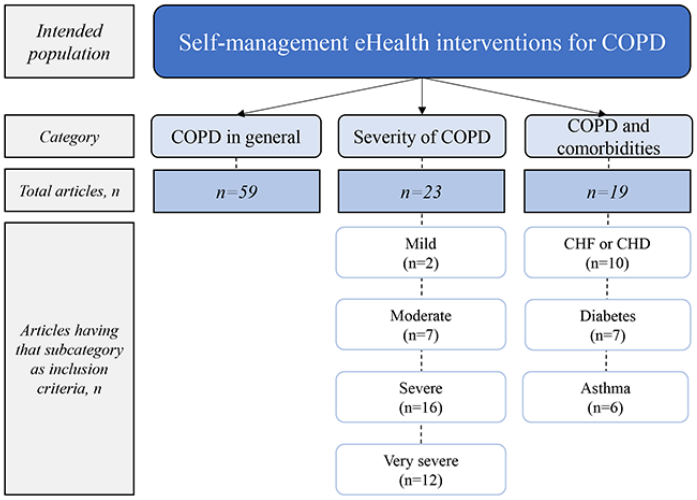
Positive health dimension	Frequency, n (%)
Bodily functioning	101 (58.7)
Daily functioning	46 (26.7)
Participation	13 (7.6)
Mental well-being	12 (7)
Meaningfulness	0 (0)
Quality of life	0 (0)

To investigate whether there may be an increase or decrease in certain positive health dimensions over time, we compared the presence of certain dimensions with the years of the studies (Figure 3). Such information can be useful to see whether the target dimensions of eHealth interventions are changing with time. When comparing the presence of the dimensions with the years of the studies, we found that in the years 2013 to 2015 and 2017 to 2018, the dimension of bodily functioning is dominantly present, followed by daily functioning. From 2017 to 2021, a small increase in the presence of the dimension of mental well-being could be seen over the years. In the years 2020 and 2021, the presence of the dimensions of daily functioning and participation was almost equal compared to bodily functioning.

Figure 3. Distribution of the positive health dimensions in articles over time. Dimensions of "quality of life" and "meaningfulness" were not displayed, as no included articles explicitly addressed these.

The Self in Self-Management

Overview



All 101 included papers (partly) described the intended population for the intervention (as stated in the intervention description), the included population (as stated in the inclusion and exclusion criteria), and the final actual study population (as stated in the demographics of study participants). In some studies, certain inclusion criteria were required to participate, thereby restricting the group of eligible participants (ie, the actual population). This scoping review extracted the following inclusion criteria: disease-specific (needing to have a certain severity of COPD), capability-related (needing to be cognitively capable, able to read and write, understand certain language, willing or able to provide consent), age-related (needing to have a minimum or maximum age), smoking history–related (being a current or former smoker), and technology-related (needing to have digital skills, internet access, own a certain device). More details about the concept of the self in self-management are provided in Multimedia Appendix 6.

Intended Population

There was some variation in the specific intended populations targeted in the articles. As shown in Figure 4, most studies (59/101, 58.4%) were targeted at persons with COPD in general, with 23 (22.8%) focusing on ≥1 specific COPD severities and 19 (18.8%) focusing on COPD in combination with other chronic conditions. Some articles included >1 comorbidity.

XSL•FO
RenderX

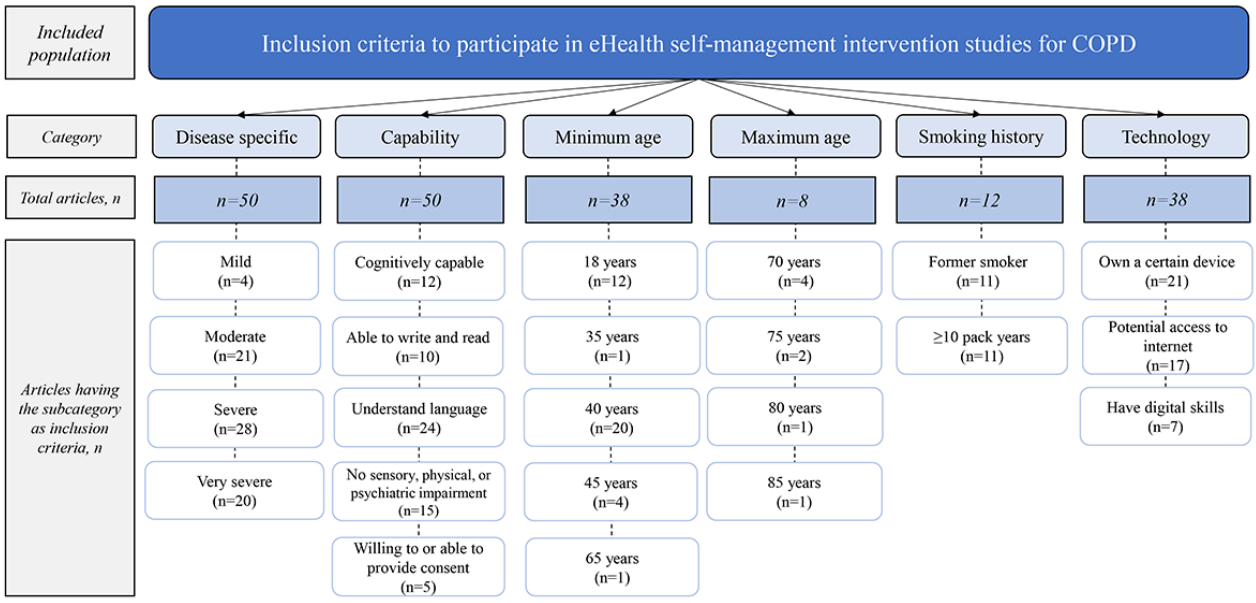


Figure 4. Intended population. CHD: chronic heart disease; CHF: chronic heart failure; COPD: chronic obstructive pulmonary disease.

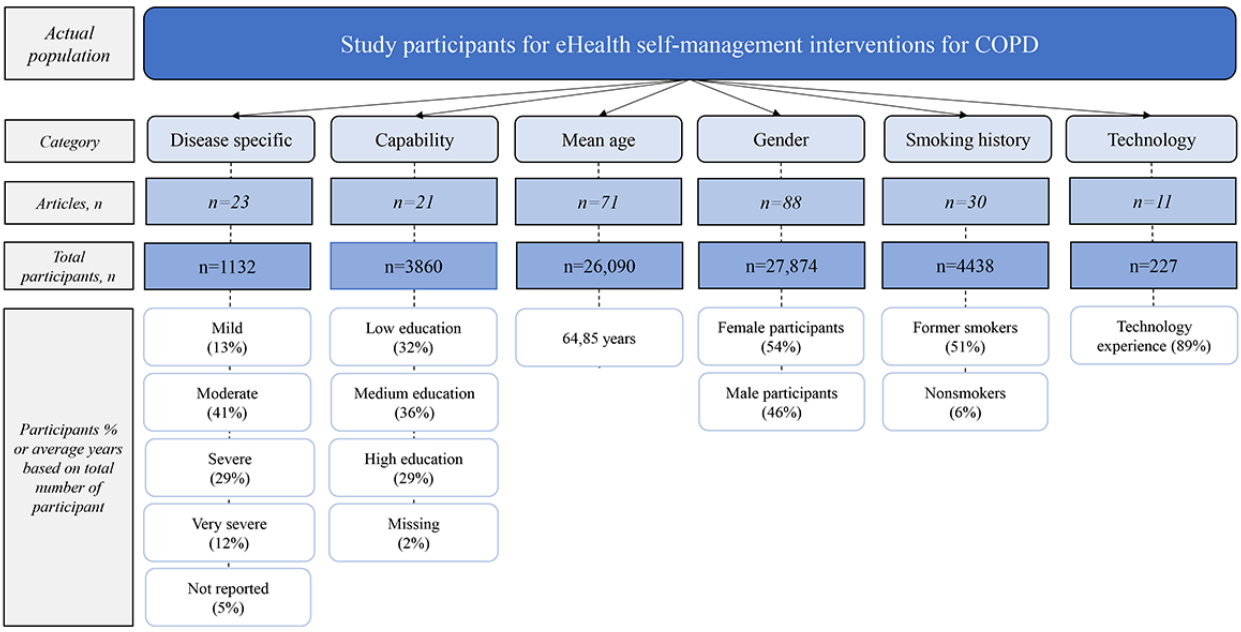
Included Population

Figure 5 presents an overview of the identified included population. More studies (50/101, 49.5%) than outlined in the Intended Population section (23/101, 22.8%) had disease-specific inclusion criteria (focusing on ≥1 COPD severities). Of the 101 articles, 50 (49.5%) had capability-related inclusion criteria, requiring participants to, for example, be cognitively capable or able to write and read to be eligible for participation. Furthermore, in 37.6% (38/101) of the articles, participants needed to have a certain minimum age, with 40 years being the most common. In 7.9% (8/101) of the articles, the age needed to be below a certain maximum. The maximum age of 70 years was the most commonly mentioned inclusion criterion, cited 4 times. A total of 12 (11.9%) out of 101 articles had inclusion criteria regarding smoking (history) in which participants needed to be, for example, a former smoker. Finally, 38.6% (39/101) of the articles had technology-related inclusion criteria. Participants needed, for example, to own a smartphone or tablet and have digital skills to participate. Only 1 study explicitly mentioned having no exclusion criteria based on age, comorbidities, and previous participation in pulmonary rehabilitation. Furthermore, in the same study, participants did not need to have previous experience using digital technology.

Figure 5. Included population. COPD: chronic obstructive pulmonary disease.



Actual Population

Figure 6 shows the actual population included in the studies. In 24.7% (25/101) of the articles that mentioned the severity of their participants, most participants had moderate or severe COPD. Out of the 101 articles, only 21 (20.8%) shared a clear description of the education level of their participants, which were then categorized for this study. The educational level of participants could be categorized as low, medium, and high, which were almost equally distributed. Of the 70.3% (71/101) of the articles that shared the mean age of their participants, we calculated the combined mean age, which resulted in 64.85 years. The gender of participants was clearly mentioned in 88 (87.1%) out of 101 articles and was almost equally distributed. In 29.7% (30/101) of the articles that shared the smoking history of their participants, almost half of the participants (51%) were

XSL•FO
RenderX

reported as current or former smokers. In 10.9% (11/101) of the articles that described technology-related experience, 89% of the participants had experience with technology.

Figure 6. Actual population. COPD: chronic obstructive pulmonary disease.

The Management in Self-Management

This section describes which self-management processes and BCTs were found within the different eHealth technologies. Details about this section are provided in Multimedia Appendix 7 (overview of self-management processes) and Multimedia Appendix 8 (overview of BCTs).

Self-Management Processes

Table 5 shows the self-management processes found in the articles. No article explicitly described which self-management processes were reflected in the intervention design. When analyzing how self-management processes were supported within the different studies, we identified that most studies (94/101, 93.1%) addressed the process of taking ownership toward health needs (eg, by including self-monitoring of symptoms or setting goals). Of the 101 included studies, 71 (70.3%) focused on the process of learning (eg, by including education within their technology), 27 (26.7%) on health care resources (eg, by enabling communication with health care professionals within the technology), 23 (22.8%) on performing health promotion activities (eg, by performing exercise or skill training), 17 (16.8%) on social resources (eg, by involving caregiver and family or peer-to-peer support), 1 (1%) on adjusting (eg, ways to cope), and 1 (1%) on integrating illness into daily life (eg, alternating daily lives to conserve energy). We found no eHealth technologies specifically focusing on the self-management processes: meaning making, spiritual resources, psychological resources, processing emotions, or community resources.

Table 5. Self-management processes within eHealth technologies. Each process is counted separately in this figure resulting in 234 self-management processes within 101 articles. “Meaning making,” “spiritual resources,” “psychological resources,” “processing emotions,” and “community resources” were not displayed, as these processes were not included.

Self-management process	Frequency, n (%)
Taking ownership of health needs	94 (40.2)
Learning	71 (30.3)
Health care resources	27 (11.5)
Performing health promotion activities	23 (9.8)
Social resources	17 (7.3)
Adjusting	1 (0.4)
Integrating illness into daily life	1 (0.4)

BCTs Used

Table 6 shows the BCTs extracted in this study. Only 2 (2%) out of 101 studies explicitly stated which BCTs were used. When analyzing the descriptions in the studies, we identified that feedback and monitoring were mostly used in the different articles (88/101, 87.1%; eg, monitoring activity status). This was followed by shaping knowledge (66/101, 65.3%; eg, receiving education), goals and planning (38/101, 37.6%; eg, action planning), associations (23/101, 22.8%; eg, receiving

XSL•FO
RenderX

status updates), social support (14/101, 13.7%; eg, communication with other people with COPD), regulation (11/101, 10.9%; eg, addressing medication adherence), repetition and substitution (10/101, 9.9%; eg, habit formation), rewards and threat (6/101, 5.9%; eg, receiving visual rewards), natural consequences (5/101, 4.9%; eg, information about health consequences), self-belief (5/101, 4.9%; eg, increasing self-efficacy), comparison of behavior (5/101, 4.9%; eg, follow along exercise video), comparison of outcomes (2/101, 2%; eg, information about the effect of physical activity), antecedents (1/101, 1%; eg, adding objects to the environment), and identity (1/101, 1%; eg, prompt identification as a role model). The BCTs of covert learning and scheduled consequences were not observed in the studies.

Table 6. Behavior change techniques within eHealth technologies. Each technique was counted separately in this figure. Resulting in 275 behavior change techniques within 101 articles. "Scheduled consequences" and "covert learning" were not displayed, as these processes were not included.

Behavior change technique	Frequency, n (%)
Feedback and monitoring	88 (32)
Shaping knowledge	66 (24)
Goals and planning	38 (13.8)
Associations	23 (8.4)
Social support	14 (5.1)
Regulation	11 (4)
Repetition and substitution	10 (3.6)
Rewards and threat	6 (2.2)
Natural consequences	5 (1.8)
Comparison of behavior	5 (1.8)
Self-belief	5 (1.8)
Comparison of outcomes	2 (0.7)
Identity	1 (0.4)
Antecedents	1 (0.4)

Discussion

Principal Findings

This scoping review outlines the state of the art of eHealth self-management interventions for COPD. In the current literature, most eHealth technologies for COPD self-management focus on the physical aspect of self-management. eHealth technologies that include other aspects (eg, the social or mental aspects) are currently underrepresented in the literature. Moreover, it appeared that although eHealth interventions often aimed to target the whole COPD population, mostly only a subgroup of the COPD population was represented within the eHealth technology studies.

Self-Management of COPD

Underlying Theories, Techniques, and Processes

Only a few studies (32/101, 31.7%) reported on using underlying theories and specific BCTs supporting their self-management eHealth interventions. No article explicitly mentioned focusing on certain self-management processes. This is surprising, given the fact that all studies aim to improve self-management and thus aim to achieve some sort of behavioral change. As the concept of self-management varies in the literature, reporting on the use of such processes, techniques, and theories may be beneficial for understanding underlying structures and processes that will initiate behavior change to improve self-management. Building on these processes, techniques, and theories and providing more detailed reports on what was perceived as useful, beneficial, and desirable for this target population can help advance the field and contribute to the existing body of work. This may simultaneously be valuable for informing future eHealth self-management initiatives as they can take into account these theories, techniques, and processes in their developments. When looking at the literature, the lack of reporting on underlying theories was prevalent in the review of Heimer et al [140], in which only 3 of the included studies reported specific BCTs. Furthermore, other studies encountered the problem of low reporting on BCTs; Hardeman et al [141] and Lorencatto et al [142] concluded that fewer than half of the planned BCTs were specified in the final published articles. In addition, a review from de Bruin et al [143] revealed that reporting about the active content of behavioral interventions varies considerably between studies. This limits the readers' ability to compare, interpret, and generalize the effects of these studies [143]. Thus, including such theories in eHealth interventions and transparency in later reporting may lead to opportunities for achieving sustainable behavioral change.

The Physical Aspects of Self-Management

As we found in this review, there is a tendency toward managing the physical aspect of one's disease in current eHealth technologies for COPD self-management. This is reflected throughout the different findings of this review. First, the functionality "self-monitoring" and the BCT "feedback and

XSL•FO
RenderX

monitoring" were most often addressed. Although self-monitoring is very valuable and exacerbations may be detected at an early stage, this, nonetheless, demonstrates that the main focus lies on what happens with or inside the body. Second, the dominant physical aspect also manifests itself when looking at the self-management processes that are supported by the different technologies: "psychological resources," "spiritual resources," and "community resources" were not found to be included. The self-management process of "taking ownership of health needs" was mostly present, followed by "learning." However, other processes, such as "integrating illness into daily life" and "adjusting," were only observed once, although the target group had to deal with these aspects every single day [144]. We believe that not addressing these processes is a missed opportunity, given that supporting people with COPD during their day-to-day activities might lead to even better improved outcomes of self-management. Finally, the dimensions of bodily functioning and daily functioning were most frequently used. This illustrates the current underrepresentation of other dimensions within current eHealth technologies for COPD self-management. Other dimensions (eg, participation and mental well-being) were not as dominantly represented or not observed at all (eg, meaningfulness and quality of life). As we observed a small increase in dimensions over the past few years, we might notice a small change of focus. However, this is not as fundamental and still leaves a lot of room for improvement on this matter. When examining other chronic diseases (eg, rheumatoid arthritis), a review by Seppen et al [145] identified 4 different types of eHealth interventions used in the included articles. Although not explicitly stated, interventions were all related to the physical aspect (ie, medication adherence, activity plan, information, disease monitoring, and activity monitoring) [145]. Thus, the tendency of the physical domain may not only be limited to COPD. Therefore, future studies should investigate whether this view is also present in other chronic diseases.

Inclusiveness and Representation of People With COPD

As all eHealth technologies target people with COPD as end users, only 14 (13.9%) out of 101 articles reported involving the patient perspective in their design or development process. This raised the question of whether and how the needs and perspectives of patients were taken into account. As including the perspective of end users leads to a better fit and increases the chances of successful adoption and sustained use [146], researchers should consider using such design principles when developing future eHealth technologies. This may provide many opportunities for improvements in self-management eHealth technologies for COPD.

Furthermore, it appeared that although articles outlined the target group to be the general population of people with COPD, they often recruited a specific subset of people with COPD. Certain inclusion criteria are made within the studies (eg, needing to own a smartphone and needing to have a certain disease severity). The consequence of such inclusion criteria leads to a restriction, in that only a selected group of individuals are included in the studies. While this may be due to practicalities (eg, the complexity of COPD as a progressive lung disease), the question remains whether the intervention is generalizable or applicable to the wider population of people with COPD, especially if they were not part of the studies in the first place. This is particularly relevant as there is no golden standard to determine, for example, when someone is considered too old to participate, and opinions on such matters are likely to vary widely among researchers. Even when the restricting the patient group may be justified for the study purposes, it still affects the generalizability of study results. Therefore, awareness and transparency should be provided regarding these potential restrictions related to the patient group within such studies.

Given that the most often used device is a (smart) measurement device (in combination with), a smartphone, or tablet, the group of people eligible to use these technologies in daily life is further limited. Effectively, this means that certain groups of people (eg, those who lack resources to buy these devices) are not included in the research and, therefore, the intervention might not be tested on people who are unfamiliar with smart devices or have low digital literacy. Previous studies showed that moderate levels of eHealth literacy and low levels of health literacy are prevalent among the COPD population [32,33]. Thus, we cannot assume that this population has access to eHealth technologies and has mastered the skills to manage such interventions without any support. Therefore, guidance should be made available to help those who need support in using these eHealth technologies. Furthermore, although there might be some practical reasoning behind the inclusion criteria (eg, lack of budget to provide devices for all participants), it may simultaneously widen the gap between people included in eHealth technology studies and the group of people who might need the support the most. This, in turn, could make health care accessible only to those with high (digital) literacy and those already equipped with the necessary resources to improve their health. This is most likely an unintentional and undesirable direction to head, but without proper awareness, it may easily become the blind spot in current and future eHealth intervention studies. Future studies must, therefore, be aware of possible subgroups, make efforts to include the underprivileged population, and be transparent in their research regarding the population reached. While we acknowledge the challenge of successfully recruiting participants who are representative of the population as a whole and recognize that this is extremely difficult to achieve, we nevertheless recommend that future studies strive to reach those people who are underrepresented and difficult to reach.

Strengths and Limitations

This review provides a very first overview and a diverse insight into different underlying components of self-management eHealth interventions for COPD. It highlights the existing gaps in the literature and uncovers opportunities for the development of eHealth self-management interventions. To the best of our knowledge, no research has yet examined all these various aspects.

However, this review also has its limitations. First, data extraction and categorization were challenging due to the style of writing in articles (which comes with certain formats and word count limitations), the lack of explicit reporting on certain aspects, and the overlap between some processes and

XSL•FO
RenderX

dimensions. It might be the case that through incomplete reporting in articles, certain self-management processes, BCTs, health dimensions, aspects of the technology, or details about the "self" could not be extracted. However, albeit being a scoping review, we followed a very systematic approach to mitigate this limitation as much as possible. Therefore, we believe that we were able to give a complete picture of the current literature about eHealth technologies for COPD self-management.

Second, some dimensions of positive health and self-management processes are closely related, intertwined with, or support each other. For example, the dimension of "quality of life" was not observed to be explicitly addressed within the eHealth interventions. However, studies may have an overarching goal of increasing the quality of life of people through the use of their intervention. One should be aware of this when interpreting these results, as the quality of life of people with COPD might still be affected by the use of eHealth intervention.

Third, most articles (470/588, 80%) were screened by 1 reviewer, leaving room for potential subjective judgment. However, by implementing several measures to ensure alignment (eg, extensive discussion of eligibility criteria, 20% of the screening conducted by 2 reviewers, and discussions to resolve discrepancies), we minimized possible implicit biases.

Finally, this scoping review investigated a broad range of aspects to grasp the state of the art, but not all. For example, this paper did not assess the effectiveness or impact of the interventions, and it also did not evaluate the quality or strength of the evidence. As this is a relatively new area of research, we should map the existing literature first. Furthermore, this review included only English articles, used COPD as a search term while it included a broad spectrum of lung diseases (such as emphysema and chronic bronchitis), and had a search date limitation. Consequently, some studies might have been missed, or some aspects may not have been investigated. However, to the best of our ability, we tried to provide a first overview while leaving opportunities for future research to focus on the aspects that were not covered within this scoping review. As such, this state-of-the-art overview could serve as a starting point for future systematic reviews and original research that will dive into more specific research areas.

Conclusions

This scoping review provides an overview of the state-of-the-art eHealth technologies for COPD self-management interventions. We showed that current eHealth technologies tend to address the physical aspect of COPD self-management. These findings reveal a gap in the available literature, as many dimensions of the positive health paradigm and self-management processes are not addressed in current eHealth interventions for COPD self-management. However, as COPD is a chronic disease and exerts its impact on all aspects of one's life, the underrepresented dimensions and processes might be very important to include. This might give people with COPD the tools needed to be able to adapt toward a new balance in life, and this would consider the person as a whole instead of only the bodily representation in the context of a disease. Our review also showcases another gap, namely, the effect of inclusion criteria that leads to a subgroup of people with COPD included in eHealth technology studies. Therefore, one should be cautious when interpreting results, as this may give a distorted view of the COPD population within these studies. These gaps demonstrate the need for more inclusive research and design of eHealth self-management interventions for people with COPD, focusing on multiple dimensions of the health paradigm. Future work should, therefore, go beyond the physical dimension and focus on including individuals in research who could benefit most from eHealth self-management interventions.

Abstract

Background: The application of intelligent robots in therapy is becoming more and more important for people with dementia. More extensive research is still needed to evaluate its impact on behavioral and psychological dementia symptoms, as well as quality of life in different care settings.

Objective: The purpose of this research is to methodically assess how well intelligence robot interventions work for patients with dementia.

Methods: In accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines, a comprehensive search was conducted on PubMed, CINAHL, the Cochrane Library, Embase, and Web of Science from the time of their founding to February 2024, to identify relevant randomized controlled trials on the use of intelligent robots in people with dementia. Two authors (WF and RZ) independently applied the Cochrane Collaboration bias assessment tool to assess the included studies' quality. The intervention effect of intelligent robots on patients with dementia was summarized using a fixed-effect model or a random-effects model with Stata software (version 16.0; StataCorp). Subgroup analysis was performed according to the intelligent robot type and the intervention duration. Publication bias was tested using funnel plots, Egger tests, and the trim-and-fill method.

Results: In total, 15 studies were finally included for systematic review, encompassing 705 participants, of which 12 studies were subjected to meta-analysis. The meta-analysis found that compared with the control group, intelligent robot intervention significantly reduced the levels of agitation (standardized mean difference –0.36, 95% CI –0.56 to –0.17; $P<.001$) and anxiety (weighted mean difference –1.93, 95% CI –3.13 to –0.72; $P=.002$) in patients with dementia. However, the intervention of intelligent robots had no significant effect on the following (all $P>.05$): cognitive function, neuropsychiatric symptoms, depression, quality of life, step count during the day, and the hours of lying down during the night of patients with dementia. Subgroup analysis revealed that the improvement of depression was related to the duration of the intervention (≤12 vs 12 weeks: 0.08, 95% CI –0.20 to 0.37 vs –0.68, 95% CI –1.00 to –0.37; $P=.26$) and was independent of the type of intelligent robots (animal robots vs humanoid robots: –0.30, 95% CI –0.75 to 0.15 vs 0.07, 95% CI –0.21 to –0.34; $P=.26$).

Conclusions: This study shows that intelligent robot intervention can help improve the agitation and anxiety levels of people with dementia. The intervention may be more effective the longer it is implemented. The appearance of the intelligent robot has no effect on the intervention effect. Further research is needed to help collect physiological data, such as physical activity in people with dementia; explore the impact of other intelligent robot design features on the intervention effect; and provide a reference for improving intelligent robots and intervention programs.

Introduction

Background

As the global aging situation becomes more serious, dementia has become a highly prevalent disease in the older population [1]. The characteristic of dementia is the degradation of memory, cognition, behavior, and daily activity abilities [2]. Symptoms such as agitation and depression increase the risk of secondary problems like fractures and falls, which can seriously impair patients' quality of life. In addition, it puts more strain on those who provide care, raising the expense of nursing and medical care. According to the August 2020 update of the "Guidelines for Dementia Prevention, Intervention, and Care" by the Lancet Committee, psychotropic medications typically have little effect on neurological or mental symptoms and can have substantial side effects [3]. As a first line of treatment for behavioral and psychological symptoms of dementia, nonpharmacological therapies are advised due to the drawbacks and safety concerns associated with medication therapy [4].

Multiple studies have shown that music therapy and multisensory stimulation intervention have significant effects in improving behavioral and psychological symptoms of dementia [5,6]. The senses enable patients to interact effectively with the environment and communicate better with others. The effects of pet therapy applied in the geriatric population are mainly in the form of improved social interaction, improved emotional state, enhanced cognitive level, and improved problems. Studies on patients with dementia have demonstrated the beneficial effects of pet therapy [7]. Based on the above evidence, using intelligent robots for intervention in patients with dementia may have the following advantages:

1. Multiplicity: Intelligent robots can comprehensively provide tactile, visual, and auditory multisensory stimulation interventions, music interventions, and pet interventions; they can also assist in social activities, accompany patients with dementia, provide social-emotional support, etc.
2. Interactivity: Intelligent robots are capable of interacting with patients, and the interaction modes mainly include touch interaction; voice interaction; and somatosensory interaction, which is a two-way active form rather than one-way passive form and is conducive to improving patient participation and enriching the emotional experience.
3. Telemedicine: The therapist can use remote control software installed in the device to control the activation and progress of the smart robot scripts, enabling telemedicine.
4. Less restriction: The use of intelligent robots to accompany patients is less restricted by place and population compared to animal interventions; for example, patients with hair allergies are not suitable to receive canine companionship but can interact with pet robots.

In recent years, intelligence robot interventions have caught the interest of scientists studying dementia. A variety of intelligent robots, including pet robots, companion robots, social assistance robots, and humanoid robots, are being used for neuropsychiatric symptoms, cognitive function, and pain in patients with dementia [8,9]. The results of intelligence robot intervention vary, nevertheless. For instance, a mixed methods study revealed that following a 6-week intervention, the robotic companion dog or cat group's feelings of melancholy and loneliness considerably dropped as compared to the control group [10]. The study's qualitative findings revealed that the robotic companion pet experience was viewed positively by the participants, their families, and professional caregivers, who felt that the robot enhanced communication and offered companionship [10]. Conversely, another study indicated that a social robot intervention did not significantly improve positive affective states [11]. There is currently conflict over the efficacy of interventions on agitation and quality of life, as well as a lack of data for objective indicators like physical activity and sleep duration, despite the publication of a few meta-analyses of intelligence robot intervention [8,9,11-13]. Subgroup analyses of intervention settings, such as the kind and purpose of intelligent robots and the length, the location, and the format of the intervention, have not been done in previous studies. New trials have been published in the last two years; thus, an updated review of this material is still necessary.

Objectives

Given this, this study aimed to examine how intelligence robots affect both subjective and objective markers in patients with dementia by a thorough assessment of the literature and meta-analysis. Furthermore, the type of intelligent robots, as well as subgroup analysis based on intervention times, are discussed. Overall, the findings will offer support for further relevant studies and therapeutic applications.

Methods

Overview

We conducted this systematic review and meta-analysis by following the PRISMA (Preferred Reporting Items in the Systematic Review and Meta-Analyses) guidelines (Multimedia Appendix 1).

Literature Search Strategy

WF and RZ conducted a comprehensive search in February 2024 across the following databases: Web of Science, CINAHL, PubMed, Embase, Cochrane Library, and CINAHL. We found additional relevant publications by searching the bibliographies of the included papers and previous relevant systematic reviews. Details about the customized search approach for each database can be found in Tables S1-S6 in Multimedia Appendix 2. The following search terms were used: "dementia," "Alzheimer's disease," "AD," "robotics," "robotic," "robot," and "robot-assisted."

Criteria for Inclusion and Exclusion

The included studies satisfied the following criteria: (1) adult patients were diagnosed with dementia; (2) the study was a randomized controlled trial (RCT); (3) the intervention group received intelligence robot intervention, with no restrictions on the kinds of intelligent robots; (4) the control group was given standard treatment; and (5) the study was published in English. The exclusion criteria are as follows: (1) absence of data for the network meta-analysis; (2) duplicate data; and (3) qualitative

XSL•FO
RenderX

research, books, review studies, conference abstracts, or study protocols.

Study Selection and Data Extraction

EndNote 20.4 (Clarivate Analytics) was used to eliminate duplicates before deciding if the searched records were eligible. Initial screening of literature by two independent authors (WF and RZ). WF and RZ discussed and settled any differences between them until they came to an agreement. A third author (XL) was consulted if a consensus could not be achieved. The first author, the country, the year of publication, the type of study, the analyzed sample size, the average age of the participants, the specifics of the intervention (methods, frequency, and duration), and assessment time points were all extracted using a sheet by two independent authors, WF and XL.

Risk of Bias Assessment

Two authors (WF and RZ) independently applied the Cochrane Collaboration risk of bias tool [14] to assess the quality of the included studies.

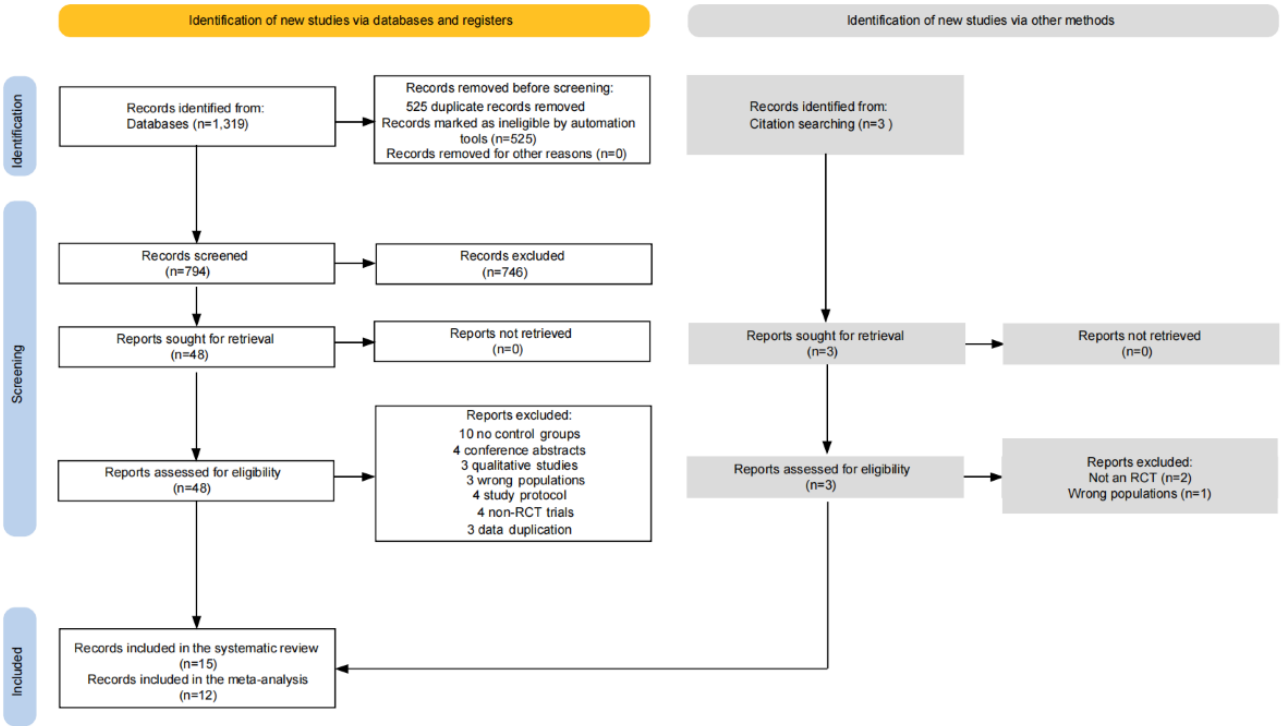
Statistical Analysis

The meta-analysis was conducted using Stata software (version 16.0; StataCorp). To address potential bias caused by differences in indicator levels between the intervention and control groups at baseline, we calculated the mean difference and SD between postintervention and baseline values to reflect within-group changes.

The effect size, which quantifies the difference in the magnitude of change between groups, was expressed as either the standardized mean difference (SMD) or the weighted mean difference (WMD). The WMD was used when studies measured outcomes on the same scale; otherwise, the SMD was applied.

Heterogeneity was considered significant when the *P* value of the Cochran *Q* test was less than 0.10 and the Higgins I^2 statistic was greater than 50%, and a random effects model was used to account for heterogeneity between studies; otherwise, a fixed effects model was used [15]. A forest plot and a funnel plot were generated for the analysis. The calculation of Egger regression tests was done to assess publication bias.

Forest plots were generated, and sensitivity analyses were performed to further assess the stability of the study results. The calculation of Egger regression tests, visualization of the funnel plot, and trim-and-fill method were used to evaluate publication bias [16].



Subgroup analyses were conducted to explore the influence of study design factors (intervention duration) and intervention conditions (types of intelligent robots) on the effect of the intervention and to assess possible sources of heterogeneity.

Results

Literature Screening

The PRISMA flowchart of study identification and screening is outlined in Figure 1. A total of 1319 records were extracted from the electronic database search, and 3 records were identified through hand searching of reference. Following the elimination of duplicates, we went over the abstracts and titles of 797 (60.29%) publications to weed out any that were not relevant. In the end, after verifying compliance with the inclusion criteria and exclusion criteria, a total of 15 (1.13%) studies were included in the systematic review, and 12 (0.91%) of these studies were included in the meta-analysis.

Figure 1. PRISMA flow diagram of the study selection process. PRISMA: Preferred Reporting Items in the Systematic Review and Meta-Analyses; RCT: randomized controlled trial.

Study Characteristics

The characteristics of the included studies in the systematic review are shown in Table 1. A total of 15 studies were conducted in 8 countries, including Australia (5/15, 33%) [17-21], Norway (3/15, 20%) [22-24], China (2/15, 13%) [25,26], Spain (1/15, 7%) [27], New Zealand (1/15, 7%) [28], Japan (1/15, 7%) [29], the United Kingdom (1/15, 7%) [30], and the United States (1/15, 7%) [31]. All studies were published after 2015, and the number of participants in each study ranged from 22 to 175, with intervention periods ranging from 6 weeks to 3 months. Participants were mainly female, with the proportion ranging from 64% to 88%, and the average age of participants was reported to be from 83.4 to 89.0 years in 13 (87%) [17-26,29-31] studies. The venues where the interventions were implemented included long-term care facilities, nursing homes, and other venues. Only 2 (13%) [27,29] studies were single-center studies, while the remaining 13 (87%) [17-26,28,30,31] studies were multicenter studies.

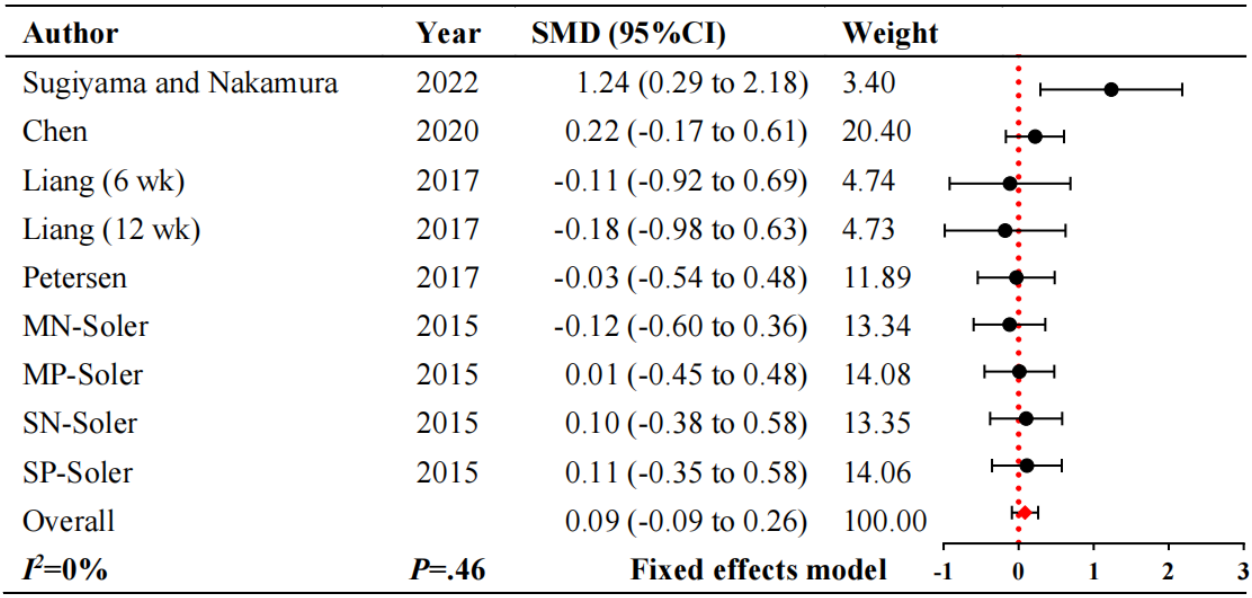
Risk of Bias Assessment



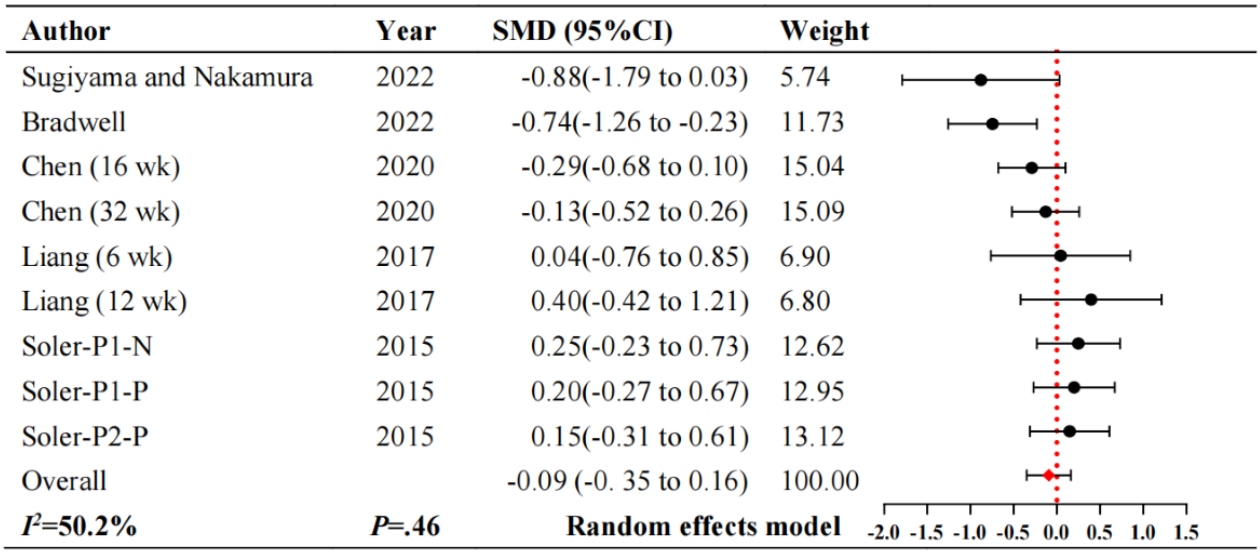
Each included RCTs' bias risk is displayed in Table S7 in Multimedia Appendix 2. A computer-generated random list was used to generate the randomization sequence in 6 of the RCTs [17,19,23,25,27,28,30], while 1 RCT [31] included coin tossing. The risk of selection bias was deemed questionable since the randomization procedure was not reported in detail in 2 other RCTs [28,29]. However, because it was challenging to blind staff members and participants in the intelligent robot interventions, only 1 RCT [19] was deemed to have a low risk of performance bias.

Analysis of Overall Effects

Cognitive Function

Cognitive function was measured in 5 studies [26-29,31], and 1 RCT [27] reported humanoid and pet robot intervention with different scales. The combined data showed that there was no discernible variation in cognitive function (SMD 0.09, 95% CI –0.09 to 0.26; *P*=.46). Furthermore, the results showed no heterogeneity (I^2=0%). In Figure 2 [26-29,31], the forest diagram is displayed.

Figure 2. Forest plot of cognitive function. M: Minimental state examination scale; N: Nao robot; P: Paro robot (Pet robot); S: Severe minimental state examination scale. SMD: standardized mean difference.



XSL•FO
RenderX

Neuropsychiatric Symptoms

Regarding neuropsychiatric symptoms, 5 studies [26-30] involving 552 participants reported changes in neuropsychiatric symptoms. Figure 3 [26-30] illustrates that intelligent robot interventions cannot significantly improve neuropsychiatric symptoms in patients with dementia compared to usual care (SMD –0.09, 95% CI –0.35 to 0.16; *P*=.46). These studies showed considerable heterogeneity (I^2=50.2%; *P*=.07).

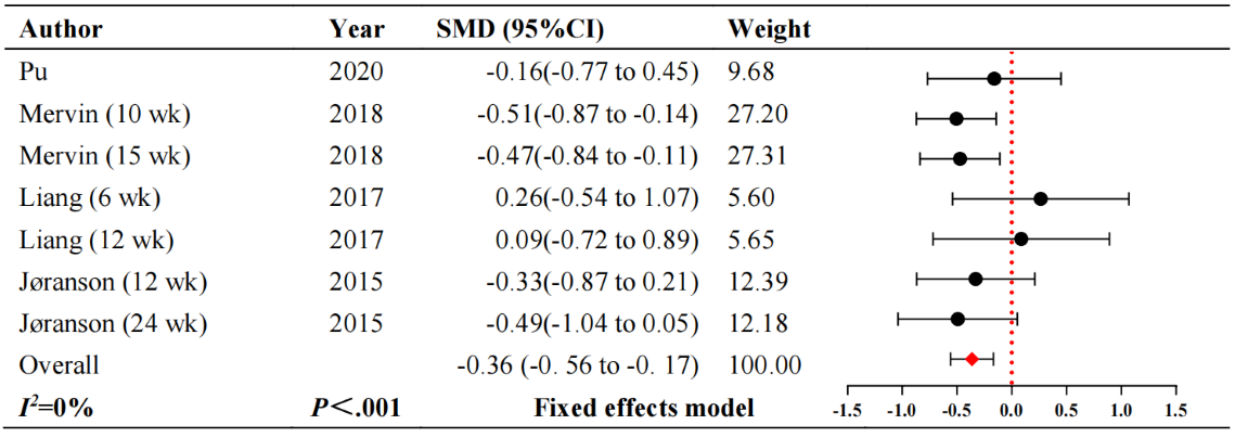


Figure 3. Forest plot of neuropsychiatric symptoms. N: Nao robot (humanoid robot); P: Paro robot (Pet robot); SMD: standardized mean difference.

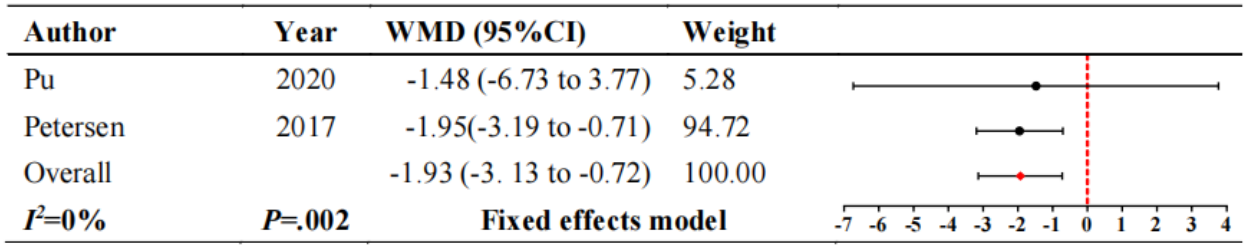
Agitation

Agitation was measured in 4 studies [18,20,24,28]. Figure 4 [18,20,24,28] displays a substantial decline in agitation levels (SMD –0.36, 95% CI –0.56 to –0.17; *P*<.001). These studies showed no heterogeneity (I^2=0).

Figure 4. Forest plot of agitation. SMD: standardized mean difference.



Anxiety

For anxiety, 2 studies [18,31] involving 102 participants reported changes in anxiety. Figure 5 [18,31] illustrates that intelligent robot interventions significantly reduce anxiety scores in patients with dementia compared to usual care (WMD –1.93, 95% CI –3.13 to –0.72; *P*=.002). These studies showed no heterogeneity (I^2=0).

XSL•FO
RenderX

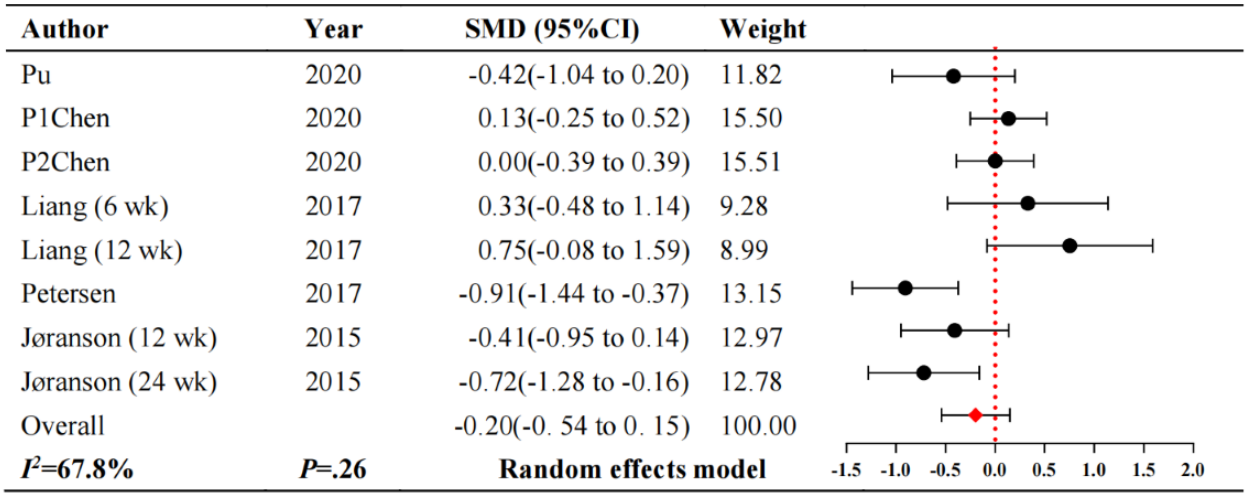


Figure 5. Forest plot of anxiety. WMD: weighted mean difference.

Depression

Regarding depression, 5 studies [18,24,26,28,31] involved 222 participants in the control group and 240 participants in the robot intervention group. Figure 6 [18,24,26,28,31] shows that the intelligent robot interventions cannot relieve depression symptoms in patients with dementia compared to usual care (SMD –0.20, 95% CI –0.54 to 0.15; *P*=.26). These studies showed considerable heterogeneity (I^2=67.8%; *P*=.003).

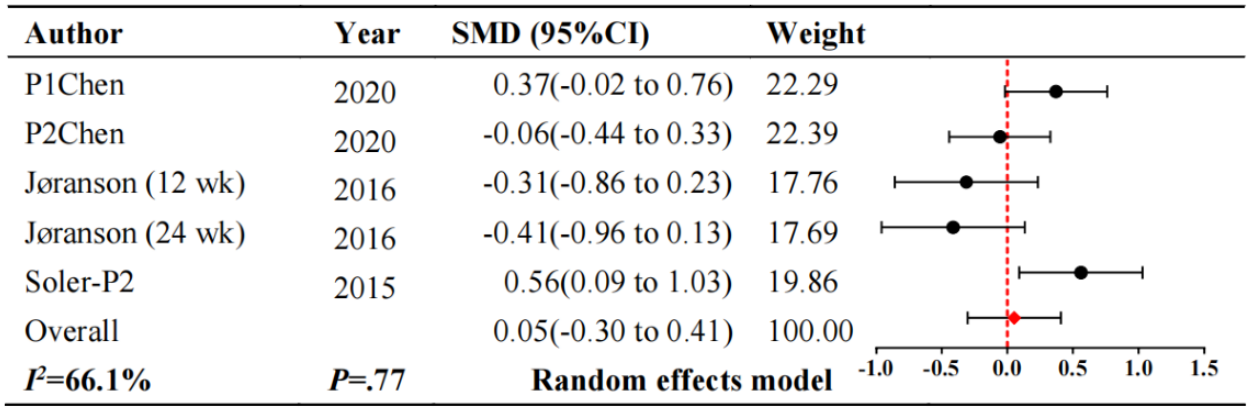

Figure 6. Forest plot of depression. SMD: standardized mean difference.

Quality of Life

For quality of life, 3 studies [23,26,27] were measured. The quality of life scores displayed in Figure 7 [23,26,27] shows that the intelligent robot interventions cannot improve the quality of life in patients with dementia compared to usual care (SMD 0.05, 95% CI –0.30 to 0.41; *P*=.77). These studies showed considerable heterogeneity (I^2=66.1%; *P*=.02).

Figure 7. Forest plot of quality of life. SMD: standardized mean difference.

Data of SenseWear Armband

Sleep and activity data were collected using the SenseWear armband from 2 RCTs [17,19]. The combined data revealed a significant decrease in the amount of time spent lying down during the day (WMD –0.48, 95%CI –0.90 to –0.07; *P*=.02; I^2=0) and reported nonsignificant impacts on length of awake during the daytime or nighttime, length of time lying down during the nighttime, and step count or length of physical activity during the daytime or nighttime (all *P*>.05; Table 2).

XSL•FO
RenderX

Table 2. Meta-analysis of sleep and activity data of SenseWear armband.

	WMD[a]	95% CI	*P* value	I^2 (%)
Daytime				
Lying down (hours)	–0.48	–0.90 to –0.07	.02	0.00
Awake (hours)	0.22	–0.12 to 0.57	.20	2.10
Step count	–31.71	–117.80 to 54.38	.47	43.80
Physical activity (hours)[b]	–0.06	–0.36 to 0.24	.69	0.00
Nighttime				
Lying down (hours)	–0.40	–0.92 to 0.11	.12	0.00
Awake (hours)	0.45	–0.07 to 0.97	.09	0.00
Step count	–10.54	–45.48 to 24.40	.55	41.90
Physical activity (hours)[a]	–0.10	–0.23 to 0.40	.17	0.00

[a]WMD: weighted mean difference.

[b]Time spent in at least light physical activity (>1.5 metabolic equivalent of task).

Subgroup Analysis

Different Durations of Interventions

The Effects on Neuropsychiatric Symptoms

Both short-duration (<12 weeks; SMD –0.18, 95% CI –0.46 to 0.10; *P*=.21; I^2=18%) and long-duration (≥12 weeks; SMD –0.03, 95% CI –0.47 to 0.42; *P*=.91; I^2=70.3%) intelligent robot interventions were not found to enhance neuropsychiatric symptoms significantly (Figure S1 in Multimedia Appendix 2).

The Effects on Agitation

The subgroup analysis results showed that different intervention durations significantly improved agitation in people with dementia. Still, the longer the intervention continued, the better the effect (12 weeks; SMD –0.41, 95% CI –0.80 to –0.03; *P*=.04; I^2=0%; Figure S2 in Multimedia Appendix 2).

The Effects on Depression

A significant effect favoring the more extended intervention on relieving depression (12 weeks; SMD –0.68, 95% CI –1.00 to –0.37; *P*<.001; I^2=0; Figure S3 in Multimedia Appendix 2).

The Effects on Quality of Life

There was no significant difference between different duration intelligent robot interventions and usual care in improving quality (Figure S4 in Multimedia Appendix 2).

Different Types of Intelligent Robots

There was no significant difference between different types of intelligent robot interventions and usual care in improving cognitive function, neuropsychiatric symptoms, depression, and quality of life (Figures S5-S8 in Multimedia Appendix 2).

Sensitivity Analysis

The research findings of the five outcome measures, namely cognitive function, neuropsychiatric symptoms, agitation, depression, and quality of life, indicate that the point estimates of the combined effect sizes were obtained after removing 1 study at a time and analyzing the remaining studies. The results showed that the exclusion of a particular study does not significantly alter the overall results, indicating that an evaluation of the 5 outcomes had considerable stability (Figures S9-S13 in Multimedia Appendix 2).

Publication Bias

Funnel plots and Egger tests were performed to evaluate publication bias of 5 outcome measures, namely cognitive function, neuropsychiatric symptoms, agitation, depression, and quality of life. The results showed no publication bias in cognitive function, neuropsychiatric symptoms, depression, and quality of life (Figures S14-S17 in Multimedia Appendix 2). For agitation, the results of the Egger test showed possible publication bias. There was no significant difference between the effect size estimates obtained using the trim-and-fill method and those obtained by meta-analysis, indicating the results were reliable (Figures S18 and S19 in Multimedia Appendix 2).

Description of Outcomes Not Suitable for Meta-Analysis

A total of 3 studies [21-22,25] were left out of the meta-analysis due to the inability to combine the inclusion of several datasets. Jøranson et al [22] looked into how the intelligent robot Paro affected the sleep habits of patients with dementia living in a nursing home. This study used wrist actigraphy to assess objectively sleep-wake patterns and showed that an intelligent robotic intervention significantly increased the percentage of sleep efficiency and reduced the frequency of nocturnal awakenings in patients with Alzheimer disease. Ke et al [25] assessed the effects of the humanoid social robot (Kabochan) on technology acceptance among older individuals with dementia; they found that being exposed to intelligent robots may enhance their perceptions of the technology's utility and attitudes toward it. Moyle et al [21] showed that participants in the PARO group were more verbally and visually engaged than participants in plush toy.

XSL•FO
RenderX

Discussion

Principal Findings

This study indicates that intelligence robot interventions effectively influenced agitation, anxiety, and length of time lying down during the daytime. The current meta-analysis did discover, however, that intelligence robot interventions had no discernible effects on depression, quality of life, cognitive function, neuropsychiatric symptoms, sleep duration, wakefulness during the day or night, step count, or frequency of physical activity.

In this study, intelligent robot intervention significantly reduces levels of anxiety in patients with dementia, which is consistent with meta-analytic reviews of Saragih et al [8]. Anxiety is highly prevalent across dementia stages, with an overall pooled prevalence of 39% [32]. In recent years, various clinical applications of intelligent robots have been used to provide high-quality emotional support and companionship [33]. Intelligent robots can provide emotional support and companionship to patients with dementia, easing anxiety by interacting with them and sharing stories, music, or simple games. In future studies, the effects of different design elements in intelligent robot interventions on the anxiety levels of patients with dementia can be further explored to understand the preferences of patients with dementia for the appearance characteristics and interaction contents of intelligent robots, so as to improve the references for the design of intelligent robots and clinical application programs, and to give full play to their effectiveness in alleviating the anxiety levels of patients with dementia.

Agitation improved in the intelligent robot intervention group. One study has shown that providing patients with dementia with sensory stimulation, mainly through sight, sound, touch, taste, and smell, can help to improve agitation [34]. Intelligent robots integrate the application of visual, tactile, and auditory multiple sensing technologies, such as the social robot (Paro) covered with artificial fur, capable of moving and emitting sounds to achieve multisensory stimulation, which can put patients with dementia in a multisensory enriched environment and alleviate their agitated state. It has been shown that agitation prolongs the hospital stay of people with dementia and imposes physical, psychological, and financial burdens on caregivers [35]. More research is needed in the future to evaluate whether these interventions also benefit shorter hospital stays, better caregiver psychological health, and lower costs.

The intelligent robot intervention was not significant for overall depression levels in patients with dementia, which is consistent with the findings of Abbott et al [36]. Subgroup analyses based on the length of the intervention were carried out, and the findings indicated that when the intervention lasted for 12 weeks, the intelligent robot intervention helped patients with dementia experience lower levels of depression; however, no such beneficial effect was observed when the intervention lasted for shorter than 12 weeks. Depression in people with dementia often involves deeper emotional issues, and the provision of emotional support and cognitive stimulation by intelligent robots may take longer to produce significant improvements [12]. Subsequent investigations ought to delve deeper into the impact of intervention duration on the efficacy of intelligent robot interventions. The humanoid and animal robots did not differ from one another in subgroup analyses depending on the type of intelligent robot, and neither had a significant impact on the depression levels of patients with dementia. The usefulness of humanoid and animal robot treatments has not been the subject of as many studies, and this study's sample size was limited. In order to provide some guidance for the appearance design and function setting of intelligent robots, the sample size should be increased in subsequent research, and various types of intelligent robots should be thoroughly examined.

Cognitive function and neuropsychiatric symptoms in patients with dementia did not significantly improve with intelligent robot interventions. The cognitive deterioration involved in dementia is usually associated with structural changes in the brain [37], and although intelligent robots can provide social interaction and behavioral stimulation, these may not be sufficient to reverse or significantly improve the cognitive impairment caused by neurodegenerative diseases. Intelligent robots lack the human caregiver's capacity for emotional depth, empathy, and complex decision processing, and their role in neuropsychiatric symptoms in patients with dementia may be limited.

The relevant data for this study came from wearable devices, and the included studies reported difficulties in wearing wearable devices in patients with dementia. The results did not suggest a significant positive effect on sleep and physical activity. Given that individuals with dementia were reticent to wear armbands, particularly at night [17], this conclusion should be interpreted cautiously. To increase patient happiness and participation, more appropriate techniques for tracking sleep and physical activity in patients with dementia should be investigated in the future.

In the group receiving intervention, the quality of life did not improve. Studies have shown that one of the main factors influencing the quality of life of patients with dementia is their capacity to carry out activities of daily living [38]. Patients with dementia also tend to be less capable of taking care of themselves, and some even experience difficulties walking. Although intelligent robots can provide a certain degree of life guidance and support, they cannot completely replace human care and assistance. The cognitive abilities, neuropsychiatric symptoms, the stress of being the primary caregiver, and other factors all affect the quality of life of patients with dementia [39].

Subgroup analysis according to the length of intervention showed that intelligent robot intervention for 12 weeks or more had a more positive effect on the depression level and agitation of patients with dementia, and there was no significant difference in neuropsychiatric symptoms and quality of life. In patients with dementia receiving 12 weeks or more of intervention, symptoms such as depression and agitation may change more significantly due to improvements in emotional regulation and behavioral interventions. However, neuropsychiatric symptoms and quality of life are affected by a combination of more complex physical, psychological, and

XSL•FO
RenderX

social factors, and the effect of the intervention may not be significantly different in these dimensions. This suggests that although long-term interventions have a positive impact on mood and behavior, longer or more comprehensive interventions may be needed to improve neurodegenerative lesions and quality of life. A subgroup analysis was performed according to whether the intelligent robot was a humanoid robot or a pet robot. The results showed that there was no significant difference in the improvement of cognitive function, neuropsychiatric symptoms, depression, and quality of life in patients with dementia between the two types of robots. Although humanoid robots and pet robots differ in appearance and behavior, their core role in providing intervention is often similar, that is, to improve the mood and behavior of patients through interaction, emotional companionship, cognitive training, and other means. This may be the reason for the similar intervention effects of the two.

Strengths and Limitations

This study has several practical implications for practice. First, interventions based on intelligent robots can be considered for inclusion in the long-term care of people with dementia. Second, the shape characteristics of intelligent robots may have no effect on the intervention effect on people with dementia, and other design characteristics need to be further explored. Third, when using wearable devices to assess sleep, physical activity, etc, in people with dementia, the wearing comfort and compliance of people with dementia should be considered.

The following limitations of this study need to be taken into account when interpreting the results. First, the sample size included in this study was small, and further analysis of the impact of factors such as the age, gender, and geographical location of participants on the effectiveness of the intervention was lacking. Second, only original studies published in English were included, and there is a possibility that relevant studies published in other languages were missed. In addition, not all studies were assessed by professional blinders, which may introduce bias into the study.

Despite these limitations, this review aims to comprehensively evaluate the impact of intelligent robot interventions on people with dementia. Seven outcome indicators, including objective indicators of sleep and activity, were meta-analyzed. The impact of the intervention duration and robot type on smart robot interventions was further explored to provide a reference for the future optimization of smart robot development and intervention program design.

Conclusions

This meta-analysis comprehensively assessed the impact of intelligent robot interventions on people with dementia and showed that intelligent robot interventions can reduce agitation and anxiety, with a limited role in improving depression, anxiety, cognitive functioning, neuropsychiatric symptoms, and quality of life, and that sleep- and physical activity-related outcomes need to be analyzed with caution. Subgroup analyses showed better results for the longer the duration of the intelligent robot intervention. The types of intelligent robots included humanoid robots and animal robots, and subgroup analyses showed no difference in their effectiveness. The use of intelligent robots in nursing is still in its infancy, although a number of nations have implemented intelligent robotic interventions for patients with dementia. These interventions have primarily involved women and have small sample sizes and have been concentrated in high-income nations, which may be related to the epidemiological features of dementia. Subsequent research endeavors ought to enhance the conceptual framework of sentient robots and delve deeper into the ways in which the nature of the sentient robot and the length of the intervention affect its efficacy. When using wearable technology to gather physiological data, researchers should take patient compliance into account.

Acknowledgments

The authors would like to thank all authors of the included studies.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

WF, RZ, and XL contributed to the conceptualization and design of the study. WF and RZ collected the data. WF, RZ, and XL analyzed the data. WF, RZ, and XL drafted the manuscript. WF, RZ, XL, and LG extensively revised the manuscript. All authors read and approved the final manuscript submitted.

Abstract

Background: Digital health interventions (DHIs) are changing the dynamic of health care by providing personalized, private, and instantaneous solutions to end users. However, the explosion of digital health has been fraught with challenges. The approach to co-design with end users varies across a diverse domain of stakeholders, often resulting in siloed approaches with no clear consensus. The concept of validating user experiences contrasts greatly between digital stakeholders (ie, user experience and retention) and health stakeholders (ie, safety and efficacy). Several methodologies and frameworks are being implemented to address this challenge to varying degrees of success.

Objective: We aimed to broadly examine the advancements and challenges to co-design DHIs with end users over the last decade. This task was undertaken to identify the key problem areas at the domain level, with the ultimate goal of creating recommendations for better approaches to co-design DHIs with end users.

Methods: We conducted a systematic search of key databases for co-design studies involving end users in DHIs. Searches were divided into 3 relevant streams: health behavior, user experience, and digital methodologies and frameworks. The eligibility criteria were guided by the PerSPEcTiF framework and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist. In line with this framework, studies were included in this review that (1) address research on DHIs; (2) focus on interaction and co-design with end users; (3) explain results such that uptake, effectiveness, satisfaction, and health outcomes are discernible, positively or negatively; and (4) describe actionable procedures for better DHI design. The search was conducted in a diverse group of 6 bibliographical databases from January 2015 to May 2024: PsycINFO, PubMed (MEDLINE), Web of Science, CINAHL, Institute of Electrical and Electronics Engineers Xplore, and Scopus. From the 13,961 studies initially screened for titles and abstracts, 489 (3.6%) were eligible for a full-text screening, of which 171 (1.2%) studies matched the inclusion criteria and were included in a qualitative synthesis.

Results: Of the 171 studies analyzed across 52 journals, we found 5 different research approaches, spanning 8 different digital health solution types and 5 different design methodologies. These studies identified several core themes when co-designing with end users: advancements, which included participatory co-design; challenges, which included participatory co-design, environment and context, testing, and cost and scale; and gaps, which included a pragmatic hybridized framework and industry implementability.

Conclusions: This research supports a pragmatic shift toward using mixed methods approaches at scale, methods that are primed to take advantage of the emerging big data era of digital health co-design. This organic outlook should blend the vision of digital health co-designers with the pragmatism of Agile design methodology and the rigor of health care metrics.

digital health; end users; user experience; health behavior; intervention; co-design; mobile health; mHealth; digital health citizen

Introduction

Background

Digital health interventions (DHIs) are revolutionizing health care delivery by providing personalized, private, and instantaneous solutions to end users. An umbrella term, a DHI is a mobile- or web-based digital solution that facilitates a diverse array of health interventions—be they emotional, decisional, or behavioral. A DHI is designed for a complex set of end users—those who use the intervention, including patients, caregivers, and health care professionals [1]. With the ever-increasing ubiquity of mobile health (mHealth) technologies, cost-effective scalable DHIs are emerging almost daily [2]. These solutions range from self-monitoring to diagnostic, educational, and behavior change–based interventions. At the heart of a DHI is the contextual adaptation [3] around the needs of end users, those who use the technology directly to impact their health [4], such as a patient with diabetes monitoring blood sugar on an mHealth app. This is an exciting yet challenging shift in health care design. It promises more autonomy to the end user through a bottom-up [5] design approach; however, it ruptures the top-down [6] traditional health care approach that positions experts as the central designers of interventions. This evolution marks a shift from visiting health facilities for health services toward the ubiquitous digital participation of end users and health experts. This has produced a new era of health literacy built around diagnostics, services, and self-help. This reciprocal, empowering approach is creating a more mutual understanding [7], evolving the dynamic [8] among health care professionals, engineers, designers, and end users in DHI co-design, ultimately shifting the balance of power toward the patient. Nonetheless, the promise of DHIs is tempered by the fact that 26% of apps are discarded after first use [9]. To address this concern, numerous design approaches such as user-centered and human-centered design, among others, are being used to varying degrees of success [10]. Each approach seeks to incorporate end users, from the primary stages of ideation to the final testing stages of production, gathered around multidisciplinary teams of digital and health care professionals. It is within this focus that we have examined the prominent plus points (ie, advancements), pain points (ie, challenges), and system-wide gaps to incorporate end users in co-design, issues that cut across the entire range of design approaches used in digital health at present.

The Complexity of Hybridizing Digital and Health Approaches to Incorporate End Users

Despite today's digital sphere increasingly being one of digital natives, the path toward a fluid, organic digital health design space has been fraught with challenges. From a digital perspective, rapid Agile development methods evolve to garner end-user satisfaction in an evolving form of iterative qualitative evaluation. From a health care perspective, slow, safe expert-led studies produce large quantitative datasets toward validating patient involvement [11]. Digital health, in its nascent stages, sits somewhat uncomfortably between these two domains. From the macrolevel of policy down to the microlevel of co-design workshops, the very *language of collaboration* may differ. Hybridizing these 2 contrarian methodologies is challenging. The concept of building validation around the user or patient varies, depending on the given perspective. These challenges, along with others, have led to a multiplicity of design approaches, a disparity in conceptualizing the end user, and competing agendas [6,7,12,13] among DHI stakeholders that muddy the waters of digital health design. In this regard, we were inspired to conduct this systematic review on the basis of the initial analysis of our previous study titled, "The Challenges Toward Real-world Implementation of Digital Health Design Approaches" [10]. In our primary study, we found that irrespective of the domain, design methodology, or user definition (Multimedia Appendix 1), there are common pain points (ie, repeated points of conflict or displeasure resulting in a poor user experience [UX]) emerging that impact digital health at the domain level.

In addition, numerous studies [3,6,11,14,15] have noted the challenge to design frameworks that effectively define and implement "co-design" or "co-leadership" around end-user involvement in DHI design. On one hand, health stakeholders may lament the lack of alignment of UX design to health care delivery [9]; on the other hand, digital stakeholders may insist that user-centered design (UCD) is essential toward acceptability [16]. In both cases, each stakeholder is viewing *efficacy* through a different lens. This cuts to the heart of the matter of co-designing DHIs with end users; the overarching philosophy and methods used are starkly different. Therefore, there is a need to better understand the common pain points in this collaboration, which in turn may lead to a better perspective on why, when, and how to incorporate end users in the design of DHIs.

Objective of This Study

This study seeks to compile the core challenges to incorporate end users in the design of DHIs over the last decade. We sought to thematically analyze current approaches, to analyze evidence of pain points that presented a challenge or conflict in the incorporation of end users in the co-design process, and to explore gaps and opportunities toward a more organic co-design approach in digital health. This includes a broad stroke of studies, including quantitative, qualitative, mixed methods, and research through design. It features the perspectives of health care, psychology, engineering, development, and design in the production of mHealth, eHealth, and extended reality DHIs. This intentionally broad approach is reflective of the nascency of digital health as a field and the open-mindedness of this study, such that the divergence and convergence of methodologies and tools is viewed as a prosperous and necessary growing pain toward a more organic digital health approach to end users.

XSL•FO
RenderX

It is hoped that through critical analysis of these advancements, challenges, and gaps, synthesized findings from the following questions lead to an improved approach toward incorporating end users in DHI co-design:

1. How are end users currently incorporated into iterative DHI design, and what is the effectiveness of current methods?
2. What are the most common pain points (ie, challenges) encountered while incorporating end users in DHI design activities?
3. What are the current gaps in end-user research at the domain level, and how can these be addressed to better integrate end users into the iterative design process in digital health, aiming to improve efficacy and uptake?

Methods

Study Design

This systematic review followed an a priori published protocol with detailed methods registered with PROSPERO (CRD42021238164) [17]. The review followed the Cochrane Handbook for Systematic Reviews [18] and was reported using the PRISMA-P (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Protocols) guidelines [19].

We followed six stages in this systematic review: (1) literature search, (2) article selection, (3) data extraction, (4) quality appraisal, (5) data analysis, and (6) data synthesis.

Eligibility Criteria

Considering the complexity of DHIs, we used the PerSPEcTiF [20] guidelines for intervention (Table 1). We selected it due to its suitability for qualitative synthesis in the health care domain.

In line with this framework, studies were included in this review that (1) address research on DHIs; (2) focus on interaction and co-design with end users; (3) explain results such that uptake, effectiveness, satisfaction, and health outcomes are discernible, positively or negatively; and (4) describe actionable procedures for better DHI co-design.

Table 1. Details of the PerSPEcTiF question formulation framework as applied to this review.

Initials	Definition	Detail
Per	Perspective	From the perspective of end users
S	Setting	In the setting of digital health
P	Phenomenon of interest or problem	What are the most prominent pain points
E	Environment	Within an environment of designing DHIs[a]
C	Comparison (optional)	—[b]
Ti	Time	During ideation and co-designing
F	Findings	In relation to understanding the challenges of successfully incorporating end users in the successful design of DHIs

[a]DHI: digital health intervention.

[b]Not applicable.

Search Strategy

We systematically searched 6 electronic databases: PsycINFO, PubMed (MEDLINE), Web of Science, CINAHL, Institute of Electrical and Electronics Engineers Xplore, and Scopus. We selected these databases according to preliminary searches and consultations with experts and librarians in this field. Keywords related to DHIs from preliminary searches were compiled and refined. We adapted the search strategy as needed to return a breadth of papers without retrieving an unmanageably large number of irrelevant articles.

A list of the search terms used in this review were grouped into 3 clusters (Table 2). In addition, we have included all search strings for replicability (Multimedia Appendix 2).

Table 2. Clusters of categorized search keywords.

Categories	Keywords
DHIs[a]	"digital health" or "mHealth" or "eHealth" and "end user*" or "end user*"
User experience	"user experience" or "UX" or "user centred" or "user centered" or "human centred" or "human centered" or "patient centred" or "patient centered" or "person based" or "person centered" or "person centred" or "participatory design" or "involvement" and "digital health" or "mHealth" or "eHealth"
Methodologies and frameworks	"agile" or "scrum" or "kanban" and "digital health" or "mHealth" or "eHealth"

[a]DHI: digital health intervention.

Cluster 1 includes DHIs (owing to behavior change in health care resulting from DHIs). Cluster 2 includes UX (owing to engineering, development, and design in digital health). Cluster 3 includes methodologies and frameworks (owing to digital project facilitation and to health care intervention design and policy).

XSL•FO
RenderX

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria were based on the peer-reviewed studies outlined in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Qualitative studies
- Case studies
- Observational studies, including cross-sectional surveys
- Nonrandomized studies (eg, before and after studies and interrupted time series studies)
- Cohort studies

Exclusion criteria

- Noncritical analysis of end-user involvement in digital health design (ie, no results or discussion on end-user incorporation)
- Single person studies
- Nonprimary research (eg, reviews and commentaries)
- Randomized controlled trials
- Nonhuman studies

Due to the rapid innovation of digital health, only studies in the English language from January 1, 2015, to May 31, 2024, were included. Broadly put, the inclusion criteria included any population group that involved the critical analysis of end-user incorporation (ie, inclusive of terms such as patient, person, and human) in the co-design of a DHI. Studies that did not meet this criteria were excluded, including those that included end users but did not provide any critical analysis of the process; reviews and commentaries due to them being nonobservational or nonexperimental; single-user studies due to the inability to generalize; randomized controlled trials (RCTs) due to a lack of focus on the end-user integration in the design of a DHI; and nonhuman studies, which are impertinent to the design of a DHI.

Screening and Article Selection

All articles identified and selected from database searches were stored in the reference management software Paperpile (Paperpile LLC), which was used to eliminate duplicates and to tag and organize the research findings. The initial screening process involved 2 independent reviewers (AD and either IR or NB) who screened titles and abstracts of all studies for possible inclusion using an Excel (Microsoft Corp) spreadsheet (Multimedia Appendices 3 and 4) to ensure no studies met the exclusion criteria. After filtering results on the basis of the possible inclusion criteria, the second stage involved a full-text review of the remaining articles, which was conducted by 3 independent reviewers (AD and IR or AS). Upon scrutiny of the full-text selections, reviewers (AD and IR or AS) removed items that did not meet the inclusion criteria. In the third and final stage, reviewers (AD and IR or AS) met to cross-reference eligibility of the final inclusion list, as well as to settle any conflicts. This cross-reference involved the individual review of all items to white list them per the inclusion criteria. For items in conflict, reviewers (AD and IR or AS) simultaneously scanned items side by side to determine whether the items met the inclusion criteria. Since this was the third round of filtering, the majority of items met the inclusion criteria, so the determining factor in conflicts was to collectively review each item to see whether the studies actively involved end users in the design of the DHI and whether critical analysis of this was present in the results or discussion sections of the respective study. This final step removed any subjectivity and resolved conflict.

Data Extraction, Analysis, and Synthesis

A data extraction template was created by one of the authors (AD) that provided a record of the study characteristics. The categorization of themes and subthemes emerged organically from the findings (Multimedia Appendix 5). The collection, extraction, and subsequent analysis and synthesis of data is outlined in Table 3.

Raw content (ie, quotes and reflective analysis) was extracted and collected in a research document (Multimedia Appendix 6). Data were extracted and analyzed relative to the goals of the research questions, following guidance from the Cochrane Handbook for Systematic Reviews of Interventions [18]. These data are synthesized and presented in narrative form in the Results section. Full characteristics of all included end-user studies are available in Multimedia Appendix 7.

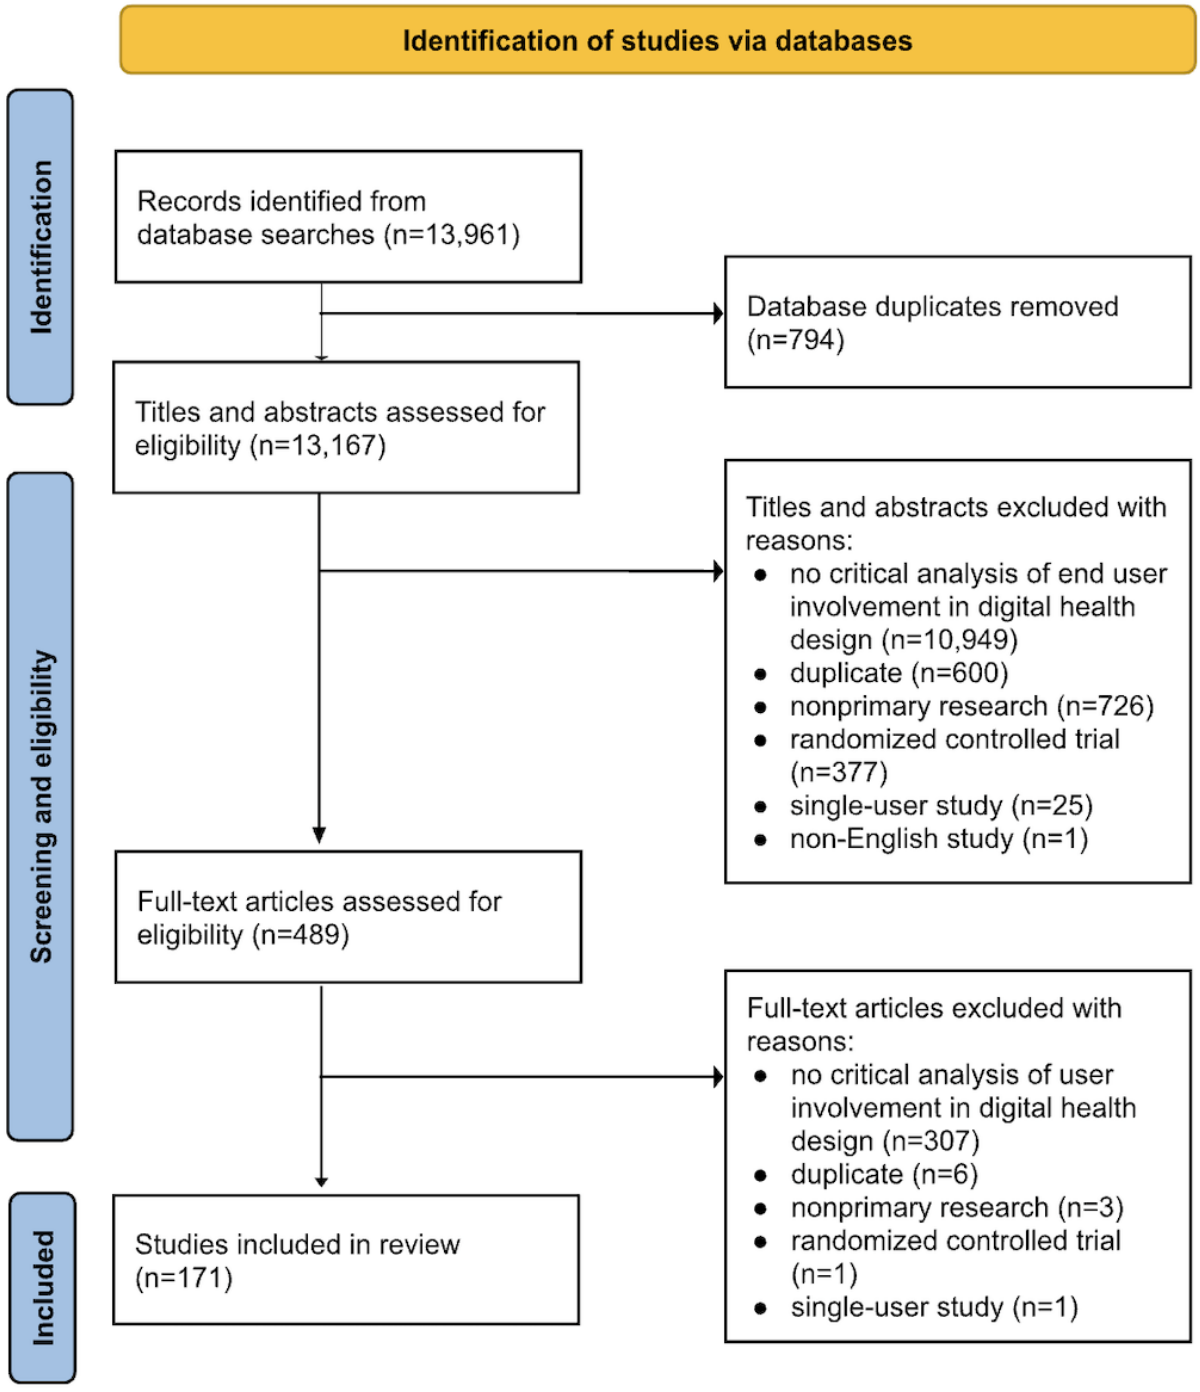
Table 3. Data extraction characteristics and the identified themes and subthemes.

Category	Description
Data extraction	
Summary of characteristics	Full citation, author, PMID[a], year, and journal
Study type	Case study, quantitative study, qualitative study, research article, and mixed methods study
Study details	Target population, end users, duration (h), and solution
Design methodology	User-centered design, human-centered design, patient-centered design, person-based approach, patient-led design, and general participatory design.
Project facilitation method	Kanban, Scrumban, Waterfall, XP[b], Agile inspired, design thinking, and unspecified
Data analysis and synthesis (themes and subthemes)	
Key plus points (ie, positives)	
Participatory co-design	Collaboration, ideation, improved mode of delivery, behavior modification, and in situ environment
Key pain points (ie, negatives)	
Participatory co-design	Collaboration, the language of digital health, co-design, competing interests, hierarchical versus democratic design, and methodological misalignment
Environment and context	Untested in situ and multiplicity of user types
Testing	Lack of participants, quality of participants, condensed time frame, lack of comprehension, technology, and cultural sensitivity
Cost and scale	
Challenges (ie, gaps in the research)	Organic co-design approaches, fluidity of digital health efficacy evaluation, Agile digital health methods, industry implementability, supply chain, medical device versus consumer app, and research and development limitations

[a]PMID: PubMed identifier.

[b]XP: extreme programming.



Results

Search Results

The search strategy identified 13,961 studies. After removing duplicates (n=794), a total of 13,167 (94%) studies were screened for title and abstract. After the initial title and abstract screening phase, 12,678 (91%) studies were excluded, leaving 489 (4%) potentially relevant papers. In the second full-text screening phase, 318 (2%) studies were excluded. This resulted in the inclusion of 171 (1%) relevant studies in this systematic review. Reasons for exclusion included a lack of critical analysis of end-user involvement in digital health co-design and nonprimary research (eg, reviews and op-eds, RCTs, and single-user case studies). A PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram (Figure 1) was used to record the details of the screening and selection process so that the study can be reproduced.

[a]Three studies identified with Scrum, which is a subset of Agile.

[b]BMC: Biomed Central.

[c]IEEE: Institute of Electrical and Electronics Engineers.

[d]mHealth: mobile health.

[e]Three studies identified more than one methodology.

Study Types

Owing to the diversity of digital health, the 171 studies identified span 5 different research approaches. Most approaches were qualitative (107/171, 62.6%), followed by mixed methods (43/171, 25.1%), indicative of the social and emotional influence on DHIs. These studies were collected from 52 different journals across multiple research domains, with JMIR accounting for the majority (94/171, 55%).

Study Details

The DHIs spanned 8 different solution types with mHealth (97/171, 56.7%) representing the majority. This development is in line with the growing dominance of mobile digital devices with up to 92% of internet traffic at present being mobile based [21].

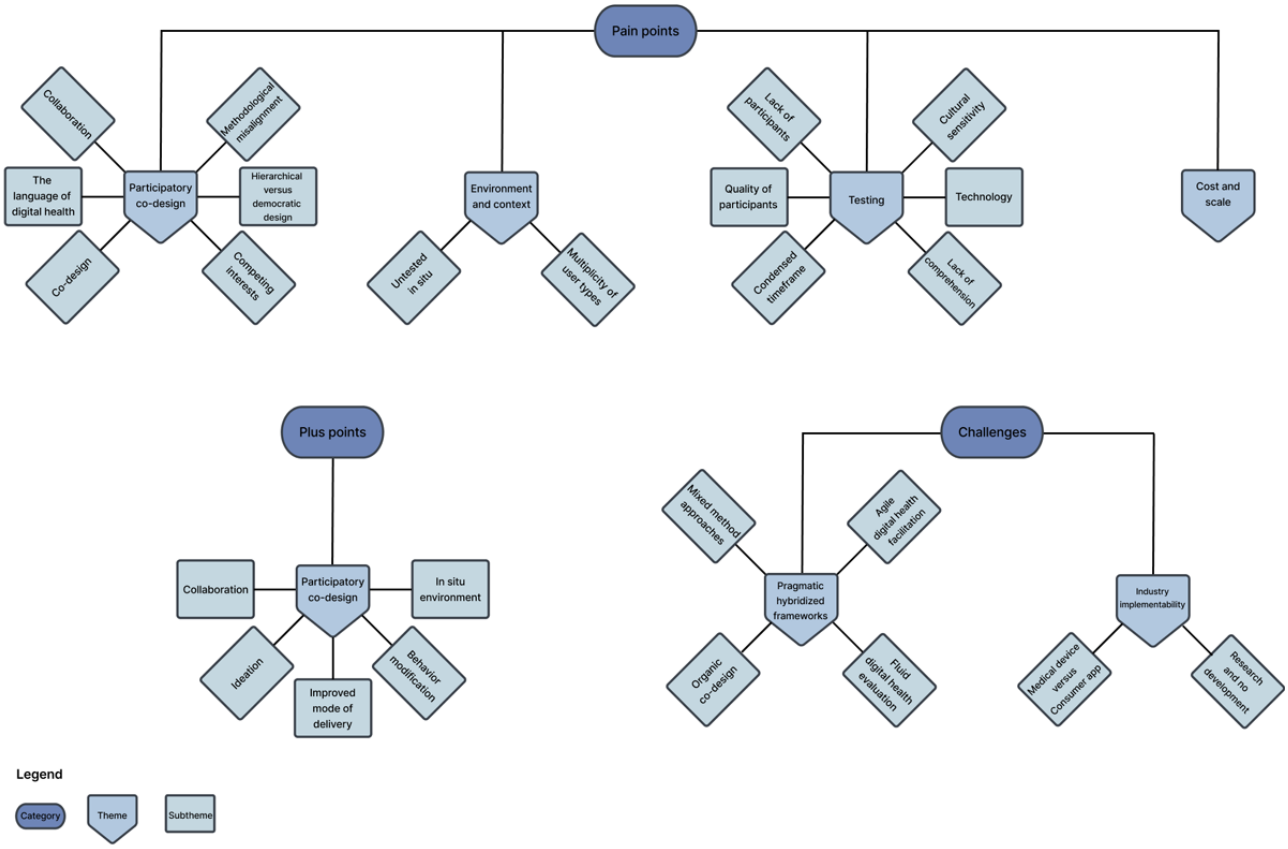
These solutions were used in 15 different populations with patient-focused populations being the most prominent (91/171, 53.2%). There was considerable variation in the number of end users involved in a DHI co-design with 6 to10 (44/171, 25.7%) end users being the most prominent, followed by 11 to15 (28/171, 16.4%), 21 to 30 (25/171, 14.6%), and 1 to 5 (21/171, 12.3%) end users. Only 9 studies (5.3%) involved >50 end users.

Study Design Methodology

As a guiding design methodology, UCD (84/171, 49.1%) was most prominent, followed by the broader approach of participatory design (58/171, 33.9%), then human-centered design (18/171, 10.5%). Other approaches such as patient-centered design, patient-based approach, and patient-led design were used sparingly.

Study Project Facilitation Method

Finally, in addition to tracking the design methodology, we tracked the project facilitation method used. The vast majority of studies did not specify a project facilitation method (133/171, 77.8%) that was used. Of those that did, Agile was used the most (24/171, 14%), followed by design thinking (10/171, 5.8%). Scrum, a subset of Agile, was next (9/171, 5.3%), while none specified other common industry methods such as Kanban, Extreme Programming, or Waterfall. This is particularly interesting when comparing how digital health prototypes are facilitated in academic research environments versus typical industry methods.



We present the aforementioned study characteristics to illustrate the diversity of investigating the incorporation of end users in co-design. As discussed, this rigorous approach sought to incorporate as many vantage points as possible to identify common advancements, challenges, and opportunities for improvement in the domain. A thematic analysis of the plus points (ie, advantages), pain points (ie, disadvantages), and challenges to incorporate end users in the co-design of DHIs

XSL•FO
RenderX

(Figure 2) as addressed in the 3 research questions is presented later.

A brief definition of the resultant themes and subthemes is presented in Table 5. This is followed by an explanation of the results relevant to each of the 3 research questions in this study.

Figure 2. Flowchart of the thematic analysis of plus points (ie, advantages), pain points (ie, disadvantages), and challenges to co-design digital health interventions (DHIs) with end users.

Table 5. Description of the themes and subthemes identified in the data synthesis.

Section and theme	Description	Studies, n (%)
Plus points		
Theme: Participatory co-design	Positive advancements from the active participation of end users in the co-design workshop phases to ideate and test DHIs[a]	95 (55.5)
Subthemes		
Collaboration	Collaboration among stakeholders (eg, developers, health professionals, and end users) in the co-design of a DHI	69 (72.6)
Ideation	Creative process to construct ideas, requirements, and design concepts in the nascent stages of co-design with end users	55 (57.9)
Immediate behavior modification	The benefits of instant behavior changes obtained by end users through the knowledge enhancing collaboration of DHI design workshops	16 (16.8)
In situ environment	Ideating and testing with end users in the actual environment the intervention is designed for (ie, hospital, care homes, among others)	7 (7.4)
Pain points		
Theme: Participatory co-design	Failures when incorporating end users in the active participation of co-design workshop phases to ideate and test DHIs	70 (40.9)
Subthemes		
Collaboration challenges	Failures to curate and implement collaboration approaches among stakeholders (eg, developers, health professionals and end users) in the co-design of a DHI	14 (20)
The language of digital health	Difficulties communicating a common language of co-design considering the various semantics that stem from differences in collaborator perspectives (ie, digital, health care, and end users)	14 (20)
Cultural sensitivity	Understanding the nuances of culturally appropriate approaches that are used to describe the content and functionality of DHIs with end users	13 (18.6)
Competing interests	Contrasting objectives defined by health and digital goals that create friction in the process of designing around the end users	18 (25.7)
Methodological misalignment	Differences in digital health intervention design stemming from methodological misalignment (ie, digital, health or behavioral approaches to co-design)	13 (18.6)
Hierarchical versus democratic design	The challenging contrast between the slow, steady, and data-driven approach to health care design and the laissez-faire rapid approach to digital design innovation, making processes and evaluation difficult in digital health	17 (24.3)
Theme: Environment and context	The collaboration and testing environment of the end user and the contextual understanding of who the end user is	38 (22.2)
Subthemes		
Untested in situ	The lack of co-designing or testing in the contextual environment of the user	23 (60.5)
Multiplicity of user types	Lack of understanding of the complexity of user types (ie, patient, person, clinician, therapist, and caregiver)	16 (42.1)
Theme: testing	Problems incurred during the testing phase with end-user collaborators that led to questions on the validity, reliability, and generalizability of results	113 (66.1)
Subthemes		
Lack of participants	In reference to a lack of end-user testers leading to questions on the validity and reliability of results and determinations	75 (66.4)
Quality of participants	In reference to a lack of broader representation of user types (ie, patient user, caregiver user, and clinician user), including demographic concerns (ie, ethnic diversity), thus weakening the generalizability of results	58 (51.3)

XSL•FO
RenderX

Section and theme	Description	Studies, n (%)
Condensed timeframe and limited participation	The condensed time frame leading to limited participation of end users in collaboration workshops and testing, raising questions on rigor and applicability of results broadly	25 (22.1)
Lack of technological comprehension	Inclusive of knowledge of technical terminology and digital device variance (ie, iPhone vs Android)	14 (12.4)
Challenges		
Theme: Pragmatic hybridized frameworks	The need for new frameworks that are friction reducing, pragmatic (ie, fit for purpose), and hybridized (ie, a collective fluid combination of digital, health and behavioral objectives), leading toward more transdisciplinary approaches in DHI design	60 (35.1)
Subthemes		
The value of mixed method approaches to end-user data	Despite the advantages that mixed methods approaches bring to DHIs (ie, blending emotional and functional feedback for better design decisions), the uptake in mixed methods approaches to data collection is low and inhibits more pragmatic approaches to DHI evaluation	24 (40)
Organic co-design approaches	The challenge to cocreate approaches to end-user involvement in co-design that are not a sum-of-its-parts approach; siloing digital (ie, usability) and health care (ie, safety) elevation as unrelated metrics	25 (41.7)
Fluid digital health efficacy evaluation	The challenge to amalgamate the *fail fast* approach of digital design and the *first do no harm* approach of health care design around end-user design involvement	39 (65)
Agile digital health project facilitation	The difficulty to implement Agile industry-styled co-design practices with the rigor and requirements of health care safety and efficacy	18 (30)
Theme: Industry implementability	The lack of consideration when co-designing with end users for downstream industry implementation within the complexity of the health care system (ie, government policy and industry constraints and regulations that impact design)	13 (7.6)
Subthemes		
Medical device vs consumer app	The challenge to navigate consumer (ie, end user) preferences that collide with medical device regulation	5 (38.5)
Supply chain	Health care delivery involves the collaboration of industry suppliers and government regulatory bodies that bring DHIs to the end users. The lack of health care business analysts in the co-design process with end users negates business modeling factors that could reduce downstream deployment challenges.	6 (46.2)
Research and no development	The lack of recognition and resolution of the aforementioned failures and challenges often leads to prototypes that never reach the development or deployment stages	5 (38.5)

[a]DHI: digital health intervention.

Research Question 1: How Are End Users Currently Incorporated Into Iterative DHI Co-Design, and What Is the Effectiveness of Current Methods?

Theme: Participatory Co-Design

The most positive and influential approach to the incorporation of end users in the co-design of DHIs can broadly be termed as participatory co-design (ie, an approach wherein end users participate in the co-design process). In total, 95 of the 171 (55.5%) included studies discussed the advantages and advancements of participatory co-design in the digital health domain, irrespective of the domain approach (ie, engineering and health among others). This overarching methodological approach culminated in subthemes such as collaboration, ideation, environment, and improved behavior modification.

Subtheme: Collaboration

Collaboration (69/171, 40.4%) [6,7,9,12,22-87] was identified as a key benefit of participatory co-design. Studies explained that collaboration in DHI design allows complex teams to co-create dynamic solutions [30] that uniquely combine a variety of digital and health approaches around the end user [23,88,89]. Collaboration may take the form of interviews, design workshops, and crowdsourcing (ie, web-based surveys and mass testing). This constructive, creative, iterative [90], and engaging process reflects the diverse mosaic of digital health stakeholders, while increasing the understanding of end-user needs due to the variety of vantage points [91]. Increasingly, studies showed that collaborating with a diverse stakeholder group around the end user, from ideation to production, increased end-user design participation [8,28,36], improving evidence-based approaches

XSL•FO
RenderX

[92]. This development is increasingly important, since earlier attempts to incorporate end users in late-production testing have been widely found to be ineffective [22]. Collaboration, particularly through the early low-fidelity stages of prototype design, increased adaptability of the solution in a low-cost phase [36]. It also created mutual understanding among all stakeholders regarding their roles and how they relate to the DHI as a sum of its parts rather than as siloed experts [37,93]. This approach is increasing sensitivity to the cultural context and personal preferences of end users, which in turn is improving the common language of communication in digital health solutions [32]. In short, collaboration is the element of participatory co-design that is closing the gap between the patient, clinician, and designer [39].

Subtheme: Ideation

Ideation (55/171, 32.2%) was identified as a key benefit in participatory co-design. Loosely defined as the ability to generate new ideas [30], studies used it as a hands-on approach to incorporate users within digital health teams in workshops [29] to cocreate and prioritize end-user preferences [30,94] and subsequent features in a DHI. This process was used early in the DHI design process, often encapsulated in design sprints or health game jams [95] that empathetically seek to understand end-user needs in a process of divergence and convergence [14,38], whereby finding differences is seen as a necessary building block on the path to agreeing on a robust co-designed solution.

Subtheme: Immediate Behavior Modification

Immediate behavior modification (16/171, 9%) [15,24,27,39,42,51,64,68,69,74,76,96-98] in participating end users was identified as a beneficial yet perhaps unexpected advantage of in situ collaboration and ideation. Studies observed instant behavior modification from incorporating end users in DHI workshops. The multidisciplinary nature of rapid iteration that organically collects design, development, health care, and end-user experience data in a decentralized experimental environment allowed for persuasive design and behavior change in real time. This reciprocal process allowed digital and health stakeholders to educate end users on how a DHI can improve their experience, while end users were able to educate other stakeholders on how and what makes a positive UX for them.

Subtheme: In Situ Environment

Co-designing in situ (7/171, 4%) [35,53,72,89,91,99,100] such that on-site collaboration with end users took place in hospitals, clinical environments, or homes [89] increased the realism of stakeholder participation, leading to a more natural evaluation of the intervention. In such studies, this led to a better ability to co-conceptualize solutions [101]. This shift is in response to studies showing limitations on the quality of data and the potential effectiveness of DHIs that were commonly not tested in situ (eg, university laboratory environments), which challenges external validity [35,100]. In situ co-design increased familiarity of surroundings, enhanced comfort, and provided a more genuine, meaningful interaction with end users [91].

Research Question 2: What Are the Most Common Pain Points (That Is, Challenges) Encountered While Incorporating End Users in DHI Design Activities?

Theme: Participatory Co-Design

Participatory co-design was simultaneously a core theme of the positive advancements as well as common failures to incorporate end users in the design of DHIs (70/171, 40.9%). This dichotomy is not unexpected considering the nascency of the burgeoning digital health industry. These challenges are related to collaboration, communication (ie, the language of digital health), competing interests, hierarchical versus democratic design approaches, and methodological misalignment. Broadly speaking, these challenges are growing pains toward blending digital and health care approaches in co-design.

Subtheme: Collaboration Challenges

Collaboration challenges (14/171, 8%) [5,7,30,41,53,65,68,71,88,89,102-105] in participatory co-design ranged from the challenge to curate collaboration approaches based on the given use-case scenario, to variance in stakeholders' knowledge bases (ie, technology, health care, and UX), to miscalculating the need for onboarding co-designers in the workshop process, to mediating disagreements [102], and misallocating stakeholder types (ie, too many clinicians, not enough end users, or vice versa) [103]. These factors led to disagreements, increased timelines, and overbudgeting that challenged the effectiveness of the co-design around the end user. These collaboration challenges are resultant of a clash of cultures (eg, digital and health care) and are defined by the following subthemes.

Subtheme: The Language of Digital Health Co-Design

Challenges to form a common language in co-design (14/171, 8%) [42,60,62,64,65,71,74-76,103,106-109] identified the difficulty of blending the semantics of health care, digital design, and the colloquialisms of end users. Design "sprints" [108] sometimes felt rushed to health care stakeholders and end users if unexplained. While safety may indicate imminent danger to end users, in health care, safety is more indicative of preventing harm from happening [107]. Conceptualizing what a prototype was or explaining what a minimum viable product represents in nascent design stages was not a given for nondigital stakeholders. Usability (ie, technical), UX (ie, emotional), and patient efficacy (ie, medical) are all by-products of the co-design process, but the language, interpretation, and implementation in the workshop meant different things to different stakeholders leading to conflicting understandings.

Subtheme: Cultural Sensitivity

Stemming from the common language issue, studies identified the challenge to collaborate with end users in a way that is culturally sensitive and appropriate (13/171, 7.6%) [38,39,42,44,47,57,68,88,110-115]). Cultural sensitivity has been observed in 4 main categories: content, functionality, technology, and user interface [3]. Studies cited the challenge of using inclusive digital media in workshops that is culturally befitting, as well as addressing sensory needs (eg, vision and hearing deficiencies) of patient end users [88]. For example, the use of gamified incentives and rewards in mHealth apps

XSL•FO
RenderX

[38] for communities that suffer from gambling addictions may be a critical oversight. Studies that incorporated cultural frameworks built with end users showed promise toward negating downstream challenges in the design cycle, particularly concerning appropriate content, features, and imagery in the interface design [3,39].

Subtheme: Competing Interests

Competing interests (18/171, 10.5%) [4,7,9,14,16,43,64,78,88,98,101-103,106,116-119] were found to be a prominent challenge within participatory co-design with end users. This can be summarized as the focus on health systems and services versus the needs of matching digital technologies to user preferences [14]. These competing lenses [101] led to contrasting perspectives on how to incorporate end users in DHI co-design. Broadly, it speaks to the clash of cultures as expert-led health care approaches and innovative user-driven approaches collide. The concept of "shared ownership" proved uncomfortable in numerous studies [9,98,101,118]. Although there was a shared vision on improving quality and safety around end users, exactly *how* this was achieved is a point of conflict [7]. Disease management, improved well-being, and UX are all facets of an intelligent design, yet they speak to different objectives [95]. Stakeholders often felt internal pressure to deliver aspects of the solution that reflect their domain (ie, digital, health care, and policy), which challenged the co- in co-design. Where a patient stakeholder may desire anonymous data tracking (eg, for privacy), a health care professional may desire mapped data tracking (eg, for safety and electronic records), and a digital stakeholder may need analytics (eg, to drive sales) [7]. The inability to corral these competing interests led to disengagement or abandonment of the collaboration in some cases [119].

Subtheme: Methodological Misalignment

Ironically, a paradox exists in that the emergence of diverse stakeholder groups seeking to co-design with end users has led to difficulties in communicating and co-designing [120]. Methodological misalignment (13/171, 7.6%) [29,35,47,58,60,64,65,69,91,120-122] in the approach to evaluating safety, usability, and efficacy differed vastly between health care and digital experts, respectively. The goals of these contrasting stakeholders were quite divergent [35]. In this regard, digital health is a domain struggling to formulate its own unique design culture around end users. Contextual barriers [91,121] exist such that the qualitative nature of rapid design sprints does not quantify the risks, safety, or efficacy of a longitudinal study, which spans large datasets (ie, RCTs). Simply put, it can be difficult to gain buy-in due to the vast variation in research approaches.

Subtheme: Hierarchical Versus Democratic Design

Methodological misalignment surfaced most prominently as a conflict between hierarchical and democratic concepts of designing DHIs (17/171, 9.94%) [3,6,9,12,15,35,38,69,90,93,113,123-128]. Traditionally, a more paternalistic relationship [3] exists between health care experts and patients (ie, end users). This hierarchical construct often relies on expert-driven "hard data" decisions. This is contrary to the more democratic, inclusive approach to digital design workshops, where the end user and other stakeholders are often seen as equal. The concept of *leadership and followership*, such that design workshops often see different stakeholders take the lead based on a given exercise [93], is a new and rupturing approach to health care interventions. Evidence-based and experience-based approaches accentuated the juggling act of balancing perspectives and soothing egos. On the design side, certain biases related to the pragmatic mode of using user-driven exercises conflicted with evidence-based research in health care, especially in the arena of safety and clinical efficacy. Design workshop approaches to user personas and user journeys tell a story about a user and their preferences, but they do not account for clinical perspectives on harm prevention and safety. Where digital experts may insist "the solution must occur organically" around the end user, this democratic approach may be viewed as oversimplification by health experts who may insist that a "first do no harm" approach must involve quantitative data that exemplifies safety and efficacy. In this context, the aforementioned challenges culminate in the battle between innovation and clinical reality [15].

Theme: Environment and Contextualization

After understanding the various challenges that participatory co-design poses to stakeholders working with end users in the design of a DHI, an emergent theme that developed was the impact of the collaboration environment and the contextualization of the end user (38/171, 22.2%).

Subtheme: Untested In Situ

Numerous studies observed the challenging impact of not designing a DHI with end users in situ (23/171, 13.4%) [3,7,15,30,68,73,74,77,99,106,110,113,116,129-138]. In situ here refers to co-designing or testing in the contextual environment of the user. For example, a triage digital tablet in a waiting room or a sleep diary app in a user's bedroom. This limited generalizability, challenged the value [110] of design workshops, and weakened the ability to evaluate the true context of use [3,116,129-131,134-137]. Without testing DHIs in their natural environment, the context of the data collected was sometimes considered incomplete. Furthermore, it does not observe how end users would interact with the data and experiences they are creating, *in real-world settings* [30,106,133]. For many mHealth solutions, app use was found to vary by time and location, with various environmental factors impacting how end users may interact with the intervention [7,132]. This made it increasingly difficult to generalize both design considerations and testing conclusions from a controlled laboratory environment. For digital stakeholders, this may render UX evaluation speculative. For health stakeholders, clinical efficacy evaluation may be incomplete.

Subtheme: Multiplicity of User Types

Another factor impacting the contextualization of the DHI was the multiplicity of user types (16/171, 9.4%) [6,47,54,58,72-74,77,80,85,130,137,139-142]. End users were viewed as patients, persons, clinicians, therapists, and passive users (ie, an observer such as a caregiver), among others. Numerous DHIs had more than one end user, each using the solution for a different objective. Unlike traditional collaborative design workshops that involve 1 end-user type or a potential

XSL•FO
RenderX

customer, mHealth solutions often provide services to numerous types of end users. For instance, in heart medication apps, a patient may objectify a knowledge base with push notifications and, as a user goal, a therapist may objectify behavior change as a user goal and a physician may objectify metrics to track medication history as a user goal—all 3 stakeholders may be end users of the same DHI [137]. Therefore, positioning the patient as the sole end user may insufficiently reflect the scope of end-user incorporation in the design process.

Theme: Testing

Foundational challenges in participatory co-design, inclusive of environmental and contextual issues, unsurprisingly culminated with pain points downstream in testing with end users (113/171, 66.1%). Testing subthemes included a lack of participants, the quality of participants, a lack of testing comprehension, and condensed time frames.

Subtheme: Lack of Participants

A lack of participants (ie, end users) challenged the generalizability of results (75/171, 43.8%) [3,7,11,15,25,27,28,32,34,36,41,42,45-49,51-57,60,61,63-66,69,71,72,74,75,80,84,90,94,98,99,104,105,108,110,119,127,129,131-134,136,140,142-163]. This limitation in the number of participants is a common challenge for co-design workshops [28]. The reliance on 5 test participants [11,131,157] is a common practice in qualitative research, where findings from 5 end users are often assumed to reflect the experiences of 50 or 500 end users. This approach is foreign to traditionally quantifiable health research, and is admittedly speculative and potentially biased, as observed in many of the study limitations. Therefore, despite the richness in emotional feedback derived from and around end users in co-design workshops, the lack of quantifiable evidence limits and weakens the broad applicability of results [129]. Terms such as "sufficient" [8] or "generally provable" were used alongside admissions of lack of generalizability. The rapid, cost-effective, human-centered approach [15] to design workshops concedes larger sample sizes, edge cases, and an overall breadth of data obtained from large-scale patient trials in health care. Ironically, while aiming to use methods that address "the needs of end users," [32,34,147,156,157,164,165] these same methods inherently reduce the scope of end user needs, conceding large-scale feedback that could further advocate for design workshops emphasizing "acceptability" and "usability," with large-scale, quantifiable validation from a broader pool of end users.

Subtheme: Lack of Diversity of Participants

The lack of diversity among participants (58/171, 33.9%) [12,14,30,35,36,38,41,42,45-49,51-57,61,63-66,88,95,98-100,104,105,111,124,130,139,145,148,152,155,159,161,166-169] was evident in a third of studies. Studies with small sample sizes were not always able to account for various cultural and educational user differences within a demographic [14,30,88,95,100,111,127,145,155]. The lack of representability, both in variety of end-user types (eg, patient, clinician, caregiver, and others) and skillset (ie, tech savvy superusers [124] vs standard users) contributed to consistent validity and generalizability concerns. With the clinician (ie, patient advisor), patient, and caregiver (ie, observer) often being co-users of the DHI, excluding one end-user group or more from the co-design or testing phases was seen as a risk of biasing results [29,139,168]. The user test of a patient and that of a clinician may vary drastically due to contrary perspectives and user needs, despite them both being end users of the same DHI [35,36,148].

Subtheme: Condensed Time Frame and Limited Participation

In some cases, the quantity and quality of participants was directly impacted by the rapid, condensed time frame (25/171, 14.6%) [14,30,35,37,53,60,64-66,71,80,83,92,99,100,108,116,119,146,148,149,152,170-172] of co-design workshops built around end users. Some studies recognized that despite the overtly flexible approach to iterating with end users, involving them alongside clinicians and digital stakeholders, from conception to validation, is a time-constrained process affected by availability and budget [14,30,100,108,148,149,152,171]. The challenge to coordinate health stakeholders' involvement in end-user co-design was more apparent, considering that design workshops are not a part of the day-to-day workflow of health professionals [170]. In addition, patient health often dictated availability and digital teams often floated between multiple projects simultaneously [116]. The short time frames often resulted in only low-fidelity prototypes with a limited scope of input, often making it difficult to speculate whether higher fidelity finished products would garner the same feedback [119].

Subtheme: Lack of Technological Comprehension

The previously mentioned pain point on the language of digital health co-design translated to further challenges downstream when testing ideas and prototypes due to a lack of technological comprehension (14/171, 8.2%) [14,23,27,32,36,71,74-76,116,144,145,173] among some stakeholders. Assumptions connecting personal experiences and digital health solutions were sometimes unvalidated, creating a disconnect among stakeholders [14,173]. In addition, familiarity with testing devices (eg, iPhone vs Android or extended reality interfaces) [144] was not ubiquitous. The lack of perception and clarity of objectives sometimes intimidated end users [36] and increased the difficulty in blending clinical, usability, and UX feedback in a constrained timeframe.

In summary, participatory co-design with DHI end users has highlighted challenges on the difficulty of amalgamating common interests, common language, and the collision of systematic and organic design approaches, culminating in methodological misalignments that produce varying testing approaches and hoped outcomes. This challenges the broader goal of defining a digital health framework around end-user involvement in co-design.

Research Question 3: What Are the Current Gaps in End-User Research at the Domain Level, and How Can These Be Addressed to Better Integrate End Users Into the Iterative Design Process in Digital Health, Aiming to Improve Efficacy and Uptake?

After assessing plus points and pain points in the first 2 research questions, our final question sought to understand the limitations

XSL•FO
RenderX

and gaps that are challenging the advancement of end-user incorporation in the design of DHIs.

Theme: Pragmatic Hybridized Framework

Despite positive advancements in incorporating end users in digital health co-design, the various aforementioned flash points led to advocating for a more pragmatic hybridized digital health framework (60/171, 35%). Subthemes centered around the need for a more mixed method, adaptable, and contextual approach to incorporating end users; one that is a fluid, whole-of-system digital health approach.

Subtheme: The Value of Mixed-Method Approaches to End-User Data

Numerous studies identified taking a more mixed-method approach (2/171, 14%) [26,36,40,48,50,52,57,66,72,80,81,96,104,138,141,154,155,161,174-178] as a cornerstone toward hybridizing digital and health approaches to incorporate end users. Unsurprisingly, mixed methods studies suffered less limitations in the form of validity and generalizability. Notably, studies found that there were discrepancies between what end users verbalized versus what was being observed from them [36], indicative of a mismatch between end-user desires and end-user actions. This observation strengthened the need for other forms of quantitative assessment for correlation. Another study found that pooling larger datasets through the System Usability Scale [26,141] and weighing them against smaller qualitative datasets was seen as a more prudent method of testing assumptions and weighing feedback. A study by He et al [176] found that end-user preferences for a tutorial (documented in qualitative interviews) was implemented, but they were subsequently found to be ignored by end users during quantitative data use analysis of the next iteration. Gaining metrics from hypothesis testing [37] was seen as an emotionally detached compliment to qualitative workshop approaches to gain personal insights from end-user preferences and behavior. An additional benefit to this approach was comparing data between experiment and control groups [149]. In some cases, the "hard data" metrics from mHealth app use were used to support or reject findings from interviews and observations. This was strongly exemplified in a study by Fico et al [37] in which a user-centered workshop design (ie, a qualitative approach) was complemented by bio-signal sensors to implement "a reliable information workflow." In this regard, valuable emotional feedback from end users was cross-referenced with sensory data analytics for stronger conclusions [148,177]. In essence, the pragmatic, synthesized coevaluation of quantitative and qualitative data may only serve to strengthen the reliability of studies by blending quantifiable statistics with emotional insights from end-user analysis.

Subtheme: Organic Co-Design Approaches

Building upon the value of richer mixed method approaches to evaluating end-user co-design involvement, the need for more organic co-design approaches (25/171, 14.6%) [3,9,16,38,40,46,47,50,52,57-59,61,64,65,68,81,82,89,106,116,126,141,177] was discussed in a number of studies. Organic, as in a holistic co-design approach, one that combines digital, health, and behavioral metrics into a more unified process. This is a response to the problem of misaligning usability and health care design objectives and the recognition that "end users" are not one single homogenous group [9]. Co-design workshops were found to have benefited from a funneling of methodologies and methods, whether qualitative or quantitative, that reflect digital (ie, technical and usability) and health care (ie, medical and psychoanalytical) around end-user involvement. Those studies that found this to be successful noted that it is only possible where diverse stakeholder involvement around the end users is consistent throughout the iterative design process [9,38,89]. Values such as impartiality [116] and interdisciplinarity [127,177] were identified as key elements toward hybridizing approaches. These values recognized that the needs of stakeholders and end users may be highly disparate [16]. Therefore, if acceptability [127] is a ubiquitous term that satisfies digital goals of usability, health care goals of efficacy, and end-user goals of usefulness, then refining a co-design approach that is organically suited to the needs of the digital health ecosystem is paramount.

Subtheme: Fluid Digital Health Efficacy Evaluation

The call for a more organic, digital health co-design approach was backed by calls to integrate digital and health efficacy metrics into a singular framework for evaluation (39/171, 22.8%) [9,12,14,16,34,35,39,46,47,50,52,55,56,58,61,64-66,69,71,78,80-82,92,96,99,104,106,107,118,142,146,157,170,171,175,179-181]. Various studies found a siloed approach that demarcated digital and health stakeholders was ineffective toward curating interventions. Studies recognized that design workshops did not always account for technical usability, behavior changes or patient engagement approaches that are all part of the digital health evaluation ecosystem [9,92,106,126,149,157,170,180]. Determining user motivation and confidence did not account for health system constraints [180], and determining health safety did not account for user engagement. Essentially, studies found a need to bridge [14,39,106,118,170] digital concepts such as increased usability, with health care concepts, such as reduced risk, in a workshop environment that fluidly and holistically facilitates both needs around the end user.

Subtheme: Agile Digital Health Project Facilitation

Numerous studies (18/171, 10.5%) [3,11,35,50,53,62,64,66,67,82,98,117,121,123,152,155,171,182] discussed the challenge to funnel digital and health co-design approaches into an adaptation of Agile methodology. Agile has been used in DHIs as a rapid design framework in response to legacy methods such as RCTs, which span years [11]. Agile uses short-cycle iterations (ie, sprints) with small sample sizes (ie, teams) [35] producing mainly qualitative results. However, efforts to port Agile "out of the box" into digital health have been met with challenges. While Agile presents exciting methods to incorporate end users and produce rapid emotional responses, studies have found that this qualitative analysis struggles to incorporate the rigor of health care development [121]. For example, some studies found that in Agile design sprints, patient end users were unsure of what a health solution should look like [152]. This exemplified the difficulty of entirely democratizing Agile digital health workshops. This, coupled with the small sample size of Agile teams, raised questions on validity and generalizability [98]. Findings exemplified the need

XSL•FO
RenderX

for having project leads, such as Scrum masters and product owners, who are familiar with health care contexts [182] and can effectively blend digital health design sprints that better satisfy the needs of all stakeholders. In this context, evidence-based and theory driven approaches can meet around user needs and preferences. As Schwartz et al [98] summarized in their study, "experimenting with agile adaptation in digital health will require a transparency of the development process, collecting shared difficulties and solutions toward a more standardized implementation suited to mHealth interventions."

Theme: Industry Implementability

Industry implementability (13/171, 7.6%) [3,13,16,24,31,35,36,91,106,146,153,171,177] represented downstream awareness of the need to develop a more fluid digital health hybridized design framework around end users. This is being fueled by the emerging policy shift toward the digital empowerment of patient end users. This new environment is further integrating government policy and administration, eHealth records, and encrypted end-to-end access through various collaborations between government bodies, industries, and end users (ie, citizens). Understanding the challenge to co-design for medical devices versus consumer devices was highlighted by studies that found conventional UCD processes hitting the wall of medical device regulation [31]. Nonetheless, medical regulation is part of the digital health ecosystem and needs to be considered in the ideation "design features" [36]. The needs of distributed health services were found to differ considerably with end-user preferences [16]. This reality addressed the complexity of propelling nascent stage DHI co-design toward the market. From industry suppliers to government regulatory bodies to end users, potential blockers in postdevelopment stages loomed large due to misalignment with clinical workflow and health policy [91,106]. Cooperation between public and private sectors to deliver DHIs added layers of bureaucracy [3]. In some cases, conceptual prototypes were not implementable in a given health care information technology ecosystem [153] due to security or privacy policies. This challenge exposed a gap in the business model to identify critical success factors [171] that are often missing in digital health stakeholder collaborations around end users.

Discussion

Principal Findings

This review examined the advancements and challenges of co-designing DHIs with end users, highlighting key gaps and limitations that cut through a wide range of design methodologies. The burgeoning growth of the digital health industry is a major advancement in health care delivery, one that is seeing exciting developments and major investment. Participatory co-design approaches that promote collaboration and ideation around the end users, often in situ, are promoting positive behavior change by seeking to absorb a diverse stakeholder group into a more fluid digital health ethos. These iterative design approaches are often centered around UCD methodologies and other similar approaches (eg, human-, person-, and patient- centered approaches) that emphasizes a more holistic empathetic approach, positioning the end users as coequal in the design phase (Multimedia Appendix 1). Co-design is an exploratory process that experiences divergence and convergence. Through this disruptive process, the collective brain of a diverse stakeholder group is sought out in order to resolve conflicts and to amalgamate design needs. It is hoped that through these approaches, a common language and improved cultural context may form, leading to a better co-design outcome, one that provides both better efficacy and UX.

These promising developments are tempered by the sheer complexity of combining digital and health approaches into one funneled, organic design around the end user. The rapidity of co-design workshops, with their limited cohort size, has raised many questions about the validity and reliability of findings. While an RCT is the gold standard in health care validation, its timeframe often outlives the development of a digital solution [11]. In response to this, researchers are experimenting within the nascent stages of digital health design, porting a variety of research methodologies (ie, observational and experimental, whether qualitative or quantitative) and design methods (ie, Agile and behavior change, among others), mixing and matching concepts seeking out how best to validate DHIs with end users.

Exactly *how* this incorporation occurs is the flash point of conflict. Digital design perspectives that are heavily borrowed from the mainstream digital industry are rooted in UX approaches. Health design perspectives focus on long-term safety and efficacy (Multimedia Appendix 8). While digital approaches are suited to rapid innovation, pivoting changes in real-time, health approaches are rooted in rigor and safety, implementing change slowly with longitudinal data. The variance between qualitative and quantitative approaches, UX and behavior change, and efficacy and usability accentuates the downstream challenges that occur in ideation, testing, and implementation of DHIs. This culture clash calls for pragmatism. Hybridizing digital and health approaches such that the demarcation between them eventually dissolves is the apex of DHI co-design. To better achieve this, the digital health domain must become comfortable with the uncomfortable, allowing the tensions of hierarchical health approaches to collide with flat-management digital approaches. Finding common ground between complaints of digital UX approaches that oversimplify health concerns and health approaches that are bureaucratic and time intensive will be paramount in creating an equilibrium that blends competing agendas.

Understanding the Advancements, Failures, and Challenges to Incorporate End Users in DHI Co-Design

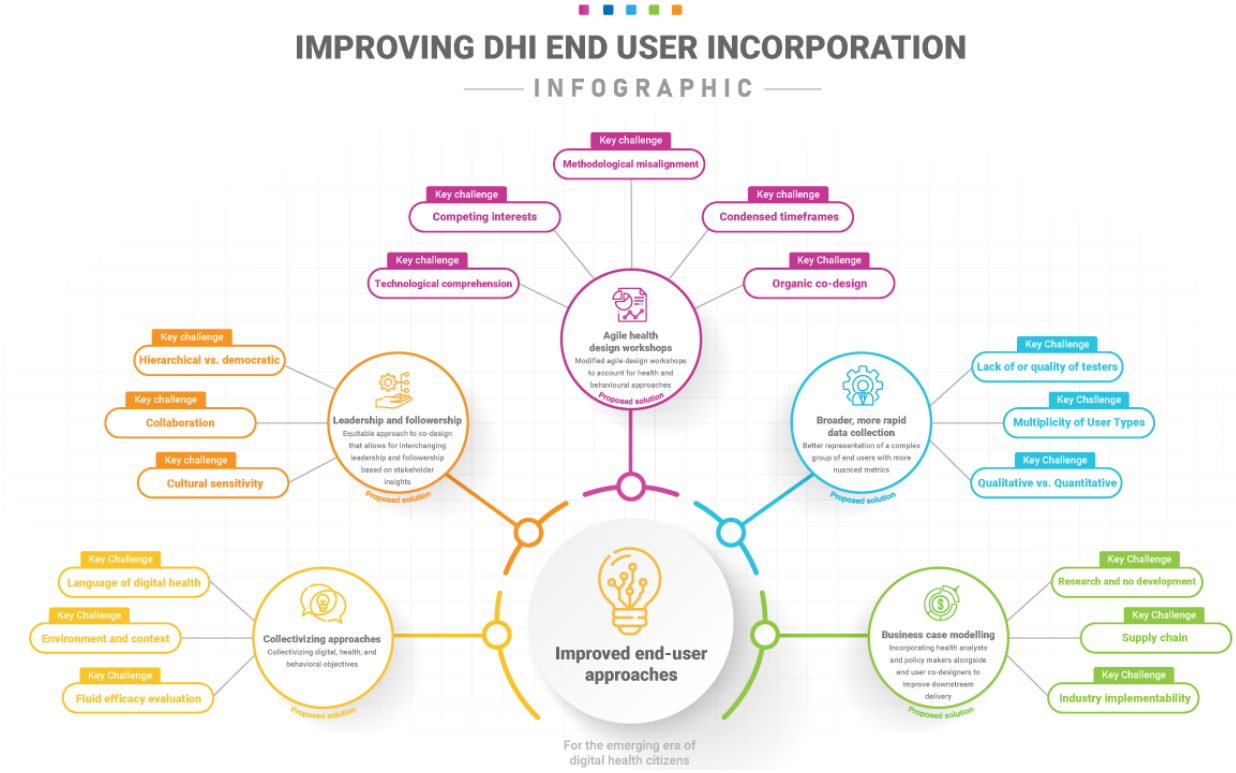
Advancements

In response to the call for better contextual design [3] to curate better health outcomes [4] around end users, various digital, health, and behavioral approaches are being implemented in digital health. From a digital perspective, collaboration and ideation with end users is a response to traditional top-down waterfall approaches that backload testing and feedback late in the development process, when it is often too late to properly incorporate fundamental changes [15]. From a health care perspective, there is a push toward digital health citizens [183];

XSL•FO
RenderX

persons who take more control of their own health care, whether observing metrics, building their knowledge base, or proactively engaging health care professionals digitally. Our findings highlight that these 2 motivating factors are driving improvements in collaborative ideation and testing with end users in their natural environments, leading to improved behavior modification. These positive findings in participatory co-design are tunneling digital health toward a more organic design process with end users, one that is seeking to balance health care and purposeful design more fluidly. These positive developments are exemplifying theoretical concepts that advocate for more reciprocal, self-empowering approaches to co-design [184] with end users, as digital health began to emerge a decade ago. Nonetheless, this is still very much a nascent exploratory stage for digital health, one that through the process of discovery continues to uncover new challenges.

Failures and Challenges



The findings in this study indicate that participatory co-design with DHI end users has interconnected challenges that underscore the difficulty of amalgamating common interests, common language among stakeholders, and both systematic and innovative design approaches. These challenges culminate in methodological misalignments that produce variance in ideating and testing, resulting in divergent goals. These themes complicate the broader objective of defining a digital health framework around end-user involvement in co-design. Optimistically, some studies focused on the core theme of pragmatism, seeking to implement digital health solutions around end users that are fit for purpose, albeit more theoretically than experimentally. To resolve the key challenges identified in the Introduction section, namely the multiplicity of design approaches, resolving disparate understandings of the end user, and dissolving competing agendas [6,7,12,13], DHIs require frameworks that are truly representative of all aspects of digital health delivery, breaking through the common silo disconnects. From the messiness of brainstorming ideation to the effectiveness of user testing right through the product implementation and system-wide distribution, an evolution is needed, one that provides broader, richer data points to better understand end-user incorporation and to provide better validation of iterative design decisions. The need for more data points and better testing methods is supported by the fact that 112 of 171 (65.5%) studies in this review encountered failures or challenges in testing phases citing either a lack of end users or the limited diversity among them. This speaks to the lack of data impacting digital health design decisions and its overarching philosophies.

The complexity of bringing DHIs to market cannot be accomplished solely with small, often speculative user studies. Downstream implementation and policy concerns can render years of research fruitless. New frameworks must emerge that are holistic and consider a global outlook on digital health distribution. Doing so may require evolving the digital health ecosystem by dissolving the tribalism of qualitative versus quantitative approaches, instead mixing methods pragmatically to better account for the sheer breadth of digital health success factors. Theoretically, hybridizing the 3 pillars—digital (eg, experience and usability), health (eg, medical and psychoanalytical), and business (eg, critical success factors)—may be crucial for better collectivizing design insights, improving industry implementability, and reducing downstream failures in product market fit. Practically, there is a need for co-designing frameworks and platforms that provide rapidly accessible, contextual, and demographic data to better justify iterative design decisions around end users. The end user is a person, a patient, a user, and a consumer. Their incorporation spans many personas and multiple user journeys that beget numerous types of data points relative to the evaluation of a DHI, from preconception to postdelivery; a “whole of system” co-design approach around health end users will be paramount to the future.

On the basis our findings (Figure 3), we propose the core recommendations illustrated in subsequent sections.

XSL•FO
RenderX

Figure 3. Mind map of key challenges and proposed solutions. DHI: digital health intervention.

Recommendation 1: Agile Health Design Workshops

Considering that Agile methodology is a project facilitation approach conceptualized outside of health care, unsurprisingly it has faced challenges when ported out of the box. To combine lightweight, rapid, qualitative Agile methods with more rigorous quantitative health methods, we recommend Agile workshops that triangulate emotional and observational feedback with statistical biosensor and analytical feedback that may soothe concerns about validity, generalizability, and attrition. This topic in itself could spawn a study on a mixed methods Agile framework design for digital health. Building on the calls for more Agile efficient approaches to digital health co-design suggested by Peiris et al [185] and Wilson et al [186], we propose the recommendations outlined in Textbox 2.

Textbox 2. Agile efficient approaches to digital health co-design.

- Involving digital health agilists who have an overarching and empathetic view of the needs of digital, health, and end-user stakeholders. Coordinators of digital health projects (ie, Scrum masters and product owners) need to align the collective goals that are unique to digital health, ones that may not be solely reflected in traditional user experience design workshops.
- A preiteration sprint (ie, sprint 0) that involves creating shared digital health milestones and backlog grooming that combines the goals of health stakeholders (eg, clinical assessment, safety, and efficacy), digital stakeholders (eg, usability and technical validation), and end users (eg, user experience and acceptability). This preliminary approach may also account for discrepancies in technical ability and comprehension, as well as cultural sensitivities.
- From this, the selection of co-design activities that seek to combine these goals into an organic digital health workshop process may occur [171]. These activities should acquire metrics, whether qualitative or quantitative, that pragmatically fit the co-design objectives of a digital health team.
- Subsequent sprint retrospectives and sprint planning that continuously engages and reevaluates the collective goals of the digital health objectives and milestones, merging user experience validators with health and behavioral assessments.

Using the analogy of the toolbox, much like a carpenter must be pragmatic when selecting the given tools for the task at hand, digital health workshops must use a similar logic by hybridizing the methodologies, methods, and metrics that are fit for purpose [121]. Standardizing this process has proven difficult [98]. Shoehorning standard Agile practices into digital health continues to prove challenging, most notably in the struggle to validate studies with small participant groups in health care [104]. Therefore, there is a need to produce rapid quantifiable methods within the Agile design cycle, which points toward crowdsourcing ideation and testing data at scale. Charting a path that is reflective of collective co-designed digital health goals may reduce previously observed methodological misalignment, improving the flow of the co-design and building toward a more organic set of collective hoped outcomes. We do not suggest this as a magic elixir or standardized framework but as a flexible Agile health toolkit that seeks to amalgamate digital health approaches around the end user in the Agile workflow. This process must be tailored, balancing what participants say, do, imagine, test, and evolve, without being exhaustive [127]. As Schwartz et al [98] summarized in their study, experimenting with Agile adaptation in digital health

XSL•FO
RenderX

will require a transparency of the development process, collecting shared difficulties and solutions toward a more standardized implementation suited to mHealth interventions. As a result, this may reduce downstream challenges of divergent objectives, hoped outcomes and failed implementation.

Recommendation 2: Account for the Multiplicity of End-User Types With Broader, More Rapid Data Collection

While traditional UCD workshops hone in on the end user as a single entity, DHIs are often more complex, with multiple types of end users. With 112 of 171 studies (65.5%) in this review citing challenges in either the number or variance of end users involved, recent digital health studies highlight the drawbacks of traditional UCD workshops, particularly in health care, where the "user (ie, patient) does not always have answers" [65] to clinical interventions [56]. The oversimplification of what a digital health end user is may deeply affect the integrity of the co-design. Considering that an mHealth app for heart medication may be used for tracking medication use; analytical data may serve multiple end users (eg, patient, caregiver, pharmacist, and clinician). Each type of end user has different goals, user experiences, and hoped outcomes. This reality was summarized well by Honary et al [139] where they keenly recognized that relatives of mHealth end users have different roles and responsibilities in the DHI. This growing pain in digital health is coming to the forefront as a study by Mak et al [48] advocated for mixed methods approaches that can better substantiate findings in diverse populations. To address this challenge and to account for the complexity of user types, broader pools of co-design data are needed; data that drill down on end-user demographics to create personas from rapid database-driven results. In this regard, a study by Tyo and Desroches [96] has experimented with the quantification of user personas to analyze clusters to better inform design requirements. These emerging studies speak to the need for quantifiable digital co-design platforms that can be deployed at scale.

Recommendation 3: Implement a Leadership and Followership Approach to Co-Design Workshops

A key flash point in the co-design process is the concept of democratic versus hierarchical approaches. The bottom-up (ie, shared and innovative) approach of design workshops is diametrically opposed to the top-down (ie, systematic and preplanned) approach of health care. In our findings, the high value of "equal coleadership" [6,14,127] was often championed as a guiding light in qualitative workshops. This has advantages and disadvantages, such that the democratic process brings many voices to the table, but this same process can eliminate evidence-based research from the solution [58]. Where criticism may exist of clinician-led studies being narrow minded, entirely democratic qualitative workshops can also be challenged for simplemindedness. For example, when a patient insists on a design preference [157] that conflicts with a safety issue backed up by years of quantifiable empirical data collected by clinicians. As Mirkovic et al [12] found, there is a need for equity over equality when it comes to workshop design with experts and end users. Undoubtedly, the value of a diverse array of stakeholders is of high importance; however, considering them all coequal through all stages of the design process does not serve to strengthen the design around the end user, rather it may weaken it if popular is preferred over practical, or entertainment over effectiveness. The plain democratization of the design process may lead to safety and efficacy concerns being voted off the island so to speak. Similarly, patient concerns with UX could be demoted since they are not central to behavior change or health policy goals.

The process of divergence and convergence in design workshops can instead benefit from a leadership and followership approach, such that design stakeholders lead the facilitation of UX objectives, health stakeholders lead the facilitation of safety and efficacy objectives, and patient stakeholders may lead discussion on their experiences and lifestyles [67,93,177]. In each example, the collaborative approach is central; however, there is identifiable leadership and followership such that a given expertise is provided enough ownership [101] to guide the workshop forward more effectively. This workshop approach may shift the perspective from *coequals* to *coleaders*, jointly seeking to learn from one another in a collaborative space. The goal of this approach would be to better balance person-centeredness, clinical acceptability, and UX [6] without eliminating expertise through a democratic design process.

Recommendation 4: Collectivizing Digital, Health, and Behavioral Objectives

A more pragmatic flexible framework that better understands the complexity of end-user types, one that seeks to blend the hoped outcomes of a disparate group of stakeholders, by necessity may benefit from collectivizing digital, health, and behavioral metrics and goals. Of the 171 studies, 70 (40.9%) studies listed various co-design challenges in collaboration and alignment. As the study by Ledel et al [7] found, both evidence-based (ie, health) and experience-based (ie, digital) approaches have merit for the end user, but friction exists when aligning these objectives. To reduce analysis in a vacuum and to align goals collectively, we suggest workshop co-design activities that blend objectives, such as safety (ie, health based) and usability (ie, digital based) can be blended into safe usability; behavior modification (ie, health based) and UX (ie, digital based) into user behavior; and efficacy (ie, health based) and uptake (ie, digital based) into effective uptake.

If the digital health end product is a fusion of digitally delivered health objectives, then the co-design process should suitably reflect this both philosophically and practically, aiming to reduce friction and combine goals and milestones. As Donovan et al [58] summarized in their study, "DHIs do not exist in isolation; they are integrated into existing clinical pathways." Considering that stakeholder disengagement and disparity in hoped outcomes is a frequent challenge, the aim of designing interviews, observations, and testing, whether qualitative or quantitative, that blend approaches would be to increase the fluidity of the co-design process with end users. This fluidity may reduce the challenge of balancing the innovation equilibrium; letting designers innovate and health stakeholders evaluate, with patient experiences provide the link between the two. This environment can better accommodate clinical reality, incorporating biomedical knowledge, clinical workflows, and overarching

XSL•FO
RenderX

health organizational requirements [35] around Agile practices that improve user collaboration, ideation, and rapid testing. This is very much an experimental process, but it begins with a change in thinking that can prevent implementation challenges downstream.

Recommendation 5: Include Business Case Modeling in the Co-Design Process for Downstream Implementability

Our final recommendation looks forward toward the downstream challenges of industry implementation and scalability. Rarely, in any of the studies observed, did we find co-design workshops that included health care policy or business stakeholders who addressed the clinical workflow challenges of delivering DHIs at scale to end users. Only 13 of 171 (7.6%) studies described the challenge of industry implementability, yet presumably every DHI project seeks to bring a viable product to market. In 2018, Hetrick et al [16] found that despite the success of their mHealth youth co-design, barriers exist toward the implementation of the app in clinical care settings that factor various service and governance factors. This identified the need to include health care analysts and policy makers in the co-design phase. Elements of public and private sector collaboration are interwoven into the fabric of health care service delivery that have their own set of needs that uniquely affect the constraints of a DHI. This factor needs to be incorporated into the co-design process to prevent blue-sky prototypes being discarded. A study by Vial et al [61] called for a transdisciplinary approach that includes business model definition coaching as a complement to the co-design team [61]. This accountability [15] recognizes the final leg of a DHI, the health care delivery platform. The inability to recognize this prevents scalability [12] and does not factor the ever-increasing integration of DHIs with government objectives to deliver ubiquitous services at scale.

Preparing for the Era of Digital Health Citizens

These 5 recommendations are responses to the challenges identified in this review, with an eye toward the emerging era of digital health citizenry, in which techno-sociality and bio-sociality are undemarcating the boundaries of digital health [187]. This “health citizen” agenda envisions digital health as more of a public good that provides tools, opportunities, responsibilities, and rights [183]. This transformation is built upon the prosumerist nature of today’s technologies, such that any given DHI may be an end-user experience of patients, clinicians, caregivers, therapists, and passive observers collectively, facilitated through algorithmically driven big data solutions (ie, artificial intelligence and machine learning) that are intuitive, customizable, and adaptable. The delivery of health care is increasingly blending government (eg, health records and policy), medical (eg, public and private sector solutions), and citizens (eg, end users) into one fluid infrastructure. This relationship is becoming increasingly reciprocal, more productive than facilitative in nature [187]. The potential for crowdsourcing data in tomorrow’s era of digital health seems boundless.

Needless to say, this vision needs to be brought to the forefront of the messier, creative stages of co-design workshops. The reliance on small qualitative datasets does not leverage the vastness of crowdsourcing end-user feedback that is equally capable of collecting quantifiable, demographically contextual statistics, while garnering emotional qualitative data in the form of asynchronous digital co-design platforms. If there is one word to define the evolution of digital health moving forward, it may be pragmatism. Leveraging the right tools to incorporate end users in the design of DHIs should mean removing any boundaries to the type of data collected. This means removing any allegiances to particular schools of thought on qualitative or quantitative, observational, or statistical, instead focusing on a pragmatic “patient activation” [187], approach to garner positive involvement from end users at scale. There is no need for competing interests methodologically; a combination of metrics that increases the understanding of digital health users only serves to strengthen the confidence of design solutions, reducing attrition rates and increasing validity and generalizability. The digital health citizen is envisioned not as a user, an expert, or a novice, but as an active participant in the health care ecosystem, one who constantly learns and adapts to their health care needs. It is fluid and proactive rather than static and receptive. Therefore, there is a clear need to move the incorporation of end users in DHI co-design from small participant workshops objective to a dynamic socio-digital platform of ideating, testing, and evaluating in real time, at scale. Looking forward, this approach involves a new outlook that leverages the vision of the digital health citizen methodology, with the pragmatism of Agile tools, and the rigors of health care metrics. Experimenting with processes and tools that expand the range of data collection may better identify end-user types, better triangulate preferences and challenges, and provide stronger integration with health policies and implementation objectives downstream. Refocusing co-design approaches within this lens serves to better use the emerging potential of big data, potentially increasing the user perspectives of all stakeholders across the digital health spectrum, without sacrificing the rapidity and innovation of the design environment.

Strengths and Limitations

This systematic review drew from a large swath of studies, using various methodologies and techniques to incorporate end users in DHIs. The strength of this approach was identifying a large number of studies for analysis and highlighting key global issues that digital health stakeholders face, including points of failure and challenges. We used the PerSPEcTiF framework due to its suitability to qualitative studies in health care. However, many of these studies were limited in the number of participants involved, bringing the validity and reliability of findings from these studies into question. The largely qualitative approach to studies selected, with vast variance in data collection approaches, did not allow for sensitivity analysis on the basis of measurement criteria (ie, setting, duration, and demographics).

A limitation also exists in the generalizability of findings toward specific scenarios (ie, mental health and patient aids) in which domain-specific usages weigh heavily on the context of end-user incorporation. We recommend further research to investigate these themes as subsets within specific digital health

XSL•FO
RenderX

communities (ie, mental health and serious gaming) In addition, in many cases, studies did not provide perspectives on risk of harm when using approaches to incorporate end users. This issue requires critical analysis itself. With digital health being a hybrid domain, there is no standardized approach to quality assessment, leaving the potential for risk of bias. These factors complicate data extraction and interpretation. This may be improved by using a health-centric qualitative framework in such studies, such as Confidence in the Evidence from Reviews of Qualitative Research [188].

Conclusions

The challenge to incorporate end users in the co-design of DHIs is complicated by a variety of methodological influences on problem definition, testing approaches, and hoped outcomes. The porting of legacy Agile, behavioral, and analytical methods has often resulted in conflicts that weaken conclusions that can be drawn from the co-design. In this study, we sought to draw a line through the common pain points and gaps in the literature that are omnipresent regardless of the design approach. The subsequent recommendations stemming from this systematic review serve as guidelines that may help soothe the path toward the big data environment that is emerging through a socio-technical digital health citizen approach into the mid-21st century.

Acknowledgments

SM received funding from Simon Fraser University Community Trust Endowment Fund and AGE-WELL, Canada's technology and aging network. AD received funding from the Graduate Dean's Entrance Scholarship at the School of Interactive Arts and Technology at Simon Fraser University. The authors wish to thank Ms Adena Brons, liaison librarian: interactive arts and technology, Simon Fraser University Library, for guiding our search strategy.

Data Availability

All data generated or analyzed during this study are included in this published manuscript and its supplementary information files.

Authors' Contributions

The study protocol was conceived by AD, GC, and SM. AD prepared and drafted the manuscript. All authors provided input into the design, edits, and revision of the manuscript. All authors read and approved the final manuscript. AD is the guarantor of the review.

Conflicts of Interest

None declared.

Abstract

Background: Gestational weight gain (GWG) is crucial to maternal and neonatal health, yet many women fail to meet recommended guidelines, increasing the risk of complications. Digital health interventions offer promising solutions, but their effectiveness remains uncertain. This study evaluates the impact of such interventions on GWG and other maternal and neonatal outcomes.

Objective: This study aimed to investigate the effect of digital health interventions among pregnant women and newborns.

Methods: A total of 2 independent researchers performed electronic literature searches in the PubMed, Embase, Web of Science, and Cochrane Library databases to identify eligible studies published from their inception until February 2024; an updated search was conducted in August 2024. The studies included randomized controlled trials (RCTs) related to maternal and neonatal clinical outcomes. The Revised Cochrane risk-of-bias tool for randomized trials was used to examine the risk of publication bias. Stata (version 15.1; StataCorp) was used to analyze the data.

Results: We incorporated 42 pertinent RCTs involving 148,866 participants. In comparison to the routine care group, GWG was markedly reduced in the intervention group (standardized mean difference–0.19, 95% CI –0.25 to –0.13; $P<.001$). A significant reduction was observed in the proportion of women with excessive weight gain (odds ratio [OR] 0.79, 95% CI 0.69-0.91; $P=.001$), along with an increase in the proportion of women with adequate weight gain (OR 1.33, 95% CI 1.10-1.64; $P=.003$). Although no significant difference was reported for the proportion of individuals below standardized weight gain, there is a significant reduction in the risk of miscarriage (OR 0.66, 95% CI 0.46-0.95; $P=.03$), preterm birth (OR 0.8, 95% CI 0.75-0.86; $P<.001$), as well as complex neonatal outcomes (OR 0.93, 95% CI 0.87-0.99; $P=.02$). Other maternal and fetal outcomes were not significantly different between the 2 groups (all $P>.05$).

Conclusions: The findings corroborate our hypothesis that digitally facilitated health care can enhance certain facets of maternal and neonatal outcomes, particularly by mitigating excessive weight and maintaining individuals within a reasonable weight gain range. Therefore, encouraging women to join the digital health team sounds feasible and helpful.

Introduction

Pregnancy is a unique physiological phase marked by significant physical, psychological, and behavioral changes that impact maternal and neonatal outcomes [1]. A key aspect of pregnancy is gestational weight gain (GWG), which plays a crucial role in maternal and infant health. However, studies indicate many women fail to meet the recommended GWG guidelines. In 2018, only 28%, 31%, and 32% of women in the United States, Europe, and Asia achieved the recommended weight gain during pregnancy [2]. This issue is even more prevalent in low- and middle-income countries. A 2023 study across 24 countries found that 55% (65,505/118,207) of participants experienced inadequate GWG, 23% (26,746/118,207) gained excessive weight, and only 22% (25,956/118,207) adhered to the recommended guidelines [3].

Maternal weight gain has a profound impact on pregnancy outcomes, including gestational complications, infant mortality, and long-term health for both mother and child [4]. Excessive GWG is linked to higher risks of complications such as large for gestational age (LGA), macrosomia, cesarean delivery, and postpartum weight retention [5-7]. On the other hand, insufficient GWG is associated with increased risks of miscarriage, infants who are small for gestational age (SGA), low birth weight, and preterm birth [8-10]. Therefore, promoting healthy gestational weight gain is crucial in reducing pregnancy complications and minimizing the risks of maternal and neonatal morbidity and mortality.

Digital health interventions, including applications, websites, digital programs, and other smart devices, have gained significant attention for their potential to enhance physical and mental well-being, particularly in low-resource settings such as Africa and South Asia [11]. Telemedicine involves using telecommunications technology to deliver clinical health care remotely, enabling health care providers to diagnose, treat, and monitor patients from a distance. Telehealth is a broader concept encompassing telemedicine and additional services, such as health education, disease prevention, and remote monitoring. Mobile health (mHealth) refers explicitly to using mobile devices like smartphones and tablets to deliver health care services, track health conditions, and promote healthy behaviors [12]. While these technologies overlap, each serves a distinct purpose, and together, they form key components of modern health care interventions.

Evidence suggests that technology-mediated interventions can be as effective or superior to routine care in improving maternal and neonatal health outcomes [13]. For example, a meta-analysis found that digital health interventions for mothers with gestational diabetes improved self-care, leading to better weight and glycemic control and lower rates of macrosomia and cesarean deliveries [14]. Another meta-analysis, combining data from 21 randomized controlled trials (RCTs) and controlled clinical trials, reported that web-based interventions significantly increased the likelihood of vaginal delivery while reducing emergency cesarean sections and neonatal complications. However, no improvements in glucose profiles were observed [15]. Furthermore, a study by He et al [16] demonstrated that mHealth interventions significantly decreased the incidence of gestational diabetes, preterm births, and macrosomia in pregnant women with overweight or obesity. In addition, participants in the intervention group gained 1.12 kg less than those in the routine care group [16]. However, some studies have contradicted these findings, reporting no significant impact of telemedicine on maternal or neonatal outcomes [17-19].

The contradictory findings underscore the need for further research into the effectiveness of digital health interventions, especially to evaluate their impact on pregnant women with varying risk profiles and refine strategies to improve maternal and neonatal health outcomes. To our knowledge, this is the first meta-analysis to broaden the participant scope, including not only high-risk groups, such as those with gestational diabetes, overweight, or obesity, but also low-risk or nonspecific pregnant women. This review aims to systematically evaluate studies investigating the impact of digital health interventions on maternal health outcomes, including gestational weight management and neonatal health outcomes in pregnant women.

Methods

Overview

The study protocol was preregistered in PROSPERO (CRD42024564331). The manuscript was structured following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist [20], and the checklist is presented in Multimedia Appendix 1.

Search Strategy

The initial comprehensive literature search for this meta-analysis was conducted in February 2024 and updated in August 2024 to capture any newly published studies. The search spanned 4 major English-language databases: PubMed, Embase, Cochrane Library, and Web of Science. Keywords derived from relevant articles were used, including terms such as telemetry, digital health, e-consultation, telemonitoring, smartphone technology, online communication, and digital health technology. Details of the search strategy are provided in Multimedia Appendix 2.

Inclusion and Exclusion Criteria

Eligible studies were required to be RCTs published in English, focusing on pregnant women aged 18 years and older. Digital health interventions, such as phone calls, text messages, and interactive apps (eg, YouTube, Twitter, and WeChat), were implemented in the intervention group, while the control group received standard care. The studies evaluated either maternal outcomes, such as GWG and pregnancy complications, or neonatal outcomes, such as preterm birth and SGA, defined as a birth weight at or below the 10th percentile for gestational age.

XSL•FO
RenderX

Studies were excluded if they did not include a control group, involved both intervention and control groups receiving digitally mediated treatments, failed to report the desired outcomes, measured them only postpartum, or lacked accessible full-text articles or usable data.

Study Selection and Data Extraction

Following the removal of duplicates, 2 researchers (JW and NT) independently screened the remaining articles by evaluating their titles and abstracts, excluding those that were irrelevant. The full texts of studies identified as potentially relevant were retrieved and further assessed to determine their eligibility for inclusion. In cases where discrepancies arose between the two researchers, these were resolved through discussion or, if necessary, by consulting a third researcher to achieve consensus.

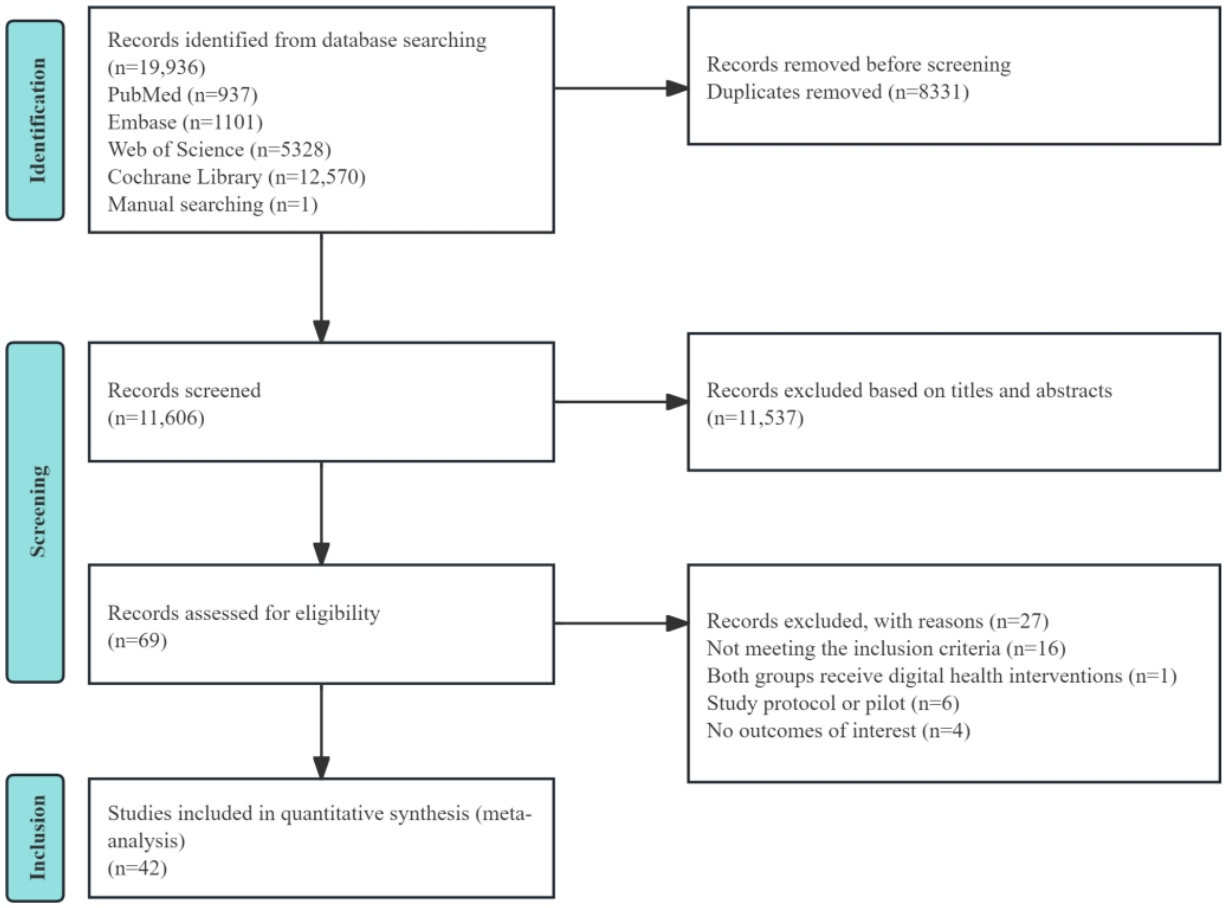
For articles selected for further analysis, JW and NT used a standardized data extraction worksheet developed in Microsoft Excel 2016. The extracted data encompassed key study characteristics, including the year of publication, authors, country, sample size, inclusion and exclusion criteria, maternal and neonatal health outcomes, gestational age at enrollment, prepregnancy maternal BMI, type of digital applications, specific interventions, control measures, duration of intervention, high-risk factors of participants, and the effects of digital care on maternal and neonatal health. Any disagreements during the data extraction process were resolved through iterative discussions between the authors until a consensus was reached.

Evaluation of the Methodological Quality of the Studies

The bias of the RCTs included in this meta-analysis was evaluated using the Revised Cochrane risk-of-bias tool for randomized trials (RoB 2) [21]. JW and NT independently assessed the risk of bias for each included study. Discrepancies between the two reviewers were resolved through iterative discussions, revisiting study details, and assessment criteria to reach a consensus. If disagreements persisted, a third reviewer provided an independent evaluation, with the final decision based on majority agreement.

Data Analysis

Data analysis for the meta-analysis was performed using Stata (version 15.1; StataCorp). Effect sizes were calculated and presented as forest plots to facilitate quantitative synthesis. Standardized mean differences (SMDs) were used for continuous variables, while odds ratios (ORs) were applied for dichotomous outcomes. The choice between fixed-effect and random-effects models was determined by the level of heterogeneity, with I^2 values above 50% indicating substantial heterogeneity; a random-effects model was used for I^2>50%, while I^2≤50% warranted a fixed-effect model. A P value of <.05 was considered statistically significant. To assess the robustness of the synthesized results, sensitivity analyses were conducted by sequentially excluding each study and reanalyzing the data, as well as by restricting the analysis to studies with a low risk of bias. To assess a potential publication bias, funnel plots were used, and the Egger regression test was used to calculate the publication bias (Multimedia Appendix 3).



Results

Search Results

A total of 19,936 studies were retrieved from the 4 databases, and 1 additional article was identified through a manual search. After removing duplicates, 11,606 studies remained for further evaluation. Titles and abstracts were screened, and 69 studies were deemed relevant. Following a detailed review of the full texts, 42 RCTs met the inclusion criteria and were incorporated into the meta-analysis. Figure 1 shows the complete screening process.

RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram of the literature screening and selection process.

Study Characteristics

This meta-analysis includes data from 42 RCTs involving a total of 148,866 participants. Its primary focus is to evaluate the impact of digital health interventions on maternal and neonatal outcomes, particularly among populations with gestational diabetes mellitus (GDM) and other high-risk pregnancy factors. The studies, conducted between 2007 and 2024, were geographically distributed across Asia (13/42 studies, 31%), Europe (13/42 studies, 31%), North America (9/42 studies, 21%), Australasia (6/42 studies, 14%), and Africa (1/42 study, 3%). The majority of studies were published in the United States (9/42 studies, 21%), Australia (6/42 studies, 14%), and China (6/42 studies, 14%).

Digital health interventions used three primary delivery modalities: (1) mobile devices, including smartphones and tablets; (2) website-based platforms; and (3) mobile apps incorporating social software (eg, Facebook [Meta Platforms], Zoom [Zoom Communications, and WeChat [Tencent Holdings Limited]) and other digital health tools. Table 1 presents the detailed characteristics of the 42 RCTs [22-63].

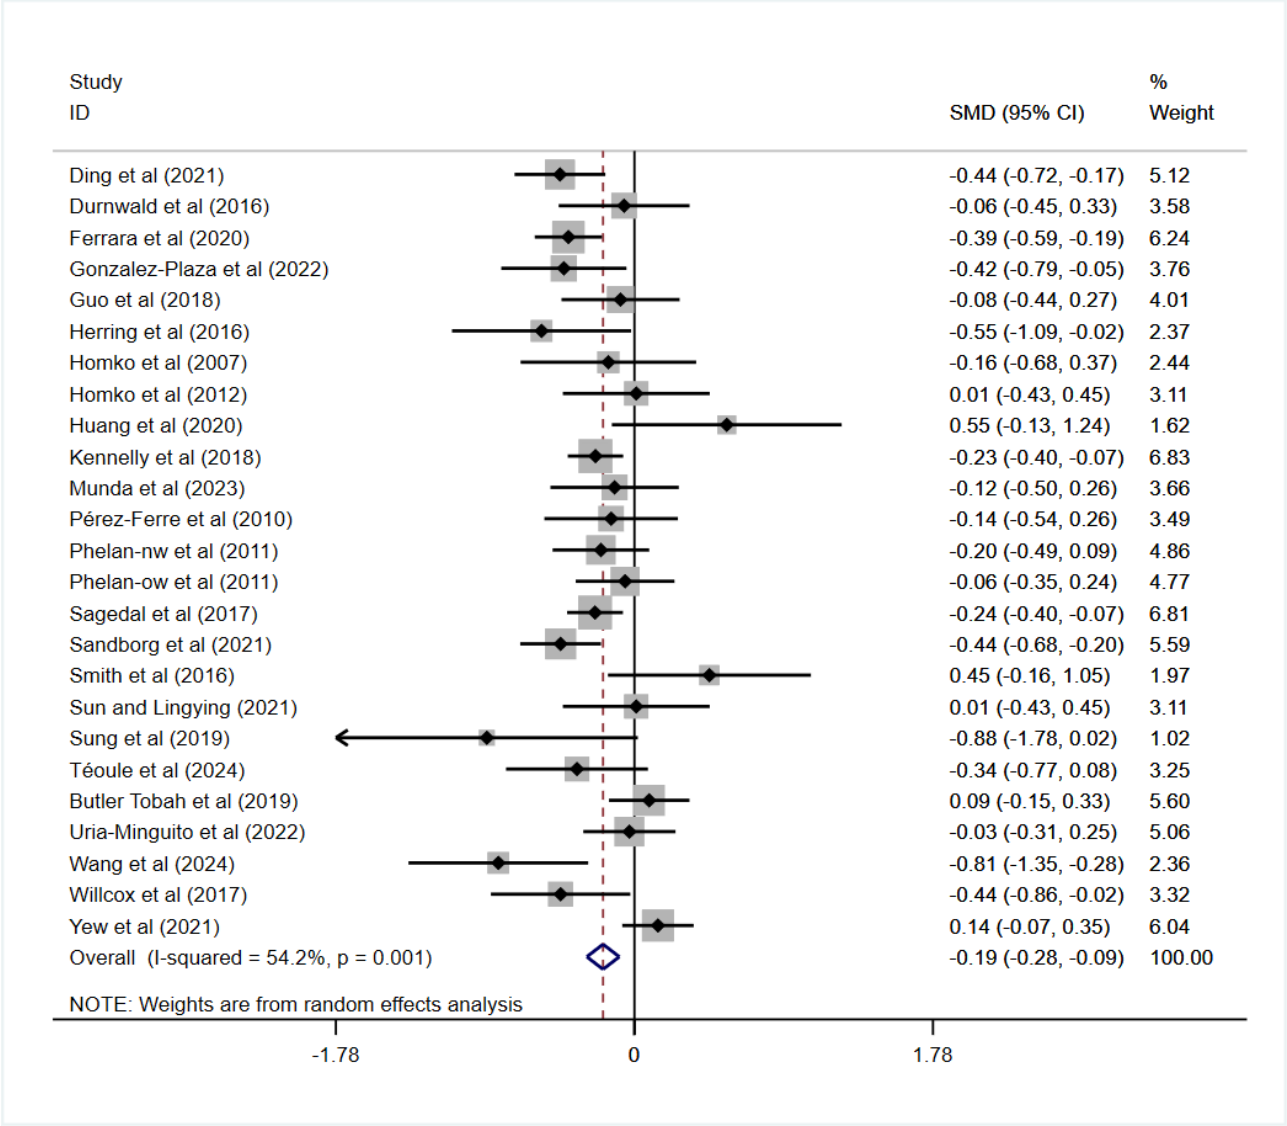
Quality Assessment Results of the Studies

A total of 25 RCTs included in this review, focusing on GWG, were evaluated using the RoB 2 tool. Among these, 11 studies were determined to have a low risk of bias, 3 were identified as high risk, and 11 presented some concerns regarding potential bias. Studies that focused on secondary outcomes, such as neonatal health, were not included in this assessment, as the RoB 2 evaluation was specifically applied to studies addressing the primary outcome of GWG. Figure 2 [22-25,27-29,31,32,34,42-46,48,50,52,54-56,58,61-63] shows the risk-of-bias assessment.

XSL•FO
RenderX

Figure 2. Risk-of-bias domains. ROB-2. RoB 2: Revised Cochrane risk-of-bias tool for randomized trials.

Meta-Analysis Results



Effect on GWG

GWG was analyzed in 25 studies involving 4315 participants. A pooled analysis using a random-effects model showed that digital health interventions effectively controlled GWG compared with routine care (I^2=54.2%; SMD –0.19, 95% CI –0.25 to –0.13; P<.001; Figure 3 [22-25,27-29,31,32,34,42-46,48,50,52,54-56,58,62,63]). Among these, 14 studies with 2675 participants reported the proportion of individuals exceeding the Institute of Medicine (IOM) recommendations for total weight gain during pregnancy, which are based on prepregnancy BMI categories for women: 12.5-18 kg for underweight (BMI<18.5 kg/m^2), 11.5-16 kg for normal weight (BMI 18.5-24.9 kg/m^2), 7-11.5 kg for overweight (BMI 25-29.9 kg/m^2), and 5-9 kg for obesity (BMI≥30 kg/m^2). In comparison, 10 studies with 1630 participants examined the proportion of women achieving sufficient weight gain according

XSL•FO
RenderX

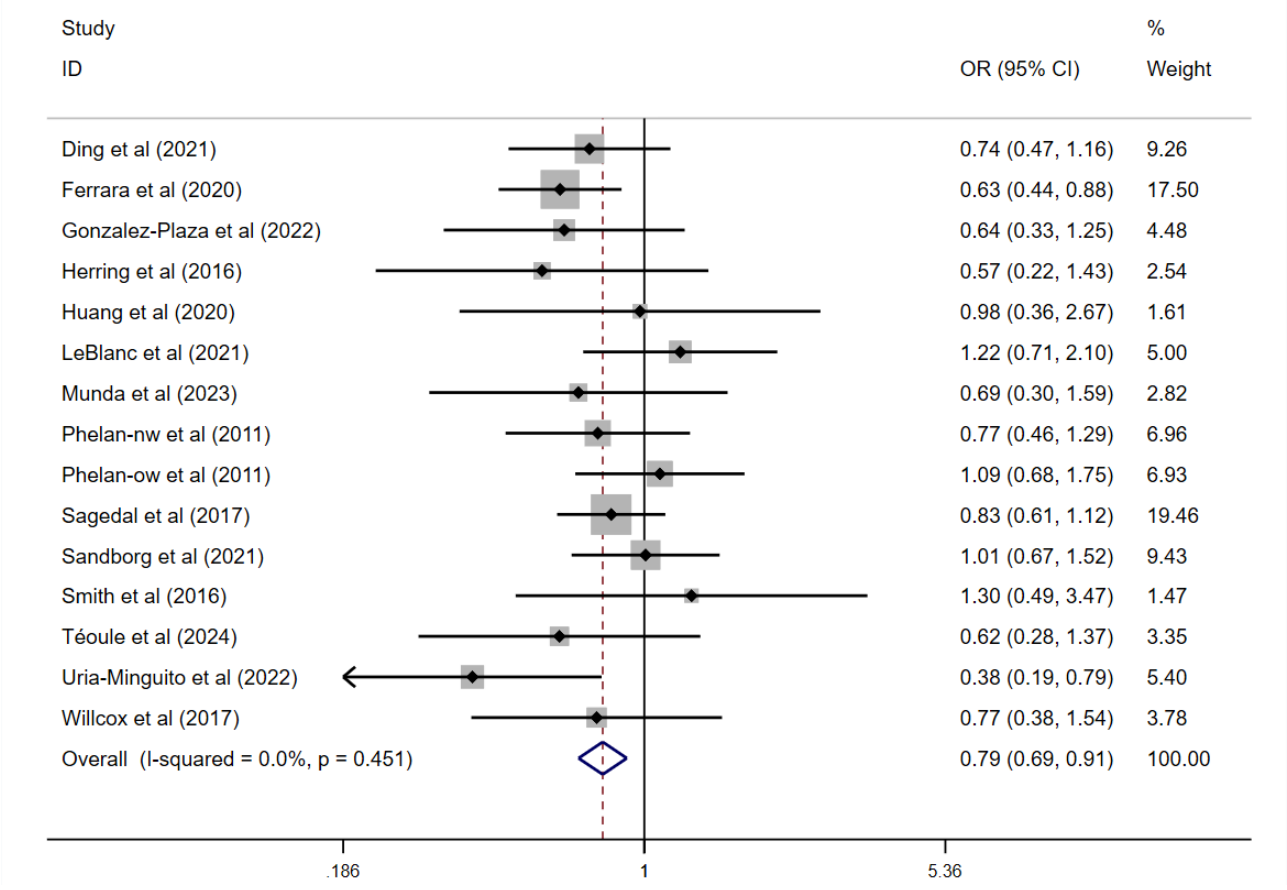
to these recommendations. Both analyses showed no heterogeneity (I^2=0%, P=.45; I^2=0%, P=.85, respectively).

Figure 3. Effect on gestational weight gain. SMD: standardized mean difference.

A fixed-effects model revealed a significant reduction in the proportion of women exceeding recommended GWG (OR 0.79, 95% CI 0.69-0.91; P=.001; Figure 4 [24,28,29,31,32,45,46,48-50,55,56,58,62]) and a significant increase in those meeting IOM GWG guidelines (OR 1.34, 95% CI 1.10-1.64; P=.003; Figure 5 [24,28,29,45,46,48,50,55,62,63]). However, no significant difference was observed in the proportion of participants falling below the IOM GWG guidelines.

XSL•FO
RenderX

Figure 4. Effect on excessive Institute of Medicine (IOM) total weight gain. OR: odds ratio.



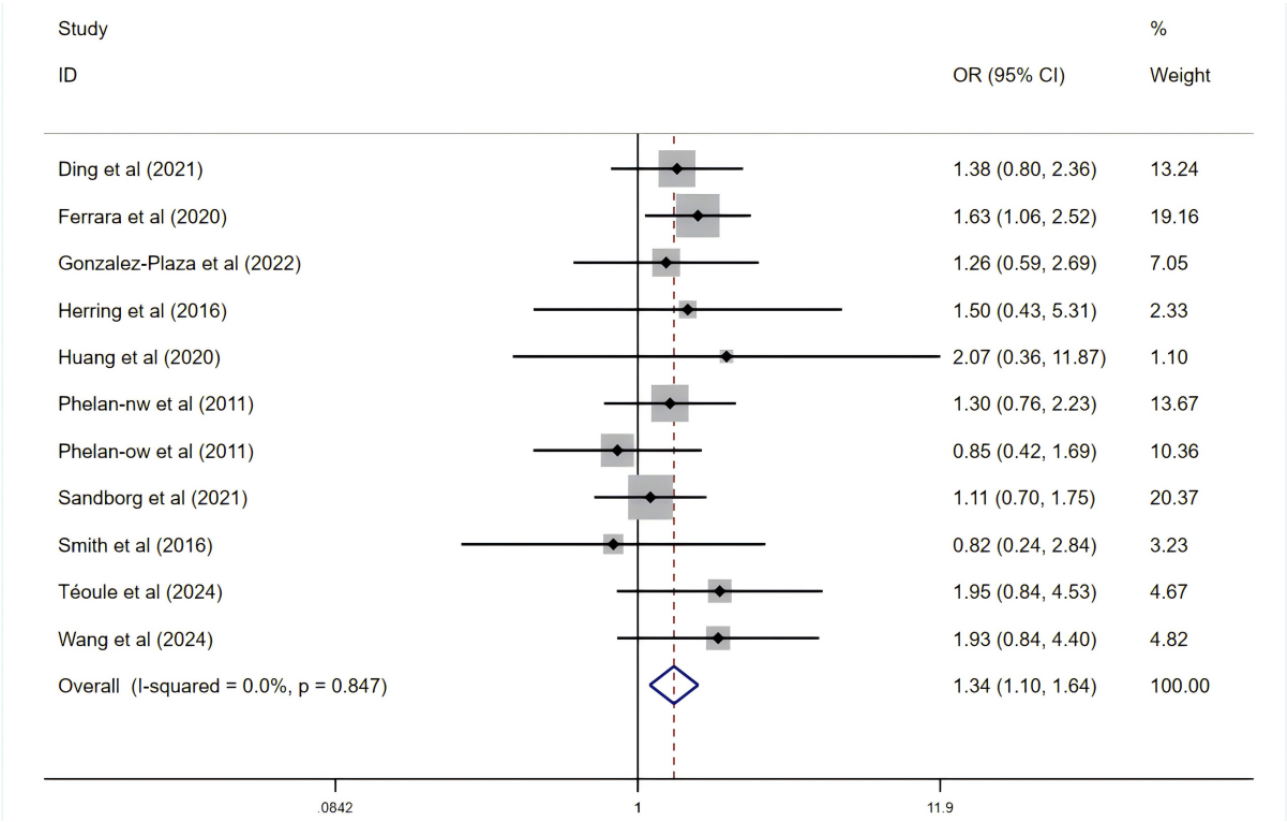


Figure 5. Effect on adequate Institute of Medicine (IOM) total weight gain. OR: odds ratio.

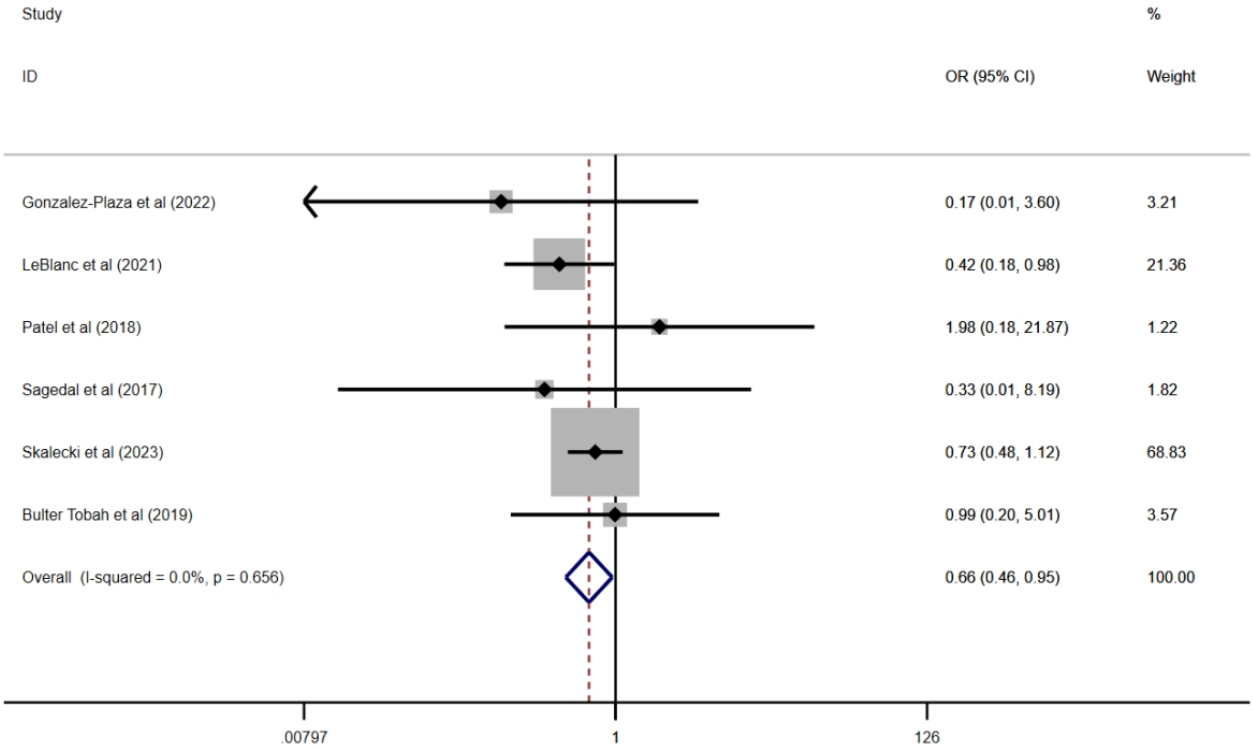
Subgroup analysis of 6 studies revealed that overweight or obese participants experienced a weight gain reduction of 0.348 kg compared with the control group (I^2=0%; SMD –0.35, 95% CI –0.45 to –0.24; P <.001). However, no significant difference

XSL•FO
RenderX

was observed between participants with GDM and those without high-risk conditions.

Effect on Delivery Mode

A pooled analysis of 34 studies (n=147,382) found no statistically significant difference in cesarean section rates between the intervention and control groups (OR 1.03, 95% CI 0.99-1.06; *P*=.12), with no heterogeneity detected. Similarly, data from 13 studies (n=4450) showed no significant impact on vaginal delivery rates (OR 1.05, 95% CI 0.95-1.15; *P*=.37), with no evidence of heterogeneity in these findings.



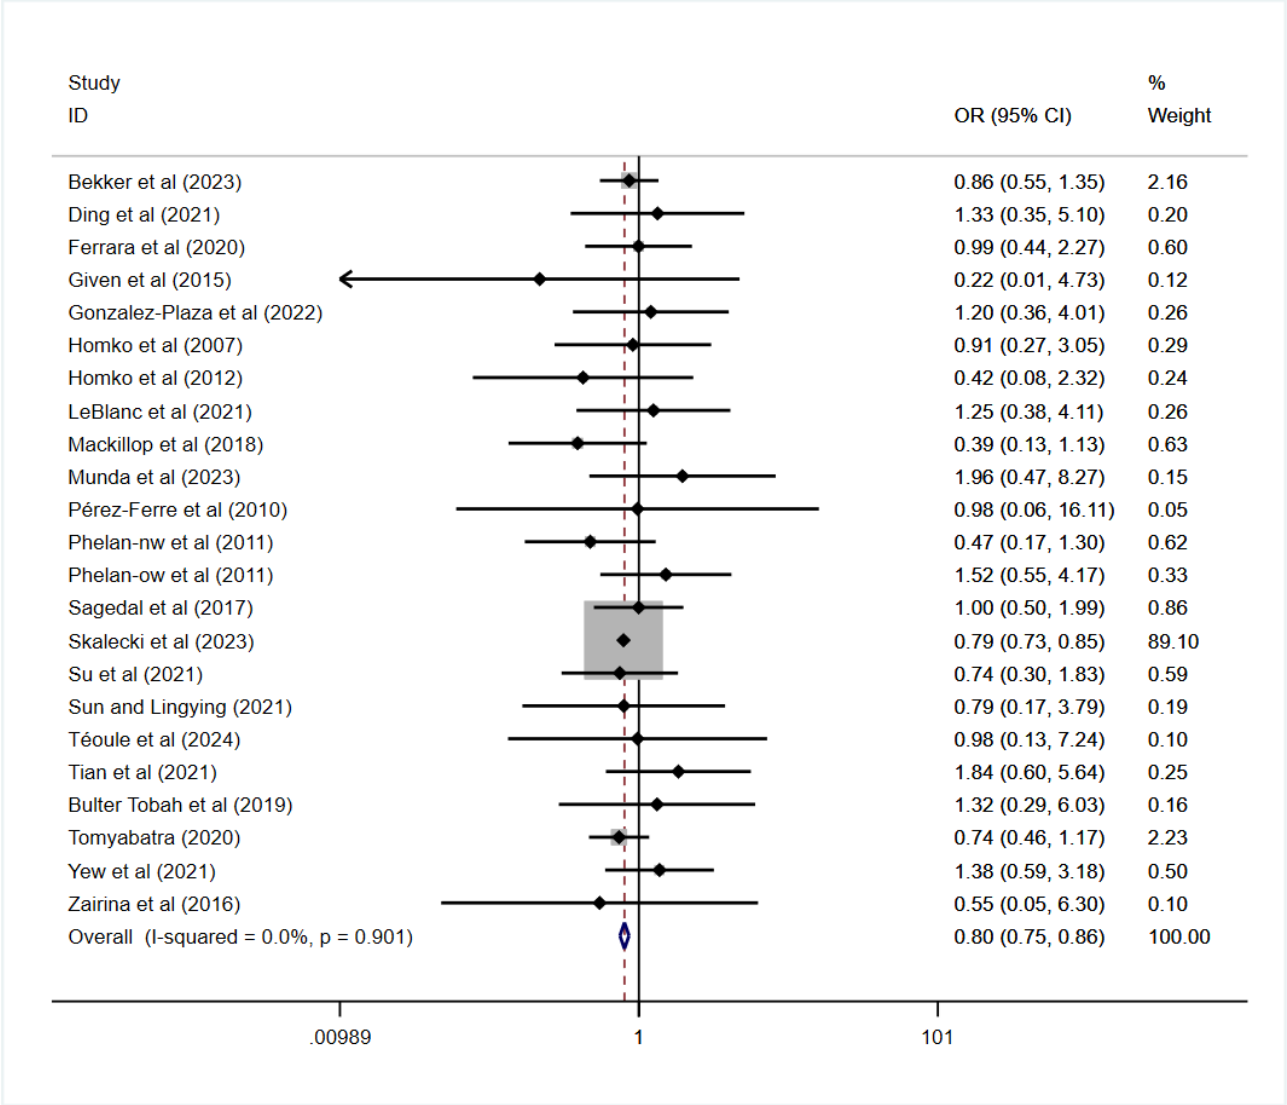
Effect on Gestational Age

Analysis of gestational week at delivery across 23 studies (n=5330) revealed high heterogeneity (I^2=94.8%; *P*<.001). Using a random-effects model, no statistically significant difference was observed between the intervention and control groups (SMD –0.004, 95% CI –0.27 to 0.26; *P*=.97).

Effect on Other Maternal Outcomes

Miscarriage was reported in 6 studies involving 142,385 participants. These studies detected no heterogeneity (I^2=0%; *P*=.66). A fixed-effects model revealed a statistically significant difference in miscarriage rates between the intervention and control groups (OR 0.66, 95% CI 0.46-0.95; *P*=.03; Figure 6 [32,37,44,49,55,60]). However, no significant differences were observed in the risk of shoulder dystocia, based on 4 studies (OR 0.35, 95% CI 0.12-1.02; *P*=.06), or in fasting blood glucose levels, analyzed in 11 studies (OR –0.16, 95% CI –0.32 to 0.01; *P*=.07).

Figure 6. Effect on miscarriages. OR: odds ratio.



A total of 12 studies (n=2769) assessed the prevalence of gestational diabetes, while 20 studies (n=3398) evaluated the incidence of gestational hypertension or preeclampsia. Both outcomes demonstrated low heterogeneity (I^2=16.9%; *P*=.27 and I^2=7.2%; *P*=.34, respectively). Using the Mantel-Haenszel fixed-effects model, no significant reduction was found in the prevalence of gestational diabetes (OR 0.87, 95% CI 0.70-1.08; *P*=.20) or gestational hypertension or preeclampsia (OR 0.88, 95% CI 0.70-1.11; *P*=.27).

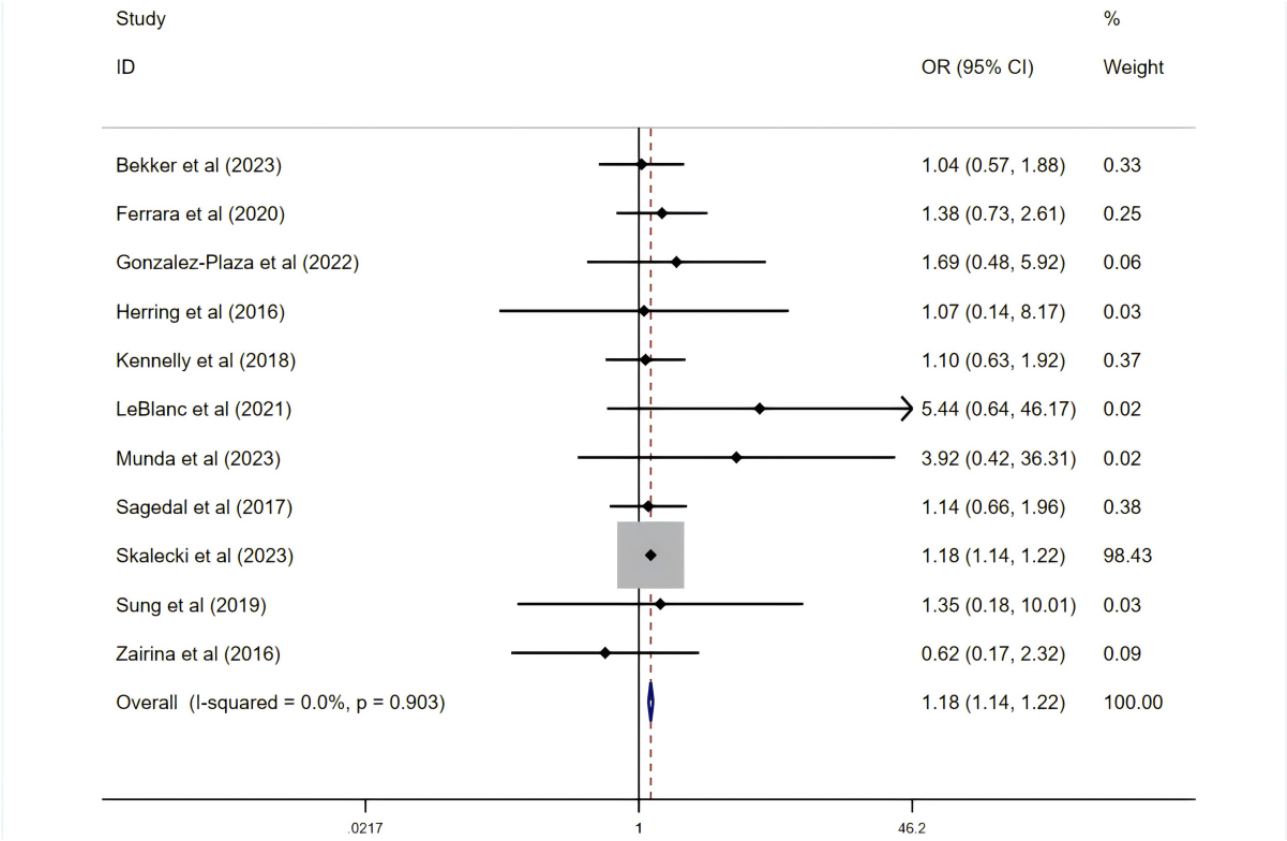
Effects on Preterm Birth

A pooled analysis of 22 studies involving 144,695 participants revealed a significantly lower prevalence of preterm births (before 37 weeks) among neonates in the intervention group compared to the control group (OR 0.80, 95% CI 0.75-0.86; *P*<.001; Figure 7 [22-26,30,32,35,44,45,47-49,51-55,57,58,60,62]). No heterogeneity was detected (I^2=0%; *P*=.90).

XSL•FO
RenderX

Figure 7. Effect on the prevalence of preterm birth. OR: odds ratio.

Effects on Infant Circumstance



A total of 26 studies assessed neonatal birth weight (I^2=39.6%; *P*=.02), and 6 examined birth length (I^2=30.6%; *P*=.21). Compared with the control group, computer-based health interventions showed no statistically significant differences in birth weight (SMD 0.02, 95% CI –0.06 to 0.09, *P*=.71) or birth length (SMD –0.06, 95% CI –0.21 to 0.10; *P*=.48). Furthermore, 5 studies evaluated infant head circumference, but no significant difference was observed between the groups (SMD 0.02, 95% CI –0.10 to 0.14; *P*=.74).

Effects on SGA and LGA

A total of 11 RCTs involving 142,303 participants evaluated the incidence of SGA and showed no heterogeneity among the studies (I^2=0%; *P*=.90). A fixed-effects model revealed a significant difference in SGA incidence between the intervention and control groups (OR 1.18, 95% CI 1.14-1.22; *P*<.001; Figure 8 [28,30,32,34,43,45,49,55,57,58,60]). In contrast, 13 studies (n=2403) assessed the incidence of LGA, also without heterogeneity, but the overall effect for LGA was not statistically significant (OR 0.91, 95% CI 0.69-1.19; *P*=.48).

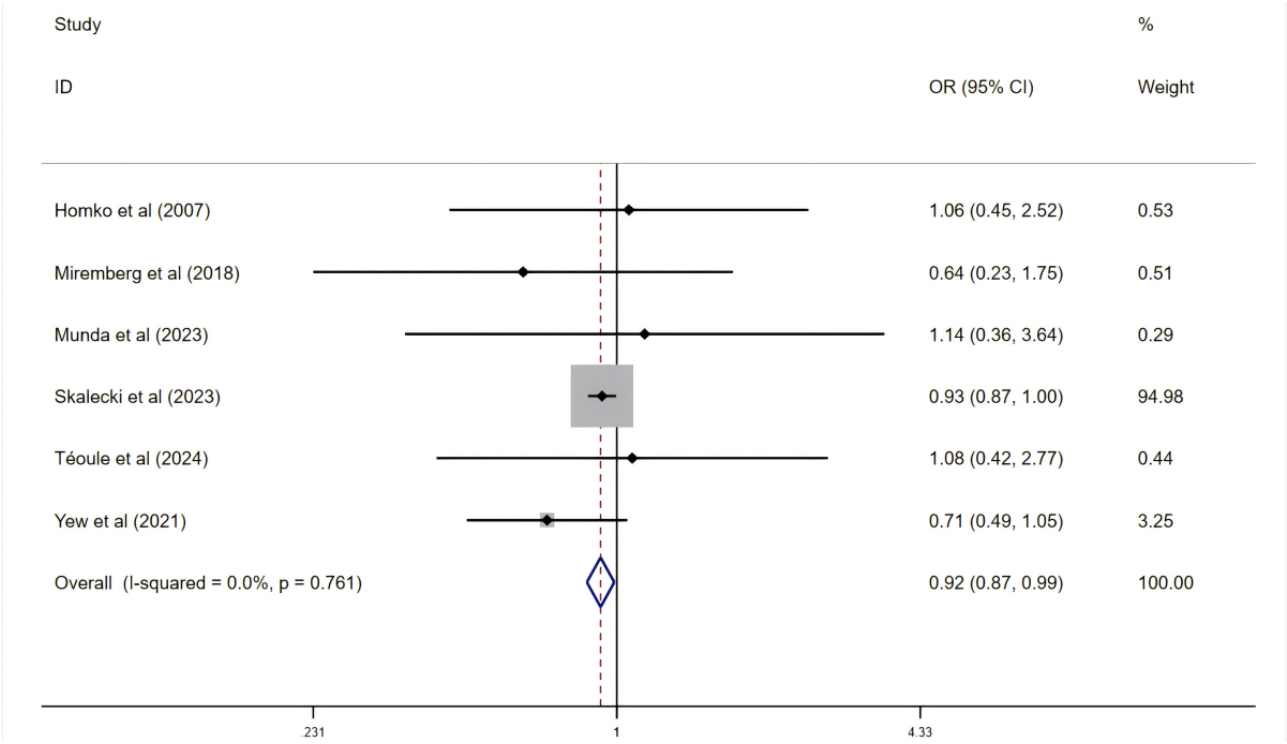
RenderX

Figure 8. Effect on the prevalence of small for gestational age (SGA). OR: odds ratio.



Effects on Neonatal Complications

In relation to neonatal complications, 12 studies addressed the issue of neonatal hypoglycemia (I^2=0%; P=.94), 16 studies reviewed ICU admissions (I^2=15.6%; P=.28), 8 studies mentioned jaundice or hyperbilirubinemia (I^2=0%; P=.94), and 8 studies assessed respiratory distress syndrome (RDS; I^2=4.6%; P=.39). For each condition, the intervention group exhibited no statistically significant decrease in incidence. However, pooled results from 6 studies involving 140,762 participants indicated that the digital health group experienced a significant decrease in combined complications (OR 0.93, 95% CI 0.87-0.98; P=.02; Figure 9 [22,36,54,58,60,62]), with no heterogeneity detected (I^2=0%; P=.76).

XSL•FO
RenderX

Figure 9. Effect on the prevalence of composite neonatal complications. OR: odds ratio.

Effects on Other Neonatal Outcomes

Based on 5 studies involving 481 newborns, the Apgar score analysis revealed no statistically significant difference between the intervention and control groups (SMD –0.11, 95% CI –0.29 to 0.07; *P*=.25). Similarly, 13 studies and 11 studies examined whether mHealth interventions reduced the risk of macrosomia (birth weight≥4000 g) and low birth weight (<2500 g), respectively, with no heterogeneity detected. Compared with routine care, the intervention group showed no significant improvement in the incidence of macrosomia (OR 0.90, 95% CI 0.72-1.14; *P*=.39) or low birth weight (OR 1.00; 95% CI 0.80-1.24; *P*=.97).

The results of the meta-analysis for 26 outcomes are summarized in Table 2.

Discussion

Principal Findings

This meta-analysis revealed that digital health interventions significantly improved excessive GWG, reduced miscarriage and preterm birth incidence, and enhanced neonatal outcomes. However, the benefits for women with insufficient weight gain were limited, and an increased rate of infants who are SGA was observed.

Comparison With Previous Work

This review evaluated the impact of digital health interventions on maternal and neonatal outcomes, with a particular focus on GWG. The findings revealed that digital interventions significantly improved GWG management among pregnant women. Compared to the control group, the intervention group showed a notable decrease in women exceeding recommended weight gain and increased adherence to the IOM GWG guidelines (P<.05). These results align with previous meta-analyses by Islam et al [64] and He et al [16]. However, the reduction in weight gain observed in our study (–0.145 kg) was less pronounced than the reductions reported by Islam et al [64] (–1.07 kg) and Antoun et al [65] (–1.99 kg). This discrepancy may be attributed to differences in the types and intensity of digital interventions and participant characteristics.

Subgroup analysis further revealed that significant GWG reductions were predominantly observed in participants who were overweight or obese rather than those with GDM. This may be explained by the intensive medical management typically provided to patients with GDM, which may diminish the additional benefits of digital interventions. These findings underscore the potential value of digital health care for individuals with prepregnancy overweight or obesity, as effective weight control in these populations is crucial. Excess weight not only increases the risk of pregnancy complications but also poses significant long-term health risks for their children [66].

The findings did not align with our hypothesis that digital health interventions would benefit participants experiencing insufficient GWG. This discrepancy may stem from the complex causes of inadequate weight gain during pregnancy, which include factors such as prepregnancy anemia, gestational diabetes, unhealthy lifestyle behaviors (eg, substance abuse), parity, and crowded living conditions [67]. Addressing these issues requires more than education on healthy diets, self-monitoring, or food supplementation alone. Additionally, 4 of the 9 studies on insufficient GWG focused on women with overweight and obese, with the digital health interventions targeting weight loss rather than promoting weight gain. This lack of individualized weight management strategies may have limited the effectiveness of the interventions in supporting appropriate weight gain for women below the recommended range.

In our study, while digital health interventions did not address insufficient GWG, they were associated with a reduction in miscarriage and preterm birth rates, as well as an increase in the prevalence of infants who are SGA. The reduction in miscarriage aligns with findings from Victa et al [68], which demonstrated that telemedicine monitoring during pregnancy significantly lowers miscarriage risk by enabling early detection of potential complications and timely medical intervention. In addition, the decreased risk of preterm birth and neonatal composite outcomes (P<.05) is consistent with the study by Guo et al [15], which highlighted the positive impact of digital health interventions on neonatal health.

Although insufficient GWG is known to increase the risk of miscarriage and preterm birth, our findings suggest that digital interventions may mitigate these risks through mechanisms beyond weight control. These interventions likely promote comprehensive health management by emphasizing nutritional intake, lifestyle improvements, and self-management efficacy, thereby improving maternal health and reducing risks associated with miscarriage and preterm labor, even without significantly addressing inadequate weight gain [69].

Further supporting this perspective, our analysis revealed a significant reduction in composite neonatal complications (P<.05), including conditions such as hypoglycemia, jaundice, and acute respiratory distress syndrome. By focusing on combined outcomes, the analysis provides a holistic view of the intervention's benefits, which aligns more closely with real-world clinical scenarios and underscores the broader potential of digital health interventions to improve maternal and neonatal health.

Pooling data revealed an unexpected correlation between digital health interventions and a higher incidence of infants who are SGA. This outcome may be attributed to the characteristics of the study population, as 9 out of the 11 studies on SGA involved participants with high-risk factors—5 focused on overweight and obesity, 2 on GDM, and 2 on other conditions. Interventions targeting weight control likely resulted in overly strict weight gain or dietary restrictions, increasing the energy gap [70] and potentially impairing placental development [71]. In addition, including participants already at substantial risk for SGA-related conditions may have amplified the negative effects of these interventions. Moreover, the inclusion of participants already at substantial risk for SGA-related conditions may have amplified the observed effects, complicating the interpretation of the actual impact of digital health interventions on SGA. While subgroup analyses could provide more nuanced insights, the variability and limited availability of stratified BMI data across studies hindered such analyses. Future studies should prioritize detailed BMI stratification and reporting to better elucidate the differential impacts of digital health interventions on SGA incidence.

Despite this, digital health interventions offer significant benefits for women and newborns through multiple mechanisms. They provide evidence-based, tailored educational resources that address women's specific needs [72,73] while encouraging active involvement in health monitoring. These tools enable women to track food intake, physical activity, and physical parameters such as weight changes and blood pressure [74], with positive feedback reinforcing their ability to manage their health effectively. Moreover, some intervention platforms facilitate online communication with skilled clinical and nursing personnel, reducing pregnancy-related stress and enhancing

XSL•FO
RenderX

health literacy [75]. These multifaceted approaches contribute to improved maternal and neonatal outcomes, even when specific challenges persist.

Strengths and Limitations

The strengths of this study encompass its inclusive population, as it considered all pregnant women rather than concentrating exclusively on specific subgroups such as those with diabetes or obesity, thereby enhancing the generalizability of the findings. In addition, we used a wide range of outcome measures, providing a comprehensive understanding of the impact of digital health interventions on maternal and neonatal health. Furthermore, our study incorporated the most recent literature, ensuring relevance to current clinical practice.

However, the study also has limitations. First, we expanded the search terms to include a broader range of eligible studies, thus enabling a more comprehensive investigation. Nevertheless, the quantity of published RCTs was restricted, indicating that the findings of our study necessitate careful interpretation and require further validation through supplementary research. Second, the follow-up period for the majority of the included studies concluded at birth, indicating a need for further investigation into the long-term effects on women and children to understand the implications of our findings fully. Third, the large sample size in the study by Skalecki et al [60], which focused on telemonitoring fetal movement, may influence the overall results. While a larger sample size is often beneficial for increasing the statistical power of a study, it may also introduce a bias toward the generalizability of the findings, especially in the context of the intervention types and outcome measures. A more specific analysis of how large sample sizes in studies with different intervention types could affect the overall results and the generalizability of the findings would provide a more comprehensive perspective. Fourth, the included studies encompassed a heterogeneous population of pregnant women with varying BMI categories (eg, underweight, normal weight, overweight, and obesity). However, some studies did not stratify participants by prepregnancy BMI or provide detailed subgroup analyses. This lack of consistent BMI reporting limits our ability to interpret the differential effects of digital health interventions across BMI subgroups. Future studies with standardized BMI stratification and detailed subgroup reporting are essential to delineate these effects better. Fifth, while the reduction in GWG observed in our study has general clinical significance due to the known risks of excessive weight gain, the lack of specific data on other contextual factors, such as dietary habits, physical activity levels, and socioeconomic status, may affect the interpretation of the results. These factors could mediate the relationship between digital health interventions and GWG, highlighting the need for more comprehensive datasets in future research.

Further Research

Further studies should investigate the potential differential impacts of these interventions across various populations, considering factors such as age, ethnicity, and health conditions, and determine the most effective digital intervention tailored to participants' backgrounds.

Conclusion

Digital health interventions facilitate maternal weight gain, which later influences neonatal health outcomes by decreasing complications such as miscarriages, preterm birth, and combined neonatal complications.

Acknowledgments

The authors acknowledge the support of the Medical Research Project of the Chongqing Health Commission (2024WSJK107), the Chongqing Education Commission Humanities and Social Sciences Research Project (23SKGH041), and the Chongqing Health Center for Women and Children in funding this research. The authors used ChatGPT (OpenAI) [76] to improve the language of this manuscript and acknowledge its use as a reference tool. However, after using this tool, authors meticulously reviewed and edited content as necessary and fully took responsibility for the content of the publication.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

NX and XZ have contributed equally to this work and share cocorresponding authorship. NX and XZ initiated the study and secured funding. JW and NT conducted the systematic literature search as the first and second reviewers, screened studies for eligibility, extracted relevant data, and assessed the risk of bias in studies. SL served as the third reviewer to resolve discrepancies between JW and NT through discussion and consensus. CJ and QJ managed data entry and provided statistical expertise. JW conducted data analysis and drafted the initial manuscript. JY and XZ critically reviewed and revised the manuscript. All authors contributed significantly to the conception and design of the study, participated in the data interpretation, and reviewed the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Corporate wellness programs are increasingly using digital technologies to promote employee health. Digital wellness programs (DWPs) refer to initiatives that deliver health interventions through digital tools. Despite a growing body of evidence on DWPs, the literature remains fragmented across multiple health domains.

Objective: This study aims to provide a comprehensive synthesis of existing research on the efficacy (eg, impact on employee's physical health, mental well-being, behavioral changes, and absenteeism) and acceptability (eg, engagement, perceived usefulness, and adoption) of employer-provided DWPs. Specifically, we aim to map the extent, range, and nature of research on this topic; summarize key findings; identify gaps; and facilitate knowledge dissemination.

Methods: We conducted a meta-review of studies published between 2000 and 2023. We adopted a database-driven search approach, including the MEDLINE, PsycINFO, ProQuest Central, and Web of Science Core Collection databases. The inclusion criteria consisted of (1) review articles; (2) publications in English, French, or German; (3) studies reporting on digital health interventions implemented in organizations; (4) studies reporting on nonclinical or preclinical employee populations; and (5) studies assessing the efficacy and acceptability of employer-provided DWPs. We performed a descriptive numerical summary and thematic analysis of the included studies.

Results: Out of 593 nonduplicate studies screened, 29 met the inclusion criteria. The most investigated health domains included mental health (n=19), physical activity (n=8), weight management (n=6), unhealthy behavior change (n=4), and sleep management (n=2). In total, 24 reviews focused on the efficacy of DWPs, primarily in relation to health-related outcomes (eg, stress and weight), while fewer reviews addressed organization-related outcomes (eg, burnout and absenteeism). Four reviews explored the mechanisms of action, and 3 assessed the acceptability of DWPs using various measures. Overall, the findings support the efficacy and acceptability of DWPs, although significant gaps persist, particularly regarding the durability of outcomes, the role of technology, and the causal mechanisms underlying behavioral change.

Conclusions: While DWPs show promise across a variety of health domains, several aspects of their effectiveness remain underexplored. Practitioners should capitalize on existing evidence of successful DWPs while acknowledging the limitations in the literature.

Introduction

Employee health is closely intertwined with stakeholders' financial interests, and technology can play a pivotal role in advancing both. A recent large-scale survey identified a clear link between employee well-being and firm performance [1]. Beyond this alignment, employee wellness has become an organizational expectation [2], with surveys indicating that most

XSL•FO
RenderX

employees believe their organizations are responsible for supporting their health and well-being [3,4]. To promote employee health, many companies invest in corporate wellness programs, with more than half of the organizations offering at least one such initiative [5]. These programs have evolved into a strategic priority, not only as an attractive job benefit but also as a means to reduce absenteeism and lower health care costs [6].

A meta-analysis found that for every one US dollar invested in corporate wellness programs, organizations save US $3.27 in health care costs and US $2.73 through reduced absenteeism [7]. Beyond financial benefits, these programs foster a sense of organizational support, enhancing employee commitment and prosocial behavior in the workplace [8-10]. In addition, the growing emphasis on corporate social responsibility has drawn practitioners' attention to wellness programs as a means to fulfill these expectations [11]. Given the significant amount of time employees spend at work, the workplace provides a unique environment for implementing wellness initiatives. Organizations can effectively scale these programs by identifying key risk factors and integrating targeted wellness initiatives into their routines and culture.

The growing integration of digital technologies into wellness programs has significantly improved their accessibility and scalability. However, despite the expanding body of research on digital wellness programs (DWPs), the literature remains highly fragmented across multiple domains and disciplines. This fragmentation poses challenges for organizational practitioners, making it difficult to adopt evidence-based best practices effectively.

In this study, we define DWPs as initiatives that deliver intervention content to employees through digital tools, either partially or fully. DWPs are not simply digital updates of traditional programs; they exhibit unique features that merit focused research for several reasons. First, participants in DWPs play a more active role than in traditional wellness programs. They can creatively adapt and personalize digital tools, which can influence the programs' outcomes [12]. Second, digital technologies add complexity to the design of wellness programs. Previous studies have highlighted factors such as interaction modularity [13], the design of digital nudges [14], and engagement with technology features [15] as critical determinants of the efficacy of DWPs. Third, digital technologies enable novel ways of interacting with employees, creating innovative wellness solutions previously unattainable. For example, automated digital interventions can provide health feedback without direct human supervision. These considerations have spurred a growing interest in research on DWPs.

Despite the considerable body of research, knowledge on DWPs is still fragmented across multiple disciplines. This fragmentation is reflected in the numerous reviews that examine the same topic yet reach varying conclusions. The effectiveness of DWPs often depends on how their boundaries are defined. For instance, some reviews report highly promising outcomes (eg, [16,17]), while others highlight conflicting evidence, raising doubts about their overall efficacy (eg, [18,19]). This poses a challenge, as review studies play a critical role in guiding practitioners' decision-making [20,21]. In addition, research on DWPs is expanding rapidly across various health domains (eg, mental health, physical activity, and weight management) yet often develops in silos, limiting the generalizability of findings beyond specific areas. This fragmentation is particularly concerning because, regardless of the health domain, DWPs share key similarities in their behavioral mechanisms, technological components, and target populations. To address this gap, this study provides a comprehensive overview of the literature on DWPs, aiming to navigate the scattered research landscape and facilitate cross-pollination of ideas to inform future research.

Given the abundance of studies and reviews on DWPs, we have adopted a meta-review methodology to cover the broad scope of the relevant literature. This approach ensures that we address all compelling evidence and identify research gaps in the field. This meta-review began with the broad research questions (RQs): "What do we know?" and "What remains unanswered?" During the full-text screening process, it became clear that the central focus of the literature revolves around the efficacy and acceptability of DWPs. Thus, the initial questions were refined into the following specific research inquiries:

1. What technologies and health domains have been investigated in prior research on DWPs?
2. What do we know about the efficacy and acceptability of DWPs?

This meta-review answers these questions by categorizing the existing literature into 6 health domains identified inductively. This classification helps to uncover avenues for future research within each domain, identify points of agreement and disagreement, compare findings across domains, and encourage the cross-pollination of ideas.

In short, the primary objective of this study is to synthesize existing research on the efficacy and acceptability of DWPs in workplace settings. Specifically, we aim to (1) assess the effectiveness of DWPs in improving employees' physical and mental well-being, (2) examine the acceptability and engagement levels of these interventions, and (3) identify gaps in the literature to inform future research and practice.

Methods

Research Design

This study uses a meta-review method, which is particularly useful in interdisciplinary research when an extensive body of literature exists, and a broad exploration of the topic is necessary [22]. This approach uses various types of literature reviews as input and adopts a comprehensive search strategy and considers diverse literature to address broad RQs [23,24].

The meta-review method aligns well with our research objectives, considering that an initial exploratory search revealed that synthesizing existing reviews would be valuable. Much of the relevant knowledge is dispersed across various review studies on closely related topics, yet many of these reviews were conducted independently, without referencing findings from

XSL•FO
RenderX

other reviews. This lack of integration limits the potential to consolidate insights across similar reviews.

As protocol registration is not a standard requirement for meta-reviews, this study was not prospectively registered. However, to ensure transparency and systematicity [25,26], we adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) framework (Multimedia Appendix 1 [27]) and followed the guidelines set forth by Paré et al [25].

Search Strategy

The search process followed 3 key steps, as recommended by Gusenbauer and Haddaway [28]. The first step involved a preliminary lookup search on Google Scholar to identify existing reviews on DWPs. This step allowed us to assess the feasibility of conducting a scoping meta-review and helped pinpoint key pieces of evidence on the topic.

The second step was an exploratory search to determine the approximate scope of the topic. The authors carried out the search with the assistance of a professional librarian and discussed initial findings to develop a comprehensive list of search terms and refine the search queries accordingly.

Finally, the third step involved a systematic search of relevant studies published between January 2000 and December 2023. The search was initially carried out in July 2023 and updated in January 2024. The search timeframe (2000-2023) was chosen to capture the evolution of DWPs in the workplace. Digital components of wellness programs began gaining traction in the early 2000s, and review articles synthesizing research in this area started appearing around this time. This timeframe ensures comprehensive coverage of relevant literature while maintaining a focused and manageable scope. We adopted a database-driven search approach [29], using 4 multidisciplinary research databases: MEDLINE, PsycINFO, ProQuest Central and the Web of Science Core Collection. This multistep process ensured that the search terms and databases used captured the breadth of this multidisciplinary topic. In addition, we conducted a forward snowballing search to complement the systematic search.

Textbox 1 presents the finalized search terms and the logical structure of the search query. Since we aimed to capture all ranges of intervention outcomes and comparisons, the search query did not include them. The search string used in each database can be found in Multimedia Appendix 2.

AND

(m-health OR mhealth OR mobile health OR e-health OR ehealth OR digital health OR digital wellness OR virtual care OR self-tracking OR self-quantification OR quantified-self OR wearable OR iCBT) OR ((physical health OR physical activity OR mental health OR sleep health OR psychological health OR well-being OR wellbeing OR prescriptions OR preventive health OR sleep health OR sleep disorders) AND (app OR information technology OR information system OR digital OR platform OR self-quantification OR quantified self OR smartphone OR internet-based OR mobile phone OR cell phone OR virtual OR teleconsultation))

Screening

A set of inclusion and exclusion criteria was developed to clearly define the scope of this review (Textbox 2). We included all reviews that reported on DWPs aimed at nonclinical or preclinical employee populations. Consistent with our definition of DWPs, interventions were considered digital if their content was delivered to employees fully or partially through digital technologies. The studies had to be available in English, French, or German. We included studies published between January 2000 and the end of 2023, which is a broad timeframe for the subject matter. However, we did not impose a date limit on the primary studies included in the review articles.

When screening literature reviews for inclusion in a meta-review, it is possible that some studies only partially meet the eligibility criteria. For instance, a review might include both digital (eligible) and nondigital (ineligible) interventions. In such cases, we only retained those reviews where the eligible part of the study was analyzed separately.

The identified studies were systematically screened in 2 steps using Covidence, a web-based platform designed for managing and screening citations collaboratively. In the first step, one reviewer screened the abstracts of the identified studies and excluded only those that clearly did not meet the inclusion criteria. Where there was uncertainty, the paper was flagged for further discussion. Flagged papers were then reviewed in working sessions where the authors reached a consensus before making any exclusion decisions. Papers not excluded at this stage were retained for full-text screening. In the second step, 3 independent reviewers conducted the full-text screening. Each reviewer read and assessed the papers independently. In 2 subsequent working sessions, any disagreements were resolved through discussion, ensuring a final consensus on the inclusion of each paper.

XSL•FO
RenderX

Textbox 2. List of inclusion and exclusion criteria.

Inclusion criteria

- Population
  - Any nonclinical or preclinical working population
  - Studies that focused on working and nonworking populations simultaneously were included only if they present their findings regarding the working population separately
- Intervention and exposure
  - Any digital health interventions used in workplace settings. It includes interventions aimed at employees' physical health; mental health; well-being; prescriptions; or preventive health, employee assistance programs, substance or alcohol misuse interventions, sexual health interventions, sleep disorders, etc
  - Studies that have focused on digital and nondigital health interventions were included only if they have presented their findings regarding the working population separately
- Outcomes
  - Efficacy or acceptability outcomes
- Study design
  - Stand-alone review articles in peer-reviewed outlets
  - Review reports from governments, industry leaders, and prominent consulting firms
- Time
  - Published between January 2000 and December 2023

Exclusion criteria

- Population
  - Any population outside of a workplace setting (eg, students)
  - Special occupational groups without typical freedoms (eg, soldiers) or with informal employment (eg, sex workers)
- Intervention and exposure
  - Digital health interventions not supported or funded by workplaces, transition-to-retirement interventions, and interventions aimed at clinical populations (eg, patients with cancer)
  - Interventions mainly based on outdated digital technologies such as CD-ROMs and PDAs were excluded
  - Interventions specifically implemented during the pandemic
  - Long-term management of mental illnesses
- Outcomes
  - No exclusion
- Study design
  - Primary studies
  - Review protocols
  - Conference abstract
  - Theses and dissertations
- Time
  - No exclusion

Data Charting

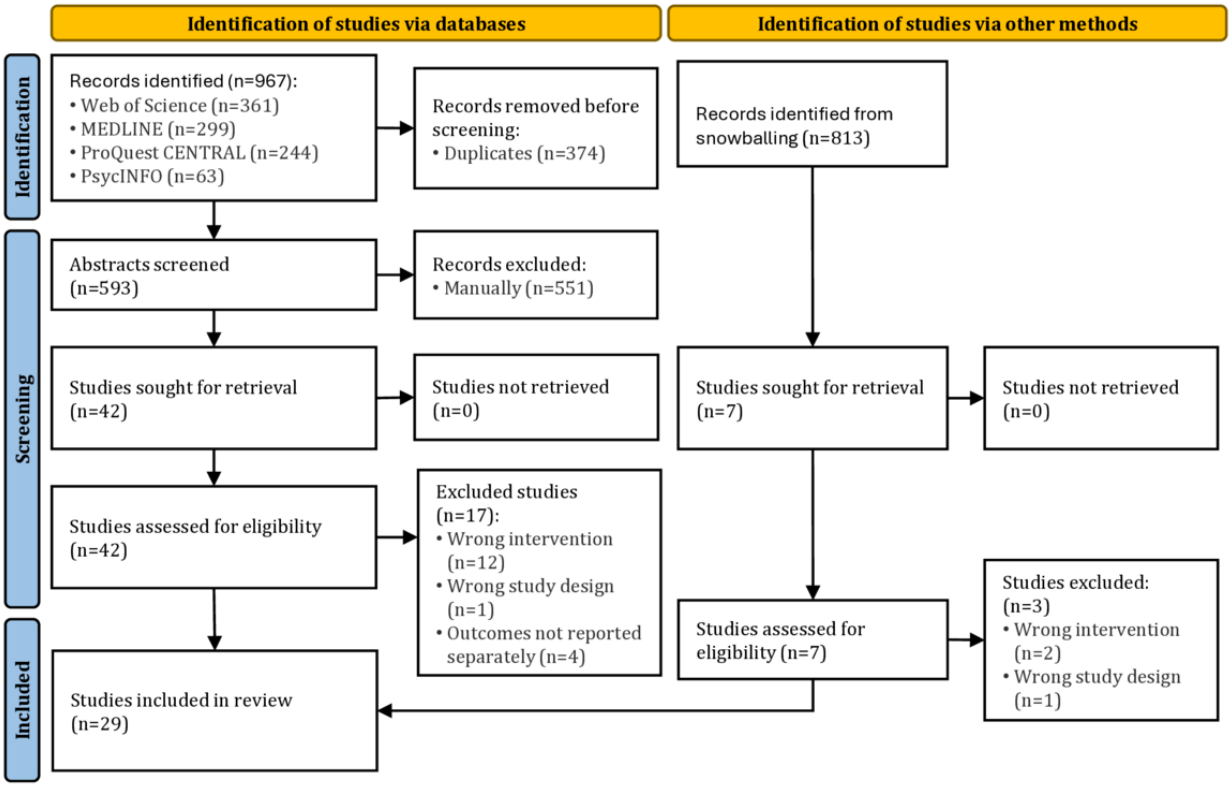
In this stage, we charted key information from the included studies. We adapted an existing data extraction tool designed for meta-review studies [30]. This tool includes 17 data items: title, author or authors, year of publication, place of publication, research objectives, review type, information sources searched,

XSL•FO
RenderX

inclusion years range, inclusion and exclusion criteria, search terms used, corpus size, aim of interventions, reported work and health outcomes, geographic dispersion of the included studies, organizational settings, intervention characteristics, intervention durations, and key findings. Microsoft Excel was used to chart the data for analysis. As recommended by review methodology guidelines, this process was highly iterative [31]. One author initially extracted the data items for all included studies. Subsequently, all authors participated in 4 working sessions to discuss and validate the data extraction table. The analysis of the extracted data is presented in the following section, and the full dataset is available upon request from the first author.

Data Analysis

The data analysis comprised a descriptive numerical summary and a thematic analysis [31]. The descriptive numerical summary involved a straightforward process of characterizing the included studies. However, the thematic analysis used a highly iterative process. Specifically, we applied conventional qualitative content analysis, which is appropriate when no prior theoretical framework exists and researchers aim to avoid using preconceived categories [32]. Although there are several behavior change theories for various health interventions, no overarching framework or theory is available for organizing the diverse interventions within DWPs across different health domains.



Following the approach outlined by Hsieh and Shannon [32], themes were allowed to emerge naturally from the data through an iterative process. This involved carefully reading the data items, deriving codes, making notes on the emerging codes, revisiting the texts to contextualize the codes, and refining the coding scheme to develop themes. This process unfolded over the course of 6 working sessions, during which the emerging themes were discussed and refined. The result of this step was the categorization of health domains, RQs, and digital technologies and the separation of evidence on efficacy outcomes from mechanisms of action. The Results and Discussion sections are structured according to these categories.

Results

Summary of the Search and Screening Process

The PRISMA flowchart shown in Figure 1 outlines the search and screening process. Initially, the search yielded 967 records, from which 374 duplicates were removed. This left 593 studies, which were screened by abstract. After this step, 42 studies were identified as eligible for full-text screening. The authors ultimately agreed to include 25 studies in the corpus. To ensure thoroughness, a snowballing search was conducted, retrieving a list of 813 papers from Google Scholar using web-scraping tools. One author screened the titles and abstracts for potentially relevant papers which were manually retrieved for full-text review. This process added 7 papers for full-text screening, of which 4 were included in the final corpus. As a result, the search and screening process concluded with a total of 29 studies included in the database.

Characteristics of the Included Studies

This section outlines the key characteristics of the included studies.

Date of Publication

Although our inclusion criteria limited the selection to studies published since 2000, the earliest identified review article appeared in 2014, confirming the appropriateness of our chosen publication period. Notably, there was a significant surge in publications in 2023, with 9 out of the 11 studies from that year focusing specifically on DWPs aimed at improving employees' mental health. Unsurprisingly, all these studies cited the recent COVID-19 pandemic as a key motivation.

Health Domains

As shown in Table 1, DWP interventions concern 6 health domains. Mental health (n=19) emerged as the most frequently investigated domain, encompassing interventions aimed at addressing employees' stress, anxiety, burnout, and overall quality of life. The next most explored domains are physical activities (n=8), weight management (n=6), unhealthy behavior change (n=4), and sleep management (n=2). Four studies were categorized as "other." These include programs aimed at screening and reducing varied health risk factors that relate to diabetes and other chronic diseases.

Type of RQs

In line with the objective of this meta-review, we categorized the literature reviews in our corpus into 2 groups based on the RQs they addressed. As shown in Textbox 2, the vast majority of reviews (27/29, 93%) focused on questions related to the efficacy of DWPs. In contrast, only 3 reviews addressed questions concerning the acceptability of these programs, examining criteria such as uptake, continued use, and compliance with the interventions. While efficacy and acceptability were predefined codes, a third category of RQs emerged inductively during the data charting process. Specifically, we identified 4 reviews exploring “how” DWPs influence intervention outcomes. These RQs were coded under interventions' mechanisms of action. Studies in this category primarily examined the behavior change techniques used in interventions and the theoretical explanations of how these interventions drive outcomes.

Types of Reviews

We categorized the identified studies according to review types as specified by their authors. In those cases where review types were not explicitly mentioned in a study (eg, [39]), we coded the paper according to the guidelines for review typologies [58].

As shown in Table 1, we identified 3 types of literature reviews in our corpus. The most frequent type was the systematic review, comprising 15 studies. These reviews focus on narrow RQs related to the efficacy of DWPs and typically use narrative synthesis methods rather than statistical techniques to analyze their findings. Similar to meta-analyses, systematic reviews limit their inclusion criteria to experimental and quasi-experimental studies. The second frequent group consisted of 8 meta-analyses, which apply statistical methods to address focused RQs about the efficacy of DWPs. These reviews include experimental and quasi-experimental studies while excluding other empirical research designs. Finally, the least frequent type was the scoping review, with 6 studies. Scoping reviews investigate broader RQs, such as exploring outcomes, theories, and behavior change techniques related to specific groups of DWPs. These reviews aim to provide a comprehensive overview of the existing literature by summarizing a wide range of available evidence.

Digital Technologies

The reviews discussing DWPs include various technological components ranging from messaging apps to website portals and telecommunication solutions. We categorized these technologies into five groups: (1) websites and online telecommunication, (2) apps and computer software, (3) email, (4) text messaging services—SMS and messaging apps—and (5) wearable devices. The types of technologies used in each health domain are presented in the mapping tables corresponding to each domain.

Main Findings

In this section, we present the findings organized according to the 6 health domains discussed earlier.

XSL•FO
RenderX

Mental Health

Overview

As mentioned earlier, mental health is the most frequently discussed domain in the literature on DWPs. The World Health Organization defines mental health as a state of mental well-being that enables people to cope with the stresses of life, realize their abilities, learn well and work well, and contribute to their community [59]. Anxiety, depression, and stress-related conditions are the most common mental health issues reported in the workforce. Many organizations are interested in mental health as it is the leading cause of disabilities, sick leave requests, and long-term work incapacities [60]. In addition, research shows that improving organizational mental wellness programs can improve productivity and presenteeism at work [61,62]. The identified reviews on mental health DWPs discuss the efficacy and the acceptability of interventions. However, no review was found that examines the mechanisms of action used in this health domain.

Table 2 maps the reviews on mental health DWPs according to the type of RQs asked, the types of digital technologies included, and 12 categories of outcomes reported in the literature. Most reviews in this domain (16/19, 84%) investigate the efficacy of DWPs and include a wide range of digital technologies and intervention outcomes. Except for 4 reviews that are limited to health care occupations [43,46,54,56], all the included reviews have no limitation on the inclusion of working populations.

Efficacy

In the domain of mental health, 17 literature reviews assessed the efficacy of DWPs. Table 3 summarizes the findings from these reviews, grouping the outcomes into 12 different categories. The wide range of efficacy outcomes in this health domain reflects the diversity of programs such as those that aim at reducing stress, anxiety, and depression as well as those that aim at enhancing overall mental wellness among employees. The following paragraphs summarize the findings according to the health outcomes of DWPs.

In some cases, the findings were pooled together, making it difficult to categorize them according to specific mental health outcomes. For instance, a meta-analysis [49] combined outcomes related to stress, anxiety, depression, and mindfulness under the broader term “mental health conditions.” This meta-analysis found a small effect size (g=0.24, 95% CI 0.13-0.35, k=23, N=1328, I^2=67%). Subsequent studies have evaluated these results as promising but noted that further clarification is needed regarding specific outcomes [16,17]. In addition, 4 literature reviews [33,34,45,56] did not synthesize or aggregate their findings around specific outcome measures. These reviews primarily conducted scoping surveys of the variability in outcomes and intervention characteristics. The following paragraphs summarize the results of both meta-analyses and non–meta-analyses according to each outcome category.

Stress is the most frequently reported outcome, with 10 reviews addressing its measurement. Two meta-analyses [16,17] evaluated the effectiveness of DWPs on stress. Phillips et al [16] reported a medium-sized effect of DWPs on stress reduction (g=0.54, 95% CI 0.35-0.72, k=22, N=not available, I^2=84%). However, Stratton et al [17], using a much larger corpus, reported a smaller effect size for DWPs on stress (g=0.25, 95% CI 0.17-0.34, k=57, N=10,160, I^2=76%). Three non–meta-analyses [52,54,55] found unanimous evidence supporting the significant effect of DWPs in reducing stress. However, 5 non–meta-analyses [39,41,43,44,46] reported conflicting findings.

Anxiety is the second most frequently discussed outcome, addressed in 9 reviews. Two meta-analyses [16,17] found small but significant effects of DWPs on anxiety reduction. Stratton et al [17] reported an effect size of g=0.26 (95% CI 0.13-0.39, k=29, N=4961, I^2=77%), while Phillips et al [16] found a slightly larger effect size of g=0.34 (95% CI 0.18-0.50, k=15, N=not available, I^2=71%). Among non–meta-analyses, 3 reviews [39,52,54] provided unanimous evidence supporting the efficacy of DWPs in reducing anxiety. However, López-Del-Hoyo et al [43] found conflicting evidence, and Park et al [46] reported no significant effect of DWPs on anxiety in the literature.

[a]Sc: self-compassion and mindfulness.

[b]Pw: psychological well-being.

[c]En: employee engagement.

[d]In this study, the results for stress, anxiety, depression, and self-compassion are pooled together.

[e]In meta-analysis studies, s+ stands for small effect size (g<0.3).

[f]Not applicable.

[g]In meta-analysis studies, ns stands for nonsignificant results.

[h]In meta-analysis studies, m+ stands for medium effect size (0.3<g<0.5).

[i]In non–meta-analysis reviews, ~ stands for found conflicting evidence.

[j](#/#) = (number of studies with significant evidence for this outcome) / (total number of studies reporting this outcome).

[k]In non–meta-analysis reviews, + stands for found unanimous evidence in favor of the effectiveness.

[l]In non-meta-analysis reviews, - stands for found no significant evidence.

[m]In this study, the results for anxiety and depression are reported together.

Depression was discussed in 7 reviews. Three meta-analyses [16,17,57] reported small but significant effects of DWPs on depression. Stratton et al [17] found an effect size of g=0.26 (95% CI 0.19-0.34, k=46, N=10,155, I^2=67%); Phillips et al [16] reported an effect size of g=0.30 (95% CI 0.18-0.42, k=17, N=not available, I^2=61%); and Xiong et al [57], specifically examining internet-based cognitive behavioral therapy programs, found an effect size of g=0.31 (95% CI 0.17-0.44, k=19, N=5898, I^2=83%). In addition, 3 non–meta-analyses [46,52,54] reported significant findings regarding the impact of DWPs on depression. However, López-Del-Hoyo et al [43] found conflicting evidence on the effects of DWPs in this area.

Mindfulness and self-compassion outcomes were discussed in 1 meta-analysis by Phillips et al [16], which found a small effect

XSL•FO
RenderX

size (g=0.42, 95% CI 0.24-0.60, k=5, N=not available, I^2=0). In addition, 2 non–meta-analyses [43,54] reported significant evidence supporting the efficacy of DWPs in these outcomes.

Various secondary outcomes were also identified in the literature, including perceived well-being, psychological resilience, and sleep-related symptoms such as insomnia. For perceived well-being, 2 meta-analyses [16,36] reported small effect sizes. Carolan et al [36] found an effect size of g=0.37 (95% CI 0.23-0.50, k=21, N=2438, I^2=81%), and Phillips et al [16] found a similar effect size of g=0.35 (95% CI 0.25-0.46, k=7, N=not available, I^2=0). However, 2 non–meta-analyses [39,55] found conflicting evidence. For psychological resilience, 1 non–meta-analysis [44] found conflicting evidence in the literature. Regarding insomnia, 1 meta-analysis [16] reported a medium effect size (g=0.52, 95% CI 0.39-0.65, k=6, N=not available, I^2=0%) after removing an outlier. In addition, 1 non–meta-analysis [44] found conflicting evidence on insomnia outcomes.

Interestingly, several reviews reported on job-related outcomes. One meta-analysis [50] focused exclusively on workplace-related outcomes, finding a small effect on employee engagement (g=0.19, 95% CI 0.10-0.28, k=10, N=2497, I^2=16%) but no significant effect on absenteeism (g=0.28, 95% CI −0.02 to 0.57, k=12, N=3325, I^2=94%) or presenteeism (g=0.18, 95% CI −0.05 to 0.41, k=8, N=2102, I^2=85%). Regarding presenteeism, 1 non–meta-analysis [44] found conflicting evidence related to tailored DWPs. For employee productivity, 2 meta-analyses found small effect sizes: Stratton et al [50] reported g=0.16 (95% CI 0.03-0.29, k=16, N=3053, I^2=62%), and Carolan et al [36] found g=0.25 (95% CI 0.09-0.41, k=13, N=1295, I^2=75%). In terms of job burnout, Phillips et al [16] found a medium effect size (g=0.51, 95% CI 0.26-0.75, k=8, N=not available, I^2=79%). Two non–meta-analyses [46,55] reported unanimous evidence supporting the efficacy of DWPs in reducing burnout, while López-Del-Hoyo et al [43] found conflicting evidence.

Acceptability

Two non–meta-analyses [36,47] investigated the acceptability of DWPs related to mental health (Table 4). According to these reviews, uptake rates—the proportion of targeted employees who start the program—are an underreported measure of acceptability in the existing literature. The average uptake rate is 11%, indicating that slightly more than 1 in 10 targeted employees initiate the program. Scheutzow et al [47] also identified several factors contributing to lower uptake rates, including employees' fear of workplace stigmatization and their preference to keep health matters separate from workplace experiences. These barriers emphasize the need for organizations to address concerns about privacy and stigma to improve participation in DWPs.

Table 4. Acceptability of mental health digital wellness programs.

Study	Acceptability measures							
	Uptake	Adherence rate	Attrition rate	Dropout rate	Compliance rate	Satisfaction score	Int[a]	PU[b]
Scheutzow et al [47]	11% (n=2)	54% (n=2)	32% (n=3)	51% (range 15%-68%; n=7)	68% (n=2)	82% (n=10)	55% positive (n=9)	85%
Carolan et al [36]	—[c]	—	23% (range 3%-54%; n=20)	—	45% (range 3%-95%; n=19)	—	—	—

[a]Int: interest or willingness to use.

[b]PU: perceived usability or usefulness.

[c]Not applicable.

Regarding adherence rates, 2 empirical studies reported an average rate of 54%, as indicated by the study by Scheutzow et al [47]. However, the definition of adherence varies across these studies. One study defines adherence as continued participation after the first day of the intervention, while the other measures it as completing a specified number of activities within a given time frame, akin to a compliance rate. As a result, these findings should be interpreted with caution.

Attrition, dropout, and completion rates—which are similar measures—vary significantly across empirical studies. According to the literature reviews, the average rates for mental health DWPs are 32% for attrition, 51% for dropout, and 68% for completion according to the results in Table 4. The most frequently cited reasons for employees dropping out of these programs include concerns about privacy, lack of time, technical difficulties, lack of motivation, confidence in their ability to manage stress independently, dissatisfaction with the interventions, and high stress levels at the start of the program. In addition, the data suggest that younger employees are more likely to drop out of these interventions [47].

Higher completion rates are observed in DWPs delivered over shorter periods, those employing self-monitoring or tailored interventions, and those using secondary modalities such as email and SMS text messaging to enhance user engagement [36]. Finally, available evidence indicates that employees generally express high levels of satisfaction with DWPs, rating them as useful and showing a strong willingness to continue using them. However, Scheutzow et al [47] note that these positive satisfaction ratings often contrast with the unfavorable attrition and completion rates observed in many primary studies.

Physical Activity

Overview

The second most frequently discussed health domain is physical activity. According to the World Health Organization, physical activity refers to any movement of the human body, whether it

XSL•FO
RenderX

involves performing daily tasks or altering one's physical position [63]. Insufficient physical activity has long been associated with a range of health complications, including cancer, anxiety, depression, cardiovascular disease, musculoskeletal disorders, and premature death [64,65]. Organizations implement interventions in both sedentary workplaces and physically demanding environments to reduce health risk factors [66]. While sedentary behavior and physical activity interventions are sometimes discussed separately in the literature, we examine them together because both aim to increase active behavior. Table 5 summarizes the literature reviews within this domain. All the reviews in this health domain assess the efficacy of the programs. While most (7/9, 77%) examine the changes in intervention outcomes, 4 out of 9 (44%) examine the mechanisms of action used in these interventions. In addition, 1 review investigates the acceptability of these programs.

[e]Am: amount of physical activity (steps, duration, metabolic equivalent of task, etc).

[f]Sb: sedentary behavior (time, frequency of transitions, etc).

[g]An: anthropometric (weight, waist circumference, etc) and blood test indicators.

[h]Pw: psychological well-being.

Efficacy

The interventions in this health domain are less varied than those in the mental health domain, and the evidence on the efficacy of these interventions can be summarized into primary and secondary outcomes. As shown in Table 6, the primary outcomes of interest are measures such as the number of steps taken and the duration of physical activity, which we refer to as the amount of physical activity. A meta-analysis conducted by Jung and Cho [40] found that DWPs have a small but significant effect on the amount of physical activity (g=0.22, 95% CI 0.03-0.41, k=8, N=not available, I^2=78%). However, 5 non–meta-analyses [18,35,38,48,52] reported conflicting evidence, with roughly half of the empirical studies finding significant changes in the amount of physical activity.

The secondary outcomes include measures of sedentary behavior (eg, sitting time and frequency of transitions to standing), anthropometric measures (eg, weight and waist circumference), physical readiness (eg, maximal oxygen uptake and aerobic capacity tests), and psychological well-being. These outcomes have been less-frequently discussed in prior studies. However, some non–meta-analyses provide evidence that physical activity DWPs can be effective in improving these outcomes.

Regarding sedentary behavior, 3 non–meta-analyses [35,38,48] reported conflicting evidence, with approximately half of the empirical studies showing significant improvements. For anthropometric measures, 2 non–meta-analyses [35,38] reported conflicting evidence, whereas Sevic et al [48] found only nonsignificant results. In terms of physical readiness, Buckingham et al [35] identified 2 interventions with conflicting results, whereas Sevic et al [48] found only 1 study with nonsignificant results. Regarding psychological well-being, Freak-Poli et al [38] reported conflicting evidence, whereas Buckingham et al [35] found significant positive effects.

[j](#/#) = (number of studies with significant evidence for this outcome) / (total number of studies reporting this outcome).

[k]In non-meta-analysis reviews, - stands for found no significant evidence.

[l]In non–meta-analysis reviews, + stands for found unanimous evidence in favor of the effectiveness.

Mechanisms of Action

Four non–meta-analyses [35,37,48,53] examined mechanisms of action. These studies mainly conducted a scoping survey of the literature on DWPs with two objectives: (1) categorizing the intervention into existing taxonomies and (2) summarizing the theories used in the development of DWPs. These non–meta-analysis reviews are summarized in subsequent paragraphs.

Three reviews [37,48,53] categorized physical activity DWPs into the established taxonomies of behavior change techniques and intervention strategies [67,68]. According to these taxonomies, behavior change techniques are specific activities used in interventions to induce a change in one's behavior, whereas intervention strategies (also known as intervention functions) are high-level approaches to design interventions. Sevic et al [48] and Tung et al [53] examined the scope of behavior change techniques and intervention strategies used in DWPs. According to these reviews, enablement and education are the most frequent intervention strategies. Enablement refers to those intervention strategies that enhance capabilities and opportunities to change behavior. It can be implemented through various behavior change techniques such as self-monitoring, feedback provision, and goal setting and action planning. For its part, education refers to the techniques that increase one's knowledge of health-related topics. It can be implemented through various behavior change techniques such as providing instructions for healthy behavior and informing of the consequences of behavior. These reviews state that they could not clarify which behavioral techniques and strategies are more successful than others due to the heterogeneous characteristics of interventions compared with the limited number of empirical studies in the literature.

The fourth non–meta-analysis review [35] presents the theories used in the development of physical activity DWPs. In this regard, the most frequently cited theories are socioecologic theory, self-determination theory, social cognitive theory, and the theory of reasoned action. Similarly, this review does not discuss which theories are more successful in designing DWPs. Three reviews in our sample [37,45,53] agree that most empirical studies lack a theoretical basis for developing DWPs in this domain.

Acceptability

The acceptability of physical health DWPs is discussed in one literature review, which focuses on mHealth technologies [35]. Three main acceptability outcomes are reported in the surveyed empirical studies. The most commonly reported outcome is the attrition rate of interventions, which refers to the number of participants who fail to provide data at the final follow-up. The average attrition rate is 18%, which is considered acceptable for health promotion interventions. However, some interventions report attrition rates as high as 74%, indicating significant variability in the acceptability of the programs. This variability is attributed to several factors including employee demographics (with higher attrition rates among females and younger employees) and the duration of the interventions (with higher attrition in interventions lasting more than 12 weeks). Buckingham et al [35] also cite possible reasons for the lack of engagement after initial use, including privacy concerns, diminished interest, and lack of trust in the accuracy of the technologies. Despite the wide range of attrition rates,

XSL•FO
RenderX

Buckingham et al [35] report that employees who continued using the programs until the follow-up generally expressed high levels of satisfaction. However, due to the high heterogeneity of interventions, the review was unable to provide a clear explanation for the variability in attrition rates or the reasons for the decline in the use of technological components.

Weight Management

Overview

Weight management interventions aim to help individuals achieve and maintain a healthy body weight, which can reduce the risk of chronic diseases and improve overall health and quality of life. Compared with employees with normal weight, employees with overweight and obesity incur higher direct costs (eg, insurance claims) and indirect costs (eg, absenteeism) for their companies. It is estimated that organizational costs associated with employees with overweight and obesity are 11% and 45% higher, respectively, than those for employees with normal weight [69]. Weight management interventions typically involve a combination of strategies such as modifying dietary intake and increasing physical activity [70]. We identified 5 literature reviews on weight management DWPs (Table 7). These DWPs adopt either a universal approach targeting all employees or a targeted approach focusing specifically on employees with obesity. Only 1 review [42] focuses solely on the targeted approach.

Table 7. Mapping of reviews on weight management digital wellness programs.

[e]An: anthropometric measures (BMI, weight, waist circumference, etc).

[f]Am: amount of physical activity (steps, duration, metabolic equivalent of task, etc).

[g]D: dietary intake.

[h]PR: physical readiness (maximal oxygen uptake and aerobic readiness).

Efficacy

Table 8 summarizes the outcomes reported for weight management DWPs. As expected, the most frequently discussed outcomes are related to anthropometric measures such as BMI, weight, and waist circumference. The only meta-analysis [16] conducted in this domain failed to establish significant support for the efficacy of DWPs on these measures (g=0.02, 95% CI −0.07 to 0.10, k=4, N=not available, I^2=0%). However, several empirical studies reported in non–meta-analyses show a significant effect of DWPs on anthropometric outcomes. Specifically, 2 non–meta-analyses [18,52] found evidence from high-quality studies indicating small to modest reductions in weight and waist circumference.

Furthermore, 1 non–meta-analysis review [42] found unanimous evidence supporting the effectiveness of weight management DWPs that adopt a targeted approach. These interventions used various strategies such as teleconsultation, health data monitoring, personalized advice, and the provision of online resources. This review highlights the notably high success rates of targeted weight management DWPs, a valuable finding given that obese employees tend to have higher absenteeism, greater health risks, and increased health care costs [69,71].

Secondary outcomes of weight management DWPs include the amount of physical activity, dietary intake, and physical readiness (eg, maximal oxygen uptake and aerobic capacity). Only 1 non–meta-analysis [18] included these secondary outcomes but did not find significant changes. This lack of evidence has been attributed to the limited number of empirical studies reporting on these secondary outcomes.

[i]In non-meta-analysis reviews, - stands for found no significant evidence.

[j]In non–meta-analysis studies, + denotes found unanimous evidence in favor of the effectiveness.

Mechanisms of Action

One non–meta-analysis review [53] examines the mechanisms of action in weight management programs. This review highlights that digital technologies can support various behavioral change strategies commonly used in these programs, such as enablement and education. The enablement strategy includes behavior change techniques such as self-monitoring of sitting time, self-monitoring of dietary behavior, and telemonitoring of physical activity data by a remote coach. The education strategy involves techniques such as delivering instructive content about nutrition, health risks, and physical activity through various online channels. Although this literature review summarizes the range and frequency of these behavior change techniques, it is unable to identify which specific techniques are most effective due to the heterogeneity of the intervention characteristics.

Unhealthy Behavior Change

Overview

The DWPs in this category are designed to modify behavioral patterns associated with higher health risks, such as smoking, poor eating habits, and excessive alcohol consumption. These modifiable unhealthy behaviors are linked to the earlier onset of chronic diseases and can lead to avoidable costs for organizations, including increased absenteeism and health care expenses [72,73]. As shown in Table 9, we identified 4 non–meta-analysis reviews related to unhealthy behavior change; however, only one of these reviews [51] exclusively focuses on unhealthy behavior change as its primary topic of interest.

Table 9. Mapping of reviews on unhealthy behavioral change digital wellness programs.

XSL•FO
RenderX

Efficacy

Table 10 summarizes the findings for the 3 types of unhealthy behaviors targeted by DWPs: smoking, poor diet, and excessive alcohol consumption. The most frequently cited outcomes in these studies relate to changes in the occurrence of the targeted behaviors, such as the frequency of alcohol consumption and the amount of healthy food intake. All included non–meta-analyses [16,18,48,51] reported conflicting evidence regarding the efficacy of DWPs in reducing smoking, improving diet, and curbing alcohol consumption. It is important to note that all the diet interventions included in these reviews were a part of multiple-component health interventions that also incorporated physical activity or weight management modules. For their part, 2 non–meta-analyses evaluated secondary outcomes of behavioral change DWPs. Aneni et al [18] found conflicting evidence regarding the effectiveness of diet-focused DWPs, which showed effectiveness in reducing weight and blood pressure. Sundstrom et al [51] also found conflicting evidence on alcohol-related DWPs, specifically concerning their impact on employees' mental health and work-life balance.

[f]Not available.

[g]The diet interventions included in this review were in a multicomponent health intervention.

[h]In non–meta-analysis studies, ~ denotes found conflicting evidence.

Mechanisms of Action

One non–meta-analysis review [48] outlines the behavior change techniques used in DWPs aimed at dietary improvements and alcohol reduction. According to this review, digital technologies facilitate several behavior change techniques, including prompting employees, providing feedback, enhancing self-belief, offering social support, giving instructions to support behavior change, introducing nudging objects to employees' immediate environment, and raising awareness about the consequences of unhealthy behaviors.

Sleep Management

Overview

The DWPs in this health domain aim to improve sleep quality and, consequently, enhance daytime alertness and performance at work. Poor sleep quality among employees is associated with productivity losses, an increased risk of chronic conditions, slower and less-accurate cognitive responses, and a higher likelihood of fatal occupational accidents [74]. Sleep management is especially crucial for shift workers in stressful or high-risk occupations. As shown in Table 11, we identified 2 non–meta-analysis reviews [19,52] that focus on the efficacy of sleep management DWPs. Bullock et al [19] examine sleep management programs delivered via mobile apps specifically designed to help shift workers. Thai et al [52] focus on sleep management interventions implemented in organizations located in low- and middle-income countries.

XSL•FO
RenderX

[e]SM: sleep-related measures (sleep duration, sleep debt, sleep difficulties, etc).

[f]SS: symptoms of poor sleep (daytime fatigue and daytime sleepiness).

[g]This study is only limited to shift workers.

Efficacy

As shown in Table 12, the outcomes of sleep management DWPs are categorized into 2 main areas. The first category involves measures of sleep quantity and quality. Two non–meta-analysis reviews [19,52] found unanimous evidence supporting the effectiveness of DWPs in improving sleep-related outcomes. The second category pertains to symptoms of poor sleep, such as daytime fatigue and sleepiness. Similarly, both reviews found consistent evidence supporting the effectiveness of sleep management DWPs in alleviating these symptoms. Thai et al [52] suggest that sleep interventions that use digital technologies to provide tailored advice to employees are more effective than those offering on-demand content. However, both reviews caution that the body of evidence is still too small to draw definitive conclusions, and thus, the findings should be interpreted with care.

Table 12. Summary of sleep management digital wellness program outcomes.

[c]In non–meta-analysis studies, + denotes found unanimous evidence in favor of the effectiveness.

[d](#/#) = (number of studies with significant evidence for this outcome) / (total number of studies reporting this outcome).

Other Health Domains

The final category includes interventions that do not fit into the previously discussed domains. Three of the identified reviews [45,48,52] only touch on these DWPs tangentially. Interventions in this category address diverse issues, such as health risk assessments, reducing risk factors for chronic diseases, improving workplace ergonomics, and lowering blood glucose levels in at-risk employees. Empirical studies referencing these interventions report significant outcomes. However, due to the heterogeneity of the health issues addressed and the limited empirical evidence available, we were unable to synthesize or aggregate the findings. As a result, we acknowledge their presence within this body of research without attempting further analysis.

Discussion

In this section, we synthesize and critically analyze the findings on DWPs with a focus on understanding efficacy, durability, mechanisms of action, acceptability, and targeting approaches across the identified health domains. While the findings reveal promising outcomes in several areas, they also underscore significant limits and gaps in the literature that necessitate further investigation to fully harness the potential of these programs.

Principal Findings

The findings on DWPs indicate that navigating this diverse body of evidence requires a detailed examination of various aspects of these programs, including their targeted health domain, their reported outcomes, and their recruitment strategies. Principal findings have been summarized according to these aspects.

First, this meta-review shows mixed or conflicting evidence regarding the efficacy of DWPs for mental health and physical activity, the two most studied domains. In the mental health domain, while some reviews highlight small to medium positive effects on outcomes such as stress, anxiety, and depression, others report conflicting or inconclusive findings. For example, while some interventions lead to meaningful reductions in stress and anxiety [16,17], these effects are not consistently observed

XSL•FO
RenderX

across all reviews [43,46]. Similarly, for physical activity, the efficacy of DWPs varies significantly. Although several studies indicate increases in the amount of physical activity mainly through goal-setting and self-monitoring features (eg, [35,40]), others show limited impact. This suggests that factors such as intervention design and participant engagement may influence outcomes. Consequently, while DWPs hold potential for improving mental health and physical activity, the inconsistent evidence highlights the need for deeper exploration of the factors that make certain interventions more successful than others.

Second, in the domain of weight management, non–meta-analyses [18,42,52] report significant reductions in BMI and body weight, especially among individuals with obesity participating in DWPs [42]. These results suggest that targeted interventions aimed at high-risk populations are more effective than generic programs. Although non–meta-analyses report many interventions with significant improvements in BMI and body weight, the only meta-analysis study on weight management DWPs [40] failed to show a significant change. The lack of convergence between the non–meta-analyses and the meta-analysis study in this health domain suggests that factors such as health risk perception may influence intervention efficacy.

Third, the evidence for unhealthy behavioral change, such as smoking cessation and alcohol reduction, is promising but limited. While the available non–meta-analysis reviews [16,18,48,51] indicate significant reductions in unhealthy behaviors, there is a lack of sufficient studies to provide comparative insights. Thus, while DWPs appear effective for behavior change, the relative effectiveness of different interventions remains unclear due to the limited evidence base.

Fourth, non–meta-analysis reviews in the sleep management domain show promising effects of DWPs on sleep outcomes, such as duration, latency, and quality [19,52]. The agreement between studies highlights the efficacy of DWPs in improving sleep health, but the body of evidence is limited to a few studies.

Fifth, DWPs are generally well-accepted by participants, particularly when they are personalized, user friendly, and easily accessible. However, acceptability measures are not free from bias. For example, satisfaction surveys typically gather feedback only from participants who complete the program, making these results susceptible to survival bias. In other words, while high satisfaction scores may suggest the program's success, they can inflate acceptability measures by excluding the opinions of dissatisfied users who dropped out. Similarly, compliance rates, often gauged through log-in data, may understate the program's success if users disengage after achieving their desired outcomes. It is crucial for researchers to recognize and account for these limitations in their studies.

In addition, the findings of this meta-review emphasize that the effectiveness and acceptability of DWPs are influenced by how user friendly and personalized they are. This aligns with prior research [75] that indicates the effective use of self-monitoring technologies depends on users' attitude toward the system and their perceived role in managing their conditions. In this respect, providing more guidance to reliant users (those who assume a passive role in managing their health) and greater autonomy to engaged users (those who assume an active role in managing their health) could enhance program success. This suggests customizing DWPs to individual user profiles can maximize benefits.

Finally, this meta-review highlights that the recruitment strategy of DWPs plays a crucial role in determining their efficacy. DWPs that use a targeted approach, recruiting participants based on risk factors or health conditions, tend to produce larger effect sizes than those with a universal approach. Review studies focusing on mental health, weight management, and unhealthy behavioral change demonstrate that targeted programs tend to yield better outcomes. In contrast, DWPs with a universal approach may produce smaller effect sizes, likely due to the dilution of outcomes across a more diverse participant pool. For example, individuals with moderate alcohol consumption may show minimal change, reducing the overall impact measured in the program [51]. Therefore, it is important to interpret the results of DWPs in light of their recruitment strategy and acknowledge that universal programs may not achieve the same level of effectiveness as targeted interventions.

Gaps and Promising Avenues for Research

This study exposed critical gaps and highlighted areas where further research is needed. The meta-review approach allowed us to survey a rich body of research that focuses on the same phenomenon but progresses in parallel with their focus on different health domains. We identified several gaps that were shared across various health domains. However, some gaps were identified by borrowing ideas from the research in other health domains. For example, a lack of focus on mechanisms of action in the mental health domain became apparent after comparing reviews in this domain with the ones in other health domains. In what follows, we highlight areas with significant gaps and provide recommendations to guide future research. The most important area concerns the inconsistent findings that were observed for the two most studied domains: mental health and physical activity.

Regarding mental health, the inconsistent findings are linked primarily to outcomes such as stress, anxiety, and depression. To resolve this inconsistency by explaining when DWPs have beneficial effects, moderation analysis is useful. This type of analysis examines whether the effects of DWPs, such as their stress-reducing effects depend on certain moderating factors [76]. Since technology is at the core of DWPs, the literature on technostress provides several moderating factors that are worth exploring. In particular, self-efficacy is a relevant factor because it assesses the extent to which persons believe that they have the ability to use technologies such as DWPs successfully (eg, [77,78]). Usually, people with higher levels of self-efficacy are more motivated to use these technologies effectively and make a greater effort to learn about them, whereas individuals with lower levels of self-efficacy give up more easily when the benefits of using the digital technology do not accrue immediately. This suggests that most people with higher levels of self-efficacy will use DWPs more effectively and will derive greater mental health benefits from using them than those with lower levels of it. However, this might not always be the case as the success of a DWP likely depends on its design elements

XSL•FO
RenderX

and content. Even expert users with high levels of self-efficacy might become frustrated or disengaged when DWPs are not well-designed or are not sufficiently user friendly. For example, poor navigation features, a clunky interface, or overly simplistic features might all hinder engagement with DWPs and thus frustrate users. This means that not all users with high levels of self-efficacy will derive greater mental health benefits from DWPs. Notwithstanding this fact, self-efficacy holds the potential to resolve some of the conflicting findings in the literature (eg, [79]).

Other moderating factors from the technostress literature are also relevant. Worker age is an important factor because older workers experience a greater mental workload when they engage with technologies such as DWPs [80-83]. Since this increased mental workload leads to stress [83], it can undermine the stress-reducing potential of DWPs. Other relevant moderating factors include differing levels of motivation to improve health-related outcomes, differing levels of IT support available to use DWPs, and differing levels of experience with such digital tools as messaging services, online telecommunication, and videoconferencing apps [78,83-86]. These factors can impact how effectively workers engage with DWPs and thus affect the degree to which the potential benefits of these technologies are realized. DWPs can be expected to lead to greater benefits when users are more motivated to improve their health when they receive more IT support, and when they have more experience with relevant tools. This means that these factors can help explain some of the conflicting findings in the extant literature.

However, the big 5 personality traits are likely the most promising moderating factors because they have been shown to moderate various relationships between engagement with technology and stress-related variables (eg, [87-89]). They have also been shown to affect the stress process more broadly [90], and they include 5 constructs: neuroticism, openness, agreeableness, extraversion, and conscientiousness. Regarding the moderating impact of personality traits on the stress-reducing potential of DWPs, individuals high in neuroticism are likely to report lower mental health benefits from engaging with DWPs. This is because they tend to experience greater dissatisfaction, frequently complain, and perceive even minor frustrations as overwhelming, making them less likely to find DWPs beneficial. In contrast, individuals high in openness are typically curious and willing to explore new experiences, which can lead to greater satisfaction with DWPs. Their openness to new approaches may result in more positive evaluations of the benefits of engaging with these systems, making them more likely to perceive DWPs as beneficial.

Regarding agreeableness, individuals high in this trait tend to be cooperative and are more likely to follow the advice of nurses, doctors, and artificial intelligence chatbots [87-89]. As a result, they are likely to derive greater benefits from their engagement with DWPs compared with those with lower agreeableness. Similarly, extraverted individuals are typically social, active, and outgoing. They often use technology strategically to maintain a positive social image, which suggests that they may view DWPs as a tool for sustaining well-being, job performance, and influence within the organization. Consequently, they are more likely to engage effectively with DWPs and perceive their engagement as beneficial. Finally, conscientious individuals tend to be detail oriented, dependable, and persistent. Even if they experience initial frustration, their intrinsic motivation and strong work ethic make them more likely to persist in using DWPs. Their commitment to efficiency and effectiveness further enhances their likelihood of successfully integrating DWPs into their routines.

Regarding physical activity, our study highlights that goal setting is a widely used behavior change technique. Goal-setting theory suggests several important moderators that influence its effectiveness. Specifically, for goal setting to be successful, individuals must possess both the ability and the situational resources necessary to achieve the goal [91]. In addition, goal importance and commitment to goal attainment serve as key moderators of effectiveness. However, one particularly noteworthy moderator is feedback, which plays a crucial role in goal progress. Regular feedback enables individuals to adjust their effort and refine their strategies, ensuring they stay on track toward goal attainment [91]. This suggests that the 2 primary drivers of increased physical activity in DWPs, goal-setting and self-monitoring features, may interact. Future research could explore whether the impact of goal setting on physical activity is enhanced when combined with self-monitoring features that provide a continuous stream of relevant feedback.

This meta-review also sheds light on methodological and structural attributes of the literature that future research should focus on. One such attribute across all health domains is the scarcity of long-term studies. Although many DWPs demonstrate initial effectiveness, the sustainability of these effects remains largely unexplored. For example, prior literature reviews on mental health and physical activity [17,35,38] have reported a decline in positive outcomes after a few months. However, the specific conditions under which these reductions occur, and whether they are more pronounced in DWPs compared with nondigital wellness programs, are still unclear. A recent study provides evidence of a temporary digital placebo effect in smartphone-based mental health interventions [92]. The digital placebo occurs when users experience benefits from digital technologies due to their beliefs in the tools rather than from their actual functionalities [93]. Initial expectancy and credibility of digital tools can taper off and potentially lead to reduced effectiveness in outcomes [92]. Yet, it is not clear who is more prone to this effect, what factors in intervention designs exacerbate it, and what practices can mitigate its impact. Hence, future research must prioritize longitudinal studies that answer these questions regarding DWPs and potentially compare them with their nondigital counterparts.

Another significant gap in the literature is the limited understanding of the mechanisms that drive the success of DWPs. Only 4 reviews in our sample have delved into the specific behavior change techniques that are used in these programs [35,37,48,53]. While these reviews offer valuable insights, many questions remain unanswered regarding the comparative advantage of various techniques. Surprisingly, despite the numerous reviews conducted on mental health DWPs, we did not find any review that examines the mechanisms of action used in this domain. Although some

XSL•FO
RenderX

reviews [17,57] compare effect sizes of various therapeutic approaches such as cognitive behavioral therapy and positive psychology, it remains unclear whether their success is attributable to the therapeutic approaches or the effective activation of causal mechanisms of action by digital interventions. Psychotherapy scholars have recently called for the integration of these mechanisms into the research on mental health interventions [94-96]. This allows researchers to develop treatment strategies that focus on the most important mechanisms [96] and to examine moderating factors that influence active mechanisms of change [95].

Moreover, recent research underscores the importance of studying behavior change techniques in light of the causal mechanisms of change [97,98]. For example, Carey et al [98] provide an extensive list of causal mechanisms of action used in behavioral interventions. Future research on DWPs can leverage this list to examine how IT-related factors (eg, design and personal innovativeness with IT) and organization-related factors (eg, organizational culture and perceived organizational support) can weaken or strengthen the mechanisms of action applied in DWPs.

In a similar vein, prior reviews [35,48] call attention to the lack of strong theoretical foundations in prior research. We echo this concern and highlight 2 potential consequences that have created a gap in our understanding of DWPs. First, an atheoretical approach to designing health interventions limits our ability to generalize findings. For example, combining behavior change techniques can "lead to combinations of counteracting mechanisms in mHealth designs that obfuscate the techniques' effects" [99]. Leveraging health and behavior change theories, researchers can articulate the boundary conditions of compatible interventions. Second, an atheoretical approach limits our ability to understand why and under what conditions DWPs influence organization-related outcomes such as burnout. For example, the theory of job demands-resources [100] provides a useful perspective in studying the organization-related outcomes of mental health DWPs. However, it should be further elaborated to explain how the characteristics of DWPs can contribute to job resources. To advance the field, it is essential that future studies are grounded in relevant theoretical frameworks, elucidate the processes by which DWPs influence health- and organization-related outcomes, and ultimately create value in organizations.

This meta-review also highlights limitations in the scope of interventions examined in the literature. While existing studies primarily focus on individual-level outcomes, such as personal health and productivity, wellness interventions can also be analyzed at higher organizational levels, including work groups and entire organizations [101]. Research on nondigital wellness initiatives has demonstrated organization-level outcomes, such as insurance claims and cost-benefit analyses of wellness programs [102]. However, similar outcomes have not yet been examined in the context of digital wellness initiatives. To address this critical research gap, future studies could leverage archival data, such as insurance claims and unit performance reports, to assess the broader organizational impact of DWPs.

As mentioned earlier, the variability in outcome measures across studies presents a significant barrier to synthesizing findings and drawing generalizable conclusions. Particularly in the domains of physical activity and mental health, there is a need for standardized outcome measures that can be consistently applied across studies. This would allow for more robust comparisons and a clearer understanding of the true impact of DWPs. Moreover, most studies focus on health-related outcomes neglecting the organizational implications of these programs. Therefore, there is a clear need for more research that links DWPs to positive organizational outcomes such as productivity, presenteeism, retention, and job satisfaction. Understanding these links is crucial for demonstrating the value of DWPs to employers and other stakeholders.

Finally, the role of technology in DWPs is often treated superficially, with scant attention given to how specific technological features influence the efficacy and acceptability of these programs. For example, engagement is an understudied factor in understanding the efficacy of DWPs beyond common measures of acceptability, such as frequency of use. Engagement in digital interventions is a multidimensional construct that involves physical, cognitive, and affective investment in the stimulus (eg, app) [103]. Research shows that using more features of wearable trackers (ie, a form of physical engagement) is associated with higher health-related outcomes [15]. Future research should demonstrate how and under what conditions each dimension of engagement contributes to intervention outcomes. Moreover, despite the large body of research on engagement with technology, there is limited understanding of how to enhance engagement in the technological stimulus in DWPs. For example, Nahum-Shani et al [103] suggest that environmental dynamics and participants' information overload are important factors in the context of information-rich digital interventions. In this respect, future research should elucidate how employee-related factors (eg, cognitive and emotional resources) and organizational environment (eg, supportive climate) contribute to the engagement and eventually to the success of DWPs.

In addition, abstracting the technology components of DWPs into a device or mobile app without considering the underlying function of technology downplays its contribution to the success of DWPs. For example, a mobile app can have various functions such as delivering nudges and facilitating self-monitoring. The reviews in our corpus did not present their findings in this aspect, suggesting that accumulated evidence is lacking regarding the role of technology in DWPs. Future research should delve deeper into the technological aspects of DWPs by examining how different features and components of digital tools contribute to or detract from the success of digital interventions.

Implications for Practice

The findings of this meta-review hold significant implications for organizations, particularly for human resource (HR) managers tasked with improving employee health and well-being. While DWPs show potential in promoting employee wellness, their effectiveness is not consistent across all health domains. The mixed evidence on mental health and physical

XSL•FO
RenderX

activity—the two most studied areas—suggests that HR managers should have measured expectations regarding the immediate impact of these programs. Although DWPs can positively influence outcomes such as stress, anxiety, and physical activity, their success depends largely on program design, employee engagement, and the specific context of implementation. Therefore, HR managers should focus on tailoring DWPs to address the diverse needs of their workforce, ensuring interventions are personalized and adaptable. Conducting employee wellness assessments (eg, anonymous surveys, biometric screenings, or focus groups) can help organizations identify key health risks, understand employee preferences, and gauge engagement levels, allowing them to tailor interventions accordingly. By leveraging data-driven insights, HR managers can design more personalized and adaptable programs, ensuring that DWPs are aligned with employees' specific needs rather than taking a one-size-fits-all approach. In addition, these assessments provide valuable feedback loops, enabling organizations to refine and optimize their wellness strategies over time, ultimately improving program effectiveness and employee well-being.

Given the variability in outcomes, regular monitoring and assessment are essential to ensure that DWPs remain relevant and impactful. HR managers should evaluate the programs over time by seeking employee feedback (eg, satisfaction) and monitoring various acceptability measures (eg, uptake rate, completion rate, and engagement) and effectiveness measures (eg, individual and organization-related outcomes). Relying solely on any one of these measures can provide a narrow perspective on the success of the programs. Implementing regular monitoring mechanisms, including A/B testing of intervention approaches, can help refine these initiatives for greater impact.

While DWPs have shown promise in facilitating behavioral changes such as smoking cessation and alcohol reduction, the evidence remains limited. HR managers should not expect immediate or significant results in these areas. To enhance the impact of DWPs on behavior change, these programs should be integrated with broader organizational strategies such as health coaching, peer support groups, and incentives for healthy habits. Creating a supportive culture that encourages ongoing healthy lifestyle choices can help sustain these behavioral changes over time. Organizations should embed digital wellness check-ins into daily workflows and encourage leadership to model healthy behaviors, such as setting boundaries for after-hours emails.

Technology plays a crucial role in the success of DWPs. Wearables, mobile apps, and online platforms have proven effective in promoting the health of employees in various domains. They enable many opportunities for implementing organizational interventions that can easily be scaled up. However, as reflected in the acceptability measures discussed in the literature, HR managers should acknowledge that there is a great deal of variation in terms of adoption, continuous use, and the extent of engagement with technological initiatives among employees. Examining the compatibility of technologies with the target population before implementing DWPs can contribute to the success of such programs. For example, if the target population of a weight reduction DWP is employees with obesity, the organization can assess their self-management style [75] before investing in those programs that highly depend on self-monitoring devices. Personalization of wellness plans, offering a mix of mobile apps, virtual coaching, and wearable devices, can further improve engagement by catering to diverse employee preferences.

For DWPs to be truly impactful, they must be part of a larger organizational culture that prioritizes employee well-being. HR managers play a pivotal role in promoting this culture by embedding wellness as a core organizational value. This involves not only offering DWPs but also aligning organizational policies with initiatives that support work-life balance, stress management, and mental health. A culture of shared responsibility for wellness can significantly enhance the effectiveness of DWPs, leading to more positive outcomes for both employees and the organization.

In addition to improving employee health, HR managers can consider the return on investment for the organization. Evidence from this meta-review suggests that DWPs can potentially impact organizational outcomes such as engagement, absenteeism, and productivity, particularly when addressing prevalent issues such as mental health, sedentarism, and weight management. Highlighting potential cost savings and productivity gains can help HR managers present DWPs as both a health initiative and a strategic investment, securing the necessary resources and support for successful implementation.

In conclusion, DWPs offer organizations a valuable opportunity to improve employee health, enhance productivity, and reduce health care costs. However, the success of these programs depends on thoughtful implementation, continuous evaluation, and a supportive organizational culture. HR managers are at the forefront of this effort, playing a critical role in designing, promoting, and sustaining effective DWPs that meet the diverse needs of their workforce. By leveraging cross-disciplinary expertise and integrating digital health interventions within existing workplace structures, organizations can maximize the potential of DWPs for long-term employee well-being and organizational success.

Study Limitations and Future Research

This meta-review has several limitations. First, the initial abstract screening was conducted by a single reviewer, which may have introduced some selection bias. However, to minimize this risk, the reviewer applied a conservative approach, excluding studies only when it was certain they did not meet the inclusion criteria. Any study with uncertainty was flagged and discussed in consensus meetings among the authors before a final decision was made. While this approach helped mitigate bias, future meta-reviews may benefit from a dual-independent screening process to further enhance reliability. Second, the quality and scope of the included reviews varied, which could have affected the generalizability of our findings. Finally, while our review methodology was efficient, it may have missed recent studies due to publication delays. Future research should address these limitations by incorporating a broader range of studies and tackling more specific RQs inspired by this meta-review. In addition, there is a need for more rigorous methodological

XSL•FO
RenderX

approaches, particularly in examining long-term efficacy, mechanisms of action, and the role of technology in DWPs. Researchers should also prioritize the development of standardized outcome measures and further explore the organizational implications of DWPs, which remain underrepresented in the literature.

Conclusions

This meta-review provides a comprehensive synthesis of DWPs across various health domains, offering valuable insights into their efficacy and acceptability. The findings highlight promising outcomes, particularly in the areas of mental health, physical activity, and weight management, where interventions typically led to small to medium improvements. However, some inconsistencies persist in the extant literature that future studies must address. This study also reveals variability in efficacy depending on recruitment strategies, with targeted DWPs generally producing more substantial effects compared with universal programs. Significant gaps also remain, especially the scarcity of long-term studies and the limited understanding of the mechanisms driving DWP success. It also emphasizes the need for theory-driven research to better explain how and why certain DWPs are effective. For HR managers and organizations, the findings suggest that implementing tailored DWPs can enhance employee well-being and organizational outcomes. However, ongoing evaluation and adaptation are crucial to ensure these programs achieve their intended goals. In summary, while DWPs show great potential for improving employees' wellness, further research is necessary to optimize their design and implementation to ensure they deliver sustainable benefits in diverse workplace settings.

Authors' Contributions

SA conceptualized this study, conducted the coding, drafted the initial paper, and contributed to its review and editing. GP conceptualized this study, participated in coding, and reviewed and edited this paper. ST conceptualized this study, participated in coding, and reviewed this paper. All authors had full access to this study's data, including supplemental material, and approved the final version of this paper for submission.

Abstract

Background: Digital interventions hold significant potential for improving physical activity (PA) and reducing sedentary behavior (SB) in adults. Despite increasing interest, there remain surprising gaps in the current knowledge of how best to deliver these interventions, including incorporating appropriate theoretical frameworks and behavior change techniques. Following numerous systematic reviews, there is now significant potential for umbrella reviews to provide an overview of the current evidence.

Objective: This umbrella review aimed to explore digital PA and SB interventions for community-living adults across effectiveness, key components, and methodological quality.

Methods: This review followed the Joanna Briggs Institute framework for umbrella reviews. Key search terms were developed iteratively, incorporating physical and sedentary activity alongside digital interventions. We searched 7 online databases (Web of Science Core Collection, CINAHL, APA PsycINFO, Inspec, the Cochrane Library, MEDLINE [Ovid], and PROSPERO) alongside gray literature databases. Information was extracted and tabulated from each included article on intervention effectiveness, key components, and content acknowledging both the digital and human elements. The study quality was appraised using A Measurement Tool to Assess systematic Reviews 2 (AMSTAR 2). The corrected covered area method was used to assess the overlap of primary studies included in the systematic reviews. All relevant research findings were extracted and reported.

Results: Search terms identified 330 articles, of which 5 (1.5%) met the inclusion criteria. The most common PA outcomes identified were daily steps, moderate-to-vigorous PA, total PA, and PA change. Reviews with meta-analysis reported that digital interventions improved multiple PA outcomes (daily steps, moderate-to-vigorous PA time, and total PA time). However, findings from the remaining systematic reviews were mixed. Similarly, the findings for SB were contrasting. Regarding intervention components, monitor- and sensor-only intervention delivery methods were most frequently implemented. Eleven theoretical frameworks were identified, with social cognitive theory being the most prominent theory. In total, 28 different behavior change techniques were reported, with goal setting, self-monitoring, feedback, and social support being the most frequently used. All 5 systematic reviews were of low or critically low quality, each incorporating unique primary studies (corrected covered area=0%).

Conclusions: This umbrella review highlights the potential of digital interventions to increase PA and reduce SB among community-living adults. However, the disparate nature of current academic knowledge means potentially efficacious research may not realistically translate to real work impact. Our review identified a lack of consensus around outcomes and components at both individual (eg, difficult to collate and compare findings) and multiple study (poor reported quality of systematic reviews) levels. Collective, concerted action is required to standardize outcomes and improve systematic review reporting to optimize future learning around digital interventions to increase PA and reduce SB in community-living adults, including traditionally overlooked populations, like informal carers.

Introduction

Background

Physical activity (PA) is defined as "any body movement generated by the contraction of the skeletal muscles that raises energy expenditure above resting metabolic rate and is characterized by its modality, frequency, intensity, duration, and context of practice" [1]. Engaging in regular PA can reduce the risk of cardiovascular disease, type 2 diabetes, cancer, weight gain and obesity, and Alzheimer disease and significantly improve mental health and quality of life [2-4]. Alongside these individual health benefits, PA also provides benefits for societies, environments, and economies [5]. Sedentary behavior (SB) is described as "any waking behaviors characterized by an energy expenditure ≤1.5 metabolic equivalents while in a sitting, reclining, or lying position" [1]. Prolonged SB has been found to increase all-cause mortality and is also associated with poor disease outcomes, such as increased risk of developing cardiovascular disease, diabetes mellitus, hypertension, and certain types of cancer [6-8].

Despite the well-documented evidence for improving PA levels and reducing SB, many adults do not engage in sufficient levels of activity and have high levels of SB. Data from the Lancet assessing global trends in insufficient PA among adults from 2000 to 2022 using population-based surveys found that nearly one-third (31.3%) of the adults worldwide were not meeting the World Health Organization recommendations for moderate-to-vigorous aerobic activity in 2022 [9]. Findings from this work also suggest that if trends from 2010 to 2022 continue, the global prevalence of insufficient PA will reach 34.7% by 2030. Therefore, there is a need for effective interventions to increase PA levels and reduce SB.

Digital health interventions (DHIs) can be used to promote PA and reduce SB. World Health Organization describes digital health as the use of digital, mobile, and wireless technologies to aid the achievement of health-related objectives and includes both mobile health and eHealth [10]. DHIs can include smartphone apps, wearable activity trackers, online platforms, and web-based interventions. A favorable feature of DHIs is their ability to be scaled for large populations while also being able to be tailored for specific populations [10]. The use of DHIs has also been recommended by the global action plan on PA 2018 to 2030 to promote and support participation in PA due to their success and benefits of use [11].

As PA is described to be a complex behavior [12,13], it requires more time and commitment to change habits than other health behaviors. It has been recommended that PA and SB interventions be informed by theoretical frameworks and include appropriate behavior change techniques (BCTs) as they can be important for increasing effectiveness and adherence toward the behaviors [14,15]. Despite such previous work, there is little consensus as to what the best theoretical frameworks and BCTs for changing PA and SB are. For example, research suggests that combined PA and dietary interventions based on specific theories, such as cognitive theory and theory of planned behavior, are no more effective in achieving changes to PA outcomes than interventions with no stated theoretical grounding [16]. However, meta-regression of this work and an additional study [17] suggest that the use of a cluster of "self-regulatory" intervention techniques had a positive relationship with increasing PA, alongside additional outcomes, such as weight loss and dietary changes. Similarly, the available evidence to support the use of BCTs to improve PA is contrasting, with positive changes to PA behavior reported, but not all findings were statistically significant. Therefore, digital interventions with a theoretical grounding and BCTs could encourage improvements in PA and SB; however, more investigation into these aspects of intervention is required.

Moreover, many groups in society face significant additional barriers to PA either in an acute or chronic perspective, including individuals who face mental and physical health conditions, those facing higher levels of economic deprivation, and individuals in later years of life. An emerging and sizable group who are facing systemic barriers to PA and reducing SB includes informal carers. Informal carers could particularly benefit from digital PA and SB interventions as Horne et al [18] found that carers often prioritize the needs of those they care for over their own health, which could result in lower levels of PA and higher levels of SB. Caring duties can also act as a barrier for where, when, and how long they can participate in PA programs. Allowing this group a digital intervention that considers their own unique circumstances, preferences, and barriers could significantly improve adherence to higher PA levels and reduce SB. There is little published evidence to understand the use of these digital interventions for improving these behaviors within this population. In contrast, there are numerous primary studies and systematic reviews exploring the use of digital interventions to improve PA and SB levels in adults. Although having numerous systematic reviews on a certain topic can be beneficial, it has been reported that too many findings on a specific topic or research area can lead to replication issues by amplifying biases, inconsistencies, and misinterpretations from the available literature [19]. To eliminate the issues caused by multiple systematic reviews, umbrella reviews have been recommended.

Umbrella reviews are used to summarize the evidence from multiple research syntheses. This type of review provides an overview of the available evidence on a chosen topic and can be used to compare or contrast findings from published

XSL•FO
RenderX

systematic reviews [20]. An umbrella review is particularly beneficial for decision makers as it provides "user-friendly" summaries of the available knowledge and literature without the need to read and understand the findings of multiple systematic reviews themselves [21]. Umbrella reviews evaluating digital interventions currently do exist [22-24]. However, only a few specifically focus on groups within society who face additional barriers to participating in PA.

This Study

The overall scope of this research is to support PA and reduce SB in informal carers via digital devices. However, the lack of published primary studies and systematic reviews exploring digital PA and SB interventions for informal carers means that this paper will focus on digital PA and SB interventions for the community-living adult population, as there are numerous published systematic reviews in this topic area. We will address, in the Discussion section, the potential implications for the caring population.

The research questions for this umbrella review were as follows:

1. How effective are digital interventions in changing PA and SBs in community-living adults?
2. What components are included in digital PA and SB interventions, including delivery methods (technologies and human elements used) and content (theoretical frameworks and behavior change strategies used)?
3. What is the methodological quality of the included systematic reviews?

Methods

The methodology for this umbrella review was guided by the Joanna Briggs Institute Manual for Evidence Synthesis [25]. A protocol for this review was submitted to PROSPERO (CRD42023450773).

Inclusion Criteria

The inclusion criteria were generated using the population, intervention, context, outcomes, and study (PICOS) method. The inclusion and exclusion criteria for this umbrella review are shown in Textboxes 1 and 2.

Textbox 1. Inclusion criteria.

Population

- Community-living adults aged ≥18 years.

Interventions

- Digital interventions that were designed to increase physical activity (PA) levels and reduce sedentary behavior (SB) in adults who are physically capable of living at home.
- Interventions could be multimodal in nature (eg, they could include a digital and in-person element) if the digital element was the main component of the intervention.

Context and outcomes

- The main outcomes of this review were the effectiveness of interventions in changing PA and SB.
- The components and content included in digital PA and SB interventions, including the technological and human components, behavior change strategies, and theoretical frameworks, were also the main outcomes of this review.
- The overlap of included primary studies and the quality of the systematic reviews were secondary outcomes of this umbrella review.

Study type

- Systematic review.

Publication date

- Published in or after 2013.

Language

- English.

XSL•FO
RenderX

Textbox 2. Exclusion criteria.

Population

- Children or young adults aged ≤18 years.

Adults who were not capable of living independently or not community living.

Interventions

- Digital interventions that were not designed to increase PA levels and reduce SB.

Interventions where the digital element was not the main component of the intervention.

Digital interventions targeting multiple behaviors (eg, diet and PA).

Context and outcomes

- Systematic reviews of digital PA and SB interventions that do not report on the included outcomes (eg, systematic reviews assessing the effectiveness of PA and SB interventions on reducing blood glucose or mental health outcomes).

Study type

- Primary studies or any other type of review.

Publication date

- Published before 2013.

Language

- Other than English.

Search Strategy

Searches were conducted in July 2023 in the following 7 chosen databases: Web of Science Core Collection, CINAHL, APA PsycINFO, Inspec, Cochrane Library, MEDLINE (Ovid), and PROSPERO. These databases were used as they contain papers from health, social care, psychology, and computing and therefore encompass the topic area of this umbrella review. The gray literature databases, such as arXiv, Core, OpenGrey, and OpenDissertations were, also searched alongside the reference list of included systematic reviews. The rationale for focusing on systematic reviews from 2013 onward allowed the research team to maximize the availability of knowledge around digital interventions for improving PA and SB. The publication period up to 2013 marked the period when digital tools became more commercial, sophisticated, and widespread. Before 2013, digital interventions often relied on less accessible or less integrated technology. However, from 2013 the advancement of sensors and integration within digital interventions became more mainstream and transformed the landscape of these interventions. The inclusion criteria allowed this review to capture technologies most relevant to the present day and the future. In addition, by including systematic reviews from the past 10 or more years, primary studies 10 years before 2013 were able to be captured.

With guidance from subject librarians, a comprehensive keyword search strategy was created. These keywords in relation to adults, digital, PA, SB, theoretical models, BCTs, and systematic reviews were all initially searched individually to help refine the search criteria and formulate a more concise and comprehensive search strategy. The final search combined all keywords to identify systematic reviews on digital PA and SB interventions for community-living adults that incorporated elements of BCTs and theoretical frameworks (Multimedia Appendix 1).

Study Selection

Results from the database and gray literature searches (excluding Core) were imported into the EndNote Online reference manager (Clarivate). Duplicates were then removed in EndNote. Core search results were unable to be exported into this system; therefore, screening of these articles remained in the CORE database.

After this removal process, the remaining articles were exported from EndNote to the Rayyan (Rayyan Systems, Inc) website [26] for further screening. Title and abstract screening was conducted in Rayyan independently by the main reviewer (ER) and a second reviewer (WH). Title and abstract screening was blinded to reviewers until the process had been completed to lessen the potential for bias to occur. Full-text screening was also conducted in Rayyan with a supplementary Microsoft Excel document used by the main reviewer for tracking progress, dividing the workload between additional reviewers, and for additional comments and reasoning for inclusion or exclusion. Full-text screening was conducted independently by the main reviewer alongside the second reviewer (WH) and an additional reviewer (MP). The full-text screening process was also blinded. Conflicts were resolved through discussion between the reviewers.

Corrected Covered Area

The overlap of the primary studies included in the chosen systematic reviews was also assessed. As systematic reviews with similar research questions may include some of the same studies within their reviews, it is important to measure the

XSL•FO
RenderX

overlap of these studies as it can disguise a lack of current research or give a false impression of new evidence.

The corrected covered area (CCA) was calculated by creating a citation matrix where primary publications were listed in rows and the included systematic reviews of the umbrella review were represented in columns. The number of times a given study was cited in the systematic reviews was then calculated using the following formula [27]:

$$CCA = N - r / rc - r$$

where N is the total number of times primary publications appeared in reviews (inclusive of double counting), r is the number of unique primary publications, and c is the number of systematic reviews included in the umbrella review. The degree of overlap was then classified, where 0% to 5% was considered "slight overlap," 6% to 10% was considered "moderate overlap," 11% to 15% was considered "high overlap," and >15% was considered "very high overlap" [27].

Data Extraction

In order to answer research questions 1 and 2 of this umbrella review, a Microsoft Excel spreadsheet for data extraction was created using the Joanna Briggs Institute Manual for Evidence Synthesis data extraction guidelines. Extracted information included article and publication information (author, date, and digital object identifier), study information (number of included studies, date range, study design, location, and inclusion of meta-analysis), population demographics (sample size, age, and sex), intervention details, measures of effectiveness, and methodological quality rating. Data extraction was also quality checked for agreement between members of the review team.

Information on changes in PA and SB was extracted to answer the first research question. The most common PA outcomes (daily step count, moderate-to-vigorous PA [MVPA] min, total daily or weekly PA time, and PA change) and SB outcomes (SB min or change in SB) were used to report the effectiveness of these behaviors. To report on the components included within digital PA and SB interventions, the extracted information consisted of the following: whether the intervention focused on PA or SB only or if it targeted both behaviors, whether the intervention was shaped by a theoretical framework and what the frameworks were, and if the intervention included BCTs and what they were. Data extracted from the systematic reviews also included information on the delivery of the intervention (eg, smartphone, web based, wearable activity tracker–only interventions, or mixed delivery methods), human and technological components included, and the duration of the interventions.

Methodological Quality

The quality of the included systematic reviews was assessed using A Measurement Tool to Assess Systematic Reviews-2 (AMSTAR-2). This tool comprises 16 questions that are used to assess the confidence of the results of the review. The AMSTAR-2 rating of a review can range from high (when a review paper has <1 critical weakness) to moderate (with >1 noncritical weakness), low (with 1 critical weakness), and critically low (with >1 critical weakness) [28]. It is recommended that the ratings of the individual items should not be combined to create an overall rating, instead users should consider the impact of each individual item to determine an overall confidence rating.

All 16 questions within the AMSTAR-2 tool are of importance; however, there are 7 critical domains that can affect the validity of a review and the conclusions that can be drawn [28]. These critical domains relate to the review methodology, literature search strategy, justification for excluded studies, techniques for assessing the risk of bias, methodology for the statistical combination of results if meta-analysis was used, accounting for the risk of bias when discussing the results, and investigating publication bias and discussing the impact on results of the review, if quantitative synthesis was performed.

The methodological quality of each included systematic review was assessed by the main reviewer. The second reviewer assessed the methodological quality of 1 included review individually to cross-check the quality assessment process. Any disagreements or conflicts were resolved through discussion.

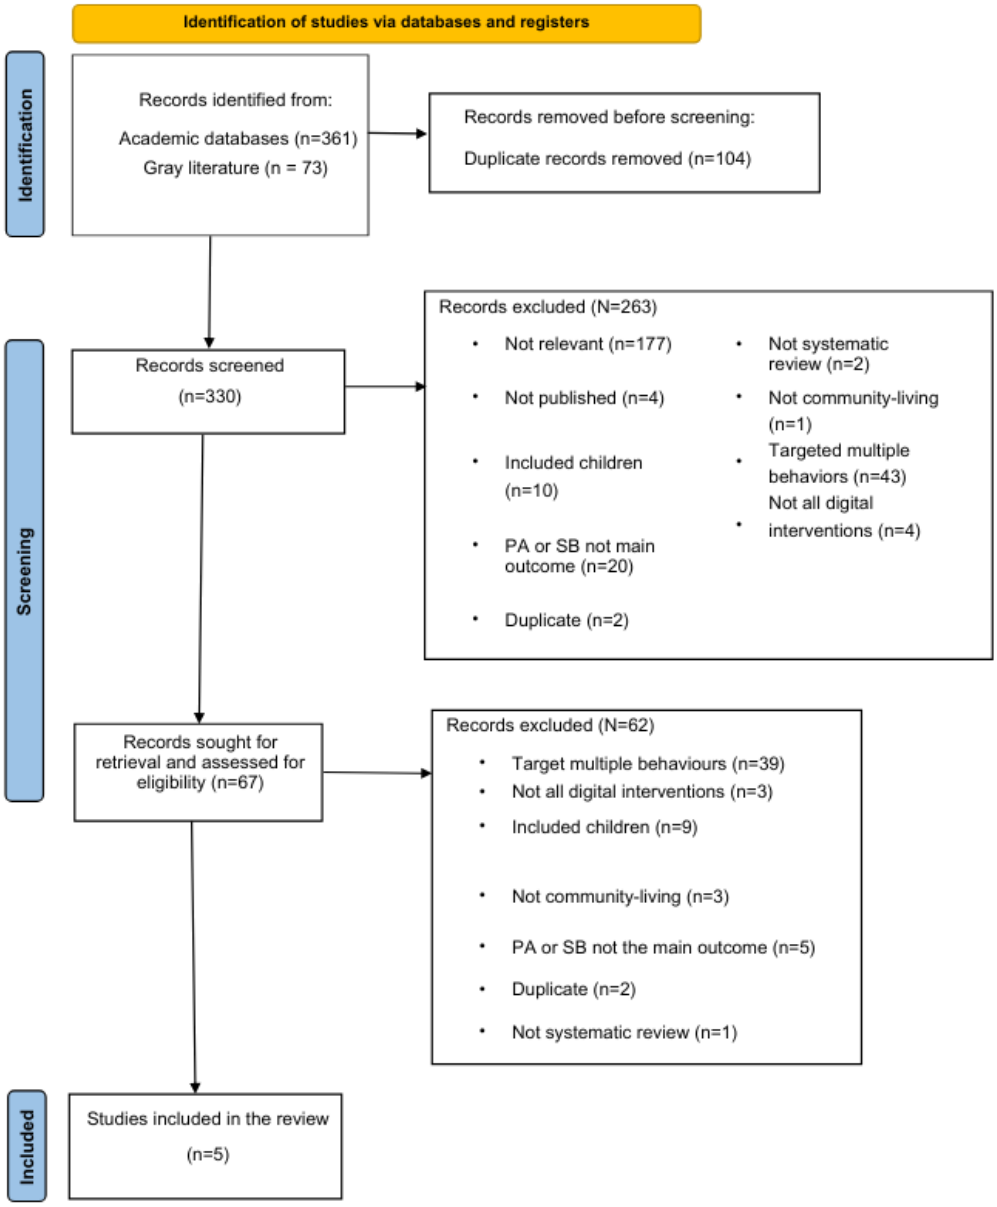
Presentation of Findings

The results of this umbrella review provided a summary of systematic reviews assessing digital PA and SB interventions for community-living adults. These results were reported as a summary of the synthesized results. Findings were summarized to identify if interventions have been beneficial or effective, if no differences between interventions and control groups have been identified or mixed results, or to show if interventions were less effective than the comparator or not effective. These summaries can be used to easily understand if a statistically significant change in PA or SB was achieved.

A quantitative summary of the included systematic reviews in relation to their delivery methods and their content (inclusion of theoretical frameworks and BCTs) was also created. The technological delivery methods were split into 6 columns consisting of web-only delivery, smartphone- or tablet-only delivery, video game–only delivery, virtual reality–only delivery, monitor- or sensor-only delivery (including wearable activity monitors, pedometers, accelerometers, and heart rate sensors), and a mixed technological delivery column. The tally of these technological delivery components matched the number in the included studies column of the table. If a systematic review mentioned the use of theoretical frameworks and BCTs, they were marked "yes" with the number of mentioned frameworks and BCTs included in brackets.

Results

Study Inclusion



Academic database and gray literature searches identified 361 and 73 articles for screening, respectively (refer to Multimedia Appendix 1 for full search strategy and outputs). These 434 articles were exported into Endnote Online for initial screening, where 104 (24%) duplicates were removed. After this process, the remaining articles (n=330, 76%) were exported to the screening website Rayyan for title and abstract screening.

Title and abstract screening removed 263 (79.7%) of the 330 articles. The reasons for removal are displayed in Figure 1. With

XSL•FO
RenderX

an agreement of 84%, the interrater reliability of title and abstract screening indicated substantial agreement between the main reviewer and second reviewer (WH; Cohen κ=0.69; *P*<.001). Conflicts (41/330, 12.4%) were resolved through discussions and clarification of the protocol.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram of the selection process. PA: physical activity; SB: sedentary behavior.

After title and abstract screening, 67 articles were eligible for full-text screening. Screening of these articles was conducted in Rayyan with an additional Microsoft Excel spreadsheet used to track decisions. A total of 62 (93%) articles were removed during the screening process (Figure 1). There was 69% agreement between the main reviewer and additional reviewers for full-text screening, corresponding to a fair agreement (Cohen κ=0.25; *P*=.02). All conflicts (21/67, 31%) were resolved through discussions. The final full-text screening resulted in 5 systematic reviews to be included within this umbrella review [29-33].

CCA Scores

The measured overlap of primary studies included in the eligible systematic reviews was measured to be 0% (Multimedia Appendix 2 [29-33]). This indicates that all included systematic reviews consisted of different primary studies.

Characteristics of the Included Studies

A summary of the characteristics of the included systematic reviews is displayed in Table 1. The total number of primary studies included in the 5 systematic reviews represented 96 original research papers conducted across 24 different countries. The included systematic reviews' publication dates ranged from 2018 [30] to 2023 [31,33]. The research designs varied within each systematic review and included randomized controlled trials, developmental studies, pre- and postintervention studies, and implementation studies. In total, 2 (40%) of the 5 systematic reviews included meta-analysis [31,33].

XSL•FO
RenderX

Table 1. Characteristics of the included systematic reviews.

Study	Countries of the studies	Papers reviewed and publication date range	Population	Sample size	The type of study included
Lee et al [29], 2023	Australia, Iran, Ireland, Japan, Spain, and the United States	18 (2010-2020)	Adults with obesity or adults who were overweight	Range 26-1755	RCT[a] and pre-post study without a control group
Berry et al [30], 2018	Australia, Canada, the Netherlands, the United Kingdom, and the United States	9 (2006-2017)	Individuals with "arthritis" and those with chronic conditions	Range 20-968	RCT, pre-post test, 2-group pre-post test, and implementation study
Wang and Kassavou [31], 2023	Australia, Canada, China, Germany, Israel, Japan, Korea, the Republic of Slovenia, Spain, Taiwan, Thailand, Turkey, the United Kingdom, and the United States	16 (2008-2021)	Adults with a history or explicit diagnosis of stroke	799	RCT
Daryabeygi-Khotbehsara et al [32], 2021	Italy, Netherlands, New Zealand, and the United States	8 (2015-2020)	Insufficiently active and sedentary healthy adults, healthy and highly educated young adults, overweight and sedentary adults, adults with chronic low back pain, and students and staff from a university setting	Range 10-104	Pre-post intervention; RCT; 3-arm quasi-experimental, single-group micro randomized trial; and developmental study
Wu et al [33], 2023	Australia, Belgium, Canada, Chile, China, Denmark, Finland, Germany, Japan, Netherlands, Portugal, Spain, the United Kingdom, and the United States	45 (2003-2022)	Individuals living with chronic diseases and other diseases	Range 15-1023	RCT

[a]RCT: randomized controlled trial.

Participant Characteristics

The sample sizes within the systematic reviews ranged from a single-group microintervention study consisting of 10 participants to a randomized controlled trial with 7144 participants. A total of 4 (80%) of the 5 systematic reviews described participants' ages, which ranged from 19 to 89 years. Most systematic reviews (4/5, 80%) reported mixed sexes of participants, but there was a greater proportion of female participants in 2 (40%) of the systematic reviews.

Intervention Characteristics

Overview

Of the 5 included systematic reviews, 2 (40%) reviews included interventions that only focused on improving PA [29,30], while the remaining systematic reviews included PA and SB interventions. The duration of interventions ranged from 2 weeks to 12 months.

Research Question 1: Effectiveness of Interventions

All (5/5, 100%) systematic reviews reported on changes in PA where there was a mixture of approaches, and 2 (40%) systematic reviews reported statistical significance of results. Both systematic reviews that included meta-analysis reported statistically significant changes in PA. Wu et al [33] reported significant increases in daily steps from 38 analyzed studies (standardized mean difference [SMD]=0.59; 95% CI 0.44-0.75; P<.001), total daily PA from 4 studies analyzed (SMD=0.21; 95% CI 0.01-0.40; P=.04), and time spent in MVPA from 18 analyzed studies (SMD=0.54; 95% CI 0.36-0.72; P<.001). Wang and Kassavou [31] found significant improvements from 10 studies analyzed, which included 326 participants, to support the use of digital interventions for increasing PA (SMD=0.39; 95% CI 0.17-0.61; P<.001; Table 2).

XSL•FO
RenderX

Table 2. Effectiveness of interventions.

Study	Meta-analysis	PA[a] or SB[b] only	PA or SB outcome assessment	Common PA outcomes				Common SB outcomes
				Steps[c]	MVPA[d]	Total PA[e]	PA change[f]	SB minutes or change
Lee et al [29], 2023	No	PA only	Self-report and device based	—[g]	—	—	Mixed results	N/A[h]
Berry et al [30], 2018	No	PA only	Self-report and device based	Mixed results	Mixed results	Mixed results	—	N/A
Wang and Kassavou [31], 2023	Yes	PA and SB	Self-report and objective measurement	—	—	—	Statistically significant improvement	Statistically nonsignificant change
Daryabeygi-Khotbehsara et al [32], 2021	No	PA and SB	Unclear	Mixed results	Statistically nonsignificant change	Statistically nonsignificant change	—	Statistically nonsignificant change
Wu et al [33], 2023	Yes	PA and SB	Objective	Statistically significant improvement	Statistically significant improvement	Statistically significant improvement	—	Statistically significant improvement

[a]PA: physical activity.

[b]SB: sedentary behavior.

[c]Steps included accelerometer, mean number of steps per day, step counts, average daily steps, daily walking time, daily step count, or daily steps.

[d]Moderate-to-vigorous PA (MVPA) outcomes included moderate PA minutes per week, MVPA time, average daily minutes MVPA, or MVPA minutes.

[e]Total PA outcomes included total PA minutes per week, total PA time, or total daily PA.

[f]PA change outcomes included PA or PA behavior.

[g]Not available.

[h]N/A: not applicable.

For 3 (60%) of the 5 systematic reviews that did not include meta-analysis, the effectiveness of digital interventions on PA was mixed (Table 2). Lee et al [29] reported 14 of the 18 interventions had a positive effect on PA; however, 4 interventions were reported to have "no effect" on PA. Similarly, Berry et al [30] found 6 studies reported significant increases in PA, but 3 studies reported nonsignificant improvements. Finally, Daryabeygi-Khotbehsar et al [32] reported significant changes in light-intensity PA, average daily steps, mean daily step time, and daily walking time. However, this systematic review also reported nonsignificant changes in daily minutes of MVPA and daily step counts.

Of the 5 included reviews, findings for the effectiveness of digital interventions to improve SB were also mixed across the 3 (60%) reviews reporting this behavior. The meta-analysis conducted by Wu et al [33] included 11 studies analyzing the effect of digital interventions on improving SB and found a small but favorable effect size for improving sedentary time by reducing time spent sedentary using digital interventions (SMD=–0.10; 95% CI –0.19 to –0.01; *P*=.03). However, 1 (20%) systematic review with meta-analysis, analyzing 11 studies, and 1 (20%) systematic review without meta-analysis, reported Statistically nonsignificant changes in SB (SMD=–0.13, 95% CI –0.31 to 0.05, N=473, *P*=.53 [31] and adjusted mean difference –9.5 min, SE 7.5; 95% CI 19.98-1.05; *P*=.08 [32]).

In answer to the first research question, digital PA interventions have the potential to improve PA outcomes. Of the 5 included systematic reviews used in this umbrella review, 2 (40%) undertook meta-analysis, which found statistically significant improvements in daily steps, minutes spent in MVPA, total PA time, and PA behavior. However, these findings were not universally true across the included systematic reviews of this umbrella review as the remaining included reviews, which did not include meta-analysis, reported mixed or statistically nonsignificant results across these outcomes. Findings from this umbrella review highlighted that the effectiveness of digital SB interventions was also contrasting. In addition, 1 (20%) systematic review with meta-analysis reported statistically significant improvements in SB through reduced sedentary time (min), but the other systematic review with meta-analysis and one other systematic review found statistically nonsignificant improvements in SB.

XSL•FO
RenderX

Research Question 2: Intervention Components and Content

Intervention Delivery

Both systematic reviews that included PA-only interventions used a range of technological delivery methods, including web-only methods (such as virtual avatars), smartphone- or tablet-only methods (including smartphone apps), monitor- or sensor-based methods (such as commercial grade accelerometers), and a mixed technological delivery method of a smartphone app linked to a wearable activity tracker (Table 3). The human components used in these interventions included feedback provided by trained moderators, private messaging, and video and audio communication between participants and moderators.

Table 3. Quantitative summary of components and content of included reviews.

Study	Included studies, (n=96), n (100%)	Web only, (n=15), n (16%)	Smartphone or tablet only, (n=10), n (11%)	Video game only, (n=5), n (5%)	Virtual reality only, (n=4), n (4%)	Monitor or sensor only, (n=36), n (39%)	Mixed technological intervention, (n=22), n (24%)	Theoretical framework (number identified)	Behavior change technique (number identified)
Lee et al [29], 2023	18 (19)	11 (61)	3 (17)	0 (0)	0 (0)	4 (22)	0 (0)	Yes (5)	Yes (11)
Berry et al [30], 2018[a]	9 (9)	4 (80)	—[b]	0 (0)	0 (0)	—	1 (20)	Yes (1)	Yes (15)
Wang and Kassavou [31], 2023	16 (17)	0 (0)	3 (19)	5 (31)	4 (25)	3 (19)	1 (6)	No (N/A[c])	No (N/A)
Daryabeygi-Khotbehsara et al [32], 2021	8 (8)	—	4 (50)	0 (0)	0 (0)	—	4 (50)	Yes (8)	Yes (7)
Wu et al [33], 2023	45 (47)	—	—	0 (0)	0 (0)	29 (64)	16 (36)	No (N/A)	Yes (5)

[a]Berry et al [30] included 9 studies evaluating 5 different interventions; therefore, the tally of intervention delivery components will equal 5.

[b]Not available.

[c]N/A: not applicable.

For the 3 (60%) of the 5 systematic reviews that targeted both PA and SB, the technological components consisted of a variety of smartphone- and tablet-only interventions, video game–based interventions, virtual reality interventions, monitor- and sensor-based interventions, and a range of mixed technological delivery methods. Wang and Kassavou [31] reported 1 mixed intervention of a mobile phone and tablet intervention with video game components. Daryabeygi-Khotbehsara et al [32] reported 4 mixed interventions, 2 of which were smartphone apps with PA monitors or sensors (heart rate wristbands and Fitbit One [Google LLC]), 1 was a smartphone app with Fitbit and web-based mobile questionnaire, and 1 was a mixed intervention that did not mention the operating system but consisted of text messages and activPAL 3 (PAL Technologies Ltd) activity tracker. Finally, Wu et al [33] reported 16 mixed interventions, 4 of which were web based and monitor or sensor interventions and 12 which were smartphone and tablet and monitor or sensor mixed interventions (Table 3). The human components used in these interventions included manual logging of activity, PA consultations, nurse consultations, group education, training courses, and activity books. Only 1 (20%) systematic review [31] did not report on the human components used within the interventions.

Theoretical Frameworks

Of the 5 included systematic reviews, 2 (40%) reviews that included only PA interventions [29,30] and 1 (20%) systematic review that included PA and SB interventions [32] reported the use of theoretical frameworks to guide the interventions (Table 3). However, 1 (20%) of these systematic reviews [30] only reported on 1 framework for guiding the interventions and did not explicitly report on the use of multiple theoretical frameworks or gave details on other frameworks used.

Of the 5 systematic reviews, 3 (60%) that reported the use of theoretical models within interventions reported that social cognitive theory was the most prominent theory and guided most interventions. The frameworks reported by Lee et al [29] and Daryabeygi-Khotbehsara et al [32], included self-regulation theory (n=2), computational agent model (n=1), control theory (n=1), exploit-explore strategy (n=1), Fogg behavior model (n=1), health action process approach (n=1), health belief model (n=1), learning theory (n=1), self-efficacy theory (n=1), and transtheoretical model (n=1).

Behavior Change Techniques

A total of 4 (80%) of the 5 included systematic reviews [29,30,32,33] reported on the use of BCTs to support interventions (Table 3), and 3 (75%) of the 4 systematic reviews [29,30,32] reported the most frequently used BCTs to be goal setting, self-monitoring, feedback, and social support. Aside from the most frequently used BCTs, the additional BCTs identified from the 4 systematic reviews include information on health consequences (2/28, 7%), action planning, body changes (1/28, 4%), the Coventry, Aberdeen, and London–Refined taxonomy of BCTs (1/28, 4%), culturally

XSL•FO
RenderX

relevant information (1/28, 4%), discussion about incompatible beliefs (1/28, 4%), distraction (1/28, 4%), emotional support (1/28, 4%), framing and reframing (1/28, 4%), habit formation (1/28, 4%), information on how to perform PA (1/28, 4%), past activity performances (1/28, 4%), PA advice (1/28, 4%), problem-solving (1/28, 4%), prompts and cues (1/28, 4%), review of goals (1/28, 4%), reviewing behavior (1/28, 4%), reward (1/28, 4%), self-efficacy (1/28, 4%), self-identity (1/28, 4%), self-talk (1/28, 4%), social modeling (1/28, 4%), theory-based strategies (1/28, 4%), and watching videos (1/28, 4%).

Only 1 (20%) of the 5 systematic reviews did not report on the inclusion of BCTs used within PA and SB interventions [31]. However, it did report on the effectiveness of self-monitoring and behavior change. For changes in both PA and SB, interventions underpinned by self-monitoring elements were more likely to explain effectiveness. In relation to PA, self-monitoring interventions had a moderate to large impact on improving behavior (SMD=0.56; 95% CI 0.21-0.91; *P*=.002). Similarly, SB self-monitoring interventions significantly explained the overall effectiveness of reducing sedentary time compared to those not including such components (SMD=–0.34; 95% CI –0.65 to –0.03; *P*=.03).

In answer to the second research question, of the 5 included systematic reviews used in this umbrella review, 4 (80%) reported the use of human elements within interventions [29,30,32,33], all 5 (100%) reported the digital elements used to deliver the interventions, 3 (60%) reported the use of theoretical frameworks to guide interventions, and 4 (80%) reported the use of BCTs to support the interventions. Monitor- and sensor-only intervention delivery methods were used most frequently followed by mixed technological delivery methods. In total, 11 different theoretical frameworks were identified from the systematic reviews, with social cognitive theory reportedly being the most prominent theory used to guide interventions. In addition, 28 different BCTs were reported in the systematic reviews, with goal setting, self-monitoring, feedback, and social support being reported as the most frequently used BCTs. Moreover, 1 (20%) systematic review also reported that self-monitoring was more likely to explain improvements in both PA and SB compared to interventions that did not include this BCT.

Methodological Quality

The methodological quality of all included systematic reviews was assessed by the main reviewer, and the quality assessment process of the main reviewer was checked by the second reviewer. This quality assessment of the process resulted in moderate agreement (69%; Cohen κ=0.43; *P*=.04).

The use of the AMSTAR-2 tool resulted in 20% (1/5) low-quality systematic reviews [32] and 80% (4/5) critically low–quality systematic reviews [29-31,33] (Table 4). The common methodological strengths of the included reviews (common in ≥3 systematic reviews) were the inclusion of Population, Intervention, Comparison, and Outcome components, reporting that the review methods were established before the conduct of the review, the explanation of study design, descriptions of the included studies, using a satisfactory technique for assessing the risk of bias in individual studies, accounting for the risk of bias when interpreting results, and reporting any potential conflicts of interest. The common areas of weakness (present in ≥3 systematic reviews) in noncritical domains were not performing study selection in duplicate, not performing data extraction in duplicate, not reporting the sources of funding for the primary studies included in the review, and not providing a satisfactory explanation and discussion of any heterogeneity observed in the results of the review. The common areas of weakness in critical domains were not using a comprehensive literature search strategy and not providing a list of excluded studies and the justification for the exclusions.

Table 4. Methodological quality of included systematic reviews.

Study	Noncritical domain strengths, n	Critical domain strengths, n	Noncritical domain weaknesses, n	Critical domain weaknesses, n	AMSTAR-2[a] rating
Lee et al [29], 2022	6	3	2	2	Critically low
Berry et al [30], 2018	4	1	4	4	Critically low
Wang and Kassavou [31], 2023	5	3	4	4	Critically low
Daryabeygi-Khotbehsara et al [32], 2021	3	4	5	1	Low
Wu et al [33], 2023	4	5	5	2	Critically low

[a]AMSTAR: A Measurement Tool to Assess Systematic Reviews-2.

Discussion

Principal Findings

This umbrella review synthesized evidence from 5 systematic reviews exploring digital PA and SB interventions for community-living adults. Social cognitive theory, goal setting, self-monitoring, feedback, and social support were found to be the most prominent theoretical frameworks and BCTs used in digital interventions. Overall, the systematic reviews reported contrasting findings for digital interventions, with some reviews reporting statistically significant improvements in PA and others reporting mixed effects for improvements in PA. Similarly, evidence regarding the effectiveness of digital interventions for SB was mixed, as only 1 (20%) systematic review reported statistically significant reductions in sedentary time, while 2 (40%) systematic reviews reported no significant changes in

XSL•FO
RenderX

SB. Finally, the included systematic reviews had 0% CCA overlap, but they were of low and critically low quality.

Effectiveness to Improve PA and SB

Digital interventions had the potential to significantly improve PA outcomes; however, findings from this umbrella review were mixed. A total of 3 (60%) of the 5 systematic reviews comprised mixed results to support the effectiveness of interventions to significantly improve PA. The 2 (40%) systematic reviews that reported statistically significant results for changes in PA consisted of smartphone or tablet, video game, virtual reality, monitor- or sensor-based interventions, and mixed technological delivery methods. Surprisingly, these systematic reviews did not report on the theoretical basis of the interventions, and only 1 (20%) systematic review discussed the use of BCTs within the interventions.

The effectiveness of interventions targeting SB varied across the included systematic reviews. While one systematic review suggested the use of digital interventions and had small but significant reductions in sedentary time, other systematic reviews found nonsignificant effects on SB. There were some differences between the intervention delivery methods of the significant and nonsignificant systematic reviews, which could explain the differences in success for changing SB, for example, of the 5 included reviews, 2 (40%) nonsignificant systematic reviews had a lower proportion of monitor- or sensor-based and mixed technological delivery methods. However, these are observations. It could be argued that the challenge in measuring PA and SB outcomes is heavily dependent on the metrics used. Previous work aiming to compare movement behavior features processed by commonly used accelerometer metrics among adults found statistically significant differences in 24-hour movement behavior across 4 different metrics used to measure these behaviors [34]. Therefore, suggesting the success of intervention may be overestimated or underestimated depending on the metrics used to measure these PA and SB outcomes, thus resulting in different results and conclusions.

In addition, although most changes to SB were nonsignificant, reductions in SB were reported. Research has found that breaking up SB with short bursts of light-intensity PA can improve metabolic health and self-reported fatigue and reduce all-cause mortality [35]. Therefore, these interventions can still be beneficial for health, but the mixed evidence suggests that further research is needed to determine the most effective strategies to include within digital interventions to reduce SB within community-living adults.

Traditionally, public health research has focused on the importance of increasing PA to improve health and, as a result, there are more interventions to improve PA. However, as worldwide levels of SBs have risen in recent years [36] and more information about the health consequences of this has been recognized, the interest in SB has grown, but the development of interventions and subsequent research exploring effectiveness is still emerging. The substantial variation in how SB is defined across accelerometer brands and studies underscores the evolving nature of SB research, interventions, and commercial products [37]. The differences in the effectiveness of SB interventions within this umbrella review may be due to the systematic reviews and primary studies within them using different technologies and terminologies to understand SB. Once again, this highlights the difficulty in interpreting whether the interventions were effective or not.

Although findings are inconclusive regarding the effect of digital interventions on SB, this research has revealed that the inclusion of self-monitoring is more likely to explain changes in behavior in favor of the intervention. Of the 5 included systematic reviews, 1 (20%) reported that interventions consisting of self-monitoring components had a moderate-to-large impact on positively changing PA behavior, and although the change in SB was reported as not statistically significant, self-monitoring interventions were more effective in changing SB than those without this component.

Previously published systematic reviews have described self-monitoring to be a valuable and effective instrument for encouraging positive changes in PA behaviors [38,39]. Accurate self-monitoring of PA and SB has the potential to increase individuals' awareness of their behavior, which can encourage them to change their habits toward PA and SB. Self-monitoring through digital devices can also provide detailed data on individuals' movement behaviors and help detect patterns and triggers of these behaviors. Allowing tailored feedback based on these data can also enhance the effectiveness of this type of intervention [40].

Although research suggests the use of self-monitoring for effective behavior change, evidence of effectiveness for this BCT has been found to vary significantly across different populations and health behaviors [41]. To achieve more effective changes in PA and SB outcomes, self-monitoring needs to be used consistently [42]. Therefore, this highlights the need for research into the use of this BCT element in different populations, including informal carers, and for different health behaviors for it to be implemented effectively to create successful interventions, including digital interventions, to improve PA and reduce SB.

Theoretical Frameworks and BCTs

Findings from this umbrella review regarding the most prominent theoretical framework and implemented BCTs have been supported by previous literature. A systematic review and meta-analysis aimed to identify the most effective BCTs for increasing PA in digital and face-to-face interventions in adults with obesity or adults who are overweight reported that 45 included intervention studies were grounded in one or multiple theoretical frameworks [43]. Social cognitive theory and self-regulation theory, alone or in combination, were used most often in digital interventions aimed at increasing PA [43]. A scoping review of user models for personalized PA interventions also revealed prominent theoretical frameworks used in interventions, including Fogg behavior model, social cognitive theory, transtheoretical model, and health action process approach [44], all of which were identified within this umbrella review. Finally, scoping reviews have also reported that the most frequently implemented BCTs in digital PA interventions for adults include goal setting, self-monitoring, and feedback on behaviors [45,46].

XSL•FO
RenderX

Although there are similarities between the findings of this umbrella review and previous work, other theoretical frameworks and BCTs have been reported in these studies that were not reported in this umbrella review. Ghanvatkar et al [44] mentioned that the theory of planned behavior, the I-change model, and the behavior change wheel were also found to frequently guide digital PA interventions [44]. Similarly, De Santis et al [45] and Meinhart et al [46] found that providing educational and motivational content, feedback on exercise, and integrated tailored responses were all present in digital interventions. In addition, a systematic review exploring the effectiveness of BCTs at increasing older adults' self-efficacy and PA reported that using barrier identification and problem-solving, providing rewards contingent on successful behavior, and demonstrating the behavior were significantly associated with higher levels of PA [47]. It also reported that the use of providing normative information about others' behavior, providing information on where and when to perform the behavior, and planning social support or social change resulted in significantly lower PA behavior effect sizes for older adults [47].

While there is overlap between the findings of this umbrella review and previous research regarding the theoretical frameworks and BCTs used in digital PA interventions, there are additional frameworks and BCTs not reported in this umbrella review, highlighting the diversity of these interventions for promoting and improving PA and SB levels. The reason for these differences may be due to the different populations targeted and the different interventions used. However, it is also important to consider that not all interventions will use the same frameworks or BCTs nor will they recognize and report on all frameworks or BCTs used. Intervention descriptions may not have been sufficiently detailed and precise enough to identify the theoretical frameworks and BCTs present within primary studies or systematic reviews. With regard to this umbrella review, the identification of the implemented theoretical frameworks and BCTs was limited to their presentation within the systematic reviews used for this research. Therefore, our findings are subject to the parameters of the systematic reviews and not the primary studies reported within them.

It is also important to note that just because certain frameworks and BCTs were not reported, it does not mean they are not used or worthwhile being used; it is simply that they were not reported to be present in the systematic reviews included in this umbrella review. There are many other theoretical frameworks and BCTs that could potentially be of use, specifically for different populations, as demonstrated by the other reviews discussed. However, more research is needed to understand the effectiveness of these theories and BCTs, especially within the informal caring population.

Quality of Included Reviews

The quality assessment process, which showed moderate agreement between reviewers, highlights the credibility of the quality assessment process. However, the methodological quality of the included systematic reviews was low (20%) and critically low (80%).

While there were some common strengths of the systematic reviews regarding methodological quality, for example, the inclusion of Population, Intervention, Comparison, and Outcome components, reporting that the review methods were established before the conduct of the review and the explanation of study design can strengthen the methodological rigor of these systematic reviews. The methodological weaknesses, such as a lack of a comprehensive literature search strategy and a lack of justification for excluded studies, could reduce the confidence in the validity of the included systematic reviews.

The low confidence ratings of these systematic reviews could be because of the high standards set by the AMSTAR-2 tool. Although AMSTAR-2 has been recognized as a useful appraisal tool to understand the quality of published systematic reviews [48], there are some challenges in using this method for quality assessment. It has been discussed in previous work and reported in other umbrella reviews that AMSTAR-2 produces a generally high proportion of critically low confidence ratings among systematic reviews of health interventions, and there is ongoing debate whether this is due to poor discriminatory powers of the tool or the low quality of systematic reviews of health care interventions [49]. Individual items of AMSTAR-2 have been discussed in work by De Santis et al [49] to highlight difficulties of the tool and potential reasons for lower quality ratings of systematic reviews, for example, the "all-or-none" ratings of items that do not allow to differentiate between missing information and incomplete reporting of information for some items. The agreement of 69% between reviewers for approaching AMSTAR-2 in this umbrella review highlights the subjectiveness of this methodological tool, which has also been criticized by De Santis et al [49]. Due to the rapid increase in systematic reviews for health care interventions, it has been recommended that the items of AMSTAR-2 be empirically tested to improve the appraisal process and increase user consensus.

As this umbrella review explores digital interventions for improving PA and SB for community-living adults, its findings may have practical implications for public health policies and future digital interventions. However, as findings are from low and critically low–quality systematic reviews, there is a need for cautious interpretation. Stakeholders and policy makers must be aware of the methodological limitations of these systematic reviews when considering the findings presented within this umbrella review. Furthermore, these findings suggest the importance and need for more high-quality research within this field to provide methodologically sound evidence for future policy makers and decision makers.

Strengths

There are multiple strengths of this umbrella review. First, this umbrella review followed the Joanna Briggs Institute framework, ensuring a rigorous and systematic approach. Adherence to this framework also promotes transparency and replicability, making the results more robust and credible. The incorporation of a large number of primary publications from the included systematic reviews allowed a broad and inclusive scope of this review to be conducted. All primary publications were unique with a CCA score of 0%, which indicates no

XSL•FO
RenderX

overlap and strengthens the robustness of the review's conclusions. Furthermore, the geographic reach of the reviews included and the primary studies within them were extensive, with studies conducted in 24 different countries. This wide geographic representation adds to the generalizability of the findings across diverse populations and different groups of community-living adults. Another strength of this review was the identification of a vast range of theoretical frameworks and BCTs, which provides a comprehensive understanding of the strategies used in digital PA and SB interventions for community-living adults. Finally, the search strategy of this review highlights a critical gap in the existing literature as very few systematic reviews focused purely on PA and SB and theoretical frameworks and BCTs, as numerous systematic reviews had to be excluded due to their inclusion of multiple behaviors, such as diet and sleep.

Limitations

The lack of high-quality systematic reviews within this umbrella review restricts the potential to use these findings to aid future decision-making. Therefore, there is a need for more high-quality systematic reviews in the digital PA and SB intervention research field that include justifications for the search strategy, provide lists of excluded studies, report the sources of funding for the included studies, and provide an explanation for heterogeneity. As most (3/5, 60%) included systematic reviews lacked meta-analysis and reported multiple different PA outcomes, it is difficult to synthesize quantitative data and nonquantitative data to provide a clear answer to understand the effectiveness of these interventions in improving PA and SB. Finally, it is possible that some relevant studies were missed due to differences in the search strategies, inclusion criteria, and the databases used. Furthermore, restricting the review to English-language publications may have excluded important research published in other languages.

Future Work

Future work should include more primary studies and systematic reviews to be published specifically focusing on PA- and SB-only interventions instead of interventions that combine these behaviors with other health behaviors, such as diet and sleep. There is also a need for more primary studies to use consistent and accurate measures of PA and SB, and standardized outcomes for measuring these behaviors should be implemented.

In addition, further investigation is also warranted for the development and refinement of intervention strategies specifically for reducing SB among community-living adults to achieve more robust outcomes of the effectiveness of digital interventions to reduce this behavior. Recommendations for future work also include better reporting of theoretical frameworks and BCTs used in digital interventions for PA and SB and meta-analysis of currently published systematic reviews to allow for further evaluation to be conducted into the effectiveness of these components to change behaviors. Finally, more meta-analyses of systematic reviews assessing the effectiveness of digital interventions on PA and SB are needed to provide a more comprehensive and accurate picture of the current evidence.

Conclusions

This umbrella review aimed to evaluate the effectiveness of digital interventions for changing PA and SBs among community-living adults, identify the components and content of these interventions, and assess the methodological quality of the included systematic reviews.

Overall, this umbrella review indicates that digital interventions have the potential to improve PA and reduce SB. Meta-analyses suggest these interventions can be effective, particularly those incorporating self-monitoring and BCTs. However, more work is needed to understand the effectiveness and impact of specific theoretical frameworks and BCTs on changing PA and SBs. The mixed findings and methodological weaknesses highlight the need for more comprehensive reporting and analyses to be conducted to understand the effectiveness of digital interventions for community-living adults.

In relation to informal carers, this umbrella review highlights that digital PA and SB interventions offer a valuable opportunity to support behavior change in this population due to their scalability and numerous delivery methods. These digital interventions have been found to consist of a theoretical grounding and can incorporate numerous BCTs, all of which could improve the effectiveness of these interventions to support and encourage PA and reduce SB in informal carers. Despite the potential benefits of these interventions for informal carers, more coordinated efforts and research are needed to understand the potential and effectiveness of digital interventions for improving PA and reducing SB in this group.

Acknowledgments

The authors would like to thank the University of Strathclyde graduate Leslie Stretch, whose philanthropy made this research possible (the funder of the study had no role in any aspect of the study design, analysis, or decision to publish this work). They would also like to acknowledge Bethan Naunton Morgan for her guidance and knowledge surrounding the umbrella review process, which she generously shared before conducting this review.

Authors' Contributions

ER designed and conducted the research; screened the studies; extracted, analyzed, and interpreted the data; and wrote this paper. KE, AK, and MDD made substantial contributions to the study conception and design of the research. WH screened the studies and assessed the methodology quality assessment process. MP screened the studies. All authors have read and agreed to the manuscript.

Abstract

Background: The use of structured electronic health records in health care systems has grown rapidly. These systems collect huge amounts of patient information, including diagnosis codes representing temporal medical history. Sequential diagnostic information has proven valuable for predicting patient outcomes. However, the extent to which these types of data have been incorporated into deep learning (DL) models has not been examined.

Objective: This systematic review aims to describe the use of sequential diagnostic data in DL models, specifically to understand how these data are integrated, whether sample size improves performance, and whether the identified models are generalizable.

Methods: Relevant studies published up to May 15, 2023, were identified using 4 databases: PubMed, Embase, IEEE Xplore, and Web of Science. We included all studies using DL algorithms trained on sequential diagnosis codes to predict patient outcomes. We excluded review articles and non–peer-reviewed papers. We evaluated the following aspects in the included papers: DL techniques, characteristics of the dataset, prediction tasks, performance evaluation, generalizability, and explainability. We also assessed the risk of bias and applicability of the studies using the Prediction Model Study Risk of Bias Assessment Tool (PROBAST). We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist to report our findings.

Results: Of the 740 identified papers, 84 (11.4%) met the eligibility criteria. Publications in this area increased yearly. Recurrent neural networks (and their derivatives; 47/84, 56%) and transformers (22/84, 26%) were the most commonly used architectures in DL-based models. Most studies (45/84, 54%) presented their input features as sequences of visit embeddings. Medications (38/84, 45%) were the most common additional feature. Of the 128 predictive outcome tasks, the most frequent was next-visit diagnosis (n=30, 23%), followed by heart failure (n=18, 14%) and mortality (n=17, 13%). Only 7 (8%) of the 84 studies evaluated their models in terms of generalizability. A positive correlation was observed between training sample size and model performance (area under the receiver operating characteristic curve; *P*=.02). However, 59 (70%) of the 84 studies had a high risk of bias.

Conclusions: The application of DL for advanced modeling of sequential medical codes has demonstrated remarkable promise in predicting patient outcomes. The main limitation of this study was the heterogeneity of methods and outcomes. However, our analysis found that using multiple types of features, integrating time intervals, and including larger sample sizes were generally related to an improved predictive performance. This review also highlights that very few studies (7/84, 8%) reported on challenges related to generalizability and less than half (38/84, 45%) of the studies reported on challenges related to explainability. Addressing these shortcomings will be instrumental in unlocking the full potential of DL for enhancing health care outcomes and patient care.

Introduction

Background

In recent decades, there has been a rapid growth in the use of electronic health records (EHRs) in health care systems, making them an important tool for health care workers and allowing for secondary use for research purposes. Structured EHRs contain temporal records of patient visits, incorporating various clinical data such as diagnosis codes, procedures, and laboratory test results, all of which may help researchers in predicting patient outcomes. Patient timelines can be organized based on diagnosis codes and their corresponding visit times, allowing deep learning (DL) algorithms to model and understand disease progression, with the time between visits representing the speed of disease progression. Using sequential diagnostic data from EHRs in this manner is a promising avenue for DL-based studies, but the degree to which this information has been used in published studies and its benefits has not yet been explored in the context of a systematic review, which is what this study sets out to do.

Classical machine learning (ML) techniques that require feature selection can be applied to include diagnosis codes as a binary feature for outcome prediction; for example, a recent study applied ML-based algorithms (logistic regression, extreme gradient boosting, and random forest) to identify cardiomyopathy [1]. However, traditional ML approaches cannot take full advantage of structured EHR data due to four key challenges:

1. Feature selection—manual feature selection, which requires medical knowledge from professional health care workers, is a time-consuming task and an expensive process.
2. High dimensionality—models suffer from a high-dimensional input representation due to the vast number of medical codes available (eg, Medical Information Mart for Intensive Care [MIMIC]-IV includes >15,000 unique *International Classification of Diseases, Tenth Revision* [ICD-10], codes that appear in the patient records) [2].
3. Hierarchy—the hierarchical structure of diagnosis codes may represent relationships between similar disease categories, but this information is ignored by traditional ML-based approaches.
4. Temporality—the majority of traditional ML techniques struggle to effectively capture information contained in the temporal chronological sequence of patients' medical history, where the time between consecutive visits may vary in length from a few days to numerous months. Significant predictive insights may be hidden in the temporal intervals and sequence of diagnosis codes in a patient's evolving medical history because deterioration or improvement in outcomes may follow specific patterns and frequencies of interactions with the health care system [3-5].

To comprehensively uncover and understand the impact of these intricate temporal and sequential relationships within the data, advanced DL methods are essential.

DL approaches have been applied previously in the health care domain. Systematic reviews show a good progression in DL-based algorithms for various medical data types, such as clinical notes [6], medical images [7], and physiological signals [8]. DL emerges as a solution to overcome the aforementioned limitations of traditional ML for the following reasons: (1) DL functions as an end-to-end system that can automatically uncover an association between input and output with minimal need for feature engineering or domain expertise; (2) DL models can generate an effective embedding space to cope with the high-dimensional problem (eg, a study demonstrated the effectiveness of an autoencoder in transforming RNA sequence data with approximately 20,000 features into a low-dimensional representation with approximately 1000 features, achieving high classification performance [9]); (3) some DL techniques, such as graph neural networks (GNNs), have been shown to give a good representation of hierarchical data [10]; and (4) to deal with temporal information, long short-term memory (LSTM) and temporal convolutional neural network (CNN) models have been adapted widely for complex sequential information in health care (eg, an LSTM model has been shown to be able to achieve a good performance in analyzing information from high-volume regular sequences such as intensive care unit [ICU] monitoring data [11]).

Although many DL techniques are well suited for hierarchical and time-series data, they face challenges in handling sequential diagnosis codes. In EHRs, diagnosis codes occur at irregular time intervals, reflecting the varying times between medical events, that is, some patients may have multiple visits within the same week, while for others, there may be months or years between visits. This irregularity complicates analysis but is also a source of information because it may capture the rapid or slow progression of conditions. Moreover, diagnosis codes require an embedding layer before being processed by a DL model, unlike continuous values from ICU monitors, which can be directly processed. Other challenges with DL are the need for extensive datasets and concerns about explainability [12]. The performance of existing DL techniques depends on the volume and quality of the training dataset, which, in the field of health data science, may be problematic because large-scale datasets may not be available due to privacy concerns. This can also contribute to the generalizability issue because models may perform well on internal training and test datasets but perform poorly on independent external data sources. Moreover, DL model predictions can sometimes be unclear to clinicians, and there is a need to explain the main factors contributing to the

XSL•FO
RenderX

model's output. Therefore, it becomes a significant challenge for researchers to use special DL techniques for outcome prediction by using sequential diagnosis codes. This systematic review will comprehensively explore these challenges and the approaches used to deal with them in the published literature.

To date, several reviews have analyzed DL methods trained on EHR data [13-16]. Various kinds of EHR data for DL-based algorithms have been surveyed: (1) structured data (diagnosis codes, medication codes, procedure codes, laboratory test results, and vital signs) and (2) unstructured data (clinical notes, medical images, and physiological signals). However, none of the reviews primarily focused on the use of sequential diagnostic data in DL for outcome prediction. Moreover, none of them reported on the inclusion of external validation, which can be problematic because models are applied to different data distributions. Many questions remain unanswered, such as common DL techniques, types of diagnosis codes, additional features (eg, time between visits, demographic data, and medications), dataset characteristics, prediction tasks, generalizability, and explainability.

Objectives

We conducted a systematic review to answer these questions and investigate the current state of DL in the context of outcome prediction using sequential diagnostic information. By summarizing the research in this area, our review can help guide future DL-based prediction studies by identifying current research gaps and challenges. The main objective of this systematic review was to identify and summarize existing DL studies that use sequential diagnosis codes as key predictors of patient outcomes. In addition, this study investigates the challenges of generalizability and explainability in these predictive models.

Methods

Definition

In this systematic review, we defined sequential diagnosis codes as medical codes (eg, Systemized Nomenclature of Medicine–Clinical Terms; *International Classification of Diseases, Ninth Revision*; and *ICD-10* codes) assigned to patients to represent their visits within the health care system. This review examined various categories of DL algorithms, including recurrent neural networks (RNNs), LSTM models, CNNs, transformer-based models, and GNNs, in addition to some techniques such as time-awareness and attention mechanisms. No restrictions were placed on study outcomes, which included mortality, hospitalization status, and onset of disease (eg, hypertension, diabetes, heart attack, stroke, and cancer).

Search Strategy

As our review combines knowledge from both health care and engineering, we sought to identify all relevant studies in both domains using 4 databases: PubMed, Embase, IEEE Xplore, and Web of Science. In addition, we conducted a manual search of the reference lists of the included studies to identify additional relevant articles. We searched the databases up to May 15, 2023. To promote transparency and prevent duplication, the study protocol was registered in PROSPERO (CRD42023434032).

We used 4 main groups of keywords centered around DL techniques, EHRs, sequence, and prediction. The literature search included the following search terms: ("deep learning" OR "RNN" OR "LSTM" OR "CNN" OR "transformer" OR "BERT" OR "time attention" OR "attention based" OR "graph neural network") AND ("electronic health records" OR "EHRs" OR "electronic health record" OR "EHR" OR "electronic medical record" OR "EMR" OR "electronic medical records" OR "EMRs") AND ("longitudinal" OR "visit" OR "sequential" OR "sequence" OR "temporal") AND ("risk" OR "predictions" OR "prediction" OR "patient outcome" OR "prognosis"). The search query returned the same set of results as those obtained using the built-in search functionality of the literature databases.

Inclusion and Exclusion Criteria

This systematic review followed the Population, Intervention, Comparison, and Outcomes framework to identify and select articles in the databases [17]. The population included patients of all ages in EHR databases, the intervention involved DL-based methods for sequential diagnosis codes, the comparison was between different algorithms, and the outcome was model performance.

We included all studies using DL algorithms to predict patient outcomes by training the models on sequential or longitudinal diagnosis codes, as defined in the aforementioned search terms. We excluded review articles and non–peer-reviewed papers. In addition, we excluded papers that primarily dealt with other nondiagnostic EHR data types, including physiological signals, clinical notes, and medical images. To reduce bias, 2 reviewers independently screened all studies. Any discrepancies between the reviewers were resolved through discussion to reach a consensus. The level of agreement between the reviewers was assessed using the Cohen κ coefficient.

Extraction and Analysis

We used the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist [18] (Multimedia Appendix 1) to report our findings. We evaluated the following aspects in the included papers: DL techniques, characteristics of the datasets, prediction tasks, and performance evaluation. For each study, we selected either the novel, proposed technique or the best-performing technique as the main DL model architecture. The findings are presented using plots, figures, and tables.

This review followed the suggestions of a previous study [19] to assess the generalizability of the applied models. Generalizability was evaluated based on the potential applicability of outcome predictive models beyond their original development context, focusing on 3 key aspects:

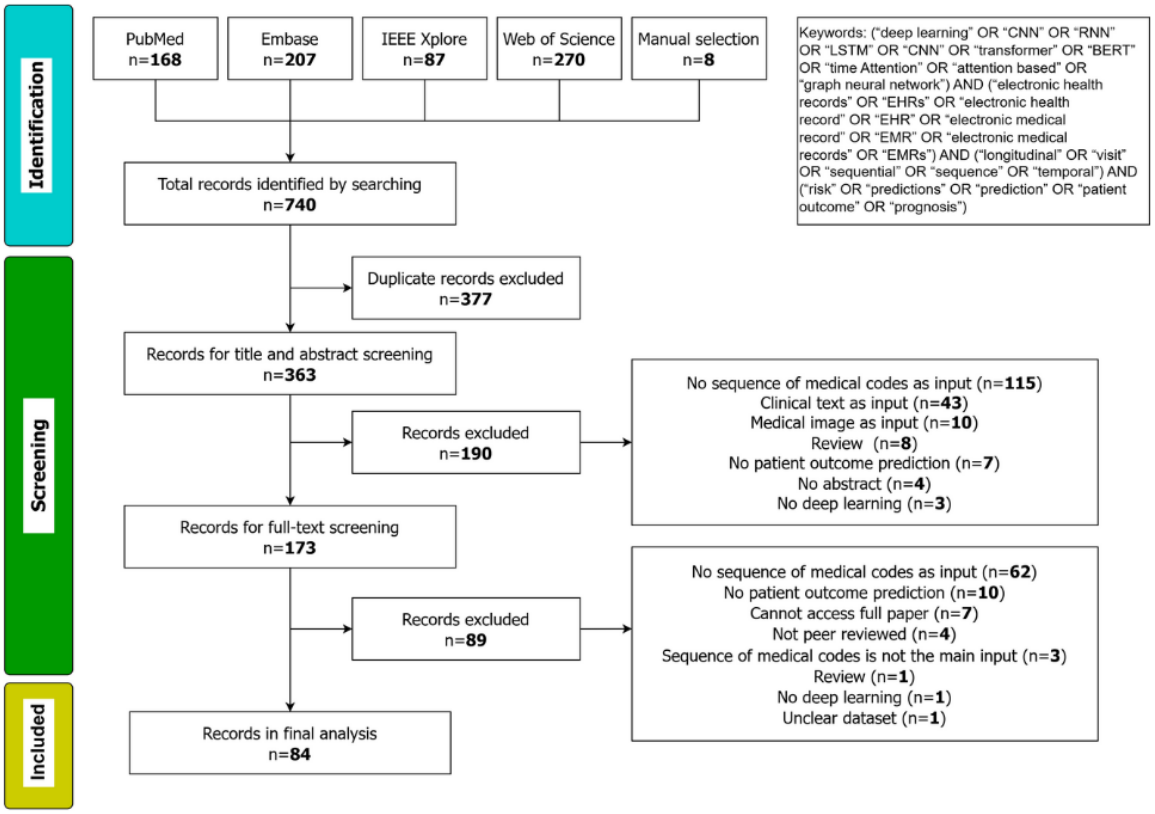
1. Demographic validation, which investigates the model's adaptability to distinct clinical contexts, including disparities related to sex or ethnicity and variations in age groups
2. Temporal validation, which focuses on assessing the model's performance over time within its original development environment

XSL•FO
RenderX

3. Geographic validation, which explores the model's capacity to extend its utility beyond its original development setting to different locations, institutions, or geographic contexts

In addition, we evaluated the explainability of the model in each included study.

Risk-of-Bias and Quality Assessment



The Prediction Model Study Risk of Bias Assessment Tool (PROBAST) [20] was used to evaluate both the risk of bias (ROB) and the applicability of the best-performing DL models in the included studies. ROB was evaluated based on a set of 20 questions categorized into 4 domains: participants, predictors, outcome, and analysis. Applicability was evaluated via a main question for each of the following 3 domains: participants, predictors, and outcomes. Each domain was rated as having low, unclear, or high ROB. If multiple models were reported in a study, only the model with the highest area under the receiver operating characteristic curve (AUROC) and F_1-score was evaluated. One reviewer conducted the PROBAST assessment for all included studies.

Results

Study Selection

Figure 1 presents the PRISMA diagram of the search and screening results. Initially, our search identified 740 records, of which 377 (50.9%) duplicates were removed. The screening process consisted of 2 stages: title and abstract screening, followed by full-text screening. During the title and abstract screening, we assessed the study aim, objectives, and methods to determine whether each paper fell within the scope of our review. Ultimately, 84 (11.4%) of the initially identified 740 articles were included in the final analysis. The agreement between reviewers had a Cohen κ coefficient of 0.65, indicative of a moderate agreement [21]. All included studies are listed in Table 1 and Multimedia Appendix 2 [22-105].

[s]NPV: negative predictive value.

DL Techniques

We analyzed 84 DL models from the included studies. Among these 84 models, the most commonly applied DL technique for learning sequential diagnosis codes was RNNs and their derivatives (n=47, 56%), followed by transformers (n=22, 26%), which have been regularly applied in studies since their introduction in 2017 (Figure 2). Among the 38 studies that used embedding techniques to represent diagnostic data, the most frequently used embedding method was Word2Vec (n=15, 39%), followed by GNNs (n=9, 24%) and transformers (n=3, 8%). More than half of the 84 studies presented their input feature as a sequence of visit embeddings (n=45, 54%), followed by a sequence of diagnosis codes (n=24, 29%), a sparse matrix (n=10, 12%), and a mixed representation (n=5, 6%).

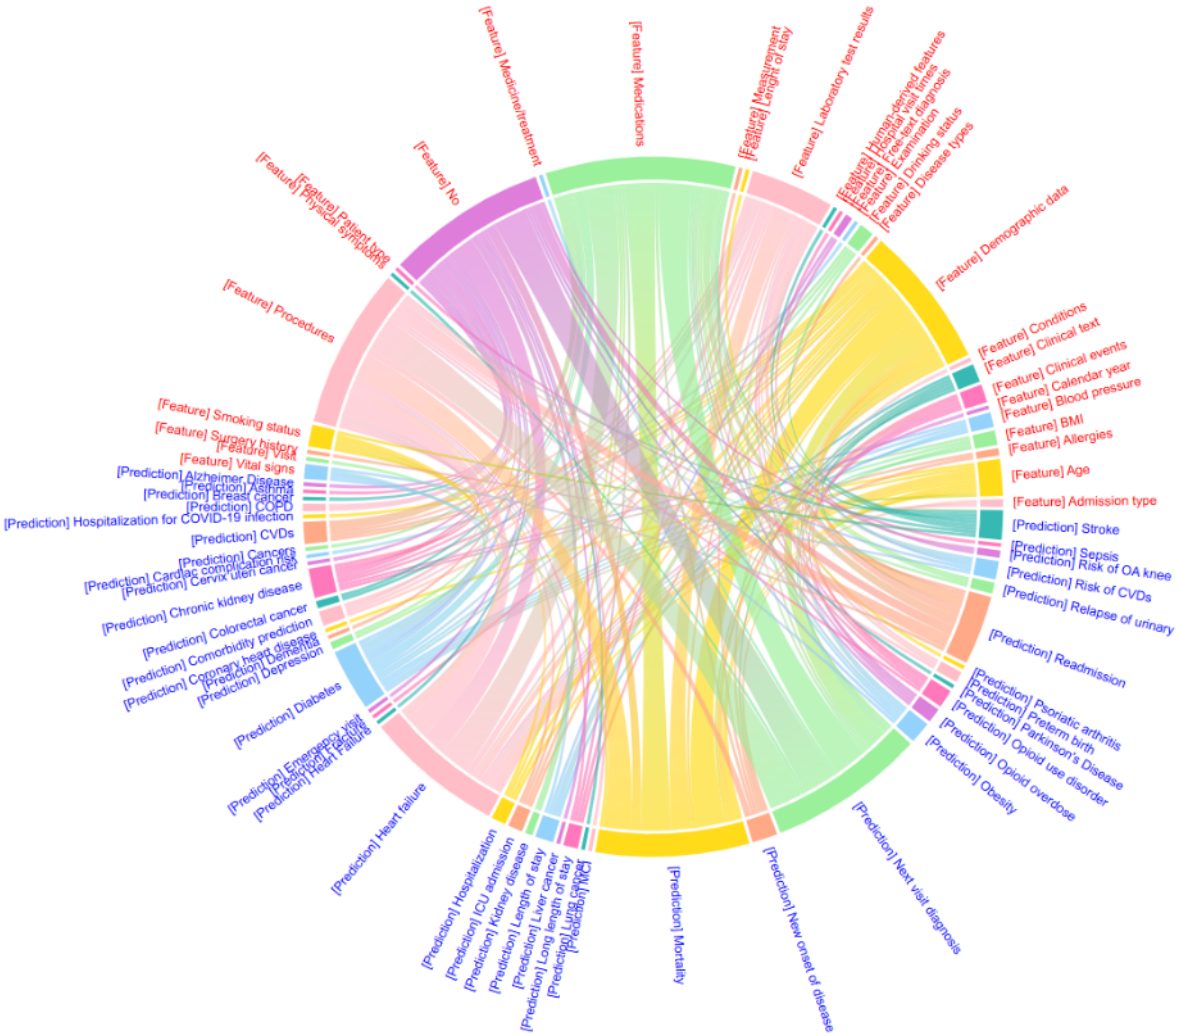
CNN: convolutional neural network; GRU: gated recurrent unit; PV-DBOW: paragraph vector–distributed bag of words; RNN: recurrent neural network.

Dataset Characteristics

Across 125 training datasets, the median sample size was 29,256 (IQR 92,572; range 1095-5,231,614) patients. The most frequently used datasets (82/125, 65.6%) originated from the United States. Moreover, there is an increase in sample size for training models (Figure S1 in Multimedia Appendix 3). The publicly available MIMIC-III dataset (31/125, 24.8%) was the most popular, followed by the Clinical Practice Research Datalink (11/125, 8.8%), Cerner Health Facts (8/125, 6.4%), Sutter Health (5/125, 4%), and MIMIC-IV (3/125, 2.4%; Figure S2 in Multimedia Appendix 3). The most frequently used coding system was *International Classification of Diseases, Ninth Revision* (82/125, 65.6%), followed by *ICD-10* (30/125, 24%). The most frequently incorporated additional feature in the 84 studies was medications (n=38, 45%), followed by demographic data (n=33, 39%), procedures (n=29, 35%), laboratory test results (n=15, 18%), and clinical events (n=4, 5%; Figure S3 in Multimedia Appendix 3). Some studies (35/84, 42%)



XSL•FO

integrated time information into their DL models for understanding patient prognosis.

Prediction Tasks

The highest frequency of predicted outcome variables were patient trajectory (n=51, 39.8%), cardiovascular disease and risks (n=33, 25.8%), admission (n=15, 11.7%), neurological diseases (n=6, 4.7%), and malignancy (n=6; 4.7%). The main subgroups of prediction tasks were next-visit diagnosis (n=30, 23.4%), heart failure (n=18, 14.1%), and mortality (n=17, 13.3%). Figure 3 presents the chord diagram illustrating the relationships between features and outcome predictions. The widest band is the connection between medications and next-visit diagnosis (10/263, 3.8%).

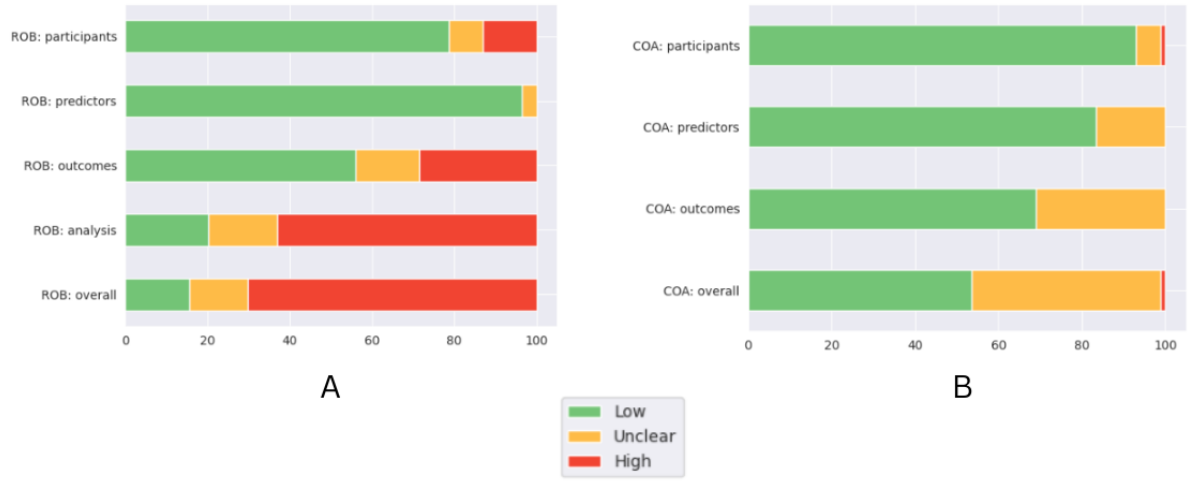
Figure 3. Chord diagram showing the relationship between features (red) and predictions (blue), derived from the "Additional features" and "Prediction task" columns in Table 1, respectively. In the chord diagram, "No" represents the absence of any features; "Visit" refers to the number of times a patient visited a health care provider; "Human-derived features" refers to features extracted from human input, such as manually recorded clinical observations or patient-reported outcomes; "Measurement" represents objective quantifications, such as laboratory test results, vital signs, and other instrument-based evaluations; "Medications" refers to prescribed drugs; "Medicine/treatment" is a broader term that includes medications and surgical procedures; "Calendar year" denotes the year of a patient's clinic visit; and "Conditions" refers to medical conditions.

Performance Evaluation

A variety of model performance metrics were reported across the 84 included studies. The best DL model performance in each study was reported using AUROC (41/84, 49%), F_1-score (25/84, 30%), area under the precision-recall curve (13/84, 15%), precision (16/84, 19%), and recall (14/84, 17%). The relationship between sample size, the number of features, and AUROC was examined (Figure S4 in Multimedia Appendix 3). A statistically significant relationship was found between sample size and AUROC (P=.02), indicating that changes in sample size have a notable impact on AUROC. However, there was no statistically significant relationship between the number of features and AUROC.

Generalizability and Explainability

An assessment of generalizability with external validation was uncommon among the included studies. Overall, only 7 (8%) of the 84 studies evaluated generalizability across ≥1 of the following categories: demographic validation (n=3, 43%)



XSL•FO
RenderX

[39,48,55], temporal validation (n=2, 29%) [100,103], and geographic validation (n=4, 57%) [24,39,68,100]. Regarding explainability, less than half of the studies (38/84, 45%) incorporated a mechanism to interpret their predictions. The publication pattern in terms of explainability is shown in Figure 2.

ROB and Concern of Applicability

Overall, the included studies had a high ROB (59/84, 70%), which was mainly driven by high ROB in the analysis domain (53/84, 63%). The main reason for high ROB in the analysis domain was the imbalance between the number of patients and their outcomes. Our assessment found low ROB in the participant (66/84, 79%) and predictor (81/84, 96%) domains due to broad inclusion criteria in general and similar predictor definitions across all participants, respectively. Within the applicability assessment, 3 domains were evaluated: participants, predictors, and outcomes. Overall, 45% (38/84) of the included studies showed either unclear or high concern of applicability because the characteristics of most included studies were not clearly mentioned. The full results of the ROB and applicability assessment are shown in Figure 4.

Figure 4. The Prediction Model Study Risk of Bias Assessment Tool (PROBAST) results: (A) risk of bias (ROB) and (B) concern of applicability (COA).

Discussion

Model Architecture

This systematic review offers insights into the contemporary DL approaches used to model patients' diagnostic history to predict outcomes. We explored 84 studies that met our inclusion criteria in this research area. The application of DL for advanced modeling of sequential medical codes is a rapidly growing research area. This is evident from the increasing number of publications found each year in this review. Considering the escalating interest in DL, there have been obvious publication patterns since 2016. After the emergence of bidirectional encoder representations from transformers (BERT) at the end of 2018 [106], transformer models have been increasingly used for sequential diagnosis codes, as reflected in the literature. More recently, there has been a prominent and highly successful showcase of transformers, with OpenAI's ChatGPT with GPT-3.5 and ChatGPT with GPT-4 [107] serving as prime examples of their capabilities.

Diagnosis code and language share some similar aspects. We can consider diagnosis codes as words and code sequences in a medical history as sentences. Typically, DL models designed for diagnosis codes aim to capture relationships between diagnosis codes within patient visits and across patient visits, which is similar to natural language processing (NLP) approaches that learn connections between words within sentences and across different sentences. Numerous studies in our review applied recent NLP techniques, such as RNNs and transformers, to sequential diagnosis codes. The main difference between diagnosis codes within patient visits and words within sentences is the irregular time interval between medical events. To accommodate this difference, many studies adjust the original DL algorithms to make them suitable for sequential diagnosis codes. Some examples include RETAIN [26], Dipole [27], EHAN [34], Timeline [35], Patient2Vec [40], DeepRisk [108], COAM [42], CLOUT [60], HAN [70], IoHAN [86], AttentionHCare [87], DeepMPM [89], and tBNA-PR [104], all of which use attention mechanisms and show superior performance compared to models without attention mechanisms.

Although RNNs and their derivatives made up the majority of the models (47/84, 56%) used for patient outcome prediction, several studies (15/84, 18%) showed that transformers have superior performance [55,56,59,62,67,72,73,81,83-85,88,90,95,104]. The transformer model consists of a multihead self-attention unit that computes in parallel. A crucial part of this architecture is the positional encoder, which enables transformers to understand the order and adjacency of information, in a similar way to CNNs and RNNs, respectively. Evidence from 2 (2%) of the 84 studies included in this review shows that positional embedding can improve model performance [55,64]. Moreover, models that combine transformers and RNNs have been introduced; for example, the medical BERT model combined with bidirectional gated recurrent unit improved the AUROC of the base models

XSL•FO
RenderX

by 1.62% to 6.14% [68]. Pretrained transformers models such as BERT for EHRs [55] and medical BERT [68] demonstrate impressive performance; however, both require a huge amount of pretraining patient data—approximately 1.6 million and 28 million samples, respectively.

Encoding diagnosis codes is a challenging task. Word2Vec is the most common method used for code-level embedding. Originally, Word2Vec was designed to capture the semantic relationships between words from large text corpora through unsupervised learning. Similarly, Word2Vec for diagnosis codes enables the encoding of meaningful relationships between medical conditions. Some models use separate training for the input data, with methods such as Word2Vec, GNNs, or transformers, while others that skip this step still require some form of embedding for codes during the training process. Consequently, it is challenging to make direct comparisons between DL models with embeddings and those without. Some studies show that learning hierarchical information through code-level embeddings can enhance the power of model prediction; for example, code-level embedding using Word2Vec can improve model performance [24]. GNNs can be a powerful tool for a hierarchical encoder with the potential to capture relationships between diagnosis codes. Many studies have demonstrated that using GNNs to embed diagnosis codes can provide effective predictions, including models such as Graph-Based Attention Model, knowledge-based attention model, Co-Attention Memory networks for diagnosis Prediction, multirelational EHR representation learning method, self-supervised graph learning framework with hyperbolic embeddings for temporal health event prediction, Sequential Diagnosis Prediction with Transformer and Ontological Representation, hypergraph-based disease prediction model using EHRs, Sequential visits and Medical Ontology, and integrated deep learning model combining long short term memory and graph neural networks. Interestingly, using multilevel representations, combining visit level and variable level, for a patient is better than single-level representation based on visit or variable alone [89].

Large language models (LLMs) have revolutionized NLP. LLMs are trained on huge amounts of text data from the internet, books, and other sources; and they can perform a wide range of language-related tasks. Recently, researchers have explored the ability of LLMs to understand medical codes; for example, a study evaluated several LLMs, including ChatGPT with GPT-3.5, ChatGPT with GPT-4, Gemini Pro, and Llama2-70b Chat, for their ability to generate correct medical codes based on code descriptions [109]. However, the study found that LLMs frequently generated incorrect codes. The findings suggest that LLMs lack an understanding of the meaning of medical codes. Therefore, it is still a challenge to use LLMs for clinical codes.

Characteristics and Features

Generally, the performance of DL models depends on the setting of the training dataset, such as inpatient or outpatient populations. Most of the included studies (31/125, 24.8%) used models trained on the MIMIC-III dataset, which focuses on ICU admissions in the United States, with a short interval between diagnosis codes and patients considered high risk [110]. Patients in the MIMIC dataset will have more severe illnesses than a general hospital population, which would be a mix of inpatients and outpatients. The type of clinical data in the training dataset is very important for robust disease prediction. The dataset should not be focused only on specific clinical settings, such as hospital admissions or ICUs, due to data availability. However, more than half of the included studies (52/92, 57%) did not clearly report the setting of their training dataset. Moreover, a study showed that patient vital signs had a greater influence on mortality prediction in ICU settings than diagnosis codes [93]; yet, vital signs are not available in every dataset. Therefore, we suggest that it is important to provide the details of the clinical setting of the training dataset.

There may be inherent biases in how diagnosis codes are recorded in EHR data, influenced by their primary billing sources. In addition, for a single appointment, acute conditions are more likely to be recorded than chronic diseases. Any biases in the recording of diagnosis codes may transfer to the learning process of a DL algorithm. This potential transfer of bias should be carefully considered when interpreting the results. Most of the included studies (42/125, 33.6%) used datasets, such as MIMIC-III and Clinical Practice Research Datalink, that provide long-term follow-up data for large patient populations. These datasets typically include diagnosis codes for a wide range of acute and chronic medical conditions. DL studies can benefit from the availability of longer sequences of these codes, reflecting longer periods of the patient's medical history and therefore more likely to capture both conditions.

The performance of the DL model in predicting patient outcomes depends not only on diagnosis codes but also on other features, such as demographic data [43], treatments [40,56,71], the number of visits [56], and the interval between visits [64,88]. Several studies have shown that diagnosis codes alone cannot provide the best predictive performance compared to models incorporating multiple features, such as medications, procedures, laboratory test results, demographic data, and so on [82,88,101,108]. Moreover, a study that applied BERT for EHRs has highlighted that combining diagnosis codes with factors such as age, segment, and position lead to improved precision scores compared to relying solely on diagnosis codes [55]. We propose that integrating a wide array of supplementary features, including demographic data, medication records, medical procedures, and laboratory test results, can potentially improve the performance of DL models when analyzing sequential diagnosis codes.

Many of the studies (33/84, 39%) included basic demographic data, such as gender and age, as model features. Ethnicity is another important demographic factor because it is a significant risk factor for many diseases, such as heart disease [111]. However, only a few studies (4/84, 5%) specifically described ethnicity as an input feature of their models. Most of the datasets reviewed (63/84, 75%) originated from the United States and European countries. In addition, research has shown that race and ethnicity data in EHRs are often incomplete and inaccurate, especially for minority populations [112]. These limitations can make it challenging to generalize the developed models to external settings with different patient populations and health care systems.

XSL•FO
RenderX

As diagnosis codes occur at irregular time intervals, adding time intervals as a feature can help a model to understand disease progression. Hypothetically, patients with shorter follow-up times are more likely to have severe conditions. Ablation studies, which assess model performance by removing some features, have demonstrated that integrating time intervals between patient visits can enhance predictive power. This improvement has been demonstrated across multiple models, including BiteNet [56], CATNet [88], CEHR-BERT [84], Deepr [23], DL-BERT [90], EHAN [34], and SETOR [81]. Moreover, research applying HiTANet has shown that integrating time intervals between the last visit and current visit can improve model performance [58]. A study that examined the impact of integrating time intervals as days, weeks, and months into model predictions found that using weeks as the unit yielded the best prediction performance, corresponding to the weekly follow-up pattern in real clinical practice [78]. We believe that the time interval between visits can serve as an indicator of disease progression.

Next-visit prediction is a widely applied task for evaluating DL performance in sequential diagnosis codes. However, this task carries an ROB; for example, while DL-BERT performs well in predicting the next disease based on a patient's existing history, its precision drops—by approximately 50%—when predicting a new-onset disease that has not previously occurred in the patient's history. This indicates that the model relies heavily on prior diagnoses rather than capturing underlying disease progression [90]. Another challenge for next-visit prediction is the issue of missing data. Sometimes, patients seek care at a different location or with a different provider, and this information may not be captured in the available data. This is a major limitation for most studies, which can be mitigated through better data linkage and information sharing across health providers.

Evaluation, Generalizability, and Explainability

Model evaluation in health care is often complicated by class imbalance due to the nature of the medical domain, where the number of individuals with a disease is usually lower than the number of individuals without it. AUROC and F_1-score are commonly used evaluation metrics in publications for health care research area and were reported by 82% (69/84) of the studies included in this review. However, F_1-score focuses on positive prediction and avoid the value of true negatives. Alternatively, a study suggested using the Matthews correlation coefficient for model evaluation because it provides a more balanced assessment of positive and negative predictions [113].

Generalizability is an important issue for outcome prediction in health care. When a model is trained on a specific population, it will only perform well on patients with similar characteristics. The evaluation should include both internal and external validation. Assessing performance on different data distributions is crucial for outcome prediction [19,114]. Predictive performance degrades when models are tested on out-of-distribution years [103]; however, only a small proportion of the included studies (7/84, 8%) validated their models using data outside of their training distribution. Validating models across different settings—demographic, temporal, and geographic—is very important for real-world applications.

While DL models can yield a good performance in outcome prediction, they are frequently regarded as black box models, lacking the explainability needed to understand their internal processes and the main contributing factor for a given prediction. This lack of explainability—when the underlying reasoning is unclear—is a significant concern because it may reduce trust in predictions among health care workers and complicate the explanation of clinical decisions to patients. In recent years, researchers have focused on explainability. Shapley additive explanations (SHAP) was introduced to understand model predictions [115]. SHAP can be used to explain the decisions of LSTM models and transformers; for instance, SHAP values can explain meaningful medical codes to predict the risk of opioid overdose with 11 codes related to medications and 2 codes related to mental disorders [102]. A study introduced a tool to visualize multihead self-attention in transformer models, which can show the relationship between 2 sentences [116]. Some studies used this tool to show disease relationship between 2 sequences of diagnosis codes [55,67]. We propose that explainable artificial intelligence should be included in research studies in this area.

Limitations

This review has several limitations. First, while our search was effective in capturing a significant proportion of the papers in this research area, it is important to note that variations in search terms may have led to the unintentional exclusion of other relevant studies, which is why we conducted a manual search to identify additional relevant articles. Second, the included studies exhibited heterogeneity, which made it difficult to compare the studies and conduct a meta-analysis. There was variability in input features and prediction tasks. Moreover, model evaluation metrics were reported differently. Although many of the included studies (57/84, 68%) introduced single, novel DL-based models, some studies (27/84, 32%) applied multiple standard models for outcome prediction. In such cases, we considered only the best-performing DL model in each study. Finally, it is important to note that PROBAST was not originally designed for evaluating DL models, and certain questions in the analysis domain are not suitable for these models.

Recommendations and Future Work

On the basis of the findings of this review, our main recommendation for future studies using DL alongside sequential diagnostic patient information is to ensure that the generalizability of the developed models is tested on independent datasets. This will significantly reduce the ROB in key findings. Given the aforementioned limitations, we also think that studies should apply a more specific ROB assessment tool to DL models because not all questions in the current PROBAST assessment framework are suitable.

Conclusions

The application of DL for advanced modeling of sequential medical codes has demonstrated remarkable promise in predicting patient outcomes. The main limitation of this study was the heterogeneity of methods and outcomes. However, our

XSL•FO
RenderX

analysis found that using multiple types of features, integrating time intervals, and including larger sample sizes were generally related to an improved predictive performance in the included studies. This review also highlights that very few studies (7/84, 8%) reported on the challenges related to generalizability and almost half (38/84, 45%) of the studies reported challenges related to explainability of DL models. Addressing these shortcomings will be instrumental in unlocking the full potential of DL for enhancing health care outcomes and patient care.

Abstract

Background: Research regarding the effectiveness of digital health interventions (DHIs) for people living with chronic pain is widely documented, although it is often measured against changes in clinical outcomes. To gain a comprehensive understanding of the full impact of DHIs, it is vital to understand the experience of individuals who are using them. An exploration of qualitative data regarding the experience of people living with chronic pain engaging with DHIs could provide a more in-depth account of how individuals interact and engage with such tools, uncovering the overall impact DHIs can have on the lives of people living with chronic pain.

Objective: This qualitative systematic review and thematic synthesis aimed to appraise and synthesize relevant qualitative evidence on patients' experiences of engaging with DHIs for the self-management of chronic pain symptoms.

Methods: A systematic literature search of qualitative and mixed methods studies published between 2013 and 2023 was conducted across 6 databases: MEDLINE, PubMed, Embase, CINAHL, PsycINFO, and Scopus. Eligible studies included adult patients aged ≥18 years with a chronic pain diagnosis (ie, >12 weeks) reporting on the experience of engaging in a DHI for the self-management of chronic pain. The Critical Appraisal Skills Program checklist for qualitative research was used to appraise each study. Following a 3-step inductive thematic synthesis approach, the researcher performed line-by-line coding of each eligible article to identify descriptive themes. Through iterative evaluation of the descriptive themes, analytical themes that facilitated a deeper understanding of the data were derived.

Results: In total, 37 qualitative and mixed methods studies were included in the review. Thematic synthesis revealed three overarching themes encompassing five subthemes: (1) personal growth, with 2 subthemes (*gaining new insights* and *renewed mindset*); (2) active involvement, with 3 subthemes (*motivation*, *improved access*, and *health care decision-making*); and (3) connectedness and support.

Conclusions: A positive experience with DHIs among people living with chronic pain is achieved through an improved understanding of their condition, greater self-awareness of how symptoms impact their lives, and an increase in motivation to play an active role in their health care. DHIs promote the confidence and independence of people living with chronic pain, as well as facilitate a sense of ongoing support between routine appointments. However, DHIs may disempower people living with chronic pain by placing too much focus on their pain and should be used as an adjunct to existing care as opposed to replacing in-person appointments. To appropriately meet the needs of people living with chronic pain, the content and features of DHIs

XSL•FO
RenderX

should be personalized. Development of future DHIs should use a co-design approach involving key stakeholders to ensure the needs of people living with chronic pain are met.

Introduction

Background

Chronic pain, defined as pain that persists past the normal healing time of 3 months [1], is one of the leading causes of disability worldwide [2]. The intricate and diverse nature of chronic pain makes it a complex condition to fully understand, as pain can occur without a clear underlying cause and cannot be attributed to injury or disease. This is described as *chronic primary pain* and includes diagnoses such as fibromyalgia, chronic primary musculoskeletal pain, and chronic primary neuropathic pain. Pain that occurs as the result of an initial injury or underlying illness is known as *chronic secondary pain*, and this includes conditions such as osteoarthritis, rheumatoid arthritis, and cancer related chronic pain [3]. A systematic review assessing prevalence in the United Kingdom estimated that approximately 43.5% of the population experience chronic pain, with 12% of people living with chronic pain reporting pain that is moderately to severely disabling [4].

Treatment

It is well known that chronic pain is multifaceted, and this can present a substantial burden to the lives of those affected [5]. Physical symptoms are often accompanied by distressing psychological, social, and economic factors that can impact every facet of an individual's life [2]. To reflect its multifaceted nature, it is crucial that treatment addresses the diverse biopsychosocial aspects of chronic pain. Evidence indicates that treatment that uses a combination of approaches is the most effective for improving pain outcomes [6,7]; however, access to adequate multidisciplinary treatment is limited [8]. Lengthy waiting times for treatment are reported around the world [9-12], leaving patients with no other option than to rely on their general practitioner for advice [8]. Self-management, defined as "the individual's ability to manage the symptoms, treatment, physical, psychosocial consequences, and lifestyle changes inherent in living with a long-term disorder" [13], poses a possible solution to the issue of limited access to treatment. Self-management techniques encompass a range of disciplines, integrating approaches such as tracking symptoms, engaging in exercise, relaxation techniques, and cognitive behavioral therapy (CBT) to address chronic pain symptoms [14]. Such strategies enable individuals to play an active role in their health care by treating and managing their pain on a day-to-day basis without relying on input from health services or health care professionals (HCPs). A growing body of evidence supports that self-management interventions are effective in assisting people living with chronic pain manage their symptoms [14-17].

Digital Health

A promising mode of delivering self-management interventions is through the use of digital health technologies. The need for digitization of health care delivery became evident following the COVID-19 pandemic, as digital technologies offer an accessible, affordable, and flexible approach to managing chronic pain symptoms [18]. Digital health interventions (DHIs) use various modes of delivery, including smartphone apps, websites, wearable activity trackers, and virtual reality [19], and the literature highlights promising effects of DHIs on clinical outcomes. Pfeifer et al [20] evaluated the efficacy of app-based interventions on a variety of chronic pain conditions. An analysis of 22 studies found that apps are significantly more effective in reducing pain compared to control groups. Another systematic review that analyzed the impact of web-based and mobile-based self-management interventions on patients with chronic low back pain indicated that there was a clinically important effect both at immediate and short-term follow-up on pain relief and improved disability [21]. Furthermore, Moreno-Ligero et al [22] reviewed 22 randomized controlled trials to evaluate the effectiveness of mobile health interventions on a range of chronic pain conditions. The results suggested that the use of mobile health interventions can have beneficial effects on pain intensity, functional disability, and quality of life (QoL).

Despite an abundance of the literature outlining the benefits of DHIs for people living with chronic pain, the findings primarily focus on clinical outcomes. Research regarding clinical outcomes plays a vital role in supporting evidence-based practice, although these studies are not able to provide a comprehensive understanding of how users interact and engage with DHIs. The literature shows clear evidence that DHIs are effective in improving symptoms of chronic pain, although the full potential of DHIs is limited as engagement and retention rates within these interventions are low. A review evaluating the efficacy of web-based CBT interventions for chronic pain found that as many as 26.6% of users dropped out before completing the intervention [23]. Similarly, a more recent review exploring the DHIs for the self-management of osteoarthritis found that 6 out of the 7 studies evaluated reported less than 70% adherence to the intervention [24]. For people living with chronic pain to obtain maximum results from self-management DHIs, users need to engage with and continue to use these tools. This strongly depends on a user's intention to use the tool [25],

XSL•FO
RenderX

although the intentions behind why a user engages are poorly understood. Research regarding the barriers and facilitators to the use of DHIs among people living with chronic pain reported that too much information, a lack of tailored or personalized content, and a lack of motivation negatively affect engagement [26,27].

To overcome these barriers, it is vital that DHIs meet the actual needs of the people who are using them. To do this, developers of such interventions require a comprehensive understanding of how users experience DHIs as this could unveil aspects that will encourage engagement and retention. A qualitative exploration of how people living with chronic pain experience the use of DHIs could provide insights into how users benefit from DHIs as well as highlight the associated challenges. These findings could inform the design and development of future DHIs, resulting in more effective tools that meet the needs of people living with chronic pain.

A recent review exploring experiences of patients with chronic pain with DHIs has found that by engaging with DHIs, participants learned new skills as to how to manage their pain and gained increased confidence and reassurance with regards to managing their condition. In addition, the review stated that users were able to improve the perception of their condition, thereby obtaining a more optimistic outlook on their life [28]. The findings from this review highlighted some key recommendations for future DHIs, including providing tailored content, structured goal setting facilitated by prompts, and prioritizing features that change patients' attitudes and behaviors. This review aims to build on this evidence with a particular focus on self-management interventions. It will also include qualitative data from mixed methods studies, which dominate this domain of research and could therefore offer valuable insights concerning the patient experience of engaging with DHIs that may have been previously overlooked.

By exploring qualitative evidence regarding patients' experiences of engaging with specifically self-management DHIs, the findings from this review could improve the development of future DHIs by providing an in-depth explanation of how self-management DHIs impact the lives of people living with chronic pain, and which features should be included or omitted in future DHIs to enhance engagement and retention. In turn, this will uncover the full potential of how self-management DHIs can benefit people living with chronic pain.

Aim and Objectives

The aim of this qualitative systematic review and thematic synthesis is to identify, appraise, and synthesize relevant qualitative evidence on patients' experiences of engaging with DHIs for the self-management of chronic pain symptoms.

The objectives of this synthesis are as follows:

1. To explore how people living with chronic pain experience DHIs for the self-management of chronic pain
2. To identify factors that could improve the design and development of future DHIs

Methods

Overview

This systematic review and thematic synthesis was conducted and reported in accordance with the Enhancing Transparency in Reporting the Synthesis of Qualitative Research (ENTREQ) guidelines [29]; a completed checklist is presented in Multimedia Appendix 1. The protocol has been published [30] and is registered on PROSPERO (CRD42023445100).

Search Strategy

The search strategy was adapted and applied to 6 electronic databases as follows: Embase, MEDLINE, PubMed, CINAHL, PsycINFO, and Scopus. The full search strategy for each database can be found in Multimedia Appendix 2. To retrieve relevant articles not identified on the electronic databases, forward and backward citation searches were performed on the included studies. The sample, phenomenon of interest, design, evaluation, and research (SPIDER) framework [31], which describes the sample (S), phenomenon of interest (PI), design (D), evaluation (E), and research type (R), was used to structure the search terms and develop a comprehensive search strategy relevant to the research question. The search terms that comply with each of the key characteristics of the SPIDER framework are outlined in Table 1 [31].

Each electronic database was searched on July 4, 2023, and updated on January 29, 2024. Each search was restricted to papers published in the English language; gray literature, other reviews, protocols, and unpublished studies were excluded from the review. Due to major advancements in technology, only articles published in the last 10 years (ie, 2013-2023) were included, those published before 2013 were excluded due to the potential risk of no longer being relevant. Search results were imported to EndNote (version 20; Clarivate), and duplicates were removed.

Eligibility Criteria

The inclusion and exclusion criteria were based on the key characteristics of the SPIDER framework outlined earlier [31]. Textbox 1 describes the inclusion and exclusion criteria, and a comprehensive account of the inclusion and exclusion criteria is detailed in the study protocol [30].

Textbox 1. Inclusion and exclusion criteria based on the sample, phenomenon of interest, design, evaluation, and research (SPIDER) framework.

Inclusion criteria

- Articles reporting on adults (ie, aged ≥18 years) who were diagnosed with any chronic pain condition exceeding 12 weeks
- Articles reporting qualitative data, including mixed methods studies with a qualitative component, on patients’ experiences of engaging with a digital health intervention (DHI) for the self-management of chronic pain
- Articles reporting on DHIs, regardless of modality, to deliver self-management strategies for managing chronic pain symptoms
- Articles published from January 1, 2013, to December 31, 2023
- Articles published in the English language

Exclusion criteria

- Articles reporting on participants aged <18 years who have not received a diagnosis exceeding 12 weeks
- Gray literature, reviews, protocols, dissertations, and articles reporting on quantitative data from mixed methods studies
- Articles describing participant expectations and perceptions rather than the experience of engaging in a DHI
- Articles describing the experience of carers or health care professionals
- Articles describing DHIs that deliver management strategies that involve regular live health care professional contact (eg, through videoconferencing or Skype)
- Articles published before January 1, 2013
- Articles published in languages other than the English language

Screening and Data Extraction

Articles retrieved from the electronic database were uploaded to EndNote and duplicates were removed. Articles were then imported to Rayyan (Rayyan Systems, Inc), a software that facilitates screening in the systematic review process. After thoroughly discussing the eligibility criteria to ensure that reviewers had a comprehensive understanding of which studies to include and exclude, all of the titles and abstracts were screened by 2 independent reviewers (AM and HM). There was a high rate of agreement, as 89% (33/37) of the papers were agreed upon. Where disagreement between reviewers did occur, this was resolved through discussion between 2 reviewers through a thorough investigation of each paper against the inclusion and exclusion criteria (AM and MI). In the following phase, full-text articles of the included titles and abstracts were obtained, and the same 2 reviewers (AM and HM) assessed the full-text articles for eligibility. During this round, there was a

XSL•FO
RenderX

96% agreement rate, and again, the reviewers resolved any disagreement through discussion. In one case, resolution between the reviewers could not be reached and a third reviewer was consulted (FM).

A data extraction table was devised by the research team, and 2 reviewers (AM and HM) independently extracted data from 20% (7/37) of the included articles. Data extraction forms were then compared between reviewers to ensure that the key characteristics of each study were extracted in a systematic and standardized way. The first author (AM) then continued to extract data from the remaining included articles.

Quality Assessment and Critical Appraisal

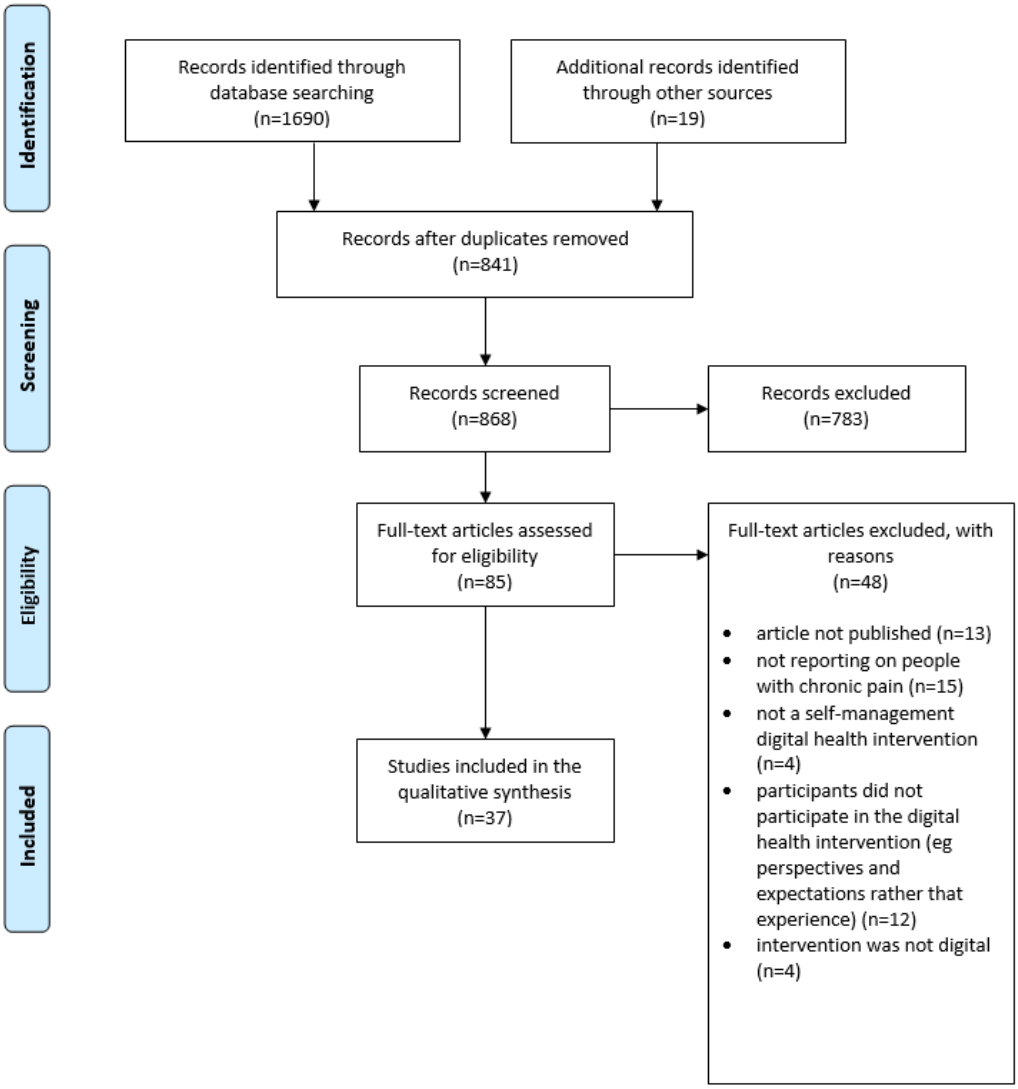
Due to the subjective nature of qualitative research, assessing the methodological quality of included studies is a crucial step to ensure the validity of results. The Critical Appraisal Skills Program (CASP) qualitative research checklist was chosen to appraise each article as the checklist is endorsed by Cochrane's Supplemental Guidance for Inclusion of Qualitative Research [32]. Assessment consists of scoring 10 questions regarding methodological quality as "yes," "can't tell," or "no." The questions concerned issues such as research design, recruitment strategy, data collection, ethics, data analysis, and presentation and interpretation of findings.

Two independent reviewers (AM and HM) assessed the CASP checklist criteria before commencing the quality assessment phase. This was to fully understand the criteria before applying each paper against the checklist. The 2 reviewers appraised 20% (7/37) of the included articles. After comparing scores of the subsample, which reached a high degree of agreement (6/7, 85%), discrepancies were resolved through discussion. The first author then continued to appraise the remaining 30 articles. There are currently no standardized rules for the exclusion of studies based on their appraisal score; therefore, all studies were included in the synthesis. The average quality appraisal score of the included articles was high (ie, 8.8/10).

Thematic Synthesis

A 3-step inductive thematic synthesis approach as described by Thomas and Harden [33] was applied to the results and discussion sections of each included article. This methodology was selected as it is recommended by the *Cochrane Handbook for Systematic Reviews of Interventions* [32]. The 3-step methodology provides an opportunity to extend beyond the findings of the primary studies by deriving analytical themes from descriptive themes, which in turn facilitates a deeper conceptual understanding of the data. Qualitative evidence syntheses have faced criticism for decontextualizing the results of individual studies [33]. Therefore, before the 3-step thematic synthesis approach began, each paper was read in its entirety to grasp a full understanding.

In step 1, the first author (AM) imported the primary studies to NVivo (Lumivero), where line-by-line coding of the results and discussion sections of each primary study was performed to identify concepts within the data. In step 2, items coded in step 1 were grouped together to create descriptive themes, closely aligning with the themes identified in the primary research. Finally in stage 3, by continually examining and interpreting the descriptive themes, analytical themes that reflected a deeper understanding of the data were derived.



Results

Study Selection

The search yielded 1709 records. After duplicates were removed, the titles and abstracts of 868 (51%) records were screened, and 85 (5%) records were retrieved for full-text screening. A total of 48 (57%) records were excluded; reasons for exclusion can be found in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart (Figure 1; Multimedia Appendix 3). A total of 37 (43%) records met all eligibility criteria and were included in the review (Multimedia Appendix 4 [34-70]).

XSL•FO
RenderX

Study Characteristics

The 37 included studies used a range of qualitative methods to collect data, including interviews [34-62], focus groups [63-67], questionnaires [68], and a combination of interviews and questionnaires [69,70]. In total, 18 (49%) studies conducted interviews remotely [34,38,41-43,45-49,52,54-56,58,62,69,70] and 5 (14%) studies had the option of both in-person or remote interviews [37,39,53,59,61]. A total of 2 (5%) studies did not detail how the interviews took place [36,60]. Focus groups were conducted in person in 2 (5%) studies [63,64], on the web in 2 (5%) studies [65,66], and 1 (3%) study used a combination of both in-person and online methods [67].

The sample sizes ranged from 7 to 36, with a total of 707 participants. A total of 4 of 37 (11%) studies included only female participants [37,45,59,65], and the remaining 33 (89%) studies included both male and female participants [34-36,38-44,46,48-58,60-64,66-70]. The interventions were investigated in the United States [42,44,45,51,54,60,61], the Netherlands [35,46,59,62,66,69,70], Canada [40,41,53,67], the United Kingdom [34,36,37,58], Australia [43,47,49], Sweden [39,50,55,63], Germany [48,52], New Zealand [64], France [68], Belgium [65], Norway [38], and Turkey [57], and 1 study was conducted in both Sweden and Denmark [56].

In terms of chronic pain conditions, 6 of 37 (16%) studies did not differentiate between chronic pain diagnoses [38,40,42,44,47,55], while the remaining 31 (84%) studies focused on specific chronic pain conditions: knee or hip osteoarthritis [34,39,41,43,49,53,54,63,64], rheumatoid arthritis [36,48,57,62,69,70], low back pain [35,52,56,61,68], cancer pain [45,51,65,67], musculoskeletal pain [46,50,60], chronic pelvic pain [37], irritable bowel syndrome [58], and temporomandibular disorder [59], and 1 study evaluated rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis [66].

A range of digital tools were used to deliver the telehealth interventions; smartphone apps [35-38,42,44,48,53,56,57,62,64,66,68,70], web-based interventions [34,39,41,43,45,46,49-52,54,58-61,65,69], virtual reality headsets [40,67], social media [47], and wearable activity trackers [63], and 1 intervention offered both a smartphone app and web-based platform [55]. The purpose of the interventions varied, with most studies using a multitude of different intervention components [34,39,41-43,45,46,50,

XSL•FO
RenderX

51,53,55,56,59,62,65,69]. While the remaining interventions also incorporated a range of components, the main focus of the intervention was on CBT or mindfulness and meditation strategies [37,38,40,58,67], self-monitoring and symptom tracking [36,48,60,64,66,70], physical activity [35,49,57,63,68], virtual auricular point acupressure [44,61], social support [47], and shared decision-making [52,54].

The study characteristics pertaining to each included article can be found in Multimedia Appendix 4, and a table of intervention characteristics can be found in Multimedia Appendix 5 [34-70].

Quality Assessment

Overview

Of the 37 studies, 35 (95%) studies included in the review were rated as "high" quality by scoring >7 out of 10 [34-46,48-68,70]. A total of 2 (5%) studies were rated as "low" quality [47,69], failing to describe multiple key aspects, such as the research design, recruitment strategy, data collection, and data analysis process; 2 (5%) studies did not clearly state the aims of the research [44,51]; 4 (11%) studies did not provide thorough detail as to how the data were collected [36,47,60,69]; and 3 (8%) studies failed to give an in-depth description of the data analysis process [47,69,70]. The item that was scored most poorly throughout the included studies was the consideration of researcher bias, with 26 (70%) studies lacking sufficient detail on the relationship between the researcher and the participants [34-37,40-43,46-48,51,53-57,60-62,65-70]. The full quality appraisal for each study can be found in Multimedia Appendix 6.

Thematic Synthesis Findings

The data revealed 3 analytical themes that encapsulated patients' experiences of DHIs for chronic pain management as follows: (1) personal growth, with 2 subthemes (*gaining new insights* and *renewed mindset*); (2) active involvement with 3 subthemes *motivation*, *improved access*, and *health care decision-making*; and (3) connectedness and support. The subsequent sections provide a description of each theme.

Theme 1: Personal Growth ("I Could See the Change That Was Happening")

Overview

A dominant theme throughout the studies was that participants experienced personal changes that made them grow and evolve as individuals, facilitating personal growth both physically and emotionally (34/37, 92%). Improved understanding of their condition led participants to adopt greater self-awareness of their symptoms. Participants obtained an optimistic outlook on life through enhanced confidence and independence, ultimately accomplishing a sense of acceptance of their diagnosis. This analytical theme encompasses 2 subthemes: gaining new insights and a renewed mindset.

Gaining New Insights: "I Understand How My Brain Controls the Pain"

Most studies reported that self-management DHIs improved participants' self-awareness, facilitating a deeper understanding of their condition [34]. Participants were able to recognize patterns and triggers that exacerbate pain by tracking their symptoms within web-based and app-based interventions [36,54,58,64]: "The one thing it did make me do was look at my diet more and made me associate different reactions and triggers for my IBS" [58]. This sense of enhanced self-awareness allowed participants to understand the relationship between different variables and how this impacted their pain, enabling them to make practical changes to their lifestyles resulting in better symptom management.

Participants were able to identify thoughts and emotions that had a negative impact on their pain using CBT [58]. Mindfulness and meditation sessions equipped participants with various skills to reduce stress and anxiety [38]. Some participants were unaware that CBT could be useful for pain management before participating in the intervention [50]. Many of the interventions encouraged participants to self-reflect, which enhanced their overall understanding of the different aspects of their pain [38,43,46,50,58,60,64].

Interventions that supported physical activity gave patients insight into what exercises they can do to alleviate pain [41,43,50,56,57,62,63]. This made participants aware of how their overall health can improve:

> *Because I'm doing a bit of exercise in combination with the diet. So, I can see if I continue this part, not only my knee will benefit, [but] also my health.* [41]

Conversely, some studies found that enhanced insights into pain can also have a negative effect [37,38,40,46,62,67,70]. Participants occasionally found that too much focus on their symptoms made them aware of how poorly they were coping, "Every time I got those registrations...you have to start to notice, and feel, that you are not actually doing so well after all" [38]. For some, this increased awareness was perceived as "heavy to encounter" [46], particularly for patients who are trying to forget about their pain. It was also highlighted that regularly tracking and monitoring symptoms can risk placing too much emphasis on the negative aspects of an individual's health [55,60,62]: "It just triggered me to start looking at my overall health" [60]. One study reported that some elements of CBT were "too confronting for patients" [62], and another study that delivered a virtual reality computer-simulated environment through a binocular headset found that focusing on pain resulted in participants experiencing more pain [67].

Renewed Mindset: "It's Brought a Positive Into My Lifestyle"

The studies reviewed suggested that DHIs instilled confidence and reassurance in many of the participants. Information within the DHIs validated some participants' beliefs and reassured them that they were not alone [58]. Collecting data on pain and other symptoms increased participants' confidence when it came to making decisions about treatment [54]. Participants felt reassured that self-management strategies were effective based on data collected [35], particularly with the help of graphical summaries that displayed patterns of their pain [48]:

> *I felt that my back was very painful this week, but actually my pain score after doing the exercises is decreasing. That is, for me, a reminder I'm going in*

XSL•FO
RenderX

> *the right direction, and I find that very reassuring.* [35]

Video instructions incorporated into exercise-based interventions promoted a sense of confidence by reassuring participants that they were completing the exercises correctly [59]. One study noted that exercises for managing knee pain promoted participants confidence to maintain their lifestyle and not give up because of their pain: "It's helped me not only with my mobility but my self-confidence to be able to go, yeah, I can get up there all right and come down there" [49].

Participants developed an optimistic attitude about their pain throughout CBT sessions [38,43,58], which offered participants alternative coping strategies so that they were confident enough to not depend heavily on medication: "I got to the stage where I wouldn't leave the house without making sure the medication was in my handbag...while I was doing the trial I never thought like that at all" [58]. Another article reported that app-based CBT was effective in changing participants' perspectives by providing hope that they can live a good QoL despite their pain [38]. In one study, family members noticed an increase in independence because of web-based pain-coping skills training [51]. Educational sessions were also found to be effective in promoting acceptance in some participants by changing the way they think about their pain [46,56]. Some studies reported that participants could use the DHIs to self-manage their symptoms instead of relying on input from HCPs [52,56,65]: "When you understand everything in the program and know how to apply this information into daily life, a conversation with a health care provider wouldn't be necessary anymore" [65].

By changing their perceptions of pain, many participants achieved a degree of acceptance which resulted in them coming to terms with their diagnosis [38,43,46,51,52,56,69]: "I'm just trying to learn to live with it [OA], and I know it's a cliché, but just accept the new normal, and not be living in the past and remembering how when I could just walk all day and not worry about it" [43].

On the other hand, some studies noted the adverse experiences of engaging in the DHIs on participants' psychological well-being [37,38,40,48,49,63,65,67]. Monitoring disease activity on a smartphone app evoked negative thoughts for one participant:

> *If you dwell too often on your own disease activity, it can be associated with negative thoughts. You may be more likely to get into such a negative vortex.* [48]

In an intervention that used a virtual reality immersive experience, some participants experienced anxiety, depression, and stress that aggravated their pain [67].

Theme 2: Active Involvement ("I Would Never Have Done It If It Hadn't Been Digital")

Overview

This theme illustrates how DHIs can promote patients to play an active role in the management of their chronic pain. As opposed to being a "passive" recipient of care, accessible self-management resources motivated participants to act and engage in conversations about their health care. This analytical theme is underpinned by 3 descriptive themes (motivation, improved access, and health care decision-making).

Motivation: "I Dare Do More Things!"

The studies continually described how participants were motivated to engage in behaviors that positively impacted their pain, and therefore promoted a greater sense of control [39,43,44,65,68]: "Thanks to the program, I got the feeling that I had more control on my pain" [65]. Participants expressed a sense of motivation that went beyond the goal of the intervention, such as inspiring them to lose weight [49] or to change their occupation to something that was less physically demanding and better suited to their needs [43]. The results from the exercised-based programs suggested that participants were motivated to exercise more as a direct result of the DHI [35,41,52,56-58,62,63,69]: "Thanks to the app, I could see what exactly it was I was supposed to do...That definitely increased how often I exercised" [35].

Notifications either as alerts or emails were noted to have a motivating effect on participant engagement throughout the interventions [34,35,39,41,43,49,57,59,63]: "Reminders and notifications are my favorite, I love that some notifications motivate me by saying 'how about moving? have a nice day!'" [57]. Nevertheless, some of the studies found that notifications and prompts had a negative impact on participants feeling of empowerment [49,63]. In a study that used wearable activity trackers to encourage physical activity, notifications prompting participants to reach their step goal were perceived as distressing when participants were in too much pain to meet their target [63].

Although most participants experienced enhanced motivation, some advised that they felt less motivated to engage with the DHI [39,41,45,49,58,62,63]. Participants struggled to stay motivated when completing a home-based yoga program due to outside distractions and other commitments [45]. Once pain had improved, some participants did not have the same motivation to continue with the program: "The pain was generally reduced...and then I did not feel as motivated as before so I quit doing the exercises" [39]. When participants felt demotivated and had not completed the recommended exercises, SMS text messaging reminders evoked feelings of shame or guilt in one study [49], and another described how the weekly content delivered to participants through a web-based self-care intervention felt like "unfinished homework" [41].

Improved Access: "It's Awfully Good to Have the Tools at Home"

Participants were motivated to play an active role in their health care because of convenient and flexible access to self-management resources. Participants in the app-based interventions commented on how having quick, convenient, and flexible access to self-management strategies encouraged them to take action [35,38,59,64]:

> *You've got your phone with you, and you can just [get it] ...done. Whereas, with a piece of paper, you've got to go and sit down somewhere, and you've got to write it out.* [64]

XSL•FO
RenderX

The flexibility of being able to choose when and where to engage in the various self-management techniques enabled participants to take control over their symptoms at a time that suited them, stimulating engagement with the DHIs [38,39,50,51,59,65]: "It's awfully good to have the tools at home to use when you can find the time" [51]. Participants advised how they were able to access the self-management strategies while on a waiting list for specialized treatment:

> *Yes, it was also like, there was such a long waiting list for primary care. So I thought...this...this I can start doing right away.* [39]

The affordability of the interventions was also valued, as participants who might not be able to afford a gym membership now have access to a range of exercises to relieve pain [41].

Health Care Decision-Making: "This Made Me Feel Safe to Share Those Thoughts"

Various features of the DHIs improved patient-physician communication during consultations, enabling them to play an active role in making decisions about their health care [35,36,41,46,48,50,52,54,60,63,66,70]. In a web-based intervention, participants noted how the CBT modules empowered them to become more involved in their rehabilitation as they had the tools to have meaningful discussions with their HCP [50]. Symptom tracking proved valuable in accurately portraying trends, highlighting exactly when pain improved or declined, which may provide insights that may have otherwise been overlooked [36,48,54]: "I don't think in that half hour that you've got that consultation doesn't always show the bigger picture of what you're actually dealing with" [36]. Some participants even advised their HCP that they wanted to change their treatment plan because of the intervention: "I said I didn't want the knee replacement yet because I found these exercises—I told him I was doing these exercises and I thought, 'they feel great.' I can walk more. I can do quite a few different things" [41].

Theme 3: Connectedness and Support (an "In-the-Pocket Friend")

This theme articulates how DHIs are valued as a source of ongoing support outside of routine health care appointments, with some participants even describing the intervention as a "friend when in need" [38]. The DHIs were found to be useful in fostering a sense of ongoing support once treatment had ended [55,65]. Others found the interventions helpful in between consultations as they could rely on the digital tool for assistance:

> *After listening to the therapist, I would come home and still have questions or forgot what the therapist said. Then, I had something to fall back on, and that was very pleasant.* [35]

Of the 37 studies, 6 (16%) studies described how the digital format of the intervention made it feel as though they had a digital "friend" or friendly motivating supporter [38,39,41,47,56,65]. In an app-based pain management CBT intervention, participants indicated that they perceived the app as a potential "friend when in need" that could offer social support to help participants feel less lonely: "If you are in a lot of pain, then you are...quite alone...I have felt that you can withdraw and listen to the soothing voice...it has given me a break..., and it has provided relaxation" [38]. Participants appreciated the conversational style of an online pain management program [65]. Another study described the app format as "an in-the-pocket friend" that encouraged participants to keep going:

> *Yes, a bit like an exercise partner who asks 'hey, shouldn't we go work out today?' and then you actually might get going. Where on the other hand, if you were on your own, you might forget about it or take the easy way out.* [56]

Sharing experiences with others was described as "emotionally cathartic" [47] in a social media–based intervention which encouraged participants to interact on various social media platforms.

However, several participants wished to be able to interact with others throughout the DHI, but the intervention lacked the features to do so [62]. Many studies noted how the DHIs lacked HCP communication [39,41,49,56,58,60,62,63,66]. Some participants preferred being able to interact with their HCP as opposed to a virtual agent:

> *For me, this [program] couldn't replace a session with a therapist. Despite that the program was very valuable, I prefer a face-to-face conversation with a HCP, where you can interact with a real person.* [65]

Despite providing a source of ongoing support and social connectedness for many participants, it was highlighted that DHIs should be used as an adjunct to usual care and should not replace routine face-to-face appointments [35,37,42,52,56,60,63,65,66]: "The app is good progress, but it's not yet a replacement of the physical therapist" [35].

A list of studies adhering to each subtheme can be found in Tables 2-4. Multimedia Appendix 7 provides additional participant quotations from the studies illustrating each theme.

Summary of Synthesis

The analytical themes that have been derived from the qualitative synthesis suggest that while many patients report positive experiences of participating in DHIs, the content needs to be tailored to fit the patients' needs otherwise DHIs can have a negative effect on patient outcomes or can lead to poor engagement. This suggests that "a one-size-fits-all" approach

XSL•FO
RenderX

is not always effective in achieving the aims of patients wishing to self-manage their chronic pain symptoms.

DHIs can support the acquisition of knowledge and understanding through improved self-awareness, while encouraging independence and confidence in patients, ultimately stimulating self-efficacy. Accessibility and features that foster motivation, confidence, and promote a sense of ongoing support outside of appointments with HCPs should be prioritized in the future development of DHIs as this is likely to facilitate engagement and improve health outcomes for people living with chronic pain.

Discussion

Overview

This qualitative systematic review aimed to identify, appraise, and synthesize qualitative evidence on the experience of engaging in self-management DHIs among patients with a varying range of chronic pain conditions. The findings revealed that most participants reported a positive experience with DHIs through improved self-awareness, confidence, and independence; through enhanced motivation; and by playing an active role in the management of their chronic pain condition. However, contradictory perspectives exist within each theme, creating a discrepancy as to what features optimize the acceptability of DHIs. These contradictions suggest that for patients to engage with and benefit from digital self-management interventions for chronic pain, it is crucial that content is tailored to the needs of the targeted patient group. The involvement of patients throughout the design and development of DHIs for the self-management of chronic pain could ensure that these needs are met. In the subsequent sections, each theme will be discussed in relation to existing literature and will outline how the results can inform the development and delivery of future DHIs.

Principal Findings

The first analytical theme "personal growth" relates to the personal attributes developed by participating in the DHIs. Patients became more self-aware of how pain impacted other aspects of their life, ultimately leading to a better understanding of their condition and improved pain management [41,58,60,64]. These findings echo the results of a review by Strain et al [28] that explored patients' experience with a range of digital pain management interventions and reported that DHIs enabled people living with chronic pain to become aware of how patterns of behavior could impact their pain symptoms, creating meaningful behavior change. Another review of qualitative studies on user experience with DHIs within psychosis found similar results, suggesting that participants' increased insight allowed them to understand links between their symptoms, mood, and behavior, which equipped them with the tools to better manage their symptoms [71]. On the other hand, many participants did not desire an enhanced level of self-awareness, coinciding with the results of an umbrella review of experiences of DHIs across a range of chronic conditions which found that too much information on a participant's health can be a risk without professional interpretation [72]. This suggests that although features that facilitate self-awareness such as symptom tracking and CBT should be prioritized in the design of future DHIs, caution should be taken during the design phase so that DHIs do not place too much emphasis on negative aspects of health or produce summaries of self-reported symptoms that could be misinterpreted.

Further to the first analytical theme of "personal growth," participant's attitude about their pain improved as patients reported feeling more confident, reassured, and independent. Confidence to communicate pain with others is a crucial factor for people living with chronic pain, who commonly suffer in silence because of barriers to treatment and the associated stigma of a diagnosis [73]. Taylor et al [72] reported similar findings, stating that participants experienced feelings of confidence and reassurance from DHIs across various chronic conditions, as participants could use their logged data to legitimize their reason for contacting an HCP. Patients also became empowered to be more independent [43,51,52,55,56,58,60,65], reporting that they did not have to rely on medication [65] or advice from HCPs [58] as they were able to use self-management strategies to manage their pain. Due to the demands and challenges of living with chronic pain, it is common for patients to lose their sense of "self," as many individuals are unable to upkeep their lifestyle and continue with activities they previously enjoyed [74]. By promoting confidence and enabling participants to become more independent, DHIs can inspire patients to have a more optimistic outlook on life, encouraging them to maintain their usual activities without fear of exacerbating their pain which will ultimately improve their QoL.

Another notable experience was that participants reported gaining a degree of acceptance regarding their diagnosis [38,43,46,51,52,56,69]. Research supports that pain acceptance and optimism are crucial steps toward self-management [75]. A systematic review of the concept of "self" among patients with chronic pain reported that negative evaluations of oneself can lead to more complications with daily functioning, and when an individual views their sense of "self" as more positive, they are more likely to experience better functioning [74]. This idea is further supported by research that states improved self-efficacy and pain acceptance are effective strategies in reducing future pain disability and protecting individuals against chronic pain [76,77]. The findings from this review suggest that patients with chronic pain can benefit from improved pain self-efficacy and acceptance of their diagnosis when engaging with self-management DHIs, and this could carry massive potential in reducing the future burden of pain.

Second, "active involvement" emerged as an analytical theme. This theme highlighted how participants were motivated to engage in positive health behaviors through increased access to self-management resources, as they were able to actively manage their pain outside of a health care setting. Strain et al [28] also reported that digital pain management interventions encouraged participants to play a more active role in their care, strengthening the idea that digital health can be an effective means of alleviating the strain on the health care system by encouraging people living with chronic pain to take control into their own hands. The importance of taking action to reduce chronic pain symptoms was demonstrated in a population-based study, which showed that patients who relied on passive coping

XSL•FO
RenderX

strategies (such as pain medication and rest) had as many as 3 times the amount of health care appointments and double the level of disability compared to those who adopted active coping strategies such as exercise [78]. In particular, exercise-based interventions that encouraged participants to hit daily exercise targets were found to be motivating [35,41,52,56-58,62,63,69]. In many of the studies, notifications motivated participants to engage with the digital tool [34,35,39,41,43,49,57,59,63], a finding consistent with other reviews on patients' experiences with DHIs [71,72]. On the other hand, notifications caused unnecessary distress for some, particularly when targets had not been reached [41,49]. By stimulating motivation to engage in health behaviors that could improve levels of pain, DHIs could potentially play a major role in improving pain-related outcomes in people living with chronic pain. However, it is important to set realistic and achievable goals, as unobtainable targets run the risk of creating an adverse effect on motivation [63]. These findings suggest that participants should be given the option to customize the frequency of notifications to align with their treatment goals, as this will avoid notifications having a negative effect and hindering engagement.

Access to specialized pain services poses a barrier to effective treatment, with many patients reporting low satisfaction with the quality of pain management care they receive because of long waiting times and lack of interest from HCPs [8]. The flexibility of being able to choose when and where to engage in the various self-management techniques motivated participants to take control of their symptoms at a time that suited them [38,39,50,51,59,65].

Another way that the participants felt that they were playing a more active role in their health care was by contributing more during consultations with HCPs. Equipping patients with tools that enable them to actively participate in health care discussions will ensure that their treatment is personalized to their specific needs, which has the potential to improve various health outcomes.

The third analytical theme "connectedness and support" outlines how DHIs were found to be useful in fostering a sense of ongoing support between health care appointments and at the end of treatment [35,55,65]. Social support is crucial in the treatment of chronic pain as research indicates that higher levels of social support are associated with lower levels of pain [79]. A systematic review exploring factors affecting engagement suggested that technology supporting human interaction with both peers and HCPs could promote engagement and enrollment as this allows users to obtain social support quickly and effectively [80]. The findings from this review demonstrate that DHIs are effective tools for facilitating social support, although social support in the included articles was perceived through time spent with family and friends and communication with virtual avatars embedded into the interventions, which many participants referred to as a virtual "friend." Most studies included in the review lacked features that allowed participants to directly interact with other patients within the intervention. In the one study that facilitated sharing experiences with others, participants described being connected with others as "emotionally cathartic" [47], although it should be highlighted that this study scored poorly on the CASP appraisal tool; therefore, these findings should be interpreted with caution. This is in line with the findings of a review exploring social media uses for various health purposes, which reported that online communities can provide invaluable advice by offering emotional support as well as sharing information such as medication, diagnosis, treatment options, and self-care activities [81].

Chronic pain is often regarded as an "invisible illness," with many patients having faced skepticism and suspicion of exaggeration or even accused of lying about their condition [82-85]. Therefore, it is important that patients with chronic pain obtain support from others in a similar position as only those with lived experience can truly comprehend the extent to which chronic pain interferes with daily life. Strain et al [28] reported similar findings, stating that interactions with other users or with HCPs have the potential to reduce anxiety and loneliness, although the anonymity offered through DHIs was also valued; therefore, it could be that users have the option to stay anonymous. Features enabling communication with HCPs might facilitate patient engagement and continued use as many patients reported an impersonal feel to DHIs as they were unable to receive feedback and did not experience accountability. Others mentioned a preference for being able to interact with an HCP as opposed to a virtual agent [65]. The inclusion of interactive features could stimulate the sense of ongoing support; however, DHIs should enhance traditional face-to-face care as opposed to serving as a replacement. Future DHIs could incorporate an element of interaction with HCPs that could be continued into routine appointments allowing for more effective consultations.

Limitations

This review should be interpreted with caution, as several limitations exist. First, this synthesis only included studies from 2013 onward in an attempt to capture the most relevant and up-to-date DHI systems that have been developed over the last decade. Consequently, the findings reported in this review may not reflect the experiences of patients with chronic pain who engaged with digital self-management interventions before 2013, which could be dramatically different due to advancements in digital technology. Second, as with all qualitative syntheses, this review relies on secondary data that were analyzed through a varying range of theoretical underpinnings and methods of data analysis [86]. Another limitation of this review is that the diversity of the samples, which included a range of chronic pain conditions, made it challenging to identify which DHI would be the most beneficial for each individual patient group. Furthermore, the DHIs encompassed multiple intervention components, which were often intertwined and difficult to separate in the results. Therefore, this review could not always draw conclusions about which intervention components elicited which experiences, reducing the richness of the findings. Another limitation was that many of the studies did not report the frequency and duration of the intervention, nor how long after the intervention the qualitative data were collected. Thus, it is unknown whether the timing or frequency of the DHI influenced the patient experience. Of the 33 included studies that did detail the intervention length, only 1 (3%) study was conducted for 12

XSL•FO
RenderX

months, with the remaining studies lasting ≤6 months; therefore, the long-term experience of DHIs for the self-management of chronic pain could not be synthesized and remains not fully understood. Future trials should explore the experience of DHIs for the self-management of chronic pain over a period of 2 years to fully grasp the long-term experience of these interventions. The largest sample size was 36 participants, with 86% (32/37) of studies obtaining samples of <30 participants. It is important to consider sampling bias that may have occurred among the studies with small samples, and that the results may not be representative of all patients with chronic pain. Future studies should involve larger samples so that the results can be generalized to the larger population. Another limitation to consider is that most of the studies were conducted in high-income countries, as the implementation of DHIs in low- and middle-income countries presents several challenges, such as resource limitations and costs [87].

Conclusions

The findings from this systematic review and thematic synthesis suggest that DHIs for the self-management of chronic pain elicit mostly positive experiences among people living with chronic pain; however, opinions on which features are optimal for improving pain outcomes are diverse, highlighting that a "one-size-fits-all" approach is not effective. Personalized content should be incorporated to ensure that DHIs address the needs of this patient group, and content should be customizable to avoid negative effects on adoption and engagement. This could be achieved by involving patients in the early stages of intervention design and development; therefore, a co-design approach for the creation of future DHIs for the self-management of chronic pain is advised. The results of this review can be used to inform the development of future DHIs, suggesting that such DHIs should be accessible, convenient, and flexible and be easily integrated into patients' lives without exacerbating the burden on those already coping with a range of challenging symptoms. Intervention components, including CBT, symptom tracking, exercise programs, and educational content should be prioritized. These features have demonstrated improvements in patients' self-awareness, confidence, independence, and acceptance, all while fostering motivation to engage in positive health behaviors, decisions about treatment and care with HCPs, and the feeling of being supported outside of routine health care appointments. The findings from this review point to a lack of social networking functionalities with both peers and HCPs in DHIs for the self-management of chronic pain, suggesting a potential gap in the research. Further investigation surrounding the availability of such social features should be conducted, as social networking functionalities could provide a means of support that could relieve the burden on both HCPs and services.

Acknowledgments

The authors would like to acknowledge the University of Strathclyde librarians Elaine Blair from the Faculty of Science and Sarah Kevill from Humanities and Social Sciences for their invaluable assistance in developing the search strategies for this review. This systematic review is part of an ongoing PhD studentship funded by the Dr David Stirling Health Research Fund aimed at supporting research into chronic pain.

Abstract

Background: Chronic lung disease (CLD) is one of the most prevalent noncommunicable diseases globally, significantly burdening patients and increasing health care expenditures. Digital health education (DHE) is increasingly important in chronic disease prevention and management. However, DHE characteristics and impacts in CLD are rarely reported.

Objective: This study aimed to provide an overview of the existing literature on DHE for CLD, with a focus on exploring the DHE mediums, content, mechanisms, and reported outcomes in patients with CLD.

Methods: We searched PubMed, Web of Science, Embase, PsycINFO, and The Cochrane Library with the assistance of a librarian specialist. Articles were screened by the reviewer team with ASReview (Utrecht University) and EndNote X9 (Clarivate Analytics) based on predefined inclusion and exclusion criteria and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. Quality assessment was conducted with the Critical Appraisal Skills Program tool. A descriptive analysis was used to summarize the study characteristics, DHE characteristics, and outcomes.

Results: A total of 22 studies were included in this review with medium or high quality. They were published between 2000 and 2022, showing an increasing publication trend with the year, mostly in developed countries (16/22, 73%). Websites and mobile apps (10/22, 45%) were the most widely used DHE medium. Education on self-management skills of CLD was the primary topic (21/22, 95%), 4/22 (18%) of which mentioned DHE mechanisms. The majority of studies reported positive changes in CLD awareness (14/16, 88%), clinical outcomes (3/6, 50%), DHE feasibility, acceptability, and satisfaction (6/8, 75%), lifestyle outcomes (3/3, 100%), and psychosocial outcomes (7/8, 88%). Only 2 studies reported cost-effectiveness (2/22, 9%).

Conclusions: Despite the heterogeneity of the study situation, some aspects can be concluded. DHE can improve disease awareness and clinical outcomes in patients with chronic lung disease, with good feasibility, acceptability, and satisfaction through different mediums and learning content. There is still relatively little research among people in low- and middle-income countries. Future research should consider the impact on cost-effectiveness, duration, frequency, and theoretical mechanisms of the DHE to maximize the potential impact. It should also be conducted in the context of health services research to better reflect the real world.

Introduction

Chronic lung disease (CLD) is one of the most prevalent noncommunicable diseases globally, placing a large burden on patients and increasing health care expenditures, primarily including chronic obstructive pulmonary disease (COPD) and asthma. The total number of deaths due to CLD increased by 18% during the past 3 decades, with the highest mortality and disability-adjusted life years in regions with a low sociodemographic index, mainly in Africa, Middle East, Central Asia, Southeast Asia, and South America, also namely low- and middle-income countries (LMICs) [1-3]. Smoking, air pollution, and occupational exposure were the most significant risk factors for CLD [4]. Considering the acute exacerbations [5], complicated comorbidities, and increasing costs of CLD [6], raising disease awareness and promoting healthy lifestyles through health education and management is crucial to improving people's health conditions among patients with CLD and the general population.

Digital health education (DHE) offers knowledge or skills about health and health care in a timely and cost-effective manner by using all kinds of information and communication technologies (computer-assisted learning, mobile learning, and digital simulation-based learning), which is increasingly important in disease prevention and management [7]. With the accessibility of the internet and the popularity of advanced electronic or digital technology, diverse DHE mediums have emerged, such as websites, multimedia, and mobile apps, providing learners with health information and instant feedback [8-11]. In addition, many studies reported a potential positive impact of digital health interventions on various diseases and mental health status, including improving people's knowledge, skills, adherence, and other health-related outcomes [12-15]. However, despite the benefits of digital health intervention, the evidence is scarce regarding the characteristics and impact of DHE, especially in patients with CLD.

Currently, suboptimal disease control in patients with CLD is noticed due to their lower medication adherence and incorrect use of inhaler devices, which further contribute to increased exacerbation and hospitalizations [16]. This highlights the importance of DHE to deliver continuous and efficient educational content that helps them better understand their condition and treatment regardless of time and space. However, to the best of our knowledge, no reviews have focused on the characteristics and impact of DHE on CLD. It is essential to conduct a review to understand what aspects of DHE have been explored that could facilitate or hinder their adherence. Furthermore, previous studies on digital health interventions in CLD focused on multidimensional interventions combining disease education with monitoring, coaching, and self-management [17-19]. A review is needed to know if DHE could also lead to significant changes, making a rationale for not giving all patients a multidimensional and, thereby, costly intervention.

Therefore, for this study, we aim to review the existing literature on DHE for CLD, with a focus on exploring the DHE mediums, content, mechanisms, and reported outcomes in patients with CLD. Specifically, we intend to address the following research questions: (1) What are the reported characteristics of the DHE for patients with CLD, in terms of type of DHE mediums, content, duration, frequency, and mechanisms? (2) What outcomes are reported in terms of the impact of DHE on patients' knowledge of CLD, treatment, management, and health-related outcomes? (3) What is known about the feasibility, acceptability, and patient satisfaction of DHE for patients with CLD?

Methods

Study Selection

Search strategies were developed with a medical information specialist from Leiden University Medical Center. Searches were conducted in PubMed, Web of Science, Embase, PsycINFO, and The Cochrane Library combining key search terms "chronic lung disease," "digital technology," "health education," and related terms. To ensure a comprehensive scope by covering all relevant studies on DHE for CLD and capturing a full breadth of the topic, studies were searched from inception to the day we conducted the search (February 26, 2023) without starting time limits. The complete search strategy is available in Multimedia Appendix 1. Literature screening was performed with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [20] checklist (Multimedia Appendix 2). Inclusion and exclusion were performed according to the Participants, Intervention, Comparison, and Outcomes (PICO) strategy [21], shown in Textbox 1.

After removing duplicates, one reviewer (CS) used the open-source machine learning tool ASReview Lab19 [22] to screen all the titles and abstracts. Another reviewer (RL) used Endnote X9 to double-screen a random proportion of all articles independently. The choice of 15% was made by the reviewer team to ensure the efficiency and reliability of screening based on ASReview developers' recommendations [23] and previously published articles that screened the same way [24]. If the agreement rate between the 2 reviewers was less than 80%, an additional random 15% of all titles and abstracts were screened by RL. Title and abstract screening were stopped only when the agreement rate exceeded 80%. Then, the included articles were selected by screening the full text by CS and HD. CS then screened all references of included articles to identify if extra articles could be included. Any discrepancies during the screening process were solved by achieving consensus or discussing with the review team.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion

- Participants: people diagnosed with chronic lung disease by a clinical professional.
- Intervention: digital health education focused on chronic lung disease (providing knowledge or skills about health and healthcare by using information and communication technologies).
- Comparison: no restriction.
- Outcome: all outcomes.
- Study design: randomized or nonrandomized controlled trials, qualitative and quantitative studies, mixed methods studies, observational studies.

Exclusion

- Not digital health education intervention or blended intervention (eg, interventions that combine education and skills training) that include less than 50% digital health education.
- Studies with subjects <18 years of age.
- Commentaries, reviews, letters, dissertations, editorials, conference proceedings, books, and protocols.
- Not published in English.
- No full text is available.
- Not peer-reviewed articles.

Justification

- To ensure a comprehensive review, different study designs were considered: qualitative studies can be used for exploring patients' experiences, opinions, and attitudes. Quantitative studies can be used to explore the impact of digital health education on chronic lung disease.
- We excluded participants aged less than 18 because there are fewer digital health education interventions directly targeting children with chronic lung disease, but more at their parents, teachers, or pediatric-care professionals.
- Studies with no full text cannot provide complete information about their methods, results, and conclusions.
- A systematic search (query of experts, professional societies, service providers, etc) of non–peer-reviewed publications could not be carried out for reasons of research economics.

Data Extraction

Reviewer teams (CS, HD, and HW) extracted data with a predesigned standardized data extraction form (Multimedia Appendix 3). Study characteristics (author, publication year, country, profession, study design, sample size, and population levels) were extracted to understand the specific context of each study and assess the relevance, research development, and quality. DHE characteristics (type of DHE medium, content, intervention mechanisms, duration, and frequency) were extracted to understand what aspect of educational platform, content, and behavioral theories were used and how. Outcomes, main findings, and conclusions of included studies were extracted to analyze the impact of DHE on patients with CLD.

Data Synthesis

Study characteristics and DHE characteristics were summarized using means and percentages where appropriate. Outcome indicators were summarized in 6 categories. CLD awareness evaluated patients' ability to perceive or to be conscious of CLD or health states (eg, health literacy). Clinical outcomes included physiological and biochemical indicators measured by clinical testing and laboratory equipment (eg, blood pressure, forced expiratory volume [FEV]). Feasibility, acceptability, and satisfaction [25] focused on the design or the development of DHE, evaluating the state or degree of being easily or conveniently used, being subject to acceptance, and the expectations, needs, and pleasure of patients. Lifestyle outcomes included diets, sleep, medication adherence, and physical activity. Cost-effectiveness evaluated the cost expenditure of patients or health care systems on the whole process of disease prevention, treatment, and management. Psychosocial outcomes were observed effects on patients' emotions, well-being, quality of life (QoL), behavior or social interactions [26]. The impacts of DHE were categorized as positive, negative, or no significant difference based on the extracted results and conclusions. Descriptive analysis was used to summarize all the coded data.

Quality Assessment

The Critical Appraisal Skills Program (CASP) checklist was used and adapted for appraising the evidence of different study designs [27]. Following CASP tool recommendations, we classified the evidence quality as high (more than 2/3 of questions are answered by "yes"), moderate (more than 1/3 of questions are answered by "yes"), or low (lower than 1/3 of questions are answered by "yes").

Results

Study Characteristics

A total of 22 articles were included in this scoping review (Figure 1), consisting of 19 interventional studies (9 randomized controlled trials [RCTs], 7 quasi-experimental studies, and 3 prospective interventional studies) and 3 mixed methods studies.

XSL•FO
RenderX

These studies were published between 2000 and 2022 in health care or related professions, showing a distinct increasing trend with the highest number after 2020 (n=11). Details of included articles and the trend of publication year were shown in Multimedia Appendix 3. Among these studies, only 27% (6/22) were conducted in LMICs, with China, India, Indonesia, Lebanon, and Iran 1 or 2, respectively (Figure 2). United States accounted for 32% (7/22) of these studies among developed countries. The sample size of the studies varied from 15 to 9452 participants, of which the population level ranged from hospitals, and clinics to general practices, communities, and recruited volunteers. By following the CASP checklist, all studies were medium (n=4) to high quality (n=18). Further details can be found in Table 1 [28-49] and the quality assessment process was described in Multimedia Appendix 4.

DHE Mediums, Intervention Mechanisms, and Contents

Regarding DHE mediums among the 22 studies, 10 (45%) of them were websites or web-based platforms developed by researchers, along with 6 (27%) studies delivered by mobile applications or tablets, 5 (23%) by video or text messaging, and 1 (5%) by MP3 (Table 2 [28-49]). No more than half (9/22, 41%) of studies conducted DHE for over 3 months. Only 7 studies reported intervention frequency and 4 provided DHE based on the "teach-to-go" strategy, Theory of Planned Behavior, and self-regulation.

Table 2. Digital health education characteristics of included articles.

[b]SARA: Service Apothecary Respiratory Advice.

Different contents of DHE in CLD were summarized and divided into several categories (Multimedia Appendix 5). Self-management skills of CLD (21/22, 95%) were the most common educational content, including managing general CLD conditions (20/22, 91%), and exacerbations or asthma attacks (7/22, 32%). Treatment of CLD, disease characteristics, motivational messages, or stories were imparted in 15, 15, and 5 studies, respectively. Specifically, medicine or inhaler education (14/22, 64%) was the most frequently mentioned topic about CLD treatment, followed by breathing exercises or physical activity (5/22, 23%) and psychosocial therapy (3/22, 14%).

DHE Outcomes for Chronic Lung Disease

After classification and synthesizing, we found that 16/22 (73%) studies explored participants' CLD awareness. Clinical outcomes (6/22, 27%), DHE feasibility, acceptability, and satisfaction (8/22, 36%), lifestyle (3/22, 14%), cost-effectiveness (2/22, 9%), and psychosocial outcomes (8/22, 36%) were also reported in different studies.

CLD Awareness

Fourteen out of 16 studies reported positive changes in CLD awareness. Among them, 9 interventional studies noticed a statistically significant increase ($P<.05$) when evaluating CLD knowledge, literacy, and skills in the intervention group compared with the control group [28,32,35,39,40,42,45,48,49].

XSL•FO
RenderX

In a cohort study, Mongiardo et al [29] found a significant improvement in knowledge about exercise, vaccination, inhaled bronchodilators, and inhaled steroids (P<.01) at 12 months among patients with COPD who used a COPD web-based platform that delivers education as part of a physical activity intervention. Similar results were reported in the study by Hsia et al [41,43] by measuring Asthma Knowledge Questionnaire scores among patients with asthma who used ASTHMAXcel—a novel, guidelines-based smartphone app designed to improve patient education and outpatient management of asthma. Chan et al [46] also evaluated an adapted ASTHMAXcel and got the same result using Asthma Knowledge Questionnaire scores among patients with asthma in India. The mean score of patients' self-management knowledge of patients with asthma was significantly increased to 4.3 (SD 0.56; P<.001) after using a smartphone-based app, according to the mixed methods study by Farzandipour et al [34]. When evaluating knowledge and skills after a 6-week home-based educational and telemonitoring program, most of the participants answered correctly [35]. However, Korsbakke Emtekaer Haesum et al [37] reported no statistically significant difference in functional health literacy between the intervention and control group when they focused on the effect of the Telekit—a tele-homecare intervention combining a tablet and software that provided information and instructions on managing COPD. No significant differences in COPD knowledge were noted between the pedometer plus website group and the control group in the RCT by Wan et al [38].

Clinical Outcomes

In total, 3 out of 6 studies reported positive clinical outcomes of DHE. These clinical outcomes mainly included changes in the impact of COPD in daily life evaluated by the COPD Assessment Test [28], FEV, forced expiratory volume in 1 second (FEV1)/forced vital capacity (FVC), peak expiratory volume, 6-minute walking distance [31], clinical parameters (systolic and diastolic blood pressure, pulse, FEV1, FVC) [37], dyspnea [38], exacerbation rates, antimycotic treatment difference [44], change in walking capacity [47]. In an RCT, patients with COPD who received a web-based animated diagram and video-guided instruction showed significant improvements in FEV, FEV1/FVC, and peak expiratory volume compared with patients who received conventional education (P<.05) [31]. In addition, a significantly lower increase in exacerbation rates over time was found compared to the control participants in participants with asthma but not in individuals with COPD [44]. The walking capacity also showed statistically significant improvements (P<.05) within the intervention group measured by the Incremental Shuttle Walk Test after a home exercise video program among patients with moderate to severe COPD [47]. According to Andre et al [28], however, the mean scores of COPD Assessment Test were not highly reduced in patients with mainly moderate COPD, and the difference is statistically insignificant between the baseline and 3-, and 12-month time point. There were also RCTs providing information on managing COPD by a tablet and a website with no statistically significant difference in clinical outcomes, although the intervention duration lasted for several weeks and even 3 months [37,38].

DHE Feasibility, Acceptability, and Satisfaction

In total, 6 out of 8 studies indicated a positive effect on DHE feasibility, acceptability, and satisfaction. In the study by Nyberg et al [28], the feasibility analysis of a COPD web page on self-management skills combining texts, pictures, videos, and interactive components was primarily focused on the number of users and the total time they spent on the site during the initial 3 months, showing that 77% (33/43) of patients having access to the COPD Web were considered users and the average total time on the site was 45 minutes, which was quite low. Another feasibility study of a novel experience-based internet intervention to support self-management in chronic asthma was also relatively low, reporting that the median number of logins during 2 weeks was 2, and the median amount of time spent on the site was 17 minutes [36]. In addition, the e-Health Impact Questionnaire scores they used to measure the respondents' attitudes toward the website were quite similar between groups. Satisfaction, ease-of-use, and usefulness were assessed when analyzing the acceptability of an education website AsthmaWise for older asthma adults, of which 69% (35/51) had decided to visit it to learn more about how to manage their asthma, 94% (48/51) found it useful and almost all participants would recommend it to others [32]. Wu et al [33] developed a virtual teach-to-goal inhaler technique learning module and found that over 80% (39/48) reported that they were likely to use virtual teach-to-goal inhaler technique learning module to gain skills to improve their health. Furthermore, they identified several domains from focus groups for optimal patient use: access, functionality, and quality. In a quasi-experiment, all 15 participants considered the educational and telemonitoring program adequate and acceptable, declaring they had no difficulty explaining it to others and would suggest it to others [35]. The satisfaction rate regarding an audio-educational method (82%, 291/357 vs 66%, 235/356; P<.05) and effective feedback (83%, 68/82 vs 53%, 42/80; P<.001) were significantly higher in the experimental group than in the control group for patients from respiratory medicine wards [42]. Patients were highly satisfied in the ASTHMAXcel group, scoring on average 27.9 out of 30 points on the satisfaction survey, but no difference was found in either intervention [43]. An average of 50 out of 54 maximum points was noted based on the questionnaire for user interface satisfaction about participants' postinterventional median satisfaction for the adapted ASTHMAXcel [46].

Lifestyle

All (3/3) studies reported positive changes in patients' lifestyle. When evaluating the effect of a COPD web in promoting self-management of patients, the amount of daily physical activity and time spent in training exercises in the intervention group at 3 months was increased compared with the usual care group, but not statistically different at 12 months [28]. The daily step count in the pedometer plus website group also significantly improved from baseline beginning and maintained to week 13 based on the theory of self-regulation [38]. When comparing medication adherence in the year after the implementation of an eHealth intervention, Service Apothecary Respiratory Advice, both study groups showed an increase in mean medication adherence over time. Especially, it was significantly higher for

XSL•FO
RenderX

Service Apothecary Respiratory Advice participants (P=.01), according to Schnoor et al [44].

Cost-Effectiveness Outcomes

Only 2 studies evaluated the cost-effectiveness of DHE. A study conducted in Lebanon estimated the overall cost of the educational and telemonitoring program was US $200 per patient (educational sessions only) and US $244 per patient (including telemonitoring services), which consisted of the general cost of materials or patients, time nurses spent on patients, hospitalizations and emergency department visits [35]. However, it was difficult for them to evaluate this intervention's relative cost given the complicated economic situation in Lebanon. The other study reported that all health care utilization endpoints, including asthma-related emergency department visits, hospitalizations, and oral prednisone use, decreased at 4 months and 6 months based on survey results [41].

Psychosocial Outcomes

Improved psychosocial outcomes were reported in 7 out of 8 studies. Notably, QoL, usually evaluated by self-reported questionnaire, was the most frequent outcome in these studies. In total, 7 out of 8 studies reported improvement in the intervention group or at the follow-up point [30,31,35,36,38,41,47]. A total of 5 of 15 patients showed lower anxiety and depression scores, and 6 had higher QoL scores compared to baseline measures, according to Rita's study [35]. Minimal differences of change from baseline between groups were noticed regarding how well patients with asthma manage their condition and self-efficacy of being able to undertake certain activities [36]. Wan et al [38] also compared health-related QoL, exercise self-efficacy, depression, social support, motivation, and confidence to exercise, but no significant differences were noted between groups. All participants showed an increase in health state from baseline based on the physical and mental component of the 36-Item Short Form Survey (including physical and mental dimensions), with a more significant improvement in the intervention group that provided a multimedia website illustrating asthma-related information [36]. No other psychosocial outcomes were analyzed in these studies.

Discussion

Principal Findings

Current evidence presents comprehensive characteristics and the potentially positive impact of DHE on CLD. A total of 22 published studies with medium to high quality from 2000 to 2022 were analyzed in this review, including 9 (41%) RCTs, 7 (32%) quasi-experimental studies, 3 (14%) mixed methods studies, and 3 (14%) prospective interventional studies. Most studies (16/22, 73%) were conducted in developed countries. Websites and mobile applications (10/22, 45%) were the most widely used medium to conduct DHE among patients with CLD, followed by mobile apps or tablets, video or text messaging, and MP3. Participants were mainly patients with CLD recruited from hospitals and general practices. No more than half of these studies (9/22, 41%) implemented DHE interventions for more than 3 months, and few (3/22, 14%) were based on theoretical mechanisms when educating the target population. The DHE content varied from a general introduction of CLD characteristics (definition and etiology), and treatment to self-management skills of CLD, motivational messages, and stories for patients and their relatives. Positive impacts were reported among most of these studies, including increased CLD awareness (14/16, 88%), clinical (3/6, 50%), lifestyle (3/3, 100%), psychosocial outcomes (7/8, 88%) and impressive feasibility, satisfaction, and acceptability (6/8, 75%). Only 2 studies reported cost-effectiveness outcomes.

Comparison With Previous Work

The growing number of publications pertaining to DHE in CLD and the widespread use of websites and mobile apps shed light on an increasingly important role of digital technology in health and health care. As of January 2023, there were 5.16 billion internet users worldwide, over 60% of the global population currently connected to the world wide web with an estimated 192 minutes per day per user spent on the web [50]. In addition, integrating digital technology in health care is revolutionary by providing easy access to health services, improving patient engagement, supporting remote supervision of physical activity regimes at home, delivering timely detection of deteriorating health status, and serving as a cost-saving alternative health service [51]. Although not mentioned in included studies, the integration of artificial technology (AI) in health care, which is another promising DHE medium, holds a significant potential to deliver more efficient and personalized educational content through advanced algorithms and predictive analytics [52,53]. Therefore, users could access a diverse range of health information with better accessibility, efficiency, and interactivity. The increasing trend of exploring the impacts of DHE intervention will continue in future research.

More attention should be paid to implementing and scaling DHE to LMICs and the general population with limited access to digital technology. As reported, the internet penetration rate of China was relatively low at 76% compared with South Korea and Japan, which ranged over the 90% mark, although it is home to the largest digital community in the world, with about 1.07 billion netizens as of 2022 [54]. The same pattern is apparent in Southeast Asian countries with little internet accessibility at home and low self-perceived digital literacy among Southeast Asian youth, thereby reducing health care engagement and hindering health information dissemination for the local people [55]. Larger gains in health can be achieved in these areas due to the huge population underserved, which could also contribute to global health in the future. Furthermore, new opportunities and challenges are presented when scaling up DHE with the increasing aging population and worldwide health problems. Digital technologies play an increasingly important role not only in health education and promotion but also in addressing issues of health equality [56].

Future studies should further elucidate DHE characteristics and mechanisms to ensure long-standing effectiveness and verifiable impacts. First, the predominance of DHE contents focusing on self-management skills of CLD highlights the importance of empowering individuals to take an active role in their own health, which corresponds to the current research trends of

XSL•FO
RenderX

chronic diseases [57,58]. Second, successful health education depends on repeatedly using a few messages of proven benefit in many forums [59]. As such, the DHE content and the authenticity of contents should be warranted, of which the latter was rarely mentioned. As an essential health education component, DHE frequency, duration, and intervention theories are closely connected with prospective health outcomes. Several existing models, such as the Unified Theory of Acceptance and Use of Technology, Technology Acceptance Model, Social Cognitive Theory, and Theory of Planned Behavior, have been identified as facilitators of adopting digital health interventions [60]. Specifically, interventions based on the theory of planned behavior tended to have more substantial effects on behavior compared to interventions incorporating fewer techniques [61]. In this review, however, few studies illuminated the frequency (7/22, 32%) and intervention theory (4/22, 18%), indicating a potential gap in understanding how DHE interventions work and the underlying mechanisms that impact patients with CLD and related outcomes.

The effects reported on awareness or knowledge are commonly acknowledged [62-64] because digital technologies can support a wide range of self-directed learning activities, providing learners with diverse resources, information, and network resources that meet their learning needs [9]. Improvement in clinical outcomes suggests the potential of DHE to empower patients to make informed decisions about their health, adhere to treatment regimens, and adopt healthier lifestyles after enhancing their understanding of disease and health conditions. Similar positive effects in QoL and health status were also reported in other reviews, but they mainly focus on digital health interventions [65,66]. Insignificant effects in several studies might be related to the intervention duration or inclusion of participants [37,38,44]. The reported impacts on DHE feasibility, acceptability, and satisfaction shed light on users' active engagement and willingness with these interventions. These positive findings align with other studies [67,68], indicating that DHE is generally well-received by individuals with CLD and implies promising practicality and scalability in real-world settings.

A limited number of studies reported impacts on lifestyle (n=3) and cost-effectiveness outcomes (n=2) in this review, which needs more evidence to illustrate in the future. The lifestyle outcomes extracted from the included studies were limited to physical activity and medication adherence. According to previous studies, however, a sedentary and unhealthy lifestyle, including smoking, having an unhealthy diet, and insufficient exercise could fuel chronic disease progression by changing interstitial cell behavior [69]. In addition, we noticed that only one study applied behavioral theories but implemented DHE for only 2 months when exploring DHE impacts on lifestyle [32]. However, evidence has shown that a successful digital intervention can influence lifestyle management [70], and the theory of behavior change maintenance can guide the development and evaluation of interventions, thereby promoting sustained change in health behavior and lifestyles [71]. As such, a deeper exploration of specific lifestyles, such as the dietary pattern, types, frequencies, and intensities of exercise and other health-related outcomes should be mapped, with validated and effective theories. Currently, few studies in this review compare the cost or health care utilization after DHE intervention, which guided future cost-effectiveness studies with more accurate and complete data to fill in the gap.

Recommendation on Future Research

Based on the current review, we recommend that future research and development in DHE for people with CLD should focus on elucidating the characteristics and mechanisms of the DHE intervention, prioritizing less developed areas, investigating more lifestyle or behavioral outcomes, evaluating cost-effectiveness among different DHE mediums and ensuring long-term sustainability, to ultimately improve the effectiveness, scalability of DHE, and the health status of patients with CLD. With the integration of AI in health care, we hope to see more personalized and efficient education content delivered and look forward to studies reporting its potential and effectiveness. Given that several studies were of medium quality based on the CASP tool, we recommend future researchers consider incorporating blinding among participants, investigators, and analysts, as well as addressing confounding factors in both study design and analysis, which will enhance the robustness and reliability.

Strengths and Limitations

This is the first review to explore the characteristics and impact of DHE on CLD. Diverse studies in this review were synthesized and analyzed under the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guideline, all showing medium or high-quality evidence with a practical quality assessment tool. The detailed descriptions of DHE and its impact on different outcomes provide an important theoretical basis and new thoughts for further research in DHE. However, this review included studies focusing more on mixed digital health intervention. Despite the potential benefits, whether it is the independent or compounding influence of DHE remains to be discussed further due to the inability of subgroup analysis. The incomplete screening of titles and abstracts by the second reviewer may have introduced potential bias into the review process. The exclusion of non-English articles and studies without full-text access could result in publication bias to some extent. In addition, it is worth mentioning the caution of extrapolating the impact to other DHE mediums, despite recognizing the reliability of health information in these studies. Variations in researchers' profession might also contribute to heterogeneity in study implementation and reporting.

Conclusion

Despite the heterogeneity of the study situation, some aspects can be concluded. DHE can improve disease awareness and clinical outcomes among patients with chronic lung disease with good feasibility, acceptability, and satisfaction through different mediums and educational content. There is still relatively limited research among people in low- and middle-income countries. Future research should consider the impacts on cost-effectiveness outcomes, duration, frequency, and theoretical mechanisms of the DHE intervention to maximize the potential effects. It should also be conducted in

XSL•FO

the context of health services research to better reflect the real-world settings.

Acknowledgments

We would like to acknowledge Claudia Pees (medical information specialist from Leiden University Medical Center) for helping with search strategies and the developers of ASReview for providing technical assistance. This study is funded by the China Scholarship Council. No generative artificial intelligence was used in any portion of the manuscript writing.

Data Availability

All data generated or analyzed during this study are included in this published article and Multimedia Appendices 1-5.

Authors' Contributions

CS led the study design, and data analysis and is the main author of manuscript writing; HD, RL, and HW contributed to the literature screening and extracting; RK, SW, CH, and NC contributed to the study design and conception, editing, and proofreading. All authors read and approved of the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Osteoarthritis (OA) is characterized by pain, functional impairments, muscle weakness, and joint stiffness. Since OA heightens reliance on heath care resources and exacerbates socioeconomic burden, remote OA rehabilitation using digital technologies is rapidly evolving.

Objective: The aim of this study was to analyze the efficacy of behavioral therapy–based digital interventions for patients with OA.

Methods: This study is a systematic review of randomized controlled trials (RCTs) that assessed the effects of behavioral therapy–based digital intervention tools for OA. These RCTs were searched from inception to June 2023 in the Web of Science, Embase, Cochrane Library, Ovid, and PubMed databases.

Results: Ten eligible RCTs comprising 1895 patients with OA were included. Digital tools based on either cognitive behavioral therapy (CBT) or behavior change technique (BCT) were investigated. All studies demonstrated low-to-moderate effects on pain reduction in the short term (standardized mean difference [SMD] –0.20, 95% CI –0.35 to –0.05). Six studies reported improvement in physical function (SMD –0.20, 95% CI –0.41 to 0.00), and 5 confirmed increased pain self-efficacy (SMD 0.22, 95% CI 0.02-0.42). In subgroup analysis, compared with CBT, BCT-based digital interventions demonstrated their effects on pain reduction (SMD –0.25, 95% CI –0.49 to 0.00) and physical function (SMD –0.26, 95% CI –0.54 to –0.01) in the short term. In addition, physiotherapist involvement in treatment had a positive effect on pain control (SMD –0.14, 95% CI –0.27 to –0.02). Furthermore, web-based digital tools improved physical function in the short term (SMD –0.28, 95% CI –0.54 to –0.01).

Conclusions: Moderate- and low-quality evidence supported that behavioral therapy–based digital tools improved pain intensity, physical function, and self-efficacy in the short term. However, affective interactions between patients and professionals may affect the clinical outcomes.

Introduction

Osteoarthritis (OA) is a prevalent joint disease affecting 29.7% of the population older than 40 years [1]. OA is characterized by pain, functional impairments, muscle weakness, joint stiffness, and reduced health-related quality of life (HRQoL) [2,3]. This causes heightened reliance on heath care resources and exacerbates socioeconomic burden [4,5]. Recent patient-centered guideline updates advocate for the implementation of rehabilitation interventions, including exercise therapy and educational programs as recommended nonpharmacological and nonsurgical treatment options [6,7]. These guidelines place a strong emphasis on the role of physical exercise, self-efficacy, and self-management strategies in the rehabilitation process for individuals with OA [8,9].

Psychological evidence–based auxiliary therapies have been integrated into the rehabilitation process to enhance rehabilitation outcomes [10]. These therapies provide a potent means of reinforcing patient education and behavior change. Behavioral theories, rooted in the social psychology of behavior change, are implemented as psychological evidence–based auxiliary therapies aimed at optimizing the positive components of interventions targeting patient health behaviors [11]. Many therapists incorporate physical therapy with behavioral therapy into their treatment protocols to alter observable maladaptive behavior patterns by eliciting new responses to given stimuli [12]. Behavioral science focuses on predicting, explaining, and altering behavior, encompassing approaches such as cognitive behavioral therapy (CBT) and behavior change techniques (BCTs) [13]. CBT, derived from the social cognitive theory, is a problem-focused approach that helps individuals identify and modify dysfunctional beliefs, thoughts, and behavior patterns contributing to their issues [14,15]. BCTs are considered active ingredients and include techniques such as feedback, self-monitoring, and behavior reinforcement. These techniques can be employed individually or in combination and in various forms [11,16]. Both CBT and BCT can enhance patients' ability to self-manage chronic diseases, particularly among those experiencing anxiety, depression, and chronic pain [17-19]. However, study outcomes have been heterogeneous. Some have confirmed that CBT is beneficial for pain improvement [20-22] and that BCT could enhance physical activity compliance in patients with lower extremity OA [23-25], while others have argued that CBT has no effect on patients who catastrophize about pain or has only a small positive effect on pain [12,26].

The increased prevalence of OA has resulted in increasing demand for therapists [27]. To this end, remote OA rehabilitation using digital technologies (eg, telephones, websites, mobile apps) is rapidly evolving to alleviate the socioeconomic burden [28-30]. Digitalized rehabilitation is comparable to physical therapist supervision in terms of exercise quality, physical training supervision, and sport-specific self-efficacy [31,32]. Accumulating evidence has demonstrated long-term improvement in pain and physical function with digital-based rehabilitation in patients with OA [33,34]. Moreover, some studies have reported that internet-based CBT and BCT have led to significant improvements in physical activity and exercise behavior compared with traditional treatments [24,35,36].

Although several studies have investigated the impact of digital behavior change interventions based on the social cognitive theory on physical activity in patients with OA [34,37], several shortcomings remain. First, different digital tools differ in terms of the digital format and underlying behavioral theories, making it challenging to provide evidence-based recommendations for their development process. Second, existing studies have not fully explored broader outcome measures. In order to fully assess the rehabilitation outcomes of patients with OA, a wider range of outcome metrics should be considered to fully evaluate the effectiveness of digital tools based on behavioral therapies. Finally, considering that relevant studies were conducted 3-5 years ago and new digital interventions for knee OA have emerged since then, there is an urgent need for an up-to-date review and evaluation of digital intervention tools incorporating behavioral therapies. Therefore, the aim of this review was to assess the effectiveness of digital interventions based on behavioral therapies for patients with OA in terms of pain, physical function, disability, and HRQoL. In addition, subgroup analyses of digital tool formats, therapist involvement, and underlying behavioral theories were conducted.

Methods

Study Design

This review was performed in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses, Multimedia Appendix 1) [38] and guidelines published in the Cochrane Handbook of Systematic Evaluation [39]. This study protocol is registered with PROSPERO (International Register of Prospective Systematic Reviews: CRD42023430716).

Eligibility Criteria

Studies fulfilling the following criteria were included in this review and meta-analysis: randomized controlled trials (RCTs); participants with knee, hip, or ankle OA; comparing CBT- or BCT-based digital interventions with other treatments; and those addressing at least one component of pain, physical function, HRQoL, pain self-efficacy, or physical activity. Only peer-reviewed studies involving participants older than 18 years were eligible for inclusion. Studies published in any language other than English and those without sufficient data were excluded. In this review, the term "digital intervention" refers to any solution or technology that delivers health information from health care providers to patients over a distance.

Literature Search

The literature search was performed using Web of Science, Embase, Cochrane Library, Ovid, and PubMed databases, from date of inception to June 27, 2023 (Table S1 of Multimedia Appendix 2). In addition, the reference lists of relevant reviews and selected papers were manually examined for potentially relevant/eligible trials.

Study Selection

All duplicate references were removed. Subsequently, titles and abstracts were manually screened for potentially eligible studies by 2 reviewers (DZ and HY), and relevant RCTs were identified.

XSL•FO
RenderX

The full text was then retrieved by both reviewers to assess eligibility for inclusion. Disagreements between the researchers were resolved through discussion or consultation with a third reviewer (BZ). The data were cross-validated by a third researcher (BZ) using EndNote 20 (Clarivate Analytics).

Data Extraction

Two independent reviewers (DZ and HY) collected the data. For continuous outcomes, the following data were extracted: mean (SD) and sample size at baseline and follow-up. For dichotomous outcomes, the number of cases and the total sample size were extracted. The dataset comprised study information, participant characteristics, type of behavioral therapy, type of digital tool, study duration, and outcome measures, including pain and function scores. If a study used multiple pain scales, the scale with the highest sensitivity to changes was used [40]. The function subscales of the Western Ontario and McMaster Universities Arthritis Index and the Knee Injury and Osteoarthritis Outcome Score/Hip dysfunction and Osteoarthritis Outcome Score Physical Function Shortform were used to assess functional improvement. Harmonized physical function was used, with higher scores indicating more severe physical dysfunction. The authors of studies with missing data were contacted. When the authors were unavailable, data were estimated using recommendations from the Cochrane Handbook (eg, estimation of SD from SEs) [39]. In trials in which SD was not reported, missing data were imputed from 95% CIs, SEs, *P* values, baseline changes, graphical representations, median (IQR), or SDs from baseline [41]. Trials in which imputations were not possible were excluded from the quantitative analysis.

The short-term effect was considered as follow-up period ≤6 months after randomization, and the long-term effect was considered as follow-up period >6 months after randomization. When >1 timepoint was available during the same follow-up period, the point closer to the end of the intervention was considered.

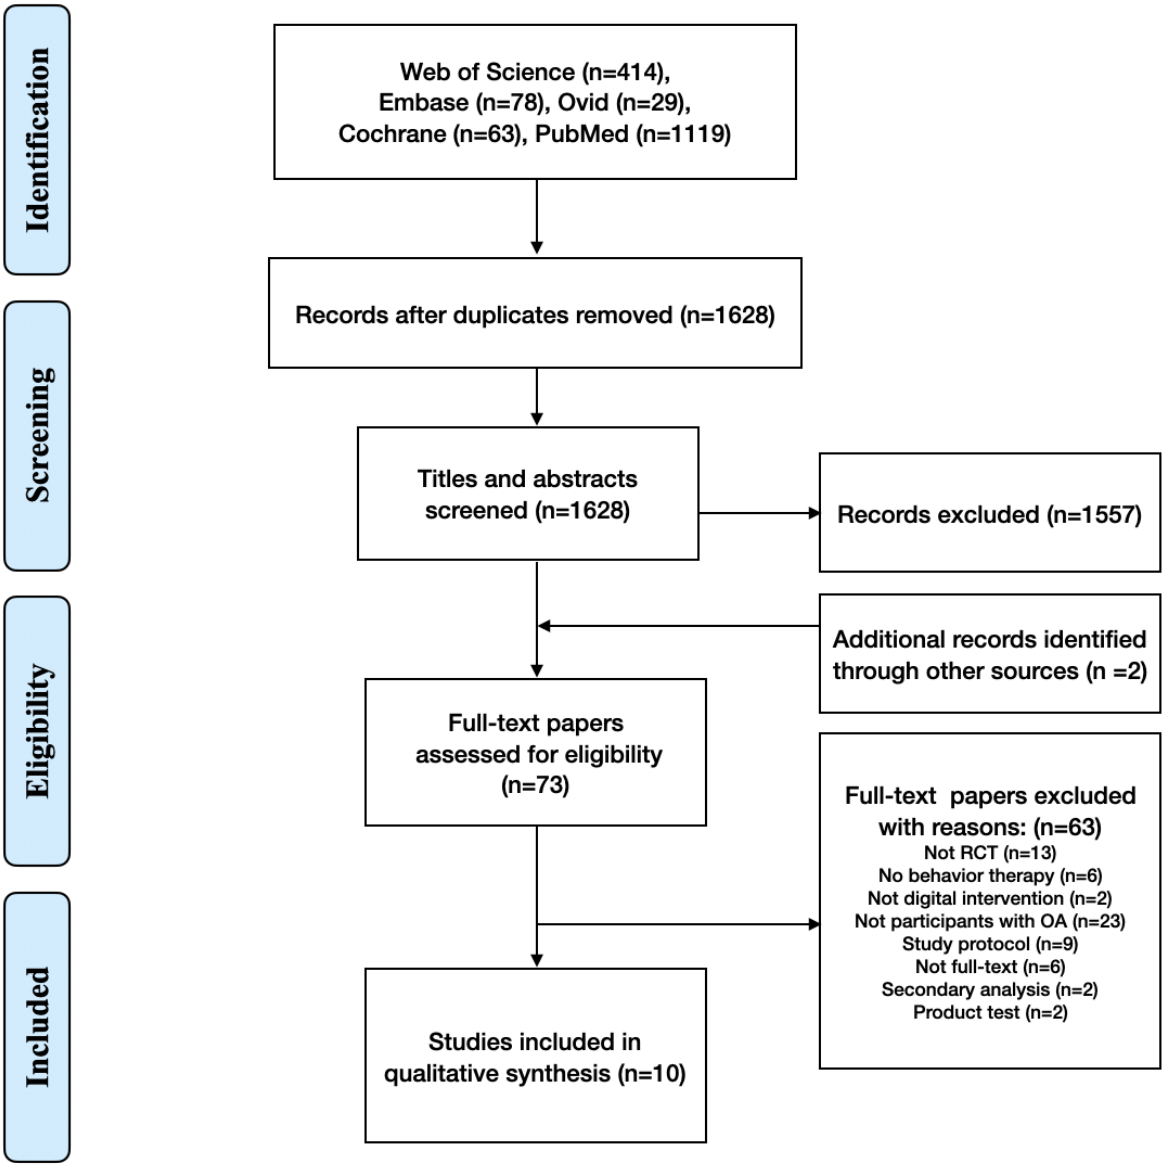
Risk of Bias Assessment

Risk of bias was assessed using the risk-of-bias tool in the Cochrane Handbook of Systematic Evaluation [42]. Seven domains, including random sequence generation, allocation concealment, blinding of participants and personnel, incomplete outcome data, selective reporting, and other biases, were used to evaluate quality of evidence [43]. Each domain was assigned a judgement of low, high, or unclear risk of bias. Furthermore, the quality level of this meta-analysis was evaluated according to GRADE (Grading of Recommendations Assessment, Development, and Evaluation) approach [44,45]. The quality of evidence was classified as high, moderate, low, or very low.

Data Analysis

A random-effects meta-analysis was performed using Review Manager version 5.4 (Cochrane Collaboration). Standardized mean differences (SMDs) were calculated to standardize the results to a uniform scale when studies assessed the same outcomes using different instruments. The SMDs for pain, physical function, HRQoL, pain self-efficacy, and physical activity were calculated by comparing interventions using behavioral therapy–based digital tools with other conventional methods. Therefore, a negative SMD value for pain and physical function and a positive SMD value for HRQoL, pain self-efficacy, and physical activity favor behavioral therapy–based digital tools. The magnitude of SMD was interpreted in accordance with the guidelines reported by Cohen [46], as follows: SMD <0.2 (small), 0.2-0.8 (medium), and >0.8 (large). For clinical interpretation, the mean differences were calculated.

Sensitivity and subgroup analyses were performed to assess the potential impact of the sources of heterogeneity. To investigate the potential impact of methodological quality on the estimates, we performed a sensitivity analysis by removing 1 study at a time, and trials with poor methodological quality were removed. Subgroups were defined in terms of the type of behavioral therapy (ie, CBT or BCT), type of digital tool (apps, wearable devices, and phones), and therapist involvement. The heterogeneity of the pooled studies was examined using the chi-square test and the I^2 statistic, with I^2>50% indicating substantial heterogeneity [47]. Publication bias was assessed by visual inspection of funnel plots and Egger test for meta-analyses ≥10 trials. All analyses were performed using Review Manager version 5.4.



Results

Study Selection and Characteristics

The initial search retrieved 1628 papers after removing duplicates, of which 1557 that did not fulfill the inclusion criteria were excluded. Two additional records were found: one through cross-referencing of bibliographies and the other by contacting the corresponding authors. Subsequently, 73 eligible full-text papers were reviewed, of which 10 RCTs were ultimately included in the quantitative analysis (Figure 1, Table 1) [24,35,36,48-53].

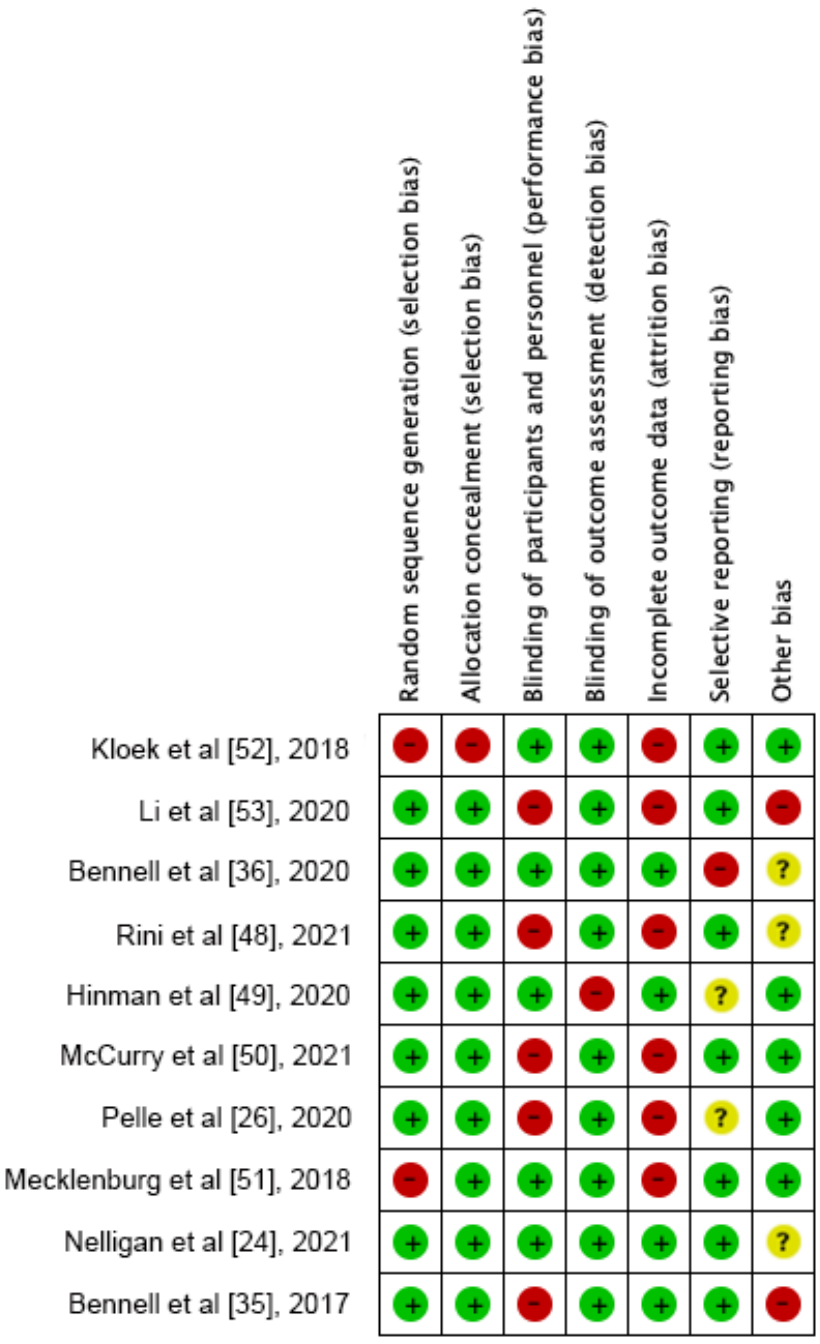
Study Characteristics



In this qualitative analysis, 9 RCTs and 1 cluster RCT, comprising 1895 patients, were included (Tables S2-S4 [24,26,35,36,48-53] of Multimedia Appendix 2). The trials were conducted in Europe (2/10, 20%) [26,52], Oceania (4/10, 40%) [24,35,36,49], and North America (4/10, 40%) [48,50,51,53]. The sample sizes of the included trials ranged from 51 to 427; the mean age of the patients was 62.5 (SD 8.1) years, and females were predominant in the pooled population (1231/1895, 64.9%), which is consistent with the global prevalence of OA. Six studies recruited participants with knee OA only [24,35,36,49,51,53], whereas 4 recruited participants with both knee and hip OA [26,48,50,52]. CBT-based (4 studies) [35,48,50,51] and BCT-based (6 studies) [24,26,36,49,52,53] therapies were the most used behavioral therapies blended into the digital intervention for patients with OA. Three types of digital tools were used: apps or websites in 9 studies [24,26,35,36,48,49,51-53], wearable devices in 3 studies [51-53], and SMS text messages in 1 study [50]. Four studies included face-to-face communication with physical therapists or fitness instructors [36,51-53]. All trials reported short-term effects (up to 6 months after randomization) [24,26,35,36,48-53] and 6 reported long-term effects (>6 months after randomization) [24,26,35,50,52,53]. Pain intensity, physical function, HRQoL, pain self-efficacy, and physical activity were evaluated in 10, 6, 6, 5, and 5 trials, respectively.

Risk of Bias in the Included Trials

In general, the most frequent risks of bias for RCTs were incomplete outcomes (6/10, 60%) and blinding of participants/personnel (6/10, 60%). Other biases and selective reporting accounted for the second most frequent risks of bias (2/10, 20%). The overall confidence in the cumulative evidence varied from very low to moderate, with low confidence being the most commonly identified (Figure 2 [24,26,35,36,48-53], Table 2).

[c]GRADE (Grading of Recommendations Assessment, Development, and Evaluation) Working Group grades of evidence. High: further research is very unlikely to change our confidence in the estimate of effect; moderate: further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate; low: further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate; very low: we are very uncertain about the estimate.

[d]– indicates low-quality evidence.

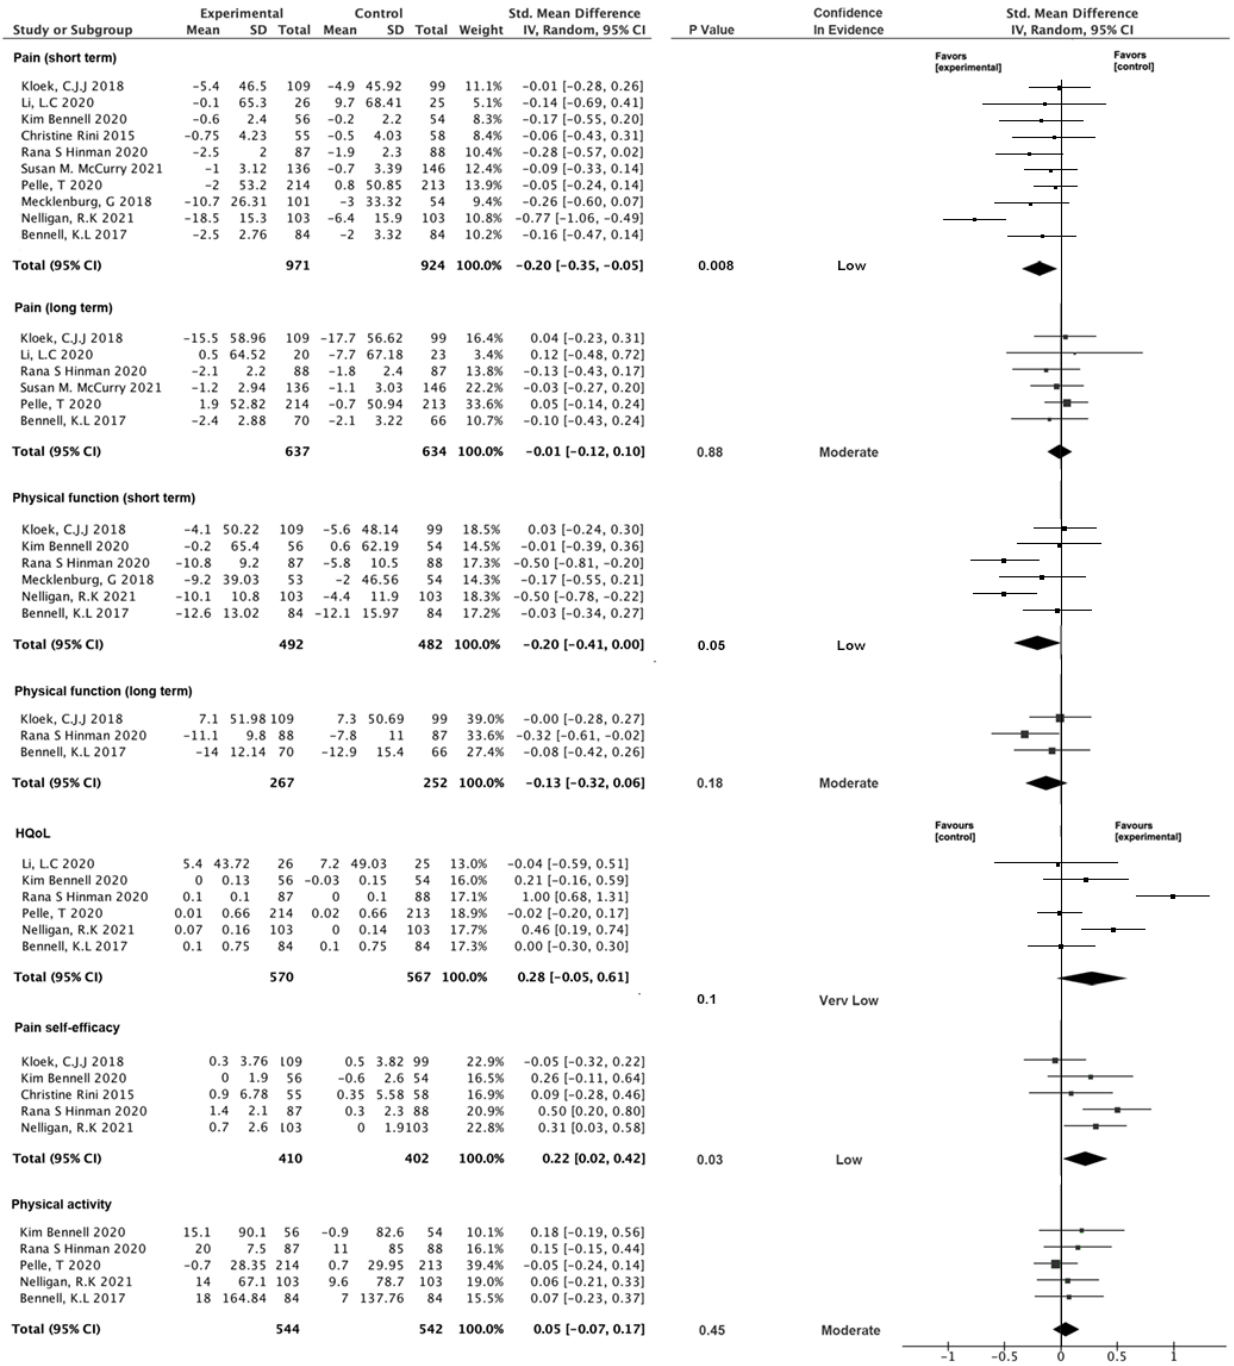
[e]+ indicates high-quality evidence.

[f]–[–2] indicates a moderate to high degree of inconsistency.

[g]BCT: behavior change technique.

[h]CBT: cognitive behavioral therapy.

[i]N/A: not applicable. Since only 1 study was included, there was no heterogeneity in the analysis.



Main Outcomes

For pain reduction, 10 trials with 1895 patients reported a moderate effect of behavioral therapy–based digital tools in reducing pain in the short term (4-24 weeks) (SMD –0.20, 95% CI –0.35 to –0.05; P=.008; I^2=58%), with low-quality evidence [24,26,35,36,48-53]. However, in the long-term follow-up (≥24 weeks), this effect was ambiguous when 6 trials with 1271 patients were included (SMD –0.01, 95% CI –0.12 to 0.10; P=.88; I^2=0%), with moderate-quality evidence [26,35,49,50,52,53]. For physical function, low certainty evidence supported significant improvement in the short term (SMD –0.20, 95% CI –0.41 to 0.00; P=.05; I^2=62%) from 6 trials with 974 patients [26,35,36,49,50,52]. However, its effect showed no significance in 3 trials with 519 patients in the long term (SMD –0.13, 95% CI –0.32 to 0.06; P=.18; I^2=17%), with moderate-quality evidence [35,49,52]. Sensitivity analysis revealed that the results of physical function were unstable;

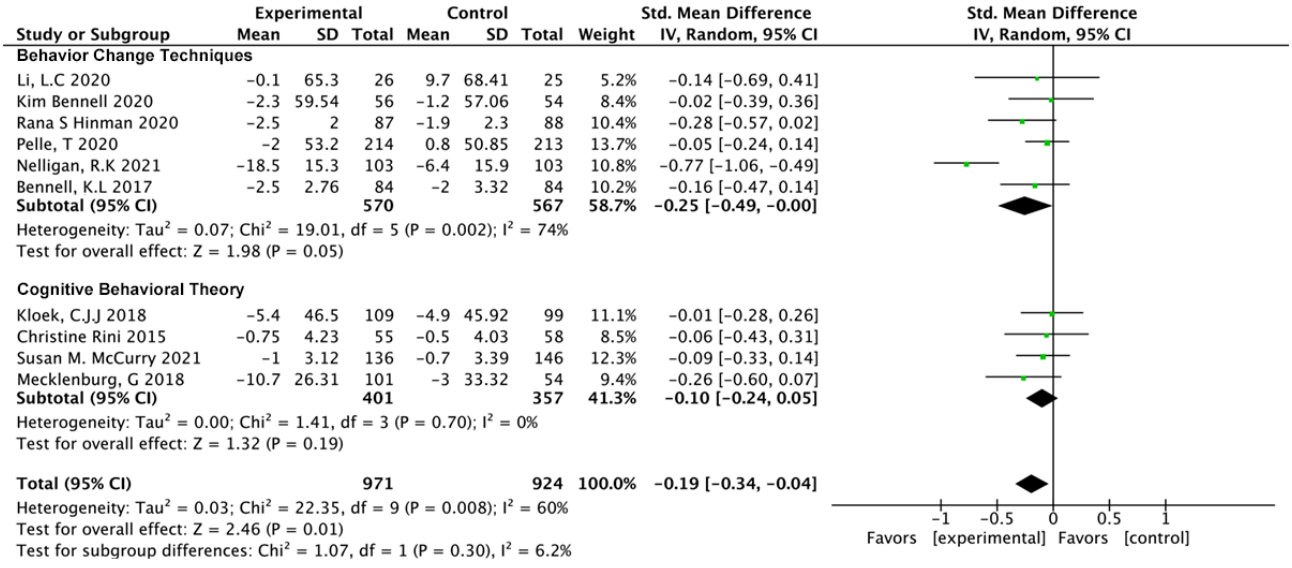
XSL•FO
RenderX

therefore, these results should be interpreted with caution. For pain self-efficacy, low-quality evidence from 5 trials with 812 patients reported a positive effect (SMD 0.22, 95% CI 0.02-0.42; P=.03; I^2=10%) [24,36,48,49,52]. However, for HRQoL, very low-quality evidence from 6 trials with 1137 patients demonstrated an uncertain effect (SMD 0.28, 95% CI –0.05 to 0.61; P=.10; I^2=86%) [24,26,35,36,49,53]. Further, moderate quality evidence demonstrated an uncertain effect (SMD 0.05, 95% CI –0.07 to 0.17; P=.45; I^2=0%) for physical activity [24,26,35,36,49]. All results are presented in Figure 3 [24,26,35,36,48-53].

Figure 3. Main results of this study. HQoL: health-related quality of life.

Subgroup Analyses

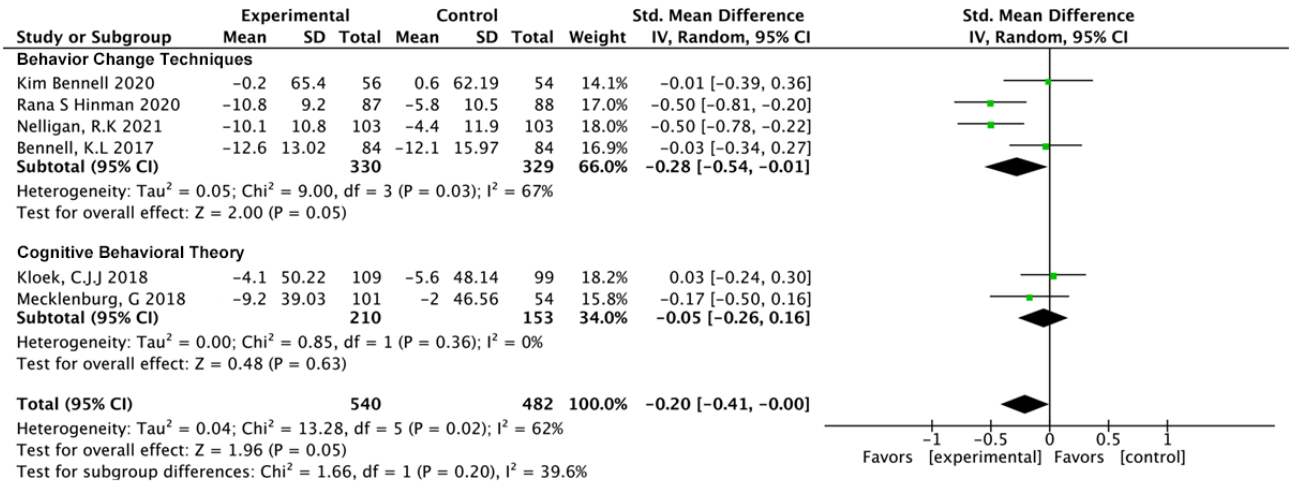
Subgroup analyses of behavioral therapy, digital tools, and therapist involvement were performed, and significant improvements were found in the short-term intervention.



Behavioral Therapy

BCTs (6 studies, 1177 participants) demonstrated a significant impact on pain reduction (SMD –0.25, 95% CI –0.49 to 0.00; P=.05; I^2=74%) [24,26,35,36,49,53]. However, our findings indicate that CBT (n=4 studies, n=758 participants) did not have

XSL•FO
RenderX

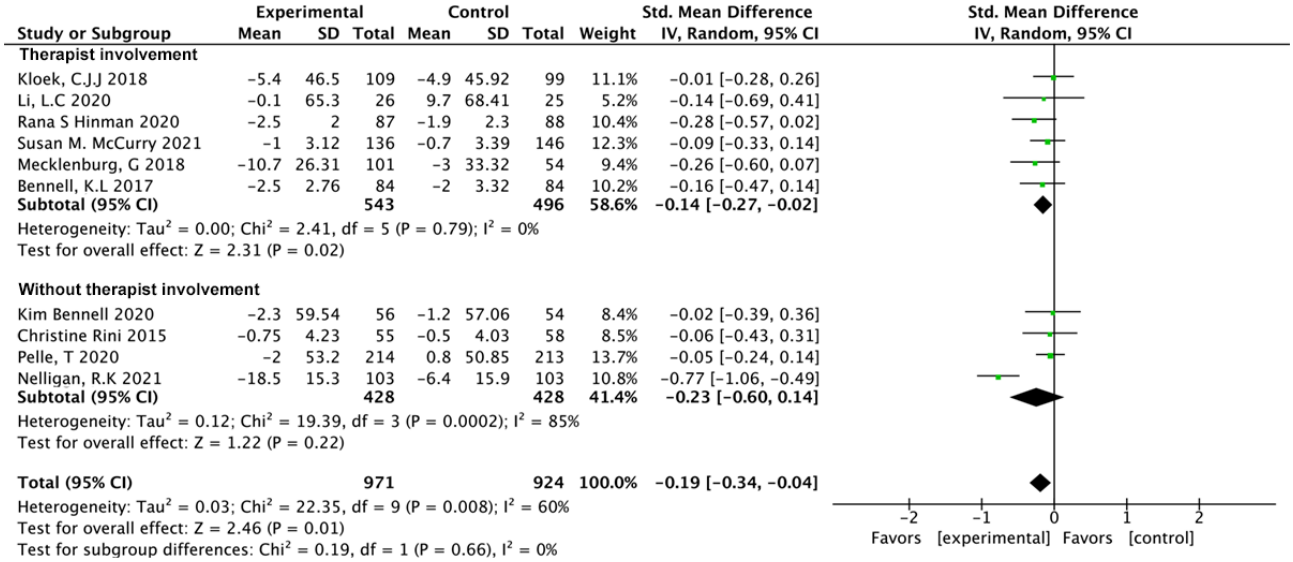


a significant effect on pain (SMD –0.10, 95% CI –0.24 to 0.05; P=.19; I^2=0%) [48,50-52] (Figure 4 [24,26,35,36,48-53]).

Figure 4. Pain outcomes in different behavioral therapy models.

BCTs (4 studies, 659 participants) were found to significantly reduce physical functional impairment (SMD –0.28, 95% CI –0.54 to –0.01; P=.05; I^2=67%) [24,35,36,49]. In contrast, our findings show that CBT (n=2 studies, n=363 participants) did not significantly affect pain (SMD –0.20, 95% CI –0.26 to 0.16; P=.63; I^2=0%) [51,52] (Figure 5 [24,35,36,49,51,52]).

Figure 5. Physical function outcomes in different behavioral therapy models.



XSL•FO
RenderX

Therapist Involvement

Six studies involving 1039 participants revealed significant effects favoring the intervention in pain reduction when therapist involvement was present (SMD –0.14, 95% CI –0.27 to –0.02; P=.02; I^2=0%) [35,49-53]. Conversely, 4 studies involving 856 participants revealed no significant effects in pain reduction for interventions without therapist involvement (SMD –0.23, 95% CI –0.60 to 0.14; P=.22; I^2=85%) [24,26,36,48] (Figure 6 [24,26,35,36,48-53]).

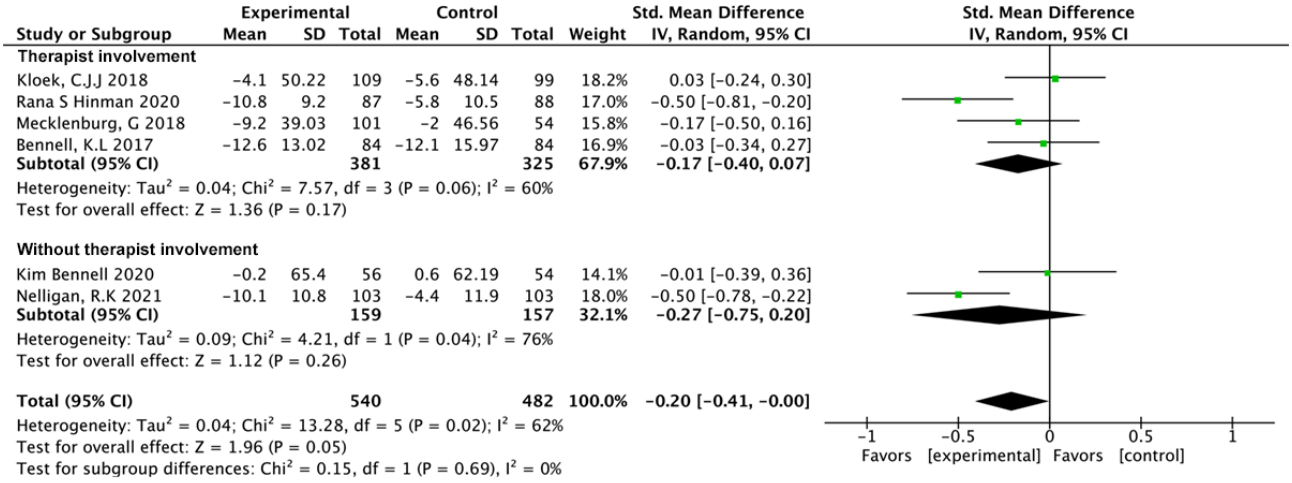


Figure 6. Pain outcomes related to therapist involvement.

Four studies involving 706 participants (SMD –0.17, 95% CI –0.40 to 0.07; P=.17; I^2=60%) [35,49,51,52] and 2 studies involving 316 participants [24,36] (SMD –0.22, 95% CI –0.37 to –0.06; P=.26; I^2=76%) revealed that therapist involvement did not result in significant improvements in physical functional impairment (Figure 7 [24,35,36,49,51,52]).

XSL•FO
RenderX

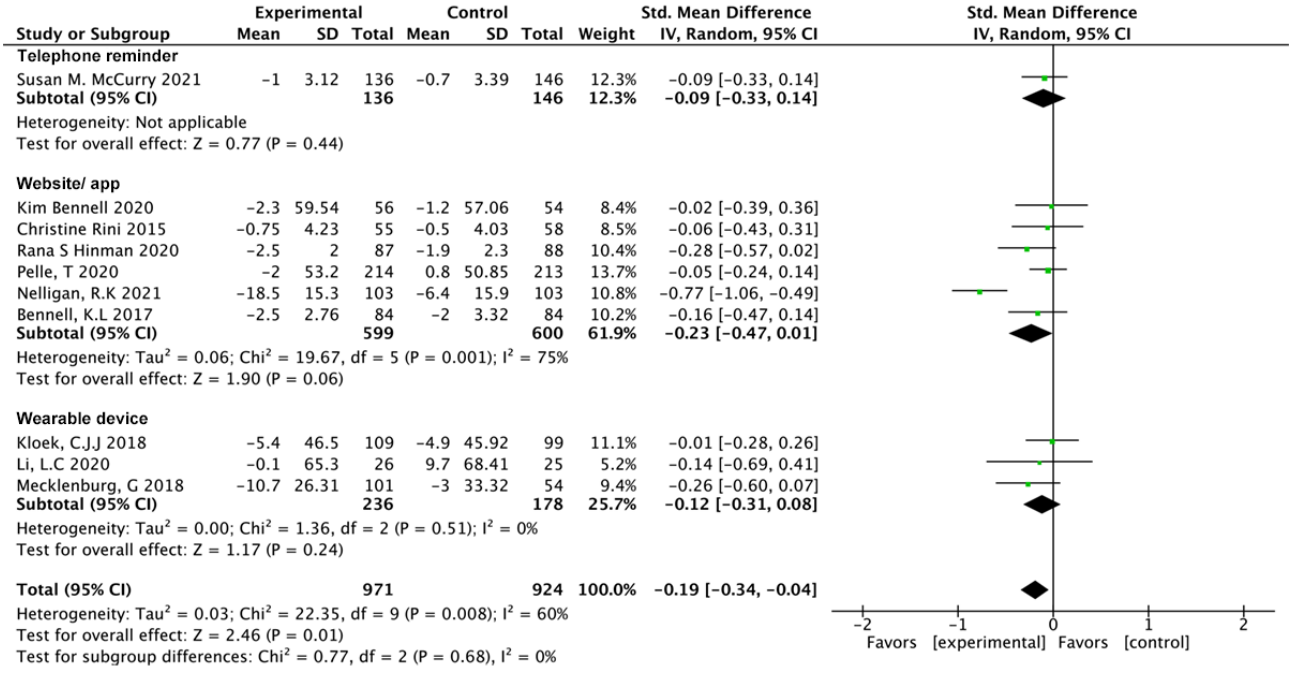

Figure 7. Physical function outcomes related to therapist involvement.

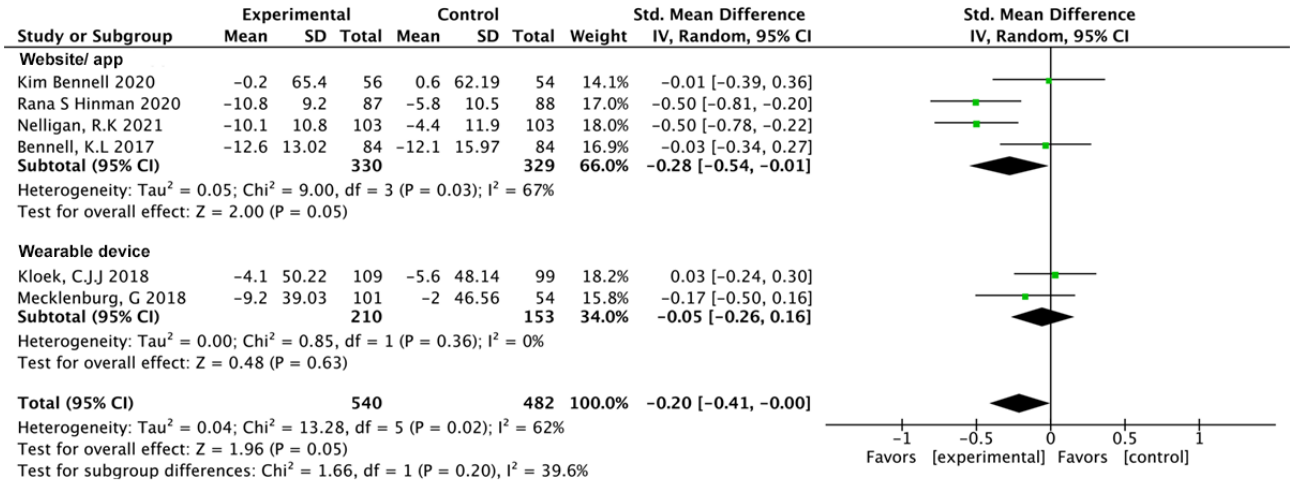
Digital Tools

Neither the use of a mobile app/website (SMD –0.23, 95% CI –0.47 to 0.01; *P*=.06; I^2=75%) [50], telephone communication (SMD –0.09, 95% CI –0.33 to 0.14; *P*=.44) [24,26,35,36,48,49] nor the use of a wearable device as a monitoring device (SMD –0.12, 95% CI –0.31 to 0.08; *P*=.24; I^2=0%) [51-53] were associated with the effect in favor of the intervention (Figure 8 [24,26,35,36,48-53]).

Figure 8. Pain outcomes with different digital tools.



Four studies involved 659 participants who used a mobile app/website and observed a significant effect in favor of the intervention in terms of physical dysfunction (SMD –0.28, 95% CI –0.54 to –0.01; *P*=.05; I^2=67%) [24,35,36,49]. However,

XSL•FO
RenderX

there was no difference for only 2 items involving wearables (SMD –0.05, 95% CI –0.26 to 0.16; P=.63; I^2=0%) [51,52] (Figure 9 [24,35,36,49,51,52]).

Figure 9. Physical function outcomes with different digital tools.

Risks of Bias Sensitivity Analysis

After excluding studies at high risk of bias, the results regarding randomization, allocation concealment, incomplete outcome reporting, selective reporting, and other biases demonstrated stability. However, instability was observed in the results when studies with unclear patient blinding were excluded. For outcomes related to physical function, studies excluding those at high risk of bias showed stability in allocation concealment and incomplete outcome reporting. Nevertheless, exclusion of trials with biases related to randomization, blinding, selective reporting, and other factors resulted in unstable findings. Therefore, these results warrant cautious interpretation (Table 3). Additionally, due to the inclusion of predominantly fewer than 10 studies, the potential impact of small-study effects was explored using only funnel plots. The inspection of funnel plots (Figure S1 of Multimedia Appendix 2) suggested small study effects/publication bias for the overall results in terms of pain in the short and medium terms.

Discussion

Main Findings

This systematic review and meta-analysis report provides moderate- to low-quality evidence regarding the therapeutic effects of 3 digital tools based on 2 behavioral therapies for patients with OA. Digital tools focusing on behavior change have shown short-term efficacy, including reductions in pain intensity and physical function impairment along with improvements in pain self-efficacy. However, our study did not find significant differences in sports and recreational activities or overall physical activity. Given the risk of bias in the included studies, the overall quality of evidence is moderate to low. Furthermore, the evidence quality regarding HRQoL outcomes is deemed very low; so, the findings should be interpreted with caution.

Our study compares the short-term and long-term effects of behavior theory–based digital interventions on pain. However, contrary to Safari et al's [34] previous findings, we found no significant long-term effects of behavior theory–based digital interventions. This discrepancy may stem from the incomplete success of digital interventions in promoting adherence to prescribed exercise regimens among patients with musculoskeletal disease [30,54]. A recent review indicated that digital interventions have not been shown to enhance compliance with therapeutic exercise among patients with chronic musculoskeletal disease [30]. Therefore, further high-quality research is needed to conclusively determine the efficacy of these interventions for long-term therapeutic effects.

Among the 10 studies included, 9 observed positive changes in patient pain [24,26,35,36,48-51,53]. Current research integrates behavior therapy principles into digital interventions aimed at enhancing patients' ability to modify their decision-making frameworks and guide behavior change in patients with OA [55]. The educational components of digital tools include pathophysiological and etiological information on OA, guideline-based therapies, exercise for OA management, and pain management strategies, and these are closely aligned with the social cognitive theories of health behavior [19]. These address motivational and volitional determinants of exercise behavior [31,56]. Our study suggests that such semisupervised, freely accessible interventions may be an effective option for reducing pain [24], as pain intensity correlates positively with the use of exercise, courses, and health self-management messaging functionalities [57]. Additionally, improvements in physical function impairment were observed in 6 studies. Research has demonstrated the impact of digital health interventions on physical function through exercise and aerobic training programs [58,59]. This is because the digital tools included in the studies mostly incorporate multicomponent exercises recommended by clinical guidelines, which can enhance balance and mobility [60,61].

Low-quality evidence revealed that a behavioral therapy–based digital tool had a positive effect on pain self-efficacy, which is consistent with previous research that found greater self-confidence activation in digital self-monitoring programs than in traditional management programs [33,62,63]. Self-efficacy refers to an individual's perception of being capable of making positive changes in their lives can help them to be more likely to initiate and maintain positive behavior changes [64,65]. Previous studies have reported significant indirect effects of digital tools on health behaviors, and we suggest that self-efficacy could be used as an indirect mediator in clinical practice [65,66].

This review indicates that behavior therapy–based digital interventions have no significant impact on HRQoL, which is consistent with that reported in a previous systematic review [67]. However, the mechanisms underlying patients' perceptions of quality of life remain unclear, necessitating validated behavior change measures such as patient activation measures to effectively assess such systems. Additionally, we found that behavior therapy–based digital interventions do not significantly influence physical activity levels [55,68]. This may be attributed to the lack of face-to-face supervision. Nonetheless, despite these findings, such interventions could potentially offer substantial public health benefits, despite the modest effect size.

Subgroup Findings

The effects of behavioral therapy were independently assessed in a subanalysis. However, our results were not consistent with those of previous studies in that only BCT-based digital tools had an impact on outcomes in patients with OA [16,20,33]. In previous studies, it was difficult to trace patient participation on a digital platform, and multiple variations could be introduced into the outcomes [69,70]. The underlying mechanism by which behavior change–based digital tools can reduce pain and physical function in patients with OA is that such interventions can elicit patient intentions and modify their decision-making structures [55]. The educational components of the digital tools include information regarding the pathology and etiology of OA, treatment according to guidelines, exercise for OA, and pain and symptom relief, which are closely related to the social cognitive theories of health behavior [19]. These factors examine the influences of motivation and willpower on exercise behavior [31,56]. Our research indicated that this semisupervised, freely accessible intervention may be effective for pain reduction [24].

Another interesting finding in our study was that physical therapist involvement was shown to be effective in pain reduction and physical function, although with low-quality evidence. This is consistent with previous evidence suggesting that communication and interaction with professionals can increase patient motivation [67,71]. Digital tools provide the opportunity to assume the role of an aid to assist patients in engaging in less complex exercises as part of independent home training [72,73]. However, it sometimes cannot replace physical therapists who achieve similar effects [31,74,75]. Typical digital intervention tools rely on self-management and lack timely reminders and professional communication [67,71]. Studies have shown that digital tools without therapist involvement do not offer significant advantages over conventional care interventions [26]. Therefore, future digital intervention tools should aim to blend traditional OA care with digital OA care solutions. Heath care should provide solutions for personalized, comprehensive, simple, reliable, and continuous mixed heath care [76,77].

XSL•FO
RenderX

Another finding is that digital tools based on website or application development show significantly better short-term improvements in physical function compared to wearable devices. This may be due to the complex wearing process of wearable devices, especially among older adults who may have resistance to wearing such devices and find them potentially hindering daily activities. Hence, future application development should fully consider patient characteristics and needs rather than solely relying on hospital staff knowledge and experience [78,79].

Clinical and Research Implications

This study confirms that digital tools combined with behavioral therapy, especially BCTs, have moderate and clinically meaningful treatment effects in patients with hip and knee OA in the short and long term. These findings echo the current guidelines that recommend rehabilitation, emphasizing exercise, self-efficacy, and self-management for patients with OA. As digital technologies rapidly evolve, the affective interaction between patients and professionals remains a crucial factor and should be considered in future studies.

Strengths and Limitations

This study has several limitations. First, we were unable to fully explore the reasons for heterogeneity because many covariates for behavioral therapy–based digital tools in OA were not usually reported in the trials. Second, subgroup analyses to explore the potential impact of a high risk of bias and characteristics of the population were limited by the small number of included trials or because the data were poorly reported. Third, despite the use of extensive search techniques, the evaluation may have been hampered by language bias because we only included studies published in English in the 5 databases. Therefore, we cannot guarantee that all potentially eligible studies were included. Fourth, this meta-analysis included only 10 studies, with 9 RCTs and 1 RCT cluster. Owing to this rather low number of studies, the Q-static was reduced in power, and I^2 could have been biased. Finally, this study was prone to publication bias and other risks of bias and was limited only to the information reported in the studies.

Conclusions

We found moderate- and low-quality evidence supporting behavioral therapy–based digital tools improving pain intensity, physical function, and self-efficacy in the short term. Low- and very-low-quality evidence demonstrated uncertain effects of physical activity on HRQoL or its long-term effects. However, affective interactions between patients and professionals may affect clinical outcomes. Our findings should be evaluated by clinicians, stakeholders, and researchers, considering that most digital tools currently have low or very low certainty of evidence. Our findings highlight the need to conduct large-scale trials with high methodological quality.

Acknowledgments

This work was supported by the Shanghai Municipal Education Commission (2024AIYB014), Huashan Hospital, Fudan University Clinical Research Project (2023YN007), and Shanghai Soft Science Project (24692108200). We thank the members of our steering committee for their oversight and expert guidance. We also thank the stakeholders who contributed to our project management group and people with lived experience of receiving or providing exercise therapy for patients with osteoarthritis who took part in the stakeholder workshops and web-based surveys for their useful feedback.

Abstract

Background: There is a growing body of robust evidence to show that lifestyle behaviors influence mental health outcomes. Technology offers an accessible and cost-effective implementation method for interventions, yet the study of the effectiveness of interventions to date has been specific to the mode of delivery, population, or behavior.

Objective: The primary aim of this review was to comprehensively evaluate the effectiveness of digital lifestyle interventions for improving symptoms of depression, anxiety, stress, and well-being as coprimary outcomes in adults. The secondary aim was to explore the technological, methodological, intervention-specific, and population-specific characteristics that were associated with major changes in mental health outcomes.

Methods: A systematic search was conducted across the MEDLINE, CINAHL, Embase, Emcare, PsycINFO, and Scopus databases to identify studies published between January 2013 and January 2023. Randomized controlled trials of lifestyle interventions (physical activity, sleep, and diet) that were delivered digitally; reported changes in symptoms of depression, anxiety, stress, or well-being in adults (aged ≥18 years); and were published in English were included. Multiple authors independently extracted data, which was evaluated using the 2011 Levels of Evidence from the Oxford Centre for Evidence-Based Medicine. Inverse-variance random-effects meta-analyses were used for data analysis. The primary outcome was the change in symptoms of depression, anxiety, stress, and well-being as measured by validated self-report of clinician-administered outcomes from pre- to postintervention. Subgroup analyses were conducted to determine whether results differed based on the target lifestyle behavior, delivery method, digital features, design features, or population characteristics.

Results: Of the 14,356 studies identified, 61 (0.42%) were included. Digital lifestyle interventions had a significant small-to-medium effect on depression (standardized mean difference [SMD] −0.37; $P<.001$), a small effect on anxiety (SMD −0.29; $P<.001$) and stress (SMD −0.17; $P=.04$), and no effect on well-being (SMD 0.14; $P=.15$). Subgroup analyses generally

XSL•FO
RenderX

suggested that effects were similar regardless of the delivery method or features used, the duration and frequency of the intervention, the population, or the lifestyle behavior targeted.

Conclusions: Overall, these results indicate that delivering lifestyle interventions via a range of digital methods can have significant positive effects on depression (P<.001), anxiety (P<.001), and stress (P=.04) for a broad range of populations, while effects on well-being are inconclusive. Future research should explore how these interventions can be effectively implemented and embedded within health care with a concerted focus on addressing digital health equity.

Introduction

Background

Mental disorders are among the leading causes of global disease burden [1] and a significant risk factor for premature mortality [2]. Recent estimates suggest that between 5% and 19% of global disability-adjusted life-years can be attributed to mental disorders [1,3], causing annual economic losses of approximately US $4.7 trillion [4]. These mental health difficulties cause enormous psychological impact, have widespread deleterious effects on health behaviors [5], and vastly increase the odds of experiencing physical health morbidities [6].

There is increasing recognition that poor lifestyle behaviors, such as diet, physical activity, and sleep, contribute to both poor physical and mental health. Concurrently, there is increasing evidence for the role of lifestyle interventions in preventing, managing, and treating mental illness [7-9]. Numerous clinical guidelines and health policy documents now call for lifestyle behaviors to be addressed alongside pharmacotherapies and psychotherapy, as part of mental health care [10].

Digital technology offers a promising avenue for revolutionizing mental health care delivery on a global scale. Digital interventions can also reduce the stigma associated with seeking help [11], while data-driven insights allow for personalized and efficient interventions tailored to individual needs.

In recent years, an increasing number of studies have demonstrated the effectiveness of digital interventions in delivering mental health treatments [12], including compelling outcomes for smartphone-delivered psychological interventions in reducing depression and anxiety symptoms [13,14]. Concurrently, research related to digital lifestyle interventions is increasing rapidly [15]. A growing body of evidence shows that these interventions can be effective for improving health behaviors such as physical activity [16], sleep quality [17], weight loss [18], and healthy diet [19]. However, there is little evidence specifically focused on the effect of digital lifestyle interventions on mental health and well-being outcomes in the general population. The few reviews in this area have focused on singular lifestyle behaviors such as physical activity [20], specific clinical populations [21], or a single delivery method [22] or have reported lifestyle behavior changes but not changes in mental health [19,23]. Moreover, only 1 review has synthesized data from >10 randomized controlled trials (RCTs) [19]. This fragmented approach limits our ability to rigorously discern the effectiveness of the various intervention components and combinations on mental health across the general population.

Objectives

This systematic review and meta-analysis takes a broad approach, aiming to provide a thorough synthesis of the evidence on digitally delivered lifestyle interventions for depression, anxiety, stress, and well-being outcomes in adults. Recognizing that mental health is more than the absence of disorders and distress [24], we also evaluated the effectiveness of digital lifestyle interventions on psychological well-being (ie, well-being), as operationalized by van Agteren et al [25]. Here, well-being refers to positive aspects of mental health, including positive affect and life satisfaction (ie, subjective well-being), as well as meaning, purpose, and related concepts (ie, psychological well-being).

Given the breadth of the review, the secondary aim was to explore the technology-specific intervention features that are associated with greater mental health outcomes. We further considered the impact of various methodological (ie, study quality), intervention-specific (ie, type, delivery method, and delivery features), and population-specific (ie, general population, those with a mental illness, and those with a physical illness) characteristics. Finally, this review aimed to shed light on the overall quality of the evidence provided in the meta-analyses and discuss the implications of the evidence for future research and lifestyle intervention delivery.

Methods

This systematic review and meta-analysis adheres to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [26] and is registered with PROSPERO (CRD42023428908). A completed PRISMA checklist for this study is available in Multimedia Appendix 1.

Search Strategy and Selection of Studies

The following electronic databases were searched from January 2013 to January 10, 2023: MEDLINE (Ovid), CINAHL (EBSCOhost), Embase (Ovid), Emcare (Ovid), PsycINFO (Ovid), and Scopus. Subject heading, keyword, and Medical Subject Headings term searches relating to technology,

XSL•FO
RenderX

modifiable lifestyle behaviors (ie, physical activity, diet, and sleep), mental health, and study design were used. Full search queries are detailed in Multimedia Appendix 2. Additional searches were conducted using Google Scholar and by scanning the reference lists of included papers and review articles to identify any additional studies. Studies were exported to Covidence (Veritas Health Innovation Ltd), and duplicates were removed. Studies were screened in duplicate with conflicts resolved between the 2 reviewers or a third independent reviewer.

Inclusion and Exclusion Criteria

To be included in this systematic review and meta-analysis, studies needed to meet the following criteria: (1) involve adults (aged ≥18 years) of any health status and (2) include a digitally delivered lifestyle intervention targeting physical activity, diet, sleep, or any combination thereof. We defined digital lifestyle interventions as interventions delivered via digital technologies (such as apps, websites, and wearable devices) that were self-guided and did not require real-time clinician delivery (eg, behavior change and education) and aimed to improve lifestyle behaviors [27]. Considering the nature of the research, we included interventions that were supplemented with contact for follow-up or adherence and technology support (eg, orientation session or phone call to create a user profile or a peer-driven social forum moderated by a clinician). Lifestyle interventions were eligible if at least 50% of the intervention was focused on physical activity, diet, and sleep. Physical activity was considered in the broadest sense, including overall physical activity levels, structured exercise interventions, and studies examining reducing physical inactivity (ie, sedentary time). Diet was considered as any intervention targeting food intake (ie, amount or type). Studies focusing on supplementation or specific nutrient treatments were excluded. Sleep interventions were considered as anything targeting sleep; therefore, psychological therapies targeting sleep (eg, cognitive behavioral therapy for insomnia) were eligible for inclusion; (3) studies that had an adequate control condition of no treatment, treatment as usual, waitlist control, or attention (ie, sham) control were included, while control groups that received an alternative intervention comprising behavior change techniques or an in-person version of the digital intervention were excluded, as they would limit our ability to evaluate the effectiveness of the intervention; (4) studies that reported changes in symptoms of depression, anxiety, psychological stress, or well-being using validated tools were included, and due to the broad and varied definitions of well-being [28], we considered well-being measures listed as per the review by van Agteren et al [25]. Studies that focused on momentary affective states were considered outside the scope of this review and were excluded; (5) RCTs were included. No restriction was placed on the setting or context of the included studies.

Data Synthesis and Analysis

In total, 2 reviewers independently extracted data using a predefined data extraction sheet, cross-checked the data, assessed study quality, and resolved disagreements by discussion or referral to a third reviewer (JB or CM). The authors of the included studies were contacted to provide additional data for inclusion in the meta-analysis if required.

Intervention effect sizes (ie, differences between intervention and control groups) for outcome data were calculated across all studies and standardized to Hedges *g* [29] along with the SE. Studies were grouped by outcomes (ie, depression, anxiety, stress, and well-being) for analyses. Random-effects meta-analyses were conducted due to expected heterogeneity. All analyses used an inverse variance method with restricted maximum-likelihood estimator for τ^2 and Hartung-Knapp adjustment for the random effects model. Standardized mean differences (SMDs) were used as the effect measure for meta-analyses to allow comparison of data from different scales. If means and SDs were not reported in a study, authors were contacted twice before means and SDs were calculated based on available data using recommended formulas (eg, using sample size, median, and range) [30]. Meta-analyses were conducted only when at least 5 studies were included. Effect sizes were categorized as small (0.2), medium (0.5), or large (≥0.8) [31], with a significance level set at .05 [32]. Cochrane *Q* test was used to assess statistical heterogeneity, and the I^2 statistic was used to quantify the proportion of the overall outcome effect attributed to heterogeneity. The following cutoff values for the I^2 statistic were used: 0%-29%=no heterogeneity, 30%-49%=moderate heterogeneity, 50%-74%=substantial heterogeneity, and 75%-100%=considerable heterogeneity [33]. Publication bias was assessed with visual inspection of funnel plots and tested using the Begg-Mazumdar [34] and Egger regression method [35], with a *P* value <.05 suggesting the presence of bias. Where significant bias was detected, a Duval and Tweedie [36] trim-and-fill analysis was applied. Heterogeneity was explored with subgroup and sensitivity analyses. Sensitivity analyses were conducted by removing outliers, studies with samples <100, studies of poor to fair quality, and those with attrition >25% to investigate changes in effect for each outcome. All analyses were conducted in R software (version 4.2.0, “Mountain Hydrangea”; R Foundation for Statistical Computing).

Quality Assessment

The risk of bias of each study was assessed using the Physiotherapy Evidence Database Scale (PEDro) [37]. The PEDro scale comprises 10 questions, each answered as yes or no. A study was deemed to be high quality with a score of 6 to 10, fair quality with a score of 4 to 5, and low quality with a score <4.

The overall level of evidence was graded using the Oxford Centre for Evidence-Based Medicine 2011 Levels of Evidence [38] as follows: grade A—consistent level 1 studies (ie, individual RCTs with narrow CIs), grade B—consistent level 2 (ie, individual cohort studies or low-quality RCTs) or level 3 studies (ie, individual case-control studies) or extrapolations from level 1 studies, grade C—level 4 studies or extrapolations from level 2 or 3 studies, or grade D—level 5 (ie, expert opinion without explicit critical appraisal) evidence or inconsistent or inconclusive studies of any level.

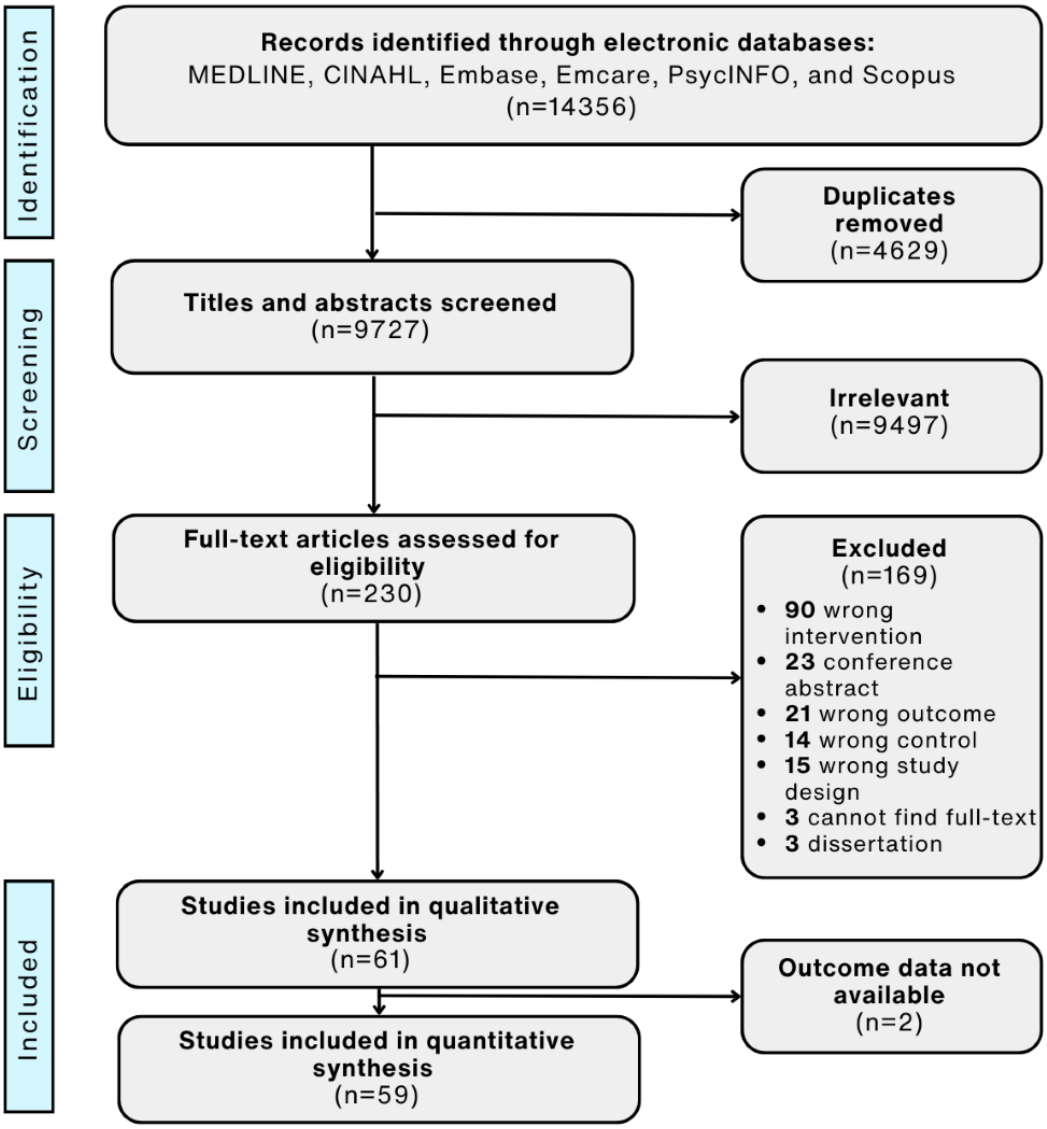
RenderX

Subgroup Analyses

The central aim of this review was to examine the effect of various methodological, intervention-specific, and population-specific factors on the effectiveness of digital lifestyle interventions for mental health outcomes [39]. Intervention-specific factors included the lifestyle behavior; the intervention targeted (ie, physical activity alone, diet alone, sleep alone, herein referred to as the respective singular behavior, or any combination of these behaviors, which is referred to herein as multibehavioral); delivery method (ie, web based, app, email or text, and wearable device); features of delivery format (ie, use of a chatbot or gamification); frequency and duration of the intervention; whether the intervention was co-designed, individualized, or publicly available; and whether it contained a theoretical underpinning. The frequency of intervention delivery was split into three categories: (1) intended daily use; (2) 1 to 4 times per week; and (3) "other," which included fortnightly, monthly, varied, once-off, and self-paced engagement. Methodological factors were control group types and study quality. Study quality was based on the risk of bias, where studies were categorized into poor, fair, good, or excellent as per the PEDro scoring. Control groups were divided into no treatment, including waitlist; treatment as usual; or attention control. To determine which populations might benefit most from digital lifestyle interventions, we conducted subgroup analyses for each outcome for apparently healthy adults; those with a physical health condition; those diagnosed with a mental health condition; and, due to the number of sleep-specific studies, people who met the criteria for insomnia.

Deviation From the Registered Protocol

We originally planned to include interventions targeting alcohol, smoking, and substance use as behaviors, considering their association with poor mental health outcomes. However, due to the unfeasible volume of search results and their distinct focus on addiction, these lifestyle behaviors were excluded from this review.



Results

Included Studies

Searching of databases yielded 14,357 results. Following the removal of duplicates, 9727 potentially eligible studies remained for which abstracts were screened. At full-text stage, 230 studies were reviewed, and 169 were removed because they failed to meet the inclusion criteria (Multimedia Appendix 3). The remaining 61 studies were included in the review, and 59 studies were included in the quantitative synthesis (Figure 1).

Figure 1. PRISMA flowchart of study selection.

Study Characteristics

In total, 22,483 participants across 61 studies were included in the review. Sample sizes ranged between 20 and 3755 participants, and the mean age ranged between 19 and 68 years. Interventions lasted between 2 and 52 weeks. Studies originated from Europe, America, Canada, Australia, New Zealand, the United Kingdom, Iran, and Asia. Full details of each study are outlined in Table 1.

[t]BAI: bay-annulated indigo.
[u]PERMA: Positive Emotions, Engagement, Relationships, Meaning, Accomplishment.
[v]PCOS: Polycystic Ovarian Syndrome.
[w]SDS: Self-Rating Depression Scale.
[x]SAS: Self-Rating Anxiety Scale.
[y]SWLS: Satisfaction with Life Scale.
[z]STAI: State Trait Anxiety Inventory.
[aa]CDS: Cardiac Depression Scale.

A total of 55 studies assessed depressive symptoms [40-42,44-58,60-83,85-90,92-95,97,98,100], 35 assessed anxiety symptoms [45,46,50-52,57,58,60,61,63,65-68,72-74,76-83,86,88,89,92,93,95,97-100], 11 assessed stress [44,46,57,59,65,78,80,82,83,93,96], and 6 assessed well-being [43,46,61,84,91,96]. Overall, 24 studies included apparently healthy adults [44,46,48,50,51,53,55,57,59,64,70,76,80,82-85,89-93,99]; 23 included adults with a physical health condition [43,45,47,52,54,56,63,65,67-69,71,74,77-79,86,88,94,95,98,100]; 6 included adults with a mental health condition, all of which were depressive disorders [40,41,62,73,81,97]; and a further 8 included adults with insomnia [49,58,60,61,66,72,75,87]. Interventions were digitally delivered via the web (38/61, 62%) [40,44,45,48-50,52-56,58-64,67,68,73-79,82-84,86,88-90,92-94,98], app (17/61, 28%) [42,43,46,47,57,60,65,66,69,72,80,81,85,91,95,97,100], email, or SMS text messages (15/61, 25%) [44,46,51,58,61,63,70,77,79-81,86,89,99,100], and 16% (10/61) of the interventions included a wearable activity tracker [41,42,57,63,71,80,91,94,96,98]. A total of 15 interventions used >1 delivery method [42,44,57,58,61,63,77,79-81,86,89,91,94,98]. Of the 61 interventions, 26 (43%) targeted physical activity [41,42,45,48,56,57,59,63,67,68,70,71,73,74,81,82,84,85,88,91-94,96,100], 17 (29%) targeted sleep [49,50,55,58,60-62,64,66,72,75-77,86,87,89,90], 2 (3%) targeted diet [51,69], and 16 (27%) targeted multiple lifestyle behaviors [42,44,57,58,61,63,79-81,86,89,91,94,98]. Of the 17 studies targeting multiple behaviors, 4 (24%) targeted physical activity, diet, and sleep [40,47,97,98]; 11 (65%) targeted physical activity and diet [44,46,52-54,65,78,79,83,95,99]; and 2 (12%) targeted physical activity and sleep [43,80].

XSL•FO
RenderX

Mental health (ie, depression, anxiety, stress, and well-being) outcomes were measured as a primary outcome in 14 studies [41,46-51,62,83,85,89,93,97,98]. The risk of bias of the included studies is detailed in Multimedia Appendix 4.

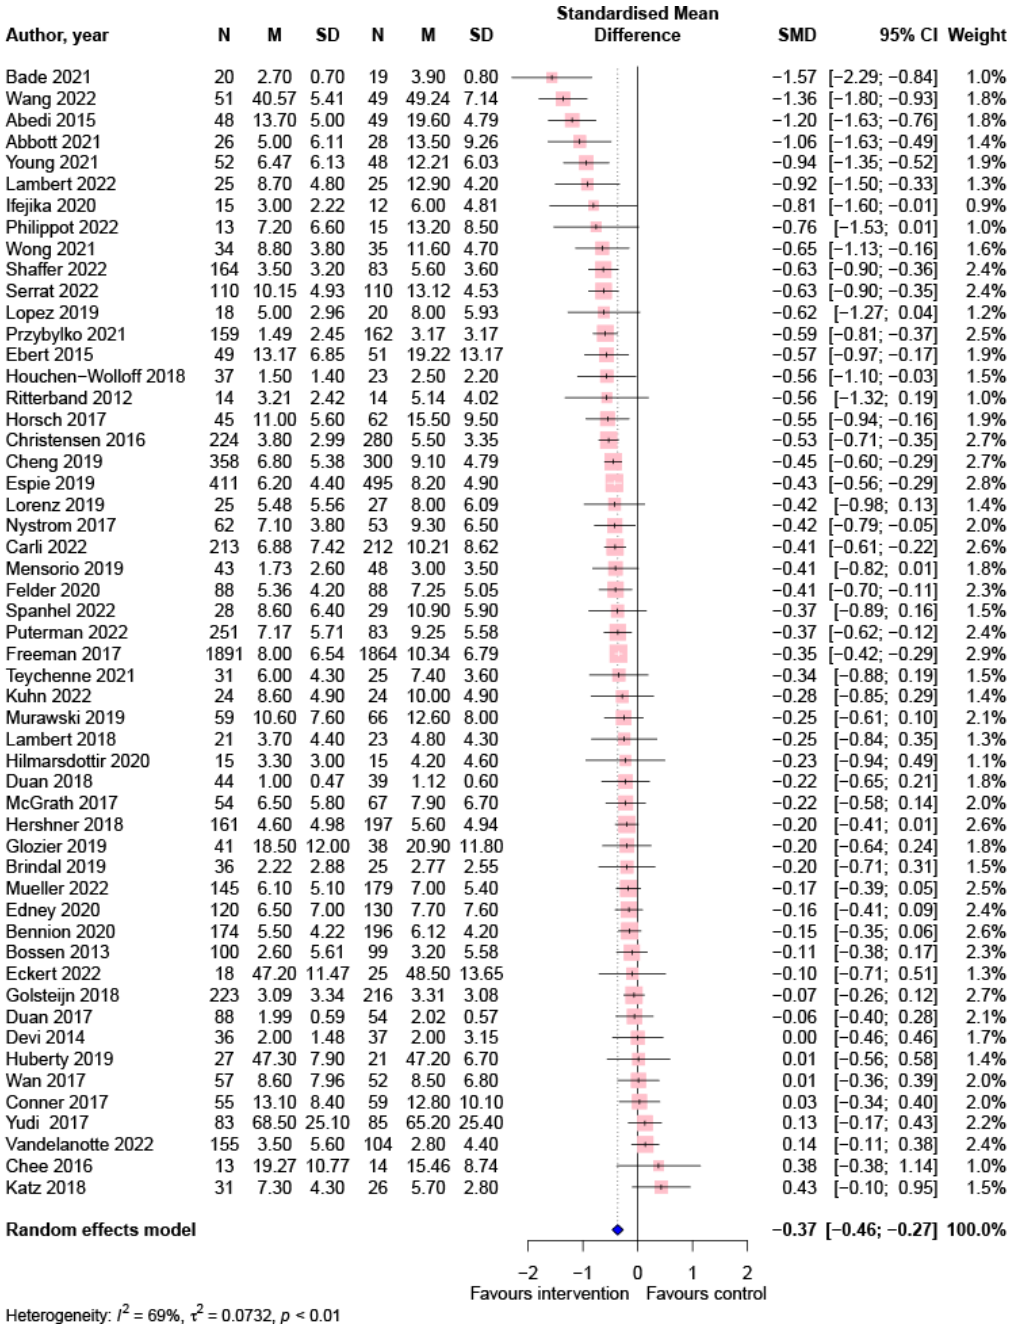
Meta-Analyses

For 2 of the included studies, the outcome data of interest was not presented in the manuscript and was unavailable after contacting the corresponding author [70,87].

Publication Bias

Visual inspection of funnel plots (Multimedia Appendix 5) suggests that there was no publication bias for depression (Kendall τ=−0.093, P=.33; Egger regression=0.19, P=.85), anxiety (Kendall τ=−0.106, P=.38; Egger regression=0.90, P=.37), or stress (Kendall τ=−0.055, P=.88; Egger regression=−0.11, P=.92).

Heterogeneity



There was significant heterogeneity across study data for depression (Q=166; P<.001; I^2=69%) and anxiety (Q=55; P=.01; I^2=39%). Stress and well-being data had moderate, nonsignificant heterogeneity (Q=17; P=.07; I^2=42% and Q=8; P=.15; I^2=39%, respectively).

Overall Effects of Digital Lifestyle Interventions on Symptoms of Depression

Pooled effects from 53 studies (ie, 12,385 participants) showed a small-to-medium significant effect of digital lifestyle interventions for reducing depressive symptoms in comparison to all control conditions (SMD=−0.37; 95% CI −0.46 to −0.27; P<.001; Figure 2).

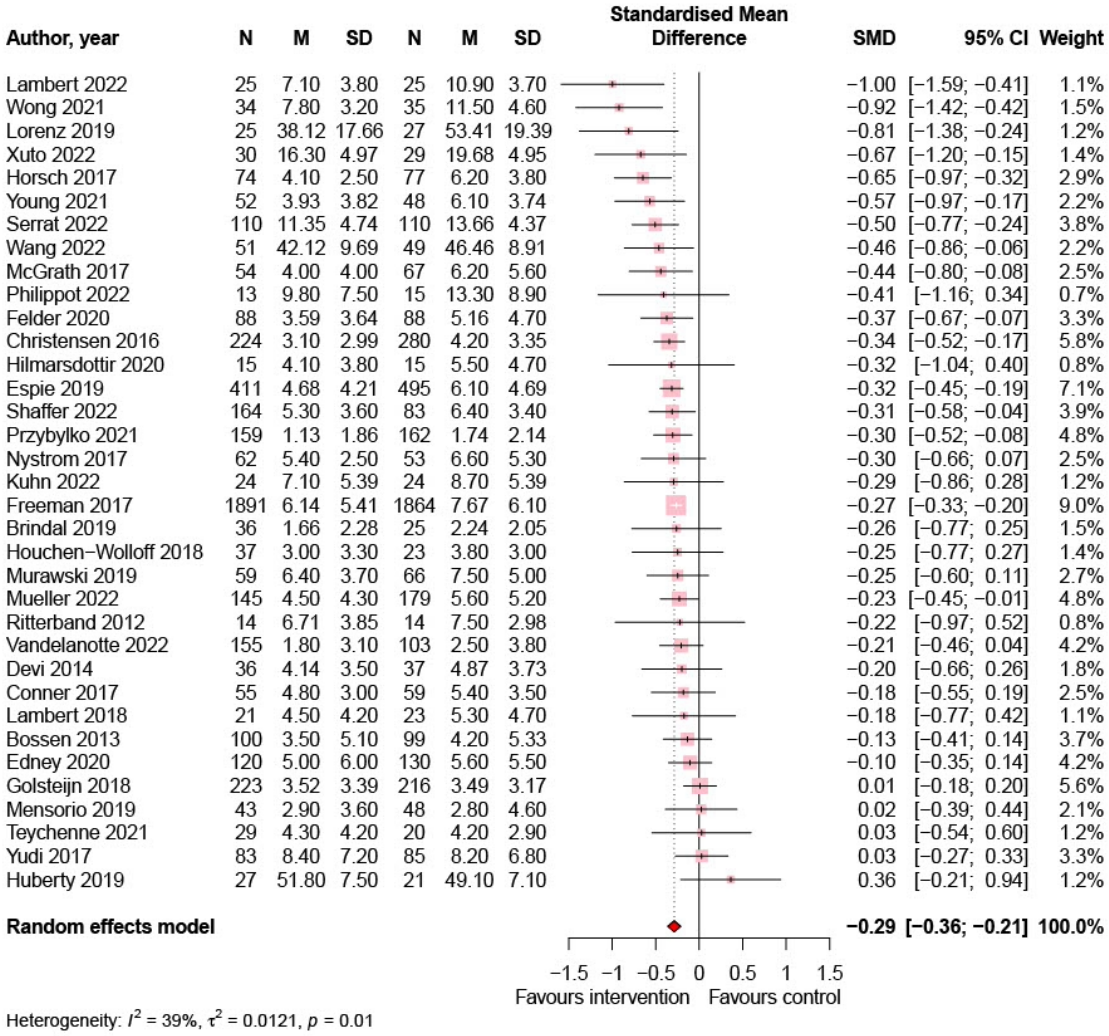
Figure 2. Meta-analysis of the effects of digital lifestyle interventions on symptoms of depression [40-42,44-58,60-69,71-83,85,86,88-90,92-95,97,98,100]. SMD: standardized mean difference.



Overall Effects of Digital Lifestyle Interventions on Symptoms of Anxiety

Figure 3 displays the pooled effect size from 35 studies (9383/22,483, 41.73%), showing a small-to-medium positive effect of digital lifestyle interventions compared to all control conditions on symptoms of anxiety (SMD=−0.29; 95% CI −0.36 to −0.21; *P*<.001).

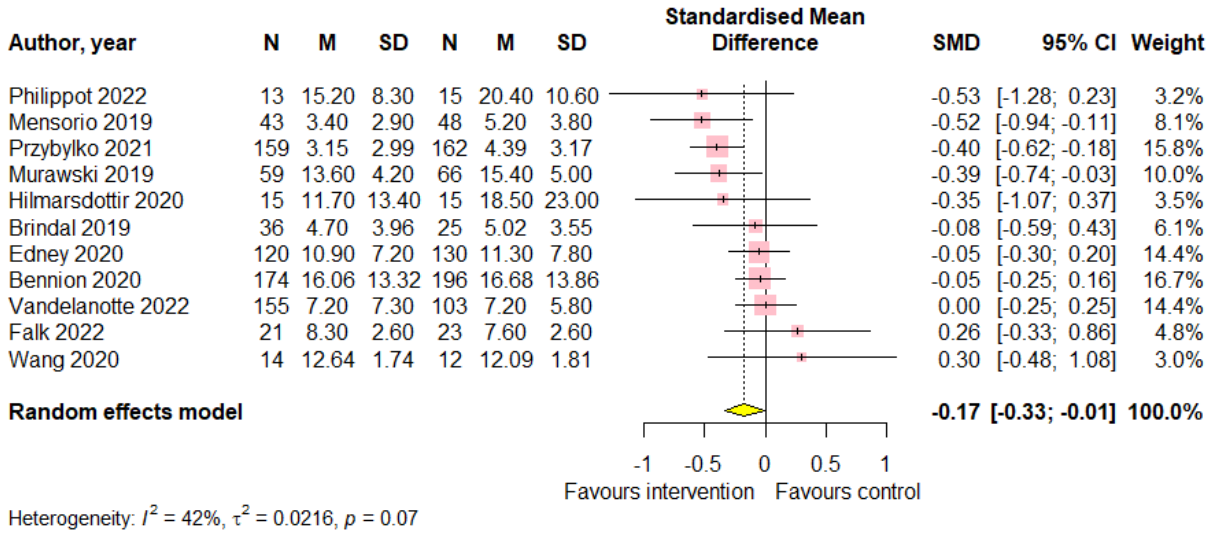
Figure 3. Meta-analysis of the effects of digital lifestyle interventions on symptoms of anxiety [45,46,50-52,57,58,60,61,63,65-68,72,73,75-83,86,88,89,92,93,95,97-100]. SMD: standardized mean difference.



Overall Effects of Digital Lifestyle Interventions on Stress

Pooled effects from 11 studies (n=1608) showed a small positive effect of digital lifestyle interventions compared to all control conditions on stress (SMD=−0.17; 95% CI −0.33 to −0.01; *P*=.04; Figure 4).

XSL•FO
RenderX

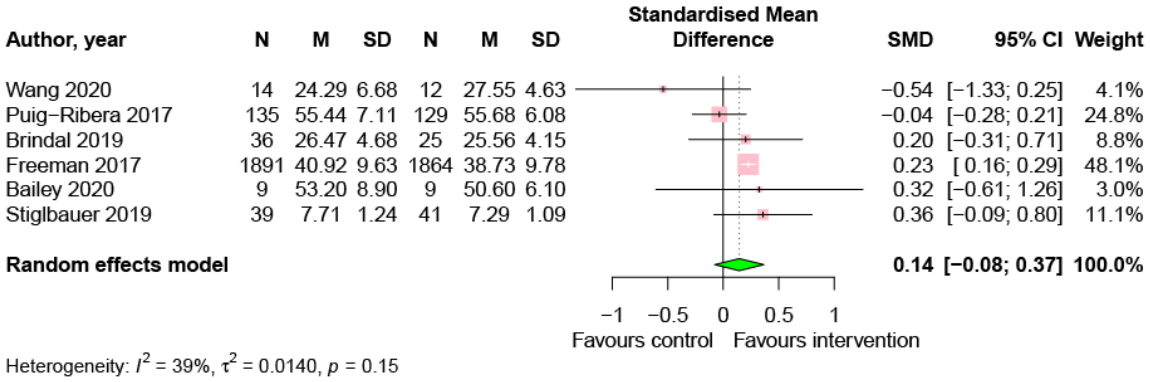


Figure 4. Meta-analysis of the effects of digital lifestyle interventions on stress [44,46,57,59,65,78,80,82,83,93,96]. SMD: standardized mean difference.

Overall Effects of Digital Lifestyle Interventions on Well-Being

Pooled effects from 6 studies (4204/22,483, 18.7%) suggest no significant effect of digital lifestyle interventions compared to all control conditions on well-being (SMD=0.14; 95% CI −0.07 to 0.37; *P*=.15; Figure 5), although the data show a nonsignificant (*P*=.15) trend in the direction that favors digital lifestyle interventions.

Figure 5. Meta-analysis of the effects of digital lifestyle interventions on well-being [43,46,61,84,91,96]. SMD: standardized mean difference.

Subgroup Analyses

Overview

To understand which aspects of digital lifestyle interventions contribute to their effectiveness in improving mental health and well-being, and for whom they are most beneficial, we conducted a series of comparative subgroup analyses. These analyses were based on technology-specific features, methodological approaches, intervention characteristics, and population characteristics. Due to the limited number of studies for stress and well-being, these analyses were conducted for depressive and anxiety outcomes only. The results are outlined in Tables 2 and 3.

Delivery Method and Features

The effectiveness of interventions for improving depression and anxiety did not significantly differ based on the digital delivery method used or their technological features (eg, video, gamification, notifications, interactive design, and social features). There was a nonsignificant trend for interventions using chatbots to be slightly more effective for reducing depressive symptoms than interventions not using chatbots (*P*=.08).

Intervention Characteristics

Interventions had similar effects on depression and anxiety, regardless of whether this was achieved through physical activity, sleep, diet, or multiple lifestyle behaviors. Diet-only interventions demonstrated nonsignificant effects on depression and anxiety, likely due to the paucity of studies.

Intervention effectiveness did not differ based on the frequency or duration of the intervention; however, long-term interventions (≥4 months) demonstrated a nonsignificant effect on depressive symptoms. Intervention effectiveness did not differ based on the intervention being personalized, based on a theoretical framework, whether they had been co-designed with consumers, or whether they were publicly available.

Methodological Characteristics

The effectiveness of interventions did not differ when comparing waitlist or no treatment controls, treatment-as-usual controls, and attention or sham controls. Similarly, effectiveness did not differ based on study quality.

Considering we included studies that did not specifically target mental health, but captured it as an outcome, we compared interventions with depression or anxiety as a primary outcome to those capturing these as secondary outcomes or exploratory outcomes. Intervention effectiveness did not differ based on whether the outcome was primary or secondary; however, the few studies that captured depression and anxiety as exploratory outcomes demonstrated nonsignificant intervention effects.

Population Characteristics

Digital lifestyle interventions demonstrated comparable effectiveness for improving depression and anxiety across all populations: apparently healthy adults, people with a mental disorder, people with a physical health condition, and people with insomnia. For depressive symptoms, the largest effect was seen in people with a mental disorder, whereas for anxiety symptoms, a nonsignificant effect was observed for those with a mental disorder.

Publication Year

The effectiveness of interventions on depression and anxiety differed significantly based on the year of publication, with more recently published interventions demonstrating the greatest effects.

Mixed-effects metaregression analysis showed no significant effect of intervention duration, study quality, or publication year on the effect of digital lifestyle interventions for depression, anxiety, stress, or well-being outcomes. A detailed overview of the metaregression analyses is provided in Multimedia Appendix 6.

Sensitivity Analyses

Sensitivity analyses for all meta-analyses are detailed in Multimedia Appendix 7. For depression, when small studies were omitted from the analysis, the effect size shrunk but remained significant (SMD=−0.28; 95% CI −0.38 to −0.19; *P*<.001). For anxiety, the effect size was slightly larger when studies with >25% attrition were removed (SMD=−0.31; 95% CI −0.43 to −0.18; *P*<.001). For stress, omitting small studies or studies with >25% attrition no longer demonstrated a significant effect (*P*=.13 and *P*=.22, respectively). The overall effect on well-being remained nonsignificant when fair to poor quality studies, small studies, and studies with >25% attrition were removed (all *P* values >.10).

Level of Evidence

Overall, the level of evidence for digital lifestyle interventions for improving symptoms of depression, anxiety, and stress is grade A: consistent level 1 studies. The grade of recommendation for digital lifestyle interventions for improving symptoms of well-being was grade D: level 5 evidence.

Discussion

Principal Findings

This systematic review aimed to comprehensively examine the effectiveness of digital lifestyle interventions for improving symptoms of depression, anxiety, stress, and well-being in adults. We identified 61 RCTs involving 22,483 participants. The findings suggest that digital lifestyle interventions had small-to-medium favorable effects on depression, anxiety, and stress symptoms across a broad range of populations and via a broad range of digital delivery methods. These effects are similar in magnitude to those observed for established mental health treatments, such as antidepressant medication [101] and psychotherapy [102]. No significant effect was observed for well-being, although in comparison to mental ill health, fewer studies (n=6) of lower average quality measured well-being outcomes. These studies operationalized well-being broadly using either global measures that span various affective and functional dimensions [43,61,84,91] or scales of overall life satisfaction [46,96]. These are broad constructs that tend to be relatively stable [103]. As a result, the available evidence offers limited precision for elucidating the effects of digital lifestyle interventions on specific well-being domains. Two-thirds of the included studies (41/61, 67%) were published within the last 5 years, reflecting the increased interest in using digital technology for health behavior change for mental health, with greater reductions in depressive and anxiety symptoms observed for more recently published interventions. This likely reflects the volume of studies published recently but may also be driven by improved quality of digital interventions as technology, particularly artificial intelligence, is better used within health promotion [104].

To better understand what factors drive the effects of digital lifestyle interventions on depressive and anxiety symptoms, we conducted a range of comparative subgroup analyses on specific

XSL•FO
RenderX

features relating to the intervention, methodology, technology, and population. These analyses found that interventions demonstrated comparable effectiveness for reducing symptoms of depression and anxiety in apparently healthy adults or adults with a mental disorder, a physical health condition, or insomnia. Equivalent effectiveness was found regardless of the lifestyle behaviors targeted, method of digital delivery (eg, app and website), technological features (ie, chatbot and gamification), intervention duration, or intended frequency of engagement. Overall, our subgroup analyses indicated that there are no specific features that drive the effectiveness of digital lifestyle interventions for improving symptoms of depression or anxiety, except for publication year.

Although differences among population groups were not significant, it appears that digital lifestyle interventions are effective for improving depressive symptoms in people with a depressive disorder but are potentially less effective at improving symptoms of anxiety in people with a depressive disorder. Interestingly, depressive disorders were the only diagnosed mental disorder in the included studies, highlighting a clear gap. Therefore, the effectiveness of these interventions as a self-management approach for other mental disorders is unclear and should be explored in future studies.

We also observed that interventions using chatbots trended toward being more effective than those without chatbots, though these results were not statistically significant. These findings have been supported with recent research,. Emerging evidence suggests chatbots can help improve lifestyle behaviors [105], although it appears their effectiveness for delivering psychological interventions (ie, therapy) is less conclusive [106]. Co-designed interventions showed a trend for being less effective. This is likely due to the small number of studies included in the subgroup analysis and the high variation of co-design approaches used in the design of health interventions, which are often poorly described and rarely evaluated [107].

A key challenge of digital health interventions is maintaining user engagement over time [13]. It is possible that the lack of significant intervention effects at 4 months was due to drop off in engagement. Alternatively, it is possible that symptoms may recur in some individuals even if they remain engaged with the intervention, reflecting the recurring nature of mental health symptoms. Digital lifestyle interventions may offer an appropriate short-term strategy to engage people in mental health–promoting behaviors and initiate positive shifts in mental health, whereas more sustainable mental health benefits may require other mental health treatment approaches. These findings reinforce the existing literature that the clinical implications of lifestyle interventions, even when delivered digitally, are compelling as a self-management tool for targeting both the risk and protective factors for mental health and should be given consideration as part of standard mental health care. This review did not directly compare digital to face-to-face delivery of these interventions; therefore, the impact that delivery method has on effectiveness should be examined directly in future research. Given the role of patient-practitioner rapport and other psychosocial benefits of in-person care, it is pivotal to understand how digital interventions may best fit and integrate within the broader health care setting, including alongside gold standard treatments, to optimize patient outcomes.

In line with previous research [108], we found interventions targeting multiple or single behaviors to have comparable effectiveness. Interventions that aim to change multiple health behaviors concurrently seem logical, given the cooccurrence of and bidirectional relationship between unhealthy lifestyle behaviors and poor mental health. In particular, some health behaviors may have synergistic impacts (eg, people who improve their sleep may have more energy for physical activity and, in turn, people who are more physically active may sleep better); therefore, future research should explore how behavior change techniques can be implemented most effectively to address multiple behaviors and aim to identify moderators of effective interventions and whether delivering lifestyle behavior change within or alongside traditional psychological interventions has synergistic effects on outcomes or improves adherence.

This review also focused on adults, although adolescence is a period when mental health issues commonly present and offers an opportune time for preventive intervention. Digital interventions would seem to be appealing and accessible for this population, given their familiarity with technology. A recent review by Raeside et al [109] included 11 interventions and found small nonsignificant effects for digital lifestyle interventions on mental health outcomes in adolescents. Considering the shared protective and risk factors for mental health and chronic diseases, future research efforts should focus on if and how digital tools can be best harnessed to address the interplay between lifestyle behaviors, mental ill health, and well-being and engage young people in the design and development of interventions through participatory research methods, such as co-design.

Strengths and Limitations

This is the largest review to evaluate the effects of digital interventions targeting lifestyle behaviors on depression, anxiety, stress, and well-being in adults. We adhered to rigorous methodological approaches for the conduct and reporting of systematic reviews and meta-analyses and conducted comprehensive database searches. In total, 87% (53/61) of the included RCTs received good or excellent quality ratings, increasing confidence in the findings of this review. Given the very large number of studies included in the meta-analyses, the dataset was sufficient to support numerous subgroup analyses, facilitating closer interrogation of the factors influencing intervention effectiveness. Our review included digital lifestyle interventions that have been evaluated using an RCT design and published in a peer-reviewed academic journal. Many commercial digital products claim to support lifestyle changes and mental health but often lack rigorous scientific assessment. The conclusions from this study should not be generalized to such unevaluated products.

Most of the study's limitations arose from the limitations of the included studies. First, only 2 studies reported on diet-only interventions, and few studies measured stress and well-being, resulting in uncertain and underpowered results for these meta-analyses and precluding subgroup analyses with stress

XSL•FO
RenderX

and well-being as outcomes. Second, all but 2 studies [41,99] were conducted in high-income countries, limiting the generalizability of our results. Third, it is important to acknowledge that our subgroup analyses, such as the comparison between single- and multibehavioral interventions, were conducted using available data from studies not specifically designed to test these differences. Consequently, these findings should be interpreted cautiously and should not be used as definitive evidence for or against any particular intervention approach. Finally, we acknowledge significant heterogeneity as a limitation, and we conducted numerous subgroup and sensitivity analyses to mitigate its impact and assess the robustness of our findings, which remained consistent with the main analyses.

Future Directions

This review highlights some key areas for future research. First, there were limited studies focused on addressing diet as a stand-alone intervention; however, a nonsignificant effect in the direction of lifestyle interventions for reducing depressive symptoms highlights that further research is needed to better determine if, and how, effective these interventions may be in addressing mental health symptoms. Second, digital interventions may be less effective over longer periods, emphasizing a need to address longer-term strategies or the potential to integrate other mental health treatment approaches, which may demonstrate greater effects over time. Research also needs to address how best to integrate these evidence-based interventions into service delivery to support health care capacity. Third, for a more complete understanding of how digital lifestyle interventions influence mental health, future research should ensure that positive aspects of mental well-being are measured alongside symptoms of mental ill health. A growing body of literature suggests that these are distinct continua, with both overlapping and unique antecedents, that should be measured in tandem [110]. Finally, as the field continues to mature and research elucidates optimal intervention designs, other factors that are imperative to consider are the influence of both health literacy and digital literacy as well as the impact of health status and socioeconomic status [111]. Furthermore, future research should consider the digital determinants of health and the direct and indirect impacts on health equity when designing health promotion interventions [112].

Conclusions

Overall, the small-to-medium effects indicate that digital lifestyle interventions may provide an effective short-term self-management strategy for mental health support by encouraging positive shifts in lifestyle behaviors. All digital delivery platforms and features demonstrated comparable effectiveness for depression and anxiety outcomes. The effectiveness on well-being is inconclusive, with few studies capturing this positive dimension of mental health. Digitally delivered lifestyle interventions support self-management and target both risk and protective factors for mental health and should be given consideration as part of mental health care and support. This is especially relevant in situations where access to in-person treatment is limited, such as due to long waitlists, financial or geographical barriers, or stigma associated with traditional treatment options.

Future research should explore how best to implement these findings and integrate such interventions with existing health care services, with concerted efforts to improve health equity by considering the digital determinants of health and impacts of digital and health literacy in the design and implementation of these interventions.

Acknowledgments

This study received no funding. CM received an Investigator Grant from the Medical Research Future Fund (1193862). JF is supported by a UK Research and Innovation Future Leaders Fellowship (MR/T021780/1). Abstract

Background: Emerging evidence underscores the potential application of artificial intelligence (AI) in discovering noninvasive blood biomarkers. However, the diagnostic value of AI-derived blood biomarkers for ovarian cancer (OC) remains inconsistent.

Objective: We aimed to evaluate the research quality and the validity of AI-based blood biomarkers in OC diagnosis.

Methods: A systematic search was performed in the MEDLINE, Embase, IEEE Xplore, PubMed, Web of Science, and the Cochrane Library databases. Studies examining the diagnostic accuracy of AI in discovering OC blood biomarkers were identified. The risk of bias was assessed using the Quality Assessment of Diagnostic Accuracy Studies–AI tool. Pooled sensitivity, specificity, and area under the curve (AUC) were estimated using a bivariate model for the diagnostic meta-analysis.

Results: A total of 40 studies were ultimately included. Most (n=31, 78%) included studies were evaluated as low risk of bias. Overall, the pooled sensitivity, specificity, and AUC were 85% (95% CI 83%-87%), 91% (95% CI 90%-92%), and 0.95 (95% CI 0.92-0.96), respectively. For contingency tables with the highest accuracy, the pooled sensitivity, specificity, and AUC were 95% (95% CI 90%-97%), 97% (95% CI 95%-98%), and 0.99 (95% CI 0.98-1.00), respectively. Stratification by AI algorithms revealed higher sensitivity and specificity in studies using machine learning (sensitivity=85% and specificity=92%) compared to those using deep learning (sensitivity=77% and specificity=85%). In addition, studies using serum reported substantially higher sensitivity (94%) and specificity (96%) than those using plasma (sensitivity=83% and specificity=91%). Stratification by external validation demonstrated significantly higher specificity in studies with external validation (specificity=94%) compared to those without external validation (specificity=89%), while the reverse was observed for sensitivity (74% vs 90%). No publication bias was detected in this meta-analysis.

Conclusions: AI algorithms demonstrate satisfactory performance in the diagnosis of OC using blood biomarkers and are anticipated to become an effective diagnostic modality in the future, potentially avoiding unnecessary surgeries. Future research

is warranted to incorporate external validation into AI diagnostic models, as well as to prioritize the adoption of deep learning methodologies.

Introduction

Ovarian Cancer Diagnosis: Status and Demands

Ovarian cancer (OC) is the deadliest gynecologic malignancy, characterized by nonspecific symptoms that often remain undetected until the disease has progressed [1,2]. The conventional diagnosis of OC principally depends on imaging techniques (encompassing ultrasound, computed tomography, and magnetic resonance imaging); serum biomarkers (such as cancer antigen 125, carcinoembryonic antigen, and human epididymis protein 4); along with the invasive procedure (histological biopsy) [3,4]. However, the sensitivity and specificity of imaging techniques and biomarkers are restricted [5]. Furthermore, the histopathological test is inherently invasive [3]. Therefore, there is an urgent need for more accurate, noninvasive, and reliable diagnostic methods.

Potential of Noninvasive Blood Markers for OC

Minimally invasive diagnostic procedures, particularly the use of blood samples, are among the foremost common methods of detection [6]. Moreover, patients are generally more willing to undergo blood tests, leading to higher compliance rates [7]. Blood contains a rich repertoire of biomolecules, including proteins, nucleic acids, and metabolites, which can potentially serve as indicators of OC diagnosis [8-11]. The development of omics has opened new doors for biomarker discovery. The genomics, proteomics, and metabolomics of blood samples can provide a wealth of information about the molecular changes in cancer [12]. For instance, Ke et al [13] systematically investigated OC metabolism through the metabolic profiling of 448 plasma samples. The analysis of dysregulated metabolic pathways extends our current understanding of OC metabolism. Similarly, Dhar et al [8] applied glycoproteomics to serum of women with OC or benign pelvic masses and healthy controls and analyzed glycosylation patterns in serum markers and supported the hypothesis that blood glycoproteomic profiling can be used for OC diagnosis and staging. Notably, the exponential growth of multiomics data has presented a major challenge that surpasses traditional analytic capabilities [14,15]. Fortunately, artificial intelligence (AI) algorithms offer a solution [16,17]. AI can manage complex datasets and spot hidden patterns and potential biomarkers, enabling more accurate OC diagnosis and personalized treatment.

Application of AI in OC Blood Markers

AI, particularly machine learning (ML) and deep learning (DL), has attracted increasing attention in medical research due to its capability to analyze large biomedical datasets [18-23]. AI-driven models have emerged as a promising tool for developing predictive models for OC by analyzing complex and multidimensional datasets to uncover biomarkers. For instance, a multicenter retrospective study screened 52 features from laboratory tests in blood samples to build an ML model. Integrating 20 base AI models, it performed well internally and externally, outperforming the CA125 and HE4 biomarkers in identifying OC [24]. In addition, a blood-based metabolite panel demonstrated independent predictive ability and complemented the risk of ovarian malignancy algorithm for distinguishing early-stage OC from benign disease to better inform clinical decision-making [25]. Despite such encouraging results, the related results are scattered. Whether the application of AI in OC blood biomarker research can significantly improve diagnostic accuracy remains controversial.

Purpose of This Study (AI and OC Blood Markers)

Therefore, there is a crucial need for a high-quality synthesis of the available evidence. The purpose of this study is to provide a systematic overview of the diagnostic accuracy of AI techniques in identifying OC blood markers as well as to elucidate their applicability, potential, and limitations.

Methods

Protocol Registration and Study Design

This meta-analysis was conducted in adherence to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist (Multimedia Appendix 1) and MOOSE (Meta-Analysis of Observational Studies in Epidemiology) reporting guidelines [26,27]. The protocol was prospectively registered with the International Prospective Register of Systematic Reviews (PROSPERO; CRD42023481232).

Literature Search and Eligibility Criteria

A comprehensive search of the MEDLINE, Embase, IEEE Xplore, PubMed, Web of Science, and the Cochrane Library databases was carried out from inception to January 16, 2024. Detailed search strategies are summarized in Multimedia Appendix 2. Two independent investigators (MQJ and HLX) assessed the records after removing the duplicates at the title and abstract level, and finally at the full-text level, according to the inclusion and exclusion criteria (Textbox 1). Two investigators (MQJ and XYL) independently appraised the articles for eligibility. An inconsistency in selection was reconciled through discussion with a third independent investigator (HLX).

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Population: adults (aged ≥18 years) with potential ovarian cancer lesions
- Intervention: artificial intelligence–assisted blood test
- Comparison: histopathology or other reliable clinical diagnosis
- Outcomes: diagnostic performance (ie, sensitivity and specificity or detailed information that could extract or construct 2×2 contingency tables)
- Studies: original articles (ie, observational studies or randomized controlled trials)
- Language: English

Exclusion criteria

- Population: nonhuman samples or other diseases
- Intervention: nonblood samples or no artificial intelligence algorithms
- Comparison: no control group
- Outcomes: no diagnostic performance data (ie, 2×2 contingency tables cannot be extracted or constructed from the provided data)
- Studies: records, such as letters, conference abstracts, case reports, or review articles
- Language: non-English

Data Extraction

Data were independently extracted by 2 investigators (QPM and XYL) using a predefined data extraction sheet, with any discrepancies resolved through the adjudication of a third investigator (HLX). Necessary data of 2×2 contingency tables that included true positives (TP), false positives, true negatives (TN), and false negatives were extracted. The details of the data are presented in Multimedia Appendix 3 [8,24,25,28-64]. In cases where these values were not explicitly reported, values were calculated using descriptive statistics available in the study. For studies presenting multiple contingency tables, either for identical or disparate AI algorithms, each table was treated as an independent result [65].

Study Quality Assessment

The risk of bias and concerns about the applicability of all included studies were assessed by 2 independent investigators (MQJ and HLX), using the Quality Assessment of Diagnostic Accuracy Studies–Artificial Intelligence (QUADAS-AI) criteria [66]. Conflicts were discussed and solved with a third investigator (XYL). The risk of bias assessment included 4 domains: patient selection, index test, reference standard, and flow and timing. For assessing clinical applicability, only the first 3 domains were evaluated [66,67]. In addition, the median was used as the threshold for determining the risk level of bias, with studies classified as low risk if ≥2 domains were deemed as low risk and high risk if <2 domains were considered low risk [68].

Data Analysis

We used the bivariate diagnostic random effects model to compute the summary receiver operating characteristics to determine summary estimates of the sensitivity, specificity, and area under the curve (AUC) with their respective 95% CIs [69]. Sensitivity was defined as the probability of a person with OC having a positive test result, indicating the capacity of the index test to identify patients, considered by the equation: sensitivity = TP / (TP + false negatives). Specificity was the probability of a woman without OC having a negative test result, reflecting the test's ability to correctly identify OC-free individuals calculated by the equation: specificity = TN / (false positives + TN) [70,71]. The performance of the test can also be assessed using the AUC. This area may be interpreted as the probability that a random woman with OC has a higher value of the measurement than a random person without OC. In general, an AUC of >0.80 is considered good [72]. A perfect test would have an AUC of 1 and a useless test would have an AUC of 0.5 [73].

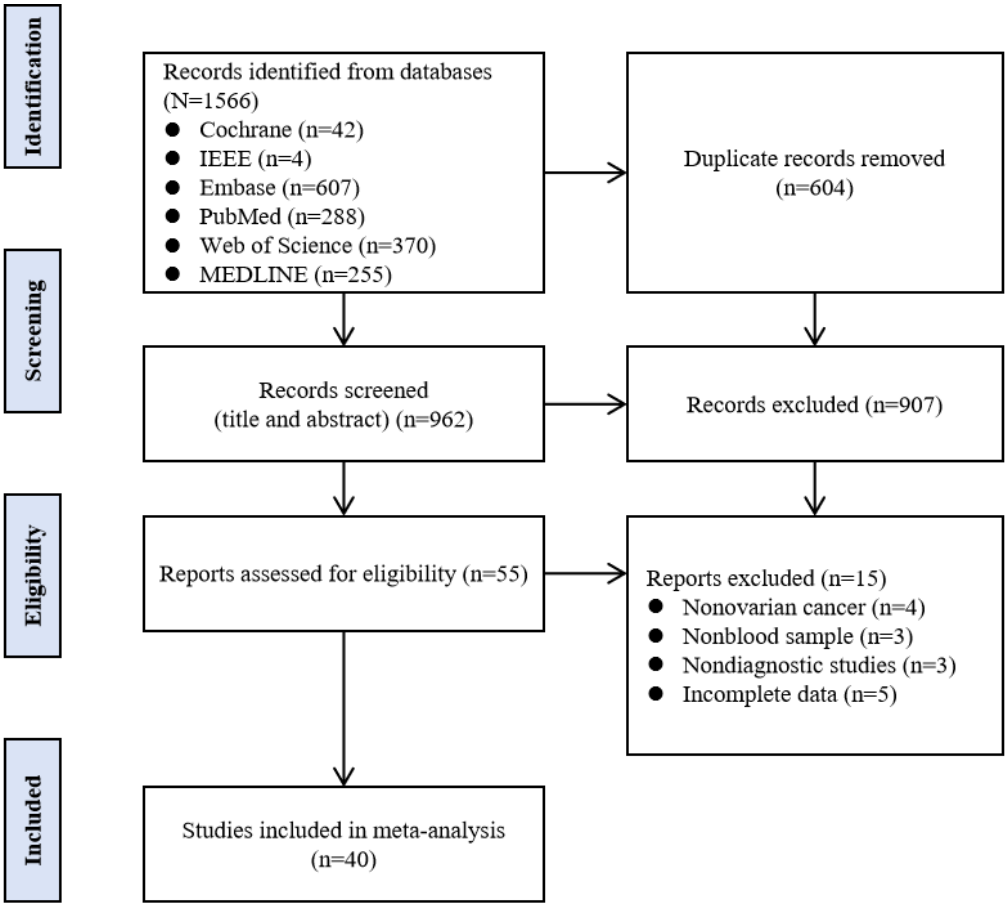
Study heterogeneity was determined using the I^2 statistic and the Q test [74]. When the same or different AI models were tested within the same article, the proposed model with the best accuracy was used for further meta-analysis [65]. Subgroup and regression analyses were performed to explore potential sources of heterogeneity. Sensitivity analysis was implemented via a qualitative systematic review of studies from which concatenated tables could not be extracted or constructed. Publication bias was assessed using funnel plot asymmetry test by Deeks et al [75].

Subgroup analyses were performed according to the following: (1) AI algorithms (ML or DL), (2) external validation (yes or no), (3) levels of risk of bias (low or high), (4) year of publication (after or before 2022), (5) geographical distribution (Asia, North America, or Europe), (6) sample size (>300 or ≤300 as median), (7) blood sample type (serum or plasma), (8) biomarkers type (protein or mixed), and (9) number of modeling biomarkers (>8 or ≤8 as median).

The variability in sensitivity and specificity estimates was graphically represented through a cross-hairs plot, generated using R software (version 4.2.1; R Foundation for Statistical Computing) [76]. All other statistical analyses were conducted

XSL•FO
RenderX

in Stata (version 17.0; StataCorp). The statistical significance was defined as $P<.05$.



Results

Study Selection and Characteristics of Eligible Studies

The database search identified 1566 records from which 604 duplicates were removed. We then performed the title and abstract screening of 962 records and subsequently a full-text evaluation of 55 records. Following the exclusion of 15 articles, as detailed in Multimedia Appendix 4 [77-91], a total of 40 studies were included in this meta-analysis (Figure 1).

Most of the studies were performed with retrospectively (21/40, 52%) and prospectively (18/40, 45%) collected data, and one study collected both retrospective and prospective data (Table 1). In total, 12% (5/40) of studies sourced their data from public databases. In terms of AI algorithm types, a total of 36 (90%) studies were classified as ML, whereas 10% (4/40) of studies were classified as DL. Most (36/40, 90%) of the studies validated their algorithms, while only some (7/40, 18%) studies carried out an external validation (Table 2). The blood samples were mainly serum (27/40, 68%), and the type of blood biomarkers was mainly protein (25/40, 62%; Table 3).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for study selection and processing in the meta-analysis.

Wilding et al [64], 1994	Serum and plasma	Radioimmunoassay	Mixed	8	8

[a]NR: not reported.

[b]LC-WGS: low-coverage whole genome sequencing.

[c]LC-MS: liquid chromatography-mass spectrometry.

[d]MS: mass spectrometry.

[e]SEC: size exclusion chromatography.

[f]ELISA: enzyme-linked immunosorbent assay.

[g]UHPLC-MS: ultra-high performance liquid chromatography-mass spectrometry

[h]ACE: alternating current electrokinetics.

[i]MALDINR-TOF MS: matrix-assisted laser desorption/Ionization neutral reflector time-of-flight mass spectrometry.

[j]CHCA: α-Cyano-4-hydroxycinnamic acid matrix.

[k]SA: sinapinic acid matrix.

[l]SERS: surface-enhanced Raman spectroscopy.

[m]SELDI -TOF MS: surface-enhanced laser desorption and ionization mass spectrometry.

[n]MB-IMAC Cu: magnetic beads MB-IMAC Cu.

[o]MB-HIC8: magnetic beads MB-HIC 8.

[p]MB-HIC18: magnetic beads MB-HIC 18.

[q]MB-WCX: magnetic beads MB-WCX.

Quality Assessment

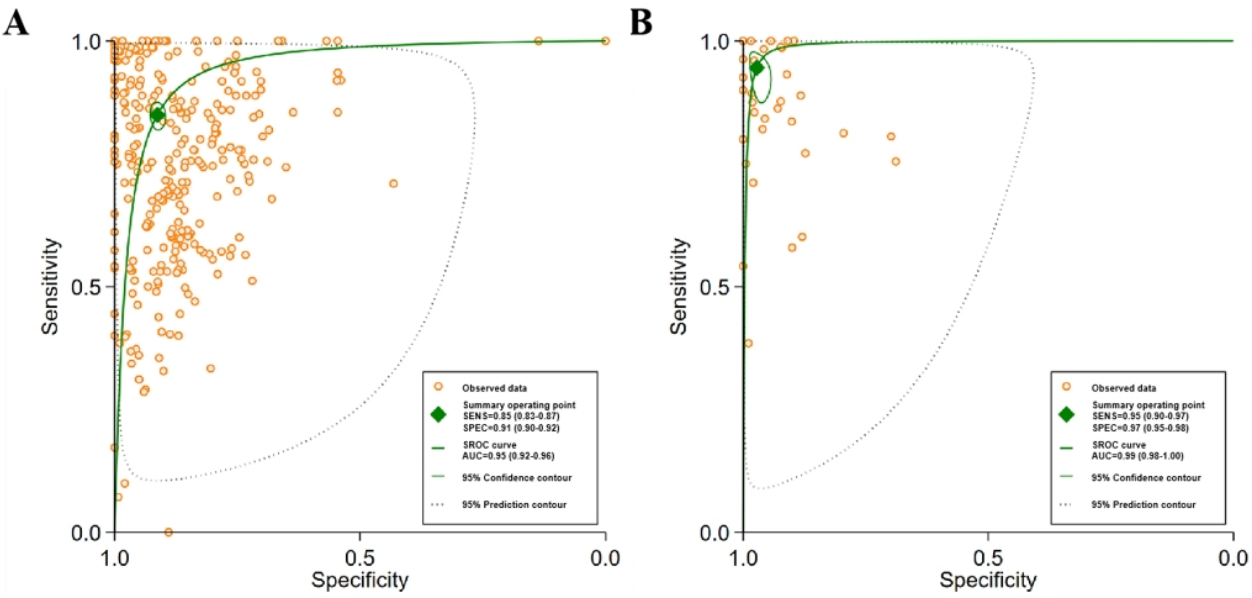
The quality of the included studies was appraised using the QUADAS-AI (Figures S1 and S2 in Multimedia Appendix 5). In detail, most of the studies were rated as having a high or unclear risk of bias based on patient selection (22/40, 55%) and index test (33/40, 82%) domains. These assessments might be attributed to the absence of explicit delineation of included patients, such as previous testing history and clinical setting, as well as to deficiencies in rigorous external validation of the AI models.

Pooled Performance of AI Algorithms

The summary receiver operating characteristics curves for the 40 included studies with 342 contingency tables are shown in Figure 2. The pooled sensitivity and specificity were 85% (95% CI 83%-87%) and 91% (95% CI 90%-92%), respectively, with an AUC of 0.95 (95 % CI 0.92-0.96) for all AI algorithms. Notably, when contingency tables with the highest accuracy were extracted from each study, the pooled sensitivity and specificity were 95% (95% CI 90%-97%) and 97% (95% CI 95%-98%), respectively, with an AUC of 0.99 (95% CI 0.98-1.00). Reported point estimates and CIs of all included studies are shown in a cross-hairs plot (Figure 3).

XSL•FO
RenderX

Figure 2. Summary receiver operating characteristic (SROC) curves of all studies included in the meta-analysis (n=40). (A) SROC curves of all studies included in the meta-analysis (40 studies with 342 tables). (B) SROC curves of studies when selecting contingency tables reporting the highest accuracy (40 studies with 40 tables). AUC: area under the curve; SENS: summary sensitivity; SPEC: summary specificity.



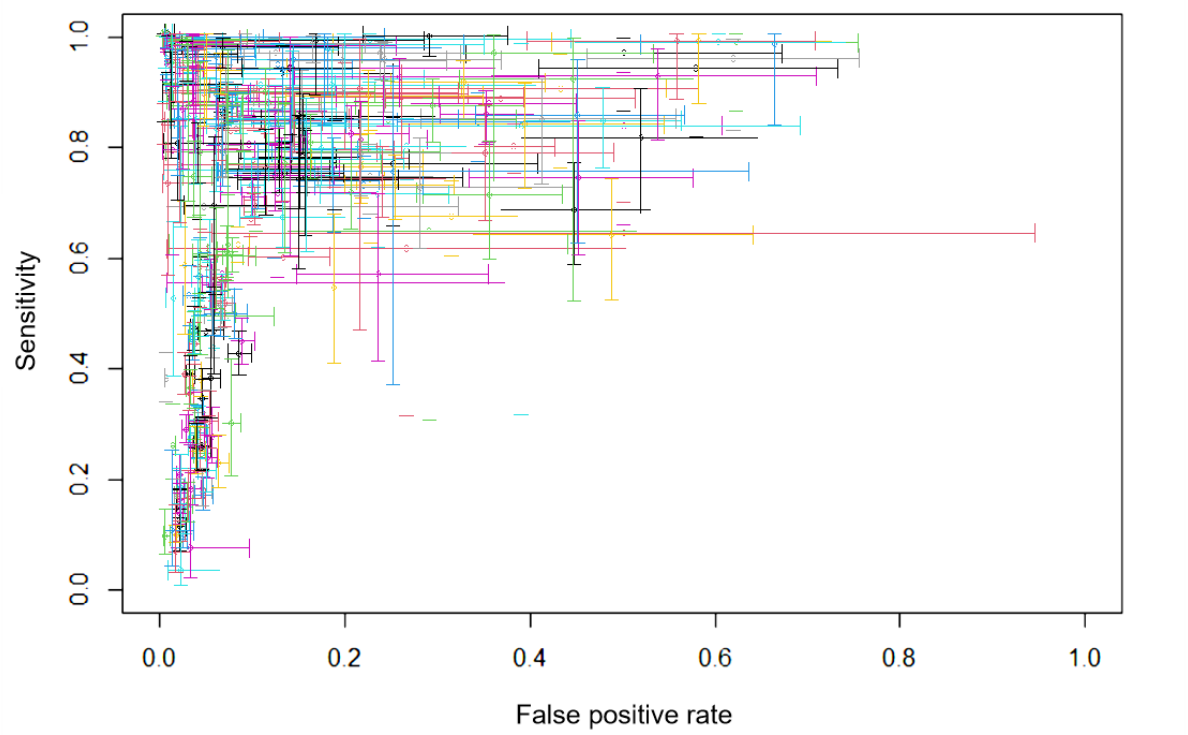


Figure 3. Cross-hair plot of all studies included in the meta-analysis (n=40).

Subgroup Analyses and Meta-Regression Analysis

Results of the subgroup analyses revealed that acceptable diagnostic performance was observed in all subgroups, ranging from 74% to 98% for sensitivity and 85% to 96% for specificity. Detailed results are shown in Table 4, and the corresponding plots are presented in Figures S3-S21 in Multimedia Appendix 5. We divided the studies into subgroups according to the modalities of algorithms (Figures S3 and S13 in Multimedia Appendix 5), existence of external validation (Figures S4 and S14 in Multimedia Appendix 5), levels of risk of bias (Figures S5 and S15 in Multimedia Appendix 5), year of publication (Figures S6 and S16 in Multimedia Appendix 5), geographical distribution (Figures S7 and S17 in Multimedia Appendix 5), sample size (Figures S8 and S18 in Multimedia Appendix 5), blood sample type (Figures S9 and S19 in Multimedia Appendix 5), biomarkers type (Figures S10 and S20 in Multimedia Appendix 5), and number of modeling biomarkers (Figures S11 and S21 in Multimedia Appendix 5).

≤8	14 (35)	0.79 (0.74-0.83)	88.11 (85.74-90.49)	<.001	—	0.90 (0.88-0.92)	79.83 (75.13-84.52)	<.001	—

[a]*P* value for heterogeneity between subgroups with meta-regression analysis.

[b]*P* value for heterogeneity within each subgroup.

[c]Not applicable.

[d]Artificial intelligence algorithms include machine learning and deep learning.

[e]Low: ≥2 domain low risk; high: <2 domain low risk.

[f]Five articles that used incomplete information on blood sample type were excluded from this subgroup analysis.

[g]Three DNA studies that used DNA and 1 study that used RNA were excluded for this subgroup analyses.

[h]In total, 11 articles used incomplete information on the number of model markers were excluded for this subgroup analysis.

The meta-analysis uncovered substantial heterogeneity among studies, as evidenced by an I^2 of 97.54% (*P*<.05) for sensitivity and 99.15% (*P*<.05) for specificity (Figure S12 in Multimedia Appendix 5). To further explore the causes of study heterogeneity, a meta-regression analysis was conducted (Table 4). The results showed that both external validation and year of publication were significant factors that influenced study heterogeneity with regard to sensitivity and specificity. Subgroups based on levels of risk of bias, geographical distribution, sample size, and blood sample type showed intergroup heterogeneity in the sensitivity of prediction (*P*<.05). In terms of marker type, specificity presented significant heterogeneity between groups (*P*<.05).

Sensitivity Analyses and Publication Bias

A qualitative systematic review was performed for studies lacking directly or indirectly available contingency tables. The findings from this review were in alignment with the main analysis (Tables S1-S3 in Multimedia Appendix 6 [77-81]). In addition, the analysis did not reveal any publication bias in this meta-analysis (*P*=.72; Multimedia Appendix 7).

Discussion

Principal Findings

The burgeoning evolution of AI within the medical field has captured the attention of an increasing cadre of researchers, particularly in its applicability to disease diagnosis [92,93]. To the best of our knowledge, this meta-analysis is a pioneering effort specifically exploring the efficacy of AI in OC diagnosis via blood biomarkers. AI algorithms exhibited exceptional diagnostic capabilities for OC, boasting a pooled sensitivity of 85% (95% CI 83%-87%) and specificity of 91% (95% CI 90%-92%). Moreover, we identified substantial heterogeneity among the selected studies and determined the potential contributing factors through subgroup and meta-regression analyses. Overall, these results should be interpreted with caution as described by the constraints mentioned in subsequent sections.

Heterogeneity

Heterogeneity is an inevitable problem in meta-analyses [94]. Significant interstudy heterogeneity was noted in terms of sensitivity (I^2=97.54%) and specificity (I^2=99.15%) in this study. External validation emerged as a crucial variable influencing study heterogeneity. Studies without external validation might yield results that were hard to generalize owing to factors such as sample selection bias and the characteristics of the research setting [95]. To address this, future research should focus on standardizing and applying the validation procedures, thus getting closer to the goal of providing more accurate and reliable diagnostic tools for clinical practice [96]. Besides, several factors contributed to the heterogeneity observed in sensitivity in this study. Studies with a pronounced risk of bias were predisposed to introduce uncertainties. Such biases could stem from flaws in study design, improper data collection, or inappropriate statistical analyses, all of which might distort the true relationship between the biomarker and the condition under investigation [67,97]. On the other hand, geographic disparities might be attributed to a complex interplay of genetic polymorphisms and environmental factors that differentially modulate biomarker expression levels, which could result in significant variability in biomarker sensitivity [98,99]. In addition, larger sample sizes generally offer enhanced statistical power and precision, enabling more reliable estimations of biomarker performance [100]. Understanding and accounting for these factors comprehensively will help to further reduce heterogeneity and enhance the validity and clinical relevance of meta-analysis results, ultimately leading to more precise and useful diagnostic tools for clinical application.

Implication of Blood Sample Types

Blood specimens are relatively stable and can be easily accessed. Therefore, blood-based biomarkers have been regarded as a minimally invasive method with great value for disease diagnosis [101,102]. Plasma and serum are rich sources of information regarding an individual's health state and are the focus of this study's investigation [103]. Particularly noteworthy is that serum samples showed higher sensitivity than plasma ones in this study, which can potentially be ascribed to multiple

XSL•FO
RenderX

factors. First, the distinct sample preparation procedures for serum and plasma may lead to variations in the concentration and availability of biomarkers. Serum is obtained after blood clotting, during which certain intracellular components can be released, potentially augmenting the repertoire of biomarkers [104]. In contrast, the anticoagulants used in plasma collection may impede the integrity or accessibility of biomarkers [105]. Second, the microenvironment within serum and plasma varies. Serum contains a more intricate milieu of proteins, enzymes, and other biomolecules that can interact with cancer biomarkers in a manner that heightens their detectability [102]. For example, the presence of specific binding proteins or proteases in serum may modify the conformation of biomarkers, rendering them more amenable to detection by the analytic methods used [106]. Furthermore, the centrifugation processes involved in separating serum and plasma can differentially partition the biomarkers. The speed, duration, and temperature of centrifugation may cause certain biomarkers to be preferentially retained in the serum fraction, contributing to the observed higher sensitivity [107]. In addition, the limited number of included studies for plasma may contribute to this phenomenon to some extent. Therefore, it is of paramount importance to judiciously select the sample type in the context of developing and implementing blood-based biomarker assays for OC.

Implication of Algorithm Types

In subgroup analysis, ML surpassed DL in both sensitivity and specificity. This phenomenon warrants an in-depth exploration of the underlying reasons and improvement directions. The edge of ML likely stems from its algorithmic traits. For structured and well-defined data, traditional algorithms (eg, logistic regression and support vector machine) can adeptly capture biomarker-disease associations via mathematical and statistical tenets, yielding high diagnostic accuracy [108,109]. DL, empowered by its strong automatic feature extraction and complex architecture, can theoretically handle large data and extract deep patterns [110]. However, in this study, the number of studies included for DL was only 4, compared with 36 for ML, presumably constraining the exertion of DL's advantages. The scant number of DL studies gives rise to data that are circumscribed in both sample variety and the expanse of feature distribution. To break through this dilemma, several optimization strategies can be considered. First, data augmentation, such as random rotations, scaling, flipping, and noise addition to the data can enhance dataset diversity, facilitating the DL model to learn more extensive features and patterns for better generalization [110-112]. Second, transfer learning is applicable. Using pretrained models from related medical or bioanalysis fields and fine-tuning with OC data, the DL model can draw on prior knowledge, accelerating training convergence and potentially improving performance [113,114]. In addition, model compression techniques, including pruning (ie, eliminating less important connections or neurons to maintain performance while reducing complexity) and quantization (ie, lowering parameter precision for faster inference and less memory use) can be used [115]. While these strategies hold promise, their implementation and efficacy in the context of OC diagnosis warrant further investigation and optimization.

Implication of External Validation

At present, the data amassed for AI applications in OC diagnosis is circumscribed by the paucity of diverse external validation. Many studies rely on a single dataset for discovery, with cross-validation to estimate algorithm performance. Given the generalizable issues to unseen data, accuracy drops when tested on other research datasets, and substantially when tested on clinical data [116,117]. To address these challenges, several strategies can be implemented. First, multicenter collaborations should be actively pursued. Combining data from different medical institutions and regions to build a heterogeneous and comprehensive dataset and exposing algorithms to wider patient characteristics and biomarker profiles will enhance generalizability [118-120]. Second, standardized data collection and annotation protocols are crucial. They ensure data consistency and comparability among studies, minimizing variability from inconsistent methods [121]. This allows algorithms to be trained on more reliable and reproducible data, strengthening the foundation for AI application. Moreover, continuous evaluation and improvement of algorithms in clinical settings are essential. Prospective studies integrating the algorithms into routine practice and monitoring their performance can offer valuable feedback [122]. This iterative testing and refinement process helps algorithms adapt to clinical complexity, leading to more accurate OC diagnostic tools. Despite persisting challenges, we anticipate that these efforts will incrementally enhance diagnostic accuracy. Sustained refinement and collaboration are essential to exploiting the full potential of AI in OC diagnosis.

Future Directions

Beyond the previous mentions, the existing literature in the field exhibits certain areas of improvement to reduce the gap between research and deployment. First, one of the richest data sources of patient health and clinical history is embedded in the electronic health records of a patient but remains hugely underutilized. AI's ability to integrate blood biomarkers with other clinically relevant nonblood biomarkers, such as age, cancer history, and family history of cancer, could potentially outpace current practices if trained on sufficiently extensive datasets [123]. Future research could explore the synergistic integration of AI tools with clinical expertise, echoing a more realistic clinical scenario. Second, the problem of explainability is the subject of intensive research and various initiatives. Although symbolic AI or simple ML models, such as decision trees or linear regression, are still fully understood by people, understanding becomes increasingly difficult with more advanced techniques and is now impossible with many DL models; this situation can lead to unexpected results and nondeterministic behavior [124,125]. Third, data privacy and patient consent are critical concerns that need to be addressed before adopting the use of AI in clinical practice [126]. The integration of AI into clinical workflows requires careful consideration of ethical, legal, and regulatory aspects [127,128]. Transparent guidelines and regulations should be established to govern the use of AI in health care and ensure its responsible and ethical implementation.

Strengths and Limitations

Our meta-analysis has several strengths. First, to the best of our knowledge, it represents a novel effort as the first systematic review and meta-analysis dedicated to evaluating the diagnostic performance of blood biomarker-based AI for OC. Our findings illuminate the considerable potential AI holds in this domain, while also highlighting the advantages of blood tests, such as their noninvasive nature, better patient compliance, and cost-effectiveness. Second, our comprehensive investigation included multiple subgroup analyses, all of which yielded acceptable diagnostic performance for the AI model. Third, the stringent quality assessment of all included studies was conducted using QUADAS-AI tool. In addition, the robustness of our meta-analysis was reinforced through a sensitivity analysis underpinned by a qualitative systematic review.

The results of our meta-analysis are likely to be overestimated or underestimated for some reasons. One limitation lies in the high heterogeneity of the studies included. Nonetheless, we thoroughly explored potential sources of between-study heterogeneity through meta-regression and subgroup analyses. Another limitation is that the contingency tables of 5 studies included in our systematic review were not directly or indirectly available. These studies provided only indicators, such as AUC, accuracy, and F_1-score, which did not allow for the construction of contingency tables [77-81]. Nevertheless, we conducted a qualitative systematic review of these 5 studies and discovered that the findings aligned with the main analysis. Moreover, although no publication bias was noticed, it is still highly likely that there is unpublished material for this topic from the ever-growing nature of the framework and the likelihood of undisclosed research for commercial development [129]. Moreover, available AI research tends to be skewed toward the publication of positive results, indicating a potential publication bias.

Conclusions

The findings of this study indicated that the use of AI for the analysis of noninvasive blood biomarkers in OC diagnostics holds substantial potential for achieving satisfactory predictive outcomes. Among the analyzed studies, those that used DL were notably fewer in number than those that used ML. This underscores a critical need for future research to prioritize the incorporation of DL methodologies. Furthermore, pursuing external validation datasets was a necessary avenue to optimize the performance and applicability of AI in this field.

Abstract

Background: Digital mental health interventions (DMHIs) offer unique strengths as emerging services with practical applications for adolescents and young adults (AYAs) experiencing depression, anxiety, and stress. Although promising, acceptance and participation in DMHIs vary across interventions, participants, and contexts. It is essential to delineate and synthesize the factors that promote or hinder DMHI use.

Objective: This review aims to assess and synthesize the facilitators and barriers to accessing DMHIs for depression, anxiety, and stress in AYAs through a scoping review.

Methods: A comprehensive search was conducted across multiple databases, including PubMed, Web of Science, PsycINFO, CNKI, OpenGrey, and APA PsycExtra, up to October 31, 2023. Articles examining facilitators and barriers to DMHIs among AYAs with disorders or symptoms of depression, anxiety, and stress were included. Data synthesis and analysis involved quality assessment, thematic analysis, and relative frequency meta-analysis.

Results: A total of 27 records met the eligibility criteria, and 14 facilitators and 13 barriers were identified across the external, intervention, and individual levels. The relative frequency meta-analysis indicated that factors influencing AYAs' use of DMHIs varied based on delivery modes. Among these factors, "quality and effect" emerged as the predominant theme—high quality and effect served as the primary facilitator, while low quality and effect acted as a barrier across both portable and nonportable devices, as well as single and multiple platforms.

Conclusions: The uptake of DMHIs among AYAs is influenced by a complex interplay of facilitators and barriers, particularly those related to quality and effect. Our syntheses provide crucial guidance for intervention designers, emphasizing the importance of user-centered approaches that balance scientific rigor with engaging and adaptive features. Enhancing the alignment of DMHIs with adolescent needs can improve both adoption and real-world mental health impact.

Introduction

Digital mental health interventions (DMHIs) have emerged and gained popularity as new tools and approaches for mental health services, driven by the development of the internet and mobile devices [1]. Nearly half of the global population with mental health needs lacks access to treatment or services, whereas more than half has access to smartphones and the internet. This contrast underscores the growing shift of mental health services toward mobile and digital health solutions [2]. DMHIs refer to intervention processes and programs that deliver mental health services through the web, technology, and mobile platforms [3,4]. Various forms of DMHIs have been found effective in promoting mental health, including smart digital apps, such as innovative communication apps designed to enhance communication and support young people experiencing low mood and suicidal thoughts [5]; web-based programs, such as a psychoeducational multimedia program for young people suffering from or at a high risk of depression, as well as their families, caregivers, friends, and professionals [6,7]; interactive games [8]; and email and text message communication [9,10].

DMHIs offer several advantages and have strong potential to become widely adopted service options, particularly for adolescents and young adults (AYAs). First, DMHIs align with the digital era and are well-suited to the new generation, who are familiar with, comfortable using, and frequent users of the web, digital media, and screen devices. According to the International Telecommunication Union's Facts and Figures 2023, 79% of people aged 15-24 years use the internet globally [11]. Second, compared with face-to-face help-seeking or treatment, DMHIs can alleviate AYAs' feelings of shame and effectively address concerns about stigmatization [12]. This was confirmed by young people's feedback on a DMHI app, which suggested that discreet and easy-to-conceal apps helped mitigate the stigma associated with mental health problems [13]. Third, DMHIs are user-friendly. Some services adopt youth-friendly language and expressions while adjusting their layout to enhance usability [12]. Additionally, DMHIs offer flexibility, as they are not restricted by time, allowing users to engage with them according to their schedules [14]. Fourth, DMHIs provide high accessibility. Unlike traditional psychotherapy approaches, such as counseling, which require significant time for queuing and waiting, DMHIs have greatly improved AYAs' access to mental health support through digital and online platforms [15]. At the same time, DMHIs can help mitigate the inaccessibility of mental health services caused by geographical remoteness or exceptional circumstances, such as lockdowns during infectious disease outbreaks [16,17]. Lastly, DMHIs offer scalability, as they have the potential to reach a wider audience due to their anonymity, accessibility, cost-effectiveness, and ability to provide timely feedback [4].

AYAs' health, including mental health, plays a crucial role throughout the life course [18]. Health during this period is fundamental to their development, shaping long-term well-being and influencing the foundation of a healthy life for the next generation [18]. However, common mental disorders (CMDs) among adolescents are highly prevalent and contribute significantly to the burden of noncommunicable diseases [19-21]. CMDs encompass distress states characterized by anxiety, depression, and unexplained somatic symptoms [22]. According to data from the World Health Organization (WHO) and various regions, 1 in 7 individuals aged 10-19 years had a mental disorder in 2021, accounting for 13% of the global burden of disease in this age group [19]. Moreover, a 2023 survey in the United States found that nearly 90% of youth faced mental health challenges [23]. In the postpandemic era, CMDs present a growing challenge, highlighting the need for more accessible mental health services [24].

CMDs in AYAs require early and timely intervention; however, the uptake of mental health services remains inadequate [25-27]. The incidence of mental disorders has been reported to increase significantly after the age of 14 years [28]. Without timely intervention, these disorders can persist into adulthood, potentially impairing both physical and mental health and limiting opportunities for a fulfilling life [19]. Although mental health services and resources are currently available [18], a large proportion of AYAs do not access them [26]. Reasons for low service utilization are stigma, limited knowledge, low trust in the therapeutic relationship, high costs, accessibility issues, and other barriers [27], preventing those in need from receiving early interventions. DMHIs may serve as a viable alternative for youth requiring mental health services.

Although DMHIs offer many advantages [8,10,17], AYAs' intention to use them and their usage patterns vary. For effectiveness, a web-based mental health intervention program for adolescents found that participants with high adherence (using the site for 30 minutes or more per week) reported significantly lower depression and stress levels, along with improved well-being [7]. Another study examining the effectiveness of a new computerized cognitive behavioral therapy program found that it led to meaningful improvements in participants' depression levels [8]. Nevertheless, the usage, intention, engagement, and adherence to DMHIs remain relatively low [29]. For instance, a study in the United Kingdom examining young people's attitudes toward computerized therapy found that only 25% expressed interest, another 25% were not interested, and half were unsure [30]. Additionally, several intervention studies have reported inadequate engagement and completion rates, with low user adherence (participants completing less than half of the intervention components) and high attrition rates (over 20%) [31]. Given the high demand for mental health services for CMDs among AYAs, it is essential to explore users' perspectives on the factors that facilitate or hinder their use of DMHIs. Identifying these facilitators and barriers is crucial for the effective development and promotion of DMHIs.

Previous studies have rarely focused on the experiences, attitudes, or perceptions of AYAs regarding DMHIs as a primary research objective [32,33]. Much of the existing research has collected participants' feedback only after evaluating a specific DMHI [17,33]. As a result, current findings on the facilitators and barriers to DMHI utilization are largely indirect and fragmented, highlighting the need for a more cohesive and comprehensive synthesis.

XSL•FO
RenderX

This study aims to conduct a scoping review to examine the existing literature on the facilitators and barriers to DMHI use among AYAs experiencing depression, anxiety, and stress. In this study, facilitators are defined as factors that enhance access to, usage of, or intention to use DMHIs, while barriers are factors that hinder use or reduce the intention to use them [34]. Synthesizing these facilitators and barriers will provide critical insights for promoting DMHIs to better address mental health needs.

Methods

Scoping Review Framework and Registration

This scoping review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews (PRISMA-ScR) checklist to identify and map key characteristics, facilitators, barriers, and related themes in AYAs' use of DMHIs (Multimedia Appendix 1) [35]. The review protocol was registered on PROSPERO (CRD42023479880).

Search Strategy

The following major electronic databases were searched as of October 31, 2023: PubMed, Web of Science, PsycINFO, and CNKI. Although ScienceDirect was initially listed in our registered protocol, it was excluded from the final search due to significant content overlap with other databases. However, we ensured comprehensive coverage by searching additional relevant databases. Given that DMHIs are emerging technologies, no start date was set for the literature search to capture a broader range of publications. To supplement the search strategy, we manually retrieved bibliographies from relevant studies and included gray literature sources (OpenGrey and APA PsycExtra). The searches were restricted to English and Chinese. Further details are provided in Multimedia Appendix 2.

Eligibility Criteria

This research included studies examining facilitators and barriers to DMHIs among AYAs with disorders or symptoms of depression, anxiety, and stress. Reviews, recommendations, comments, newspapers, letters, conference abstracts, and research from other stakeholders' perspectives were used to enhance the understanding of the topic but were excluded from the analysis. The following exclusion criteria were applied: (1) studies involving participants with serious illnesses (eg, heart failure or trauma), as these conditions could impose greater limitations on their thoughts and behaviors; (2) studies with participants younger than 10 or older than 26 years; (3) studies on digital health services unrelated to mental health; (4) studies assessing only the effectiveness of DMHIs, participants' attitudes, or willingness—without discussing influencing factors; and (5) studies with unavailable full texts due to access restrictions or incomplete records were excluded to ensure transparency and replicability of the review.

Study Selection and Data Extraction

The literature screening process was conducted using EndNote 20 (Clarivate Plc), and Microsoft Excel 2020 was used to record the extracted data. Two independent researchers (YW and YH) reviewed the literature and extracted data. First, YW identified and removed duplicate records, which were then manually checked for accuracy by YH. Second, the researchers independently screened studies based on titles and abstracts, followed by a full-text review to determine eligibility. Third, data extraction was conducted independently by both researchers. Any discrepancies at each stage were discussed and resolved by 3 researchers (YW, YH, and SZ). The extracted data from each included study comprised 4 dimensions: (1) metadata and study context (eg, authors, year, study design, and sample size); (2) characteristics of the study population (eg, country or region, race, sample type, and basic demographics); (3) characteristics of DMHIs (eg, type, delivery mode, number of sessions, and inclusion of self-help or self-directed tools); and (4) facilitators and barriers influencing AYAs with CMDs in accessing DMHIs.

Data Synthesis and Analysis

In line with the WHO's 3-level digital health outcomes assessment framework [36], which includes the health system, provider, and client perspectives, this review adopted a thematic analysis framework comprising 3 levels: (1) external level, (2) intervention level, and (3) individual level.

Thematic analysis in this study followed a 6-phase process (Textbox 1) [37].

XSL•FO
RenderX

Textbox 1. Thematic analysis.

1. **Familiarization with data**

   All researchers (SZ, YW, and YH) thoroughly read the literature, annotating key insights and recording analytical ideas for discussion.

2. **Initial coding**

   YW and YH independently conducted manual coding, identifying and categorizing relevant data segments on facilitators and barriers. Their coded results were compared and collated to ensure accuracy and comprehensiveness.

3. **Theme development**

   SZ, YW, and YH discussed and organized the codes into themes, subthemes, and levels, refining their relationships. YW then supplemented and structured the original data for clarity.

4. **Review of themes**

   YW reexamined the data extraction, subthemes, and thematic framework, engaging in discussions with SZ and YH until a consensus was reached.

5. **Definition and refinement**

   The essence of each theme and subtheme was defined. YW drafted the initial narrative, which was then reviewed and refined by SZ and YH for coherence, consistency, and minimal overlap.

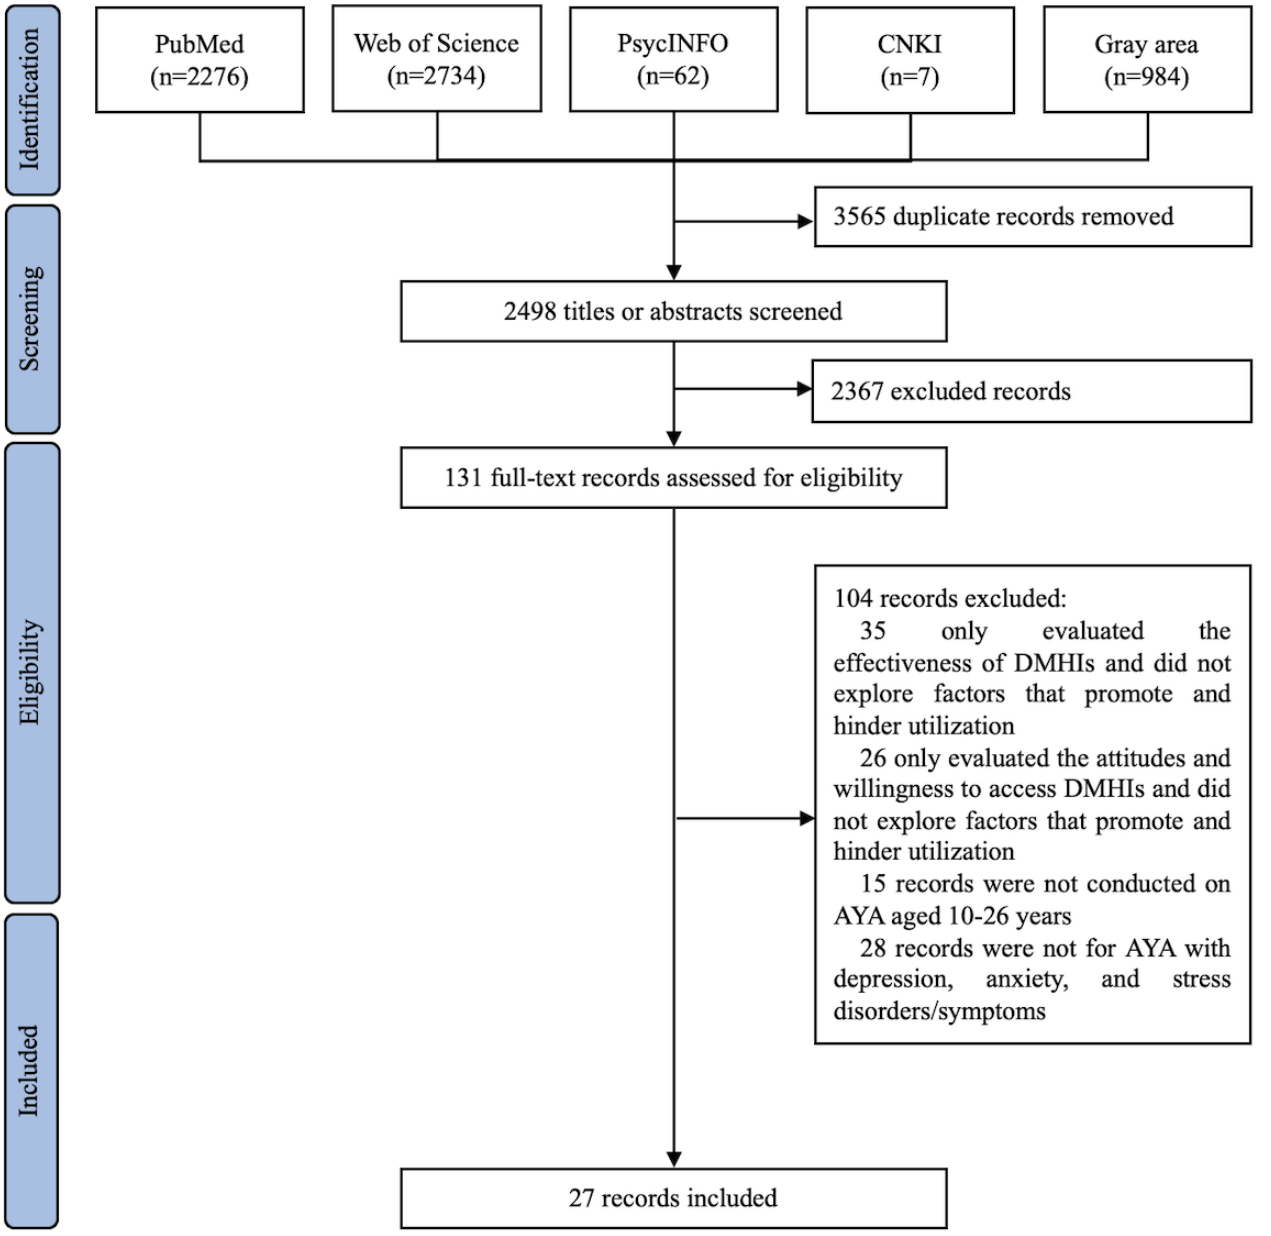
6. **Final reporting**

   A structured and logical report was generated, presenting the thematic findings.

After identifying themes and subthemes, a relative frequency meta-analysis was conducted to assess the occurrence of each facilitator and barrier across different delivery modes: completely nonportable devices, portable devices, single-platform, and multiple-platform interventions. Studies that did not specify the delivery model were excluded. The analysis used the relative frequency of occurrence (RFO) with 95% CIs, performed using the metaprop function in R (R Foundation) [38].

Quality Assessment

The quality of the included literature was assessed using the Mixed Methods Appraisal Tool (MMAT) [39]. This study applied the 2018 version, which was developed through a literature review of critical appraisal tools, user interviews, and electronic Delphi consultations with international experts. The MMAT evaluates 5 research categories: (1) qualitative studies, (2) randomized controlled trials, (3) nonrandomized studies, (4) quantitative descriptive studies, and (5) mixed methods studies. In addition to 2 general screening questions applicable to all study types, 5 specific criteria were established for each research category—qualitative, quantitative randomized controlled trials, quantitative nonrandomized studies, quantitative descriptive studies, and mixed methods studies [39].



Results

Search Selection

A total of 6063 records were retrieved from electronic databases and gray literature sources. After removing duplicates, 2498 records remained. Title and abstract screening identified 131 studies for full-text review, of which 27 met the inclusion and exclusion criteria and were included in data extraction, synthesis, and analysis (Figure 1; also see Multimedia Appendix 1).

XSL•FO
RenderX

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) flow diagram. AYA: adolescents and young adult; DMHI: digital mental health intervention.

Description of Included Studies

Table 1 presents the characteristics of the included studies. Among the 27 studies, 7 (26%) were quantitative, 6 (22%) were qualitative, and 14 (52%) applied mixed methods. Geographically, 4 (15%) studies were conducted in England, 5 (19%) in the United States, 3 (11%) in New Zealand, 7 (26%) in Australia, 2 (7%) in Ireland, and 2 (7%) in China. Additionally, 1 (4%) study was conducted in each of Canada, Sweden, and South Africa, while 1 (4%) spanned both Chile and Colombia. Regarding participant recruitment channels, 5 (19%) studies recruited participants from health institutions, 4 (15%) from the community, 6 (22%) from schools, and 2 (7%) from youth centers and a survey, respectively. Additionally, 10 (37%) studies recruited participants from multiple sources, including health institutions, schools, communities, teams, and existing research studies. The DMHIs examined in the included studies can be broadly categorized into web/internet-based, computer-based, app-based, game-based, and other formats. Specifically, 13 (48%) studies delivered DMHIs via web/internet-based programs, 6 (22%) were app-based, and 2 (7%) were game-based. One study (4%) utilized a text messaging tool, while 1 (4%) implemented a chatbot. Several interventions employed hybrid delivery methods, such as text messaging combined with web-based programs (1/27, 4%), computer-based combined with web-based programs (2/27, 7%), and web-based combined with app-based interventions (1/27, 4%). Regarding conflicts-of-interest disclosures, 19 studies included a conflicts-of-interest component, with 7 studies [5,8,10,16,17,40,41] explicitly declaring potential or actual conflicts of interest.

Regarding the mental health symptoms and therapeutic approaches covered by the DMHIs in the included studies, 22 out of 27 (81%) aimed to improve depressive symptoms. Additionally, 14 studies addressed other mental health

XSL•FO
RenderX

challenges, including anxiety, stress, worry, anger, and suicidal ideation. Notably, 3 studies [12,32,42] specifically targeted anxiety disorders. Among the 20 studies that explicitly stated a theoretical foundation for intervention development, 14 incorporated cognitive behavioral therapy, with 3 [8,15,30] utilizing computerized cognitive behavioral therapy. Furthermore, 2 studies [17,43] were based on peer support, 1 on behavioral activation [44], 1 on behavior change and resiliency [40], 1 on positive psychology [7], and 1 on mindfulness [45].

Thematic Synthesis

Overview

The thematic analysis identified facilitators and barriers across 3 levels: external, intervention, and individual. Figure 2 presents the themes, while Multimedia Appendix 3 provides an overview of the subthemes and corresponding examples. A detailed breakdown of all themes, subthemes, and supporting extracts from the original studies is available in Multimedia Appendix 4.

XSL•FO
RenderX

Figure 2. Themes of facilitators and barriers under the three-level framework.

Facilitators: External Level

It is recommended that the adoption and implementation of DMHIs be integrated with other services [46,47], with schools serving as a key environment for AYAs [6]. Social norms, particularly subjective norms, exert pressure based on the expectations of AYAs [48]. Additionally, the strategic marketing and broad accessibility of DMHIs play a crucial role in shaping user motivation [6,45,47], stigma, and social isolation [15]. Endorsements from friends, peers, care providers, professionals, and reputable programs can further enhance assessment and engagement [10,47].

Facilitators: Intervention Level

Literature suggests that key factors promoting widespread acceptance of DMHIs are closely tied to program features, including diverse information types, personalization, comprehensive support, and communication sessions for feedback and sharing [6,14,16,32,33,40,41,44-47,49,50]. Testimonials and entertainment elements were recommended and well-received, alongside retention strategies such as notifications, messages, and incentives [15,41,44,46,49]. Evidence indicates that multimedia delivery, a professional and polished design, co-design, character inclusion, personalization, diverse presentation formats, and appropriate language are critical for enhancing product quality and user appeal [6,10,12,15,16,32,33,41,42,44-47,49,50]. Many participants were surprised by the high quality of the programs and appreciated their overall design and feel [44,49]. Concrete benefits, such as the ability to track progress, were highly praised [14]. Factors contributing to sustained acceptance included an engaging and enjoyable experience, positive emotional responses, ease of interaction and use, high relevance, and appealing visual design [5-7,10,12,14-16,40,41,43-46,48,49,51,52]. The importance of appropriate durations and flexible schedules was also emphasized, ensuring convenience and adaptability to users' needs [6,12,16,41,44-46]. High accessibility further expanded user reach, allowing engagement at any time and from remote locations [6,14,16,41]. Additionally, many participants identified free or low-cost access as a crucial factor in promoting DMHI use [14,46,47].

Facilitators: Individual Level

Female participants reported significantly higher perceived helpfulness of the intervention [14]. Individuals with more severe psychological symptoms, greater knowledge, and prior experience with online therapies demonstrated stronger motivation to seek help and enroll [14,42,48]. AYAs were more likely to engage with DMHIs if they had genuine mental health needs [6,33,43,50,53], preferred solitude or home-based interventions, valued anonymity and autonomy [5,30,33,45], and held positive attitudes toward mental health issues and technology [14,48]. Frequently cited perceived benefits of DMHI use included support during difficult periods, perceived usefulness, privacy, and improved time management [33,49,51]. Additionally, a supportive environment—encompassing both technical infrastructure and interpersonal influences—played a crucial role in facilitating engagement [6,47].

XSL•FO
RenderX

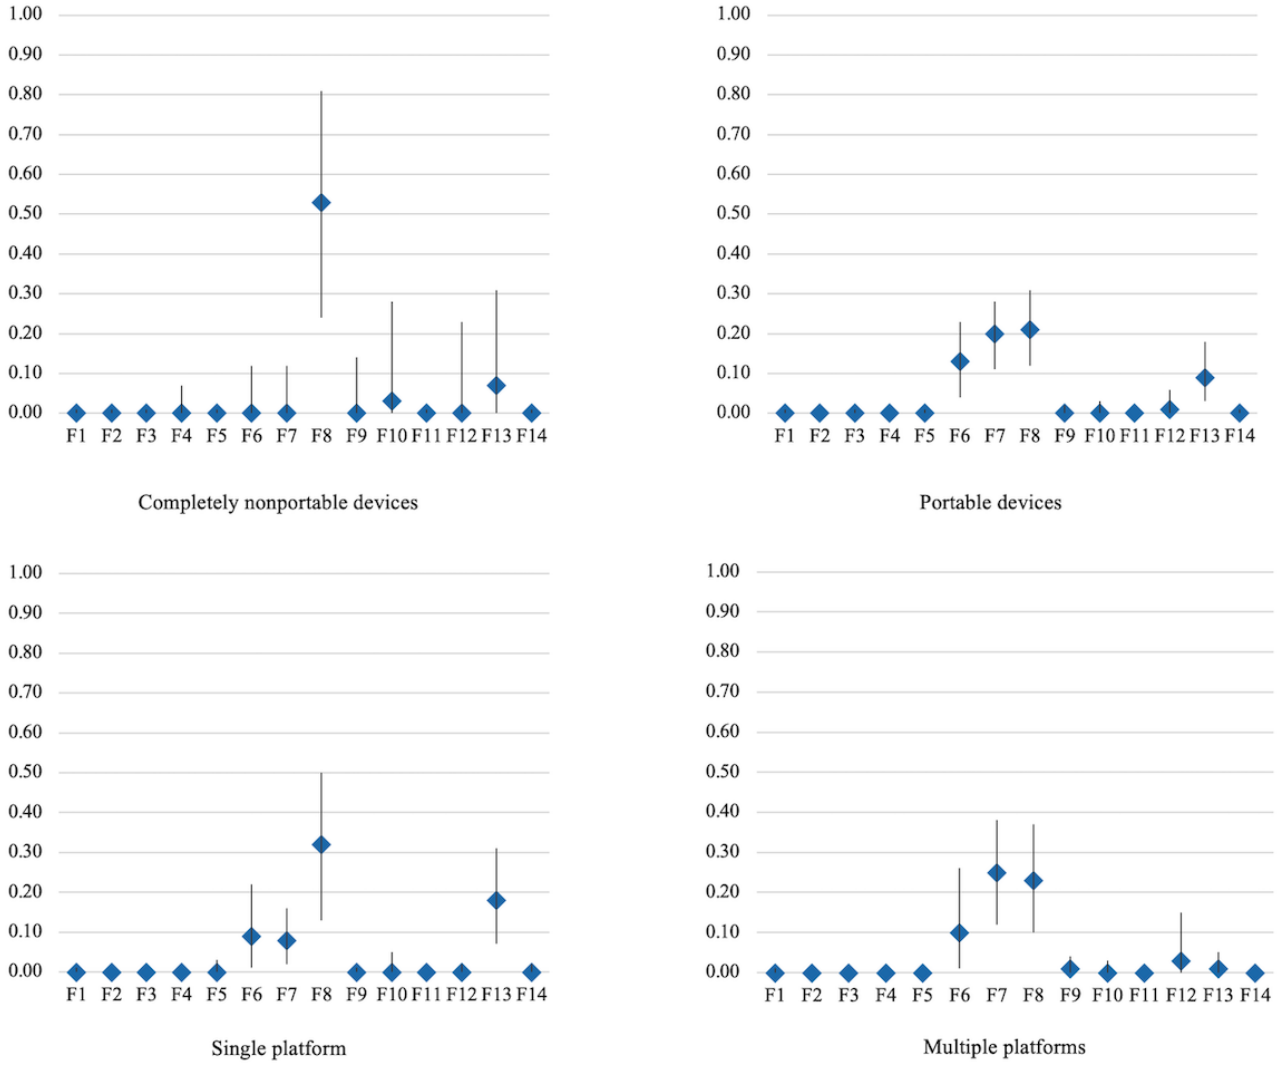
Barriers: External Level

Several studies presented an opposing perspective, suggesting that integrating DMHIs with schools could reduce their appeal [46] and lower participation rates [40,54]. Students might find the association with school tasks frustrating [46], and school policies restricting the use of electronic mobile devices could further limit engagement [54].

Barriers: Intervention Level

Some content components faced criticism. Religious overtones, particularly elements related to meditation and spirituality, were not well received [45]. Additionally, the absence of therapist support and direct human interaction led to frustration and disappointment among users [14,33,44]. Issues such as robotic responses, inappropriate multimedia elements, and poor language choices in design were perceived as barriers, causing confusion and disengagement [5,45,46]. Opinions on personalization varied: while excessive customization [15,44] could create confusion, difficulty, and cognitive burden [5,15], insufficient personalization resulted in overly generalized content [14]. Regarding quality and effectiveness, unattractive design, lack of relevance, and unsatisfactory user experiences were significant hindering factors [7,14,15,51]. Repetitiveness was particularly noted for diminishing the initial appeal of a DMHI website over time [7]. Inappropriate durations and scheduling further contributed to negative experiences [15,44,45,51]. Additionally, inaccessibility—primarily due to technical issues and financial constraints—was identified as an objective barrier to engagement [5,16,47,49,52].

Barriers: Individual Level



Physical illness was identified as a potential reason preventing participants from attending to or completing DMHIs on time [8]. Additional barriers included a lack of confidence and necessary connections to engage with internet-based therapies [17,32]. A lack of motivation was cited as a reason for not even downloading the app [17]. Participants who preferred face-to-face support or had reservations about human-like messaging systems expressed hesitation toward DMHIs [30,50,53]. Perceived risks were particularly emphasized by many AYAs, including concerns about privacy, security, and credibility, as well as fears of stigma and cyberbullying [14,42]. Nonuse or noncompletion of DMHIs was often attributed to doubts regarding their helpfulness, validity, and usefulness, as well as low priority, low interest, and a lack of persistence [5,8,14,17,33,43,45,49,53]. Additionally, limited time and technical issues remained significant barriers to engagement [7,8,14,17,33,49].

Relative Frequency Meta-Analysis

Based on the generated themes, the predominant facilitators and barriers varied across different delivery modes, as shown in Figures 3 and 4. For completely nonportable devices, quality and effect emerged as the most relevant facilitator (RFO=53%, 95% CI 0.24-0.81) and barrier (RFO=42%, 95% CI 0.01-0.91) to DMHI use. By contrast, for portable devices, the primary facilitators included high quality and effect (RFO=21%, 95% CI 0.12-0.31), design harmony (RFO=20%, 95% CI 0.11-0.28), and content engagement (RFO=13%, 95% CI 0.04-0.23), while the dominant barrier was low quality and effect (RFO=15%, 95% CI 0.02-0.35). For single-platform DMHIs, usage was primarily associated with 2 key facilitators: high quality and effect (RFO=32%, 95% CI 0.13-0.50) and perceived benefits (RFO=18%, 95% CI 0.07-0.31). The predominant barrier was low quality and effect (RFO=30%, 95% CI 0.05-0.60). Regarding DMHIs available across multiple platforms, the most influential facilitators were design harmony (RFO=25%, 95% CI 0.12-0.38), high quality and effect (RFO=23%, 95% CI 0.10-0.37), and content engagement (RFO=10%, 95% CI 0.01-0.26). The primary barriers were perceived risks (RFO=17%, 95% CI 0-0.54) and low quality and effect (RFO=13%, 95% CI 0-0.36). Further details are provided in Multimedia Appendix 5.

Discussion

Principal Findings

This review systematically identified facilitators and barriers to AYAs' access to DMHIs by analyzing quantitative, qualitative, and mixed methods literature using a 6-step thematic analysis approach. Following WHO guidelines, a 3-level theoretical framework was used to categorize these influential factors. Fourteen facilitators were identified, including integration with schools and other resources, social norms, and strategic marketing. Conversely, 13 barriers were recognized, such as integration with schools, content gaps, and design limitations.

The DMHIs examined in our review primarily targeted depression and were largely based on cognitive behavioral therapy. However, their development and application vary widely. Some studies have shown that DMHIs incorporating mindfulness training and peer support can effectively alleviate psychological challenges, including anxiety, stress, and resilience [43,45]. These findings underscore the potential of diverse DMHI approaches in mental health support and contribute to the growing digital landscape of psychological interventions.

During the RFO analysis, we focused specifically on digital modes of intervention, excluding studies that did not specify their delivery modes. Research supports the notion that different platform types may lead to variations in functionality, usage, and performance [55]. In our study, the theme of "quality and effect" emerged as the predominant facilitator and barrier across all DMHI delivery modes. This finding suggests that the perceived quality and effectiveness of DMHIs were central concerns for both participants and researchers. High-quality interventions that demonstrate positive outcomes are more likely to enhance user engagement, support sustained use, and encourage recommendations to others [51]. Conversely, interventions that fail to meet user expectations or inadequately address their needs may result in disengagement or abandonment [7].

When examining the subthemes, the most common and consistent points across the 3 levels were summarized. Participants showed greater willingness to engage when DMHIs were integrated with other resources [46,47], possibly due to increased accessibility and a reduced risk of judgment or embarrassment [56]. Previous research and professionals particularly valued the benefits of combining DMHIs with traditional medical resources and incorporating them into daily

XSL•FO
RenderX

life [54,57,58]. The use of multimedia, also referred to as "aesthetics" or "visual assets," was widely accepted and recommended for its ability to attract attention, generate interest, facilitate understanding, and enhance usability and satisfaction [12,59,60]. Perceived helpfulness or usefulness aligns with the Technology Acceptance Model, as it influences participants' attitudes toward use, thereby shaping behavioral intentions and actual usage behaviors [61]. Negative emotional experiences led to reduced engagement among AYAs [15], with certain emotions, such as frustration and nervousness, contributing to physical and mental stress [62]. Privacy, security, and credibility concerns remained common barriers in DMHIs, similar to traditional psychotherapy. Despite technological advances and digitization, these remote services pose unique and heightened privacy risks to clients [54,63].

Furthermore, 2 factors—DMHI integration with schools and personalization—can serve as both facilitators and barriers. On the one hand, integrating DMHIs into school settings may significantly enhance accessibility to psychological support by streamlining delivery to students and potentially addressing gaps in resources and teacher training [46]. Embedding mental health interventions within the school environment allows students to access support without requiring external referrals or additional logistical arrangements. On the other hand, integrating DMHIs with schools may make them less appealing to students and could evoke negative feelings [45,46]. Additionally, strict school regulations on smart device usage may limit students' ability to engage freely with DMHIs [54], potentially reducing their effectiveness by restricting flexible and convenient access to these digital tools. Regarding personalization, participants frequently highlighted its advantages, such as greater flexibility, tailored monitoring experiences, feedback, and additional benefits [44,45]. However, some participants viewed personalization negatively, as it often required additional actions and steps, adding to their burden and inconvenience [15]. Balancing the positive and negative aspects of these 2 factors requires strategies that maximize benefits while minimizing drawbacks. Suggested approaches include offering opt-in participation and flexible access options, allowing students to decide whether to engage and choose between on-campus or off-campus access to school-integrated DMHIs to enhance their sense of control and reduce stress. Additionally, making personalization optional by preconfiguring basic settings can improve ease of use, enabling users to engage with personalized features only to the extent they require.

Although many randomized controlled trials indicated that DMHIs were satisfying [8,10], they were not considered a substitute for traditional mental health services but rather an augmentation, potentially expanding accessibility and enhancing engagement [56,64,65]. From users' perspectives, the most intuitive feedback was their preference for face-to-face communication, along with concerns and dissatisfaction regarding privacy issues and the mechanical, fixed responses of DMHIs [5,14,66]. However, this does not imply that users are inclined to reject DMHIs; rather, they support DMHIs as a supplementary form of care alongside traditional mental health services [65]. From a scientific research and development perspective, a hybrid model integrating DMHIs with traditional mental health services can maximize the advantages of both, such as addressing low retention rates in DMHIs and assisting mental health professionals in providing follow-up care [67,68]. Consequently, the notion that DMHIs can serve as a "digital glue" to enhance user engagement in mental health services is more widely accepted, as it facilitates a seamless transition between digital and nondigital services [56]. Therefore, supporting hybrid digital and traditional mental health services should be the central focus for the future development and implementation of DMHIs.

An effective design process is crucial for the success of DMHIs in the mental health field, with a particular emphasis on human-centered or user-centered design [69,70]. Developers and designers must adopt this approach to refine and enhance DMHIs, ensuring they align with users' needs. Future research should focus on identifying the key components among the myriad and complex facilitators and barriers, sharpening the design process, and exploring which types of DMHIs are best suited for different mental health conditions.

Additionally, basic user characteristics may serve as unique influencing factors. Current findings suggest that women tend to spend more time using mental health apps [71], whereas men show greater interest in simulation game-based DMHIs [72]. Limited research has explored differences in DMHI usage based on race and ethnicity, though some evidence indicates that people of color may face barriers to accessing culturally responsive care in DMHIs [3]. Further systematic exploration and synthesis are needed to identify specific cultural factors that facilitate or hinder DMHI uptake among AYAs.

This scoping review summarized the facilitators and barriers to DMHIs for AYAs with depression, anxiety, and stress, categorizing them in a structured manner. By synthesizing the literature, the review offers insights for future intervention service designers and therapists, supporting the translation of DMHIs from research to practice—an essential step for advancing mental and public health. However, our review has some limitations. First, due to our inclusion and exclusion criteria, the quality of the included studies varies, with some not meeting high-quality standards. Second, the participants' characteristics and age ranges in the reviewed studies were constrained by our exclusion criteria. Factors that facilitate or hinder adults or older adults with CMDs from engaging with DMHIs may similarly affect AYAs. Third, we excluded studies published in languages other than English and Chinese, which may have led to the omission of culturally specific factors. Another potential limitation is the search strategy. While we used keyword searches across multiple databases, this approach may have been less comprehensive than using built-in search structures (eg, MeSH terms in PubMed), potentially resulting in the omission of relevant studies. Finally, we acknowledge that the frequency of an individual factor does not necessarily indicate its significance, underscoring the need for follow-up studies to clarify its importance.

Conclusion

This scoping review systematically searched, screened, and synthesized the literature on facilitators and barriers to DMHIs for AYAs with depression, anxiety, and stress. Through thematic

XSL•FO
RenderX

synthesis, we identified a series of themes and subthemes at the external, intervention, and individual levels, highlighting key factors influencing the use and adoption of DMHIs. By consolidating these factors, this review provides insights that can inform the design and implementation of more effective DMHIs for AYAs.

Acknowledgments

We appreciate the contributions of previous researchers to this research topic. We also thank the editors and reviewers for their valuable comments, which have significantly improved this manuscript. SZ received funding from the General Research Fund of the Hong Kong Research Grants Council (grant 15608322). The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Data Availability

The data sets generated or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

SZ conceptualized the study, developed the methodology, validated the results, supervised the research activity planning and execution, and revised and edited the manuscript. YW developed the methodology; selected the studies; extracted, processed, and analyzed the data; wrote the first draft of the manuscript; and reviewed and edited the manuscript. YH selected the studies; extracted, processed, and analyzed the data; and reviewed and edited the manuscript.

Abstract

Background: Diabetic foot (DF) is one of the most common and serious complications of diabetes. Effective self-management by patients can delay disease progression and improve quality of life. Digital intelligent technologies have emerged as advantageous in assisting patients with chronic diseases in self-management. However, the impact of digital intelligent technologies on self-management of patients with DF remains unclear.

Objective: This systematic review aimed to determine the effects of digital intelligent interventions on self-management in patients with DF.

Methods: A systematic literature search was conducted across PubMed, Web of Science, Embase, Cumulative Index to Nursing and Allied Health Literature, PsycINFO, Cochrane Central Register of Controlled Trial, ProQuest, China National Knowledge Internet, WanFang, China Science and Technology Journal Database, and SinoMed up to February 6, 2025, to identify eligible articles. Randomized controlled trials (RCTs) that assessed the effects of digital intelligent interventions on self-management of patients with DF were included. In total, 2 researchers independently conducted literature screening, quality assessment, and data extraction. The Cochrane Risk of Bias 2.0 tool (revised version 2019) for RCTs was used to assess the quality of the studies. A qualitative synthesis was conducted on the extracted data.

Results: In total, 1079 articles were retrieved, and 18 RCTs were included. All studies were rated as having a high risk of bias. The digital intelligent interventions in the included studies varied in forms, components, and durations. The intervention forms included WeChat (Tencent Holdings Limited; 7/18, 39%), apps (4/18, 22%), electronic platforms (3/18, 17%), mixed interventions (3/18, 17%), and smartphone thermography (1/18, 6%). The intervention components included self-management education (17/18, 94%), blood glucose and foot condition monitoring (8/18, 44%), self-management supervision and follow-up (6/18, 33%), and other components like foot risk assessment, foot care reminders, visit reminders, and remote consultations. Intervention durations ranged from 5 weeks to 12 months, with the majority (10/18, 56%) lasting 6 months. Among the 18 included studies, 17 studies (17/18, 94%) indicated that, compared with routine care, digital intelligent interventions significantly improved the self-management behaviors of patients with DF, including diabetes control, foot care behaviors, and blood glucose monitoring. Only 1 study (1/18, 6%) showed that the effects of digital intelligent interventions were not significantly different from those of routine care.

Conclusions: In this systematic review, evidence suggests that digital intelligent interventions can improve self-management behaviors and capabilities in patients with DF. However, due to the overall low quality of the included studies, current evidence should be interpreted and applied with caution. This field is still in the exploratory stage, with significant heterogeneity among different studies and a lack of consensus on intervention strategies, necessitating further exploration tailored to different populations. Future RCTs with large sample sizes and rigorous design are needed to develop high-quality evidence.

KEYWORDS

diabetic foot; self-management; digital intelligent intervention; systematic review; mobile phone

Introduction

Diabetic foot (DF) refers to foot conditions in patients with diagnosed or past diabetes mellitus (DM), manifesting as one or more of the following: peripheral neuropathy, peripheral arterial disease, infection, ulcers, Charcot neuroarthropathy, gangrene, or amputation [1]. DF is one of the most common and severe chronic complications of DM. Data from the International Working Group on the Diabetic Foot (IWGDF) indicated that 85% of patients with DF were at risk of amputation, with a mortality rate of 50% to 68% within 5 years post amputation, and a 10-year survival rate of only 24% [2]. Compared with patients with typical DM, those with DF face higher treatment costs, more frequent clinic visits, longer treatment journeys, greater physical trauma and psychological burdens, and higher mortality rates [2]. The treatment journey for DF is lengthy, as the disease persists and presents both long-term and intricate aspects, requiring patients to engage in prolonged, continuous, and steadfast self-management. In addition to regular DM self-management activities such as monitoring blood sugar, maintaining a balanced diet, and exercising, the self-management for patients with DF also includes foot monitoring and care such as daily inspection of both feet (temperature, blisters, wounds, etc), wearing well-fitting shoes, wearing seamless socks and changing them daily, washing feet daily and carefully drying them, avoiding the use of heating pads or warmers for the feet, using moisturizers for skin care, but not between the toes, and trimming nails in a straight line [3]. Studies showed that proficient self-management notably enhanced treatment adherence and slowed disease progression in patients with DF, thereby diminishing the likelihood of adverse outcomes like amputations [4]. However, due to factors such as lack of knowledge, inadequate social support, and low self-efficacy, the self-management status of patients with DF is often poor [5].

For self-management of patients with DF, traditional intervention methods often involve health education during hospitalization, followed by follow-ups through phone calls or home visits after discharge, which are time-consuming and costly, and have lower communication efficiency [6]. Digital intelligence is the integration of digitalization and intelligence, including core technology clusters such as big data, cloud computing, artificial intelligence, the internet, the Internet of Things, and 5G [7]. Digital intelligent interventions are developed based on digital intelligence, using technologies driven by digital intelligence, such as mobile apps, machine learning algorithms, virtual reality, wearable devices, and brain-computer interfaces, to provide patients with more convenient and real-time health management solutions, characterized by real-time capability, intelligence, quantifiability, visualizability, and optimizability [8]. Compared with traditional intervention methods, digital intelligent interventions can overcome the limitations of time and space, providing more efficient and personalized self-management support for patients through text, pictures, audio, and video anytime and anywhere [8]. In light of the current poor self-management levels of patients with DF, digital intelligent interventions may offer a potentially promising path forward.

At present, the applications of digital intelligent interventions in the self-management of patients with DF mainly include health monitoring, health education, and follow-up, with forms such as apps, electronic platforms, and wearable devices [9-12]. These technologies provide convenient guidance and support for health care professionals to assist patients in self-management, showing certain advantages in enhancing patient satisfaction. However, applying digital intelligent technologies in the self-management of patients with DF is still in the exploratory stage, with significant differences in intervention forms, intervention durations, and specific strategies among various studies [9-12]. Furthermore, due to methodological challenges such as small sample sizes and insufficient representativeness of the study population [9,10], the effectiveness of these intervention measures in the self-management of patients with DF remains unclear. To address this knowledge gap, there is an urgent need for a systematic review of digital intelligent interventions' impact on self-management among patients with DF. To the best of our knowledge, this is the first systematic review focusing on the impact of digital intelligent interventions on self-management in patients with DF. Such a study would help clarify the role of digital intelligent technologies in DF management and provide valuable insights for improving self-management strategies tailored to the unique needs of patients with DF.

Methods

Overview

A systematic review was carried out following the guidelines outlined in the Cochrane Handbook for Systematic Reviews of Interventions, and the reporting standards specified in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) Statement 2020 [13]. Based on the registered protocol, we had initially intended to use RevMan 5.3 software (Cochrane) for data synthesis and meta-analysis. However, due to the great heterogeneity of the included studies and the limited availability of comparable data, a quantitative analysis could not be performed. As a result, we opted for a qualitative analysis to summarize the findings. This deviation from the original protocol is reported here to maintain transparency.

Eligibility Criteria

Eligibility criteria were meticulously devised by the PICOS (P: population, I: intervention, C: comparison, O: outcome, S: study design) framework [13]. This framework entails defining the Population (P), Intervention (I), Comparison (C), Outcome (O), and Study design (S) characteristics to ensure clarity and consistency in study selection.

XSL•FO
RenderX

Population

Patients with a confirmed diagnosis of DF. This study used the definition of DF according to the IWGDF [1], which refers to a foot condition in individuals with current or previously diagnosed DM characterized by one or more of the following: peripheral neuropathy, peripheral artery disease, infection, ulcer, neuro-osteoarthropathy, gangrene, or amputation.

Intervention

Digital intelligent interventions. As mentioned in the introduction, digital intelligent interventions refer to health management solutions that integrate both digital technologies and intelligent features. These interventions rely not only on digital tools but also on intelligent capabilities, enabling real-time, dynamic, and personalized health management through data analysis, real-time feedback, and personalized adjustments. Intervention forms include apps, electronic platforms, wearable devices, and so on. It is important to emphasize that simple digital tools, such as static and noninteractive health education videos, although possessing certain digital characteristics, do not fall within the scope of digital intelligent interventions due to the lack of intelligent analysis and personalized adjustments. Furthermore, the digital intelligent intervention was the core intervention of the intervention group.

Comparison

Nondigital intelligent interventions refer to health management approaches that either lack digital technology entirely or use digital tools without intelligent features. These interventions include conventional, nondigital methods such as face-to-face health education, printed materials, or standard counseling. They may also involve digital tools that are not equipped with intelligent functionalities, such as static, noninteractive health education videos, which provide information but do not offer real-time feedback, personalized adjustments, or data-driven insights. Essentially, these interventions lack the dynamic, real-time, and personalized capabilities that characterize digital intelligent interventions.

Outcome

Patients' self-management behavior or self-management ability. For patients with DF, self-management activities include monitoring blood sugar, a healthy diet, regular exercise, medication adherence, foot monitoring, and care. Commonly used scales to assess the self-management behavior or ability of patients with DF include the Summary of Diabetes Self-Care Activities (SDSCA) [14], Type 2 Diabetes Self-Care Scale (2-DSCS) [15], and Diabetic Foot Self-Care Questionnaire of the University of Malaga (DFSQ-UMA) [16].

Study Design

This review exclusively included randomized controlled trials (RCTs) with full text that were published in either English or Chinese.

Based on the above PICOS, there were certain inclusion and exclusion criteria for this study (Textbox 1).

Textbox 1. The inclusion and exclusion criteria for screening studies.

Inclusion criteria:

- Population: patients with a confirmed diagnosis of diabetic foot.
- Intervention: the intervention group received digital intelligent interventions.
- Comparison: the control group received nondigital intelligent interventions.
- Outcome: patients' self-management behavior or self-management ability.
- Study design: randomized controlled trial.

Exclusion criteria:

- Duplicate published articles.
- No full text available.
- Not in Chinese or English.

Search Strategy

A systematic literature search was conducted across PubMed, Web of Science, Embase, Cumulative Index to Nursing and Allied Health Literature, PsycINFO, Cochrane Central Register of Controlled Trials, ProQuest, China National Knowledge Internet, WanFang, China Science and Technology Journal Database, and SinoMed up to February 6, 2025. A combination of subject terms and free words was used with logical operators for searching. In addition, the reference lists of included studies were scrutinized, and when necessary, studies were manually retrieved to identify other potential studies meeting the inclusion criteria. The detailed search strategies for each database are provided in Table S1 in Multimedia Appendix 1. The detailed information on the PRISMA checklist can be found in Multimedia Appendix 2.

Study Selection

References from databases underwent deduplication using NoteExpress (Beijing Aiqinhai Software Company). In total, 2 reviewers (JZ and SD) independently assessed the titles and abstracts of studies for initial screening. Subsequently, a full-text–level assessment was conducted by 2 independent reviewers (JZ and SD) to select the eligible articles for inclusion. Any disagreements were resolved through discussion or arbitration involving a third researcher (YX).

XSL•FO
RenderX

Quality Assessment

Two researchers (JZ and SD) independently conducted quality assessments using the Cochrane Risk of Bias 2.0 tool (revised version 2019, developed by Sterne et al [17]) for RCTs, which evaluates five bias domains, that are (1) randomization process, (2) deviations from intended interventions, (3) missing outcome data, (4) measurement of outcome, and (5) selection of reported results. Each domain and the overall bias were assessed as either low risk of bias, some concerns, or high risk of bias [13]. Any disagreements were resolved by seeking input from a third senior expert (YX).

Data Extraction

The data extraction process adhered to the "checklist of items for data collection form" outlined in the Cochrane Handbook and aligned with the specific PICOS principle of this review. In total, 2 reviewers (JZ and SD) independently extracted the following data from each study: first author, year published, country, included centers, participant, intervention content, intervention duration, use of intention-to-treat (ITT), outcome measures, and results of interest. Any disparities were addressed through discussion, leading to a consensus on all extracted data. In cases where additional data were needed, the authors of the included studies were contacted for further information.

Data Synthesis

The differences in the intervention methods, intervention durations, outcome assessment methods, and reporting formats across the included studies led to significant heterogeneity among the studies, hindering the quantitative synthesis of the data. Therefore, this study focused on qualitative synthesis. Tables 1 and 2 summarize the basic characteristics of the included studies. Table 3 summarizes the intervention details and the intervention outcomes of the included studies. We narratively synthesized the extracted data in terms of the population of intervention, digital intelligent intervention forms, components and durations, control group interventions, evaluation indicators and tools, and the effects of digital intelligent interventions on the self-management of patients with DF.

[a]This study applied the Wagner grading system to classify patients with diabetic foot, which is currently the most widely used grading system in clinical practice and research. Grade 0 indicates risk factors for foot ulcers but currently no ulcers are present, while grades 1 and above indicate varying degrees of ulcers or necrosis. A higher grade indicates a greater severity of the disease. The corresponding grade was extracted from the original literature or graded according to its description (the grade in parentheses indicates our grading according to the description), if the original literature had neither grade nor sufficient description to judge, the grade was not recorded.

Table 2. Interventions and results of the included studies.

Authors, year	Digital intelligent intervention, content	Control intervention, content	Results of interest (I[a] vs C[b])	*P* value
Qin et al, 2023 [12]	Smartphone thermography evaluation+personalized foot care and education	Usual care and education using a booklet	LSM[c] 67.5 (SE 1.20) versus LSM 51.9 (SE 1.52)	<.001
Marques et al, 2023 [10]	Standard nursing consultations+application use	Standard nursing consultations	Mean 4.52 (SD 0.78 versus mean 4.51 (SD 0.93)	.99
Firdaus et al, 2023 [9]	Diabetic Care Self-Management Mobile Health Application Program	Standard care	After controlling for age, monthly income, and family history, the foot care behavior of the intervention group was significantly better than that of the control group; F_1=30.374	<.001
Xu et al, 2023 [18]	"Internet+" follow-up nursing intervention (WeChat group, WeChat official account, and blood glucose monitoring app)	Health guidance was given before discharge and routine telephone follow-up	The scores of self-care skills, self-care responsibility, self-concept, and health knowledge in the intervention group were higher than those in the control group	<.01; <.01; .02; .03, respectively
Zhang, 2022 [6]	Transitional care based on WeChat platform (WeChat patient group, WeChat official account, educational knowledge in the form of text, pictures, cartoons, audio, and video)	Telephone follow-up was conducted after discharge	Mean 65.11 (SD 6.15) versus mean 54.26 (SD 7.94)	<.001
Zhang et al, 2021 [19]	Goal-oriented hospital-community linkage continuous nursing care (WeChat official account, WeChat patient group)	Health guidance was given before discharge and regular telephone follow-up after discharge	Mean 58.65 (SD 5.46) versus mean 53.44 (SD 5.81)	<.001
Chu et al, 2021 [20]	WeChat platform follow-up and continuous care (WeChat official account, WeChat patient group)	Routine telephone follow-up and outpatient education	The scores of self-management ability in all dimensions (prevention and treatment of high and low blood glucose, foot care, blood glucose monitoring, reasonable diet, medical compliance, and regular exercise) in the intervention group were higher than those in the control group	<.05
Li et al, 2021 [21]	The diabetic foot app was used for remote management after discharge	Telephone follow-up	Self-monitoring of blood glucose: n=36 (62%) versus n=18 (31%); Regular return visit: n=49 (84%) versus n=33 (57%)	<.05; <.05, respectively
Ye and Yu, 2021 [22]	Transitional care based on WeChat platform (WeChat official account, WeChat patient group)	Routine nursing follow-up	The scores of medication, exercise, diet, blood glucose measurement, and foot care in the intervention group were significantly higher than those in the control group	<.001
Qu, 2020 [23]	Routine nursing+continuing care by WeChat	Routine nursing	The proportion of self-management ability indicators in the intervention group was higher than that in the control group	<.001
Xie et al, 2020 [24]	Internet+blood glucose management (blood glucose management platform+blood glucose manager app)	Conventional blood glucose management	The scores of all dimensions (healthy diet, exercise, self-monitoring of blood glucose, monitoring of blood glucose according to medical advice, self-examination of feet, and medication) in the intervention group were significantly higher than those in the control group	<.001; <.001; <.001; <.001; .01; <.001, respectively
Xu, 2019 [25]	Extended care group combined with "Internet+" mode (WeChat, SMS, QQ [Shenzhen Tencent Computer System Co Ltd] and other internet communication tools, internet extended nursing platform)	Routine nursing	Mean 87.36 (SD 9.27) versus mean 71.68 (SD 9.68)	<.05

Search Results and Study Selection

The flowchart of the literature screening process and reasons for exclusion is illustrated in Figure 1. A total of 1079 records were identified through databases and registration systems. After removing duplicates and screening the titles and abstracts, we conducted a full-text review of 82 articles. Finally, 18 RCTs were included.

Study Characteristics

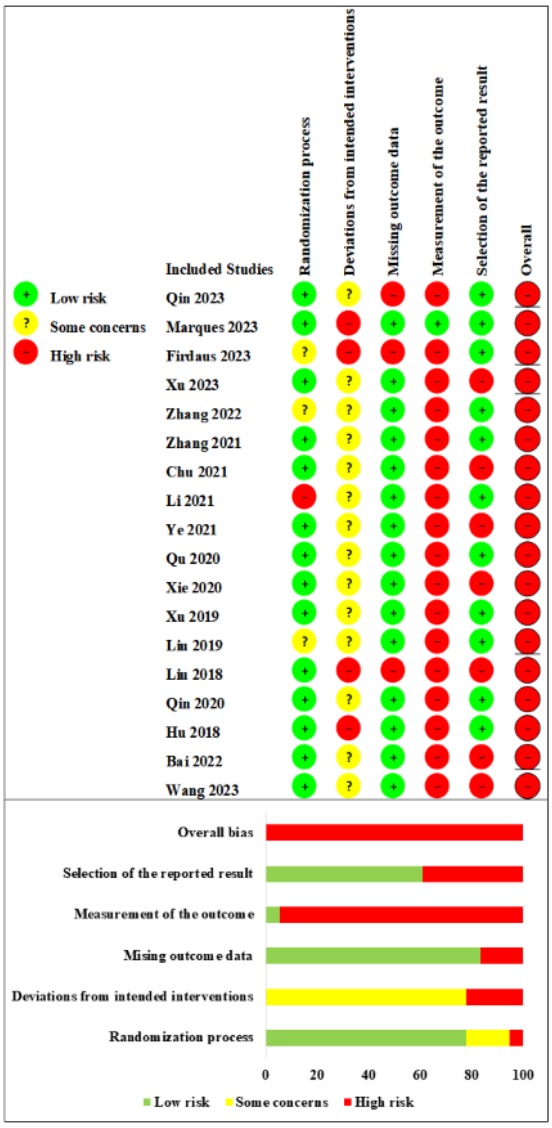

Table 1 summarizes the basic characteristics of the participants in the included studies. Table 2 summarizes the interventions and results of the included studies. Details of the included studies are provided in Table S2 in Multimedia Appendix 1. The publication years were from 2018 to 2023 [6,9,10,12,18-31], and 78% (14/18) of the studies were published in the past 5 years (2020 and beyond) [6,9,10,12,18-24,28,30,31]. Except for 1 study [12] conducted at 2 centers, all other studies [6,9,10,18-31] were single-center studies. Studies were conducted in Indonesia [12], Brazil [10], Malaysia [9], and China [6,18-31], with sample sizes ranging from 42 to 195. The age of participants ranged from 50.03 to 66.31, and the proportion of males ranged from 31% to 90%. The intervention forms for the intervention group included WeChat (Tencent Holdings Limited) [6,19,20,22,23,27,28], app [9,10,21,26], electronic platform [29-31], smartphone thermography [12], and mixed interventions (WeChat+app [18], electronic platform+app [24], and WeChat+electronic platform [25]). The control group primarily received standard or usual care interventions focused on diabetes management and foot care. The interventions included health education, health monitoring and follow-up through paper leaflets [12,25], face-to-face communication or examination [9,10,12,18-20,23-25,28-31], and phone calls [6,18-22,24-31]. The intervention duration ranged from 12 months [24] and 6 months [12,18,19,21,22,27-31] to 3 months [10,20,25,26] and 5 weeks [9]. The measurement tools for outcome indicators included Self-care Agency Scale [18], SDSCA [6,19,24,28,29], 2-DSCS [20,22,27], Diabetes Self-care Activities Questionnaire (QAD) [10], Diabetes Self-management Behavior Scale [6,28], DFSQ-UMA [30,31], diabetic foot care behavior (DFCB) [12], Diabetic Foot Selfcare Behavior Scale (DFSBS) [9], and Self-management Model Questionnaire [25]. In addition, some studies [21,23,26] evaluated the self-management behavior of patients by observing their behaviors such as blood glucose monitoring and regular return visits. In terms of the reporting form of the results, some studies [6,10,12,19,25,28,29] compared the total score of the scale between the intervention group and the control group, some [9,18,20,22,24,27,30,31] compared the scores of each dimension of the scale between the 2 groups, and others [21,23,26] compared the number and proportion of people who adopted self-management behaviors between the 2 groups.

RenderX

Study Quality

All of the 18 studies were assessed as having an overall high risk of bias (Figure 2 [6,9,10,12,18-31]). In the randomization process domain, 2 studies [6,26] lacked details on randomization, and the results of baseline between-group comparisons in 1 study [9] suggested potential differences, raising some concerns. One study [21] grouped participants based on odd and even discharge orders, deemed high risk due to inadequate concealment of allocation sequence before grouping. In the domain of deviations from the intended interventions, only 1 study [10] implemented double-blinding, 1 study [29] did not blind participants, 1 study [12] did not blind participants or researchers, and information on blinding was missing in the remaining studies [6,9,18-31]. All studies lacked sufficient information to determine whether intervention deviations from the expected were due to the trial environment. 14 studies [6,12,18-26,28,30,31] conducted ITT analyses, while four studies [9,10,27,29] excluded some randomized participants in their analyses. In the domain of missing outcome data, 5 studies [9,10,12,27,29] had a considerable amount of missing outcome data. The reasons for participant attrition in 2 studies [9,12] were health-related, in 2 studies [10,29] were unrelated to health, and in 1 study [27], the reasons for attrition could not be determined due to insufficient information. In the domain of measurement of the outcome, 3 studies [21,23,26] did not use standardized measurement scales, and 2 studies [6,23] did not specify the measurement timing. In 2 studies [12,29], self-reported scales were used for measurement without blinding participants, so the assessors were aware of the interventions received by the participants. For the 12 studies [6,9,18-20,22,24,25,27,28,30,31], the lack of information made it impossible to determine whether assessors were aware of the interventions received by the participants. Since self-reported scales were used for measurement in the studies [6,9,12,18-20,22,24,25,27-31], which inherently carried subjectivity, knowing the interventions received by the participants could potentially influence the outcomes. In the selection of the reported result domain, 7 studies [18,20,22,24,27,30,31] were rated as high risk due to not reporting the total scale score and total score comparison results between groups.

Figure 2. Risk of bias summary: review authors' judgments about the risk of bias item for each included study [6,9,10,12,18-31].

Population of Intervention

The intervention details and the intervention outcomes of the included studies are shown in Table 3. The intervention population consisted of patients with DF. In the included studies, most of the participants were classified as Wagner grade 0 [6,9,10,12,21,24,27-29] (9 out of 18 studies, 50%), while some studies included patients with Wagner grade 0-2 [30,31] or Wagner grade 0-3 [26], and others included patients with Wagner grade 1-2 [19], Wagner grade 1-4 [23], or Wagner grade 3-4 [18]. Wagner grade 0 indicates the absence of foot ulcers but the presence of risk factors for ulcer development (such as a history of foot ulcers, peripheral neuropathy, or peripheral arterial disease). Wagner grade 1 and above indicates the presence of foot ulcers or necrosis of varying severity. Some studies [20,22,25] did not apply the Wagner classification system to assess the severity of foot disease in the patients (3 out of 18 studies, 17%).

Digital Intelligent Intervention Forms, Components, and Durations

Digital intelligent intervention forms, components, and durations of the included studies (N=18) are shown in Multimedia Appendix 3. The forms of digital intelligent interventions included WeChat (7 studies [6,19,20,22,23,27,28], 39%), app (4 studies [9,10,21,26], 22%), electronic platforms (3 studies [29-31], 17%), mixed interventions (WeChat+app [18], WeChat+electronic platform [25], app+electronic platform [24], 3 studies, 17%), and smartphone thermography (1 study [12], 6%). The components of digital intelligent interventions included self-management education (17 studies [6,9,10,18-31], 94%), blood glucose and foot condition monitoring (8 studies [18,21,23-25,27-29], 44%), self-management supervision and follow-up (6 studies [6,9,18,19,30,31], 33%), foot risk assessment (1 study [12], 6%), foot care reminders (1 study [9], 6%), reminders for subsequent visits (1 study [26], 6%), and hospital-community remote consultation and 2-way referral (2 studies [30,31], 11%). The duration of the interventions ranged from 12 months (1 study [24], 6%), 6 months (10 studies [12,18,19,21,22,27-31], 56%), 3 months (4 studies [10,20,25,26], 22%) to 5 weeks (1 study [9], 6%), with 2 studies [6,23] (11%) not specifying the duration of the intervention.

Control Group Interventions

The control group interventions in the included studies consisted of routine care, including routine risk assessment (1 study [12]), face-to-face education (12 studies [9,10,18-20,23-25,28-31]), and telephone follow-up (14 studies [6,18-22,24-31]). The intervention content primarily involved face-to-face self-management health education provided by nurses at discharge, as well as follow-up and self-management guidance via telephone by nurses after discharge.

Evaluation Indicators and Tools

The evaluation indicators in the included studies encompassed four categories: (1) foot care behavior (5 studies [9,12,25,30,31], 28%), diabetes self-management ability (9 studies [6,10,19,20,22,24,27-29], 50%), general self-management ability (1 study [18], 6%), and specific behaviors (3 studies [21,23,26], 17%). The tools used to assess foot care behavior included the DFCB questionnaire [12], DFSBS [9], Self-management Model Questionnaire [25], and DFSQ-UMA [30,31]. The assessment content focused on whether patients regularly checked their feet, the condition of their foot care, and whether they selected appropriate footwear. The tools used to evaluate diabetes self-management ability included the QAD [10], Diabetes Self-management Behavior Scale [6,28], SDSCA [19,24,29], and 2-DSCS [20,22,27]. The assessment content primarily covered blood glucose monitoring, proper diet, regular exercise, foot care, and medication adherence. The tool used to assess self-management ability was the Self-care Agency Scale [18], which evaluated a patient's general disease self-management ability, including 4 dimensions, that is, self-care skills, self-care responsibility, self-concept, and health knowledge level. Specific behaviors reflecting the patient's self-management status, consisted of blood glucose monitoring, foot examination, and regular follow-up visits in the included studies [21,23,26].

Effects of Digital Intelligent Interventions on Self-Management of Patients With DF

Among the 18 included studies, 17 studies [6,9,12,18-31] (94%) indicated that, compared with routine care, digital intelligent interventions significantly improved the self-management levels of patients with DF. However, 1 study [10] (6%) showed that the effects of digital intelligent interventions were not significantly different from those of routine care. Based on the results of the included studies, when using WeChat for intervention, a 6-month intervention for patients with Wagner grade 0 [27,28] or 1-2 [19], or a 3-month [20] or 6-month [22] intervention for patients without classification, can significantly improve patients' self-management ability in diabetes. When using an electronic platform for intervention, a 6-month intervention for patients with Wagner grade 0 [20] or 0-2 [30,31] can significantly enhance patients' diabetes self-management or foot care levels. When using an app for intervention, a 5-week [9] or 6-month [21] intervention for patients with Wagner grade 0 can improve patients' foot care behaviors, self-monitoring of blood glucose, and regular return visits; a 3-month [26] intervention for patients with Wagner grade 0-3 can improve behaviors of blood glucose monitoring and regular dressing changes, but had no significant effect on regular follow-up visits; while a 3-month [10] intervention for patients with Wagner grade 0 cannot significantly improve their diabetes self-management ability. Using smartphone thermography [10] for a 6-month intervention for patients with Wagner grade 0 can significantly improve foot care behaviors. Using WeChat combined with app [18] for a 6-month intervention for patients with Wagner grades 3-4 can significantly improve general self-management ability. Using an electronic platform combined with app [24] for a 12-month intervention for patients with Wagner grade 0 can significantly improve their diabetes self-management ability. Using WeChat combined with electronic platform [25] for a 3-month intervention for unclassified patients can significantly improve foot care behaviors.

Discussion

Principal Findings

A total of 18 RCTs were included in this systematic review, all of which were assessed as high-risk studies. Methodological deficiencies in the included studies primarily included unclear details of randomization, lack of allocation concealment before grouping, absence of blinding, failure to conduct ITT analysis, high rates of missing data and loss to follow-up, absence of standardized assessment tools, unclear assessment timing, potential awareness of intervention status among assessment personnel, and failure to report total scores of scales. Due to the significant heterogeneity among studies, we conducted a qualitative synthesis of the included studies. The results showed that overall, digital intelligent interventions improved self-management ability among patients with DF. However, the target populations, intervention forms, intervention durations, and assessment tools vary across different studies, and there is currently no standardized intervention paradigm in this field.

The most noteworthy point is that, among the 18 studies, only 1 study [10] did not show a significant effect of digital intelligent intervention, and the reasons for this phenomenon need to be analyzed in depth. In that study [10], the participants were patients with Wagner grade 0, the intervention form was an app (used for foot care education), the intervention duration was 3 months, and QAD was used to assess the patients' diabetes self-management ability. In another study [9], where the app intervention (used for foot care education, foot care reminders, and foot care behavior supervision) also targeted patients with Wagner grade 0, but the duration was 5 weeks, the DFSBS assessment showed significant improvements in patients' foot care behaviors. This seems to illustrate the importance of the intervention components, suggesting that even with a shorter intervention duration, focusing on more aspects of self-management (not just education, but also reminders and supervision) can lead to better outcomes. In 1 study [21], a 6-month intervention with the app (used for foot care education, blood glucose, and foot monitoring) in patients with Wagner grade 0, improvements in self-monitoring of blood glucose and regular visits were observed. Similarly, for app interventions targeting patients with Wagner grade 0, the outcomes are better when the intervention included more components and lasted longer. When we broaden our perspective beyond just app interventions and patients with Wagner grade 0, and compare this study [10] with others, we find that regardless of the intervention form (WeChat, App, electronic platforms, or mixed interventions), the intervention duration (shorter or longer), and target population (Wagner grade 0 or Wagner grade ≥1), it seems that as long as the intervention is not limited to health education alone (but also includes reminders, supervision, or follow-ups, etc), the significant effects of digital intelligent interventions can be observed.

The deeper reasons for these results need to be discussed. Health education does have an effect on self-management behaviors of patients with diabetes, as existing studies [32,33] have confirmed. However, our results suggest that, compared with conventional face-to-face health education, health education delivered solely through digital intelligent means (such as apps) does not show more significant effects than traditional interventions. A possible reason is that, although apps can overcome the boundaries of time and space, allowing patients to receive health education anytime and anywhere, such interventions do not guarantee that patients will actively engage with the app for health education. In such cases, the intervention may be less effective than the conventional 1-time "forced" face-to-face health education during discharge. In other studies, the inclusion of intervention components, such as reminders, supervision, and follow-up, helped to enhance patients' adherence to using digital intelligent tools for health education. At the same time, these interventions directly reminded and supervised patients in implementing self-management behaviors, enabling the real-time, dynamic, and personalized features of digital intelligent interventions to be fully used, resulting in significantly better outcomes compared with conventional interventions.

This provides us with an important insight that it is not only the functions of digital intelligent tools themselves that are important, but it seems even more crucial to focus on how to attract users to continuously use these tools in order to fully leverage the advantages of digital intelligent technology. In the included studies, the methods used to remind and encourage patients to use the tools included setting up learning contracts [9] and real-time reminders in WeChat groups [18,21,27,28]. While these measures achieved good results, there was a lack of (or no report on) efforts made to enhance the attractiveness of the digital intelligent tools themselves. Factors that influence people's use of digital intelligent tools have been explored in previous studies. One study [34] explored the technology adoption intention of users of smart wearable health technologies and identified the key factors affecting user technology adoption. The research [34] found that the more the user's experience of smart health technology aligns with personal needs, the more positive the user's emotional response, which in turn promotes higher user engagement. In addition, the operability and interaction design of the technology (such as the intuitiveness and ease of use of the interface) are also important factors in determining user engagement [34]. Based on this, the following strategies can be adopted to improve user engagement with digital intelligent tools. First, the users' experience should be personalized. Personalization can strengthen users' emotional attachment to the technology because they feel that the tool is more closely aligned with their lives, which in turn increases engagement and ultimately promotes usage [35]. Specific measures include (1) offering customized features, that is, developing features that cater to specific health goals and needs; for example, allow users to customize exercise plans, track specific health indicators (eg, blood sugar levels), or set personalized reminders (eg, foot check-ups). (2) Developing adaptive interfaces [36], that is, providing adaptive interfaces that change based on user preferences, usage patterns, and health progress. This can also include adjusting the complexity of information based on the user's knowledge level and health literacy. Second, the focus should be on intuitive and user-friendly design. A user-friendly design increases the likelihood of long-term engagement because users feel more confident and comfortable when using the device, encouraging

XSL•FO
RenderX

continued usage [37]. Specific measures include (1) simple and clear interface (ie, ensure the interface is simple, navigation is easy, and information is clear and straightforward; make sure buttons, menus, and options are simple and intuitive, reducing the complexity of setup procedures); (2) user testing and feedback (ie, continuously improve the design through user feedback; conduct usability tests to identify potential barriers in the interface and simplify them). Third, emotional engagement and motivational incentives are also crucial. Emotional engagement, driven by motivation and rewards, can strengthen the bond between users and the device, leading to higher usage frequency and adherence [38]. Specific measures include (1) gamification and reward mechanisms [39], that is, introduce gamification elements such as achievement badges, points, or milestones to recognize users' health progress. These rewards can be linked to self-management behaviors (eg, monitoring blood sugar and performing foot care) or improvements in health indicators (eg, blood sugar levels and foot condition). (2) Social sharing features [40], that is, allow users to share their progress with friends or on social media. Social support can significantly increase motivation and promote engagement. Community-driven challenges (eg, foot care goals) can also enhance a sense of belonging and competition. Finally, continuous support and updates for the tool are essential. Ensure that the device is regularly updated, adding new features and improvements based on user feedback. Software updates should not only address issues but also enhance overall functionality, improving the value of the user experience [40]. Ongoing support and updates increase the reliability of the technology and the commitment to the users, thus encouraging long-term adoption.

The final aspect worth discussing is the regional distribution of the studies. The 18 studies we included were all conducted in limited-income countries (Indonesia, Brazil, Malaysia, and China), with 15 of them being conducted in China. One of the reasons for the high number of studies from China could be the inclusion of 4 Chinese language databases in our search. However, this is not the only or primary reason, as we also conducted systematic searches across 7 authoritative English language databases. In addition, after carefully reviewing the search terms, we consider our search to be reasonably comprehensive. Therefore, it is more likely that the regional distribution of the studies reflects the current global distribution of the application of digital intelligent technologies in self-management of patients with DF. Although digital intelligent technologies have been rapidly developed in high-income countries, this study focuses specifically on their application in the self-management of patients with DF. Compared with high-income countries, limited-income countries, due to relatively lower economic levels and uneven distribution of medical resources, face significant challenges in diabetes management and early prevention of DF, resulting in a higher number of patients with DF and consequently, a greater focus on self-management research within this patient group [41]. Similarly, the possible reason for the large number of studies from China is that it has the world's largest population and the highest number of patients with diabetes [42]. In addition, due to the vast territory of China and the uneven distribution of health care resources [43], managing diabetes and preventing DF pose significant challenges, resulting in a higher number of patients with DF [44] and, consequently, more research on their self-management.

Limitations

First, the overall quality of the included studies is relatively low, with several methodological flaws that may affect the reliability of the results. Second, due to significant heterogeneity among the included studies, a meta-analysis could not be conducted. Although most included studies indicated that digital intelligent interventions were effective, the lack of quantitatively synthesized results hinders the determination of the optimal intervention strategy, such as the best form of intervention or the ideal duration of the intervention. Finally, although we made efforts to ensure the comprehensiveness of the search terms (keywords and their synonyms) and databases (4 Chinese databases and 7 English databases), the majority of the included studies were conducted in China, which may introduce cultural and regional biases and limit the generalizability of the findings.

Conclusions

In this systematic review, evidence suggested that digital intelligent interventions can improve self-management behaviors and capabilities in patients with DF. However, due to the overall low quality of the included studies, current evidence should be interpreted and applied with caution. At present, this field is still in the exploratory stage, with significant heterogeneity among different studies and a lack of consensus on intervention strategies, necessitating further exploration tailored to different populations. Future RCTs with large sample sizes and rigorous design are needed to develop high-quality evidence and determine the optimal intervention strategies. In addition, in order to fully leverage the advantages of digital intelligent technology, the human-centered design of digital intelligent tools, including personalization, ease of use, and intuitiveness, should also be given attention, alongside their health management functions.

Abstract

Background: Wearable technology has evolved in managing COVID-19, offering early monitoring of key physiological parameters. However, the role of wearables in tracking and managing long COVID is less understood and requires further exploration of their potential.

Objective: This review assessed the application and effectiveness of wearable devices in managing long COVID symptoms, focusing on commonly used sensors and their potential for improving long-term patient care.

Methods: A literature search was conducted across databases including PubMed, Embase, Web of Science, and Cochrane Central, adhering to PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) reporting guidelines. The search was updated regularly throughout 2024. Abstract and full-text screening and selection were facilitated using Rayyan software developed by Qatar Computing Research Institute. Quality appraisal was conducted using the Joanna Briggs Institute (JBI) critical appraisal tool to ensure the methodological rigor of the included studies. Data were extracted on study characteristics, wearable devices, sensors used, and monitored physiological parameters, and the results were synthesized in a narrative format.

Results: A total of 1186 articles were identified, and after duplicate removal and screening, 15 studies were initially included, with 11 studies meeting the criteria for final data synthesis. The included studies varied in design, ranging from observational to interventional trials, and involved sample sizes from 3 to 17,667 participants across different countries. In total, 10 different wearable devices were used to monitor long COVID symptoms, capturing key metrics such as heart rate variability, body temperature, sleep, and physical activity. Smartwatches were the most used wearable devices and fitness trackers with electrocardiography and photoplethysmography sensors were used to monitor heart rate, oxygen saturation, and respiratory rate. Of the 10 devices, 4 were Food and Drug Administration–approved, emphasizing the reliability and validation of the physiological data collected. Studies were primarily conducted in the United States and Europe, reflecting significant regional research interest in wearable technology for long COVID management.

Conclusions: This review highlights the potential of wearable technology in providing continuous and personalized monitoring for long COVID patients. Although wearables show promise in tracking persistent symptoms, further research is needed to improve usability, validate long-term efficacy, and enhance patient engagement.

KEYWORDS

wearable devices; long COVID; physiological sensors; review; COVID; COVID-19

Introduction

Wearable devices have emerged as essential tools in the detection and management of COVID-19 due to their ability to continuously monitor key physiological metrics such as heart rate, oxygen saturation, and body temperature in real time [1,2]. These devices provide a proactive approach to identifying early signs of COVID-19, enabling timely interventions even before severe symptoms appear. Unlike acute COVID-19, where symptoms typically manifest and resolve within a few weeks, long COVID involves persistent and varied symptoms that can last for months or even years after the initial infection [3]. This complexity requires not only the ability to detect acute symptoms but also to monitor and manage chronic and fluctuating conditions over extended periods. Long COVID is a multifaceted condition that requires not only a deep understanding of its complex pathophysiology but also the integration of advanced digital technologies like wearables to effectively monitor, analyze, and manage its persistent and fluctuating symptoms over time. For patients with long COVID, wearable technology offers invaluable insight into persistent and fluctuating symptoms, helping to track and manage the condition over extended periods [4]. Despite their potential, there is still a need to refine and enhance the effectiveness of wearable technology, ensuring consistency in how different devices capture and analyze data for long COVID's complex health effects.

Although a few studies have investigated the use of wearable devices for long COVID detecting symptoms, findings have varied due to differences in device types, sensor configurations, and analytical methods [5,6]. This variation underscores the need for a comprehensive review to synthesize existing knowledge, evaluate the effectiveness of different wearable technologies, and identify best practices for their application in long COVID management. A thorough review can help bridge the gaps in this research and guide future innovations in wearable technology for more effective monitoring and management of long COVID.

Wearable devices equipped with sensors for monitoring heart rate, respiratory rate, oxygen saturation, and body temperature have shown promise in detecting anomalies associated with COVID-19 [7]. Previous studies have explored the role of wearable devices in the detection of COVID-19 symptoms, demonstrating their potential to provide early warnings and facilitate timely interventions [7-9]. Research has demonstrated that changes in these metrics can indicate the onset of infection before severe symptoms manifest [10]. However, while these devices have been effective in detecting acute COVID-19 symptoms, managing long COVID presents a more complex challenge, as it involves tracking persistent, fluctuating symptoms over extended periods, requiring continuous and adaptable monitoring strategies.

Understanding physiological sensors equipped in wearable devices is crucial because it enables continuous and precise monitoring of post-COVID complex symptoms, providing insights into their patterns and severity over time. Effective management of long COVID relies on identifying which sensors are most used and how they perform in capturing relevant physiological data. Current literature reveals a variety of sensors used in wearable devices, such as those for monitoring heart rate variability, oxygen saturation, and respiratory rate [11]. Given the urgency to address long COVID effectively, a comprehensive scoping review is essential to consolidate existing research, evaluate the efficacy of different sensors, and inform the development of more targeted and effective monitoring solutions. The primary objective of this scoping review is to evaluate and summarize existing research on the application of wearable technology for monitoring and managing persistent long COVID symptoms. This review seeks to identify the various wearable devices and sensors used, the specific physiological parameters they monitor, and the impact of this monitoring on the management of long COVID.

Methods

Overview

This scoping review was conducted in adherence with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) reporting guidelines [12]. Ethical approval was not required for this Scoping review. Refer to Multimedia Appendix 1 for the PRISMA checklist.

Search Strategy and Selection Criteria

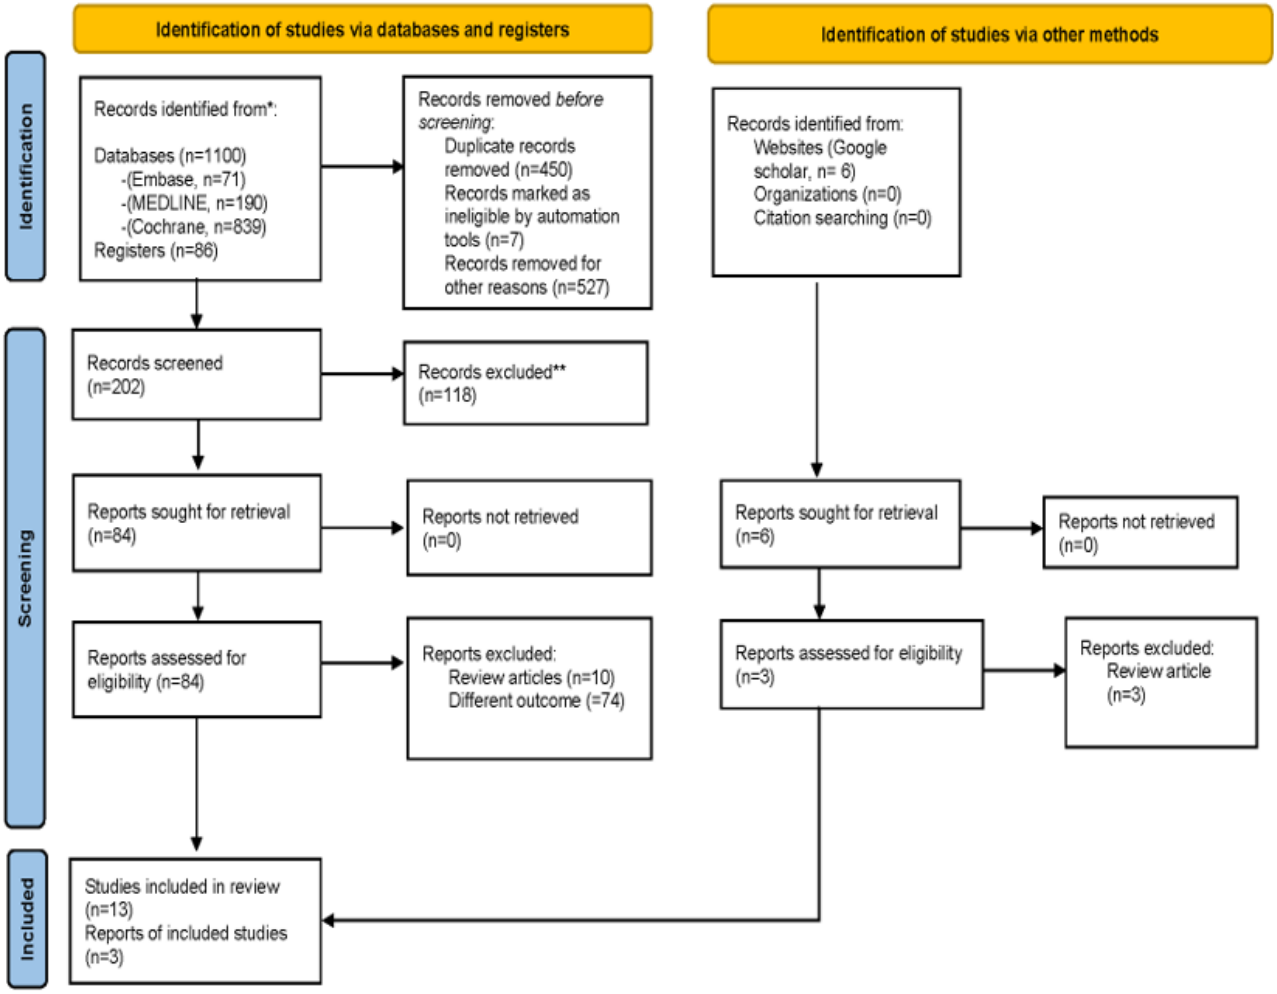
A comprehensive literature search was conducted across electronic databases, including PubMed (MEDLINE), Embase, Cochrane Central Register of Controlled Trials (known as CENTRAL), and the international clinical trials registry platform. An additional search for datasets was conducted by SK using Google Scholar. The reference lists of included articles and reviews were manually searched to identify additional relevant studies for full-text screening. To ensure as current a review as possible, we repeated the above searches on June 15, 2024, and July 10, 2024, and again on November 15, 2024, before final analysis. The search strategy combined keywords related to long COVID (eg, "Long COVID," "Post-Acute Sequelae of SARS-CoV-2 Infection," "PASC"), wearable technology (eg, "wearable devices," "smartwatches," "fitness trackers"), and physiological monitoring (eg, "heart rate variability," "blood oxygen saturation," "respiratory rate;" Multimedia Appendix 2).

Selection Process and Data Extraction

This scoping review focused on studies that involved the use of wearable technology for monitoring or managing long COVID symptoms, specifically those published in peer-reviewed journals. It included research that reported on specific physiological parameters monitored by wearable devices, such as heart rate, respiratory rate, and oxygen saturation. The review excluded studies that did not specifically focus on long COVID,

XSL•FO
RenderX

those that did not involve wearable technology, and those that were not available in full text, including review articles, conference abstracts, or incomplete articles. The initial abstract screening was conducted using Rayyan [13], a web-based tool for systematic reviews. The title and abstracts were independently reviewed by 2 reviewers (SK and MTL), and a third reviewer (NYK or CYL) acted as an arbitrator in case of disagreements between the 2 other reviewers.



Data were extracted from the included studies using a JBI standardized form. Information on study characteristics (eg, author, year, country), type of wearable device used, sensors used, physiological parameters monitored, and the outcomes related to long COVID management were recorded. A narrative synthesis was conducted to summarize the findings, with a focus on the types of wearable devices and sensors used, the physiological parameters monitored, and the impact on long COVID symptom management.

Results

Overview

A total of 1186 articles were identified from 3 databases, 1 registry, and Google Scholar. Following the removal of duplicates and the initial eligibility screening, 16 studies were included in the review (Figure 1). These 16 studies underwent a JBI quality assessment by the 2 authors, and out of these, only 11 met the criteria for data synthesis. Therefore, a total of 11 studies were included in the final review.

Figure 1. Preferred Reporting Items for Systematic reviews and Meta-Analyses (PRISMA) 2020 flow diagram showing identification of studies from search databases.

Study Characteristics

A total of 11 studies met the inclusion criteria and were included in the review [5,6,14-22]. These studies varied in design, ranging from observational studies to interventional trials, and were conducted across different countries (Table 1). The studies' sample sizes ranged widely from as few as 3 participants [20] to as many as 17,667 participants [21].

[b]Not applicable.

Wearable Devices and Sensors

The wearable devices identified in the studies included a mix of commercially available devices (eg, smartwatches, fitness trackers) and research-specific devices designed for health monitoring. In total, 10 different wearable devices were used to monitor long COVID symptoms, capturing key metrics such as heart rate variability (HRV), body temperature, sleep, and physical activity, providing a comprehensive understanding of the physiological effects of the condition. The most used devices were smartwatches (eg, Biostrap, Fitbit, Garmin) and fitness trackers, which are widely accessible and user-friendly.

In the included studies, seven different types of sensors were used, including photoplethysmography (PPG), electrocardiography (ECG), accelerometers, temperature sensors, gyroscopes, near-infrared spectroscopy, and electromyography (Table 2). These sensors were used across multiple devices to monitor key physiological metrics such as heart rate, heart rate variability, peripheral capillary oxygen saturation (SpO_2), respiratory rate, temperature, physical activity, and sleep-related movements [5,6,14-22]. Sensors integrated into these devices were primarily focused on monitoring cardiovascular and respiratory parameters.

XSL•FO
RenderX

Table 2. Study wearable device details of included 11 studies.

Number	Author	Sensor	Physiological characteristics
1	Mekhael et al (2022) [5]	• PPG[a] • Accelerometer	• Heart rate • Heart rate variability • Respiratory rate • SpO2[b] • Movement
2	Lonini et al (2021) [14]	• Adam sensor	• Body motions • Vibrations induced by sounds produced by heartbeats, coughing, or breathing
3	Mekhael et al (2024) [19]	• PPG • Accelerometer	• Heart rate • Heart rate variability • Respiratory rate • SpO2 • Movement
4	Xue et al (2022) [15]	• Digital artery photoplethysmography • Near-infrared spectroscopy • Electromyography	• Heart rate • Heart rate variability • SpO2 • Fatigue
5	Laguarta-Val et al (2024) [16]	• ECG[c] • temperature • accelerometer	• Heart rate • Temperature • Physical activity
6	Corrado et al (2024) [17]	• ECG • PPG • Accelerometer or gyroscope	• Heart rate variability • Heart rate • Sleep rotation movement
7	Corrêa et al (2023) [18]	• Accelerometers • Gyroscopes (inertia sensors)	• Physical activity or mobility
8	Romaszko-Wojtowicz et al (2022) [20]	• ECG • Temperature • PPG	• Heart rate • Temperature • Respiratory rate
9	Kerling et al (2024) [6]	• ECG • Accelerometer	• Physical activity • Heart rate • Sleep
10	Stewart et al (2024) [21]	• ECG • Accelerometers	• Heart rate • Heart rate variability • Physical activity and step count
11	Radin et al (2024) [22]	• ECG • Accelerometers	• Resting heart rate • Physical activity and step count • Sleep

[a]PPG: photoplethysmography.

[b]SpO_2: peripheral capillary oxygen saturation.

[c]ECG: electrocardiography.

ECG was used in 6 out of the 10 studies [14,16,22] and was used to monitor heart rate, and heart rate variability, and to detect arrhythmias and other cardiac abnormalities.

PPG was used in 3 studies [5,17,19] and was also used to measure heart rate, SpO_2 levels, and respiratory rate.

Accelerometers were integrated in 6 studies [6,17] and used to monitor physical activity, sleep patterns, and mobility. They are critical for measuring movements and providing insights into daily activity levels and sleep quality.

Some studies reported the use of more advanced sensors, such as Adam sensors [14] which are used to monitor body motion as it works on vibrations.

XSL•FO
RenderX

Food and Drug Administration Approval and Device Validation

Devices like Fitbit [17,21,22], Polar Ignite [16,17], Garmin [17], and Biostrap [5,19] got Food and Drug Administration (FDA) clearance for ECG functionalities, ensuring regulatory oversight and validation of the accuracy, safety, and reliability of the data collected (Table 1). In addition, the medical device Aidmed is approved by the American National Standard for Ambulatory Electrocardiographs.

Physiological Parameters Monitored

The physiological parameters monitored by these wearable devices included heart rate, heart rate variability, blood oxygen saturation, respiratory rate, skin temperature, and physical activity levels (Figure S1 in Multimedia Appendix 2). These parameters were chosen for their relevance to the symptoms experienced by individuals with long COVID, such as fatigue, autonomic dysfunction, and respiratory distress.

Country of Origin and Regional Focus

The studies were predominantly conducted in the United States and Europe.

Five studies originated in the United States, reflecting a significant research interest in wearable technology for long COVID in this region. The studies by Mekhael et al [5], Radin et al [22], and Lonini et al [14] demonstrated extensive use of wearable devices like Biostrap (Sontakey), Fitbit (Google), and the Suprasternal notch device (Sonica Health**)** [19].

European studies (United Kingdom, Spain, Poland, Germany, and Ireland) were also included, indicating a broad European engagement in the field. The study by Xue et al [15] in Ireland used the Shimmer device (Shimmer Sensing) and Finapres NOVA (Finapres Medical Systems), while the United Kingdom–based study by Corrado et al [17] used the Polar H10 chest strap (manufactured by Polar Electro) and Fitbit Charge 5 smartwatch. Similarly, the study by Kerling et al [6] in Germany used a Garmin device (Garmin Ltd).

Measurement Approaches in Long COVID Studies

Devices like Biostrap and Fitbit tracked sleep stages, HRV, and physical activity, helping to identify sleep disruptions and reduced physical endurance in patients (Multimedia Appendix 3). Tools such as the Suprasternal notch device and Shimmer captured critical data on altered respiration, cough frequency, and neurocardiovascular responses, shedding light on the multisystem impacts of long COVID. Interventions using devices like the Polar H10 and Garmin provided insights into HRV biofeedback and energy expenditure, aiding rehabilitation and symptom relief. Overall, these devices offer valuable tools for understanding and managing long COVID symptoms, enabling tailored care and long-term monitoring for affected individuals.

Discussion

Principal Findings

This scoping review offers a comprehensive evaluation of the existing literature on the use of wearable health devices for monitoring and managing long COVID symptoms. The findings highlight the potential of wearable devices to revolutionize the management of this complex and persistent of long COVID symptoms by continuous physiological monitoring. This review identifies a wide range of wearable devices used in published studies, including commercially available smartwatches, fitness trackers, and research-specific medical devices. The use of 10 different wearable devices in detecting long COVID symptoms highlights the potential of these technologies in early symptom identification [5,6,14-22]. Sensors such as PPG, ECG, and accelerometers were commonly used to monitor cardiovascular and respiratory functions, reflecting the prevalence of these symptoms in long COVID patients. These devices continuously track key physiological parameters like heart rate, HRV, SpO_2, and sleep patterns, allowing for the early detection of subtle health changes and proactive management of symptoms. The widespread use of accelerometers also emphasizes the growing importance of physical activity and sleep monitoring in managing chronic conditions like long COVID.

One notable finding in this review is that only a limited number of wearable devices have received FDA approval for specific health monitoring features. For instance, Fitbit's ECG app, cleared by the FDA in 2020, is accessible on models such as the Sense, Sense 2, and Charge 5 [23]. Garmin has also secured FDA clearance for its ECG app, now available on compatible models like the Venu 2 Plus and Epix Pro series [24]. The inclusion of FDA-approved devices brings a level of regulatory oversight, which is critical in clinical settings where wearable data may influence patient care decisions. FDA-approved wearables are validated for safety and effectiveness, offering health care providers more confidence in the data collected, especially when managing complex conditions like long COVID. In contrast, studies that do not emphasize the use of FDA-approved devices may face challenges in translating their findings into clinical practice. Comparing these studies underscores the need for standardized protocols and further validation studies to assess the long-term efficacy of wearable devices, ensuring their integration into routine health care for monitoring and managing long COVID symptoms.

This review also highlights issues related to user adherence and engagement. The success of wearable technology in managing chronic conditions like long COVID depends not only on the accuracy of the data collected but also on the willingness of users to consistently wear the devices and engage with the data. A few studies reported issues with user adherence, which could be attributed to factors such as device comfort, battery life, and the user interface of the accompanying apps [19,25]. Despite advancements in wearable technology, a significant gap exists in ensuring the seamless, secure, and standardized handling of the vast amounts of personal health data collected by these devices. In agreement with Smith et al [26], data interoperability and secure sharing across platforms, underscore the need for improved systems for data management and privacy to effectively integrate wearable technologies into clinical practice [26]. These issues highlight the need for more user-centered design approaches in the development of wearable devices, ensuring that they are not only functional but also comfortable and easy to use over extended periods.

XSL•FO
RenderX

In terms of the geographic distribution of the studies, the majority were conducted in the United States [5,14,19] and Europe [15-17,20,21], reflecting a significant research interest in these regions. This regional focus may be influenced by the availability of resources and funding for research on wearable technology, as well as the higher prevalence of long COVID in these areas due to the earlier and more widespread outbreaks of COVID-19. However, there is a need for more research in other regions, particularly in low- and middle-income countries, where the burden of long COVID may be significant but less well-documented. Furthermore, this review also found that while wearable devices offer valuable insights, the complexity and vast symptomatology of long COVID remain underexplored. Included studies focused on specific symptoms, with limited attention to common issues like fatigue, which is less frequently measured by these devices. This highlights the limitations of wearable technology in addressing the full spectrum of long COVID symptoms, underscoring the need for more comprehensive research.

This review provides a distinct perspective from typical COVID-19 wearable device studies by focusing on the long-term management of long COVID, rather than acute symptom detection. The key difference lies in the chronic nature of long COVID, where persistent and fluctuating symptoms, such as fatigue, cardiovascular issues, and sleep disturbances, require continuous, long-term monitoring. In contrast, COVID-19 reviews often emphasize short-term monitoring for acute symptoms, such as changes in respiratory rate and oxygen saturation, during the active phase of infection. Moreover, this review addresses unique challenges like user adherence and device validation for chronic use, which are less of a concern in acute COVID-19 monitoring.

There are several limitations to this review that must be acknowledged. One key limitation is the reliance on small sample sizes in some studies, which may reduce the statistical power and the ability to draw broader conclusions. In addition, the use of self-reported data in certain studies could introduce bias and affect the accuracy of the findings. Another limitation is the study design, with most studies lacking a longitudinal approach, which is crucial for assessing the long-term effectiveness of wearable technology in tracking long COVID symptoms. Furthermore, the number of studies available for review remains limited, highlighting the urgent need for more high-quality research to address the evolving challenges of long COVID management through wearable technology.

Conclusion

This review highlights the significant potential of wearable technology in managing long COVID by leveraging sensors like ECG, PPG, and accelerometers to monitor crucial physiological metrics such as heart rate, oxygen saturation, and physical activity. Wearable devices provide real-time insights into persistent and fluctuating symptoms, offering a more personalized approach to patient care. The advancements in device accuracy and the increasing availability of FDA-approved options further reinforce their importance in clinical use. Furthermore, enhancing the usability of these devices to improve user engagement will enable broader adoption and sustained monitoring over extended periods. Ultimately, wearable technology stands out as a promising tool to support individualized care and improve outcomes for long COVID patients, shaping the future of health care monitoring.

Future Implications and Requirements

For wearable technology to fully realize its potential in managing long COVID, several future implications are required. Standardization of protocols for sensor use and data interpretation is critical. This will allow for greater consistency across studies and ensure that health care providers can rely on the data generated by wearable devices. Wearability plays a crucial role in adherence, and future innovations should focus on compact, lightweight designs and hypoallergenic materials to enhance comfort and minimize user burden. Equally important is ensuring that sensors are accurate, durable, and capable of sustained performance in diverse real-world conditions. User-centered design is essential for improving adherence to wearable devices, ensuring that they are comfortable, easy to use, and integrated seamlessly into patients' lives. Longitudinal studies are also needed to assess the sustained benefits of wearable technology in managing long COVID symptoms and improving health outcomes over time.

Building on the current research, the future applications of wearable health devices extend beyond long COVID management to other infectious diseases, such as influenza or emerging infectious diseases with similar symptomatology. Wearable devices that continuously monitor vital signs such as body temperature, heart rate, and respiratory functions could facilitate early illness detection and proactive management by identifying subtle physiological changes indicative of infection. Such applications are particularly relevant for influenza, where symptoms frequently overlap with long COVID, including fatigue, respiratory issues, and fever. In addition, integrating wearable data into public health systems could provide real-time insights into disease trends and hotspots, supporting more responsive and informed health interventions. Future efforts should also explore the integration of advanced data analytics and artificial intelligence to interpret sensor data more effectively, paving the way for personalized health care solutions.

This review illustrates that wearables have the potential to reshape not only individual patient care but also population-level disease management, positioning them as vital tools in addressing both chronic and acute public health challenges. Overall, to fully integrate wearable devices into long COVID management, a concerted effort is required to address these challenges. By developing standardized methods, improving device usability, and expanding research across diverse populations, wearable technology could become a cornerstone in the effective long-term management of long COVID.

Abstract

Background: Within hemodialysis patient populations, eHealth interventions have been considered as an alternative and complementary option to routine care services. However, the efficacy of eHealth interventions for hemodialysis patients remains poorly understood owing to a lack of rigorous quantitative evidence synthesis.

Objective: This meta-analysis aimed to evaluate the efficacy of eHealth interventions in improving quality of life, treatment adherence, and psychological outcomes (anxiety and depression) among hemodialysis patients. In addition, the study sought to identify specific intervention components and methodological quality associated with enhanced quality of life and health outcomes in this population.

Methods: A comprehensive search was performed across PubMed, Web of Science, Embase, CINAHL, Cochrane Library, PsycINFO, China National Knowledge Infrastructure, WanFang, China Science and Technology Journal Database, and China BioMedical Literature Database databases from their inception to September 7, 2024. Randomized controlled trials on eHealth interventions for hemodialysis patients published in English or Chinese were included. Critical appraisal was carried out independently by 2 reviewers to assess the bias risk of the studies included. Quantitative synthesis of the outcomes of interest was conducted using a random-effects model. The quality of evidence for the outcomes was evaluated following the Grading of Recommendations, Assessment, Development, and Evaluation approach.

Results: A total of 17 randomized controlled trials involving 1728 participants were included in this meta-analysis out of 5741 articles identified in the initial database search and additional search references. In the 17 studies, 8 kinds of eHealth intervention delivery formats were used, including text messages, telephone sessions, video, network platforms, social media, computers, websites, and mobile apps. The majority of research studies used a single form of eHealth intervention, and 7 studies adopted a combined approach of 2 or more eHealth technologies. The duration of eHealth interventions demonstrated substantial variability across studies, spanning from 4 weeks to 12 months, of which 3 months was the most common. A total of 14 (82%) studies were considered to have “some concern” about selection bias. In addition, 15 (88%) trials were classified as having a “high risk” of performance and detection bias, and all trials were judged to be at “low risk” of attrition and reporting bias. The pooled results revealed a significant difference between the eHealth interventions and control groups on quality of life (standardized mean difference [SMD]=0.87, 95 % CI 0.38 to 1.37, low certainty evidence), treatment adherence (SMD=1.11, 95 % CI 0.30 to 1.91, moderate certainty evidence), anxiety (SMD=–2.11, 95 % CI –3.25 to –0.97, moderate certainty evidence), and depression (SMD=–2.46, 95 % CI –3.68 to –1.25, moderate certainty evidence).

XSL•FO
RenderX

Conclusions: eHealth interventions could be a beneficial approach for improving quality of life and treatment adherence and reducing anxiety and depression among hemodialysis patients. However, future high-quality randomized controlled trials are essential to draw more reliable conclusions.

KEYWORDS

hemodialysis; eHealth interventions; quality of life; treatment adherence; anxiety; depression; meta-analysis; kidney; systematic review; kidney diseases; kidney function; chronic diseases

Introduction

End-stage renal disease (ESRD), which arises as a consequence of the progression of chronic kidney disease (CKD), is a condition that affects millions globally and is recognized as one of the most widespread and significant chronic diseases [1-3]. Hemodialysis (HD), the primary modality of renal replacement therapy for advanced kidney failures, plays a crucial role in mitigating the otherwise inevitable progressive decline in kidney function [4]. As of 2020, it is estimated that 88.07% of patients with ESRD in the United States were undergoing HD, compared with 46% to 98% of patients in Europe [5,6]. HD functions as a partial replacement for kidney activity and plays a critical role in maintaining water-electrolyte homeostasis and, as a result, significantly contributes to the prolongation of patient survival [7,8]. However, while undergoing long-term HD treatment, patients are often accompanied by adverse effects such as anxiety, depression, and fatigue, which significantly impair their compliance with treatment and quality of life [9,10]. Furthermore, the financial burden on HD patients, their families, and society is typically substantial due to the prohibitive cost of dialysis and loss of productivity [11]. Therefore, effective, accessible, and cost-effective interventions aimed at alleviating the negative emotions experienced by HD patients, while improving their adherence and quality of life, are urgently sought.

With the continual refinement of dialysis technology, the life expectancy of HD patients has increased markedly [12]. As a result, their focus has shifted from merely extending survival to enhancing quality of life [13]. To achieve this, HD patients must comply with a strict and well-structured treatment protocol that comprises regular medication intake, diet management, fluid control, and physical activity [14]. However, given the poor accessibility of medical resources and inadequate health literacy, they frequently find it difficult to obtain appropriate self-management support, including health guidance and supervision, psychological counseling, and scheduled follow-up visits [15,16]. These barriers tend to precipitate adverse emotions, such as anxiety and depression, which diminish treatment adherence and ultimately impede the enhancement of the quality of life [17,18]. Furthermore, HD patients primarily receive care services in outpatient clinics and spend the remainder at home or in the community. In contrast, in low- and middle-income countries, underdeveloped community care networks further limit access to timely care and health monitoring, and the effectiveness of their treatments for this condition is usually significantly compromised [19,20].

Benefiting from the rapid development of electronic information technology, eHealth interventions have been recognized as a powerful approach for disease prevention, health behavior maintenance, and improved health outcomes owing to their accessibility and cost-effectiveness [21,22]. In the field of health care, eHealth interventions mainly deliver continuous and personalized services to patients, primarily through digital platforms including the internet, mobile apps, websites, and text messaging [23,24]. Multiple studies have revealed the substantial potential of eHealth interventions, not only in enhancing the quality of life but also in enhancing self-efficacy and significantly reducing anxiety and depression in patients with chronic diseases, thereby underscoring their effectiveness as a multifaceted therapeutic approach capable of addressing both physical and psychological dimensions of patient health [25,26]. However, while a growing body of original research has evaluated the effects of eHealth on quality of life, treatment adherence, anxiety, and depression in HD patients, substantial variability remains in terms of intervention formats, duration, control conditions, and outcome measures [20,27,28]. For instance, a Thailand-based study demonstrated that a tele-home health care model (including video visits, telephone counseling, web-based education, and monitoring) significantly improved the quality of life of patients with HD at 3 months [27]. Similarly, another research conducted in Iran reported that a 1-month period of nurse-delivered tele-nursing significantly reduced the levels of anxiety and depression in HD patients [29]. However, a recent study evaluating the difference between an internet-based self-help intervention and usual care in improving anxiety, depression, and quality of life among HD patients revealed no significant difference in the clinical efficacy of both interventions [28]. Variations in these results may stem from a variety of factors such as different cultural backgrounds, patient characteristics, intervention format, and duration of the intervention. In other words, the mechanisms through which eHealth interventions improve health outcomes in HD patients remain unclear. In addition, the complexity of eHealth interventions also poses serious challenges for health care providers in their implementation [30]. Last but not least, most of the previous research on the application of eHealth in HD patients was conducted with small samples, feasibility trials, or qualitative methods, making it difficult to draw reliable conclusions. To our knowledge, no meta-analyses have been conducted to date that comprehensively investigate the efficacy of eHealth interventions specifically targeting HD patients, highlighting a significant gap in the literature and underscoring the need for comprehensive evidence synthesis in this area. Therefore, a meta-analysis is warranted to clarify the

XSL•FO
RenderX

effectiveness of eHealth interventions in HD patients and to identify the optimal form and duration of these interventions for standardized clinical applications in the future.

Methods

Design

This meta-analysis was reported in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement (Multimedia Appendix 1) [31]. The study protocol was registered with PROSPERO (CRD42024589799).

Literature Search

A literature search was conducted in PubMed, Web of Science, Embase, CINAHL, Cochrane Library, PsycINFO, China National Knowledge Infrastructure (CNKI), WanFang, VIP, and CBM from the inception to September 7, 2024. We used the following search terms: dialysis, hemodialysis, hemodialysis, maintenance hemodialysis, eHealth, website, internet, text messaging, email, digital health, telephone, smartphone, phone, mobile phone, mobile device, mobile health, mHealth, app, application, video, computer, RCT, and randomized controlled trial. The search strategy was designed using Boolean operators to combine relevant terms. For example, in PubMed, the following search string was used: ("dialysis" OR "hemodialysis" OR "haemodialysis" OR "maintenance hemodialysis" OR "maintenance haemodialysis" OR "MHD") AND ("telemedicine" OR "internet-based intervention" OR "telerehabilitation" OR "web" OR "website" OR "internet" OR "text messaging" OR "email" OR "digital health" OR "eHealth" OR "e-health" OR "telephone" OR "smartphone" OR "phone" OR "mobile phone" OR "mobile device" OR "technology" OR "mobile health" OR "mHealth" OR "m-health" OR "online" OR "app" OR "application" OR "video" OR "computer") AND ("RCT" OR "randomized clinical trial" OR "randomized controlled trial" OR "randomized trial" OR "randomised controlled trial" OR "randomised trial"). In addition, we complemented the search with a list of references that were incorporated into the literature or relevant definitive reviews. The specific details of all search strategies are contained in Multimedia Appendix 2.

Inclusion and Exclusion Criteria

The eligibility criteria were determined based on the PICOS (Population, Intervention, Comparison, Outcomes, and Study design) acronym (Textbox 1).

Textbox 1. Eligibility criteria.

Inclusion criteria:

- Population: adult patients (aged 18 years or older) received hemodialysis treatment.
- Intervention: the interventions were administered through a variety of eHealth technologies, including websites, the internet, social media platforms, telephone communications, video consultations, and other digital health tools.
- Comparison: the control groups were assigned to usual care (routine health education and counseling, periodic follow-up, psychological care, and standard physical examinations) without placebo and eHealth technology.
- Outcomes: the study results were focused on the outcomes of quality of life, treatment adherence, and anxiety or depression.
- Study design: adhered to a randomized controlled trial format. In addition, we only included studies published in English or Chinese.

Exclusion criteria:

- Duplicate publications.
- Conference abstracts, study protocols, letters, case reports, and reviews.
- Without sufficient data for meta-analysis.

Study Selection and Data Extraction

All citations were imported into Endnote X20 for data management. Following the import of all references, duplicate entries were removed, after which 2 reviewers independently screened the remaining records by reading the title, abstract, and full text using the predefined inclusion criteria. To ensure methodological rigor in data extraction, 2 independent reviewers (XHZ and HC) retrieved data and recorded them in a structured spreadsheet, which was subsequently cross-verified. From each study, the following data were meticulously extracted: author, publication year, country, age, sample size, details of the experimental and control conditions, duration of the intervention, and measures. In cases where discrepancies arose between the 2 reviewers, a third reviewer (WWY) was consulted to achieve consensus.

Risk of Bias Assessment

Two reviewers (XHZ and HC) independently assessed the methodological quality of the included studies using the Cochrane Risk of Bias Tool, and any disagreements between them were clarified by discussion with a third researcher (WWY). In cases where consensus could not be reached, the final decision was made by arbitration, with the third reviewer casting the deciding vote. The tool comprises 7 components, including random sequence generation, allocation concealment, blinding of participants and personnel, blinding of outcome assessment, missing outcome data, selective reporting, and other biases [32]. Each domain within the assessment was categorized as presenting either a "low risk," "unclear risk," or "high risk" of bias, and for the overall risk of bias evaluation, a study was deemed to carry a "low risk of bias" only if all individual items within the assessment were consistently identified as

XSL•FO
RenderX

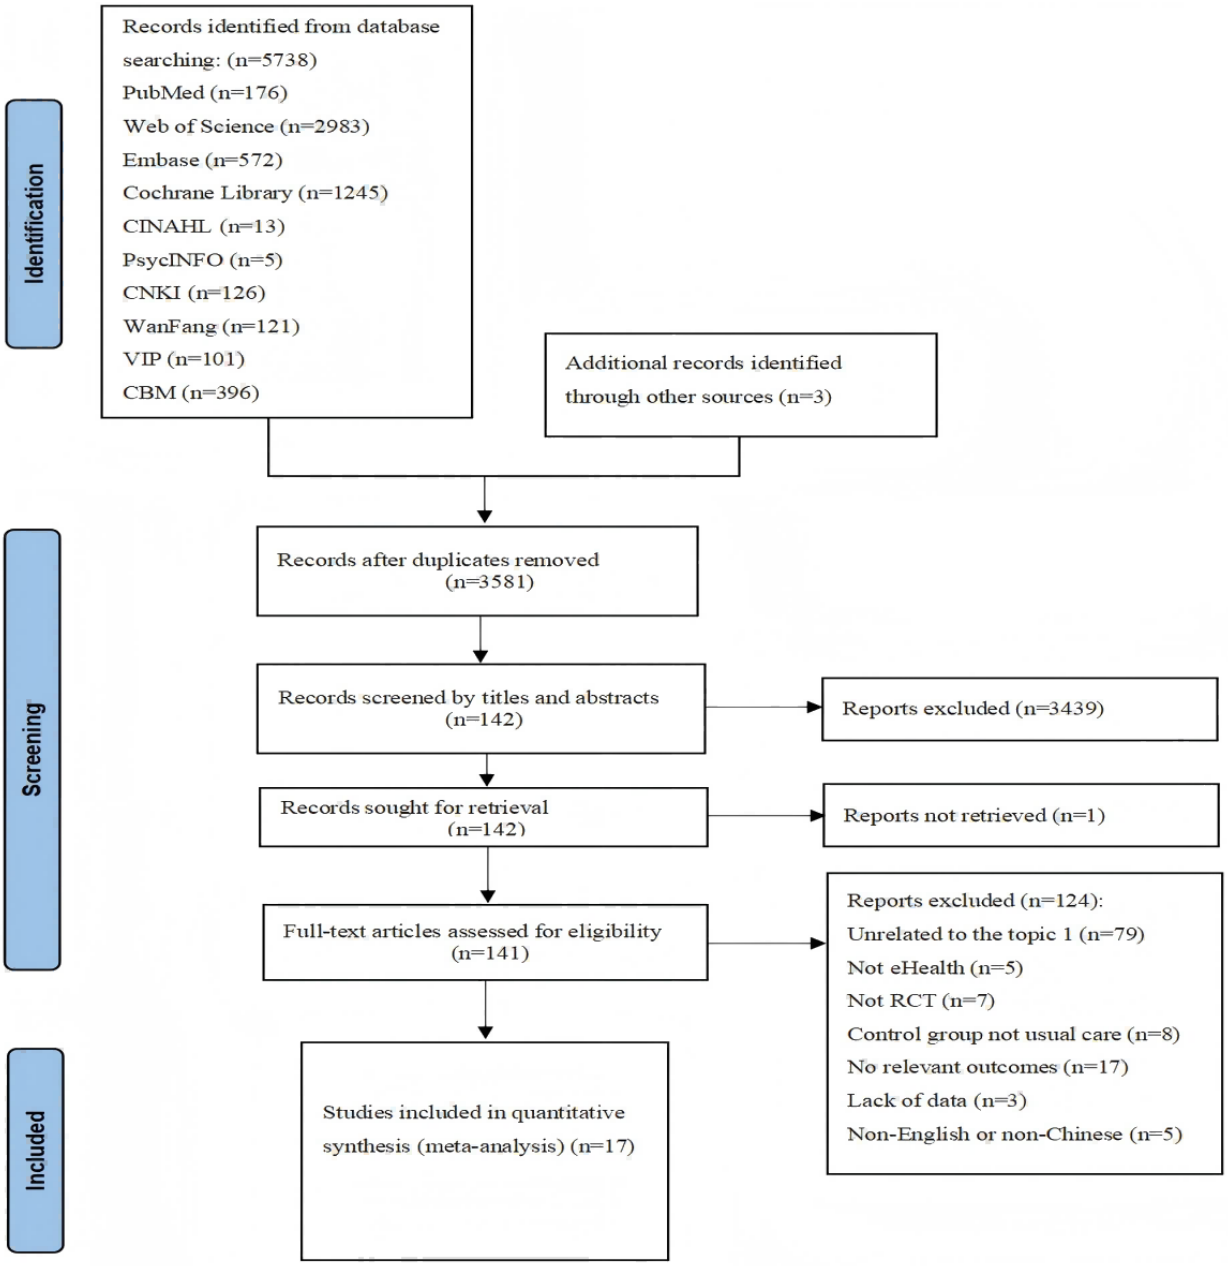
representing low risk. A study was rated as having "some concerns" when it raised concerns in at least 1 area. It was deemed to have a "high risk of bias" if at least 1 domain exhibited a high risk or if multiple domains indicated concerns.

Quality of Evidence Assessment

Two researchers separately appraised the quality of evidence for outcomes such as quality of life, treatment adherence, anxiety, and depression, which were evaluated using the Grading of Recommendations, Assessment, Development, and Evaluation (GRADE) framework. Discussion with a third researcher was conducted to clarify disagreements. The framework categorized evidence into 4 levels, "high," "moderate," "low," and "very low" based on limitations in the dimensions of risk of bias, inconsistency, directness, imprecision, and publication bias [33]. In addition, if the effect size was substantial or the dose-response ratio strong, the evidence grade for the outcome could be upgraded by 1 level.

Statistical Analysis

This study identified quality of life and treatment adherence as primary outcomes and anxiety and depression as secondary outcomes. The meta-analysis and heterogeneity test were conducted with RevMan (version 5.3; Cochrane) and Stata (version 17.0; StataCorp). As the trials measured the outcomes of interest in various tools, the standardized mean difference (SMD) with 95% CI was used to estimate the pooled intervention effect [34]. The SMD magnitudes were interpreted as small (<.5), moderate (.5-.8), and large (>.8) [35]. The I^2 statistic and P values were used to evaluate heterogeneity. A fixed-effect model would be applied to collapsed data if $I^2 \leq 50\%$ and $P>.1$, otherwise a random-effect model would be performed to provide more reliable estimates [34]. In addition, we conducted a subgroup analysis stratified the duration and format of interventions to identify potential contributors to heterogeneity [36]. Given that over 10 studies reported quality of life as an outcome, publication bias was evaluated both visually using a funnel plot and quantitatively through the Egger linear regression method. The trim and fill analysis was performed to adjust for any publication bias and to estimate its effect on effect sizes. Finally, a sensitivity analysis was undertaken to assess the stability of the pooled results by applying a leave-one-out approach.



Results

Study Selection

The initial database search resulted in the retrieval of 5738 articles, with an additional 3 studies identified through a manual review of reference lists. After removing duplicates, 3581 articles were reviewed based on their titles and abstracts. As a result, 142 articles met the initial validation criteria. Subsequently, following a full-text examination, 17 papers were included in this review. The study selection and literature screening process are detailed in Figure 1.

RenderX

Figure 1. PRISMA flowchart of study selection and literature screening process. RCT: randomized controlled trial.

Characteristics of the Included Studies

A total of 1728 HD patients were recruited in 17 trials [10,17,20,27,28,37-48], of which 879 were assigned to the experimental group based on eHealth technologies, while 849 were in the control group and received usual care. Of the 17 randomized controlled trials, 2 were clustered trials, 1 was a three-arm trial, and 2 were feasibility trials. The studies were conducted in China (n=8), Iran (n=4), Australia (n=1), Turkey (n=1), Oman (n=1), the Netherlands (n=1), Thailand (n=1), with the publication years spanning between 2015 and 2024. The mean ages of all participants ranged from 27 (SD 11.5) to 69.13 (SD 11.82) years old. Nevertheless, three studies failed to provide the age of the participants [20,37,38]. Multimedia Appendix 3 details the characteristics of the included studies.

Main Features of Interventions

In the 17 studies, 8 kinds of eHealth intervention delivery formats were used, including text messages, telephone sessions, video, network platforms, social media, computers, websites, and mobile apps. The majority of research used a single form of eHealth intervention, and 7 studies adopted a combined approach of 2 or more eHealth technologies [17,20,28,37-40]. The duration of eHealth interventions demonstrated substantial variability across studies, spanning from 4 weeks to 12 months, of which 3 months was the most common.

Main Features of Controls

All HD patients in the control group were assigned to receive usual care during the intervention, including health assessment, advice and counseling, laboratory and physical examinations, and follow-up care. Nevertheless, there were large gaps between studies in terms of descriptions of the components of usual care,

XSL•FO
RenderX

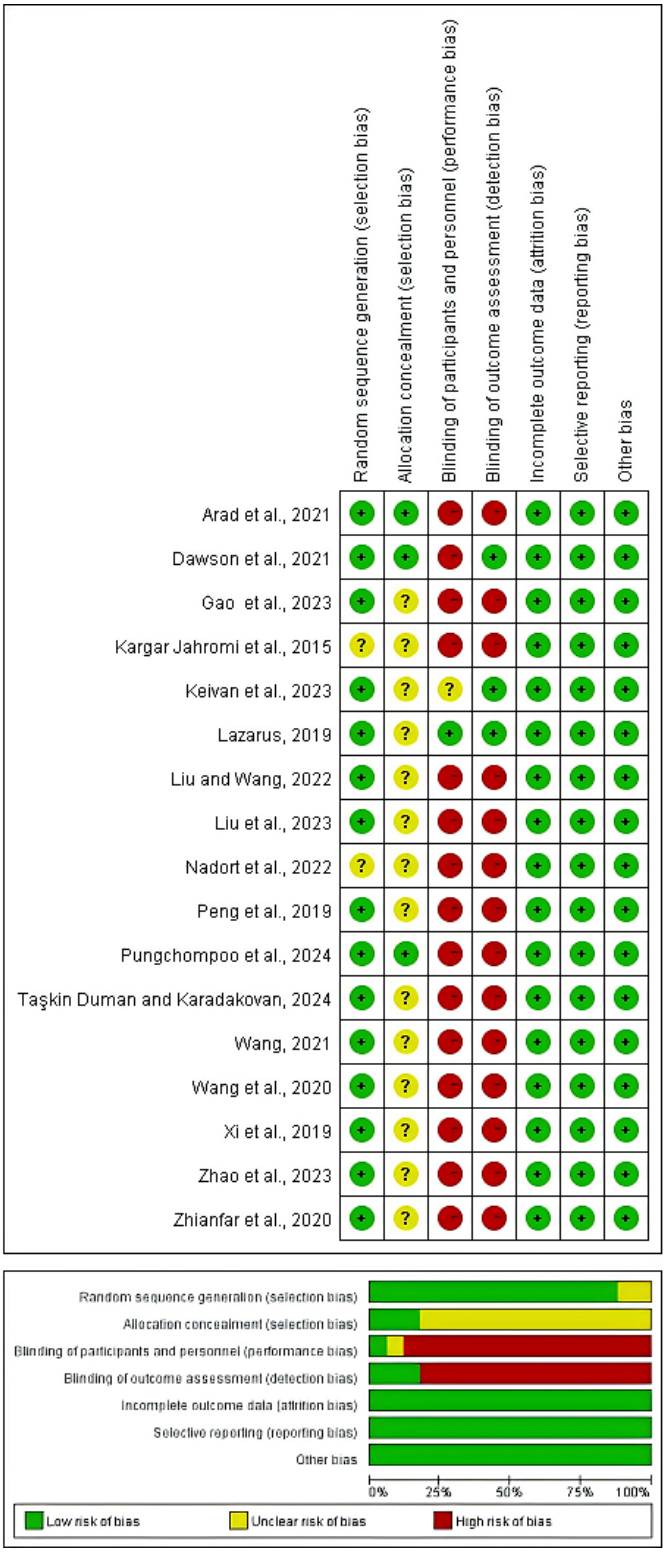
with 6 of the studies [10,20,27,39,41,42] not detailing the elements of the intervention in the control group.

Outcome Measures

In total, 7 validated scales were used to measure the quality of life among HD patients: the EuroQol 5-Dimension (EQ-5D) [41], the 36-Item Short Form Health Survey (SF-36) [10,37,43-45], the 12-Item Short Form Health Survey (SF-12) [28], the Kidney Disease Quality of Life–Short Form (KDQOL–SF) [39,42], the 9-item Thai Health Status Assessment Instrument [29], the World Health Organization Quality Of Life-BREF (WHOQOL-BREF) [40], and World Health Organization Quality Of Life-SF (WHOQOL-SF) [20].

Five studies that reported on treatment adherence in HD patients applied 2 various instruments to measure this indicator, including the End-Stage Renal Disease Adherence Questionnaire (ESRD-AQ) [17,20] and the Treatment adherence scale for maintenance hemodialysis patients with end-stage renal disease [44,47].

Three scales were administered to determine HD participants' anxiety: the Depression Anxiety and Stress Scale (DASS) [27], the Self-Rating Anxiety Scale (SAS) [45-47], and the Beck Anxiety Inventory (BAI) [28,48].



Four solid instruments were used to assess the level of depression among HD patients: DASS [27], the Self-rating Depression Scale (SDS) [45-47], the Beck Depression Inventory-II (BDI-II) [28,48], and the Beck Depression Inventory-Short Form (BDI-SF) [20].

Risk of Bias

A total of 14 studies were considered to have "some concern" about selection bias due to not reporting the specific methods used for random sequence generation or the details of allocation concealment [10,20,27,28,37,39,40,42-48]. In addition, 15 studies were considered to be at "high risk" of performance and detection bias as they did not apply blinding to participants, personnel, or outcome assessors [10,17,20,27-29,37,40,41,43-48]. Ultimately, all trials were judged as having a low risk of attrition and reporting bias because of their low rate of missing outcome data and explicit reasons for missing data, as well as the reported results were consistent with those described in the published study protocols or in the methods sections of the articles. A summary of the risk of bias assessment for the included studies is detailed in Figure 2.

Figure 2. Risk of bias assessment summary of included studies.

Main Results of Meta-Analysis

Quality of Life

Twelve trials investigated the effect of eHealth interventions on the quality of life of HD patients [10,20,28,37-45]. The pooled result demonstrated a statistically significant efficacy of eHealth interventions in enhancing quality of life, with a substantial effect size (SMD 0.87, 95% CI 0.38-1.37; Multimedia Appendix 4). The sensitivity analysis indicated that no single trial was sufficient to alter the overall result. The sensitivity analysis confirmed the robustness of the meta-analysis findings, as the exclusion of any individual study did not alter the overall results (Figure S2a in Multimedia Appendix 5).

In the analysis categorized by intervention duration, eHealth interventions of short duration (≤3 months) were effective in improving quality of life among HD patients, with a substantial

XSL•FO
RenderX

reduction in heterogeneity (SMD 0.5, 95% CI 0.28-0.73; I^2=61%; Multimedia Appendix 4). However, it showed a significantly higher positive impact on quality of life than long-term (>3 months) eHealth interventions (SMD 2.25, 95% CI 0.29-4.21; I^2=98%; Multimedia Appendix 4). Subgroup analysis of the different intervention formats revealed that a single eHealth intervention (SMD 1.5, 95% CI 0.45-2.55; I^2=97%; Multimedia Appendix 4) had a greater positive impact on quality of life than a combination of eHealth interventions.

Treatment Adherence

Five trials evaluated the impact of eHealth interventions on adherence among HD patients [17,20,44,47,48]. The pooled results demonstrated that eHealth interventions significantly enhanced HD patients' treatment adherence (SMD 1.11, 95% CI 0.3-1.91; Multimedia Appendix 4). The sensitivity analysis demonstrated the robustness of the results (Figure S2b in Multimedia Appendix 5).

In the analysis classified by intervention duration, the short-term (≤3 months) eHealth interventions were effective in terms of treatment adherence among HD patients (SMD 1.34, 95% CI 0.31-2.37; I^2=95%), whereas long-term (>3 months) eHealth interventions failed to demonstrate a significant impact (SMD 0.25, 95% CI −0.11 to 0.61; Multimedia Appendix 4). When comparing the relative effects between subgroups of different intervention formats in terms of treatment adherence, it was found that neither single (SMD 0.64, 95% CI −0.05 to 1.33; I^2=91%) nor combined eHealth interventions (SMD 1.89, 95% CI −0.69 to 4.48; I^2=97%) had a significant effect on treatment adherence (Multimedia Appendix 4).

Anxiety

Six trials provided sufficient data about the impact of eHealth interventions on anxiety among HD patients [27,28,45-48]. The pooled results revealed that eHealth interventions led to a significant reduction in anxiety levels among HD patients (SMD −2.11, 95% CI −3.25 to −0.97; Multimedia Appendix 4). Despite the very high heterogeneity of the combined results, sensitivity analysis confirmed the stability of the result (Figure S2c in Multimedia Appendix 5). When comparing the effects between subgroups of different intervention duration on anxiety of HD patients, short-term (≤3 months) eHealth interventions (SMD −1.95, 95% CI −3.84 to −0.07; I^2=98%) had significantly lower pooled effects than long-term (≤3 months) eHealth interventions (SMD −2.29, 95% CI −3.74 to −0.83; I^2=95%; Multimedia Appendix 4). In addition, the subgroup analyses revealed that single eHealth interventions significantly reduced anxiety in HD patients (SMD −2.54, 95% CI −3.71 to −1.39; I^2=96%), while mixed eHealth interventions showed no statistically significant impact (SMD 0.08, 95% CI −0.28 to 0.43; Multimedia Appendix 4).

Depression

Seven trials reported adequate data on the effect of eHealth interventions on anxiety among HD patients [20,27,28,45-48]. The pooled results showed that eHealth interventions had a statistically significant impact on reducing depression, with a large effect size (SMD −2.46, 95% CI −3.6 to −1.25; Multimedia Appendix 4). The sensitivity analysis revealed that the results remained consistent, with no significant changes after excluding any individual studies (Figure S2d in Multimedia Appendix 3).

When comparing the effects between subgroups of different intervention duration on depression of HD patients, short-term (≤3 months) eHealth interventions (SMD −1.69, 95% CI −3.03 to −0.35; I^2=97%) had significantly lower pooled effects than long-term (≤3 months) eHealth interventions (SMD −3.53, 95% CI −6.50 to −0.57; I^2=98%; Multimedia Appendix 4). Furthermore, a subgroup analysis stratified by intervention formats revealed that a single eHealth intervention was more effective in reducing anxiety in HD patients (SMD −3.40, 95% CI −5.07 to −1.72; I^2=95%; Multimedia Appendix 4).

Publication Bias

We used the Egger test and a funnel plot to evaluate potential publication bias in studies related to quality of life. The asymmetry observed in the funnel plot indicated the presence of publication bias among the included studies (Figure S3 in Multimedia Appendix 6). Furthermore, the results of the Egger test indicated a significant bias, with a regression coefficient (beta1) of 13.92 (SE 2.084). The corresponding z value was 6.68, and the P value was <.001, suggesting that small-study effects are present in the analysis. This result (P<.001) indicates that the observed effect size may be influenced by small sample studies, which could lead to potential publication bias. Thus, the trim-and-fill analysis was performed to counteract the bias. However, there were no missing studies during the analysis and the corrected effect sizes remained unchanged, indicating the stability of the meta-analysis results.

Quality of Evidence

Following the guidance in the GRADE standard, the certainty of the evidence for the quality of life, treatment adherence, anxiety, and depression were classified as low, moderate, moderate, and moderate, respectively. The justification for the ratings and other details are listed in Table 1.

XSL•FO
RenderX

Table 1. Grading of Recommendations, Assessment, Development, and Evaluation summary of the quality of the evidence for the outcomes.

Outcome	Quality assessment					Number of participants (studies)	Effect size, SMD (95% CI)	Quality of the evidence (GRADE[a])
	Risk of bias	Inconsistency	Indirectness	Imprecision	Other considerations			
Quality of life	Serious[b]	Serious[c]	Not serious[d]	Not serious[e]	Publication bias strongly suspected[f] large effect size[g]	1243 (12)	0.87 (0.38 to 1.37)	Low
Treatment adherence	Serious[b]	Serious[c]	No serious[d]	No serious[e]	Large effect size[g]	508 (5)	1.11 (0.3 to 1.91)	Moderate
Anxiety	Serious[b]	Serious[c]	No serious[d]	No serious[e]	Large effect size[g]	536 (6)	−2.11 (−3.25 to −0.97)	Moderate
Depression	Serious[b]	Serious[c]	No serious[d]	No serious[e]	Large effect size[g]	634 (7)	−2.46 (−3.68 to −1.25)	Moderate

[a]GRADE: Grading of Recommendations, Assessment, Development, and Evaluation.

[b]Most information is from studies rated as high risk of bias.

[c]I^2>50%; heterogeneity could not be explained by the form and duration of intervention.

[d]The various eHealth interventions are compared directly with usual care among cancer patients.

[e]The 95% CI excludes pooled effect sizes that are not clinically significant.

[f]The results of the Egger test and funnel plot revealed the evidence for publication bias.

[g]The pooled effect size >0.8.

Discussion

Principal Findings

As far as we know, this study was the first meta-analysis of randomized controlled trials to systematically assess the efficacy of eHealth interventions on quality of life, treatment adherence, anxiety, and depression among HD patients. A total of 17 trials involving 1728 HD patients were included in this meta-analysis. We found varied quality of evidence for the effects of eHealth interventions on quality of life, treatment adherence, anxiety, and depression in people with HD. Specifically, low-quality evidence demonstrated that eHealth interventions have significant clinical effects in enhancing the quality of life among HD patients compared with the control groups. In addition, moderate quality evidence indicated that eHealth interventions can significantly enhance treatment adherence and reduce anxiety and depression in HD patients. However, given the worrying overall methodological quality, more high-quality clinical trials remain essential to draw reliable conclusions in the future. Specifically, the majority of studies included in the meta-analysis had selection, performance, and detection biases, and these potential biases may limit the generalizability of the findings to a wider population, and the lack of blinding may have led to exaggerated estimates of the efficacy of the eHealth interventions. In addition, the subjectivity of the outcome measures combined with unblinded assessments may have affected the results. Furthermore, although the sensitivity analysis results indicated the robustness of the estimated outcomes, significant heterogeneity was still observed that was difficult to explain through subgroup analysis. First, differences in the methodological quality of the included studies, particularly inconsistencies in randomization and blinding, may have contributed to the variability in the results. Second, differences in sample characteristics, such as age, gender, and disease severity, could also be an important source of heterogeneity. Finally, different measurement tools and evaluation standards may lead to the same variable being recorded and assessed in various ways, thereby increasing the inconsistency of the results.

Our findings demonstrated a large effect of eHealth interventions on enhancing the quality of life among HD patients, consistent with a previous meta-analysis evaluating the impact of eHealth intervention on the quality of life of breast cancer patients [49]. Currently, the Internet, telephones, and mobile apps are essential components of people's daily lives, and they have laid a good foundation for the application of eHealth interventions in HD patients [29]. According to the biopsychosocial model, the individual health status is the consequence of the interaction of biological, psychological, and social factors [50]. The timeliness, rapidity, and accuracy of eHealth interventions enable HD patients to receive continuous care, based on which they can constantly monitor their physiological status and reduce complications [27,28]. Furthermore, through channels such as email and mobile apps, HD patients are able to receive psychological support from family and society as well as psychological counseling from health care professionals, thus enhancing mental health [46]. Finally, over the internet, social media, or apps, HD patients could seek help from health care professionals (health counseling, psychosocial support, and visit coordination), thus improving social adaptation [48]. These positive aspects of improvement in physical, psychological, and social factors ultimately boost the overall health of the patient and achieve an overarching quality of life [37,41]. However, the estimated effect size of eHealth interventions on quality of life exhibited substantial heterogeneity. When the study by Zhao et al [45] was excluded, a significant reduction in the overall effect size was observed, with I^2 decreasing from 93.87% to 79.9%. This suggests that a substantial impact was made on the overall result of this study, which may have been a significant

XSL•FO
RenderX

source of the detected heterogeneity. The potential overestimation of the intervention effect in the study of Zhao et al [45] may be attributed to the lack of rigorous randomization and blinding procedures. Therefore, the effectiveness of eHealth interventions on the quality of life of HD patients should be carefully considered. In addition, it is noteworthy that the subgroup analyses indicated that a long-term and single form of eHealth intervention appeared to be more efficacy in enhancing HD patients' quality of life. This could be because HD patients improve their disease management knowledge and skills over time as the intervention progresses, which helps in effectively preventing and reducing complications. However, if the intervention is overly complex and time-consuming, such as involving multiple eHealth technologies that require extensive eHealth literacy, it may lead to poor patient adherence and potentially increase the overall burden on the patient [49]. Therefore, when implementing eHealth interventions for HD patients, careful consideration should be given to optimizing the duration and format of the intervention to avoid placing unnecessary burdens on patients.

In line with findings on quality of life, our findings demonstrated that eHealth interventions exerted a favorable effect on treatment adherence among HD patients. Treatment adherence among HD patients primarily encompasses dialysis schedule, prescribed session time, medication regimens, and dietary restrictions (namely salt and water intake) [14,47]. In recent years, eHealth interventions have emerged as an effective approach for assessing, monitoring, and managing self-care activities in HD patients [51,52]. The Health Belief Model holds that an individual's health behaviors depend on his or her perception of the threat of disease and assessment of the benefits of and barriers to behavioral modification [53]. Through the vehicle of eHealth technology (mobile health apps and remote monitoring), HD patients can maintain closer contact with health care professionals, facilitating access to personalized health information and reminders, thus increasing awareness of the severity of the disease and the imperative for treatment [17,20]. In addition, eHealth platforms make it possible to systematically collect health data from HD patients, and with real-time feedback and visualization of data (eg, dialysis outcomes and lab metrics), it is easier for patients to perceive the benefits of their treatment, thus increasing their insights into treatment adherence [48]. In subgroup analyses, short-term eHealth interventions seem to be more effective in enhancing treatment adherence among HD patients. Furthermore, no statistically significant difference was observed in the impact on treatment adherence among HD patients, regardless of whether they received a single form of eHealth intervention or a combination of multiple forms. This underscores the ongoing need to further investigate the optimal timing and format of eHealth interventions to enhance treatment adherence among HD patients in the future.

Due to the severe burden of the disease, HD patients generally exhibit high levels of anxiety [54]. Although routine nursing interventions may temporarily reduce anxiety, their effectiveness commonly declines over time due to a lack of continuity, leading to decreased compliance and affecting patients' quality of life [55]. This review identified a significant impact of eHealth interventions in alleviating anxiety among HD patients. This finding might be explained through self-efficacy theory. Self-efficacy refers to the individual's belief in his or her ability to successfully perform the necessary behaviors to achieve a desired outcome [56]. Monitoring, reminding and feedback were the most common eHealth intervention components in the included studies, and these features provide HD patients with the tools and resources to actively manage their disease. When patients perceive tangible gains in their health status, their self-efficacy increases, resulting in a reduction in anxiety associated with disease management [46]. Subgroup analyses indicated that anxiety reductions were more pronounced when patients received eHealth interventions for over 3 months, compared with shorter-term interventions. In addition, a single form of eHealth intervention showed statistically significant effects in reducing anxiety among HD patients, whereas the impact of combined interventions was not significant. However, the effectiveness of eHealth interventions in alleviating anxiety among HD patients requires further validation through more rigorous clinical trials, given the limited number of studies using combined intervention formats, the heterogeneity of interventions, and the moderate quality of the current evidence.

Similar to the pooled results of anxiety, our findings suggested that eHealth interventions had a significant efficacy in decreasing depression among HD patients. Consistent with our findings, a previous study reported that providing psychological counseling services, along with sharing health knowledge and communication skills through a WeChat chatbot, can effectively alleviate depression in HD patients [45]. However, another study found no statistically significant effect of web-based problem-solving therapy on depression levels among HD patients [28]. This inconsistency may be explained by variations in the duration and format of eHealth interventions across different studies. According to the Stress and Coping Theory, equipping patients with effective coping strategies, such as emotional support and problem-solving skills, to help them manage stress could reduce the psychological burden associated with chronic illness [57]. In the included studies, psychological counseling was frequently a crucial element of eHealth intervention, and with the online platform, health care professionals were able to support patients in venting their negative emotions promptly, thereby reducing depression levels. The subgroup analyses revealed that reductions in depressive symptoms were more pronounced when participants received eHealth interventions lasting longer than 3 months or delivered in a single format. The prevalence of depression in HD patients has been estimated at 56.8% [58], which highlights the urgency of targeted interventions. As a chronic mental condition, depression typically requires sustained and consistent interventions to achieve significant improvements [59]. eHealth interventions shorter than 3 months may be insufficient for alleviating depression in HD patients, and combined interventions may present challenges in implementation. Therefore, extending the duration and increasing the frequency of interventions are recommended in future studies to facilitate the demission of depression.
