Our DCE included three attributes (A) with three levels (L) and two attributes with four levels, which, following the formula L^A would have led to 432 possible choice alternatives in a full factorial design [28]. To limit participant burden, we used a fractional factorial design. We generated 48 choice tasks applying Bayesian D-efficient design principles using Ngene software (ChoiceMetrics) [29] and blocked them into four survey versions each containing 12 choice tasks (Multimedia Appendix 2). The choice tasks in each block and the order of the attributes were fixed. Each participant was randomized to complete one survey. An additional repeat choice task was added to test choice consistency which was excluded from the primary data analysis. This means one task was repeated which allowed us to examine the percentage of people who consistently chose the same alternative This design aimed to estimate the main effects and assumes no interaction between attributes in the design.

The initial version of the DCE was piloted web-based with 49 participants. During the pilot phase, the understanding of the tasks was explored, and feedback on the wording of the attributes was sought. Based on the feedback received, the wording of the survey and the order in which attributes were listed in the table were revised. Coefficients from the pilot phase were used as priors to estimate a Bayesian D-efficient design. Data from the pilot phase were not included in the final analysis.

To imitate real-world decisions regarding app uptake, an opt-out option was included ("Neither of these two"; Figure 1). Participants who chose the opt-out option were prompted to repeat the decision and make a forced choice between the two alternatives. As the rate of the opt-out was low, the complete dataset was used for the analysis of choice data, including the opt-out option.

Data Collection

Participants and Recruitment

This study was conducted digitally. Eligible participants were adults (1) aged 18 years and older, (2) residents in the United Kingdom, (3) able to give consent, (4) owned or had primary use of a smartphone, (5) smoked cigarettes, and (6) interested in quitting smoking using a smartphone app. Recruitment took place between December 2020 and February 2021, through social media, the "Call for Participants" platform, and the Prolific platform. Recruitment posts were shared on Facebook, Twitter, and LinkedIn to reach potential participants. This study was advertised on the "Call for Participants" platform as well. Participants recruited through these channels accessed a link to the survey in Qualtrics (Qualtrics International Inc) that included a screening questionnaire to determine eligibility. Those who met the criteria were able to complete the survey.

Prolific is a crowdsourcing platform that connects researchers with individuals willing to participate in studies. Prolific enabled efficient and targeted recruitment without the need for advertising. Since Prolific screened participants based on specified criteria, eligible individuals were redirected to a second version of the Qualtrics survey that contained only the survey questions, without the additional screening.

Sample Size

The sample size calculation was based on a rule-of-thumb formula (equation 2) [30].

$$N>500c/(t\times a) \quad \textbf{(2)}$$

In equation 2, "N" represents the sample size, *t* the number of tasks per participant (=12), "*a*" the number of alternatives in each choice task (=2), "*c*" the number of analysis cells (=4, as this is the largest number of levels for any of the attributes). Equation 2 suggests a minimum sample size of 83. With four versions of the survey, we targeted a sample size of at least 332 (4×83) participants.

Procedure

The survey was administered using Qualtrics survey software. Once consent was obtained participants were explained the DCE and were randomly assigned to one of the four DCE versions containing 13 choice tasks (12 from the design plus one repeat choice task) and were asked to complete further measures (see *measures*).

Measures

Attributes That Are Likely to Influence Smoking Cessation App Preferences

The primary outcomes are the marginal effects estimated for each attribute level in the choice model, represented by the β coefficients in equation 1.

Factors Perceived to Influence Uptake and Engagement With the Smoking Cessation App

We used the TDF to identify 13 potential facilitators and barriers to uptake and engagement with health apps based on factors identified as important in our previous work [7,10]. These were included in the survey as a set of statements with the level of agreement with the statements measured using a 5-point Likert-type scale. For analysis, responses to these statements were dichotomized into agree (strongly agree and agree) versus not (neither agree nor disagree, disagree, and strongly disagree; Multimedia Appendix 2).

Other Variables

The survey included questions about the previous use of smoking cessation apps and other health apps, user type (power user or minimal user) based on preferences exploring app features (ie, whether individuals use basic features and spend the minimum amount of time navigating the app [minimal users] versus those who would enjoy spending time navigating through features and engaging with the app regularly [power users]). Smoking behavior measures were heaviness of smoking index [31], frequency of smoking, attempts to stop smoking, strategies used in an attempt to quit smoking, intention to stop smoking, defined as whether the participant is planning to quit in the next 6 months, determination to stop smoking, and the main reason for stopping smoking. Sociodemographic characteristics were also measured (age, gender, level of education, household income, ethnicity, sexuality, and disability). See Multimedia Appendix 2 for the complete questionnaire.

Statistical Analysis

The pilot data were analyzed using the Apollo package in R (R Core Team; programming language developed by the R Foundation for Statistical Computing) [32], and the final data using Stata (version 16.1; StataCorp LLC). Participants' characteristics and the TDF factors perceived to influence the engagement with smoking cessation apps were summarized using descriptive statistics. Associations between attributes and uptake responses were estimated using a mixed logit model (MIXL). This approach accommodated the existence of preference heterogeneity within the sample by allowing one or more model parameters to be specified as having a random distribution [33]. In the model, all attributes were dummy-coded as categorical variables, except for cost, which was treated as continuous after verifying a linear relationship with utility, and all were treated as normally distributed random parameters. The model allowed for correlation between parameters. We analyzed data of participants who completed the full survey. The model was fit using 2000 Halton draws. We investigated the uptake of the most preferred and least preferred apps by calculating their utility values and the probabilities for selecting these hypothetical apps, using the approach described by Jonker et al [34]. To facilitate willingness to pay (WTP) estimation, the same model was used but specified cost as a fixed parameter. We analyzed the choice data of participants who were consistent with the repeat choice task and compared it to the results of the choice data including all participants. As part of a post hoc analysis poolability of the two different samples (incentivized Prolific sample; nonincentivized "other" sample), was assessed following the Swait and Louviere [35] procedure. The TDF factors perceived to influence the engagement with smoking cessation apps were described using proportions and 95% CIs.

Ethical Considerations

Ethical approval for this study was obtained from the University of East Anglia Faculty of Health Ethics Committee (reference: 2020/21-017). This approval covered all aspects of participant recruitment, data collection, and analysis. The study protocol was preregistered on the Open Science Framework [36]. Participants recruited on Prolific were paid US $1.90 (UK £1.50) for participation and those recruited on other platforms were invited to participate in a prize draw to win one of ten US $25.36 (UK £20) shopping vouchers. Participants provided informed consent before beginning the survey. Consent was obtained through Qualtrics survey software from participants who met the eligibility criteria, where participants were presented with an information sheet and consent form prior to accessing the DCE and additional questions. Participant data were anonymized to protect privacy. No identifiable information was collected, and all data were stored securely in accordance with institutional data protection policies. Responses were deidentified before analysis to ensure confidentiality.

Results

A total of 499 eligible participants were recruited, 469 participants consented, and 337 participants completed the experiment and measures. Out of these 337 participants, 196 participants were recruited through the Prolific website, and the rest through social media and through the Call for Participants website. Data from 337 participants yielded 4029 observations (15 choices were omitted by participants). Participants were aged between 19 and 65 years, with a mean age of 35 (SD 11) years, 168 (49.8%) were female participants, 176 (52.2%) participants showed low dependency on the heaviness of smoking index, and 107 (31.8%) participants had used smoking cessation apps before. Participants' characteristics are reported in Table 2.

[a]DCE: discrete choice experiment.

[b]GSCE: General Certificate of Secondary Education.

[c]LGBTQ+: lesbian, gay, bisexual, transgender, and queer or questioning.

[d]Questions answered by those who have used smoking cessation or health apps before.

[e]Computed from number of cigarettes smoked a day and the time the first cigarette is smoked in the morning [31].

On 89.9% of the choices, participants selected one of the two smoking cessation apps over "neither." There was no participant who opted out of all choices. Most of the attributes influenced participants' preferences, except for the description of the app (Table 3). Relative to other attributes and given the levels included in the DCE, social proof (the star rating of the app) was the most important attribute. Relative to the referent app (developed by Mhealth Essentials, star rating not shown, generic app description, with a logo shown only), having a 4.8-star rating (mean preference parameter 2.27, SD 1.55; 95% CI 1.95-2.59) was around twice as important as the 4-star rating (mean preference parameter 1.06, SD 1.32; 95% CI 0.78-1.34), and twice as important as having a credible source (it being developed by the NHS Digital, mean preference parameter 0.93, SD 1.23; 95% CI 0.72-1.15). Participants marginally preferred an app that showed screenshots (mean preference parameter 0.35, SD 0.50; 95% CI 0.19-0.52) or both screenshot and logo (mean preference parameter 0.39, SD 0.96; 95% CI 0.19-0.59) over logo only. An app with a low monthly price was also preferred (mean preference parameter –0.38, SD 0.33; 95% CI –0.44 to –0.32). However, the wide SDs, relative to their coefficients for many attributes indicate a broad variation in attribute importance among participants. There was significant preference heterogeneity across all attribute levels.

The characteristics of the most preferred app were having a monthly cost of US $0 (UK £0), a rating of 4.8 stars, developed by NHS Digital, having a generic description, and presenting both types of images (app logo and screenshots). The least preferred app has a monthly price of US $11.40 (UK £8.99), the developer is not shown, ratings of 3.2 stars, a long description, and shows the app logo only. The uptake level of the best app was estimated at 95%, and for the worst was estimated at 10%.

Table 4 reports marginal WTP estimates for improvement in the attributes of the app, relative to the reference category. Participants were willing to pay an additional US $6.96 (UK £5.49; 95% CI $6.15 [£4.85]-$7.75 [£6.11]) and US $3.58 (UK £2.82; 95% CI $2.89 [£2.28]-$4.26 [£3.36]) for app with 4.8- and 4-star ratings, respectively. Participants were willing to pay US $2.61 (UK £2.06; 95% CI $2.03 [£1.60]-$3.20 [£2.52]) for development by a trusted organization (NHS Digital) compared to Mhealth Essentials Ltd.

A total of 71 (21%) individuals were inconsistent with their choices. The demographics of this group were similar to those who were consistent with their choices. The results of the MIXL model with and without the individual's response who gave an inconsistent response to the repeat choice task returned comparable results (data not presented, available from author). However, in a post hoc analysis to investigate whether the preference parameters of the two sample groups were equal, strong evidence was found to reject this hypothesis (P<.001), indicating different choice preferences.

Participants indicated that the strongest facilitators that might promote their engagement with a smoking cessation app were user guidance of how to use the app (72.4% agreement, 95% CI 67.37%-76.93%), additional health information (75% agreement, 95% CI 70.16%-79.42%), and rewards (75.4% agreement, 95% CI 70.47%-79.69%; Table 5). Key barriers were concerns around data protection (66.8% agreement, 95% CI 61.54%-71.61%) cognitive load (47.5% agreement, 95% CI 42.16%-52.87%), reminders as triggers for cravings (40.7% agreement, 95% CI 35.51%-46%), and peer support (46.9% agreement, 95% CI 41.59%-52.25%).

Table 5. Percentage of potential factors influencing smokers' uptake and engagement with smoking cessation apps, as identified in a survey conducted among adult smokers in the United Kingdom[a].

	Percentage, %	95% CI
TDF[b] construct: Skills		
App literacy (facilitator): In general, I can easily use a newly installed app on my phone		
Agree	92.6	89.24-94.95
TDF construct: Knowledge		
App awareness (barrier): I was aware of the existence of smoking cessation apps prior to taking part in this study		
Agree	55.5	50.12-60.73
User guidance (facilitator): A guide of how to use features would help me use the app more often		
Agree	72.4	67.37-76.93
Health information (facilitator): Information in the app about how quitting smoking improves my health would make me use the app more often		
Agree	75	70.16-79.42
TDF construct: Memory, attention, decision processes		
Cognitive load (barrier) : In general, I don't want to use an app with features that would take some time to learn		
Agree	47.5	42.16-52.87
Reminders (facilitator): It would be important that an app to help me quit smoking sends personalised reminders to me		
Agree	68.3	63.07-73.02
Reminders (barrier): I wouldn't want to use an app that sent me reminders about quitting smoking in case it would trigger my cravings to smoke		
Agree	40.7	35.51-46
TDF construct: Social influence		
Peer-support (facilitator): Being connected with other app users would motivate me to stay on track with my intention to stop smoking		
Agree	65.6	60.32-70.48
Peer-support (barrier): Being connected with other app users would make me feel ashamed or disappointed if I started smoking again after quitting		
Agree	46.9	41.59-52.25
Professional support (facilitator): Being connected with online helpers (quit smoking advisors) within the app would make want to use the app more		
Agree	69.5	64.29-74.14
TDF construct: Beliefs about capabilities		
Self-confidence (facilitator): I am confident I could quit smoking by using an app		
Agree	50.7	45.4-56.07
TDF construct: Beliefs about consequences		
Data protection (barrier): I am concerned how my personal data is handled in apps		
Agree	66.8	61.54-71.61
TDF construct: Goals		
Goal setting and action planning: Receiving guidance of how to achieve goals is more important for me than just simply setting goals		
Agree	84.3	79.97-87.79
TDF construct: Social identity		
Social identity (barrier): When using a smoking cessation app, I don't want to feel that I am being treated like a patient		
Agree	61.4	56.1-66.49
TDF construct: Reinforcement		
Rewards (facilitator): Receiving badges or awards for achieving a set goal, would make me use the app more often

[a]Factors were derived using the theoretical domains framework and measured through participant responses collected between December 2020 and February 2021.

[b]TDF: theoretical domains framework.

Discussion

Main Findings

This study investigated five potential attributes each mapped to domains from the TDF, potentially relevant to the uptake of smoking cessation apps. Participants made choices between hypothetical app alternatives with predefined attributes: (1) monthly price (environmental resources), (2) developer credibility (social influence, as a credible source), (3) app rating (social influence, as social proof), (4) app description (beliefs about consequences), and (5) images (beliefs about consequences).

Participants preferred apps demonstrating strong social proof (high star ratings) and a credible source (trusted organizations as developers), along with a lower monthly cost. The description of the app shown to participants did not influence preferences.

Relative to other attributes, social proof (a high star rating) emerged as a particularly influential factor, consistent with findings from previous studies [7,17]. Familiarity with highly rated apps may contribute to this preference, as these apps are likely to appear at the top of search lists. However, not all high-quality evidence-based smoking cessation apps have high star ratings [16,18], which suggests that social proof may influence uptake more than evidence-based content.

The preference for credible sources, in this case, apps from trusted organizations, such as NHS Digital, aligns with existing evidence. Our findings are similar to a DCE that investigated the uptake of a COVID-19 tracing app in the United Kingdom where participants were more likely to adopt an NHS contact tracing app [37]. This reflects broader user concerns about reputable sources [38] and a preference for apps developed by experts over those from unknown or less reputable sources [39].

Interestingly, descriptions, however, did not seem to influence the uptake of a smoking cessation app. A plausible explanation is that this attribute may not have been described or presented in a way to capture the participants' attention. To avoid cognitive load, we provided brief, verbal definitions for generic, short, or long descriptions rather than examples. This presentation choice may have limited the salience of the app description attribute in this study, potentially impacting its relevance to participants.

Consistent with similar studies, our findings suggest that participants most preferred apps with no cost [10,40]. However, some individuals indicated a WTP for an app if it offers features aligned with their preferences, such as being developed by a credible source [7]. Preliminary estimates of marginal WTP suggest that users may accept a small fee if the app demonstrates strong social proof or is from a trusted organization, though these estimates should be interpreted with caution.

Only around half of our participants were aware of smoking cessation apps, indicating that further awareness efforts could help make these tools more accessible. In line with previous findings, access to health information and a user guide to using the app were viewed as factors that could improve engagement [7,10], particularly among participants with limited app literacy. Less than half of the participants reported they would not want to use an app with complex features. We previously found mixed views on reminders, with some believing they may negatively influence behavior change by triggering cravings [7,10]. In this study, we found that less than half of the participants reported reminders as barriers. Consistent with previous findings [7,10], potential users believed that peer and professional support could increase engagement [7,10], and fewer than half indicated that failure to quit would lead to disappointment. This shows the difficulty app developers may face when developing an app to suit most individuals' needs and the potential importance of guidance from organizations such as the UK National Institute of Health and Care on developing digital behavior change tools.

Overall, our findings suggest that social proof (star ratings) and credible source (apps developed by trusted organizations) may be more important for individuals than the price of the app. Additionally, we investigated additional factors related to engagement, mapped under the TDF. Together, these findings offer preliminary insights into user preferences that may be considered in app presentations on curated health app portals.

Implications

The findings of this study offer preliminary insights that may assist public health organizations in increasing the uptake of evidence or theory-informed smoking apps. They could also guide health app providers and curators of health app portals, such as the NHS Apps Library, in optimizing app presentation to better align with user preferences, potentially enhancing app uptake within curated health platforms.

App uptake was found to be driven primarily by price and social influence (app ratings), while presentation factors, such as the app's description and visual elements, were found to have a limited influence on choice, with a combined relative importance of under 8%. This relatively low level of importance ascribed to presentation may be partly due to the generic descriptions of these attributes used in the experiment, which may not have captured participants' attention or preferences fully.

While the information presented may help app curators prioritize specific information, such as cost and user ratings, when presenting apps, the scope of this study is limited to uptake drivers and does not extend to factors influencing ongoing user satisfaction or engagement.

The WTP estimates quantify the relative preference of smokers for the attributes in an accessible format. However, these values

XSL•FO
RenderX

should be interpreted with caution, as they represent initial estimates that require further validation before being applied more widely.

The integration of the TDF in this study aimed to provide a structured overview of attributes influencing app choice, building on previous research where the TDF was similarly applied. While these findings complement prior qualitative data [7,41] and systematic review [10], further research is warranted to establish a more comprehensive understanding of how individual app features impact social proof (user ratings), quality perceptions, and long-term engagement.

Limitations

Although the recruitment was designed to include a wide range of participants, the sampling strategy used is unlikely to have generated a representative sample of smokers. Some views may have been missed by recruiting exclusively digitally, including views of individuals experiencing homelessness, those living in deprived areas, and those living in areas without suitable internet coverage.

The design of this study investigated main effects only, therefore, possible interactions between attributes were not assessed. The sample size was inadequate to enable investigating stratifications of certain demographics. The DCE was piloted and refined based on feedback but the clarity and usability, ease of completion, or understanding of the DCE were not further assessed in the main study, for example, no think-aloud cognitive pilot interviews were conducted. While respondents were screened based on willingness to use an app to aid quitting, prompting participants to make a forced choice when they chose the opt-out option might have influenced their choice behavior. An example of this might be the avoidance of selecting the opt-out, in anticipation of the forced choice question, however, opt-out choices were evenly distributed across the 12 choices, indicating that this is not the case.

Prompting participants to make a forced choice when they chose the opt-out option might have influenced their choice behavior and in anticipation of the forced choice question, they may have chosen an alternative throughout the survey, which could be a reason for the small number of cases where the opt-out option was chosen Additionally, using a hypothetical company may have influenced smokers' preferences (in either positive or negative direction), compared to if a real company was used.

This study investigated the uptake of a smoking cessation app based on stated preferences, which may be different from the uptake of a smoking cessation app in real life. This study focused primarily on the uptake of smoking cessation apps and did not consider all previously identified uptake and engagement factors that may shape choice behavior (eg, the aesthetics of the app, reminders, social networking, and embedded health professional support [7,10]), which limits our conclusions about the relative importance of the factors studied. Additionally, this study included one attribute—user ratings—that indirectly reflected app quality and functionality. Future studies may benefit from including further attributes that indicate other quality parameters.

The specification of our model also introduces limitations. By specifying a normal distribution for cost in the main model, 12.5% of respondents are predicted to have positive price parameter. Behaviorally, this seems counterintuitive, however, some people may prefer a paid app over a free app (eg, because they associate cost with quality). Second, in order to facilitate a straightforward estimation of WTP, we specify cost as a fixed parameter. This is of course inconsistent with the results from the main model, which indicate significant heterogeneity with regards to preference for the cost of the app. This approach has the potential to severely bias WTP estimates, which should consequently be interpreted with caution.

The results on the poolability of the sample indicate that pooling of the 2 samples (those recruited from the incentivized Prolific site, and those recruited from elsewhere) was not appropriate, as there were substantial differences between how the independent variables influenced choice in each group. Despite highly similar demographic characteristics between the 2 groups, choice behavior may have been influenced by incentivization or other, unobserved differences between the 2 groups, biasing our results.

The relative importance of the attributes may vary between genders and age groups. Future DCEs may want to consider recruiting a larger sample size to investigate the relative importance of the attributes stratified based on sociodemographical factors. Knowing the preferences of certain groups with specific demographics may help to target the presentation of apps to increase uptake. To build on our limited conceptualization of the perceived utility of the app, future DCEs could borrow ideas from interaction design and user research studies and apply a visual representation of apps, instead of textual description. In this case, participants are shown images of apps as opposed to a table where logos are visually represented as opposed to described. Similarly, "app descriptions" could include typical feature content presented in different ways rather than abstractly reflecting different types of description (generic, short, or long). Finally, the impact of health apps is a combination of uptake and effectiveness. The measured factors influencing the uptake and engagement with smoking cessation apps suggest that more empirical studies, including testing in real-world situations, are needed to fully understand the extent of facilitators and barriers. There is very limited opportunity to investigate the external validity of this study, but it is hoped that as technology advances, opportunities will arise and test this research in real-life settings.

Conclusions

This study found that uptake is more likely if smoking cessation apps demonstrate strong social proof (high star ratings), are developed by a credible source (trusted organization), include screenshots, and are low cost. However, star ratings showed a relatively stronger influence on app selection compared to other attributes within the range of rating scores investigated.

Acknowledgments

The authors thank the patient and public involvement representatives and the University College London Alcohol and Tobacco group (UTARG) for their input on the conceptualization of the study. We also thank Prof Michiel Bliemer and Prof Stephane Hass for their input on the choice modeling in Ngene software and R using the Apollo package, respectively.

Data Availability

The dataset generated during this study is available on Open Science Framework [36].

Authors' Contributions

DS, FN, AJ, JAW, JB, and TC conceptualized the study design. DS wrote the study protocol with contributions from FN, AJ, JAW, JB, and TC. DS preregistered the study on OSF. DS generated the choice tasks with support from JAW. DS conducted the data collection and data investigation. DS undertook the data curation. DS analyzed the data with statistical support from RC. RC accessed and verified the underlying data. DS drafted the original manuscript, which was edited by critical review by FN, AJ, RC, JAW, JB, and TC. All authors read and approved the final version of the manuscript.

Conflicts of Interest

FN is an unpaid member of the scientific committee of the Smoke Free app, which is unrelated to this article.

Abstract

Background: A greater understanding of the effectiveness of digital self-management programs and their ability to support longer-term weight loss is needed.

Objective: This study aimed to explore the total weight loss and patterns of weight loss of CSIRO (Commonwealth Scientific and Industrial Research Organisation) Total Wellbeing Diet Online members during their first 12 months of membership and examine the patterns of platform use associated with greater weight loss.

Methods: Participants were Australian adults who joined the program between October 2014 and June 2022 and were classified as longer-term members, meaning they completed at least 12 weeks of the program, had baseline and 12-week weight data, and had a paid membership of ≥1 year (N=24,035). Weight loss and percentage of starting body weight loss were calculated at 3, 6, 9, and 12 months using 3 statistical approaches: (1) multiple imputations method, (2) all available data, and (3) complete data only. Among members with complete data (6602/24,035, 27.5%), patterns of weight loss and gain were examined, and how this related to total weight loss and platform use was explored.

Results: Members were mostly female (19,972/24,035, 83.09%), aged 31 to 50 years (9986/24,035, 41.5%) or 51 to 70 years (12,033/24,035, 50.06%), and most members were classified as overweight or obese (23,050/24,035, 95.9%). Using multiple imputations, the average estimated weight loss was 5.9 (SE 0.0245) kg at 12 weeks, 6.7 (SE 0.0348) kg at 6 months, 6.2 (SE 0.0400) kg at 9 months, and 5.5 (SE 0.0421) kg at 12 months. At 12 months, more than half the members (12,573/24,035, 52.3%) were at least 5% below their starting body weight and 1 in 4 (5865/24,035, 24.4%) were at least 10% below their starting body weight. In the subsample with complete data, the average weight loss at 12 months was 7.8 kg. The most common (961/6602, 14.56% members) weight loss pattern over the first 12 months was 6 months of weight loss, followed by 6 months of weight maintenance. This group had an average weight loss of 10.6 kg at 12 months (11.9% of their starting body weight). In a subgroup of participants who consistently lost weight over the 12-month period (284/6602, 4.3% of the sample), weight loss reached up to 22.3 kg (21.7% of their starting body weight). Weekly platform use was positively associated with total weight loss (r=0.287; P<.001). Members who used the platform >30 times per week (approximately >4 times/d) were more likely to lose weight in the first 6 months of the program.

Conclusions: This commercial weight loss program was shown to be effective, with 1 in 2 members achieving clinically significant results after 1 year. Greater engagement with the platform was associated with consecutive periods of weight loss and greater weight loss success overall.

Introduction

Background

Obesity is a global public health challenge that has substantial individual, societal, and economic impacts. It is predicted that, if the current trends continue, the majority (51%) of the global population will be living with either overweight or obesity by 2035, and 1 in 4 people will be classified as obese [1]. High-income countries tend to have the highest rates of obesity. For example, in Australia, 66% of the adult population is classified as overweight or obese, with approximately 1 in 3 individuals classified as obese [2]. The economic impacts of overweight and obesity are expected to reach 3% of the global Gross Domestic Product by 2035 [1]. The costs to the Australian economy attributable to overweight and obesity were estimated to be Aus $11.8 billion (US $7.4 billion) in 2017 to 2018 [3], and without significant action, these costs may rise to an estimated Aus $87.7 billion (US $54.9 billion) by 2032 [4]. In response to the impacts of obesity, the World Health Organization has set a global target to stop the increases in rates of overweight and obesity, and there have been calls to develop national strategies to address obesity. In line with this, the National Obesity Strategy for Australia aims to "halt the rise and reverse the trend in the prevalence of obesity in adults by 2030" [5]. The strategy acknowledges that achieving this ambitious goal will require coordinated efforts, and if successful, it will significantly enhance the population's quality of life.

Commercial Weight Loss Programs

Among the range of approaches to address obesity, improving dietary intake and increasing physical activity are considered useful lifestyle strategies for losing weight. Reviews of commercial weight loss programs have been primarily based on randomized controlled trials and suggest that individuals who complete these programs can achieve significant weight loss in the short term [6]. However, longer-term weight loss, and weight maintenance after weight loss, is challenging [6-8]. The literature, including randomized controlled trials [9] and studies on real-world commercial programs [10,11], commonly reports a pattern of short-term weight loss (at 3 and 6 months) followed by some degree of weight regain by 12 months and beyond.

Longitudinal and longer-term studies need to manage missing data. Randomized controlled trials often use statistical techniques, such as intention-to-treat analysis, to use data from all participants regardless of their adherence or completion of the program. However, a common limitation of real-world type studies that have evaluated the longitudinal effect of weight loss programs is that they often report results from a small proportion of the enrolled participants [12,13]. Therefore, findings are more likely to represent the results of a highly motivated subsample and less likely to represent the expected weight loss for an average participant or be applicable to the broader population. In fact, reported dropout rates for weight loss programs range from 10% to 80% at 12 months [14], often due to reasons associated with lack of, or less than, desirable weight loss [15]. Data from participants included in follow-up analyses would suggest that longer-term weight loss success is a real challenge. Approximately 80% of weight lost is regained within 5 years [16], and only 1 in 5 people are successful in achieving longer-term weight loss [17].

Studies of weight loss maintainers report some common behavioral strategies associated with longer-term success. Frequent self-monitoring of body weight and food intake, high levels of physical activity, and following a low-fat diet were shared behaviors among successful longer-term weight loss maintainers in the National Weight Control Registry [17-19]. Portion control, habitual healthy snack choice, and program engagement have also been shown to be positively associated with weight loss maintenance among individuals enrolled in a digital commercial program [16].

Purpose of This Study

The Commonwealth Scientific and Industrial Research Organisation (CSIRO) and Digital Wellness have partnered to deliver a commercial, digital version of the CSIRO Total Wellbeing Diet. CSIRO is Australia's national science agency and Digital Wellness is an Australian digital health solutions company. The CSIRO Total Wellbeing Diet is a weight loss program that has evolved from clinical trials [20-22] to a popular series of books [23] and now a digital platform [24]. The program includes personalized eating plans, customized weekly meal plans, food and exercise diaries, the ability to record and see progress of weight loss, a member forum, and supportive correspondence via email. The CSIRO Total Wellbeing Diet Online program launched in 2014. The results of members who joined the program in the first 5 years have been published previously [24]. In a sample of >60,000 members who joined between 2014 and 2019, the average weight loss of all members was 2.8 kg (3.1% of their starting body weight), and for those who finished the 12-week program, the average weight loss was 4.9 kg (5.3% of their starting body weight). This study focused on longer-term weight loss and therefore used data from members who had joined the program between 2014 and 2022 and who had been members for at least a year. The analysis explored the total weight loss and patterns of weight loss of members during the first 12 months of membership and examined whether the patterns of platform use were associated with greater longer-term weight loss.

Methods

Study Design and Participants

Participants of this secondary analysis included all adults who joined the CSIRO Total Wellbeing Diet Online and had data in the platform between October 2014 and June 2022 (n=155,075 people referred to as members). In the registration process, individuals who were aged <18 years or had a BMI that placed them in the underweight category (BMI <18.5 kg/m^2) were automatically excluded. Participants excluded from this analysis were pseudo-members (ie, platform testers and affiliated staff), individuals whose membership was paid for by their employer because their motivations for weight loss might have been different from those who paid for their own membership, or people living outside of Australia because the context in which they were following the program might be different. Members

XSL•FO
RenderX

missing a starting weight as part of the setup process were removed because the primary outcome of weight loss could not be calculated (2172/155,075, 1.4%), and an additional 8 participants were removed because their recorded weight value was deemed invalid or unreliable using cutoff values of <13 kg or >250 kg.

This analysis focused on weight loss among longer-term members, defined as individuals who had completed at least 12 weeks of the program, had weight data recorded at baseline and approximately 12 weeks (61,514/152,895, 40.23%), and maintained a paid membership for about a year or longer. This left a sample of 24,035 longer-term members to examine the longer-term weight loss results of members on the CSIRO Total Wellbeing Diet Online program. To examine the patterns of weight loss over the first 12 months of membership, complete weigh-in data were required for the 4 time points of interest (12 weeks, 6 months, 9 months, and 12 months). There was a subsample 6602 members with complete weigh-in data used for the analysis of weight loss patterns.

Intervention

A detailed description of the program has been published previously [24]. Briefly, the CSIRO Total Wellbeing Diet Online is a commercial weight loss program managed by Digital Wellness and is available to individuals at a cost of Aus $199 (US $123) for the first 12 weeks and up to Aus $449 (US $278) for 12 months. The diet is a higher-protein, lower–glycemic index dietary pattern, with meal plans consisting of 3 meals and up to 2 snacks each day. The program contains a food group system where portions of food are presented as standard units for each food group. There are 7 food groups: fruit, vegetables, meat and alternatives, breads and cereals, dairy, healthy fats and oils, and indulgences. Meals are designed around a template of standard units, which ensures daily allowances of food groups are met and provides optimal nutrition and energy to promote weight loss. The weight loss program is promoted via media and digital channels, and the Australian public can join the program of their own volition. The user registration process collects information on year of birth, sex, physical activity levels, and weight loss goals to tailor eating plans. A food group unit system allows standard menu templates to be customized by swapping meals using the recipe database.

The platform is a fully responsive web application with an interface that is optimized for viewing on a desktop and mobile devices. The program content provides general information and advice, and weekly tutorials. Self-monitoring and goal setting are key behavior change techniques used within the program. A weight loss goal is provided during the onboarding process. The food diary can be used to log meals and snacks, either by entering prepopulated recipes from the meal plan or by entering individual foods from a comprehensive food database. The food search function allows members to search a database to view information about their composition. The food tracker allows food units and total energy consumed over the day to be logged and reviewed, with graphical feedback provided comparing intake to daily food unit targets. A large database of recipes is available within the platform, and members can swap recipes in and out of the menu plan to suit their taste preferences, time, and cooking skills. Members receive weekly emails on their nominated weigh-in day to remind them to weigh themselves and record their weight into the weight tracker. Progress data are presented in a graph and table form. Members are encouraged to engage with the platform regularly, with recommendations provided to weigh in weekly, use the self-monitoring tools daily, and view program tutorials. The platform also has a forum for members to share their stories or discuss relevant issues with other members. Seasonal content is shared with members, and the program content is reviewed and updated periodically. The platform functionality is updated with a focus on enhancing the user experience and engagement.

Data Collection and Study Outcomes

Digital Wellness manages the collection and storage of data from the program. Information collected at the time of joining included date of birth; sex; ethnicity; postcode; as well as body measurements such as height, weight, and waist circumference. Other data collected included program details such as paid membership duration and platform use data including entries into the food diary, views of the menu plans, views of exercise plans, views of program content information, forum visits, searches of the food database, and weight entries. These data were provided to the research team in a deidentified format, with each individual member assigned a unique identifier. Weigh-in data were provided for each member weekly from weeks 1 to 13 and then in 3-month blocks thereafter until membership ceased. The last recorded weight was provided within each 3-month block. Platform use data (number of weigh-ins, food diary entries, menu plan views, exercise plan views, program content views, forum views, food search views, and total platform activity) were provided at similar time intervals.

The primary outcome was weight loss, calculated as the difference in kilograms between weight on joining (baseline) and the 4 time points of interest, with a larger number representing greater weight loss. Weight loss was also calculated as a percentage of starting body weight and was categorized into 4 groups: weight gain, weight loss of >0% and <5% of starting body weight, 5% to <10% of starting body weight, and ≥10% of starting body weight lost.

Ethical Considerations

Ethics approval to conduct this research was received from CSIRO Health and Medical Human Research Ethics Committee (2022_055_LR). As part of registration, participants agreed to their data being shared with CSIRO and used for research purposes; therefore, no direct participant consent was sought. All data were provided to the research team in a deidentified format, and individuals could not be reidentified by the research team. Participants did not receive compensation.

Statistical Analysis

Overview

Statistical analyses were performed using the SPSS statistical software package (version 29; IBM Corp). Descriptive analysis was conducted to describe the characteristics of program members. The average weight loss of members was calculated

XSL•FO
RenderX

in three ways: (1) using multiple imputations as a method to replace missing data (24,035/24,035, 100%); (2) using the available weight data (ranged from 18,032/24,035, 75.02% at 3 months to 9413/24,035, 39.16% at 12 months); and (3) using only members with complete data at all time points (6602/24,035, 27.47%).

Weight loss in kilograms and as a percentage of starting body weight were calculated. Weight loss was calculated at each of the time points of interest and by subgroups, including by sex, age group, starting weight status category (normal weight, overweight, or obese [obesity class 1, 2, and 3]), state of residence, quintiles of Socio-Economic Indexes for Areas, and duration of paid membership. Total platform use was aggregated and divided by weeks of membership to estimate an average weekly platform use for each member. The association between platform use and weight loss was assessed using Pearson correlation coefficient, where a positive value indicates a positive association between use and weight loss.

Primary Analysis

Weigh-in data were needed to calculate weight loss. The amount of missing weigh-in data increased over time. At 12 weeks, 25% of weigh-in values were missing; at 6 months, 29% were missing; at 9 months, 50% were missing; and at 1 year, 61% were missing. To explore the effect of missing weigh-in data on weight loss estimates, analyses were conducted on the raw data (missing data ignored) before applying the multiple imputations method. The monotone multiple imputation model was used, which included weight loss at each time point, age group, sex, state, starting weight, starting BMI, and Socio-Economic Indexes for Areas quintiles. A total of 20 imputation datasets were created. The model assumed missing data were missing not completely at random. Results presented are the average of separate, identical analyses performed on each of the 20 complete imputation datasets, with appropriate adjustment of SEs to incorporate the added variability from the imputation process.

Sensitivity Analysis

Weight loss was also calculated using the available weigh-in data in the system. The amount of weigh-in data ranged from 75.02% (18,032/24,035) at 3 months to 39.16% (9413/24,035) at 12 months. Weight loss was also calculated using only members with complete weight data at all time points (6602/24,035, 27.47%). Weight loss patterns in four 3-month blocks over 12 months were examined and recorded as a sequence. Weight loss during each 3-month period was categorized as weight loss (L), weight gain (G), or weight maintenance (M). Consistent with previous research [25], a change in weight within 1.4 kg of previous weight was considered weight maintenance, and anything greater was considered weight loss or weight gain. For example, if a member lost weight from baseline to week 12 and also lost weight in months 3 to 6, 6 to 9, and 9 to 12, then the weight loss pattern was labelled as L|L|L|L to indicate 4 consecutive periods of weight loss. Alternatively, if a period of weight loss was followed by a period of maintenance and then 6 months of gradual weight gain, the pattern was labelled as L|M|G|G. Total weight loss over 12 months and average weekly platform use were examined by the pattern of weight loss.

Results

Characteristics of Members

Longer-term members (24,035/61,514, 39.07%) had an average of 600 days of paid membership (Table 1). The average starting weight was 92.6 kg, and the average BMI was 33.1 kg/m^2 on commencement of the program. Most members were female (19,972/24,035, 83.09%) and aged between 31 and 50 years (9986/24,035, 41.5%) or 51 to 70 years (12,033/24,035, 50.06%). Nearly all the longer-term members were classified as overweight or obese (23,050/24,035, 95.9%), with 64.68% (15,546/24,035) classified as obese. Approximately one-third of the longer-term members (8291/24,035, 34.49%) were in the highest quintile of socioeconomic status (ie, most advantaged), and similar to the general Australian population, three-quarters of the sample (18,094/24,035, 75.28%) lived in the eastern states of Australia (Victoria, New South Wales, and Queensland).

RenderX

Longer-term members with complete data (6602/24,035, 27.47%) were slightly older than the longer-term members generally (54 vs 52 years), with 61.89% (4086/6602) of the members with complete data aged >51 years compared to 53% (12,738/24,035) of all longer-term members. However, their starting weight and BMI were similar, and the proportion classified as obese was also similar (4366/6602, 66.13% vs 15,546/24,035, 64.68%) to longer-term members generally (Table 1).

Compared to all members of the CSIRO Total Wellbeing Diet, longer-term members were, on average, 1.5 kg heavier at the start of the program and had a slightly higher BMI (33.1 vs 32.4 kg/m^2). The percentage of longer-term members classified as obese was 64.68% (15,546/24,035) compared to 60.35% (37,123/61,514) for all members (Table 1).

Weight Loss Over 12 Months

Using multiple imputations, the average weight loss of the longer-term members (24,035/24,035, 100%) was estimated as 5.9 kg (or 6.3%) at 12 weeks, 6.7 kg (or 7.2%) at 6 months, 6.2 kg (or 6.6%) at 9 months, and 5.5 kg (or 5.9%) at 12 months. Weight loss for male members was estimated to be 7.0 kg at 12 months compared to 5.2 kg for female members. At 12 months, 57.71% (2345/4063) of male members had lost ≥5% of their starting body weight compared to 51.21% (10,228/19,972) of female members, and 26.43% (1074/4063) of males and 23.99% (4791/19,972) of females had lost 10% of their starting body weight. Overall, it was estimated that 52.31% (12,573/24,035) and 24.4% (5865/24,035) of the members had lost 5% and 10% of their starting body weight, respectively (Table 2).

As a sensitivity analysis, the average weight loss was calculated using the weigh-in data available. The average weight loss of longer-term members was calculated to be 6.4 kg (or 6.8% of starting body weight) at 12 weeks, 7.1 kg (or 7.6%) at 6 months, 7.0 kg (or 7.4%) at 9 months, and 6.3 kg (or 6.7%) at 12 months (Table 3). At 12 months, male members lost an average of 7.7 kg (or 7.1%) and female members lost an average of 6 kg (or 6.6%). At 12 months, just more than half the members (5055/9413, 53.78%) had lost ≥5% of their starting body weight and slightly more than 1 in 4 members (2595/9413, 27.57%) had lost ≥10% of their starting body weight. There were slightly more male members than female members who achieved a weight loss of ≥5% after 12 months (815/1409, 57.84% vs 4250/8004, 53.1%). At 12 months, 29.88% (421/1409) of the male members had lost ≥10% of their starting body weight, which was similar to female members (2174/8004, 27.16%; Table 3).

Weight loss among those members with a valid weight in the system at all time points (6602/24,035, 27.47%) was 6.8 kg (or 7.2%) at 12 weeks, 8.5 kg (or 9%) at 6 months, 8.4 kg (or 8.9%) at 9 months, and 7.8 kg (or 8.2%) at 12 months. Male members in this subgroup lost 9.1 kg (or 8.4%) at 12 months and female members lost 7.5 kg (or 8.2%; Table 3).

Approximately 2 in 3 members (4232/6602, 64.1%) in this subgroup had lost ≥5% of their starting body weight at 12 months, and 1 in 3 members (2342/6602, 35.47%) had lost ≥10% of their starting body weight at 12 months (Table 3).

Weight Loss Patterns Over 12 Months

Weight loss patterns were examined in 3-month blocks among members with a valid weight in the system at all time points (6602/24,035, 27.47%). The average weight loss of this group was 7.8 kg after 12 months of membership. The most common pattern of weight loss for these members over the first 12 months of membership was weight loss in the first two 3-month blocks (ie, first 6 months), followed by weight maintenance in the second two 3-month blocks of membership (ie, second 6 months). This pattern (L|L|M|M) was observed in 14.6% (961/6602) of the members, and this subgroup achieved an average weight loss of 10.7 kg at 12 weeks and 10.6 kg at 1 year (or 11.9% of their starting body weight; Table 4).

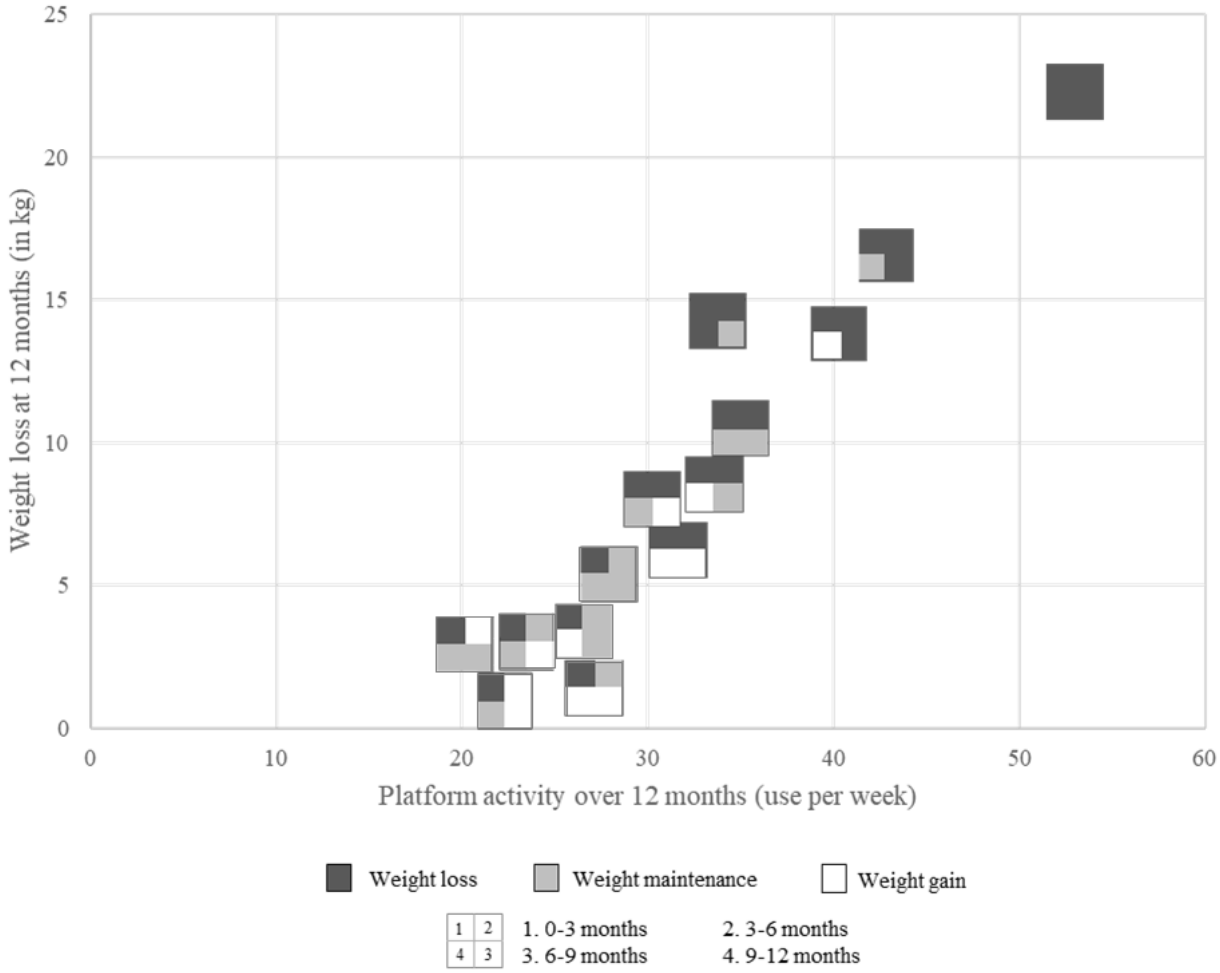
[a]Data are presented for weight loss sequence groups containing ≥2% of the total sample.

[b]Weight loss during each 3-month period was categorized as weight loss (L), weight gain (G), or weight maintenance (M). Consistent with previous research [25], a change in weight within 1.4 kg of previous weight was considered weight maintenance, and anything greater was considered weight loss or weight gain.



The second most common pattern was weight loss recorded in the first 3-month block and then maintenance for the remainder of the year. This group (L|M|M|M, 734/6602, 11.1% of this sample) lost an average of 5.1 kg in 12 weeks (5.7% of their starting body weight) and maintained this loss through to 1 year. The other common pattern was weight loss over the first three 3-month blocks, followed by weight maintenance (L|L|L|M, 590/6602, 8.94% of this sample). This group was heavier when they started the program than the more common L|L|M|M and L|M|M|M groups and lost 16.6 kg over 12 months, equivalent to 17.1% of their starting body weight. Although less common, those achieving weight loss in each 3-month block (L|L|L|L, 284/6602, 4.3% of this sample) were among the heaviest members at the start of the program, and they lost an average of 22.3 kg over 12 months, which was equivalent to 21.7% of their starting body weight (Table 4).

Platform Use by Weight Loss Pattern

There was a positive relationship between the average weekly platform use and weight loss over the first 12 months of membership, with higher weekly platform use associated with greater weight loss (r=0.287; P<.001). Table 3 shows the relationship between platform use, weight loss, and the pattern of weight loss. For example, weekly platform use in the group that consistently lost weight (L|L|L|L) was 24% to 56% higher at each time point throughout the year than other weight loss patterns where use and weight loss were lower. Figure 1 shows the platform use and weight loss at 12 months for each weight loss pattern. The quadrants of the box represent 3-month intervals, with darker colors indicating weight loss and lighter colors indicating weight gain. It was evident that when platform use exceeded ≥30 times per week approximately >4 times per day), the pattern of weight loss included loss for the first 6 months of the program, whereas the groups using the platform for <30 times week recorded a loss in the first 3 months, followed by a period of maintenance or gain (Figure 1). It is also evident that within clusters of weight loss patterns, for example, losing weight in 3 of the 4 blocks of time over 12 months, total weight loss was higher when use was higher (Figure 1).

Discussion

Principal Findings

This study examined the longer-term weight loss of members of a commercial weight loss program, the CSIRO Total Wellbeing Diet Online. In a large sample of 24,035 members who had approximately 12 months of paid membership, the average estimated weight loss was 5.9 kg at 12 weeks, 6.7 kg at 6 months, 6.2 kg at 9 months, and 5.5 kg at 12 months. At 12 months, it was estimated that more than half the members (12,573/24,035, 52.3%) remained at least 5% below their starting body weight and 1 in 4 (5865/24,035, 24.4%) were at least 10% below their starting body weight. A modest reduction in weight of 5% has been accepted as clinically meaningful [26], and 5% to 10% is a recommended goal for medically supervised weight loss, as outlined in guidelines for managing overweight and obesity [27,28]. On a smaller subset of members with complete weigh-in data at 3, 6, 9, and 12 months, 64.1% (4232/6602) and 35.5% (2342/6602) reached the recommendations of 5% and 10% body weight loss, respectively. The most common weight loss pattern on this program was 6 months of weight loss, followed by a 6-month period of weight maintenance, with this group achieving a total of 10.6 kg weight loss over 12 months. Although less common, when weight loss was achieved in each of the four 3-month blocks of time, the average weight loss over 12 months was 22.3 kg. Achieving higher weight loss was associated with higher platform use, specifically at a frequency of approximately ≥4 times per day.

Comparison to Other Literature

The health benefits of modest weight loss are well established. A 5% body weight loss is associated with improved systolic and diastolic blood pressure, glucose control, and cholesterol [29]. However, achieving this level of weight loss is difficult. A cohort study of >18 million health care–seeking Americans found that 1 in 10 adults achieved a 5% body weight loss [30]. Among successful individuals, approximately half report to do it on their own and the other half through a formal program [31]. The do-it-yourself approach can work, and when in a controlled trial (which likely overrepresents effectiveness), up to 1 in 4 people were reported to achieve 5% body weight loss after 12 months [32]. Commercial weight loss programs are an effective option for weight loss, and digital programs, in particular, might be more accessible. The weight loss results of this program compare favorably to similar commercial or digital weight loss programs. For example, an evaluation of another commercial weight loss program, *WW* (formerly known as *Weight Watchers*), reported an average weight loss of 3.8 kg at 3 months and 4.4 kg at 12 months, with 42.8% of participants achieving a loss of 5% body weight at 12 months [32], compared to 52.3% (12,573/24,035) for the CSIRO Total Wellbeing Diet

XSL•FO
RenderX

Online. This is one of the few examples of published weight loss results from a commercial weight loss program with a longer follow-up, although the sample size is smaller than the one presented here. Another example of an evaluation of a commercial program is a cross-country comparison of *Noom Coach*, which included 18,459 participants and reported weight losses across countries ranging from 3% to 3.7% of starting body weight loss at 16 weeks, with 27% to 33% (cross-country range) achieving 5% body weight loss [33]. Meanwhile, *MetaWell*, a digital weight loss program, reported comparable short-term (ie, 3 months) weight loss results to the CSIRO Total Wellbeing Diet Online (5.6 vs 5.9 kg for CSIRO Total Wellbeing Diet) in a larger sample of approximately 250,000 members [34]; however, no longer-term follow-up data have been reported yet. Key strengths of this study are the large sample from a commercial weight loss program, with longer-term follow-up and the use of multiple imputations to account for missing data in the estimation of weight loss. Without the use of statistical methods to account for missing data, which can be significant for self-recorded weight data in commercial platforms, the weight loss results are likely to be more favorable and, therefore, less generalizable in terms of expected weight loss outcomes.

The results of this study are consistent with other studies where a weight loss "tick" curve is commonly reported, meaning that initial weight loss success is followed by a plateau at or approximately 6 months and then some weight regain by 12 months [9]. Although the average weight loss difference at 6 and 12 months on this program was 1.2 kg, this would be considered weight maintenance according to the standard definition [25]. Different weight loss patterns are rarely explored beyond the short term [35]. In this study, weight loss patterns were examined in 3-month blocks of time over 12 months. The 3 most common patterns, accounting for one-third of members in this subgroup analysis, involved various combinations of weight loss and weight maintenance, without periods of weight gain. These findings contrast with another study on weight loss patterns from an internet-based weight management program [36], which involved daily weighing over a 1-year period. It found a shift from weight loss directly to weight gain, with weight regain starting much earlier, approximately 11 weeks, and not preceded by a weight maintenance period [36]. Half the sample in this study achieved weight loss in the first 6 months, and most often, this was followed by additional weight loss or maintenance. When weight loss was recorded for ≥3 periods throughout 12 months, the average weight loss was approximately 15 kg regardless of whether the other was a period of maintenance, loss, or gain. This is an important message for the public when embarking on a weight loss journey. Periods of weight gain and maintenance are common, and the trajectory of a longer-term journey will likely not be linear; however, meaningful overall weight loss can still be achieved with time.

There is compelling evidence that increased self-monitoring is associated with greater success in weight management [37]. How to best promote and sustain self-monitoring, as well as the necessary dose required, remain areas of investigation. A previous weight loss study that tracked self-monitoring in a digital system showed that there were no significant differences in time spent self-monitoring based on amount of weight loss at 6 months; however, there were differences in the number of times people logged in. Those who lost >5% of their starting body weight logged into the system approximately 2.5 times per day compared to 1.5 times per day for those who lost <5%, and log-ins were 2.7 times versus 1.7 times per day for those losing >10% compared to <10% of their starting body weight [38]. This supports the results of this study, where those with the highest platform use had a pattern of sustained weight loss and a greater total weight loss over 12 months. These users were interacting with the platform >30 times a week (or >4 times per day), which is higher, but given that the CSIRO Total Wellbeing Diet Online system allows for weight, diet, and exercise monitoring, it would be expected that daily interaction is more regular.

There are several challenges with sustained engagement with digital programs, notably attrition [39]. These are made more significant by growing evidence that sustained engagement may be more important than self-monitoring alone. In a study comparing degrees of weight loss [40], highly successful people were those who lost more weight initially and recorded continued weight loss over time, while less successful people lost smaller amounts of weight initially and then regained half that weight back over time. In the initial 6-month period of that study, there were no differences in the frequency of self-monitoring for moderately and highly successful people; however, longer-term self-monitoring remained high for those in the most successful group, recording significantly more self-monitoring entries than other groups. Together with our observations, this suggests that sustained self-monitoring may be more important for longer-term weight loss results. Self-monitoring in digital programs is typically measured by interactions with the system, which can also serve as a proxy for motivation. A small study in women showed a sustained increase in autonomous motivation at 5% weight loss but a decline for failing to reach this milestone [41]. It also suggested that motivation at week 4 predicted adherence to self-monitoring and weight loss. Thus, achieving clinically significant weight loss may increase motivation, which then improves self-monitoring.

It is clear that digital interventions need to leverage self-monitoring to support more successful weight management. System interactions are one indication of a person's motivation, emotions, and actions, and it is likely that greater appreciation of these personal factors will be needed to address use attrition. Supporting this, a recent review of 497 self-management randomized controlled trials for obesity found that information sharing, self-monitoring, and goal setting were frequently used techniques in interventions, but a broader scope is needed in interventions to consider social support, emotional management, and shared decision-making in obesity self-management interventions, which are all important outcomes for patients [42]. Interventions for obesity will also need to evolve to responsibly incorporate artificial intelligence to enhance the user experience and support more people in their weight loss journey. In behavioral interventions, artificial intelligence could analyze patterns in datasets to predict behavioral and clinical

XSL•FO
RenderX

outcomes early, allowing for more personalized content that enhances learning and motivation [43]. This approach could potentially improve weight loss outcomes for people living with obesity. The use of artificial intelligence might also enhance the user experience throughout the varying stages of weight management [44]. Early weight loss success provides motivation for continued efforts and later success, but a greater understanding of the "ups and downs," or patterns, of longer-term weight loss is needed.

Strengths and Limitations

Published data on the longer-term weight loss results from real-world commercial programs are limited. A strength of this study is the large sample of members used to report weight loss results, which is significantly larger than those published for other commercial programs. Weight loss was calculated in several ways, including the use of multiple imputation to address missing data. Missing data can be problematic in real-world programs, and using only the available data may inflate weight loss results, as these data could represent more motivated individuals who use the platform features more often. Multiple imputations as an approach helps to reduce bias and accounts for some of the uncertainty in imputed values by creating multiple complete datasets, which are separately analyzed and combined. A total of 20 datasets were created with values imputed using several different demographic variables known to be associated with weight loss, such as age, sex, and starting weight, among others. As a result, the weight loss results presented are more likely to be reflective of what might be achieved by a member who joins the program in their own everyday context and not a selected subsample [16]. Another strength of this study was the examination of weight loss patterns over an extended period. This analysis was conducted in a subsample of members with complete data, but the sample was still large enough to examine weight loss patterns in four 3-month blocks over 12 months. To the authors' knowledge, no other commercial program has examined weight loss in this way. These results provide a deeper understanding of the cycles of weight loss success and are critical to managing the expectations of those embarking on a weight loss journey. The CSIRO Total Wellbeing Diet is delivered through a partnership between Australia's national science agency and a digital health company (Digital Wellness). This is a unique partnership in which both organizations are dedicated to enhancing engagement with the platform to improve weight loss success and retention in the program, offering mutual public health and commercial benefits.

There are some limitations of this study that should be considered. While the sample was large, a limitation was that most members were female, and individuals from the lowest socioeconomic groups were underrepresented compared to the general Australian population. The cost associated with joining the program might be a barrier for those with lower income. Exploring strategies to attract a diverse member base that is more representative of the broader Australian population is a focus of ongoing research. Although real-world trials provide insight into the "true" success of people who follow a program of their own volition, a second limitation is that real-world, commercial programs are limited in what data they can collect. The registration process for this program collects various demographic data, but other factors, such as past dieting history or motivation, were not collected. Such information may allow for better predictions of weight loss success. A third limitation is the measurement of engagement used in this study. Platform use provided an indication of engagement with the program, but more objective measures of compliance, such as dietary intake, may better represent program compliance.

Conclusions

This analysis presents one of the most comprehensive evaluations of a commercial weight loss program, providing insights on weight loss success over 1 year among a large cohort of members as well as examining patterns of weight loss in a smaller subsample to better understand the "ups and downs" in achieving longer-term weight loss success. Given the prevalence of obesity and the challenges in losing weight, more evidence-based programs that achieve meaningful weight loss are needed. These results show that the CSIRO Total Wellbeing Diet Online is effective for longer-term weight loss with approximately 1 in 2 members achieving clinically significant results after 1 year. Members who engaged with the platform more were able to achieve multiple periods of weight loss over the year, and this was associated with greater weight loss success overall. Future research should focus on understanding how to drive motivation for early and sustained engagement, knowing that self-monitoring is an important factor influencing this complex health challenge. In practice, the findings on the patterns of weight loss within a longer-term journey should be used to help prepare people for a realistic weight loss journey.

Acknowledgments

The authors acknowledge the team at Digital Wellness for their support in maintaining the CSIRO (Commonwealth Scientific and Industrial Research Organisation) Total Wellbeing Diet Online platform and assisting in the data management before analysis. This study was cofunded by CSIRO and Digital Wellness. Digital Wellness manages the CSIRO Total Wellbeing Diet Online under a commercial agreement. Authors from CSIRO designed the study, conducted the analysis, and were responsible for the interpretation of results and preparation of the manuscript. Digital Wellness was not involved in the analysis or preparation of results. Digital Wellness reviewed and approved the manuscript before submission but did not alter the text or change it in any way.

Abstract

Background: Perinatal mental health problems, such as anxiety, stress, and depression, warrant particularly close monitoring and intervention, but they are often unaddressed in both obstetric and psychiatric clinics, with limited accessibility and treatment resources. Mobile health interventions may provide an effective and more accessible solution for addressing perinatal mental health. Development and evaluation of a mobile mental health intervention specifically for pregnant women are warranted.

Objective: This study aimed to evaluate the effectiveness of a 4-week, self-administered mobile mindfulness intervention in reducing anxiety, depression, and stress, and improving emotional well-being, maternal-fetal attachment, and mindfulness skills in a general population of pregnant women.

Methods: Pregnant women were recruited and randomized to an intervention or a wait-list control group. The intervention group participated in a self-administered 4-week smartphone-based mindfulness program. Anxiety, depression, and stress were assessed as primary outcomes at baseline and postintervention. Secondary outcomes were mental health well-being, maternal-fetal attachment, and skills of mindfulness. The usability of the mobile intervention was also evaluated.

Results: A total of 133 pregnant women were randomly assigned to the intervention (n=66) or the control group (n=67). The overall dropout rate was 30% (39/133). Anxiety scores of the intervention group significantly decreased from baseline to postintervention (*P*=.03, Wilcoxon Signed-Rank test), whereas no significant changes were observed in the control group. Depression and stress scores showed no significant changes. Emotional well-being significantly improved in the intervention group (*P*=.01). Improvements were observed in maternal-fetal attachment, particularly in attributing characteristics to the fetus (*P*=.003) and in differentiating the self from the fetus (*P*=.006). Mindfulness awareness also showed significant improvement (*P*=.008). Significant between-group effects were identified for mindfulness awareness (*P*=.006) and attributing characteristics to the fetus (*P*=.002). After applying the false discovery rate corrections, within-group improvements in emotional well-being,

XSL•FO
RenderX

maternal-fetal attachment, and mindfulness awareness remained significant, while between-group differences for emotional well-being and differentiation were not significant.

Conclusions: A mobile mindfulness program effectively reduced anxiety and improved emotional well-being, maternal-fetal attachment, and mindfulness awareness in the general population of pregnant women. Mobile interventions may offer a cost-effective and feasible method for promoting perinatal mental health.

anxiety; perinatal mental health; depression; mobile health care; mindfulness; mobile phone

Introduction

Pregnancy is a major period of change in a woman's life. Perinatal women are reported to be at a higher risk of developing newly-onset mental health problems or experiencing a relapse of existing ones compared with the general population [1]. The percentage of women in pregnancy who meet 1 or more diagnostic criteria for an anxiety disorder ranges from 12.2% to 39%, which is 2-3 times higher than the general population [2]. Furthermore, the prevalence of antenatal depression is estimated at 20.7% for any depression and 15% for major depression [3]. Stress associated with pregnancy and childbirth is known to increase the risk of perinatal anxiety and depression, and the risk is increased in those with previous mental health vulnerabilities [4]. Concerning such widespread prevalence, the World Health Organization (2024) emphasizes the need for health care professionals to recognize and provide adequate interventions for mental health problems in pregnant women [5].

Mental health problems during pregnancy have far-reaching effects, influencing both the immediate and long-term outcomes of mothers and their children [6,7]. Antenatal depression and anxiety increase the risk of pregnancy complications and obstetric outcomes such as preeclampsia, edema, hemorrhage, preterm birth, and low birth weight [8]. Negative mental health conditions during pregnancy can hinder self-care, increasing risks such as poor nutrition and substance misuse. Consequently, these factors may harm the physical and mental health of the mother and restrict healthy fetal growth and development [9,10]. Antenatal depression also increases the risk of postnatal depression [11], which will further impact the health of both the mother and the infant. In the long term, untreated perinatal mental health conditions can lead to lasting consequences such as impaired neurocognitive development and poor emotional regulation during infancy and childhood [12-14].

Despite the significant impact of perinatal mental health issues, many women face barriers that prevent them from accessing necessary mental health care [15]. In obstetric clinics, routine mental health evaluations for anxiety, depression, and stress are often neglected or overlooked, and it is uncommon for pregnant women to seek mental health care directly from psychiatric services. Stigma further discourages help-seeking in pregnant women, and finally, there is a lack of available resources. Even when clinical problems are identified, many pregnant women are reluctant toward pharmacotherapy due to concerns about fetal safety and the potential effects of medication [16,17]. This low acceptability of pharmacotherapy emphasizes the need for nonpharmacological approaches, which many pregnant women may find more acceptable. However, access to nonpharmacological treatments, such as psychotherapy, remains limited due to resource constraints, including availability and cost. Given these barriers, there is a clear need for effective and more accessible nonpharmacological interventions for women during this critical period, including digital and mobile-based programs, that can overcome obstacles like stigma and limited resources.

The integration of digital technology in psychotherapeutic interventions for perinatal women has shown promising results. A systematic review and meta-analysis by Lau et al [18] showed that digital psychotherapeutic interventions may significantly reduce symptoms of depression, anxiety, and stress in perinatal women. This review emphasized that interventions delivered through digital platforms, such as websites and mobile apps, were particularly effective in improving psychological outcomes [18]. A mobile or web-based approach may alleviate space-time barriers, overcome women's resistance to treatment, and address limited resources. Research indicates that perinatal women frequently use mobile apps to access information about pregnancy, childbirth, and childcare [19]. These results, along with others, show that many women find mobile apps highly accessible and usable for improving their self-care and enhancing their pregnancy experience [20]. Mobile health apps have been reported to significantly enhance areas of both treatment and health care delivery [21]. Therefore, employing mobile and web-based technologies provides a promising way to address the unique needs of perinatal women, improving their access to adequate care.

Mindfulness-based interventions (MBIs) have emerged as an effective method for psychological self-care and symptom management [22]. By fostering conscious awareness and acceptance of one's present state, mindfulness equips individuals with the ability to navigate through physical and emotional distress [23]. Numerous studies highlight its efficacy in reducing anxiety and depression symptoms, as well as enhancing overall psychological well-being [24-28]. Mindfulness-based stress reduction and mindfulness-based cognitive therapy (MBCT) have shown efficacy in reducing anxiety and preventing depression relapse, as well as enhancing a broad range of other mental health problems [29,30].

XSL•FO
RenderX

Mindfulness training techniques through mindfulness-based stress reduction or MBCT have been shown to be effective for pregnant women in reducing stress, anxiety, depressive symptoms, and emotional distress during pregnancy [26,28,30,31]. A systematic review on the effectiveness of MBIs on maternal perinatal mental health outcomes showed reductions in perinatal anxiety and less consistent results for the effect on depression, but the review was limited by the number of studies available and their methodological quality [25]. Even though mindfulness interventions may be effective in perinatal mental health care, gold-standard mindfulness training often requires rigorous hours of in-person instruction and training. Thus, traditional mindfulness programs pose similar accessibility barriers to pregnant women.

Mobile-based MBIs may offer a promising solution to overcoming these barriers in perinatal mental health care [32-35]. Sun et al [33] implemented an 8-week mindfulness program, which was shown to be effective for pregnant women who screened positive for depressive symptoms. In the study, only 8% (7/84) completed the entire 8-week training program. As smartphone-based mobile interactions are mostly self-administered, the acceptability of the intervention by the participant is an important part of treatment viability. We aimed to address this point by developing a shorter, more usable self-administered mobile MBI that is effective for perinatal mental health. Furthermore, increased depression, anxiety, and stress during pregnancy are associated with negative prenatal outcomes, even at a subclinical level. Subclinical anxiety and stress were linked to increased risks of preterm birth, low birth weight, and lower Apgar scores [36]. In addition, mild depressive symptoms are reported to be associated with heightened cortisol levels, impacting fetal neurodevelopment and increasing the likelihood of neonatal complications [36]. This suggests that addressing even mild symptoms in pregnancy could improve maternal and neonatal health outcomes. Thus, in developing the intervention, we aimed to target the general population of pregnant women to improve their mental health and well-being, compared with previous studies that often focus on the clinical population.

In this randomized controlled trial, we evaluated the effectiveness of our newly developed, 4-week mindfulness-based mobile app in reducing perinatal anxiety, depression, and stress among a general population of pregnant women. We also investigated mental health well-being, maternal-fetal attachment, and mindfulness skills as secondary outcomes, and assessed the usability of the intervention to determine feasibility for broader application.

Methods

Trial Design and Randomization

This study was a single-center, randomized wait-list controlled trial with assessments at baseline and post intervention (trial registration KCT0007166). Participants were randomized using a list created in the R (4.0.2 version; R Core Team) program, which was set to randomize in a 1:1 ratio. To ensure the integrity of the data analysis and eliminate potential bias, the data analysts remained blinded to the group allocation of each participant. The randomization was performed by a designated member of the research team who was not involved in the data analysis. The randomization sheet was only accessible to the person responsible for assigning participants to their respective groups. A designated member of the research team allocated the participants to the intervention or control group using the randomized list. Those randomly assigned to the wait-list control group received the intervention after 4 weeks. The reporting of this trial adheres to the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines (Multimedia Appendix 1).

Sample Size

The sample size was determined using G*Power (version 3.1.9.7), based on standard assumptions for detecting differences between 2 groups over time. The calculation assumed a small-to-medium effect size and a statistical power of 80%, with the required sample size estimated at 90 participants (45 per group) [18,25]. To account for potential attrition, which has been reported to reach up to 33% in similar interventions [18,25], the recruitment target was set at 134 participants.

Participants

Participants were recruited both from internet-based advertisement and on-site at the Obstetrics and Gynecology Department of the CHA Bundang Medical Center in Seongnam, South Korea, from March to November 2020. The hospital is the largest and first specialized center for pregnancy and women's health in the country. Informational posters displayed in the hospital and internet-based advertisements were used for recruitment. Potential participants were provided with detailed information about the study, and those interested were invited to contact the research team for further screening and enrollment. The inclusion criteria were as follows: (1) at least 18 years of age, (2) between 1 and 32 weeks of gestation, (3) having a smartphone, (4) being able to use the app on a smartphone for the study, (5) being able to read and understand Korean, (6) willing to be randomized, and (7) willing to provide informed consent. Exclusion criteria were as follows: (1) over 32 weeks of gestation and (2) expected to give birth within 4 weeks (during the intervention period). The study did not exclude participants based on medical history (eg, obstetric complications or mental illness) unless these conditions reached a clinically significant level that would affect participation or safety of the participant.

Upon obtaining informed consent and ensuring random allocation, all participants completed a baseline evaluation, including sociodemographic, medical, pregnancy-related, and mental health information. If participants could not visit the obstetric department or complete the questionnaire at the site, they received a Google survey link of the questionnaire through email or smartphone.

Participants assigned to the intervention group were instructed to download a mobile-based mindfulness intervention app named AvecMom (Digital Medic Co) and were instructed to use it for 4 weeks. They received printed guides on how to use the mobile app and direct download links for both Android (Google) and

XSL•FO
RenderX

iPhone (Apple Inc) devices. Participants were instructed to practice each practice session at least 3 times a week for the 4 weeks of participating in the program.

Participants assigned to the wait-list control group were instructed not to participate in any events of meditation, yoga, or mindfulness-based activities during the 4 weeks. After the 4-week period, all participants received a Google survey link for a postintervention assessment through email, messenger, or in person at the site. The control group received access to the mobile app with instructions after the 4 weeks and the postintervention assessment.

Ethical Considerations

This study was approved by the institutional review board, CHA Bundang Medical Center, CHA University College of Medicine (HI18C0911). All participants provided written informed consent before enrollment. Participants were fully informed about the study's purpose, procedures, potential risk, and their right to withdraw at any time without consequence. To ensure privacy and confidentiality, all data were deidentified before analysis and securely stored on encrypted servers, accessible only to authorized research staff. For data with potential reidentification risks, access was strictly limited to authorized research staff. Comprehensive data management protocols were implemented to prevent unauthorized access and ensure participant confidentiality throughout the study. Participants received pregnancy-related gifts, valued at approximately US $41 (50,000 KRW), as an incentive for their participation in the study.

Development of the Mobile-Based Mindfulness Intervention

The mindfulness-based mobile intervention was developed by an interdisciplinary research team. The development was led by a professor of psychiatry who has over 5 years of mindfulness experience as well as experience with leading the development of several preventive interventions for mental health-related at-risk populations. The team also consisted of a psychiatrist with expertise in mobile apps, obstetricians, psychologists, a research professor of user interface and user experience design, and research assistants with mindfulness experience. The development process of the intervention began with a comprehensive review of previous MBIs to identify essential components relevant to perinatal mental health [37]. Following this, we focused on component selection, choosing mindfulness practices that address perinatal stress, anxiety, and depression, with content tailored to meet the unique physical, social, and psychological needs of pregnant women. To ensure feasibility and accessibility, the program was designed as a 4-week intervention, a modification supported by existing research on shorter programs' effectiveness [38]. Finally, the program underwent expert review by a panel of experienced advisors in mindfulness and perinatal mental health, whose insights helped refine the content and structure. The recorded sessions were guided by an experienced mindfulness trainer who was also pregnant at the time, strengthening the intervention's relevance and the empathetic element of the intervention. Participants were reminded that this app is not equivalent to psychotherapy, and they were recommended to seek professional help when necessary.

The intervention program consisted of 4 sections—breathing mindfulness meditation, body scanning, emotional awareness, and self-kindness mindfulness (Multimedia Appendix 2). Each session was divided into 2 subsessions—instruction and practice sessions. In the instruction session, participants learned about mindfulness techniques according to the thematic curriculum and were guided through the mindfulness training. In the practice session, participants entered the mindfulness practice directly without the introduction content of the instruction session. Participants needed to complete the instruction session to enter the practice session. The sessions were designed to be completed sequentially, with the subsequent session automatically unlocking once the participant performs the previous session at least twice. This sequence was clearly outlined in the user manual provided to the participants.

Each session had a duration of about 20 minutes. Participants were instructed to practice each session at least twice, ensuring they engaged with the content multiple times to reinforce their learning and practice. This structured approach aimed to enhance usability and effectiveness, providing a comprehensive yet manageable intervention for pregnant women. Sessions took into consideration the prenatal-specific psychological, physical, and emotional changes specific to pregnancy. After each session, participants received a sequential worksheet to complement the session and aid in understanding and developing mindfulness skills (Multimedia Appendix 3).

Measures

Depression, Anxiety and Stress Scale–21 Items

Depression, anxiety, and stress were assessed with the 21-item Depression, Anxiety and Stress Scale (DASS-21) [39-41]. This scale consists of 21 items used to assess depression (7 items), anxiety (7 items), and stress (7 items). The response items were scored on a 4-point Likert scale ranging from 0 to 3. Higher scores for each factor indicate a higher intensity for each symptom. A depression score of 9 or higher, an anxiety score of 7 or higher, and a stress score of 14 or higher indicate moderate symptoms for each factor [40]. The internal reliability for DASS-21 was found to be high (α=.94, at baseline).

Edinburgh Postnatal Depression Scale

The Edinburgh Postnatal Depression Scale (EPDS) [42,43] was also used to assess depressive symptoms during the peripartum period. This scale contains 10 items scored using a 4-point Likert scale ranging from 0 to 3. A higher score indicates a higher intensity of depressive symptoms. A score of 8 or less on the recommended cutoff indicates no likelihood of depression [42]. The reliability of the EPDS for pregnant Korean women was good (Cronbach α=0.85) [43]. The scale reached good-to-excellent internal reliability in our sample (at baseline, Cronbach α=0.88). Although the EPDS is a frequently used measure to assess postnatal depression, it has been used in many studies as a valid screening tool to detect depression in pregnant women [44,45].

XSL•FO
RenderX

Mental Health Continuum-Short Form

Mental health well-being was measured using the Mental Health Continuum-Short Form (MHC-sf) [46,47]. This scale consists of 14 items measuring social (5 items), psychological (6 items), and emotional (3 items) well-being, which is scored using a 6-point Likert scale ranging from 0 to 5. Higher scores indicate better mental health. The 3 MHC-sf subscales had high test-retest reliability, discriminant validity, and convergent validity in Korean adults [47]. Adequate reliability was found in this study (Cronbach =0.096, at baseline).

Maternal-Fetal Attachment Scale

Attachment between the mother and fetus was assessed using the Maternal-Fetal Attachment Scale (MFAS) [48]. In this study, 23 items of the revised Korean version were used, which were scored using a 4-point Likert scale. The 5 subscales of the MFAS are designed to measure differentiation of self from the fetus (3 items), interaction with the fetus (4 items), attributing characteristics to the fetus (6 items), giving of self (4 items), and maternal role-taking (6 items). Construct and criterion validity and reliability have been reported for pregnant Korean women [49]. The study's α coefficient for the baseline MFAS score was 0.92.

Cognitive and Affective Mindfulness Scale-Revised Version

Mindfulness was assessed with the Cognitive and Affective Mindfulness Scale-revised (CAMS-r) [50,51]. The scale contains a 10-item inventory. The response items were scored on a 4-point Likert scale ranging from 1 to 4. The CAMS-r consists of 3 factors that assess mindfulness levels—awareness, attention, and acceptance. The awareness and attention factors comprise 4 items, and acceptance consists of 2 items. Higher scores indicated higher levels of mindfulness. The CAMS-r has good internal reliability (Cronbach α=0.73), internal validity (Cronbach α=0.70), and test-retest reliability (r=0.77, P<.001) among Korean undergraduate students [51]. This study's α coefficient for the baseline CAMS-r score was 0.86.

Usability

To assess the usability of the mindfulness mobile app, the Usefulness, Satisfaction, and Ease of Use questionnaire (USE questionnaire) [52] was used after 4 weeks of using the app. This scale consists of 30 items measuring usefulness (8 items), ease of use (4 items), ease of learning (11 items), and satisfaction (7 items). The scale used was a 7-point Likert scale ranging from strongly disagree (1) to strongly agree (7). The reliability of the questionnaire in this study was assessed using Cronbach α, with results demonstrating high internal consistency across all 4 dimensions (usefulness: 0.914, ease of use: 0.898, ease of learning: 0.883, satisfaction: 0.905). These findings are consistent with those reported by Gao et al [53], who found similarly high reliability (Cronbach α=0.98 overall).

Data Analysis

All statistical analyses were conducted using SPSS (version 18.0; IBM Corp) and Python 3 (Python Software Foundation). Demographic characteristics were analyzed in SPSS 18.0. An independent samples t test was used for continuous variables, while categorical variables were analyzed using the chi-square test to ensure baseline comparability between the intervention and control groups.

For demographic variables, missing data points related to smoking (1 participant) and alcohol use (2 participants) were imputed using the last observation carried forward method [54]. This method involved using the most recent patient records to impute the missing values, ensuring completeness of the demographic dataset for analysis.

The primary analysis was conducted using an intent-to-treat approach, ensuring that all randomized participants were included in the analysis based on their originally assigned groups. Due to the nonnormal distribution of the primary and secondary outcome data, nonparametric methods were applied using Python 3. The Mann-Whitney U test was used to compare outcomes between the Intervention and Control groups, while within-group changes from pre- to postintervention were assessed using the Wilcoxon Signed-Rank test.

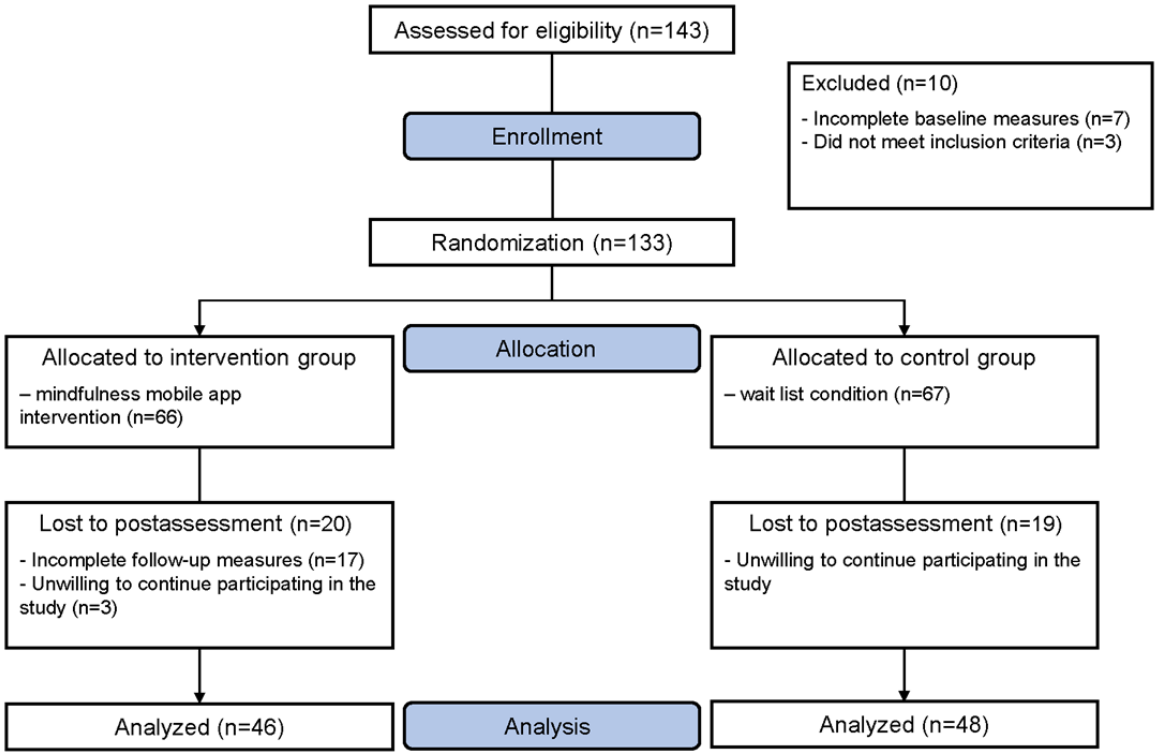
Effect sizes for both the Mann-Whitney U and Wilcoxon tests were calculated using the following formula:

where Z is the test statistic and N is the number of observations. Effect sizes were interpreted based on the following guidelines: small (r=0.1), medium (r=0.3), and large (r=0.5).

To account for the nonparametric nature of the data, 95% CIs for the effect sizes were calculated using the bootstrapping method with 1000 resamples. These CIs provide a measure of precision, indicating the range within which the true effect size is likely to lie with 95% CI.

For secondary outcomes, multiple comparisons were addressed using the false discovery rate (FDR) correction method to control for Type I errors [55]. This method ensures that the statistical significance of the results is maintained while minimizing the risk of false positives due to multiple testing, particularly in the analysis of secondary outcomes.

All statistical results, including test statistics, P values, effect sizes, and 95% CIs, are reported to provide a comprehensive understanding of the intervention's effectiveness.



Results

Participant Enrollment and Flow

A total of 143 perinatal women were recruited as eligible for the study. Of the 143 participants, 2% (3/143) did not meet the inclusion criteria, and 5% (7/143) did not complete the baseline assessment. Thus, 133 participants were allocated randomly, of which 66 were allocated to the intervention group and 67 to the wait-list control group. During the follow-ups, 13% (17/133) did not complete the follow-up assessment and 17% (22/133) were not willing to continue participation. The overall completion rate was 71% (94/133; Figure 1; see Multimedia Appendix 1 for the CONSORT-EHEALTH checklist).

RenderX

Figure 1. Participant enrollment flowchart.

Demographics and Clinical Characteristics

Demographic characteristics are presented in Table 1. All 133 participants were pregnant and married at baseline. The mean ages of the participants for the intervention (n=66) and control groups (n=67) included in the analysis were 32.6 (SD 4.3) years and 32.8 (SD 4.44) years, respectively, and the mean gestational weeks of the 2 groups were 20.61 (SD 6.42) months and 20.04 (SD 6.76) months, respectively. There were no significant differences between the 2 groups across all the baseline characteristics, including pregnancy period, occupation, education level, income, pregnancy plan, medical diagnosis, and other characteristics.

Effectiveness of the Mobile-Based Mindfulness Intervention

Primary Outcomes: Anxiety, Depression, and Stress

Table 2 shows the mean scores of pre- and postmeasures of the DASS-21, EPDS, CAMS-r, MHC-sf, and MFAS in the intervention and control groups. The DASS-21 mean scores of the intervention group at preintervention were 6.7 (SD 7.2), 6.9 (SD 5.5), and 9.7 (SD 8.2) for depression, anxiety, and stress, respectively. The mean scores of depression, anxiety, and stress of the compared control group were 7.4 (SD 7.7), 6.9 (SD 7.3), and 11.7 (SD 8.6), respectively. Considering the recommended cutoff scores from previous research, mean scores for depression, anxiety, and stress were in the normal range [42]. The baseline mean scores of the EPDS in the intervention and control groups were 7.1 (SD 5.1) and 7.6 (SD 6.3), respectively.

Table 2. Comparison of depression, anxiety, and stress scores at pre- and postintervention time points between the intervention and control groups using nonparametric analysis.

[c]DASS-21: Depression, Anxiety and Stress Scale, 21-question version.

[d]IG: intervention group.

[e]CG: control group.

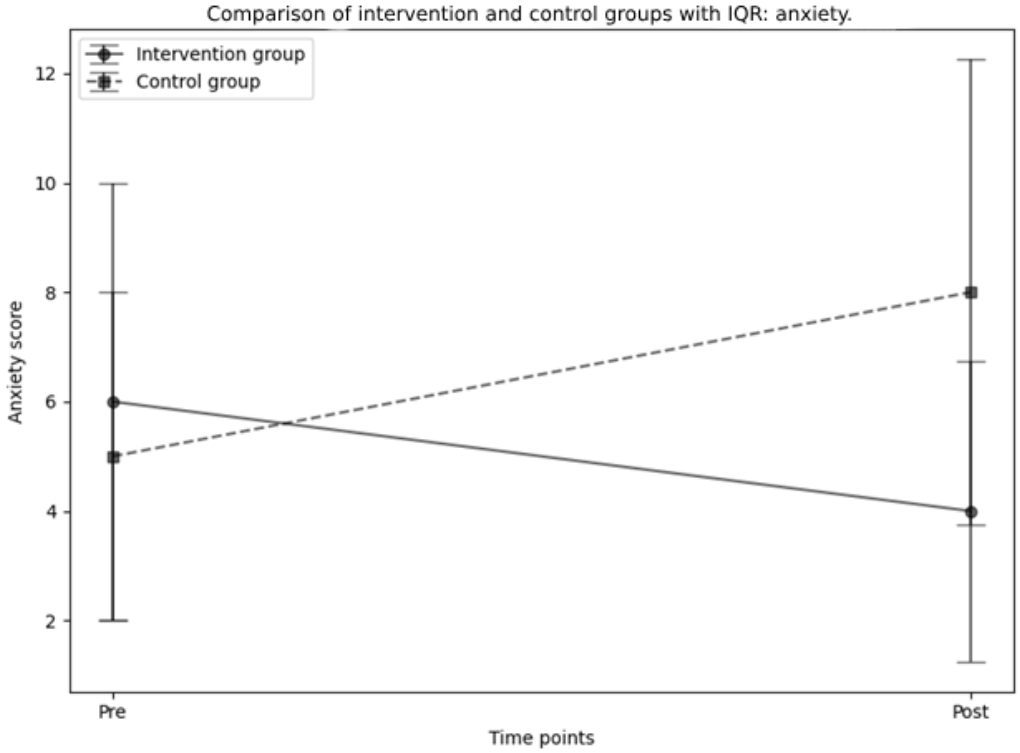
[f]Not applicable.

[g]EPDS: Edinburgh Postnatal Depression Scale.

Anxiety scores, measured using the DASS-21, significantly decreased in the intervention group from pre- to postintervention, with the median score dropping from 6 (IQR 2-10) to 4 (IQR 2-7.5), as shown by the Wilcoxon Signed-Rank test (*W*=295, *P*=.03, *r*=6.413, 95% CI –2 to 5). In contrast, no significant changes were observed in the control group, where anxiety scores increased from a median of 5 (IQR 2-8) to 8 (IQR 2-10.5; *W*=244, *P*=.11, *r*=5.083, 95% CI –5 to 1). The Mann-Whitney *U* test showed no significant difference between the groups at baseline (*U*=1191, *P*=.51, *r*=–0.068, 95% CI –2 to 4). Postintervention comparisons approached significance,

XSL•FO
RenderX

favoring the intervention group (*U*=869, *P*=.08, *r*=–0.183, 95% CI –6 to 0).



Depression scores, measured using the DASS-21, did not significantly change in the intervention group, with the median remaining at 4 (IQR 2-9.5) for preintervention and 4 (IQR 2-8) for postintervention (*W*=352.5, *P*=.60, *r*=7.663, 95% CI –4 to 4). Although the control group showed an increase in depression scores from a median of 4 (IQR 2-10.5) to 7 (IQR 2-12), this change was not statistically significant (*W*=238, *P*=.09, *r*=4.958, 95% CI –6 to 0). No significant difference between the groups was observed at baseline (*U*=1068.5, *P*=.79, *r*=–0.028, 95% CI –3 to 3), and postintervention group comparisons did not reach statistical significance (*U*=903.5, *P*=.13, *r*=–0.156, 95% CI –6 to 1).

Stress scores, measured using the DASS-21, remained stable in the intervention group, with a median score of 8 (IQR 4-13.5) for preintervention and 8 (IQR 2-13.5) for postintervention time points (*W*=321.5, *P*=.48, *r*=6.989, 95% CI –4 to 5). The control group also showed no significant change in stress scores, with medians of 10 (IQR 4-18) for preintervention and postintervention (IQR 4-16) time points (*W*=387.5, *P*=.98, *r*=8.073, 95% CI –5 to 6). The Mann-Whitney *U* test revealed no significant differences between the groups at baseline (*U*=951.5, *P*=.25, *r*=–0.119, 95% CI –8 to 2), nor postintervention time points (*U*=911.5, *P*=.15, *r*=–0.150, 95% CI –9 to 2).

The intervention group showed no significant changes in EPDS scores, with a median score of 6 (IQR 4-9) for preintervention and 6 (IQR 2-9.75) for postintervention (*W*=272.5, *P*=.16, *r*=5.924, 95% CI –3.5 to 3.0). In the control group, EPDS scores increased slightly from a median of 6 (IQR 2-10.5) to 8 (IQR 3.75-11.25), but this change was not significant (*W*=331.5, *P*=.29, *r*=6.906, 95% CI –5.0 to 2.5). Baseline comparisons showed no significant differences between the groups (*U*=1094.5, *P*=.95, *r*=–0.007, 95% CI –5 to 3), and postintervention group differences were also nonsignificant (*U*=888, *P*=.11, *r*=–0.169, 95% CI –5.0 to 1.5).

The primary outcomes results are summarized in Table 2 and depicted in Figure 2.

Figure 2. Comparison of median anxiety scores with IQR at pre- and postintervention between intervention and control groups using nonparametric analysis.

Secondary Outcomes: Mental Health Well-Being, Maternal-Fetal Attachment, and Mindfulness

The secondary outcomes including changes in well-being, maternal-fetal attachment, and mindfulness are summarized in Table 3. Emotional well-being significantly improved in the intervention group, with the median score increasing from 9 (IQR 8-12) to 11.5 (IQR 8-12) as reflected in the Wilcoxon Signed-Rank test (*W*=154, *P*=.02, effect size *r*=3.348, 95% CI –4.0 to 0.5). No significant changes were observed in the control group over the same period (*W*=287.5, *P*=.47, effect size *r*=5.99, 95% CI –1.5 to 2.5). The Mann-Whitney *U* test postintervention approached significance (*U*=1348, *P*=.07, effect size *r*=–0.19, 95% CI –0.5 to 4.0). According to the FDR correction, the within-group improvement in emotional well-being in the intervention group remained significant, while the between-group difference was not significant.

[c]MHC-sf: Mental Health Continuum-Short Form.

[d]IG: intervention group.

[e]CG: control group.

[f]Not applicable.

[g]Significant changes after false discovery rate correction.

[h]MFAS: Maternal-Fetal Attachment scale.

[i]CAMS-r: Cognitive and Affective Mindfulness Scale-revised.

Differentiation self from fetus dimension of maternal-fetal attachment significantly improved in the intervention group, with median scores increasing from 9 (IQR 8-10) to 10 (IQR 9-11), as reflected in the Wilcoxon Signed-Rank test (*W*=129.5, *P*=.006, effect size *r*=2.815, 95% CI –1.5 to 0.0). No significant changes were found in the control group (*W*=206.5, *P*=.81, effect size *r*=4.302, 95% CI –0.5 to 0.0). Postintervention comparisons revealed a significant difference between groups, favoring the intervention group (*U*=1379, *P*=.04, effect size *r*=–0.215, 95% CI 0.0-1.5). After FDR correction, the within-group improvement in the intervention group remained significant, while the between-group difference was not significant.

The attributing characteristics to fetus dimension of maternal-fetal attachment significantly improved within the intervention group, with median scores rising from 21 (IQR 18-22) to 22 (IQR 20.25-24), as indicated by the Wilcoxon Signed-Rank test (*W*=107, *P*=.003, effect size *r*=2.326, 95% CI –3 to 0). No significant changes were observed in the control group (*W*=316, *P*=.79, effect size *r*=6.583, 95% CI –2.0 to 2.5). The Mann-Whitney *U* test revealed a significant postintervention difference between the groups, favoring the intervention group (*U*=1506.5, *P*=.002, effect size *r*=–0.314, 95% CI 0.5-4.0). After FDR correction, both the within-group improvement in the intervention group and the between-group difference remained significant.

Awareness from CAMS-r showed a significant increase in the intervention group from pre- to postintervention time points. The median score rose from 10 (IQR 8-12) to 11 (IQR 9-13.75), as indicated by the Wilcoxon Signed-Rank test (*W*=200, *P*=.008, effect size *r*=4.348, 95% CI –3.0 to 0.5). In contrast, the control group did not exhibit significant changes in awareness over the same period (*W*=406.5, *P*=.97, effect size *r*=8.469, 95% CI –1 to 1). Postintervention comparisons between the groups revealed a significant difference favoring the intervention group (*U*=1467.5, *P*=.006, effect size *r*=–0.284, 95% CI 0-3). The FDR correction confirmed that both the within-group improvement and the between-group difference were significant.

Subscales within the secondary outcomes, such as (1) social and psychological well-being (MHC-sf); (2) interaction with the fetus, giving of self, and maternal role-taking (MFAS); and (3) attention and acceptance in mindfulness (CAMS-r), did not show significant changes postintervention, as indicated by the FDR-adjusted analyses.

The comprehensive effects of both primary and secondary outcomes, including statistical significance and CIs, are detailed in Table 4.

Usability

Of the 133 participants, 80 responded to the USE questionnaire. Around 88% (70/80) of participants strongly agreed to the usability of the app. The total mean score was 5.7 (SD 0.62). Around 75% (60/80) of participants agreed regarding the app's usefulness. The mean score of usefulness was 5.4 (SD 0.79); 98% (78/80) of participants agreed that the app was easy to learn from. The mean score of ease of learning was 6.4 (SD 0.67); 91% (73/80) of participants agreed that the app was easy to use. The mean ease of use score was 5.9 (SD 0.68). In addition, 81% (65/80) of participants agreed with the satisfaction of the app. The mean score of the satisfaction was 5.6 (SD 0.79).

Discussion

Principal Findings

This study supports the effectiveness of the mobile-based mindfulness intervention developed for pregnant women in reducing perinatal anxiety. Furthermore, the intervention enhanced emotional well-being, maternal-fetal attachment, and mindful awareness during pregnancy. While previous studies have demonstrated the benefits of MBIs for perinatal mental health [25,31], our study is among the first to evaluate a fully self-guided, short-term (4-week) mobile intervention without the need for in-person guidance. This distinguishes our work as a widely applicable and accessible approach, particularly suited for populations with limited access to traditional mental health services. The findings provide evidence for both the effectiveness and usability of the mobile app as a tool for promoting mental health during pregnancy.

Perinatal anxiety was significantly reduced in pregnant women who used the self-administered mobile mindfulness program compared with the control group. Anxiety during pregnancy has been linked to various adverse outcomes, including mental health issues (such as postnatal depression) and perinatal complications (such as preterm birth). Our findings suggest that this intervention can help prevent and manage anxiety before it escalates to a clinical level. Even when anxiety is not at a clinical threshold, it can still have a significant impact, and interventions like ours can play an important role in addressing and controlling it early on. In a randomized controlled trial by Sun et al [33], there was a significant reduction in anxiety in pregnant women at risk of perinatal depression using an 8-week smartphone-based mindfulness training. Compared with these high-anxiety participants, those in this study were a general pregnant population with lower baseline anxiety levels. Our findings suggest that the mobile mindfulness intervention can effectively reduce anxiety even in a general pregnancy population.

Our 4-week intervention was designed to be more feasible and accessible, addressing the need for shorter, yet effective, interventions. This study stands out due to its shorter duration compared with similar interventions, such as the 8-week program used in previous studies [18,33]. A full 8-week MBCT program may provide a more comprehensive intervention for those willing to participate. In reality, however, committing to a long-term regular in-person treatment during pregnancy may

XSL•FO
RenderX

be very challenging with demands on the time and cost of the pregnant mothers, along with other barriers to treatment including the scarcity of perinatal treatment resources and stigma of going to psychiatric clinics. In previous research, the mean number of completed training weeks of the 8-week intervention was 3 [33]. Mobile-based or internet-based forms of treatment delivery may help overcome these limitations and promote access to timely interventions. Our study demonstrates that an MBCT-modified, short-term, self-administered mobile mindfulness intervention may benefit mental health during the perinatal period.

An analysis of the secondary outcomes from the mobile mindfulness intervention program revealed significant improvements in emotional well-being, a subscale of the well-being questionnaire (MHC-sf), among pregnant women following the 4-week intervention. Previous research has shown that poor maternal emotional well-being is associated with childbirth complications, such as low birth weight and fetal developmental issues, as well as long-term cognitive and behavioral problems in the child [56]. Enhanced emotional well-being has also been linked to better physical and mental health outcomes for pregnant women, improved labor outcomes, better health outcomes for offspring, and stronger maternal attachment [27,56]. Our findings suggest that mobile mindfulness training has the potential to promote emotional well-being during pregnancy and could serve as an accessible and effective tool for supporting mental health during this challenging period. In addition, the significant improvements in emotional well-being observed in the intervention group reinforce the effectiveness of MBIs in enhancing mental well-being, even in populations not at high risk for mental health disorders [56].

Another notable finding from our study was the positive effect of the mobile program on maternal-fetal attachment. Attachment, or the relationship between the mother and her infant, begins before birth (during pregnancy) as a result of dynamic psychological and physiological events. During pregnancy, women have intellectual, physical, and kinesthetic awareness of the fetus. Gradually, they become aware of the fetus as a separate individual. Women notice and interpret different movements of the fetus, elaborating personal relationships. Using the MFAS, domains of differentiation from the fetus and attribution of characteristics to the fetus were significantly increased in the intervention group. Differentiation of the self from the fetus indicates that the woman recognizes the fetus as an individual separate from her body [57]. The ability to attribute characteristics, such as personality, emotions, and physical space in the uterus, to the fetus is part of the dynamic relationship between mother and fetus [48,57]. Increased scores on these characteristics mean that mothers have a high level of attachment with their fetuses, by forming an identity as a mother and recognizing their developing fetuses; in turn, they may be more prepared and invested in their pregnancy [49]. Being in a mindful state means being aware of both the self and others, as well as one's inner and outer self. Mobile-based mindfulness training may lead to an increased awareness of the fetus as an individual, leading to qualitative changes in the interaction with the fetus. Improved maternal-fetal attachment has long-term benefits, such as a reduction in postpartum depression [57]. This study shows that a self-administered mindfulness program may promote maternal-fetal attachment, even in a relatively short duration of 4 weeks. Whether these effects may have a lasting, long-term benefit should be evaluated in the future.

Increased mindful awareness was shown in the intervention group, and supporting the newly developed 4-week mobile mindfulness program may cultivate or increase skills of mindfulness. Mindful awareness is nonjudgmental and nonreactive attention to experiences occurring at the present moment, including cognition, emotion, and bodily sensations, as well as surrounding environmental stimuli [58]. When one is mindfully aware, adaptation to stressful situations increases by enhancing attention to the negative emotional states [59]. Promotion of actual skills may have more persisting benefits, as these skills can be used in everyday life. Our findings suggest that these skills can be fostered through mobile-based, self-administration, even within a relatively short period of 4 weeks. Maintaining awareness, without judgment or reactivity, toward emotions about the dramatic changes that come with childbirth and related beliefs or automatic thoughts, may help in emotion regulation and behavioral adaptation. In a previous study that investigated the effect of the in-person MBCT program for 9 weeks increased natural childbirths for pregnant women with high fears of childbirth, increased mindful awareness was the most powerful mechanism of change to better adapt to the challenges of childbirth [60]. The present mobile intervention may be an accessible tool to effectively cultivate mindful awareness to increase tolerance to negative emotional states and cope with them better.

The mindfulness program scored high on usefulness, ease of use, ease of learning, ease to use, and overall satisfaction. Previously, it was noted that the traditional mindfulness intervention was challenging to access for women who already had children because of time limitations and existing family responsibilities, which led to a high loss to follow-up [60]. While mobile apps may be a preferable mode of delivery for mental health interventions to mitigate these barriers, the benefits of the intervention may be limited if it is difficult for users to administer. Current findings suggest that the mobile program is both feasible and acceptable. Furthermore, the responses from the usability study provided useful information for future program modifications. The mobile app used in our study automatically provides push notification services to serve the purpose of the mindfulness intervention program (eg, a reminder to use the app at least twice a week). This feature helped improve adherence for some participants. Features like these within a mobile app have the potential to enhance adherence and effectiveness, while a user-friendly design can facilitate the broad and efficient implementation of the app to provide motivation for continued use [61].

Limitations

Several limitations should be acknowledged. First, we only found results from the immediate effects of postintervention because our study design did not include a long-term follow-up. Future research should explore the long-term effects, potentially including postpartum outcomes for both the mother and infant,

XSL•FO
RenderX

to better inform perinatal care. Given the relatively short study period (4 weeks), it is important to determine whether the observed benefits are long-term, or if additional or booster sessions might be necessary to maintain or enhance these benefits. Second, our sample consisted of a general pregnancy population, and thus, the results of the current study do not represent effectiveness in a clinical sample such as that of a depressive disorder group [25]. No significant effect was observed on depression scores in this study, which may be attributed to the low scores that represent no clinical depression at baseline. It will be helpful to investigate whether the intervention can reduce clinical levels of anxiety or depression in the future. Finally, the effect sizes of depression, anxiety, and stress in this study were small, potentially due to the limited sample size. This also suggests that outcomes such as depression and stress may have shown no significant effect due to insufficient power. Future studies should aim to recruit a larger sample size to ensure adequate power to detect significant effects.

Conclusions

Mindfulness-based mobile interventions offer an effective tool for alleviating prenatal anxiety and improving emotional well-being as well as maternal-fetal attachment. This intervention may serve as a cost-effective and highly accessible method of intervention to overcome the current limitations of perinatal mental health management. Further research is needed to investigate whether the program provides lasting benefits for both mother and infant.

Acknowledgments

This research was supported by a grant from the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant RS-2022-KH131144).

Data Availability

The datasets generated and/or analyzed during this study are not publicly available because of restrictions containing information that could compromise the privacy of study participants but are available from the corresponding author upon reasonable request.

Authors' Contributions

SP contributed to the study design, data acquisition, organization of the data, all statistical analyses, and interpretation of data, and wrote all sections of the manuscript. HYC was involved in the study concept, funding acquisition, recruitment of participants, and data acquisition. JYP was involved in the study concept, design, interpretation of data, and supervision. KC was involved in the protocol development, technical supervision, and interpretation of data. KJ was involved in the study concept, design, data acquisition, interpretation of data, preparation and review of the manuscript, and supervision. All authors have read and approved the final manuscript.

Abstract

Background: Hand and foot eczema is a frequent chronic dermatological condition. The persistent itching, pain, and blistering can impair hand and foot function, leading to difficulties in performing tasks requiring fine motor skills. In addition, the impact on the quality of life for affected patients is significant, as the symptoms can be extremely uncomfortable and disruptive to daily activities. By incorporating digital health apps and educational programs into the management of hand and foot eczema, patients may receive ongoing support, optimize their clinical outcomes, and ultimately enhance their overall quality of life.

Objective: The purpose of this study was to evaluate the effect of a smartphone app combined with educational training on the clinical outcomes and mental health of patients with chronic hand and foot eczema during a 60-week study period.

Methods: Patients in the intervention group participated in an educational program focused on chronic hand and foot eczema at baseline and had in-person visits at weeks 0, 12, 24, 36, and 60, as well as access to our study smartphone app. The app allowed patients to upload pictures of their hands and feet and answer questions about pain severity, itching, mood, and quality of life. A chat function was also available for patients to contact their dermatologist. The control group received only the in-person study visits described above.

Results: A total of 87 patients were included in the study and randomized to the intervention (n=43) or control (n=44) groups. In total, 23 patients from the intervention group and 34 patients from the control group completed the study. Throughout the 60-week study period, a significant reduction in Hand Eczema Severity Index (HECSI) was consistently observed in all patients (week 60: linear regression coefficient [Coef]=–1.108; $P \leq .001$). A trend toward a greater improvement of the HECSI in the intervention group compared to the control group was noticed (week 60: Coef=0.597; $P=.05$). Subgroup analysis revealed that patients who used the app with a usage frequency of less than 20% demonstrated a significant reduction in the HECSI from week 0 to week 60 (week 60: Coef=–1.275; $P=.04$) and a significant reduction in the Dermatology Life Quality Index (week 60: Coef=–1.246; $P=.04$) compared to the control group. We were able to demonstrate a significant correlation between the HECSI calculated based on pictures uploaded by patients through the app and the HECSI assessed during personal visits ($\rho=0.885$; $P<.001$), despite the potentially lower image quality of the pictures uploaded through the app.

Conclusions: This study provides further evidence that digital health apps can provide valuable support in improving patient clinical outcomes and management, especially as the app-based assessment of hand and feed images appears to be reliable.

Introduction

Hand eczema is one of the most common dermatologic conditions responsible for a very large proportion of dermatological consultations. According to a systematic review and meta-analysis, the 1-year prevalence is estimated to be 9.1% in the general population [1].

The probability of developing hand eczema at least once in a lifetime is 17% [2]. This likelihood varies greatly depending on occupational groups. Occupations that involve a lot of manual labor or chronic exposure to mild toxins or irritants, such as hairdressers and bricklayers, have a higher chance of developing hand eczema at least once in their lifetime [2]. The incidence of the disease is currently on the rise due to improved hygiene standards, increased life expectancy, and more frequent atopic predisposition [2].

Hand eczema is considered chronic if it lasts longer than 3 months or is recurrent more than twice a year [3]. Clinical manifestations are usually highly variable. In the acute stage, macules, papules, edema, vesicles, or even bullae may appear, whereas in the chronic stage, scales and crusts, hyperkeratosis, rhagades, and lichenification prevail [4]. These skin lesions can cause itching, burning, and pain, thereby leading to sleep disturbances and mood changes [5]. Chronic hand eczema is of high health-economic and sociomedical importance, as this diagnosis is responsible for many cases of prolonged sick leave and avoidance of social and public life [4,6]. In particular, the hands are an important organ of communication that is difficult to conceal from the public. Stigmatization thus causes significant psychosocial distress and a reduction in quality of life [7,8].

As hand and foot eczema is an intermittent disease, it is often our clinical experience that patients miss the optimal time to seek medical attention. Appointments are frequently not available on short notice, leading to patients presenting with very vigorous symptoms. This highlights the need for an easily accessible alternative for people with chronic hand and foot eczema such as a digital health app.

Germany recently launched the directory for Digital Health Applications (DiGA), which lists Conformité Européenne–marked medical devices. These apps are approved by the Federal Institute for Drugs and Medical Devices and are designed to improve patient outcomes through digital means, offering support in managing medical conditions, tracking symptoms, and providing tailored care plans. Such DiGA can be prescribed by the doctor and are paid by German health insurance companies. Although chronic hand and foot eczema is a dermatological disease easy to monitor through pictures taken by the patients, there are currently no specific DiGA available that offer support for these patients [9]. Furthermore, to the best of our knowledge, scientific data on the beneficial effects of DiGA for patients with hand and foot eczema is limited. This lack of evidence highlights a critical need for further research, especially given the prevalence of these conditions.

We developed a monitoring app for patients with chronic hand and foot eczema, enabling them to regularly photograph their condition and answer disease-specific questions. The app also facilitated teledermatology appointments tailored to individual patient needs.

To evaluate the effectiveness of this tool for chronic hand and foot eczema, we conducted an interventional study comparing a control group (without the app or educational program) with an intervention group over a 60-week period. Interim results from a 24-week analysis already showed an improvement in quality of life [10].

The main objective of the 60-week study was to assess the impact of regular physician-patient interactions and a prestudy educational program on disease progression, quality of life, and overall patient outcomes over the long-term period of 60 weeks.

Methods

Study Design

This intervention study was undertaken at the Department of Dermatology, Venerology and Allergology at the University Medical Center Mannheim, Germany, between August 2018 and August 2021. This is the analysis of the data from the study weeks 0 (V0), 12 (V2), 24 (V3), 36 (V4), and 60 (V5). The inclusion criteria that had to be fulfilled by the patients in order to be eligible to participate in the study were (1) a physician-confirmed diagnosis of chronic hand and foot eczema, (2) possession of a smartphone and being able to use it, (3) an age between 18 and 75 years, as well as (4) the ability to provide informed consent. Exclusion criteria were the inability to provide informed consent and being younger than 18 years old or older than 75 years old. During the first study visit (V0), patients were randomly assigned to the control or intervention group in a 1:1 ratio by shuffling a deck of cards.

A total of 90 patients were included in the study. Of the total, 43 patients were in the intervention group, 44 in the control group, and 3 patients dropped out from the study before being assigned to the respective group.

The control group started the first visit at week 0. At the first visit, a detailed medical history including sociodemographic data and eczema-related data were collected. In addition, the Dermatology Life Quality Index (DLQI; 0-30) was assessed and the Hand Eczema Severity Index (HECSI; 0-36) was calculated. Using a numerical rating scale (0-10), each patient was asked how much the eczema negatively affects activities and mood, and how much the eczema currently itches or hurts. Face-to-face follow-up was performed at weeks 12 (V2), 24 (V3), 36 (V4), and 60 (V5).

XSL•FO
RenderX

In addition to this first face-to-face visit, the intervention group participated in an educational program. This 2-hour educational session provided patients with information on the etiology, pathogenesis, exacerbating factors, and treatment of chronic hand and foot eczema. It was conducted by experienced specialists in dermatology (AS and JB). The patients had the opportunity to exchange information with specialists. In addition, each patient in the intervention group received a personal anonymized access code to our app, Dermascope Mobile (DermaIntelligence GmbH), as well as instructions on how to use it. Screenshots of the app can be found in the article by Domogalla et al [11].

Participants were asked to take pictures of their eczema once a week through the app and answer questions about their current state of health, including their psyche, and complete questionnaires on quality of life (DLQI) and current symptoms. The app also had a chat function with which patients could contact their treating dermatologist. The app could not be used more than once a week.

Each image uploaded through the app was classified by us into good or bad quality depending on the sharpness of the image, the light conditions, and whether you could see the whole hand or foot or not. An image could only be rated as good if every criterion was positively evaluated. Based on these images, we calculated the electronic HECSI (eHECSI), which we then compared to the HECSI assessed in person.

Ethical Considerations

The Medical Ethics Committee of the Medical Faculty Mannheim, Heidelberg University approved the study (ethics approval 2017-655N-MA), and the implementation complied with the Helsinki Declaration. Informed consent was obtained from all participants before the study, and in the case of secondary data analysis, the original consent allowed for such use without requiring additional permissions. To protect privacy and confidentiality, all data were deidentified, with access restricted to authorized personnel. Participants received no compensation except from a good medical care, and no identifying information or images of individuals were included. The CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist can be found in Multimedia Appendix 1.

Statistical Analysis

Linear panel data regression analyses estimated outcome trajectories. Linear regression coefficients (Coef) used throughout the text describe the mathematical relationship between each independent and dependent variable, while *P* values indicate whether these relationships are statistically significant. Random effects regressions determined the main and interaction effects of group membership (intervention vs control) and visit time (V1, V2, V3, V4, and V5) on DLQI, pain, activities of daily living, and HECSI scores. In total, 2 adjustment models were calculated. The first model was unadjusted, whereas the second model was adjusted for sex, age, and disease duration. Additional analyses included the effect of app usage frequency over 60 weeks (group membership: control vs <20% app usage frequency vs ≥20% app usage frequency). Therefore, the intervention group was divided into 2 groups—one consisting of patients with app use frequency <20% and the other consisting of patients with app use frequency ≥20% during the 24-week observation period. The chosen cutoff of 20% corresponds to an app use frequency of once every 5 weeks. Variables were tested for normal distribution and, where appropriate, transformed to approximate normal distribution (power transformation of the square root of the DLQI and log10 of the HECSI). All statistical analyses were performed with Stata Special Edition (version 14.0; StataCorp).

Results

Patient Demographics

Of the 90 patients included in the study, 43 patients were in the intervention group and 44 in the control group (Table 1, Figure 1). In addition, 3 patients dropped out of the study before being assigned to the respective group. Furthermore, 57 patients completed the study and could be included in the final analysis, 23 patients were from the intervention group, and 34 were from the control group. The most common reasons for withdrawal were lack of time, improvement of local findings, or long distance to the clinic.

Figure 1. Flow diagram of the study cohort.

Comparison of Clinical Outcomes Between the Intervention and Control Groups

At the end of the 60-week study period, there was a reduction of pain in both groups compared to their baseline visits (week 60: Coef=–0.400; *P*=.53; Table 2, model 0). There were no significant differences between the control group and the intervention group (week×group: week 60: Coef=–0.175; *P*=.83; Table 2, model 0; Figure 2). The greatest reduction in pain in both groups was noted between week 12 and 24 (week 12: Coef=–0.478; *P*=.44; week 24: Coef=–0.739; *P*=.24; week 36: Coef=–0.608; *P*=.33; week 60: Coef=–0.400; *P*=.53; Table 2, model 0; Figure 2).

RenderX

Figure 2. Comparison of pain development between intervention and control groups over the 60-week study period (observant=290; n=57).

In terms of activity, we were able to demonstrate a significant reduction in impairment regardless of group membership (week 60: Coef=–2.712; $P \leq .001$; Table 2, model 0; Figure 3). No significant differences or changes in the course and development were observed between the control and intervention group (week 60: Coef=1.183; $P=.15$; Table 2, model 0; Figure 3).

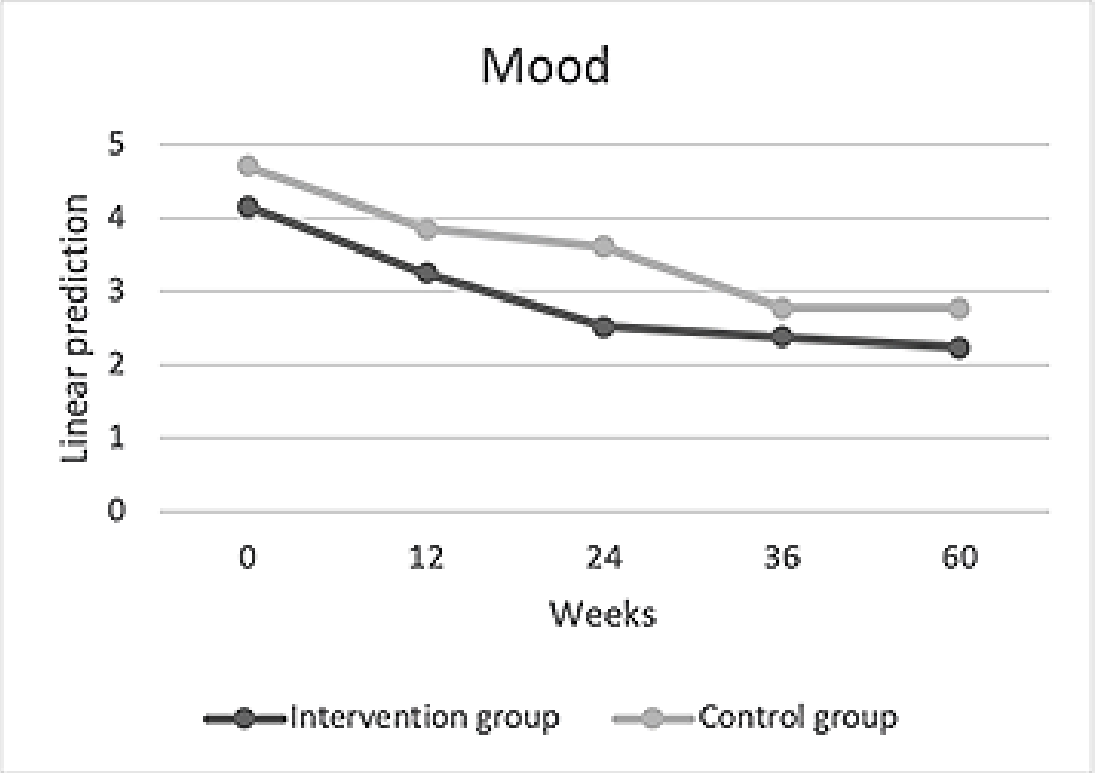

Figure 3. Activity development in the intervention group compared with the control group over the 60-week stud period (observant=290; n=57).

XSL•FO
RenderX

In addition, the mood of patients with hand and foot eczema was ameliorated in both study groups. Significant reductions in scores were observed in nearly all subsequent visits compared to baseline without significant differences between both groups (week 12: Coef=–0.913; *P*=.16; week 24: Coef=–1.652; *P*=.01; week 36: Coef=–1.782; *P*=.005; week 60: Coef=–1.924; *P*=.003; Table 2, model 0; Figure 4).

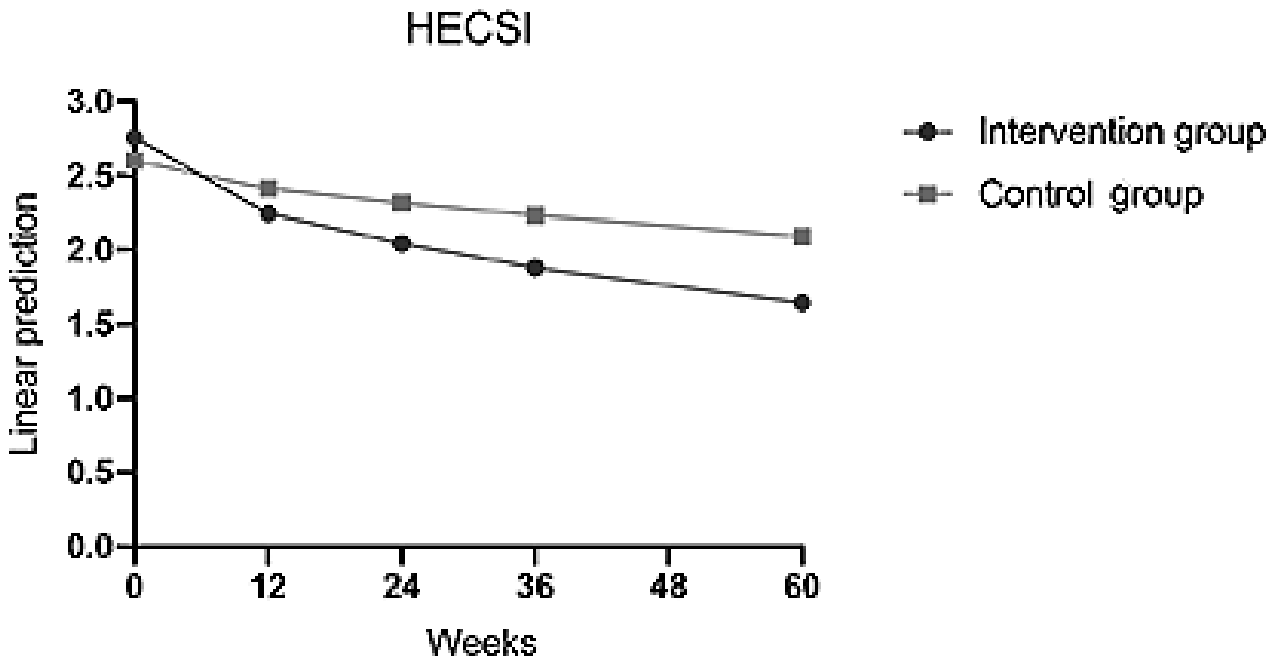

Figure 4. Mood development in the intervention group compared with the control group over the 60-week study period (observant=219; n=57).

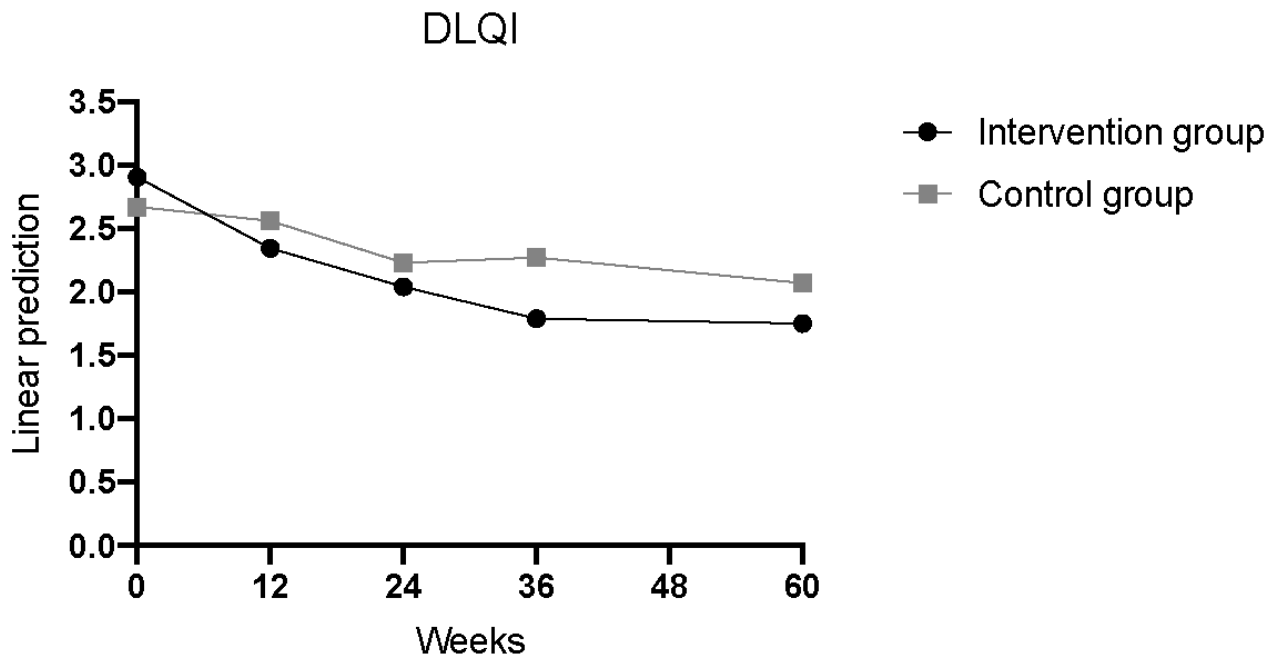
A significant reduction in HECSI scores was consistently observed across all patients over the course of 60 weeks, indicating substantial improvement compared to the initial assessment at week 0 (week 12: Coef=–0.512; *P*=.03; week 24: Coef=–0.715; *P*=.003; week 36: Coef=–0.873; *P*<.001; week 60: Coef=–1.108; *P*≤.001; Table 2, model 0; Figure 5). We observed a trend of greater improvement in the HECSI over time in the intervention group compared to the control group (week×control: week 36: Coef=0.509; *P*=.10; week 60: Coef=0.597; *P*=.05; Table 2, model 0; Figure 5).



XSL•FO
RenderX

Figure 5. HECSI development in the intervention group compared to the control group over the 60-week study period (observant=219; n=57). HECSI: Hand Eczema Severity Index.

A significant reduction in the DLQI was detected at any time in all patients (week 12: Coef= –0.560; *P*=.008; week 24: Coef=–0.855; *P*≤.001; week 36: Coef=–1.105; *P*≤.001; week 60: Coef=–1.152; *P*≤.001; Table 2, model 0; Figure 6). Starting from week 36, a notable and statistically significant improvement was noted in the intervention group compared to the control group (week×control: week 24: Coef=0.420; *P*=.12; week 36: Coef= –0.710; *P*=.009; week 60: Coef=0.553; *P*=.04; Table 2, model 0; Figure 6).

Figure 6. DLQI development in the intervention group compared to the control group over the 60-week study period (observant=219; n=57). DLQI: Dermatology Life Quality Index.

XSL•FO
RenderX

The findings did not differ for sex, age, and disease duration (matching coefficients and *P* values in Table 2, model 1).

App Usage Frequency Subgroup Analysis

For subgroup analysis, the intervention group was divided into 2 groups with patients using the app more or less frequently than once every 5 weeks, which equals an app use frequency of more or less than 20%. The frequency of app usage is measured solely by the actions of uploading images and completing the associated questionnaires. Messages sent to us through the chat function are not included in this count. The ability to ask questions and send messages was unrestricted.

Based on our data, the app usage frequency is influenced by gender (*P*=.006; Table 3) and age (*P*=.03; Table 3). Disease severity (HECSI) and itching had no impact on the frequency of app usage (Table 3). Women did use the app more often than men (women: 42/51, 82% vs men: 29/50, 58%; Table 3), and older women did use the app the most (mean age of women using the app more than 20%=54.787, SD 14.827 years and mean age of men using the app more than 20%=46.833, SD 15.099 years Table 4).

Table 3. Logistic regression of the app usage frequency subgroups ≥20% over 60 weeks (observant=101).

App frequency ≥20%	Odds ratio (95% CI)	SE	*P* value
Gender	4.309 (1.517-12.236)	2.294	.006
Age (V0[a])	1.041 (1.004-1.081)	0.019	.03
HECSI[b]	1.005 (0.609-1.657)	0.256	.99
Itching	0.812 (0.636-1.036)	0.101	.10

[a]The age refers to the age at the time of the first visit (V0).

[b]HECSI: Hand Eczema Severity Index.

Table 4. Two sample t test with equal variances that show which average age (V0) has used the app the most among those people with a frequency more than 20% app usage.

Age	Observants	Mean[a] (SD)	SE	95% CI
Men	30	46.833 (15.099)	2.756	41.194-52.471
Women	71	54.787 (14.827)	1.759	51.279-58.298
Combined	101	52.425 (15.276)	1.520	49.41-55.44

[a]Mean: mean age.

A significant reduction in terms of pain was assessed in patients using the app less than 20%, at weeks 12 and 24 compared to baseline, but this effect did not persist until week 60 when compared to the controls (interaction week×<20%; week 12: Coef=–2.958; *P*=.009; week 24: Coef=–2.972; *P*=.009; week 36: Coef=–2.581; *P*=.06; week 60: Coef=–1.711; *P*=.34; Table 5, model 1; Figure 7). Patients with an app usage frequency of more than 20% showed no significant reduction in pain over the study period (Table 5, model 1; Figure 7). Results were dependent on gender, age, and disease duration (Table 5, model 1).

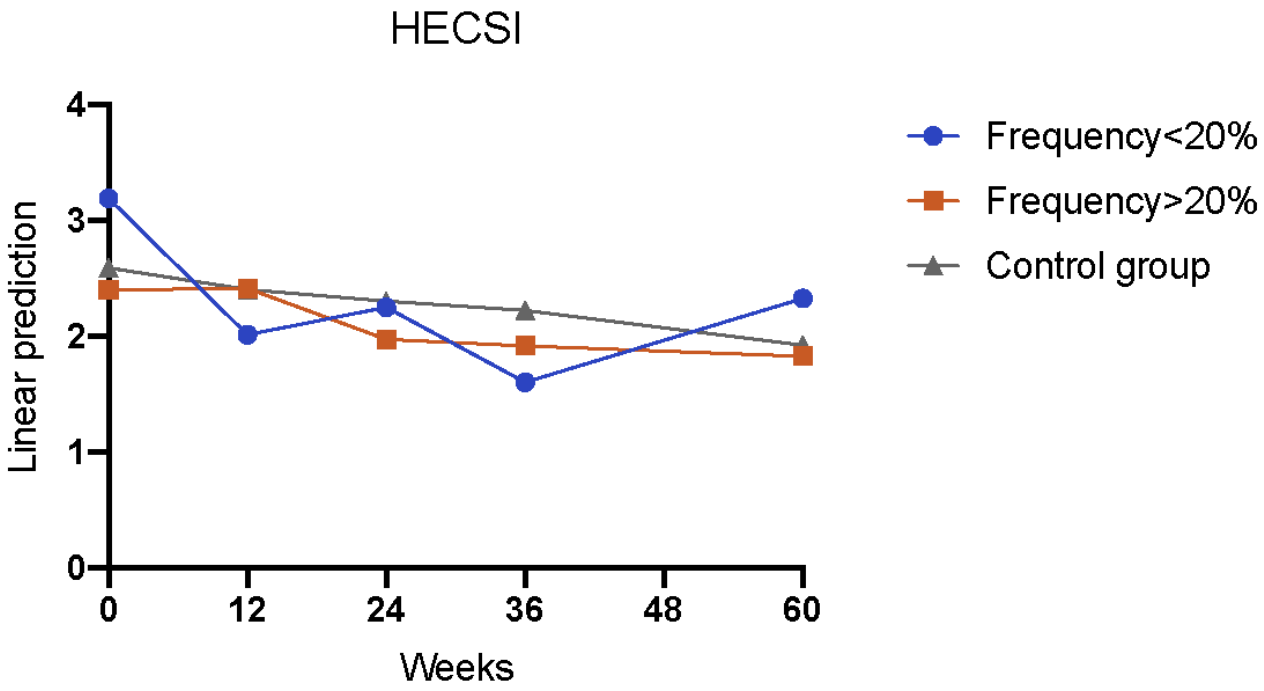
[a]HECSI: Hand Eczema Severity Index.

[b]DLQI: Dermatology Life Quality Index.

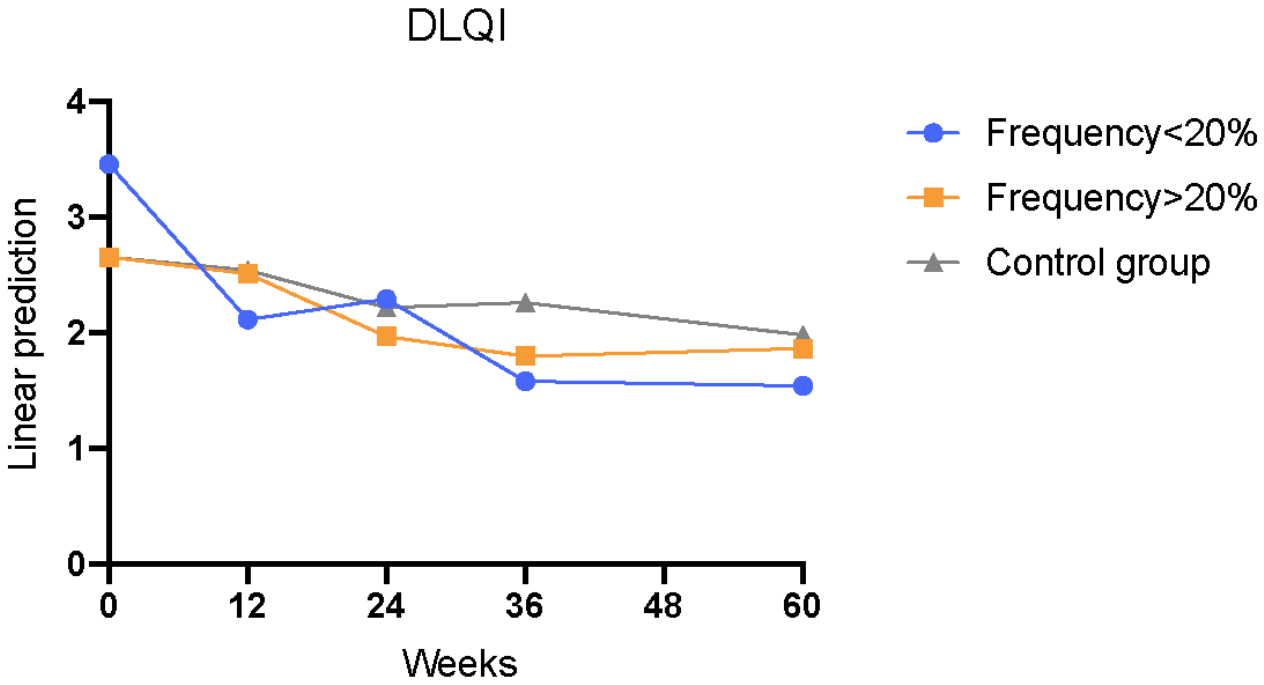


XSL•FO
RenderX

Figure 7. Development of the pain comparing the control to the intervention group (observant=290; n=57; interaction week×<20%: week 12: *P*=.009; week 24: *P*=.009; week 36: *P*=.009). NRS: numerical rating scale.

Patients who used the app less frequently than once every 5 weeks exhibited a consistent and statistically significant reduction in HECSI scores from week 0 to week 60, except for week 24, in comparison with the control group (interaction week×<20%: week 12: Coef=–1.234; *P*=.002; week 24: Coef=–0.732; *P*=.06; week 36: Coef=–1.500; *P*=.002; week 60: Coef=–1.275; *P*=.04; Table 5, model 0; Figure 8). Throughout the 60-week study period, no significant reduction in HECSI scores was found among patients who used the app more frequently than once every 5 weeks (Table 3, model 0; Figure 8).

Figure 8. Development of HECSI regarding the control versus the intervention group with <20% frequency usage versus ≥20% usage frequency (observant=290; n=57; interaction week×<20%: week 12: *P*=.002; week 36: *P*=.002; week 60: *P*=.04). HECSI: Hand Eczema Severity Index.



In addition, patients with an app usage frequency of less than 20% demonstrated a consistently significant reduction in DLQI scores throughout the entire study period, except for week 24. From the beginning to week 60, there was a significant improvement in DLQI scores (interaction week×<20%; week 12: Coef=–1.234; *P*=.002; week 24: Coef=–0.732; *P*=.06; week

XSL•FO
RenderX

36: Coef=–1.485; *P*=.002; week 60: Coef=–1.246; *P*=.04; Table 5, model 1; Figure 9). On the other side, no significant reduction was noticed in the group with app frequency of more than 20% (Table 5, model 1; Figure 9). Results were dependent on gender, age, and disease duration (Table 5, model 1).

Figure 9. Development of DLQI regarding the control versus the intervention group with <20% usage frequency versus ≥20% usage frequency (observant=290; n= 57; interaction week×<20%: week 12: *P*=.002; week 36: *P*=.002; week 60: *P*=.04). DLQI: Dermatology Life Quality Index.

A significant improvement in mood was also observed in patients with less than 20% app usage frequency at weeks 12 and 36 (interaction week×<20%; week 12: Coef=–0.990; *P*=.03; week 36: Coef=–1.289; *P*=.02; Table 5, model 0), consistent with the DLQI results.

No significant effects on activity and itching were noticed in patients with an app usage frequency of less or more than 20% (Table 5).

Comparison of Data Collected From the DLQI and HECSI Through the App Compared to Those Collected During Personal Visits

The intervention group was asked to upload a picture of the affected area on hands and feet once a week. Doctors then calculated the eHECSI based on the uploaded pictures. The eHECSI was compared to the HECSI documented in personal visits. The same applied to the DLQI and electronic Dermatology Life Quality Index (eDLQI).

The eHECSI was comparable with the HECSI obtained during in-person visits (ρ=0.885; *P*≤.001; Multimedia Appendix 2). The same was true for the DLQI as the DLQI and the eDLQI showed a strong correlation (ρ=0.474; *P*≤.001; Multimedia Appendix 2). The assessment involved evaluating image quality in terms of lighting, sharpness or focus, and completeness. Despite the presence of suboptimal image quality, the calculated eHECSI still demonstrated a strong correlation with the in-person assessed HECSI (for good quality: ρ=0.884; *P*<.001; for bad quality: ρ=0.901; *P*≤.001; Multimedia Appendix 3).

Discussion

Principal Findings

In this study, we investigated the effect of an educational program combined with a smartphone app on the clinical outcome and well-being of patients with chronic hand and foot eczema. Results of the interim analysis at week 24 have already been published and demonstrate the efficacy of our intervention in terms of improvements in patients' quality of life, pain levels, activity, and clinical outcomes [10]. The 60-week data presented here showed that the positive effects, particularly regarding quality of life and, to a lesser extent, clinical outcome, were maintained over 60 weeks. Therefore, the educational program combined with the app, which facilitates communication with the doctor through the chat function, seems to have positive long-lasting effects. The intervention may help patients cope better with the disease, understand it better, and ultimately adhere to treatment regimens. That educational programs lead to better outcomes in patients with hand eczema, is not new. Corti et al [12] retrospectively analyzed the records of 36 patients who participated in an educational program and showed that 67% (24/36) of patients with hand eczema benefited from the intervention, mainly due to behavioral changes regarding skin care and protection [12]. However, the follow-up visit was after 12 weeks, so long-term effects were not analyzed.

In our study, improvement in pain, activity, HECSI, and DLQI were observed in the whole study population. The improvement observed in both groups may be study related to the more intensive care of the patients by their dermatologists. Stewart

XSL•FO
RenderX

et al [13] showed that close doctor-patient contact and good communication between both parties have positive healing effects [13], which underlines the importance of the control group when evaluating the effect of an intervention such as an educational program or an eHealth device.

Regarding the frequency of use of the app, we were able to show that less frequent use of the app resulted in better outcomes, mood, and quality of life. The reasons for this unexpected finding may be multifaceted. First, patients may not want to be confronted with their disease on a regular basis. Similar results were observed in our previous study, which was a 60-week monitoring app intervention study focused on assessing patients with psoriasis. In the group that used the app less than once every 5 weeks, patients showed significant improvement in depression and anxiety symptoms as measured by the Hospital Anxiety and Depression Scale. The conclusion of this study highlighted the preference of patients with chronic diseases to avoid frequent reminders of their conditions [11]. We recently held a workshop with patients with psoriasis and asked them what features an app should have to make it worth using (unpublished data). Interestingly, one of the most important pieces of feedback was that the app should help save time in health care. Patients do not want to spend time filling out long questionnaires or documenting their disease but want an app that can be used according to their health needs. This should be considered when developing future patient-centered apps.

Interestingly, gender and age had an impact on the frequency of app use; especially older women were most likely to use the app. There could be several reasons for this observation. The fact that older people use the app more often may be explained by the fact that they have more free time than younger people who are still pursuing their careers. The paper by Rosales and Fernández-Ardèvol [14] examines the smartphone usage and app preferences of older individuals residing in Spain. Their findings indicate that older adults tend to use smartphones and smartphone apps in a more utilitarian manner. Specifically, they frequently access personal information manager apps, such as calendars, address books, and notes, more often than younger age groups. This highlights how older users prioritize and use apps that serve practical purposes in their daily lives [14]. Older women may have a higher motivation for diligent self-monitoring of their condition, leading them to use the app more regularly. It would also be interesting to investigate whether the design or usability of the app specifically met the needs of older women, which might explain their higher usage. Further research and analysis could contribute to a better understanding of this result and provide valuable insights for future studies and developments. In terms of gender differences, the study by Graziano et al [15] found notable gender differences in the relationship between parent-reported self-regulation skills and adolescents' management of type 1 diabetes. Specifically, among boys, it was observed that deficits in executive functioning and emotion regulation were significantly linked to poorer treatment adherence and glycemic control [15]. In another study examining the development of self-regulation in the first 4 years of life, it was found that girls exhibited higher levels of committed compliance compared to boys [16]. In general, there seem to be significant gender differences in the use of eHealth devices, which is also an important fact to consider in the development of health-related apps and needs further investigation.

In comparing the eHECSI obtained through photo documentation through the app with the in-person assessments during regular visits, we showed that the image quality uploaded in the app did not impact the objective assessment. Consistent results were found for both the eHECSI and the HECSI assessed in person. This suggests that even in cases where the image quality was not ideal, possibly due to the patient's camera or photography technique, the HECSI could still be effectively assessed. This is certainly not true for all dermatologic conditions, especially those that can affect the entire body, and highlights that hand and foot eczema is a perfect candidate for teledermatologic monitoring. The implementation of a monitoring app, possibly combined with artificial intelligence, could therefore have a huge socioeconomic impact, saving time not only for the patient but also for the health care system.

It is important to note that the dropout rate in the intervention group was relatively high (46.5%) compared to the control group (22.7%). The most important factor contributing to the high dropout rate in the intervention group was the educational program required of patients in the intervention group. At the beginning of the study, it was difficult to schedule a time for the intervention group to receive the training and introduction to the app. Some participants initially agreed to attend, but later either did not show up or canceled at short notice, especially since many participants lived several miles from the clinic, making attendance a significant challenge. Based on our experience, for future studies, online training sessions could potentially engage more participants who are unable to travel long distances or have only a few minutes to attend the training from home.

Limitations

The main limitations of our study are that the cohort became smaller over time and there is an imbalance in the number of patients in the groups. In particular, the number of patients in the intervention group became small over the 60 weeks of care, which may lead to misinterpretation of the results and differences between the 2 groups and the subgroup analysis. In addition, the patients in our study tended to be older, which means that it may be difficult to extrapolate the results to all age groups. In the scope of our app-focused study, a noteworthy limitation lies in our inability to disentangle the distinct effects of the educational program and the app within the intervention group. The intertwined nature of these 2 interventions makes it challenging to attribute the observed outcomes solely to 1 component. Further research could delve deeper into this aspect, potentially conducting separate investigations to better understand the individual contributions, interactions, and impact of the educational program and the app on our intervention group's outcomes. Further studies are needed to verify our results and findings in a larger patient population.

Conclusion

In summary, the combination of the educational program and the app had a clear positive influence on patients' mental

XSL•FO
RenderX

well-being and disease severity, particularly when the app usage frequency was moderate. It is worth noting that the app, when used in conjunction with in-person visits, contributed to the observed positive effects. Therefore, the app should be viewed as a supplementary tool and not a complete replacement for real-time medical consultations. As shown in the study by Baldwin et al [17], telemedicine can lead to a 75% reduction in outpatient clinic visits saving time for both patients and health care institutions. Teledermatology therefore offers the potential for a cost-effective supplementary health care approach, which should be integrated into the daily care of dermatological patients, especially in easy-to-monitor dermatological conditions such as hand and foot eczema [18].

Acknowledgments

We express our special thanks to the physicians and nursing staff of the Dermatology Department of the University Hospital Mannheim and to Novartis GmbH for their financial support of the study. All named authors and Novartis GmbH had full access to the study data.

Abstract

Background: Medication-related adverse events are common in pregnant women, and most are due to misunderstanding medication information. The identification of appropriate medication information sources requires adequate medical information literacy (MIL). It is important for pregnant women to comprehensively evaluate the risk of medication treatment, self-monitor their medication response, and actively participate in decision-making to reduce medication-related adverse events.

Objective: This study aims to examine the effectiveness of a medication education course on a web-based platform in improving pregnant women's MIL and decision self-efficacy.

Methods: A randomized controlled trial was conducted. Pregnant women were recruited from January to June 2021 in the Department of Obstetrics and Gynecology of a large hospital in a major city in central China. A total of 108 participants were randomly divided into a control group (CG), which received routine prenatal care from nurses and physicians, and an intervention group (IG), which received an additional 3-week web-based medication education course based on the theory of planned behavior as part of routine prenatal care. Participants completed a Medication Information Literacy Scale and a decision self-efficacy questionnaire at baseline, upon completion of the intervention, and at a 4-week follow-up. Generalized estimation equations (GEE) were used to analyze the main effect (time and grouping) and interaction effect (grouping×time) of the 2 outcomes. The CONSORT-EHEALTH (V 1.6.1) checklist was used to guide the reporting of this randomized controlled trial.

Results: A total of 91 pregnant women (48 in the IG and 43 in the CG) completed the questionnaires at the 3 time points. The results of GEE indicated that there was no statistically significant difference in time×group interactions of MIL between the 2 groups (F_2=3.12; P=.21). The results of the main effect analysis showed that there were statistically significant differences in MIL between the 2 groups at T1 and T2 (F_1=17.79; P<.001). Moreover, the results of GEE indicated that there was a significant difference in decision self-efficacy regarding the time factor, grouping factor, and time×group interactions (F_2=21.98; P<.001). The results of the simple effect analysis indicated a statistically significant difference in decision self-efficacy between the 2 groups at T1 (F_1=36.29; P<.001) and T2 (F_1=36.27; P<.001) compared to T0. Results showed that MIL and decision self-efficacy in the IG were found to be significantly higher than those in the CG (d=0.81; P<.001 and d=1.26; P<.001, respectively), and they remained significantly improved at the 4-week follow-up (d=0.59; P<.001 and d=1.27; P<.001, respectively).

Conclusions: Web-based medication education courses based on the theory of planned behavior can effectively improve pregnant women's MIL and decision self-efficacy, and they can be used as supplementary education during routine prenatal care.

KEYWORDS

decision self-efficacy; self-efficacy; decision efficacy; medication information literacy; information literacy; web-based medication education; medication education; web-based platforms; pregnant women; pregnancy; RCT; randomized controlled trial

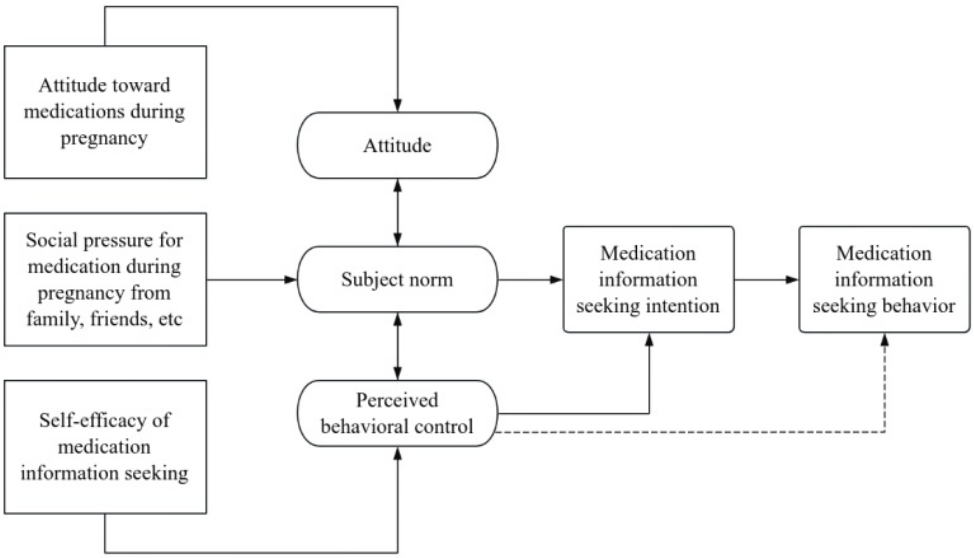
Introduction

Pregnancy is a unique and sensitive period, accompanied by a series of temporary physiological and metabolic changes, which can directly affect the absorption, distribution, metabolism, and excretion of drugs [1]. With the prevalence of medication use during pregnancy and the occurrence of more and more safety accidents during this period, the safety of medications used during pregnancy has been paid increased attention [2,3]. Previous studies have shown that medication exposure during pregnancy is related to adverse pregnancy outcomes (eg, cumulative toxicities in pregnant women, birth defects, or preterm birth) and has long-term effects on fetal development [4].

Overestimating the teratogenic risk of medication [5,6], misinterpreting medication-related information [7], unconfirmed information and exaggeration of adverse medication reactions on the internet [8,9], and a large amount of terminology and vagueness of precautions in instructions [10] can lead to women's confusion about medication use. This can increase the risk of optional medication withdrawal and exacerbate health conditions. Therefore, pregnant women not only need the ability to obtain appropriate medication information but also need to correctly interpret this information. They should be able to effectively distinguish the authenticity of medication information. This is influenced by medication information literacy (MIL) to some extent.

MIL refers to the information behavior related to medications, including the ability to seek, comprehend, identify, and use medication-related information [11]. This term combines medication literacy and information literacy, which is important for pregnant women to determine the risks of medication treatment and self-monitor medication reactions [12]. In addition, MIL represents the conceptualization of functional health literacy, emphasizing comprehensive, critical, proactive, and interactive capabilities and includes not only the demands identified, acquisition, understanding, evaluation, integration, and application of information but also medication information exchange, dosage calculation, and use of drug data to make smart health decisions [13]. Decision self-efficacy refers to self-confidence or a belief in one's ability to make decisions, including shared decision-making [14]. It is an important factor affecting individual coping ability, individual choice, and the motivation and effort of trying to achieve a set of goals [15]. Pregnant women with low levels of MIL and decision self-efficacy have difficulties in correctly interpreting medication information and accurately implementing medication instructions, which may be a predictor of adverse medication events [16].

A previous survey showed that the MIL of pregnant women in China was generally low, but the demand for medication information was strong [11]. Therefore, it is urgent to carry out targeted interventions to improve the MIL of pregnant women.



The theory of planned behavior (TPB) is used to help predict and explain health behaviors and guide intervention programs [17] and is one of the most famous theories used in interpreting attitude-behavior relations [17,18]. According to TPB, behaviors are jointly determined by attitude toward the behavior, subjective norms, and perceived behavioral control. Previous studies have revealed the influencing factors of medication compliance and health literacy of pregnant women through the TPB [19-21]. The application of TPB in this study is shown in Figure 1.

During the COVID-19 pandemic, web-based education played an important role in meeting the needs of pregnant women [22]. To a certain extent, web-based education also provided protective isolation for pregnant women [23]. At present, WeChat (Tencent) has become a major social media web-based platform in China and has also received widespread attention from pregnant women [24]. Because of its convenience, timeliness, and intelligence, WeChat has made great efforts in the field of prenatal education related to blood glucose management [25], weight management [26], nutritional intervention [27], and breastfeeding promotion education [24]. Among pregnant women, the feasibility and effectiveness of health education based on the WeChat platform have been highlighted.

This study was undertaken to offer a health education course on the WeChat platform to empower pregnant women with the ability to inquire about, use, and evaluate medication information to actively participate in medical decisions and consciously resist adverse medication behaviors. Therefore, it is hypothesized that the web-based medication educational course would be effective in improving pregnant women's MIL and decision self-efficacy.

XSL•FO

Figure 1. Application of the theory of planned behavior in this study.

Methods

Study Design

This study is a parallel randomized controlled trial delivering an additional 3-week web-based course about MIL to the intervention group (IG) with a 4-week follow-up. Pregnant women were recruited by convenience sampling from January to June 2021 in the Department of Obstetrics and Gynecology of a large hospital in a major city in central China. The study was registered in the Chinese Clinical Trial Registry (ChiCTR2100041817).

Feasibility Trial

In order to explore the feasibility of a 3-week web-based course based on TPB, the researcher conveniently selected 10 pregnant women who met eligibility criteria in the department mentioned above from November to December 2020, for a feasibility trial. Based on the feedback of the pregnant women, the intervention program was further improved to the formal version. Participant's completion of the interventions, attendance, and absences were recorded. Retention, compliance, and adherence rates were calculated.

The feasibility trial was well attended, all participants were engaged, interested in the course, and endorsed the intervention adaptations as culturally appropriate. All participants at session one indicated a desire to attend the remaining sessions, and 8 participants completed all the sessions, for an 80% adherence rate. However, only 7 of the women who attended all the sessions completed the questionnaire after the intervention, for a 70% retention rate. A number of barriers to attendance were identified as family obligations, the need to travel, and work obligations.

Participants

Inclusion and Exclusion Criteria

Inclusion criteria were: primipara, at 24 weeks or less of gestation, reads and speaks Mandarin, is able to complete a questionnaire independently, agrees to take part in an education course, and has access to the WeChat platform. Exclusion criteria were: current participation in other research on similar topics and health care workers. In selecting the inclusion criterion of 24 weeks of gestation or less for primiparas, we considered multiple factors to ensure the validity and practicality of our study. One significant reason is that after 24 weeks, there is an increased likelihood of premature delivery, which could lead to participants dropping out of prenatal classes prematurely. This would not only disrupt the continuity of the intervention but also introduce bias by excluding those who might have experienced premature birth. By focusing on primiparas at or before 24 weeks, we aimed to minimize such dropouts and maintain a more homogeneous study population that could fully benefit from and complete the intervention program. This approach allowed us to accurately assess the intervention's impact without any confounding effects of early termination due to premature.

Sample Size

The sample size was calculated according to the formula

using a power of 0.8 and an α of 0.05, Z_{α}=1.96 and Z_{β}=0.84, as used in similar research [11], σ=8.22 and δ=6.00. The study required a minimum sample size of 29 (each group). Considering a 15% attrition rate, a minimum of 68 participants were needed for the study.

Procedures

Recruitment

Women meeting eligibility criteria were invited to participate. The researcher explained the purpose of the study and informed that participation in the study was voluntary and that no prejudice would result from nonparticipation, termination, or withdrawal from the study. After all questions about the study were answered, participants were invited to sign an informed consent form.

XSL•FO
RenderX

Randomization and Blinding

Eligible participants were randomly assigned to the IG and the control group (CG) using a third-party organization [28]. The results of random allocation were placed in an opaque envelope. The researchers did not interfere with the random assignment, but, after allocation, the nature of the intervention made it difficult to blind participants and researchers.

Interventions

Participants in the CG received routine prenatal outpatient care from a physician. At the same time, they were contacted by the researchers upon initial enrollment in the study but received no further education courses.

Participants in the IG were offered an additional 3-week web-based course to improve MIL (Table S1 in Multimedia Appendix 1). The course was designed based on TPB [19] and used content from Drugs for Pregnant and Lactating Women [29] and the Risk Classification Systems of the US Food and Drug Administration [30]. The course focused on medication sensitivity during pregnancy, the popularity of essential medication, individual and social attitudes, and understanding, seeking, and evaluating medication information. The course arrangement was modified following the recommendations of pharmacists, obstetricians, and registered nurses. Feedback from study participants led to adjusting the course schedule to better meet the medication information needs of the women.

The web-based health education course consisted of 2 parts: an education module and a consultation module. The education module was delivered using the WeChat official account (Maternal and Child Guardian). Teaching strategies used in the course included both visual and auditory. Taking into account the concentration ability of pregnant women, each class was 15 minutes in length [31]. For the consultation module, the researchers established a WeChat group (individual account). Recent informational studies were shared with group participants every evening. A group chat was conducted weekly to review information and obtain feedback. In addition, participants were encouraged to contact researchers privately to ask questions, which would be answered within 24 hours. At follow-up, participants could review classes repeatedly. After 4 weeks of follow-up, an electronic questionnaire was sent to participants via the WeChat platform.

Instrument

Sociodemographic Characteristics and Medication Use Questionnaire

Sociodemographic information included age, ethnicity, education level, location of residence, profession, household monthly income (in RMB), and gestational weeks. The medication use questionnaire included: (1) How many acute illnesses (such as fever and cold) did you have during pregnancy? (2) Have you ever used medications due to acute illnesses (such as fever and cold) during pregnancy? (3) How many chronic diseases did you experience during pregnancy (such as gestational hypertension, gestational diabetes, and coronary heart disease)? (4) Have you taken any medication for your chronic disease (such as gestational hypertension, gestational diabetes, and coronary heart disease) during pregnancy? (5) How many over-the-counter medications did you take during pregnancy?

Medication Information Literacy Scale

The Medication Information Literacy Scale (MILS) is designed to assess the MIL of pregnant women. It uses a 5-point Likert scale and consists of 22 items, including the 5 dimensions of medication information needs, medication information sources, medication information quality discrimination, medication information source awareness, and medication-taking behavior [11]. The MILS is scored by totaling the scores of all items. A higher score indicates a higher level of MIL. Pregnant women with scores below the threshold (80% of the total score) are considered to have insufficient MIL [32]. In this study, the Cronbach α coefficient of the total scale was 0.761 and the subdomains were approximately 0.564-0.824 [11].

Decision Self-Efficacy Scale

The decision self-efficacy scale, also called the decision confidence scale, is used to measure one's confidence in making decisions, including the ability to take part in joint medical decisions. The scale consists of 11 items with a 5-point scoring system (0=not confident at all to 4=very confident) [14]. A higher score is associated with a higher level of self-efficacy [33]. The Cronbach α coefficient was 0.92 [33].

Data Collection and Analysis

Data collection was divided into 3 points: pretest at baseline (T0), immediately after the intervention (T1), and at 4 weeks follow-up (T2). The basic information questionnaire was only assessed at T0. The MILS and the decision self-efficacy scale were measured at T0, T1, and T2 using web-based questionnaires. To ensure the quality of the electronic questionnaires, the researchers stipulated that each participant had only one opportunity to submit the questionnaire, and incomplete questionnaires were not accepted.

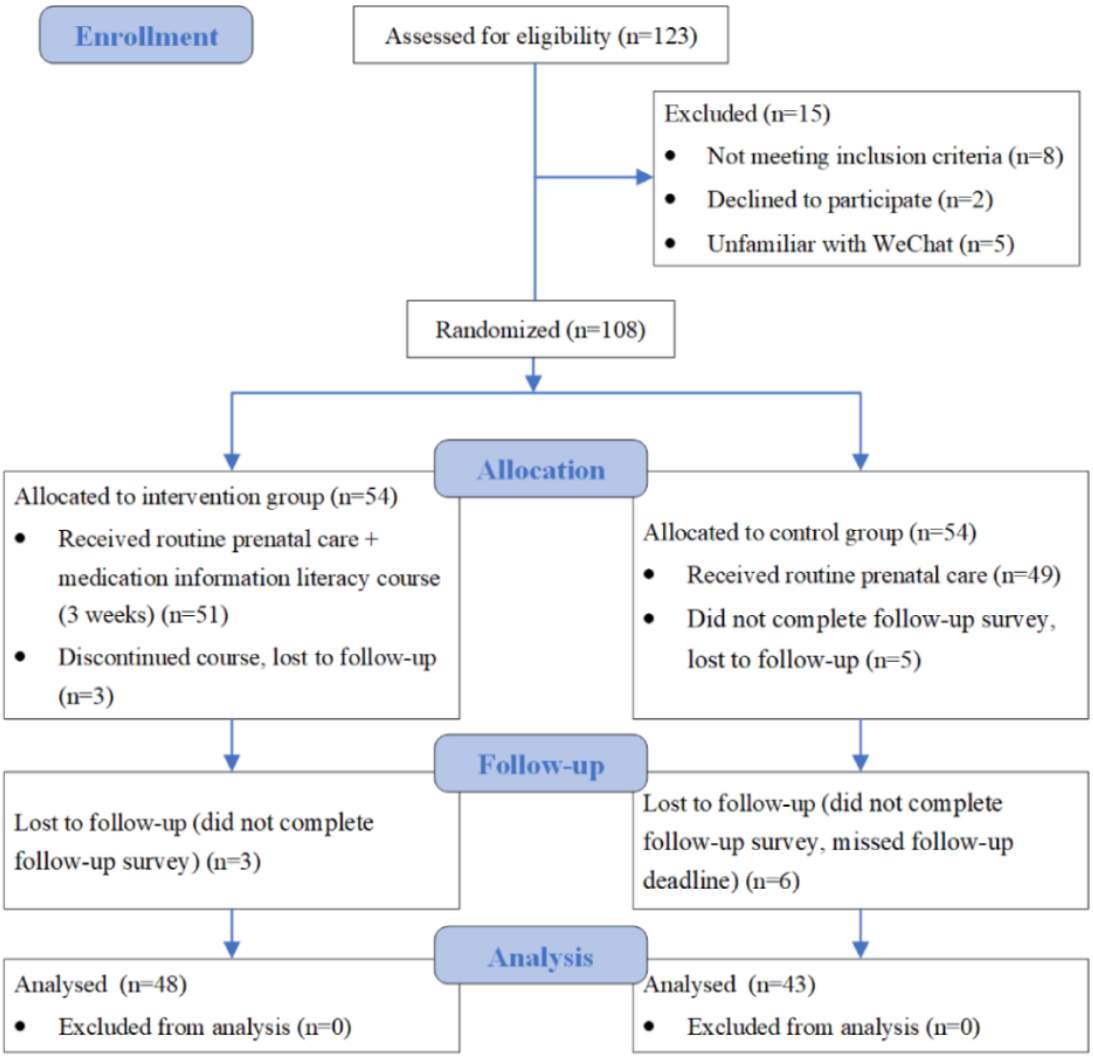
Two-sample 2-tailed *t* test and chi-square test were used to compare the difference at baseline between the 2 groups. In addition, 1-way ANOVA analysis and independent 2-tailed *t* test were used to explore the influencing factors of MIL and decision self-efficacy. Data from the MIL and decision self-efficacy scales at T0, T1, and T2 were tested using generalized estimation equations (GEE). Data at T1 and T2 were added as the outcome and data at T0 were added as covariates. Time points and groups were added as independent variables. The effect of time, group, and time×group were analyzed. If the interaction effect of the time×group was not significant, the main effect analysis was performed; and if the interaction effect of the time×group was significant, the simple effect analysis was performed. Cohen *d* was used to evaluate the magnitude of the difference between the 2 groups. According to the standard established by Cohen, the large, medium, and small effects of *d* was divided into 0.8, 0.5, and 0.2 [34]. Missing values were replaced by the mean value if the missing items were less than 10% of the entire items in one scale, while the mean values were deleted if the missing items were more than 10% [35]. Data were entered in the SPSS (version 22.0; IBM

XSL•FO
RenderX

Corp) and a 2-tailed *P* value of <.05 was considered statistically significant.

Ethical Considerations

This study was approved by the Medical Research Committee of Wuhan University Medical College (2020YF0083), and informed consent was obtained before any study procedures. All participants were informed of the right to withdraw voluntarily. Data were maintained confidential and participants were allowed to complete the questionnaire or scale anonymously. Complying with the report's comprehensiveness and authenticity, no data tampering or concealing of adverse results occurred. Maintaining the fairness principle, the CG was entitled to participate in the education course at the end of the study. Participants did not receive compensation for their participation.



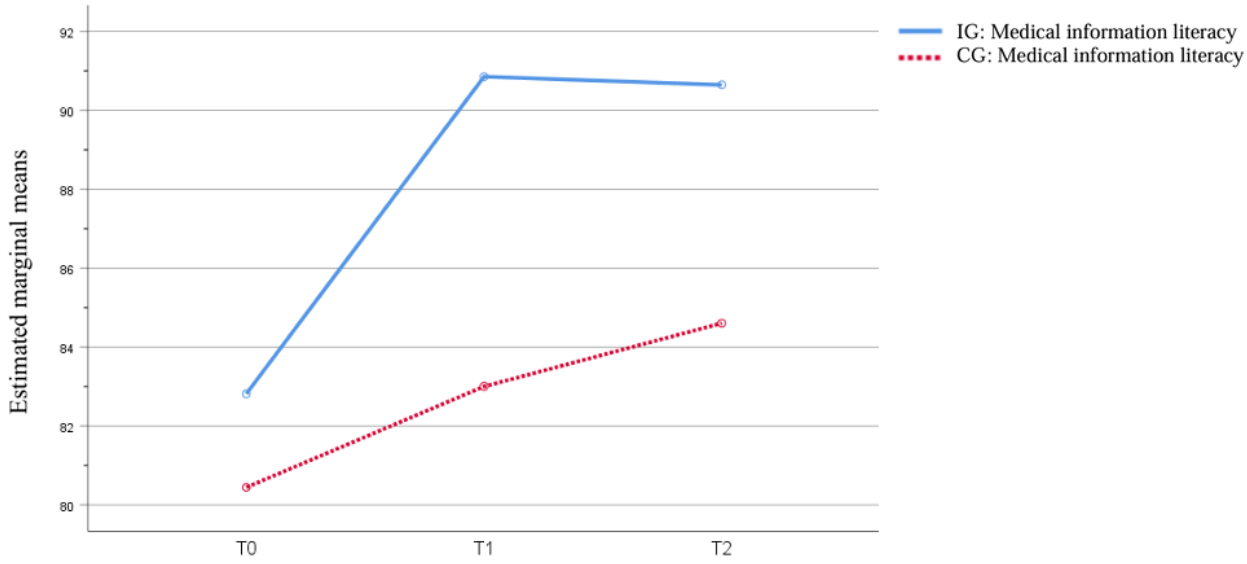
Results

Baseline Characteristics of Participants

In total, 108 participants completed the baseline test. Their average age was 29.46 (SD 5.03) years, and the average gestational week was 18.31 (SD 2.76). There was no significant difference between the 2 groups regarding sociodemographic characteristics, medication use, MIL, and decision self-efficacy at baseline (*P*>.05; Table S2 in Multimedia Appendix 1). Among the 2 groups, the average scores of MIL and decision self-efficacy were 81.00 (SD 10.94) and 22.31 (SD 4.43), respectively, and only 31% of participants had sufficient MIL. The implementation and data collection process are presented in Figure 2. The CONSORT-EHEALTH (V 1.6.1) checklist was used to guide the reporting of this randomized controlled trial (Multimedia Appendix 2).

Regarding the influencing factors, ANOVA analysis showed that there were statistically significant differences in the MIL and decision self-efficacy of participants related to education levels (F_{107}=5.60; *P*=.001 and F_{107}=3.03; *P*=.03, respectively) and gestational weeks (F_{107}=0.80; *P*=.64 and F_{107}=2.45; *P*=.01, respectively).

Figure 2. CONSORT diagram study flow.



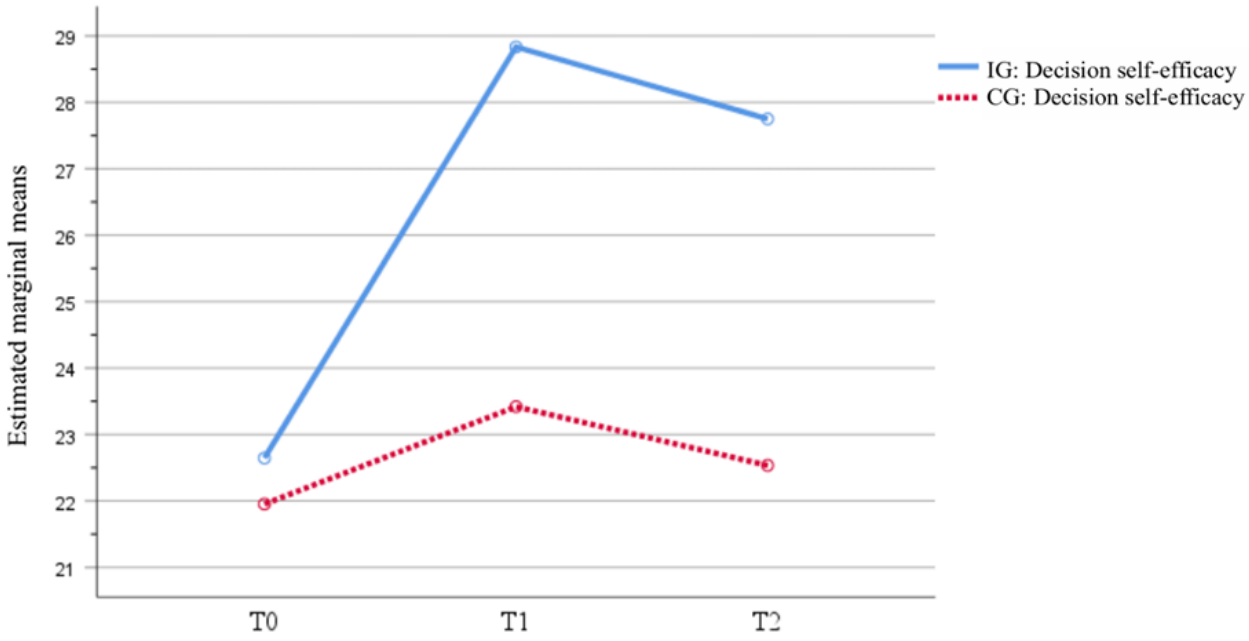
XSL•FO
RenderX

Primary Outcome: MIL of Participants

At baseline, MIL scores showed no statistically significant difference between the IG and the CG (Table S3 in Multimedia Appendix 1). The results of GEE indicated that there was no statistically significant difference in time×group interactions of MIL between the 2 groups (F_2=3.12; P=.21). Therefore, the main effects of the time and grouping factors were analyzed separately.

The results of the main effect analysis showed that there were statistically significant differences in MIL between the 2 groups at T1 and T2 (F_1=17.79; P<.001). The MIL of participants at T1 (mean difference 5.30, 95% CI 2.16-8.44; P<.001) and T2 (mean difference 6.00, 95% CI 2.80-9.20; P<.001) was significantly higher than at T0. Compared with the scores at T1, improvement in MIL in the follow-up phase was not as obvious, but it remained significantly improved compared to scores at T0 (Table S4 in Multimedia Appendix 1 and Figure 3).

Figure 3. Estimated marginal means of medication information literacy. CG: control group; IG: intervention group.



Secondary Outcome: Decision Self-Efficacy of Participants

At baseline, the scores on decision self-efficacy showed no statistically significant difference between the IG and the CG (Table S3 in Multimedia Appendix 1). The GEE results indicated that there was a significant difference in decision self-efficacy regarding the time factor, grouping factor, and time×group interactions (Table S4 in Multimedia Appendix 1 and Figure 4).

Since it was not meaningful to analyze the main effects of the time and grouping factors separately when the time×group interactions were significant (F_2=21.98; P<.001), the simple effect of time and grouping were analyzed. Results displayed in Table S5 in Multimedia Appendix 1 indicated a statistically significant difference in decision self-efficacy between the 2 groups at T1 (F_1=36.29; P<.001) and T2 (F_1=36.27; P<.001) compared to T0; and there was a statistically significant difference between the self-efficacy of the IG at T1, T2, and T0 (F_1=33.50; P<.001).

XSL•FO
RenderX

Figure 4. Estimated marginal means of decision self-efficacy. CG: control group; IG: intervention group.

The Effect Size of MIL and Decision Self-Efficacy

The results of Cohen *d* showed: (1) Compared with the CG, MIL of the IG had a large effect (*d*=0.81) at T1 and a medium effect (*d*=0.59) at T2. In addition, decision self-efficacy of the IG had a large effect (*d*=1.26 and *d*=1.27, respectively) at both T1 and T2. (2) Compared with T0, MIL had a moderate effect (*d*=0.76 and *d*=0.69, respectively) at T1 and T2, while decision self-efficacy showed a large effect (*d*=1.47 and *d*=1.24, respectively) at T1 and T2.

Discussion

Principal Findings

The results of this study suggest that the current web-based education based on the WeChat platform can improve the MIL and decision self-efficacy of pregnant women.

Studies estimating the effects of web-based medication education courses on MIL and decision self-efficacy in pregnant women are scarce. However, the current findings of the beneficial effects of web-based medication education in improving MIL and contributing to the safe use of medications are in line with a study that focused on older people [36]. In addition, it has been shown that decision self-efficacy can be improved through web-based education [37].

This study found that most pregnant women showed insufficient MIL which is in line with the study by Zhang et al [11], which revealed that the MIL of pregnant women was related to education level, residence, occupation, income, and gestational weeks. However, this research found that the MIL of pregnant women was related to their education level. This could be explained by the relatively small sample size. Current findings noted a significant improvement in MIL after 3 weeks of intervention.

Pregnant women's negative beliefs about medications have been emphasized in previous studies [38-40]. Negative attitudes toward medications were also related to lower levels of pregnancy-related knowledge [41]. At the same time, excessive anxiety caused by overestimating the teratogenic risk of medication was one of the important reasons for low medication compliance and even self-discontinuation [5,38]. Furthermore, in the research of Barnes et al [42], the use of medication has been confirmed to be related to an individual's religious and spiritual beliefs. According to previous findings, most respondents reported they needed more information about medication use and were concerned about inconsistent information from different sources [40,43]. Accordingly, this study developed a web-based medication education course in an attempt to change negative attitudes toward medication use among pregnant women, improve their medication beliefs, and strengthen their skills in obtaining, evaluating, and using medication information. The results of the study confirmed the effectiveness of this web-based course.

In this study, the average score of decision self-efficacy was much lower than that in Scaffidi et al's [15] study, which might be interpreted that participants in this study were primiparous women. Compared with the decision self-efficacy of older people in previous studies [37,44], the decision self-efficacy of participants in this study was relatively low, assuming that the uniqueness and sensitivity of pregnancy make it more difficult for pregnant women to make medication-related decisions. Moreover, in this study, it was found that the decision self-efficacy of pregnant women was related to education level and gestational weeks, which is consistent with a previous study [15]. Lack of sufficient knowledge is the major factor affecting women's decision-making [45,46]. The intervention in this study not only included the popularization of knowledge but also paid attention to the transformation of beliefs and improvement of skills to help pregnant women actively

XSL•FO
RenderX

participate in medical decision-making, as well as express their concerns. After the 3-week course, the decision self-efficacy of the IG was significantly improved. The improvement of health literacy has a positive effect on perinatal women's participation in medical decision-making [47]. The combination of effective communication skills and interactive health information technology is a potentially important exploration approach that can improve women's enthusiasm for participating in medical decision-making [45]. The results of this study confirm the effectiveness of improving decision self-efficacy by increasing the MIL of pregnant women.

Strengths

The overall attrition rate in this study was 16%. It may be related to the flexible class time and limiting each session to 15 minutes [31], which has been shown to improve the validity of research findings [48]. Overall, this study confirmed the effectiveness of the intervention content and the feasibility of web-based education, providing new ideas for improving MIL levels of pregnant women, especially those with limited access to health care resources in remote areas.

Limitations

There are limitations to this study. Due to geographical restrictions, this study recruited pregnant women from only a tertiary hospital in a large city in central China and 71% of the participants were from cities, which might lead to sampling bias and further limit the external validity of the results. It could also limit the generalizability of findings to other areas. In addition, this study was carried out in the context of the COVID-19 pandemic, such that a potential impact on medication behavior cannot be excluded. Another limitation of this study centers on the researchers' inability to adequately monitor the time that participants spent completing the learning modules. The researchers sent daily course updates to the women to encourage participation, help focus on content areas, and improve learning outcomes. Other teaching-learning strategies should be explored.

At the 4-week follow-up, MIL and decision self-efficacy were found to have declined slightly. Extending the web-based course over a longer period, as well as the follow-up evaluation, could improve the retention of content and test its effect on maternal and fetal outcomes. Another limitation may be that most of the participants did not take medications during the intervention, thus, there was no exploration of the relationship between medication adherence and MIL.

Conclusions

Web-based medication education courses based on the TPB can improve pregnant women's MIL and decision self-efficacy. After receiving web-based education, the average score of MIL of pregnant women rose significantly. As a function of health literacy, the improvement of MIL is expected to reduce the occurrence of adverse medication events in pregnant women. Future studies are needed to explore the long-term effects of similar courses, as well as content retention. A combination of web-based and offline education is also worthy of further exploration in the MIL and decision self-efficacy of pregnant women.

Acknowledgments

This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors. We confirm that generative artificial intelligence was not used in any portion of the manuscript writing.

Data Availability

The data sets generated during or analyzed during this study are not publicly available because the data also forms part of an ongoing study but are available from the corresponding author upon reasonable request.

Authors' Contributions

SL wrote the manuscript and collected all the data. HJC provided data sources, conducted research project management, and guided research methods. JZ wrote the manuscript and made tables. YBZ conducted all statistical analyses, drew figures, and conducted copyediting. RW, JG, and YQO guided the discussion section. SRR guided language modifications. All authors reviewed the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Efficient emergency patient transport systems, which are crucial for delivering timely medical care to individuals in critical situations, face certain challenges. To address this, CONNECT-AI (CONnected Network for EMS Comprehensive Technical-Support using Artificial Intelligence), a novel digital platform, was introduced. This artificial intelligence (AI)–based network provides comprehensive technical support for the real-time sharing of medical information at the prehospital stage.

Objective: This study aimed to evaluate the effectiveness of this system in reducing patient transport delays.

Methods: The CONNECT-AI system provided 3 key AI services to prehospital care providers by collecting real-time patient data from the scene and hospital resource information, such as bed occupancy and the availability of emergency surgeries or procedures, using 5G communication technology and internet of things devices. These services included guidance on first aid, prediction of critically ill patients, and recommendation of the optimal transfer hospital. In addition, the platform offered emergency department medical staff real-time clinical information, including live video of patients during transport to the hospital. This community-based, nonrandomized controlled intervention study was designed to evaluate the effectiveness of the CONNECT-AI system in 2 regions of South Korea, each of which operated an intervention and a control period, each lasting 16 weeks. The impact of the system was assessed based on the proportion of patients experiencing transfer delays.

Results: A total of 14,853 patients transported by public ambulance were finally selected for analysis. Overall, the median transport time was 10 (IQR 7-14) minutes in the intervention group and 9 (IQR 6-13) minutes in the control group. When comparing the incidence of transport time outliers (>75%), which was the primary outcome of this study, the rate was higher in the intervention group in region 1, but significantly reduced in region 2, with the overall outlier rate being higher in the intervention group (27.5%-29.7%, *P*=.04). However, for patients with fever or respiratory symptoms, the group using the system showed a statistically significant reduction in outlier cases (36.5%-30.1%, *P*=.01). For patients who received real-time acceptance signals from the hospital, the reduction in the percentage of 75% outliers was statistically significant compared with those without the system (27.5%-19.6%, *P*=.02). As a result of emergency department treatment, 1.5% of patients in the control group and 1.1% in the intervention group died (*P*=.14). In the system-guided optimal hospital transfer group, the mortality rate was significantly lower than in the control group (1.54%-0.64%, *P*=.01).

XSL•FO
RenderX

Conclusions: The present digital emergency medical system platform offers a novel approach to enhancing emergency patient transport by leveraging AI, real-time information sharing, and decision support. While the system demonstrated improvements for certain patient groups facing transfer challenges, further research and modifications are necessary to fully realize its benefits in diverse health care contexts.

emergency patient transport; transport time; artificial intelligence; smartphone; mobile phone

Introduction

Emergency patient transport plays a critical role in providing timely and appropriate care to individuals in emergencies [1]. By swiftly and safely transporting patients to the nearest health care facility equipped to handle their specific needs, it helps to improve their chances of receiving timely medical intervention and contributes to better patient outcomes [2]. On the contrary, delays faced by the emergency medical services (EMS) in transport of patients to health care facilities can result in increased patient morbidity, mortality, and complications [3-5]. Ambulance diversion, a major factor delaying patient transport, is a practice in EMS where an ambulance is redirected from its original destination hospital to another medical facility [6,7]. Ambulance diversion typically occurs when the emergency department (ED) of a hospital is temporarily unable to accept new patients due to high patient volumes, lack of available beds, or other capacity constraints [8,9]. As the demand for medical services increased with the COVID-19 pandemic, ambulance diversions became more frequent [10,11]. Eventually, as cases of severely ill patients dying in ambulances without being able to get to the ED became more common in Korea, the country amended its Emergency Medical Services Act to prohibit emergency medical institutions from refusing to accept critically ill emergency patients.

Along with securing a transfer hospital as soon as possible, it is crucial to provide accurate information about the condition of the patient to the medical staff of the ED to which they will be transferred in order to provide optimal treatment [12-15]. In addition to the most basic clinical information such as their main symptoms, blood pressure, and state of consciousness, information on interventions performed by the prehospital care provider on-site or during transport (eg, oxygen administration, intravenous fluids, medications, or immobilization techniques) and time stamps (eg, time of the report, arrival at the site, and time at which treatment was performed) help the receiving ED medical staff to prepare for the arrival of the patient and deliver appropriate care [16,17]. However, in most prehospital phases, the transmission of patient information between prehospital care provider and ED medical staff mainly relies on telephones, and comprehensive information cannot be sufficiently delivered, leading to a potential risk of communication errors such as mishearing [18,19].

With the rapid development of digital information devices such as tablets and smartphones, various medical information systems are being introduced to EMS and emergency medical institutions [18-21]. These technologies allow prehospital care providers in the field to find hospitals with available resources and ED medical staff to receive patient information in real-time to provide medical services in continuity through mobile phones [18,19]. The use of these technologies is expected to enhance communication and data sharing between prehospital care providers and ED medical staff, ensuring a smoother transition of care and improving patient outcomes. However, the evidence is insufficient, and the process has not yet been widely commercialized.

We developed a new medical information system called CONnected Network for EMS Comprehensive Technical-support using Artificial Intelligence (CONNECT-AI). CONNECT-AI system used voice and image recognition technology for real-time sharing of information at the prehospital stage. It also included AI algorithms that supported first aid by prehospital care providers and the selection of transfer hospitals, as well as a platform that shared information and videos of patients being transported to the ED in real time. This study aimed to report on the development of the CONNECT-AI system and to evaluate its effectiveness in reducing transfer delays and facilitating the timely transfer of emergency patients. Our hypothesis was that the implementation of this system would decrease the occurrence of transport delays for emergency patients.

Methods

Study Setting

The study was conducted in 2 geographically adjacent areas, each under the jurisdiction of different local fire departments: the northwest region of Seoul (region 1) and Goyang City in Gyeonggi-do (region 2). The demographic characteristics and the composition of the EMS in these 2 regions are detailed in Table 1. A total of 5 fire stations and 9 EDs participated in this study. Prehospital care providers working in the NFA (National Fire Agency) assessed patients' urgent conditions and, when necessary, performed a limited range of advanced care techniques in the prehospital setting. These techniques included administering intravenous fluids such as normal saline and glucose solution, placing advanced airways, and administering specific medications under the supervision of a medical director [22]. All patients assessed by prehospital care providers were transported to one of the EDs in accordance with the standard field first aid protocol developed by the NFA. This protocol included standardized first aid procedures and guidelines for selecting a hospital for transfer [23]. Prehospital care providers use their cell phones when they need to communicate with the

XSL•FO
RenderX

medical staff of EDs to select a transfer hospital. During the study period, prehospital care providers were supposed to check for isolation unit availability at EDs to which they transfer patients with febrile or respiratory symptoms in response to COVID-19 pandemic. Prehospital care providers are required to manually record the prehospital run sheets (PHRS) managed by the NFA using tablet devices.

Table 1. Demographic characteristics and composition of the emergency medical system of the 2 regions.

Characteristics	Region 1	Region 2
Area (square miles)	27.5	110.5
Resident population (million), n	11	10
Fire station, n	3	2
Ambulance, n	20	17
Emergency department, n (n)[a]

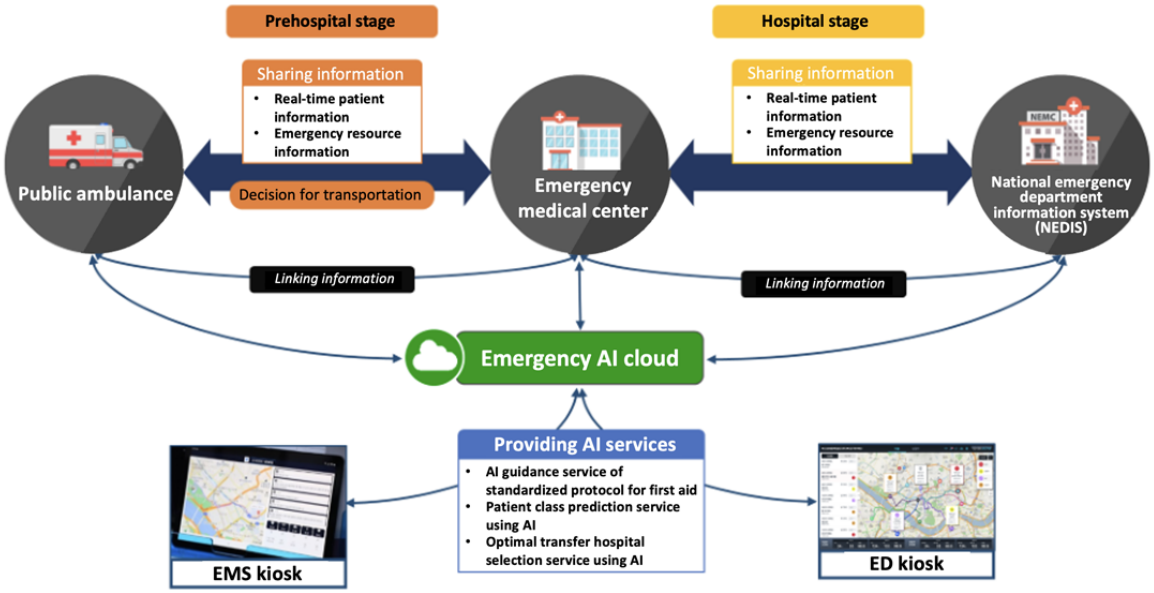
Level 2	3 (3)	2 (0)

[a]The number in parentheses indicates the number of emergency departments that participated in this study.

Study Design and Population

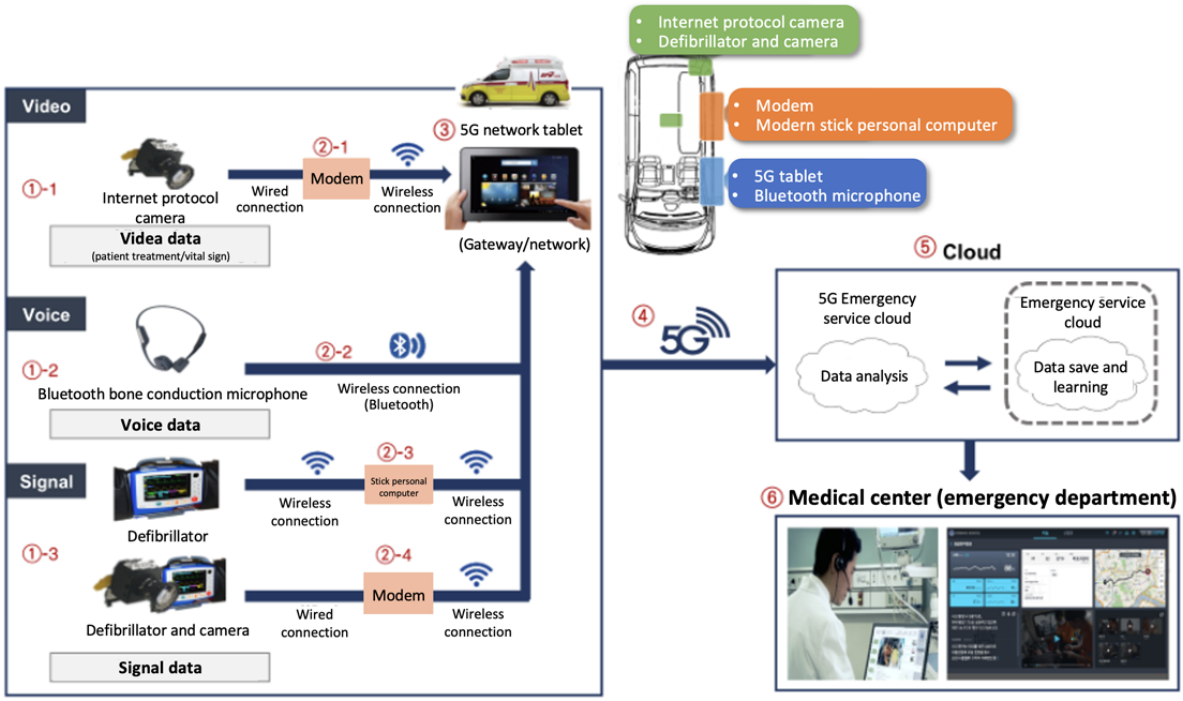
This community-based nonrandomized controlled intervention study with a blinded outcome assessment was designed to evaluate the effectiveness of the CONNECT-AI system for transporting patients by public ambulances in 2 communities (region 1 and region 2) that were selected as demonstration areas. The intervention group was defined as patients who were transported by public ambulance with an activated CONNECT-AI system, and the control group was defined as patients who were transported by public ambulance without an activated CONNECT-AI system (which is the same as the conventional practice). Public ambulances in region 1 underwent a 16-week intervention period beginning April 19, 2021, followed by a 1-week washout period and then a 16-week control period that ended on December 31. On the contrary, the public ambulances in region 2 had opposite intervention and control periods during the same time period.



During the study period, all patients transported by public ambulance in regions 1 and 2 to the 9 participating EDs were enrolled in the study. During the intervention period, all public ambulances in the regions were required to use the CONNECT-AI system, but if the situation was determined by prehospital care providers to be not appropriate for the use of the system, it was withdrawn, and the transported patients were excluded from the study. Patients were also excluded from enrollment if the ambulance had a special mission, such as transporting a person with COVID-19 infection or if the patient arrived at the ED but returned home or went to an outpatient clinic without treatment at the ED.

System Development and Protocol (Intervention)

The CONNECT-AI system captures all prehospital information in real-time through 5G communication technology and Internet of Things (IoT) devices. It provides 3 AI services on a cloud-based platform that can support the aids and decisions of prehospital care providers. The platform also enables medical staff in the ED to share real-time information in the prehospital setting before the ambulance arrives at the hospital. Furthermore, the present system can provide prehospital care providers with real-time information about ED crowding status and the availability of emergency medical resources at the hospital (Figure 1). This system collects patient information in real time from the transport scene during the prehospital stage using 5G communication technology and internet of things devices, while also gathering real-time data on emergency department crowding status and the availability of emergency medical resources from national emergency department information system. The collected information is processed through a cloud-based platform, providing 3 artificial intelligence (AI) services: standardized protocols for first aid, prediction of critical patients, and selection of the optimal hospital for transport. In addition, this platform enables real-time sharing of prehospital information with emergency department medical staff before the ambulance arrives at the hospital through emergency medical services kiosks and emergency department kiosks.



XSL•FO
RenderX

Figure 1. The overall architecture of the CONNECT-AI (CONnected Network for EMS Comprehensive Technical-Support using Artificial Intelligence) system. AI: artificial intelligence; ED: emergency department; EMS: emergency medical services.

To use the CONNECT-AI system, a networking device that can collect and communicate video, voice, and vital sign information with the hospital in real time through a digital platform was installed in all ambulances; a schematic representation of this data flow is shown in Figure 2.

Figure 2. The flow of multimodal data from the public ambulance to the emergency department.

Real-time video, audio, and patient vital sign data, collected from a Bluetooth bone conduction microphone worn by prehospital providers and from a camera and defibrillator installed in the public ambulance, are transmitted to the medical staff in the emergency department by the 5G emergency service cloud.

Before the intervention period, all prehospital care providers were trained to use the CONNECT-AI system through a 1-hour in-person lecture with hands-on training. During the intervention period, prehospital care providers wore equipment (bone conduction microphones and EMS kiosks) to use the system, in contrast to the control period when they followed traditional practice. The following 3 AI assistant services have been developed to support prehospital care providers in performing first aid that was appropriate to the patient's condition and to facilitate the transfer of the patient to the optimal hospital as quickly as possible: (1) AI guidance service of standardized protocol for first aid, (2) patient class prediction service using AI, and (3) optimal transfer hospital selection service using AI. Textbox 1 describes the details and purpose of the 3 AI assistant

XSL•FO
RenderX

services as compared with the current prehospital practice without the CONNECT-AI system. Previous research has introduced the algorithm used in the optimal transfer hospital selection service [22].

Textbox 1. Three artificial intelligence (AI) assistant services for prehospital care providers.

AI guidance service of a standardized protocol for first aid

- Service description: This service uses real-time patient information as an input to predict the treatment that should be performed on the patient at the hospital and outputs the results to the prehospital care providers.
- Current practice: Prehospital care providers use their experience and medical knowledge to assess patient severity.
- Expectancy of effects: Reduce the number of unpredictable, critically ill patients for inexperienced prehospital care providers.

Patient class prediction service using AI

- Service description: This service uses real-time patient information as input to predict the treatment that should be performed on the patient at the hospital and outputs the results to the prehospital care providers.
- Current practice: Prehospital care providers use their experience and medical knowledge to assess patient severity.
- Expectancy of effects: Reduce the number of unpredictable, critically ill patients for inexperienced prehospital care providers.

Optimal transfer hospital selection service using AI

- Service description: This service provides prehospital care providers with a real-time, prioritized list of hospitals that can provide predicted care, and allows for simultaneous requests for acceptance to multiple hospitals.
- Current practice: Prehospital care providers use their own judgment to determine the hospitals for transfer or use their cell phones to sequentially contact hospital medical staff to inquire about acceptance for transportation.
- Expectancy of effects: By using data communicated in real-time through the CONnected Network for EMS (emergency medical services) Comprehensive Technical-support using Artificial Intelligence system, prehospital care providers can quickly arrange the optimal hospital for a patient's condition.

The EDs in this study were equipped with kiosks to monitor the status of patients transported by public ambulance and to communicate with ambulances. This kiosk also allowed the physician in charge of the ED to monitor the real-time transport status of public ambulances enroute to the hospital, as well as information on available beds and emergency capacity in the ED (Figure 3).

Figure 3. Main screens provided by the emergency department kiosk, (A) a screen that monitors a patient's real-time transport status and displays the predicted severity of the patient, (B) a screen that shows the public ambulances that are currently on their way to the hospital, and (C) a screen of real-time emergency resource information that be available in hospitals with kiosks installed.

The medical staff were provided with 1-hour hands-on training on how to communicate with prehospital care providers in real time through the kiosk. During the control period, prehospital care providers used their cell phones to communicate the status of patients requiring transport to ED medical staff and to inquire about patient acceptance sequentially as a traditional practice.

XSL•FO
RenderX

In contrast, during the intervention period, the CONNECT-AI system provided prehospital care providers with a hospital list that was appropriate for the patient's condition and allowed the patient to be transferred without additional contact if the ED medical staff did not send an unacceptable message on the system. In cases where prehospital care providers determined they needed to transport to EDs that showed that they could not accept the patient, providers clicked a button on the EMS kiosk to simultaneously send a request for acceptance to these EDs; the transport was then performed when they received an acceptance signal from the ED (Multimedia Appendix 1).

Data Collection

In our study, prehospital stage information was obtained through the PHRS, which is electronically stored to provide basic prehospital operation information under the NFA. Data extracted from the PHRS included age, gender, past medical history, mental status, vital signs (blood pressure, pulse rate, respiratory rate, oxygen saturation, and body temperature), patient symptoms, and the first aid timeline. Mental status was assessed using the AVPU scale (A for awake, V for verbal response, P for pain response, and U for unresponsiveness). Hospital stage information was obtained from a dataset submitted by the participating medical institutions to the National Emergency Department Information System (NEDIS); this is a nationwide computerized system used to collect and analyze medical information of patients who visit EDs in South Korea, in accordance with the Act on Emergency Medical Care and managed according to the standardized protocol distributed by the National Emergency Medical Center [22]. Information on patient severity and ED treatment outcomes for those transported by public ambulance was extracted from the NEDIS. Patient severity was assessed using the Korean Triage and Acuity Scale (KTAS), a classification system used in EDs across Korea. The KTAS, derived from the Canadian Triage and Acuity Scale, is a 5-level classification system where 1 indicates resuscitation and 5 represents nonemergent cases [24]. Based on the linkage of these 2 main datasets, log records of events that occurred when prehospital care providers used the system during the intervention period were added by extracting them from a cloud-based digital platform.

Outcome

The primary outcome of our study is the proportion of outliers with long transport times among the transported patients. Transport time is defined as the period from the time the prehospital care provider left the scene to the time of arrival at the hospital. Patient mortality was defined as the death of a patient who was alive upon arrival but died during treatment in the ED.

Sample Size Calculation

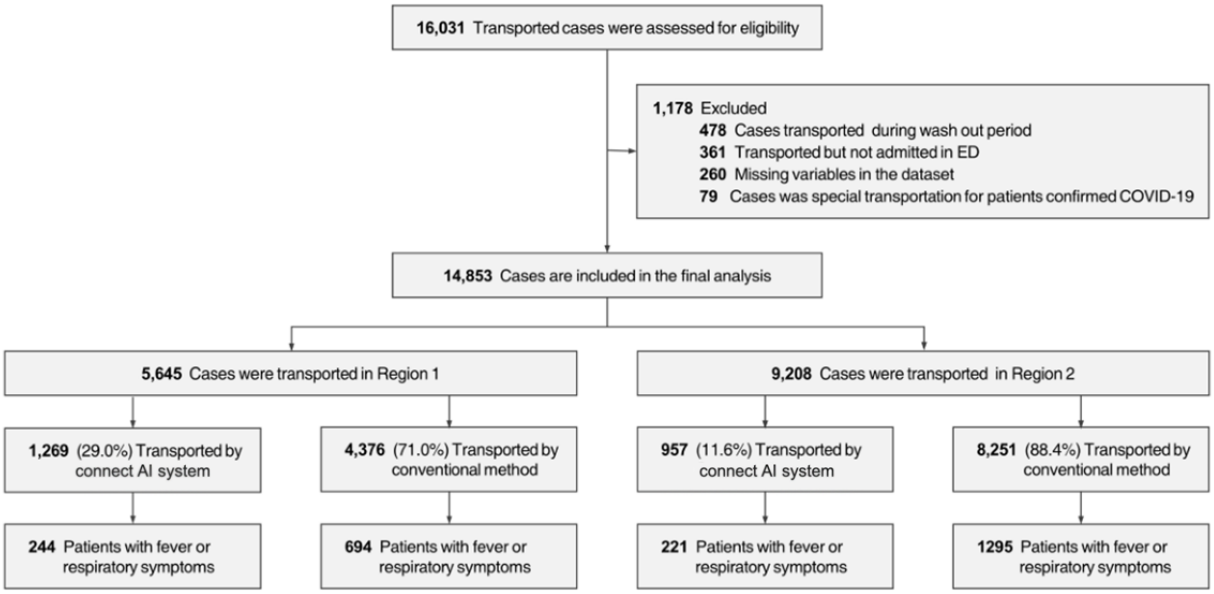
In 2018, the mean of transport times for one year were 21 (SD 10) minutes for region 1, 16 (SD 8) minutes for region 2, and 20 (SD 25) minutes overall. Based on these figures, the primary outcome of this study, transport time, was assumed to show an improvement of more than 10% (a 2-minute difference) when using the CONNECT AI system, compared with the conventional ambulance transport standard. The largest standard deviation of 25 minutes was conservatively chosen for calculations, and it was predicted that a statistical power of over 90% could be achieved. Since transport time is a continuous variable, the sample size was calculated based on a 2-sample *t* test, resulting in an estimate of approximately 10,000 cases. A proposal was made to the regional administrative authorities for a pilot period during which 10,000 transports were expected to occur, and this proposal was accepted by the regional administrative authorities.

Statistical Analysis

Continuous variables were expressed as mean values with standard deviations and compared between groups using the Student *t* test or Mann-Whitney *U* test. Categorical variables were expressed as frequencies and percentages and compared using the chi-square test. All tests were 2-sided, with a statistical significance of $P<.05$. All statistical analyses were performed using SAS software (version 9.4; SAS Institute).

Ethical Considerations

This community-based interventional study was performed in accordance with the revised Declaration of Helsinki and was approved by the institutional review board of Severance Hospital, South Korea on April 14, 2021 (approval number 4-2021-0217). This research was prospectively registered on ClinicalTrials.gov (NCT04829279). As the patient information covered by this study was within the scope of being provided by the NFA and the National Emergency Medical Center (NEMC) under the Ministry of Health and Welfare with personally identifiable information removed based on the law, informed consent from the patients included in the study was waived. However, as audio and video data of the prehospital care providers were collected and processed during the intervention, written informed consent for the use of this information was obtained from them voluntarily before the start of the intervention, and no material and financial compensation was provided for participation in the study.



Results

Population Characteristics

During the study period, there were a total of 16,031 patients transported by public ambulance who met the inclusion criteria. After excluding patients transferred during the washout period and those eligible for exclusion, 14,853 patients were finally selected for analysis. Of them, 1269 (29.0%) and 957 (11.6%) patients were included in the intervention group from regions 1 and 2, respectively (Figure 4). The baseline characteristics of the intervention and control groups are presented in Table 2. The proportion of the intervention group enrolled was higher in region 1 than in region 2. Febrile and respiratory symptoms were more frequent in the intervention group than in the control group.

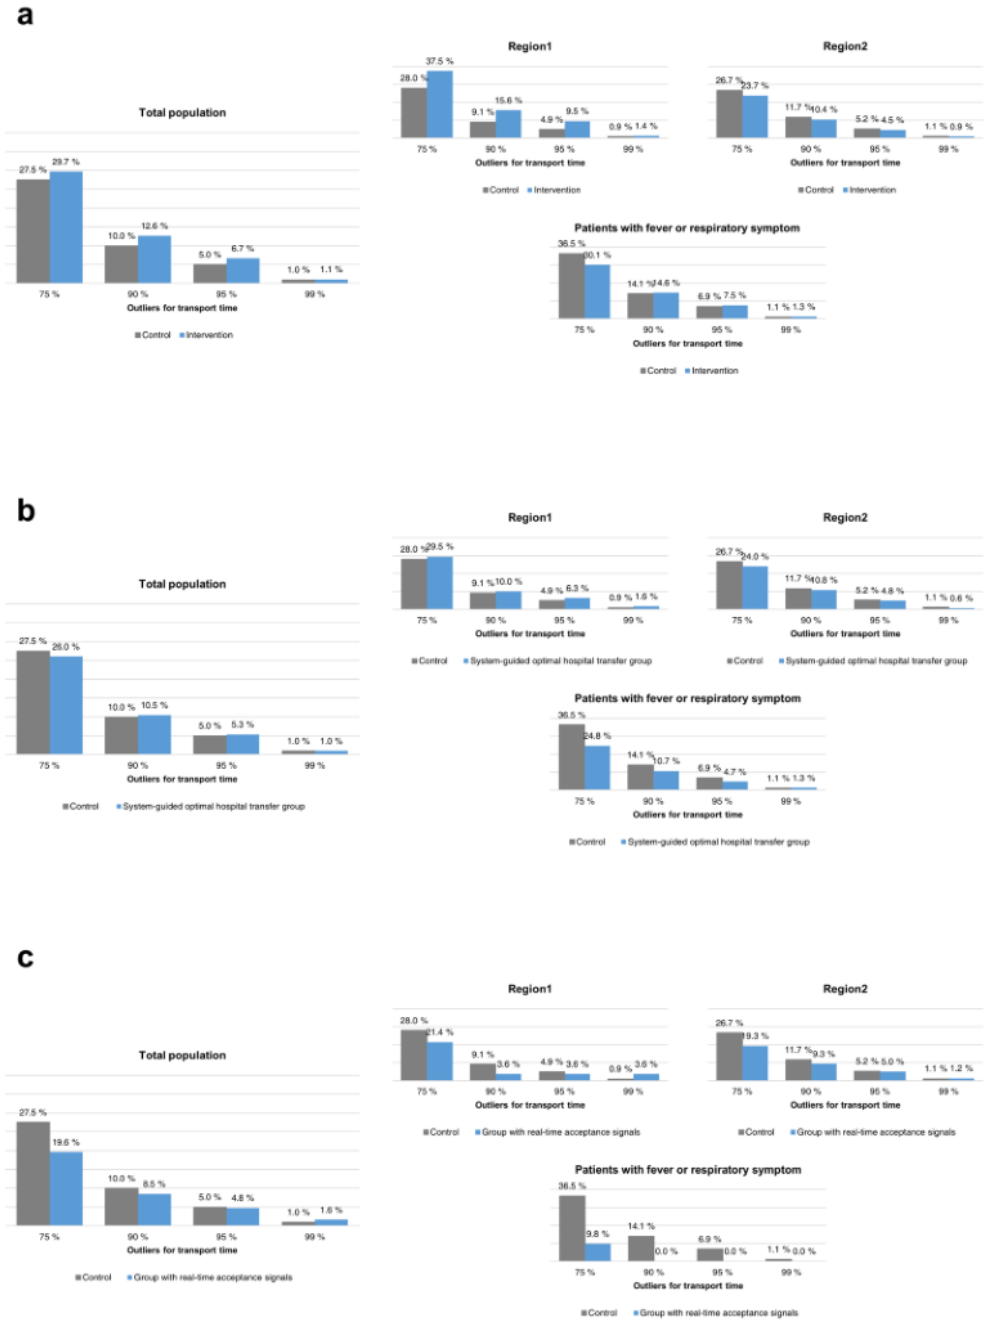
[a]KTAS: Korean Triage and Acuity Scale. The KTAS was evaluated from 1, resuscitation, to 5, nonemergency.

[b]Mental status was assessed using the AVPU scale.

[c]Not applicable.

[d]ED: emergency department.



The median transport time was significantly longer for the intervention group (10, IQR 7-14 min) with the system activated than for the control group without the system (9, IQR 6-13 min). For a comprehensive analysis of the study results, we presented a table showing the comparison of transport times as a continuous variable (Multimedia Appendix 2). In addition, to determine whether delays were caused by prehospital care providers struggling to adapt to the new system, we analyzed trends in weekly median transport times throughout the entire intervention period and found no delays related to adaptation (Multimedia Appendix 3).

Proportion of Outliers With Longer Transport Times According to the Intervention

Figure 5 shows the difference in the proportion of outliers with longer transport times according to the intervention. In the overall population and region 1, a higher proportion of outliers in transport time occurred in the intervention group. On the contrary, region 2 showed a significant reduction in the proportion of cases with a percentile transport time greater than 75% (26.7%-23.7%, *P*=.05). For patients with fever or respiratory symptoms, there was a statistically significant reduction of more than 75% in the proportion of outlier cases in the group that used the system (36.5%-30.1%, *P*=.01).

XSL•FO
RenderX

Figure 5. The proportion of outliers with longer transport times according to the intervention.

In the system-guided optimal hospital transfer group, there was no significant difference in outlier proportions, compared with the control group; however, for patients with fever or respiratory symptoms, a significant reduction was noted in outliers greater than 75% (36.5%-24.8%, *P*<.001).

For patients who received real-time acceptance signals from the hospital, the proportion of outliers was reduced, compared with the group without the system, and the 75% reduction in the percentage of outliers was statistically significant (27.5%-19.6%, *P*=.01). For patients with fever or respiratory symptoms, the group that transferred after receiving the acceptance signal had no 90% outliers for transport time.

Patient Mortality in the ED

Multimedia Appendix 4 shows the proportion for deaths after arrival at the ED according to the intervention. The mortality rate in the ED was 1.5% in the control group and 1.1% in the intervention group (*P*=.14). In the system-guided optimal hospital transfer group, the proportion for deaths after arrival at the ED was significantly smaller than the control group (1.54%-0.64%, *P*=.01).

A total of 114 prehospital care providers who participated in the study were surveyed about their satisfaction with three AI assistant services. The optimal transfer hospital selection service using AI was found to be the most satisfactory for prehospital care providers (Multimedia Appendix 5).

Discussion

Principal Results

As a result of applying this system, there was no significant change in the overall proportion of delayed patients and patient transport time. The median time required for patient transfer in this study was 9-10 minutes, which is extremely short when compared with that from previous studies in other countries [18,19]. In Korea, as the EMS system is exclusively operated by the NFA with government funds, patients are not obligated to pay for transportation, and public ambulances are relatively accessible compared with other countries [25]. High accessibility to public ambulances was accompanied by the side effect that even patients with low case severity frequently use public ambulances. Likewise, in this study, it was confirmed that mild patients with KTAS 4 and 5 accounted for 44.6% of all the transferred patients. Patients with low severity have a wider choice of hospitals compared with severe emergency patients; therefore, the risk of delay in transfer is low, even without using the CONNECT-AI system. This explains why the effectiveness of CONNECT-AI system was dominated by specific groups, such as patients with fever or respiratory symptoms who had difficulty selecting a transfer hospital, rather than a reduction in the proportion of outliers with long transport times among all the transferred patients. In this subgroup, it was confirmed that the transfer delay was noticeably reduced when the hospital responded to transfer acceptance through the ER kiosk.

In our study, compared with the control group, the rates of system usage by prehospital care providers in the intervention group were 29.0% and 11.6% for regions 1 and 2, respectively, considerably low. As this system was not unified with the existing EMS system, it depended on the prehospital care provider's decision whether or not to use our system. As prehospital care providers were not obligated to use this system, it was used more frequently on patients with fever and respiratory symptoms who had difficulty obtaining transfer permission from the hospital than on patients who had no difficulty in hospital assignment.

According to the results of a survey conducted on users who used this new medical system, the function that prehospital care providers were most satisfied with was the role of the EMS kiosk as a platform to easily obtain information on crowding in the ED, particularly because the EMS kiosk can contact multiple hospitals simultaneously and help to find a transfer hospital more quickly. However, in this study, the number of cases in which the medical staff responded with an acceptable answer to the transfer request by the prehospital care provider was insufficient to demonstrate the effectiveness of this system in reducing transport time. We hypothesize that this situation can be attributed to 2 primary reasons. First, ED medical staff faced challenges in promptly addressing requests from prehospital care providers due to their busy engagement in providing emergency treatment to existing patients within the ED. The second reason is the challenging nature of the ED, which lacks control over patient input and is susceptible to overcrowding, rendering it difficult for medical staff to actively decide on accepting new patients [26].

To provide the best emergency care to more patients with limited medical resources in the region, it is not only important to transfer each patient promptly, but emergency patients must also be properly distributed to each hospital [27-29]. The AI prediction algorithm for selecting the optimal transfer hospital of this system contains a strategy to guide patients, who need resuscitation or emergency procedures, to hospitals with sufficient resources and patients with mild symptoms to small hospitals. Such a resource-saving strategy is expected to be advantageous for more efficient use of limited resources but cannot be an absolute solution in a situation where the demand of patients exceeds the supply of medical resources. To balance the demand of patients and the supply of medical resources in a region, a system that leads to policy decisions on the supply of additional emergency medical resources is needed through real-time monitoring of the overall status of resource use and prediction of impending resource depletion [30,31]. We anticipate that real-time information on patient transport and hospital acceptance collected through our EMS kiosk and ED kiosk will be used as valuable data in these emergency medical resource management systems in the future.

To globally expand our initiative, several challenges must be addressed. First, discussions need to take place regarding existing legal restrictions and concerns about privacy and security when transmitting patient information over networks, as the legal framework varies by country. In addition, legal issues surrounding telemedicine must be resolved in advance [32,33]. Furthermore, many underserved and rural areas may lack access to networks capable of real-time communication, making the establishment of broader network infrastructure a priority over specific technologies.

Comparison With Previous Works

In this study, a prehospital clinical decision support system and a patient information-sharing system during transport were developed. To the best of our knowledge, this AI-enhanced digital network system is the first clinical decision support system that determines the transfer hospital by comprehensively considering a wide range of information, including the clinical characteristics of the patient and the hospital resource information, at the prehospital stage. Hospital resource information such as ED crowding and the availability of emergency interventions is an important factor for hospital medical staff to provide the best care to patients, but it is not easy for prehospital care providers to verify hospital information and consider the same when selecting a transfer hospital. This system included machine learning algorithms that can effectively use vast amount of information. In recent years, AI systems that support decision-making have been widely introduced in the medical field but are rarely found in the EMS domain [34-36]. This is because data input is required to operate the AI algorithm, but real-time data input is almost impossible from the site of rescuing emergency patients [37]. Accordingly, voice- and image recognition technologies were applied to use information from the scene in real-time. This clinical information of the patient being transported was transmitted to the ER kiosk so that the ED medical staff could check the condition of the patient before arrival and prepare for emergency treatment.

XSL•FO
RenderX

Limitations

This study has a few limitations. First, the number of patients who used this system was extremely small to sufficiently confirm the effect of the system. The cumbersomeness of having to use additional equipment such as an EMS kiosk and a microphone in addition to the existing tablet made prehospital care providers reluctant to use it. The proportion of patients with fever or respiratory symptom was higher in the group where the system was used compared with the control group. This could be explained by the prehospital providers' assessment that the potential benefits of using the system outweighed the inconvenience, especially when the transport was more challenging. To address the resulting selection bias, we separated the group of patients with fever or respiratory symptom and confirmed that the system's effectiveness was more pronounced in cases where transport difficulty was greater. Second, as this study did not cover patients transferred to hospitals outside the study area or patients transferred from other areas to hospitals in the study area, a comprehensive analysis of patient transfers within the area was not possible. The effectiveness of this system may be affected by the availability of medical resources across the region and therefore needs to be evaluated at the regional level. Including these patients in the study likely led to longer transport times for the outliers, as the transport distances were greater compared with transfers within the local area. Finally, in Korea, prehospital care providers receive permission from hospital medical staff to transport patients, but they can be transported without permission. Regulations on emergency patient transport may vary with the country; therefore, this aspect needs to be considered when understanding our system and interpreting the study results. Given that the intervention effect was more pronounced in the group with real-time acceptance signals in our study, it is likely that the system's effectiveness was underestimated in this study setting compared with regions where transport authorization is mandatory.

Conclusions

This digital platform offers a novel approach to enhancing emergency patient transport by leveraging AI, real-time information sharing, and decision support. While the system demonstrated improvements for certain patient groups facing transfer challenges, further research and adaptations are necessary to fully realize its benefits in diverse health care contexts.

Acknowledgments

This study was funded by the AI (artificial intelligence) Ambulance project for digital health care of precision medicine software development through the National Fund of the Korean government (Ministry of Science and Information and Communications Technology). The funding body had no rule in the design of the study; in the collection, analysis, or interpretation of data; in the writing of the manuscript; or in the decision to publish the results.

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author on reasonable request.

Conflicts of Interest

Abstract

Background: Patient portals, or secure websites linked to electronic medical records, have emerged as tools to provide patients with timely access to their health information. To support the potential benefits of patient portals such as improved engagement in health care, it is essential to understand how patients and caregivers experience these portals.

Objective: This study aimed to explore patient and caregiver experiences, facilitators, and barriers to accessing and using a patient portal called MyChart during the initial stages of its implementation.

Methods: We applied explanatory sequential mixed methods to conduct a web-based questionnaire and semistructured interviews with MyChart users and nonusers at a large community hospital in Ontario, Canada. Among users, we explored user satisfaction with MyChart, its impact on care, and areas for improvement. For nonusers, we explored barriers to MyChart access and willingness to use it in the future. Descriptive statistics and thematic analysis were used for data analysis.

Results: A total of 5651 patients and caregivers completed the web-based questionnaire and 18 (12 users and 6 nonusers) participated in interviews. MyChart users primarily learned about the portal through email (n=1288, 39%), after-visit summaries (n=953, 29%), and hospital staff (n=408, 12%). Nonusers cited lack of awareness (n=1291, 59%) and registration difficulties (n=707, 32%) as some barriers to activation and adoption, but the majority would consider activating and using MyChart if they could learn more about it (n=1126, 54%). Users valued MyChart for preparing for health care encounters but expressed dissatisfaction with limited features and access to medical history and test results, whereas nonusers tended to be unsure about the benefits of using MyChart, especially if they were infrequent health care users.

Conclusions: Patient portals offer benefits, but barriers to access and limited functionality can hinder widespread use. To enhance the adoption and potential benefits of patient portals, targeted outreach and comprehensive access to health information are essential to promote positive and seamlessly integrated health care experiences.

Introduction

Patient portals are secure websites or mobile apps tethered to electronic health records that allow patients to view medical notes and test results, visit summaries, manage appointment schedules, and update personal information [1]. Designed to empower patients, they can promote patient engagement in care, increase self-management [2], improve patient-provider communication, and foster shared decision-making between patients and health care providers [3,4]. Portal use has led to improved communication and trust between patients and providers [5,6], adherence to care plans [7], and satisfaction with care [8]. Patient portals also have the potential to reduce anxiety about test results, avoid unnecessary visits, and improve health understanding [5,9,10]. However, patient portal uptake can be limited by low digital and health literacy [11,12], hesitancy about privacy and security of personal health information [13], and poor alignment of patient expectations for portal functionalities and features actually offered [12].

As health systems transition to electronic health records, many offer access to patient portals and have opportunities to learn from introducing these tools. Exploring patient experiences with accessing and using portals, barriers to activation and use, and perceived impacts on daily life and care is crucial to inform how portals can support high-quality care, identify barriers and enablers to their use, develop tailored supports for specific populations (eg, older patients), and highlight areas for improvement [14]. Particularly, when patient populations are diverse, health systems need to understand how patient portals may inadvertently exacerbate existing equity issues related to accessibility and technological literacy [15].

This study was an evaluation to generate transferable knowledge about the implementation of a patient portal called MyChart within the first 6 months of its launch at a large community hospital in Ontario, Canada. Specifically, we sought to answer the following questions:

- Among patients who activated MyChart, what were their initial experiences, perceived impacts, and suggestions for improvement?
- Among patients who did not activate MyChart, what were the barriers to doing so, and what were their preferences for support to access and use MyChart?
- How can health systems offer portals that meet patients' needs and expectations?

Methods

Setting

This mixed methods evaluation took place at Trillium Health Partners (THP), a large community hospital comprised of 3 sites in Mississauga, Canada. Mississauga is a very diverse community in Canada with 51% of residents identifying as newcomers and 62% as visible minorities. THP operates 1457 inpatient beds and has more than 1.7 million annual patient visits (including 225,723 emergency and urgent care visits and 776,308 outpatient visits), with more than 11,000 staff and physicians [16].

THP implemented the Epic electronic health record in October 2020, and deployed Epic's patient portal, MyChart, in September 2023 [17]. At THP, patients can activate MyChart on a desktop computer or through the MyChart mobile app through links to create an account included in reminder emails about upcoming visits, unique codes provided on after-visit or discharge summaries, or in-person during a care encounter. THP offers technical support for MyChart via telephone and email, tip sheets, and instructional videos on their website about activating accounts and using the available features. MyChart is advertised through posters in hospital waiting rooms and corridors, social media, the THP website, and word of mouth (eg, clinical clerks during visit check-in and health care provider champions who encouraged their peers to socialize MyChart with patients). At THP, MyChart functionalities were introduced in a staged manner with new features launching every quarter; the first stage included viewing after-visit and discharge summaries, outpatient test results, and viewing or updating personal information, medications, allergies, and vaccinations. The second stage added viewing appointment schedules, electronically checking in for or canceling appointments, launching video visits, and requesting additional information. Messaging between patients and providers was not offered as part of MyChart's launch at THP. This approach was taken to reflect organizational capacity and early engagement with health care providers that suggested limited readiness for comprehensive features to be introduced all at once, especially messaging.

Approach

We applied an explanatory sequential mixed methods evaluation approach to understand patient and caregiver experiences, both among those who had activated MyChart and those who had not [18]. This mixed methods evaluation included: (1) a web-based questionnaire of MyChart users and nonusers with different questions for each group and (2) semistructured interviews with users and nonusers to add richness and depth to the questionnaire data. The RE-AIM Implementation Framework [19] and its extension [20] to enhance sustainability and promote equity guided our approach and informed questionnaire and interview content. This framework allowed us to focus on key areas such as reach (identifying users and barriers), effectiveness (assessing patient-perceived impacts and potential negative outcomes), adoption (examining use patterns and disparities), implementation (identifying effective facilitators), and maintenance (evaluating long-term impact).

Data Collection and Analysis

We invited all THP patients to participate in a web-based questionnaire (Multimedia Appendix 1), hosted on Qualtrics for 4 weeks during March 2024 [21]. We explored users' satisfaction with MyChart, perceived impacts on care, and suggestions for improvement. For nonusers, we investigated barriers and potential enablers to activating MyChart, and alternative ways they would like to be involved in their care. Participants had the option to provide their age, gender identity, ethnicity, and postal code to help characterize user and nonuser populations. The questionnaire included both closed- and open-ended questions and was created based on available

XSL•FO
RenderX

literature [9,13,22,23] and peer health systems' evaluations. It was revised based on feedback from a MyChart patient advisory council at THP.

All patients with an email address recorded and who had provided consent to receive nonclinical communication were invited by email to participate; caregivers were able to participate if their email was linked to a patient's record. Two reminder emails were sent 3 and 5 days following the initial invitation. We advertised the questionnaire on the hospital's website, social media pages, and posters with QR codes in waiting areas. MyChart users saw a banner with a link to the questionnaire upon signing into the platform. Acknowledging that not all patients would be reached virtually, hospital volunteers also recruited patients to complete the questionnaire on tablets from clinic waiting rooms and offered navigational support when necessary. The questionnaire took approximately 5 minutes to complete, and participants were not offered incentives. At the end of the questionnaire, participants could indicate if they would like to participate in a follow-up interview.

Descriptive statistics were used to summarize responses to closed-ended questions and participant demographics, and thematic analysis was used to identify key concepts among answers to the open-ended questions. The Ontario Marginalization Index (ON-Marg) was used to classify postal codes according to socioeconomic status. ON-Marg assigns quintiles to postal codes based on relative material deprivation (representing education, low income, unemployment, lone-parent families, and dwellings in need of major repair) and ethnic concentration (representing immigrants within the past 5 years and visible minorities) [8]. Participants were excluded if they indicated that did not receive care at THP in the questionnaire. Statistical analysis was completed on SAS (version 9.4; SAS Institute).

We used a combination of purposive sampling and maximum variation to invite 18 questionnaire participants to individual semistructured interviews while seeking variability in age, ethnicity, gender, and overall sentiment of questionnaire response [24]. Separate interview guides were used for MyChart users and nonusers (Multimedia Appendix 1). All interviews were conducted by one team member (ST) via Zoom (Zoom Communications Inc), lasted approximately 30 minutes each, and were recorded and transcribed verbatim. Transcripts were reviewed by the interviewer to verify completeness and accuracy and were not reviewed by the participant. Two members of the research team (ST and SV) conducted thematic analysis on NVIVO (version 12; Lumivero); following data familiarization, they conducted an initial coding phase, combining a deductive and inductive approach. Deductive coding was based on the RE-AIM framework [19], which guided the identification of text related to reach, effectiveness, adoption, implementation, and maintenance indicators, as well as the acceptability and accessibility of MyChart. Inductive coding was used to explore patients' experiences and perspectives. Codes were used to generate themes, each built around a central organizing concept, which were then refined iteratively to produce a final set of themes.

Ethical Considerations

This study was reviewed by the THP Research Ethics Board and classified as quality improvement. This study was classified as quality improvement as it aimed to enhance existing processes within our health care system. All participants provided informed consent prior to participating in the questionnaire and interviews. They were informed that the study results would be deidentified and published in peer-reviewed journals and potentially shared with the broader public. Interview participants were given a CAD $30 (US $21) honorarium for their time.

Results

Overview

In total, 5651 patients and caregivers completed the questionnaire. Of those 5651 participants, 3336 (59%) participants were MyChart users and 2315 (41%) participants were nonusers, and most of their characteristics were similar across groups except for age; younger individuals were less represented among MyChart users (Table 1). Of the MyChart users, 3098 (93%) participants used MyChart for their own care, and 417 (13%) participants used it as a parent or caregiver. A total of 18 patients and caregivers participated in interviews; twelve (67%) were MyChart users and 6 (33%) were nonusers. Three MyChart users interviewed were parents or caregivers, and 2 used MyChart as users and as family members.

Most MyChart users learned about the patient portal through various channels, including hospital emails (1288/3336, 39%), after-visit summaries (953/3336, 29%), their care team (935/3336, 28%), hospital staff (408/3336, 12%), informational posters (340/3336, 10%), knowledge of MyChart at other health care systems (163/3336, 5%), through recommendations from family or friends (125/3336, 4%), or social media (60/3336, 2%). While 775 (34%) of nonusers were aware of MyChart and expressed interest in learning more, the most reported barrier was a lack of awareness that it was offered (1291/2315, 59%). Other commonly reported barriers included uncertainty about how to sign up for an account (707/2315, 32%) or use the portal (516/2315, 23%). A smaller proportion of nonusers reported low digital literacy (322/2315, 15%) or concerns about privacy and security (267/2315, 12%) as barriers to activating MyChart. Nonusers indicated that they would consider activating and using MyChart if they had the opportunity to learn more about its features (1126/2315, 54%), and how to create an account (968/2315, 47%). Web-based videos were the most preferable method for learning (943/2315, 62%).

[d]Data only available for postal codes that could be matched with ON-Marg.

Perspectives of MyChart users about the portal are shown in Figure 1. Most MyChart users who participated in the questionnaire agreed or somewhat agreed that the portal was easy to use independently (2907/3336, 88%), they could understand the information available in MyChart (2897/3336, 88%), and they felt more informed about their care with MyChart use (2744/3336, 85%). Similarly, 79% (2558/3336) of users agreed or somewhat agreed that MyChart helped them prepare for health care encounters. When asked whether accessing their information caused worry, there were varying responses; over half of the participants (1804/3336, 57%) disagreed or somewhat disagreed that MyChart use caused any worry while 663 (21%) participants agreed or somewhat agreed that it did cause worry. A total of 80% (2605/3336) of users agreed or somewhat agreed that their personal health information was secure and private in MyChart.

Thematic analysis of responses to open-ended questionnaire items and interview questions produced 2 main themes, which are summarized below.

Figure 1. User perspectives about using MyChart. THP: Trillium Health Partners.

Access to Information

Patients and family members using MyChart praised the platform for its user-friendly interface and convenient access to health information. They appreciated the right to review their own health records and found it empowering to be informed about their health care. A few patients described the feature of revisiting past notes from their care team to be particularly helpful with information recall.

And so what I have found is MyChart has been very helpful for me in providing one spot for me to know, what are my upcoming appointments at this hospital, what test results are there that I can refer back to if another doctor asks me did I do this or what was this or how is this looking. And at least giving me some insight and awareness into what's happening and not having to wait for a doctor's appointment to get answers to questions I have. [User 2]

XSL•FO
RenderX

One nonuser who had an interest in MyChart described how beneficial it could be for caregivers who could not attend appointments, as it offered a window into the discussion and decisions made, fostering a better understanding of their loved one's care.

> *It'd be interesting to see if you can integrate notes or directions on what to do when you get home and that kind of thing so that when you have the elderly going in ... he has his phone. My in-law is in his late 60's. He has an iPhone. To have that integrated for him so when me or my husband go back and we look at the notes we're like, OK this is what happened when he went. Then we can go and say ... I don't have to take time off work, we can understand the notes, translate it for him and then go back and go, OK, this is what you need to do now. Or this is what you have to look out for versus having to take the time off work, go with him to literally be there. That would be interesting, I don't know if that's a feature or a future feature.* [Nonuser 4]

While patients and caregivers appreciated access to MyChart, they perceived the available features and functionalities at THP to be very limited, especially relative to other health systems. They desired access to a wider range of information, including consultation notes, medical images, emergency department results, and a more comprehensive medical history. After-visit summaries were available on MyChart, and while accessible, were seen as lacking detail (since they did not include health care providers' chart notes from the visit) and were often outdated, hindering patients' understanding of their care plan.

> *One thing that would be really nice to have is access to the doctor's notes ... like, the notes from your appointment. I tend to try to take my own notes when I'm at clinical appointments but sometimes it's hard because I'm trying to be present in the appointment and listen and try to understand in the moment. Sometimes my recall isn't great and my note-taking isn't great. So having access to a doctor's summary of what it is that they've talked about and the direction and guidance that they've given would be helpful to be able to go back to and refer to, and even just to update my own notes. So, that's another thing because right now that is not something that I see or that's accessible in terms of their note. But I know it gets documented and shared with other providers in my circle of care but I don't get to see that. And so sometimes it's hard. It's ... like, that would be great. It would be great if that was accessible.* [User 2]

Beyond limited information, patients and caregivers identified issues with MyChart's lack of content and functionality. They envisioned MyChart bridging the gap between care providers but felt it operated in isolation, hindering its full potential.

> *There's no connectivity. The whole thing is to streamline the process and to make sure that the patient has access to their records ... So, if that's not being sent to the technology, to the app, then I'm not getting the information. So, what's the use of spending all this money on technology that is not being used to its fullest?* [User 4]

Among current users, there was a desire for additional features such as chat or messaging with providers (n=476), access to more information such as imaging, historical information and notes (n=550), sending records or providing access to family members or proxies (n=169), linking to other hospitals and care providers (n=271), and supporting information for interpreting results (n=111). Some of these features were in fact available to MyChart users, such as adding proxy users and high-quality resources to help understand medical information, but this finding highlighted low awareness of MyChart's full range of functionalities.

Access to medical records and test results presented a double-edged sword for both users and nonusers. Some users saw it as a source of comfort, reducing anxiety by eliminating the stressful waiting periods and uncertainty before appointments; viewing results ahead of appointments allowed them time to process information and prepare questions for follow-up visits.

> *For example, my family doctor suspects there's something wrong. Sends for a biopsy. The biopsy results are back. Good or bad. Most of the time let's say it's good. But you have that two weeks of stress that you didn't really need. And let's say it's negative. It's still better to know that you have cancer and how to deal with it because you've got time to process. So, by the time you go to the doctor you're prepared to ask the questions that need to be asked. So, it's a more productive meeting between the patient and the doctor and it alleviates the stress level.* [User 4]

However, nonusers expressed that immediate access to sensitive test results before appointments would increase their anxiety. While some patients and families may have medical knowledge to interpret the notes, nonusers described it as a "folder of anxiety" as it does not contain context and next steps provided by a health care provider.

> *So if we could see the results and know we were talking to our doctor either on phone or in person, within 24 hours, we would sign up for MyChart, I guess is the most simple ... When you're talking hypertension, cholesterol, thyroid. I guess, like, regular run-of-the-mill stuff. Then fine. Like, I know what's going to happen. You're going to adjust my dose. You're going to add another medication. You're going to, like, whatever it is. When you're talking about life-threatening and life-changing things, like everything changes.* [Nonuser 1]

Barriers to Activation and Adoption of MyChart

Despite MyChart's potential benefits, patients and caregivers who were aware of MyChart but had not activated accounts shared hesitations about signing up. This included difficulty navigating the registration process, misperceptions about the cost to activate an account, a perceived low need for MyChart since they were infrequent health care users or felt the available features were too limited, and a preference for face-to-face

XSL•FO
RenderX

interactions. The registration process was a significant challenge for both MyChart users and nonusers, as they attempted to register MyChart accounts but faced roadblocks; despite some patients trying to seek assistance from the hospital or family members, a few encountered difficulties such as 2-factor authentication, which combined with their limited technical skills, ultimately led them to abandon the registration process.

> *I have to put all these numbers, whatever it is and then they say it's not right. Again, I'm putting in the numbers, it's not right. I did it three times, after that I think it says your time has expired so come back. So, how many times am I going to put in the numbers and still I'm not getting anyplace? That is where my frustration starts. One time, two times, three times. It's hard to understand why they have to think that every ... I know the younger generation picks it up very fast. Why do they think that everybody is that fast, especially the seniors.* [Nonuser 3]

Some nonusers who were accustomed to advanced features and interconnectedness in other apps found MyChart underwhelming. They questioned the effort involved in registration and some were frustrated by the fragmentation of separate patient portals offered by different providers (eg, family physicians and physiotherapists). This fragmentation hinders information flow, creates repetitive tasks to create accounts and add personal information, and forces patients to manually connect the dots between health care providers.

> *But in addition to my doctor, everybody I've been to has one of these portals, and they're all different. If you had all signed up for the same premade system, I'd be willing to learn it in order to talk to all the medical people in my life ... So the thing is it adds up and it adds up and they're all different. And the thing is as a patient you might only use it two or three times and never see that specialist again.* [Nonuser 2]

Some infrequent health care users mentioned they did not need features like record keeping and checking medical results and felt comfortable receiving information through face-to-face interactions, especially if they lacked the health literacy required to understand the information presented in MyChart.

> *[...] It's no use to me if I'm not talking to the doctor about it ... I get the general drift of things because I know medical vocabulary and I work in that area. But I don't have the knowledge of a doctor. And without that you can go very far astray.* [Nonuser 2]

Discussion

Principal Results

This mixed methods study explored the initial experiences and perspectives of 5651 patients about MyChart implementation at a large community hospital, including facilitators and barriers to accessing and using the portal. While most patients learned about MyChart through postvisit summaries, hospital staff, and email communications, barriers such as limited awareness, misconception around cost, registration difficulties, and unclear benefits of the portal hindered its uptake among nonusers. Users generally perceived MyChart to be user-friendly and enhance their ability to understand and prepare for their care. However, both users and nonusers highlighted the importance of a portal meeting their needs and expectations as a condition for uptake and impact on their care. Many participants highlighted a desire for more functionalities, such as access to imaging results, consultation notes, messaging with providers, and tools for interpreting medical information, which was often driven by comparisons to patient portals at other hospitals that offered more features. Expectations also included connectivity across a range of providers and institutions, frictionless account set-up and access, and technical support. Nonusers expressed interest in learning more about MyChart and its specific functionalities through educational materials to help them better understand the portal and its benefits, as well as technical and registration support to facilitate easier access.

Comparison With Prior Work

Our study participants consistently highlighted MyChart as a valuable tool for accessing timely health information, preparing for visits, managing appointment schedules, and actively participating in their health care. However, whether they were MyChart users or not, participants in this study identified several barriers to accessing the patient portal, including a lack of knowledge of the platform, registration difficulties, limited interest in available features, a preference for face-to-face interactions, and low digital literacy. MyChart users were more often older individuals, which may reflect an increase in health care use with age and a higher need for managing personal health information. Notably, a similar proportion of users and nonusers resided in neighborhoods characterized by racialized or newcomer populations, or those with low material resources, which is inconsistent with use patterns observed in other studies—often, portal users have higher socioeconomic status than nonusers [14,25,26]. Our findings may be reflective of the patient population in our health system's catchment area, which has a high proportion of newcomer and lower-resourced groups. In both our study and the literature, access to medical records and clinical notes can be beneficial for marginalized populations in understanding and managing their own care, as it may help overcome challenges to do with language, digital literacy, and recalling information, for example [27].

In this study, immediate access to medical records and test results was a complex issue. The majority of MyChart users believed this access empowered them with greater control and understanding of their health information and lessened anxiety associated with waiting for test results. Conversely, nonusers worried about potential misunderstandings and negative outcomes of viewing concerning medical information, especially before they could discuss it with a health care provider. Numerous studies in the literature [28,29] align with these perspectives, indicating that patients appreciate timely information but there is potential for negative emotions. From our findings, it is unclear whether nonusers only perceive the risk of higher worry, or if self-awareness of anxious tendencies causes certain patients to avoid portals altogether. Health and digital literacy may also differ among MyChart users and nonusers, where those who feel more equipped to understand health information and use other tools such as credible health

XSL•FO
RenderX

websites to interpret complex details may be more likely to use MyChart [30]. Some research [29] revealed a strong patient preference for receiving test results through a portal regardless of whether they were normal or abnormal; however, health care providers have expressed concerns about this practice [28,31,32], suggesting increased patient anxiety and workload changes due to potential increases in messages, calls, and urgent visits to discuss the results. Many health care providers have advocated for a more structured approach, suggesting that patients should receive access to medical records and test results postappointment, allowing for discussion and clarification of results in a clinical context. However, this contradicts the strong preference MyChart users have for access to their complete health information as soon as possible, even if there is a risk of viewing concerning results without the immediate guidance of a health care provider, and may cause strain on health care providers to review and release results to patients within certain timeframes [2,28,29].

Strengths and Limitations

This study examined the early experiences of patient portal implementation among users and nonusers at a large community hospital in Canada that serves a diverse population. With a strong response rate of over 5000 patients and caregivers, this study captures the experiences and perspectives of a wide range of health users. The use of a mixed methods design that combined both qualitative and quantitative approaches enabled us to understand the facilitators and barriers associated with portal adoption and use. By capturing the perspectives of both users and nonusers with different ethnicities and socioeconomic backgrounds, we generated a comprehensive understanding of the factors that influenced patient portal adoption and engagement. These rich insights improve the transferability of our findings across patient populations and health system settings and can inform a range of patient portal implementation strategies.

This study has limitations. While we used multiple recruitment strategies including in-person invitations, posters, and email communications, this study was limited to English speakers due to the language requirements of the questionnaire and interviews. Given this, the findings may not reflect all the views and perspectives of those in the Mississauga and West Toronto region and may not apply to other linguistically diverse populations. We also were not able to determine the exact number and characteristics of patients who were invited to participate using our multipronged recruitment strategy, which limited our ability to identify response rates among specific patient populations (eg, newcomer groups). As this study examined a staged roll-out of MyChart features, the results may not be applicable to other health care organizations using different implementation approaches. Finally, given that this study was about MyChart, our sample of nonusers may not have been fully representative of that population if the questionnaire was perceived to be less relevant to their experiences.

Conclusions

In conclusion, our findings reveal actionable and transferable learnings about the implementation of MyChart. Low digital literacy and lack of awareness of MyChart's available features were barriers to MyChart activation and use among both users and nonusers. A surprising barrier to accessing MyChart was a misperception about the costs associated with creating an account; given that several digital health tools require payment, health systems should clearly communicate when available portals are free to maximize uptake. Widely marketed and accessible interventions to support digital literacy and help patients learn about and navigate MyChart could increase patient awareness of available features and their potential to positively impact patient experiences. Similarly, improving patients' health literacy could reduce perceived worry associated with viewing concerning results in MyChart, and drive additional benefits of using the portal by increasing the interpretability of information. This study highlighted a strong desire among some patients and caregivers for access to additional medical records and test results, and to exchange messages with health care providers. While expanding access to these features can improve patient engagement and care management, it is crucial to consider the potential impact on patient-provider relationships and provider workflows. At the same time, some patients had little interest in MyChart, which is important for health systems to consider when setting targets for patient portal uptake. As health systems increasingly offer patient portals to increase patient and family engagement in care, support shared decision-making, and provide patients access to their health information, a culture of timely, comprehensive access to complete medical records is building. To ensure uptake and positive experiences with portals, health systems need to meet patient expectations by providing access to a variety of features, especially when multiple health systems offer portals to the same population.

Acknowledgments

We would like to acknowledge the Trillium Health Partners (THP) MyChart Project Executives: Dr Chris Hayes, Dr Joan Murphy, and Danielle Sanagan, and the Steering Committee, Adam Gdyczynski, Ying Mi, Raj Patel, Hassaan Khurram, Marvelyn Oni, and Shelby Roloson for their support of recruiting participants, extracting and organizing data, and advertising this project. We thank the THP MyChart Patient and Family Advisory Council members who reviewed the protocol, questionnaire, and interview guides to ensure they were relevant, meaningful, and clearly written, as well as questionnaire pilot testers Selina Brudnicki, Charlotte De Souza, Kathleen Carlin, and Sam Padayachee for reviewing the tool for usability and clarity. Finally, we thank the volunteers who helped administer the questionnaire in clinical areas. Funding for this work was provided by THP as it was a quality improvement project.

Abstract

Background: Sarcopenia is closely associated with a poor quality of life and mortality, and its prevention and treatment represent a critical area of research. Resistance training is an effective treatment for older adults with sarcopenia. However, they often face challenges when receiving traditional rehabilitation treatments at hospitals.

Objective: We aimed to compare the effects of a digital rehabilitation program with those of traditional therapist-supervised rehabilitation training on older adults with sarcopenia.

Methods: In total, 58 older adults with sarcopenia were recruited offline and randomized (1:1) into 2 groups: the telerehabilitation group (TRG, n=29, 50%) and the in-person rehabilitation group (IRG, n=29, 50%). Both groups underwent 4-week resistance training targeting 6 major muscle groups. The TRG received exercise guidance via a mobile app, while the IRG received in-person training from a therapist. Offline assessments of body composition, grip strength, and balance using the 30-Second Arm Curl Test (30SACT), 30-Second Sitting-to-Rising Test (30SSRT), quadriceps femoris extension peak torque (EPT) and extension total power (ETP), Berg Balance Scale (BBS), Timed Up-and-Go Test (TUGT), 6-Minute Walk Test (6MWT), and Instrumental Activities of Daily Living (IADL) scale, were conducted before and after the intervention.

Results: Of the 58 patients, 51 (88%; TRG: n=24, 47%; IRG: n=27, 53%) completed the trial. After 4 weeks of intervention, the mean grip strength increased from 18.10 (SD 5.56) to 19.92 (SD 5.90) kg in the TRG (P=.02) and from 18.59 (SD 5.95) to 19.59 (SD 6.11) kg in the IRG (P=.01). The 30SACT and 30SSRT scores increased from 12.48 (SD 2.68) to 14.94 (SD 3.68) times (P=.01) and from 15.16 (SD 7.23) to 16.58 (SD 8.42) times (P=.045), respectively, in the TRG and from 12.25 (SD 4.19) to 14.68 (SD 4.36) times (P=.003) and from 14.31 (SD 4.04) to 16.25 (SD 4.91) times (P=.01), respectively, in the IRG. The quadriceps femoris EPT increased from 26.19 (SD 10.26) to 35.00 (SD 13.74) Nm (P=.004) in the TRG and from 26.95 (SD 11.81) to 32.74 (SD 12.33) Nm (P=.003) in the IRG. The BBS scores significantly improved in both groups (P<.001), with the mean TRG score increasing by 3.19 (SD 2.86) points and the mean IRG score by 3.06 (SD 2.44) points. Neither group exhibited significant within-group changes on the TUGT or the 6MWT. Both groups reported significant improvements in the IADL (TRG: P=.04; IRG: P=.02). Between-group comparisons revealed no significant differences in changes in all indicators.

Conclusions: A 4-week remote resistance training program is effective in improving strength, balance, and the IADL in older adults with sarcopenia, with effects comparable to rehabilitation supervised by a physical therapist. Telerehabilitation may be a convenient and effective alternative for older adults with sarcopenia who have limited access to rehabilitation resources.

Introduction

Muscle reduction typically progresses gradually between the ages of 40 and 50 years but accelerates rapidly after the age of 60 years, with approximately 30% of skeletal muscle mass lost between the ages of 50 and 80 years [1,2]. Sarcopenia is characterized by a substantial reduction in skeletal muscle mass and function. This condition heightens the risk of falls, fractures, and physical disability and is closely linked to a poorer quality of life, as well as increased mortality rates [3,4].

According to a systematic review from 2022, the prevalence of sarcopenia worldwide is estimated to be 8%-36% in individuals under the age of 60 years and 10%-27% in those over 60 years [5]. Based on the literature from 2016 to 2019, in Asian countries, the prevalence ranges from 5.5% to 25.7% [6]. More specifically, in China, recent data suggest that the overall prevalence of sarcopenia among individuals aged 60 years and older is about 20.7%, and this rate has been rising over the past 5 years [7]. Thus, the prevention and treatment of sarcopenia represent a critical area of research, with significant implications for the health of the older population.

Resistance training has been shown to enhance muscle strength, aerobic endurance, and muscle mass [8]. This includes various exercises using free weights, machines, resistance bands, or body weight. Resistance training has demonstrated notable efficacy in improving strength in patients with sarcopenia [9-12]. Guidelines from the World Health Organization, as well as those from the United Kingdom and Australia, recommend 2-3 sessions of resistance training per week to prevent and manage sarcopenia [13,14]. Furthermore, consistent adherence to exercise is crucial, as irregular or intermittent training may impair treatment outcomes [15].

However, older adults (defined in this study as individuals aged 60 years or older, according to standards set by the World Health Organization [16]) with sarcopenia often face challenges when engaging in resistance training. In middle-income countries in particular, access to professional rehabilitation services is limited due to inadequate rehabilitation facilities, transportation barriers, financial constraints, and diminished physical ability, all of which reduce patient participation [14,17]. Additionally, older adults tend to have low adherence to self-guided home training programs, largely due to the lack of professional supervision, fear of injury, and low motivation [9].

Given these challenges, digital programs delivered through mobile apps offer a potential solution, allowing patients to receive professional guidance and monitoring from the comfort of their homes. This approach could alleviate the burden on hospital resources and improve patient adherence to training programs [18]. Recent studies have shown that home-based programs can have a positive impact on improving the function and quality of life of older adults [19,20]. Therefore, this study aimed to compare the effects of a digital rehabilitation program with traditional therapist-supervised rehabilitation training in older adults with sarcopenia, addressing the aforementioned challenges.

Methods

Study Design

This single-center randomized controlled trial (RCT; Multimedia Appendix 1) was conducted at the Peking Union Medical College Hospital, affiliated with the Chinese Academy of Medical Sciences. The study is registered with the Chinese Clinical Trial Registry (registration number: ChiCTR 2300071648).

Ethical Considerations

This study was approved by the Ethics Committee of the Peking Union Medical College Hospital (approval number: JS-2648). All participants provided written informed consent prior to enrollment, ensuring their voluntary participation with a full understanding of the study's objectives, procedures, and potential risks. All personal data collected were anonymized and stored in encrypted electronic databases accessible only to the research team members. Neither the manuscript nor the supplementary materials include any identifiable information or photographs of individual participants. Additionally, no form of financial compensation was provided to participants; participation was entirely voluntary and would not influence their routine medical services.

Participants

All participants in this study were recruited offline from the Peking Union Medical College Hospital, a large comprehensive hospital. The specific process was as follows: First, the researchers posted recruitment advertisements in the hospital's outpatient hall. Second, potential participants contacted the recruitment team (2 geriatricians and a rehabilitation physician with extensive experience in sarcopenia) over the phone, and the recruitment team conducted an initial telephone screening. Third, potential participants who passed the initial telephone screening were invited to the hospital for a face-to-face detailed assessment, including medical history taking, physical examination, and necessary laboratory tests. Finally, if the conditions of the potential participants met all the eligibility criteria, they were formally included in the study after obtaining written informed consent. During the informed consent process, participants were not informed whether they were in the intervention group or the control group in order to avoid bias. The inclusion and exclusion criteria are outlined in Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria for the study.

Inclusion Criteria

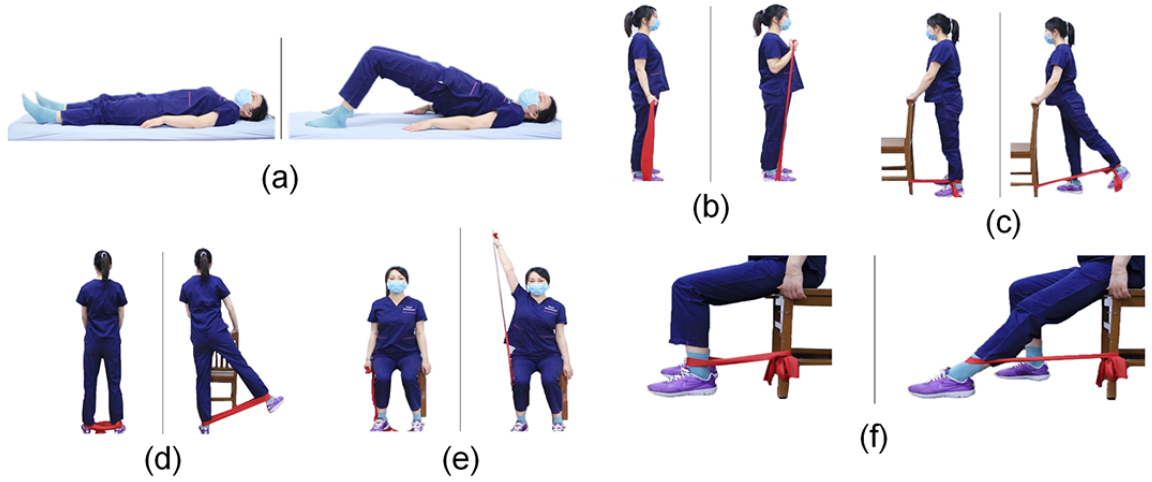
- Diagnosed with sarcopenia based on the 2019 Asian Working Group for Sarcopenia (AWGS) criteria [6]
- Age between 60 and 80 years
- Able to operate a smartphone and follow the exercise regimen, with sufficient literacy in the local language to navigate a Chinese language mobile app
- No participation in any rehabilitation program within the past 30 days

Exclusion Criteria

- Severe cognitive impairment (Mini-Mental State Examination [MMSE] score<24), hearing impairment, or vision impairment
- Severe neurological, musculoskeletal, or organ (cardiovascular, pulmonary, hepatic, renal) diseases or malignant tumors
- Uncontrolled hypertension, unstable metabolic diseases, or any other condition deemed inappropriate for participation by the researchers

Sample Size Calculation

The sample size was calculated using PASS 15 software (NCSS, LLC). Based on the principle of noninferiority RCTs and previous clinical studies [21], the mean difference in the grip strength between the home-based exercise group and the therapist supervision–based exercise group was 3, the SD was estimated to be 4 for both groups, and the noninferiority margin for the grip was 1. A sample size of 46 was required based on a 1-sided α=.025 and β=.1, and a sample size of 58 was required to account for a 20% dropout rate. The formula used is the following:



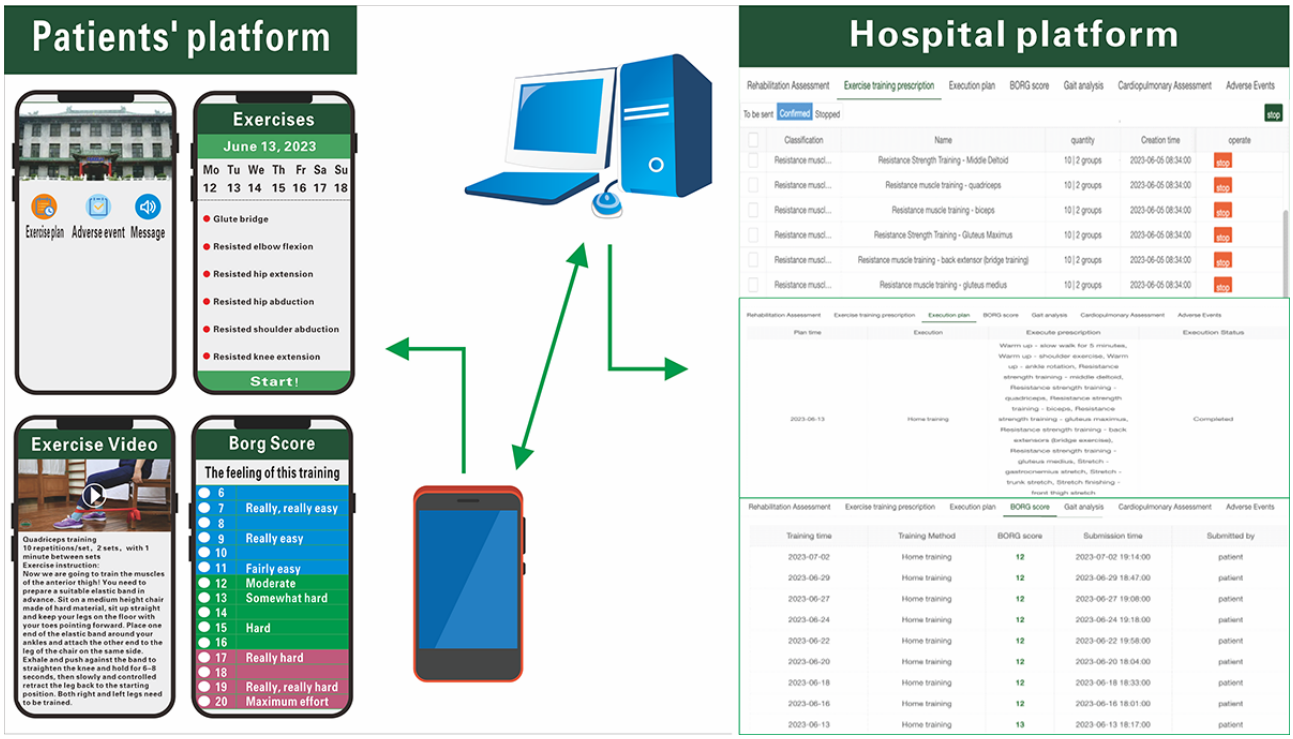
Randomization

A total of 58 participants were randomly assigned to either the telerehabilitation group (TRG, n=29, 50%) or the in-person rehabilitation group (IRG, n=29, 50%) using a randomization platform. Based on the platform's results (eg, C, T, C, T, T, C), slips of paper labeled "T" and "C" were placed into sealed, opaque, and uniformly sized envelopes. After completing baseline measurements, the envelopes were opened in sequence to reveal group assignments. The allocation sequence was generated using a blocked randomization model by 2 researchers who were not involved in the study.

Exercise Program

The training program for patients with sarcopenia in both the TRG and the IRG was identical. The program consisted of 6 resistance exercises targeting specific muscle groups, including back extensors, biceps brachii, gluteus maximus, gluteus medius, the deltoid, and quadriceps femoris. The specific exercises included glute bridges, resisted elbow flexion, hip extension, hip abduction, shoulder abduction, and knee extension (Figure 1). Participants performed resistance training 3 times a week, with each exercise performed in 3 sets of 10 repetitions per set, over a 4-week period (Multimedia Appendix 2). Effective training intensity was ensured through the use of the Borg rating of perceived exertion (RPE), with a target RPE of 12-14 at the end of each exercise session. Each session included approximately 10 minutes of warm-up, 40 minutes of resistance training, and 10 minutes of stretching, totaling around 1 hour.

Figure 1. Exercises included (a) glute bridge, (b) resisted elbow flexion, (c) resisted hip extension, (d) resisted hip abduction, (e) resisted shoulder abduction, and (f) resisted knee extension.



XSL•FO
RenderX

Intervention Group (TRG)

Before initiating at-home training, each participant attended an individual, face-to-face introductory session at the hospital's rehabilitation outpatient clinic. A physical therapist demonstrated the exercises, ensured the participants understood the correct technique, and assisted them with downloading and registering the mobile app on their personal smartphones. Each participant received a personalized exercise protocol via the app and was provided with resistance bands with appropriate tension levels based on their initial assessment. Following this initial session, participants performed the exercises independently at home, guided by instructional videos and written instructions embedded in the app, which were marked with the hospital's logo (Figure 2).

Figure 2. The 3 different parts of the telerehabilitation system (the language of the interface is translated from Chinese). The doctor's portal can be used to create and modify exercises, monitor training progress, and view patient data. Patients can use the user portal to complete the prescribed exercises and provide feedback to physical therapists. Finally, the transmitter portal encrypts and transmits the data collected, ensuring the overall system's integrity.

The telerehabilitation system comprised 3 main components:

- Physician portal: Accessed by the medical team to upload exercise videos and protocols and track patient adherence.
- User portal (patient interface): Accessed via a password-protected smartphone app in the local (Chinese) language. Patients navigated using simple menus and icons to view exercise instructions, watch demonstration videos, and report session completion. The interface includes step-by-step written instructions and demonstration videos. Patients were required to input their RPE values after each session.
- Transmission portal: A secure data transmission platform integrated within the system automatically records the exercise duration, frequency, and patient-reported RPE. Patients were instructed to report any adverse events through the app immediately, triggering an alert to the research team.

Control Group (IRG)

Participants assigned to the IRG attended scheduled sessions in the hospital's rehabilitation department, which is a typical form of training currently in practice. A physical therapist supervised each session, providing on-site guidance, feedback, and adjustments to ensure correct exercise performance. The IRG followed the same exercise protocol, frequency, and intensity guidelines as the TRG, but all training took place face to face under professional supervision.

Measures

All assessments were conducted by a dedicated blinded physical therapist with professional certification. This individual conducted all tests within 3 days in the hospital before and after the 4-week intervention for every participant.

Body Composition

Body composition was measured using bioelectrical impedance analysis (BIA-101 Anniversary Sport Edition, Akern-RJL Systems), with specific metrics including the total skeletal muscle mass (TSM), body fat percentage (BFP), and skeletal muscle mass index (SMI).

Strength

Strength was assessed using grip strength, the 30-Second Arm Curl Test (30SACT), the 30-Second Sitting-to-Rising Test (30SSRT), and the quadriceps femoris extension peak torque (EPT) and extension total power (ETP). For the grip strength test, participants used their dominant hand to apply the maximum pressure to the dynamometer handle (Jamar Hydraulic T, Patterson Medical). In the 30SACT, participants sat with

XSL•FO
RenderX

their upper arms pressed against their torso while holding 8 lb dumbbells (men) and 5 lb dumbbells (women). They were instructed to perform elbow curls as quickly as possible for 30 seconds. In the 30SSRT, participants sat on a 43-cm-high chair and alternated between sitting and standing as many times as possible within 30 seconds. Each of these tests was performed 3 times, with a 1-minute rest between trials, and the maximum value was recorded as the final result.

Quadriceps extension strength indices were measured using an isokinetic dynamometer (ISOMOVE, TecnoBody). The seat of the dynamometer was reclined at approximately 85°, with the participant's thigh, pelvis, and torso secured by straps. The rotation axis of the device was aligned with the lateral epicondyle of the femur, and the lever pad was positioned 3 cm above the lateral malleolus. The test consisted of 5 maximal repetitions at a speed of 20°/second, during which participants extended their knees as fast as possible against the resistance shown on the screen, reaching the target end point indicated by the graphical display.

Balance, Cardiopulmonary Endurance, and Self-Care Ability

Balance was assessed using the Berg Balance Scale (BBS) and the Timed Up-and-Go Test (TUGT). The BBS evaluated 14 tasks, with each task scored from 0 (unable to complete) to 4 (completed independently), and the total score represented the sum of all individual task scores. The TUGT assessed functional mobility and fall risk by timing how long it took a participant to rise from a chair, walk a short distance (3 m), turn, walk back, and sit down again.

Cardiopulmonary endurance was measured using the 6-Minute Walk Test (6MWT), which quantified the distance a participant could walk on a flat, hard surface in 6 minutes. The primary outcome was the total distance walked, with longer distances indicating better cardiopulmonary function.

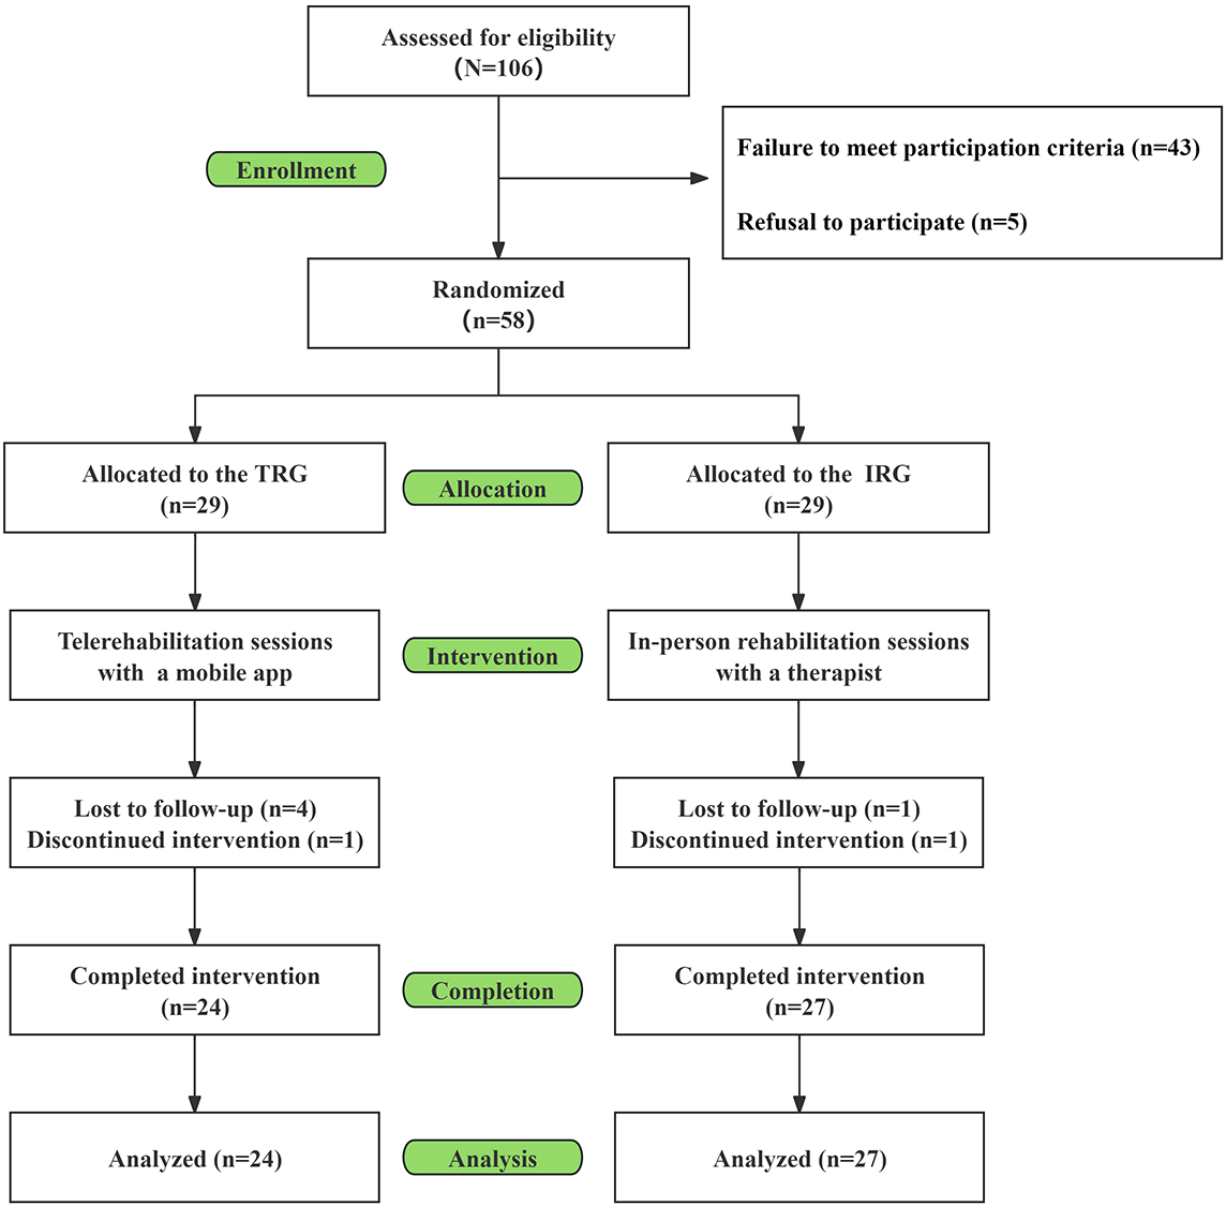
The Instrumental Activities of Daily Living (IADL) scale was used to assess participants' self-care abilities.

Statistical Analysis

Data analysis was performed using IBM SPSS version 26.0. Categorical variables were expressed as numbers, while continuous variables were presented as the mean (SD). Categorical variables were compared using the chi-square test. Paired *t* tests were used for within-group comparisons before and after the intervention, while independent-sample *t* tests were applied for comparisons between groups. $P<.05$ was considered statistically significant.

Results

Study Flow and General Participant Characteristics



Between May 30, 2023, and July 1, 2024, 106 patients were assessed for eligibility. Of these, 43 (40%) patients were excluded based on the criteria, while 5 (5%) declined participation after the initial screening. As a result, 58 (55%) patients were included in the final study. As shown in Figure 3, participants were randomly assigned to 1 of 2 groups: the TRG (n=29, 50%) or the IRG (n=29, 50%).

During the study, 4 (14%) participants in the TRG and 1 (3%) participant in the IRG did not complete the 4-week follow-up. Additionally, 1 (3%) participant from each group discontinued the training due to worsening pre-existing conditions: hip pain in the TRG and elbow pain in the IRG. After discontinuing the exercise, their hip pain subsided, and the elbow pain returned to baseline levels. Ultimately, 24 (83%) patients in the TRG and 27 (93) patients in the IRG completed both the training program and the 4-week follow-up. Adherence to the exercise intervention was defined as the proportion of completed sessions relative to the total prescribed sessions, with adherence rates of 97% in the TRG and 92% in the IRG. The most commonly reported adverse effect was muscle soreness, and no exercise-related injuries or major adverse events were reported.

The baseline characteristics of the patients in the TRG and IRG were comparable. There were no significant differences between the 2 groups in terms of age, gender, height, weight, the TSM, the BFP, the SMI, grip strength, quadriceps femoris EPT, the BBS score, the 6MWT score, or the IADL score (Table 1).

Balance, Cardiopulmonary Endurance, and the IADL

Postintervention, both groups exhibited significant improvements in BBS and IADL scores ($P<.05$), while the improvements in TUGT and 6MWT scores were not statistically significant (Table 4). There were no significant differences between the groups in the changes observed in balance, cardiopulmonary endurance, or the IADL (Figure 4).

Table 4. Baseline, 4-week, and pre- and postintervention changes in balance, cardiopulmonary endurance, and the IADL[a].

Discussion

Principal Findings

With the increase in life expectancy and the decline in birth rates worldwide, the proportion of older adults in China has risen sharply over the past few decades. As the aging population grows, national health care expenditures have also surged, prompting the Chinese government to prioritize addressing the health challenges associated with population aging. Sarcopenia, characterized by a significant decline in muscle mass due to factors such as nutritional status, physical activity, genetics, or hormonal changes, along with the deterioration of tendon performance and neural patterns [22], leads to a loss of muscle strength and mobility. Sarcopenia is one of the most critical factors contributing to functional decline and loss of independence in older adults. It not only reduces their quality of life but is also associated with increased morbidity and mortality, as well as elevated public health costs [22]. Supervised exercise is considered an effective strategy for managing sarcopenia and frailty, yet many patients lack access to such resources. This study found that a 4-week remote resistance training program significantly improves the strength and balance of patients with sarcopenia, with outcomes comparable to face-to-face rehabilitation supervised by therapists. These findings highlight the potential of telerehabilitation as a feasible solution for populations with limited access to health care resources and demonstrate how digital health solutions can enhance care for older adults and address the unique needs of an aging society.

Previous studies have reported mixed findings on the effects of resistance training on body composition. Some scholars have observed that 12 weeks of resistance training can increase muscle mass in patients with sarcopenic [23,24]. In another study, women with obesity-related sarcopenia underwent 12 weeks of resistance training, 3 times per week. Although the training group experienced an increase in the lean mass of the lower limbs, the increase in the total body lean mass did not reach statistical significance compared to the control group [25]. Another study found that after 3 months of resistance training in older adults with obesity-related sarcopenia, reductions were observed in the fat mass, total fat mass, and BFP in the upper limbs, but there was no significant increase in lean mass [26]. Two systematic reviews and meta-analyses also yielded conflicting conclusions [9,10]. Mechanistically, the increase in muscle mass in older adults following resistance training may be attributed to enhanced muscle protein synthesis [27], increased satellite cell activity and quantity [28], elevated secretion of anabolic hormones [29], improved mitochondrial quality and function [30], and decreased activity of catabolic cytokines [31]. In our study, we found both groups demonstrated an increase in lean mass and a decrease in the BFP, though these changes did not reach statistical significance. This may be due to the relatively short duration of the 4-week resistance training intervention, which may not have been sufficient to induce significant alterations in body composition. It is also possible that extending the training period could result in more pronounced changes in body composition.

In this study, both the TRG and the IRG showed significant improvements in strength-related indicators, including grip strength, 30SSRT and 30SACT scores, and knee extension torque indices. These findings are consistent with previous systematic reviews and meta-analyses [9,10]. Studies have shown that resistance training can increase muscle fiber volume, particularly type II fast-twitch fibers [32]. Similarly, Ruiz et al [33] and Nunes et al [34] confirmed that resistance training enhances muscle function by improving muscle fiber adaptability and optimizing strength output mechanisms. At the molecular level, Sousa-Victor et al [35] demonstrated that resistance training increases satellite cell activity and muscle protein synthesis, reduces muscle degradation, and improves muscle mass. Coletti et al [36] and Gadelha et al [37] showed that this type of exercise activates the mammalian target of rapamycin (mTOR) signaling pathway, influencing protein synthesis, autophagy, and the expression of peroxisome proliferator–activated receptor-gamma coactivator 1 alpha (PGC-1α), thereby promoting sustained muscle growth and enhancing muscle performance. In this study, these effects were observed after just 4 weeks of resistance training, further demonstrating the significant therapeutic role of resistance training in the treatment of sarcopenia. The lack of significant differences in training outcomes between the 2 groups supports the application of telerehabilitation therapies in older adults with sarcopenia.

Lower limb muscle endurance is critical for dynamic balance. The reduction in the muscle cross-sectional area and neural fibers, particularly fast-twitch fibers, leads to a decline in muscle strength, especially in the lower limbs. This decrease in lower limb strength causes patients to spend extended periods sitting or lying down. Prolonged inactivity and sedentary behavior further exacerbate muscle loss and strength decline [25,35]. Reduced lower limb function impairs the ability to perform daily tasks, such as standing up from a chair, picking up items from the floor, walking, and climbing stairs [38]. In situations of instability, the central nervous system compensates by increasing muscle recruitment. One study [39] found that with aging, there is a loss of up to 75% of type II fibers, which diminishes functional mobility and muscle strength output. Concurrently, the synaptic input to α-motor neurons and the number of cortical neurons forming the corticospinal tract also decrease [40]. Resistance training can activate more motor units and muscle fibers, enhance synaptic input to α-motor neurons, and recruit more cortical neurons within the corticospinal tract, thereby improving coordination, reaction time, and strength to support dynamic balance [41,42]. Studies [43,44] have demonstrated that 3 months of resistance training improves muscle mass, physical fitness, and functional outcomes. In another study [11], participants' functional fitness, such as the walking time, the chair stand test score, and the 8-foot up-and-go score, improved compared to the control group. In this study, after 4 weeks of training, both groups showed improvements in their BBS scores, which is consistent with previous findings. However, there was no significant improvement in TUGT scores, likely due to the relatively short duration of the training. The effective stimulation of key muscle groups, such as the gluteus maximus, quadriceps, and tibialis anterior, by resistance

XSL•FO
RenderX

training may improve lower limb strength and neuromuscular coordination, enhancing stability and balance.

In terms of cardiorespiratory endurance, although resistance training primarily focuses on muscle strengthening rather than endurance, research suggests that resistance training may also improve endurance. For patients with sarcopenia, increased lower limb strength can translate into faster walking speed [25], and training peripheral muscles may improve indices related to respiratory function, thereby providing more substantial support for endurance [45]. One study [46] indicated that resistance training could enhance the 6-minute walking distance in frail older adults, while another systematic review [47] found that resistance training improves cardiorespiratory function in healthy older adults, including the peak oxygen uptake, anaerobic threshold, and 6-minute walking distance. In this study, both groups demonstrated improvements in the 6-minute walking distance, though neither reached statistical significance, possibly due to the short duration of the training program. Regarding the IADL, previous systematic reviews have shown that patients with reduced muscle mass are more likely to experience impairments in activities of daily living (ADL) and IADL, with reduced grip strength also being associated with impairments in ADL and IADL [48]. In this study, both groups showed significant improvements in the IADL after training, with no significant differences observed between the groups.

Limitations

One of the limitations of this study is that it was a single-center RCT with a relatively small sample size. To address this limitation, the research team plans to conduct follow-up multicenter studies in regions with limited health care resources. Additionally, the follow-up period was relatively short. Future studies will involve a larger cohort over 8 weeks, 12 weeks, or even longer. Lastly, although participants were instructed to maintain consistent dietary habits throughout the study, detailed nutritional data were not adequately recorded. In addition, participants were not blinded, which may have introduced bias. In this study, the TRG received one-time offline instruction from a physiotherapist and were provided with resistance bands of appropriate tension. Furthermore, the pressure of having a follow-up assessment 1 month later may have increased patient compliance compared to routine application settings.

Conclusion

A 4-week mobile app–based telerehabilitation program produced improvements in muscle strength, balance, and the IADL comparable to those achieved by traditional in-person therapy in older adults with sarcopenia. Additionally, this telerehabilitation approach reduced health care resource use and logistical barriers. By offering an accessible, cost-effective, and patient-centered model of care, telerehabilitation shows promise as a viable alternative for patients with sarcopenia lacking convenient access to conventional rehabilitation services.

Acknowledgments

This research was funded by the Enhancement of the Capability for Technological Innovation in Aging-related Services of the Beijing Municipal Science & Technology Commission (Z191100004419009) and the Central High-Level Hospital Clinical Research Special Fund of the Peking Union Medical College Hospital (2022-PUMCH-B-131) . We are grateful for the organization's financial support. We appreciate information engineer Kai Wang for his kind support and help. We are grateful to the patients and families who participated in this study, without whom the work reported in this paper would not have been possible.

Data Availability

All data generated and analyzed during this study are fully presented in this paper and the multimedia appendices.

Authors' Contributions

Study conception and design was handled by YL and LZ, patient recruitment by LK and QW, rehab video production by XS, intervention management and data collection by YG and WZ, data analysis and draft preparation by LZ, and editing by YL. All authors have approved the final version of the paper.

Abstract

Background: Mental health problems in university students are associated with many negative outcomes, yet there is a gap between need and timely access to help. Single-session interventions (SSIs) are designed to be scalable and accessible, delivering core evidence-based intervention components within a one-off encounter.

Objective: COMET (Common Elements Toolbox) is an online self-help SSI that includes behavioral activation, cognitive restructuring, gratitude, and self-compassion. COMET has previously been evaluated in India, Kenya, and the United States with promising results. This study tests the acceptability, appropriateness, perceived utility, and efficacy of COMET among UK university students during the peripandemic period.

Methods: We conducted a randomized controlled trial evaluating the efficacy of COMET compared with a control group, with 2- and 4-week follow-ups. Outcome variables were subjective well-being, depression severity, anxiety severity, positive affect, negative affect, and perceived stress. We also measured intervention satisfaction immediately after completion of COMET. All UK university students with access to the internet were eligible to participate and were informed of the study online. The data were analyzed using linear mixed models and reported in accordance with the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist.

Results: Of the 831 people screened, 468 participants were randomized to a condition, 407 completed the postintervention survey, 147 returned the 2-week follow-up survey, 118 returned the 4-week follow-up survey, and 89 returned both. Of the 239 randomized, 212 completed COMET. Significant between-group differences in favor of the COMET intervention were observed at 2-week follow-ups for subjective well-being (Warwick-Edinburgh Mental Well-Being Scale; mean difference [MD] 1.39, 95% CI 0.19-2.61; P=.03), depression severity (9-item Patient Health Questionnaire; MD –1.31, 95% CI –2.51 to –0.12; P=.03), and perceived stress (4-item Perceived Stress Scale; MD –1.33, 95% CI –2.10 to –0.57; P<.001). Overall, participants were satisfied with COMET, with the majority endorsing the intervention and its modules as acceptable, appropriate, and exhibiting high utility.

XSL•FO
RenderX

The self-compassion module was most often reported as the participants' favorite module and the behavioral activation module was their least favorite. Qualitative analysis revealed that participants found COMET generally accessible, but too long, and experienced immediate and long-term beneficial effects.

Conclusions: This study demonstrated high engagement with the COMET intervention, along with preliminary short-term efficacy. Almost all participants completed the intervention, but study attrition was high. Participant feedback indicated a high level of overall satisfaction with the intervention, with perceived accessibility, immediate benefits, and potential long-term impact being notable findings. These findings support the potential value of COMET as a mental health intervention and highlight important areas for further improvement.

KEYWORDS

Common Elements Toolbox; mental well-being; online interventions; single-session interventions; university students

Introduction

Mental health problems are common in young people, with at least one in five 16- to 24-year-olds being affected, particularly females [1,2]. University students represent a substantial portion of this population and are at high risk of developing mental health problems due to the unique stressors they may face, such as living away from home for the first time, financial hardship, balancing studying with other responsibilities, and changing social relationships [3,4]. A recent meta-analysis that investigated the mental health of university students found a pooled prevalence rate of 25% for depression and 14% for suicide-related outcomes (eg, suicidal ideation, suicide attempts) [5], with other studies finding that 35% of first-year students reported symptoms indicative of a lifetime mental health disorder [6]. For university students, mental health problems are associated with negative academic outcomes including lower grades [7] and increased dropout rates [8]. Even subthreshold depression and anxiety can lead to substantial impairment [9]. If left untreated, these mental health disorders can increase the risk of more severe mental health and physical health problems developing across the lifespan [10,11]. Early interventions are therefore vital in reducing disease burden on a societal level and are highlighted by students as a priority for mental health and well-being support [12].

The restrictions imposed during the COVID-19 pandemic further exacerbated the global mental health burden [13], particularly in young adults and university students [14,15], while also limiting access to informal and formal support systems. There is concerning evidence that only 20% of UK students struggling with their mental health during the pandemic sought help [16]. Even before the pandemic, only an average of 1 in 3 students experiencing psychological distress used mental health services [17]. Although universities in the United Kingdom do provide internal psychosocial support services for students, such as cognitive behavioral therapy (CBT) and counseling, there are numerous barriers to help-seeking, including self-reliance, poor mental health literacy, feeling too uncertain or unwell to seek help, lack of knowledge on how to access university services, preferences for alternative support (eg, online), and stigma [18-21]. Thus, there is a substantial gap between need and treatment access in this population. Even when support has been accessed, disengaging before completing the full course of treatment is common, meaning that some do not receive the full dose and optimal benefits [22].

Digital interventions (eg, online CBT) are one way of overcoming barriers students may experience in accessing mental health support by addressing concerns regarding anonymity, privacy, accessibility, and stigma [20]. Digital interventions also have a growing evidence base supporting their efficacy in addressing mental health problems [23,24]. For example, a recent network meta-analysis found that guided self-help interventions (including digital support) were more effective in reducing depression than waitlist control conditions [25]. Another meta-analysis, which compared 10 digital multisession interventions of a mean duration of 4 weeks with active and waitlist controls in university students, found small but significant improvements in psychological well-being after the intervention [26]. However, despite the promise of digital support, engagement is less than optimal due to factors such as lack of time and interest [27]. One way to address poor engagement with digital interventions is through online single-session interventions (SSIs). SSIs have the advantage of being more scalable and accessible because they are designed to deliver the core components of an active intervention within a one-off encounter, without an expectation that an individual will engage in longer-term therapy. Thus, SSIs could be a useful and effective addition to the suite of therapeutic options offered by university student services, which tend to be longer courses of treatment [28-34].

One such example is COMET (Common Elements Toolbox), an online (web-based) SSI without therapist contact. COMET was originally designed by Professor Rob de Rubeis' team [35] for adolescents in India, and subsequently adapted and evaluated in US college students. COMET includes 4 modules based on evidence-based principles, namely, (1) behavioral activation (BA); (2) cognitive restructuring; (3) gratitude, from the discipline of positive psychology [36]; and (4) self-compassion. Versions of COMET have been developed with Kenyan and Indian adolescents and tested with US graduate students during the pandemic [35,37,38]. These versions are acceptable and useful, with US postgraduate students reporting pre- to post-program improvements in their perceived ability to manage the personal and psychological impacts of objective conditions or events (secondary control [39]). However, this online SSI has yet to be implemented and evaluated in a randomized

XSL•FO
RenderX

controlled trial (RCT) among university students in the United Kingdom, with potential cultural differences meaning that existing findings cannot simply be extrapolated into the UK context. Additionally, UK higher education is typically shorter and less expensive than in the United States, and UK students apply for specific courses, whereas US students can switch majors during their university years.

We aimed to test the efficacy of COMET, an online mental health SSI, in undergraduate and postgraduate university students. Specifically, we sought to address the following questions:

- Compared with attention control, does COMET improve the mental health and well-being of university students at 2- and 4-week follow-ups?
- Do demographic variables (ie, age or gender) or clinical variables (ie, baseline depression severity, anxiety severity, mental health diagnoses, or treatment status) moderate the efficacy of COMET at 2- and 4-week follow-ups?
- How do participants perceive the acceptability and appropriateness of COMET, how do their utility ratings compare across the 4 COMET modules, and which modules do they prefer?

Methods

Trial Design

The study was a 2-arm, individually (1:1) randomized controlled trial design, comparing short-term (2- and 4-week) mental health outcomes of UK university students exposed to COMET (ie, the intervention group) or an attention-control questionnaire (ie, the control group). A nontherapeutic control was chosen to reflect the fact that SSIs are often provided as an alternative to receiving no support or being put on a waiting list for another intervention. The study was reported in accordance with CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth; Multimedia Appendix 1) recommendations for the reporting of RCTs of eHealth interventions [40] and the TIDieR (Template for Intervention Description and Replication) recommendations on the reporting of behavior change interventions [41]. The trial was registered at ClinicalTrials.gov (NCT05718141) toward the end of data collection.

Important Changes to Methods After Trial Commencement

We identified a Qualtrics error in January 2022, with participants who had completed the baseline survey not receiving the automatic 2- and 4-week follow-up surveys. This error was resolved in February 2022. We emailed a final follow-up survey link to the 36 participants who had completed the intervention before resolution and were outside the 4-week follow-up window by 1 week to 2 months. We also emailed survey links to the 45 participants who had completed the intervention but were still within the 2-week follow-up window and the 37 participants within the 4-week follow-up window. The follow-up data from the 36 participants who were 1 week to 2 months outside of the 4-week follow-up window were excluded from the main analyses, with these participants reflected in attrition rates.

Participants

The study was set in the nonclinical, peripandemic context of UK universities and recruited currently registered undergraduate and postgraduate students with internet access. Those without internet access and those younger than 16 years were not eligible. The decision to offer the intervention more widely rather than just within clinical settings was to minimize barriers to access.

During the recruitment phase, potential participants were informed of the study through study adverts shared via social media platforms (eg, Facebook, Twitter, Instagram, TikTok), university-held mailing lists, and mailing lists/newsletters of charities and organizations with an interest in student mental health, such as Student Minds. The study was also advertised via psychology research participation schemes at the University of Bath and the University of Reading, which provide students with credits in exchange for taking part in research studies. It was also promoted on research recruitment websites such as MQ Mental Health Participate and Call for Participants. All adverts directed participants to a Qualtrics survey (Silver Lake Technology Management, L.L.C.) where they could learn more information about the study and take part.

Using power calculations based on the effect size of a previous iteration of COMET on the 9-item Patient Health Questionnaire (PHQ-9) [38], to detect a small effect of d=0.3, we required 378 participants to complete follow-up. A previous RCT of an SSI in adolescents had an attrition rate of around 28% at 3 months [32]. However, given our shorter follow-up rate of 4 weeks, we raised the recruitment target to 473 to allow for 20% attrition.

Measures and Materials

All study documentation, including the information sheet, consent form, baseline assessment survey, experimental conditions, posttreatment survey, and follow-up surveys, was accessed through the Qualtrics platform. Brief demographic information was collected by self-report, including age in years, gender identity (female, male, or other), sexual orientation (heterosexual, bisexual, homosexual, other, or unlisted), and ethnicity (White or White British, Asian or Asian British, Black or Black British, or mixed). Participants were also asked about their mental health in relation to diagnoses, past and current experiences, and treatment status.

Measures of Mental Health and Well-Being

For all participants, mental health and well-being were assessed at 3 time points, including a baseline assessment pretreatment, a 2-week follow-up, and a 4-week follow-up. Several dimensions of mental health and well-being were assessed, including (1) subjective well-being, (2) depression severity, (3) anxiety severity, (4) positive affect, (5) negative affect, and (6) perceived stress.

The Warwick-Edinburgh Mental Well-Being Scale (WEMWBS), a commonly used measure of well-being [42], was used in this study. The WEMWBS has 14 items that capture participants' feelings and thoughts that best describe their

XSL•FO
RenderX

experience over the previous 2 weeks using a scale from 1 (none of the time) to 5 (all of the time). The WEMWBS has robust psychometric properties [43]. The WEMWBS demonstrated good reliability, with a Cronbach α of 0.88 at baseline, 0.82 at the 2-week follow-up, and 0.83 at the 4-week follow-up.

The PHQ-9, a commonly used measure for depressive symptoms [44], was also used in this study. The 9 items of the questionnaire (α=.84) capture the frequency of depressive symptoms over the preceding 2 weeks using a scale from 0 to 3. A total score of 0-4 indicates no depression, 5-9 indicates mild depression, 10-14 indicates moderate depression, 15-19 indicates moderately severe depression, and 20-24 indicates severe depression. The PHQ-9 has a sensitivity and specificity of 88% for detecting clinical depression [45]. The PHQ-9 has demonstrated good reliability, with a Cronbach α of 0.84 at baseline, 0.89 at the 2-week follow-up, and 0.86 at the 4-week follow-up.

The 7-item General Anxiety Disorder (GAD-7) checklist is a commonly used measure for evaluating symptoms of anxiety [46]. The 7 items of the checklist (α=.87) capture the frequency of anxious symptoms over the preceding 2 weeks using a scale from 0 to 3. A total score of 0-4 indicates no anxiety, 5-9 indicates mild anxiety, 10-14 indicates moderate anxiety, and ≥15 indicates severe anxiety. The GAD-7 has a sensitivity and specificity of 89% and 82% respectively [46]. The GAD-7 demonstrated good reliability, with a Cronbach α of 0.87 at baseline, 0.85 at the 2-week follow-up, and 0.84 at the 4-week follow-up.

The Positive and Negative Affect Schedule (PANAS) is a commonly used measure of participants' affective states [47]. This scale includes two 10-item subscales measuring positive affect and negative affect on a 5-point Likert scale (1=very slightly or not at all and 5=extremely). The PANAS has been shown to be reliable and valid [48]. The PANAS demonstrated good reliability for positive affect, with a Cronbach α of 0.88 at baseline, 0.90 at the 2-week follow-up, and 0.91 at the 4-week follow-up. The PANAS also demonstrated good reliability for negative affect, with a Cronbach α of 0.87 at baseline, 0.85 at the 2-week follow-up, and 0.87 at the 4-week follow-up.

The 4-item Perceived Stress Scale (PSS-4 [49]) is an abbreviated, 4-item scale designed to measure the extent of perceived stress in individuals' lives over 4 weeks. However, to better align with our assessment intervals, this scale was adapted to specifically assess perceived stress over 2 weeks. The PSS-4 demonstrated good reliability, with a Cronbach α of 0.78 at baseline, 0.84 at the 2-week follow-up, and 0.80 at the 4-week follow-up.

Measures of Intervention Satisfaction

Immediately after completing COMET, satisfaction with the intervention was assessed within a posttreatment survey using measures of (1) perceived appropriateness (perceived fit, relevance, or compatibility of treatment to address a particular issue or problem), (2) perceived acceptability (perception that a given treatment is agreeable, palatable, or satisfactory), (3) perceived utility, and (4) module preferences. These measures were added after trial registration because, as the study progressed, it became evident that the initial measures might not fully capture participants' experiences with COMET. Therefore, we aimed to obtain a more detailed understanding of the intervention's acceptability and align with best practice guidance, which emphasizes the importance of ongoing assessment and refinement in accurately evaluating complex interventions.

Intervention Appropriateness Measure is a 4-item measure assessing intervention appropriateness. Each item has a 5-point scale ranging from 1 (completely disagree) to 5 (completely agree) [47]. The Intervention Appropriateness Measure demonstrated good reliability, with a Cronbach α of 0.90.

Acceptability of Interventions Measure is a 4-item measure assessing intervention acceptability. Each item has a 5-point scale ranging from 1 (completely disagree) to 5 (completely agree) [47]. The Acceptability of Interventions Measure demonstrated good reliability, with a Cronbach α of 0.92.

Perceived utility is a bespoke measure where participants in the intervention group were asked to rate their feelings toward each module concerning helpfulness, engagement, and intention to apply intervention techniques in their daily lives. These questions were measured on a 7-point Likert scale from 1 (strongly disagree) to 7 (strongly agree), with 3 items per module. Across each of the 4 COMET modules, perceived utility also demonstrated good reliability, with Cronbach α values ranging from 0.90 to 0.94.

Participants indicated their preferences toward the 4 modules with the prompt questions asked: "Which exercise was your favorite?" and "Which exercise was your least favorite?." All participants in the intervention group were also asked to complete a free textbox asking about their experiences with COMET.

Procedure

Interested students were directed to a web-based Qualtrics survey including an information sheet, a consent form, a baseline assessment survey, descriptions of the experimental conditions, a posttreatment survey, and a debrief sheet. The information sheet explained the purposes of the research and the process of data collection and management. Following completion of the consent form, participants were directed to complete a baseline assessment survey measuring participants' mental health and well-being. Participants were then randomly assigned to the intervention or control condition using the automated simple randomization tool embedded within Qualtrics. Thus, the research team was blind to treatment allocation. However, due to the intervention's nature, the actual treatment assignment was not concealed from participants.

In addition to the preintervention measures, participants in the control group were also asked to complete additional questionnaires at baseline, which acted as an attention control for COMET.

XSL•FO
RenderX

Intervention

Overview

Participants randomized to the intervention condition received and completed COMET, an online self-guided SSI. The intervention was accessible via any device which could connect to the internet, without any need to register or download software. It was based on the core principles of CBT, combined with principles from positive psychology. All 4 COMET modules were designed to be completed in a single session, taking 60-75 minutes. The modules featured short reading exercises, informational videos, and writing tasks.

Behavioral Activation

In this module, participants could identify and reflect on activities that were important to them, list activities they found enjoyable and meaningful, reflect on why these activities mattered to them, and schedule in time to perform these activities in the weeks ahead.

Cognitive Restructuring

In this module, participants were invited to identify and reframe negative beliefs. They were first asked to read about a hypothetical character who is adjusting to changes in their routine. Then, using the character's story as an example, they were asked to try to identify negative beliefs that the character may have been experiencing and ways the character could reframe the belief. They could then apply this technique to a situation in their own life.

Gratitude

In this module, participants could reflect and write about 3 things they were grateful for. They were then asked to think and write about things they noticed around them that they enjoyed and were grateful for.

Self-Compassion

In this final module, participants were asked to write a self-compassion letter to themselves, expressing compassion toward themselves just as they would toward a friend or family member. They were also requested to create a few sentences that they would like to hear when feeling self-critical.

Further rationale for all 4 modules can be found in previous publications [35,38]. Participants could only access the intervention once. Outcome measures were collected immediately after they completed COMET.

Attention Control

Participants allocated to the attention control group were asked to complete 5 additional measures, including a Symptom Importance Rating Questionnaire, the Chalder Fatigue Questionnaire [48], the Pittsburgh Sleep Quality Index [50], the Snaith-Hamilton Pleasure Scale [51], and the Fatigue Associated With Depression Scale [52]. These measures are not reported in this study. These were not completed by the intervention group nor reported as main outcomes on the RCT and will be reported elsewhere.

Immediately upon completion of these conditions, a posttreatment survey collected data related to their satisfaction with the COMET (only for the intervention group) and brief demographic information (for both groups). A debrief sheet signposted information about sources of mental health and well-being support. The initial intervention modules and assessment measures were designed to take participants approximately 60-75 minutes to complete.

Emails were sent out at 2 and 4 weeks after the intervention asking participants to complete follow-up assessment measures, which were designed to take approximately 10-15 minutes at each time point. All assessments took place online. Those who completed both follow-up assessments were able to opt into a prize draw for 1 of 16 £50 (US $63) Amazon vouchers. Additionally, those who completed the study as part of a student research participation scheme could earn course credits for taking part.

As a result of the pseudo-anonymous nature of the study, distress management was based on signposting, without direct or personal contact from the research team. It was the responsibility of the participants to decide whether they acted on this advice. If a participant scored >0 on the PHQ-9 item which asks about suicidal ideation (item 9), the participant saw an additional pop-up box suggesting that they may want to seek extra help, with a list of potential sources and contact details. They were reminded that the research team will not routinely monitor the answers to these questions. However, these participants were still included in the study.

Ethical Considerations

All research was performed in accordance with relevant guidelines and regulations set by the Declaration of Helsinki. Ethical approval was granted by the University of Bath Psychology Research Ethics Committee (reference 21-212). Reciprocity was also granted by the University of Reading and Kings College London. All participants provided informed consent.

Analysis Plan

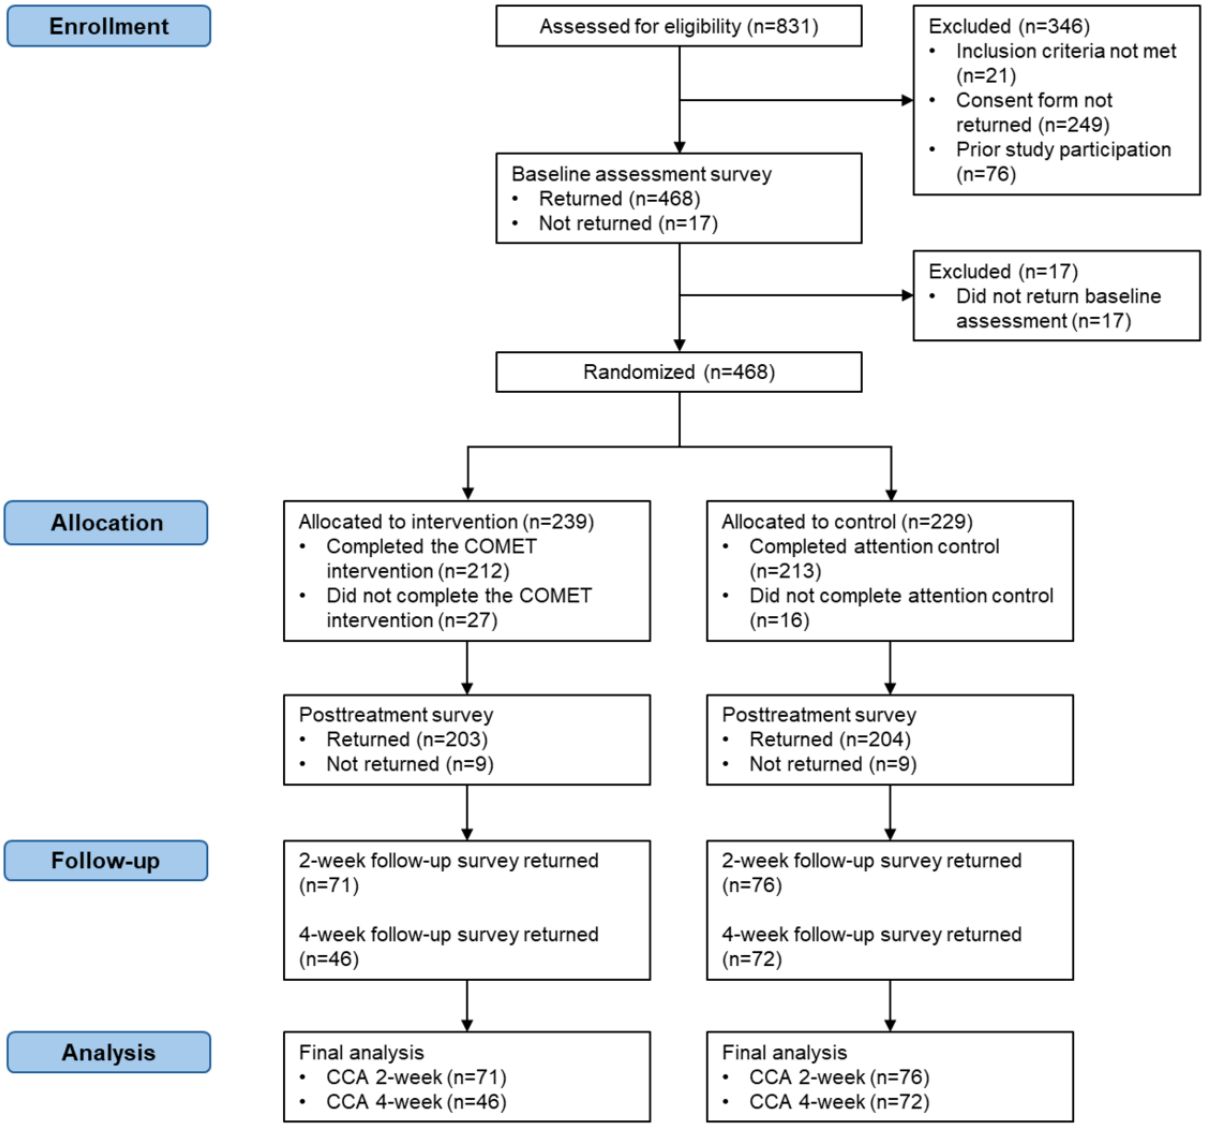
All quantitative data were analyzed descriptively overall and by each arm. Continuous data were summarized using means and SDs. Categorical data were presented using frequencies and percentages. Data on feasibility (ie, recruitment, intervention engagement, and outcome completion rates) and acceptability (ie, intervention acceptability and appropriateness) were reported along with baseline characteristics in the 2 trial arms. All outcome data were analyzed using linear mixed models, adjusted for individual-level variation in baseline measures.

To address the first research question, intervention and control groups were compared based on complete case data at (1) the 2-week follow-up and (2) the 4-week follow-up using intention to treat (ITT). Between-group differences are presented as adjusted mean differences (MDs) and 95% CIs. Effect sizes were also calculated for the results of this study. For the second research question, exploratory moderation analyses were conducted to determine if baseline characteristics moderated the relationship between group assignment (intervention or control group) and each outcome measure. Age, anxiety, and depression were not recoded into categories. Gender, diagnoses, and current treatment were dummy-coded into binary values.

XSL•FO
RenderX

To address the third research question, ratings of acceptability and perceived utility (at postintervention) were summarized using means and SDs. Sensitivity analysis using multiple imputations was conducted to assess the likely impact of missing data. Data were first analyzed using ITT (ie, all participants randomized who provided follow-up data). The data were then analyzed using ITT with all imputed data.

We analyzed the free textbox data using principles from inductive content analysis [53] in conjunction with Braun et al's [54] method for analyzing qualitative data collected from online surveys. Specifically, 2 research team members (BS and ML) independently familiarized themselves with all the qualitative data by reading and re-reading the responses. Next, BS and ML independently focused on 15-20 responses and generated initial codes. These initial codes were then applied to the remaining free-text responses, utilizing constant comparison to determine whether additional codes were warranted for different meanings. After coding the data separately, BS and ML convened to compare their codes and discuss patterns in the responses. Through discussion and iterative review of the qualitative data, with supervisory input from M Loades, they refined and finalized the themes. Illustrative quotes were then selected to exemplify each theme.



Results

Participant Flow

The participant flow is shown in Figure 1 (also see Multimedia Appendix 1). Participant recruitment and follow-up took place between September 2021 and December 2022. Of the 831 individuals assessed, 468 completed baseline measures and were randomized to either the COMET intervention (n=239) or the attention control (n=229). Of the 239 that were randomized and initiated COMET, 212 (88.7%) completed COMET, with 203 (84.9%) completing the posttreatment survey. A total of 213 out of 229 (93%) individuals completed the attention control, with 204 (89.1%) completing the postattention control survey. Of those randomized, 147 participants completed the 2-week follow-up survey, 118 completed the 4-week follow-up survey, and 89 participants completed both follow-up surveys.

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram illustrating the progression of university students through the different phases of the randomized controlled trial. CCA: complete case analysis.

Baseline Data

The mean age of participants was 22.49 (SD 7.28) years, with most participants identifying as female (339/407, 83.3%), heterosexual (296/407, 72.7%), and White or White British (272/407, 66.8%); 126 of 407 (31%) participants had been previously diagnosed with a mental health disorder and 85 of 407 (20.9%) were actively receiving treatment for a mental health disorder during the study. Further, 162 of 407 (39.8%) participants had at least moderate depression and 95 of 407 (23.3%) had at least moderate anxiety (Table 1).

[a]COMET: Common Elements Toolbox.

[b]Demographic information was reported by participants after exposure to their allocated treatment condition. Completed posttreatment surveys were returned by 407 participants across the intervention (n=203) and control (n=204) conditions.

Intervention Outcomes: Primary Analysis

At the 2-week follow-up, the complete-case ITT analysis showed that subjective well-being (WEMWBS) was significantly higher in the intervention group compared with the control group, with an MD of 1.39 (95% CI 0.19-2.61, *P*=.03) and a small effect size (Cohen *d*=0.24). Depression scores were also significantly lower in the intervention group compared with the control group (PHQ-9: MD –1.31, 95% CI –2.51 to –0.12; *P*=.03), with a small effect size (*d*=0.23). Perceived stress was also significantly lower in the intervention group compared with the control group (PSS-4: MD –1.33, 95% CI –2.10 to –0.57; *P*<.001), with a small effect size (*d*=0.37). No significant differences between groups in subjective well-being (*P*=.16), depression (*P*=.08), or perceived stress (*P*=.19) were observed at the 4-week follow-up. For the remaining outcome measures (ie, GAD-7, Negative Affect Scale, and Positive Affect Scale), no between-group differences were observed at the 2- (*P*=.31, *P*=.80, and *P*=.20) or 4-week (*P*=.33, *P*=.37, and *P*=.41) follow-ups (Table 2).

Table 2. Between-group differences in primary and secondary mental health outcomes among university students participating in the randomized controlled trial at the baseline, 2-week, and 4-week follow-up assessments[a].

Outcome	Intervention, mean (SD)	Control, mean (SD)	Between-group difference (95% CI)	*P* value
Subjective well-being (Warwick-Edinburgh Mental Well-Being Scale)				
Baseline	22.04 (4.85)	21.53 (5.17)	N/A[b]	N/A
2 weeks	22.83 (4.37)	21.72 (4.76)	1.39 (0.19 to 2.61)	.03
4 weeks	22.89 (4.39)	21.75 (5.06)	1.01 (–0.39 to 2.42)	.16
Depression severity (9-item Patient Health Questionnaire)				
Baseline	8.30 (5.80)	9.05 (5.76)	N/A	N/A
2 weeks	7.42 (5.27)	8.78 (6.41)	–1.31 (–2.51 to –0.12)	.03
4 weeks	6.80 (5.12)	8.92 (6.34)	–1.39 (–2.92 to 0.15)	.08
Anxiety severity (7-item General Anxiety Disorder Checklist)				
Baseline	6.05 (4.43)	6.73 (4.62)	N/A	N/A
2 weeks	5.44 (3.59)	6.68 (4.80)	–0.51 (–1.49 to 0.47)	.31
4 weeks	4.85 (3.33)	6.40 (4.63)	–0.59 (–1.81 to 0.61)	.33
Negative affect				
Baseline	22.55 (7.33)	23.20 (8.02)	N/A	N/A
2 weeks	21.29 (6.27)	22.76 (8.29)	–0.24 (–2.08 to 1.60)	.80
4 weeks	20.41 (6.77)	22.85 (8.06)	–1.08 (–3.42 to 1.27)	.37
Positive affect				
Baseline	28.02 (8.06)	27.16 (7.71)	N/A	N/A
2 weeks	28.73 (7.73)	26.53 (8.11)	1.33 (–0.70 to 3.36)	.20
4 weeks	28.76 (8.55)	26.89 (7.98)	1.06 (–1.47 to 3.58)	.41
Perceived stress (4-item Perceived Stress Scale)				
Baseline	7.67 (3.27)	7.67 (3.07)	N/A	N/A
2 weeks	6.86 (3.20)	8.04 (3.13)	–1.33 (–2.10 to –0.57)	<.001
4 weeks	6.54 (2.96)	7.42 (3.43)	–0.68 (–1.69 to 0.33)	.19

[a]Analysis includes complete case data for 2 (n=147) and 4 weeks (n=118).

[b]N/A: not applicable.

Intervention Outcomes: Moderation Analysis

For those receiving COMET, individuals who were not currently receiving treatment showed greater improvements in subjective well-being at both 2-week (B=–3.37, 95% CI –6.34 to –0.41; *P*=.03) and 4-week follow-ups (B=–4.11, 95% CI –7.57 to –0.65; *P*=.02) than those individuals who were receiving another treatment.

At the 4-week follow-up, younger individuals also showed greater improvements in depression (B=0.19, 95% CI 0.01-0.37; *P*=.04) and anxiety (B=0.15, 95% CI 0.01-0.30; *P*=.04) compared with their older counterparts.

Compared with those with lower baseline anxiety, individuals with higher baseline anxiety exhibited greater improvements in perceived stress at the 4-week follow-up (B=–0.23, 95% CI –0.45 to –0.01; *P*=.047).

No moderation effects were observed for gender, baseline depression severity, or mental health diagnoses. Please see Multimedia Appendix 2 for full analyses.

Intervention Outcomes: Sensitivity Analyses

Missingness ranged from 0.00% to 68.42% for cases (mean 44.46%, SD 25.28%) and from 0.00% to 73.29% (mean 44.46%, SD 34.93%) for variables. Little's Missing Completely At Random (MCAR) Test was applied and indicated that the data were missing completely at random (χ^2_{100}=99.10, *P*=.51); hence, it was assumed that missingness was purely random and not related to any observed or unobserved data.

Given the high proportion of missing data, multiple imputation was carried out to estimate follow-up outcomes for all participants who did not provide data at the 2- and 4-week follow-ups (Multimedia Appendix 3). Depression and perceived stress were lower in the intervention group compared with the control at the 2-week follow-up but only bordering significance

XSL•FO
RenderX

(PHQ-9: MD –0.53, 95% CI –1.10 to 0.04, *P*=.07; and PSS-4: MD=–0.57, 95% CI –1.15 to 0.01, *P*=.05). No between-group effects between the intervention and control were observed for any of the other variables or follow-up points.

Intervention Acceptability

Overall, participants found COMET to be acceptable, with between 166 out of 203 (81.8%) and 188 out of 203 (92.6%) participants agreeing or strongly agreeing that they approved of, liked, and welcomed COMET and found it appealing. Participants also found COMET to be appropriate with between 162 out of 203 (79.8%) and 188 out of 203 (92.6%) agreeing or strongly agreeing that COMET was fitting, suitable, applicable, and a good match (Table 3). Each of COMET's 4 modules was also perceived to have high utility (Table 4). Most participants at least slightly agreed that BA (169/203, 83.3%, to 181/203, 89.2%), cognitive restructuring (145/203, 71.4%, to 175/203, 86.2%), gratitude (174/203, 85.7%, to 182/203, 89.7%), and self-compassion (150/203, 73.9%, to 174/203, 85.7%) were helpful, engaging, and applicable. Participants most liked the self-compassion module (66/203, 32.5%) followed by gratitude (59/203, 29.1%), cognitive restructuring (55/203, 27.1%), and BA (23/203, 11.3%). Participants least liked the BA module (83/203, 40.9%), followed by self-compassion (51/203, 25.1%), gratitude (38/203, 18.7%), and cognitive restructuring (31/203, 15.3%).

Table 3. Assessment of the acceptability and appropriateness of the COMET[a] intervention among university students (n=203).

Assessment	Agrees or strongly agrees, n (%)	Neutral, n (%)	Disagrees or strongly disagrees, n (%)
Acceptability (Acceptability of Interventions Measure)			
Approve	188 (92.6)	12 (5.9)	3 (1.5)
Appealing	166 (81.8)	27 (13.3)	10 (4.9)
Like	177 (87.2)	21 (10.3)	5 (2.5)
Welcome	177 (87.2)	23 (11.3)	3 (1.5)

[a]COMET: Common Elements Toolbox.

Qualitative Analysis

The free-text content analysis of participants' experiences of COMET resulted in the formulation of 4 categories: time/length, accessibility, immediate effects, and long-term effects. Participants expressed that COMET introduced valuable skills in a manner that was simple and easy to understand, with many participants also noting the immediate effects of increased positivity, relaxation, and self-compassion upon completion. They also reported that the intervention helped to improve their thinking and outlook by rationalizing worries and recognizing the positive aspects of their lives. Participants believed that COMET had the potential for long-term impact, especially in helping them plan positive activities to regain a healthy routine and restructure their thinking. However, participants did reflect that some of the exercises were too long or boring, which could have potentially contributed to study dropout. Several participants also reported technical issues (eg, images not loading), which acted as a potential barrier to engagement. See Multimedia Appendix 4 for full analysis.

Discussion

Principal Findings

UK university students engaged well with the COMET online SSI and exhibited small, significant improvements in well-being, depression severity, and perceived stress over a 2-week follow-up period compared with the control arm. Changes in anxiety severity, positive affect, and negative affect were nonsignificant. Exploratory analysis also revealed that COMET was potentially more effective at reducing stress for those with elevated symptoms of anxiety. We also found that COMET was largely well-received in terms of acceptability, appropriateness, and feasibility, although users commented that it was too long, and some had technical issues.

A high level of intervention completion was observed, with 212 of 239 (88.7%) students randomized to COMET completing the intervention. This rate is particularly noteworthy when compared with completion rates in multiweek digital interventions, where a significant drop-off in engagement is common. For example, a systematic review of digital mental health interventions for depression, anxiety, and well-being in students found that most studies saw high completion rates after module 1 but reduced engagement over time, with only a minority completing all modules [55]. The structure of multiweek interventions may unintentionally contribute to attrition, as participants might find it difficult to commit to long-term engagement due to competing demands, a lack of immediate benefits, or the gradual loss of motivation. By contrast, SSIs such as COMET potentially address this challenge by minimizing the time commitment required, making it easier for participants to complete the program in a single sitting.

While COMET led to improvements in well-being, depression, and perceived stress at the 2-week follow-up, these changes were not observed for anxiety or positive and negative affect and had disappeared by the 4-week follow-up. This contrasts with another SSI RCT in adolescents, which found sustained effects on depression at 3 months [32]. One possible reason for this difference is the inclusion criteria. The previous study included participants based on depression criteria, whereas COMET aimed to be more inclusive by not using such criteria.

XSL•FO
RenderX

In COMET, the mean baseline PHQ-9 score was below 10 (the cutoff for moderate depression), and only 126 of 407 (31.0%) participants had any mental health diagnosis. This may have led to ceiling effects, limiting the potential for long-lasting changes. Moderation analysis further supports this, showing that the effects were more pronounced for those with elevated baseline symptoms and a previous diagnosis. Additionally, the analysis found that older participants benefited less from COMET than younger ones. This could reflect that during our recruitment period between September and December, older participants, likely in later years of study, may experience higher levels of depression and anxiety due to increased pressure related to final-year projects and concerns about future employment compared with first-year students [56].

Our observed effect sizes at week 2 for well-being (d=–0.24), depression (d=0.23), and perceived stress (d=0.37) compare favorably with other online SSIs [30,32,57]. However, after multiple imputations, the effect on well-being became nonsignificant, and the effects on depression and perceived stress were bordering on significance. These effect sizes are smaller than those of more extensive internet-based CBT programs for anxiety and depression, with a previous meta-analysis found to have pooled effects of g=0.51 (95% CI 0.29-0.73) in young adults [58]. However, SSIs such as COMET could make a considerable difference at the population level, given their scalability and potential reach [59]. It is particularly encouraging that participants mentioned in the free text feedback how they could apply their learning from COMET in their daily lives, aligning with student priorities for mental health support [12].

In terms of participant preference, self-compassion was found to be the most liked aspect of COMET, while BA received lower ratings. Several possible reasons were identified to explain this discrepancy. First, BA is typically designed to be delivered over multiple weeks [60,61], including goal setting and regular goal reviews. In the COMET intervention, which consisted of a single session, the absence of goal reviews may have undermined the efficacy of BA. Second, previous studies have found self-compassion to be particularly valuable for students adjusting to university life with its various demands and stressors [62]. Our qualitative findings also suggest that participants found self-compassion to be a helpful coping strategy in this population. Third, COMET had no inclusion criteria for elevated symptoms of depression or anxiety. BA primarily targets depression and may be most suitable for individuals experiencing depressive symptoms. The BASIL trial, for instance, found that participants without depression perceived the relevance of BA to be limited, although this was in older adults [63]. Fourth, while activity monitoring has previously been regarded as beneficial for students, such as during the transition to college [64], the contextual limitations imposed by the pandemic made BA less effective in supporting participants due to the restrictions on engaging in pleasurable activities.

Participant recruitment was challenging, and it took 15 months to recruit the current sample. Online SSIs aimed at adolescents in the United States have recruited considerably larger samples in much shorter periods via social media [32]. A likely explanation for the difference is the guaranteed vouchers as an incentive to participate [65], whereas in our study, they were entered into a prize draw. When recruiting university students with subclinical anxiety or depression symptoms, a study in the Netherlands found that emailing all students via the central student administration was the most effective strategy, as compared with flyers, media, and social media adverts, among others [66]. Similarly, campus-wide recruitment emails resulted in over 80% recruitment of the 651 participants in a US-based trial of a universal, web-based prevention program for anxiety and depression [67]. Unfortunately, we were unable to secure agreement within our institutions to do this in our study. The pandemic context within which we recruited also made it more difficult to recruit using flyers/posters in physical locations on campus, and we, therefore, relied predominantly on social media and undergraduate research participation schemes, although we did also list the study on the research studies section of the student services web page at a UK university.

Once students had signed up to participate, our study had considerable study attrition, like other studies of digital mental health interventions in student populations [68-72]. Our high attrition could be explained by the qualitative feedback provided, which indicated that some participants experienced COMET as too long, with others having technical issues. Other studies have found that students prefer interventions that they can use in short bursts of time [73], and it may be that future iterations of COMET could give choices so that students can choose which components they want to do. This would also add a degree of personalization, which young people say aids their engagement in online interventions [74]. Technical issues are a common barrier to engagement in digital mental health interventions [75].

Strengths and Limitations

We evaluated an existing intervention in a novel population, using a broad, well-validated series of psychometric instruments which spanned different dimensions of mental health problems and well-being. This is important, given that no single measure captures all stakeholder priorities in university student mental health [76], and our comprehensive approach including both mental health symptom measures and a well-being measure allowed for a more holistic understanding of COMET's impact.

Like other digital mental health intervention studies in university student samples [68-72], we experienced high attrition rates from the study. Although the absence of patterned missingness suggests that this attrition did not bias the results, it substantially impacted the sample size. While we recruited and randomized 468 participants, only 147 returned the 2-week follow-up survey (attrition: 321/468, 68.6%) and 118 returned the 4-week follow-up survey (attrition: 350/468, 74.8%). Our a priori calculations indicated that a sample size of 378 participants would be required to detect statistically significant differences in the PHQ-9. Therefore, we had insufficient power, and our findings may be prone to type II errors. After multiple imputations, many of our estimates became nonsignificant, except for depression and perceived stress at the 2-week follow-up, which were only marginally significant. This suggests that even with imputation, the effect size might have been

XSL•FO
RenderX

smaller than initially thought, and the study may need a larger sample size to be sufficiently powered.

Most participants were young, White, heterosexual women, like other university mental health intervention studies [67,77]. While this helps to provide valuable insights into the effects of COMET within this demographic, it does pose a limitation regarding the generalizability of the findings to the broader spectrum of UK university students. Furthermore, due to insufficient diversity in the sample, exploratory moderation analyses for demographic variables could not be meaningfully conducted.

While the efficacy of COMET was established across various domains, it is important to note that contrary to real-world settings, participants were given either monetary rewards or course credit incentives for completing these interventions. This raises concerns about the applicability and genuine impact of COMET outside of an incentivized research context [78]. Accordingly, to ensure results are driven by inherent value and user commitment rather than external rewards, future research should examine the intervention's impact in contexts devoid of external motivators.

This study also focused on short-term outcomes at 2- and 4-week intervals, leaving questions about sustained efficacy over the long term. This is particularly important for making fair comparisons with longer, multisession interventions that collect follow-up data over extended periods. Future investigations should emphasize extended follow-ups to provide a comprehensive understanding of an intervention's enduring benefits [79]. In contemporary psychotherapeutic research, a benchmark of at least six months is considered standard.

Finally, we were unable to measure the amount of time participants spent on COMET due to limitations in the intervention platform's functionality. It is possible that individuals who spent more time on the platform experienced greater benefits. Future research should investigate the total time spent on SSIs and examine whether time spent on different components varies among users.

Future Directions

Future studies should further explore how best to support underserved groups (eg, explore the experiences of minority groups [80]). Artificial intelligence–driven adaptive trials may also help us to answer what works for whom [81]. To reach university students before mental health symptoms become functionally impairing, early interventions or prevention efforts may achieve greater reach by embedding them within courses and ensuring maximal engagement through coproduction [82].

Conclusions

This study demonstrated the preliminary short-term efficacy of the COMET intervention, as evidenced by the significant between-group differences favoring the intervention at the 2-week follow-up. However, attrition was high, potentially biasing the results. Participant feedback indicated overall satisfaction with the intervention, with perceived accessibility, immediate benefits, and potential long-term impact being notable findings. These findings support the potential value of COMET as a mental health intervention and highlight important areas for further development in future SSI interventions.

Abstract

Background: Health systems are increasingly offering patient portals as tools for patients to access their health information with the goal of improving engagement in care. However, understanding health care providers' perspectives on patient portal implementation is crucial.

Objective: This study aimed to understand health care providers' experiences of implementing the MyChart patient portal, perspectives about its impact on patient care, clinical practice, and workload, and opportunities for improvement.

Methods: Using an explanatory sequential mixed methods approach, we conducted a web-based questionnaire and semistructured individual interviews with health care providers at a large Canadian community hospital, 6 months after MyChart was first offered to patients. We explored perspectives about the impact of MyChart on clinical practice, workload, and patient care. Data were analyzed using descriptive statistics and thematic analysis.

Results: In total, 261 health care providers completed the web-based questionnaire, and 15 also participated in interviews. Participants agreed that patients should have access to their health information through MyChart and identified its benefits such as patients gaining a greater understanding of their own health, which could improve patient safety (160/255, 62%). While many health care providers agreed that MyChart supported better patient care (108/258, 42%), there was limited understanding of features available to patients and expectations for integrating MyChart into clinical routines. Concerns were raised about the potential negative impacts of MyChart on patient-provider relationships because sensitive notes or results could be inappropriately interpreted (109/251, 43%), and a potential increase in workload if additional portal features were introduced. Suggested opportunities for improvement included support for both patients and health care providers to learn about MyChart and establishing guidelines for health care providers on how to communicate information available in MyChart to patients.

Conclusions: While health care providers acknowledged that MyChart improved patients' access to health information, its implementation introduced some friction and concerns. To reduce the risk of these challenges, health systems can benefit from engaging health care providers early to identify effective patient portal implementation strategies.

Introduction

Providing patients with access to their health data through patient portals has become an important focus for health care systems [1]. These portals are designed to strengthen patient and provider relationships, foster greater patient engagement, improve patient education, and ultimately improve patient care [2-4]. Offering various functionalities such as appointment reminders and scheduling, access to notes and test results, and prescription refills, patient portals can equip patients to manage their health and care [5]. This increased autonomy is intended to allow them to actively participate in shared decision-making with their health care team [6,7].

While patients and families desire access to patient portals and have reported benefits of using them [8], health systems have faced challenges in implementing them. These challenges include integrating portals into existing technological infrastructure and clinical workflows [6,9]. In addition, health care providers have expressed concerns about the increased workload associated with managing patient portal inquiries and the potential for information overload and misinterpretation by patients [3,8,10,11]. This is particularly concerning in the post–COVID-19 era, where health care providers are already facing burnout due to increased patient complexity and staffing shortages [12]. Moreover, there is often a lack of agreement between patients and health care providers about which features, and content should be accessible through patient portals, leading to potential misalignment and confusion [3].

Many hospitals have adopted or are in the process of adopting digital health information systems with accompanying patient portals. While patient portals are primarily designed for patients and their families, the acceptance and influence of health care providers can significantly impact the adoption of these digital health tools [9,13]. Their endorsement can shape patient and caregiver attitudes, influencing whether they perceive the portal as a worthwhile investment of time and effort to learn and use [14-16]. As health care providers are at the forefront of care and are encouraged to increase patient engagement, it is crucial to understand their perspectives to best improve how patient portals can support patient and health care provider needs. Our objective was to understand and describe the initial impact of a patient portal on patient care and health care provider workload and suggest areas for improvement.

Methods

Setting and Implementation

This study was conducted at Trillium Health Partners (THP), a large community hospital comprised of 3 sites in Mississauga, Ontario, Canada. THP employs over 11,414 physicians, nurses, and allied health professionals, and provides care to a diverse population in the Mississauga and West Toronto area. During 2023-2024, THP had over 1.7 million patient visits and had 1457 inpatient beds [17]. This evaluation represents a strategic partnership to explore the initial impacts of implementing a vendor-developed patient portal (MyChart) across THP.

MyChart is the patient portal provided by Epic, a digital electronic health record used in health systems across the world [4], which was implemented at THP on October 10, 2020. MyChart was made available in English at THP in September 2023 to all patients aged 12 years or older. For children aged 12 years or younger, parent or guardian proxy access was provided as requested. At the time of this study, 35,387 patients had activated MyChart accounts. MyChart offered patients several features to manage care, such as access to after-visit and discharge summaries, outpatient test results, and the ability to update personal information, medications, allergies, and vaccinations. Patients can view their appointment schedule, electronically check in, cancel appointments, launch video visits, and request information for themselves or to share with other providers or people involved in their circle of care [5]. Though some health systems offer messaging between patients and providers through MyChart, THP had not activated this feature at the time of the study. At THP, MyChart functionalities were introduced in a staged manner, with new features launching every quarter. Before MyChart was implemented, THP did not have a patient portal, and patients were required to request the release of their health information from the Health Records department.

Study Design

Six months after MyChart was first offered to patients, we conducted an explanatory sequential mixed methods evaluation [18] to understand health care providers' perspectives about the initial impacts of MyChart on patient care and their workload and gather suggestions for improvement. We applied the RE-AIM (Reach, Effectiveness, Adoption, Implementation, Maintenance) framework and its extension to dimensions of sustainability and equity to guide our evaluation, to ensure a comprehensive assessment of MyChart's impact and its potential for long-term sustainability and equitable outcomes [19,20]. We used a framework to guide the development of our questionnaire and interviews, focusing on key components of MyChart adoption and use. These components included effectiveness, such as provider-perceived impacts, negative outcomes, and patient engagement; adoption, such as provider comfort with using and promoting MyChart to patients; implementation, such as time spent by providers teaching patients about MyChart; and maintenance, such as provider capacity and resources for ongoing patient support with MyChart.

In phase 1, we conducted a cross-sectional web-based questionnaire via Qualtrics to explore health care providers' experiences and satisfaction with using MyChart in clinical practice, perceived impacts on their workload and patient care, and suggestions for the future (refer to Multimedia Appendix 1). The questionnaire was pilot-tested by 7 health care providers and revised based on their feedback. In phase 2, we conducted individual semistructured qualitative interviews with health care providers to provide additional richness and depth to questionnaire data (refer to Multimedia Appendix 2).

Participants

We recruited health care providers (physicians, nurses, and allied health) across the entire THP organization to complete a

XSL•FO
RenderX

5-minute web-based questionnaire. Health care providers were invited to participate through various institutional networks including an organization-wide email, weekly email newsletters, emails from clinical managers and directors in their departments, and daily email announcements.

For the semistructured interviews, health care providers who participated in the questionnaire were asked to indicate their interest in participating in a 30-minute follow-up interview at the end of the questionnaire. We used a combination of purposeful and maximum variation sampling to select health care providers with varying experiences, and perspectives about MyChart implementation in clinical practice [21,22]. This approach allowed us to recruit health care providers from various clinical programs with different clinical roles spanning a range of years of experience.

Data Collection

The questionnaire consisted of closed and open-ended questions and was open throughout March 2024. Health care providers provided implied consent to participate after reading an informational sheet at the beginning of the questionnaire. Questionnaire items were mostly optional to gather as much data as possible, even if responses were partially complete.

Questionnaire participants who were interested in a follow-up interview completed one semistructured interview with a female mixed-methods researcher (ST). These were conducted over Zoom between March and May 2024. Participants provided verbal consent at the start of the interviews, during which they were asked to describe their experiences with using MyChart in clinical practice, identify challenges, and make suggestions for improvement. Interviews were audio-recorded, deidentified, and transcribed verbatim; transcripts were not reviewed by participants. Data collection occurred until the research team determined information power was reached, based on the study's objective, the sample specificity, dialogue quality, and analysis strategy [23].

Data Analysis

We used descriptive statistics to analyze data from closed-ended questions in the questionnaire. Quantitative data were analyzed using Microsoft Excel and Qualtrics and presented as counts and percentages.

We applied thematic analysis to analyze qualitative data from the open-ended questionnaire items and interviews [24]. First, we familiarized ourselves with the data through repeated readings of the transcripts. After, repeating readings, 2 researchers separately generated initial codes based on key patterns and concepts. ST and SV met to develop a draft codebook and applied it to a sample of 5 transcripts and open-ended responses. After initial coding, the codebook was refined and applied to the remaining transcripts. NVivo 12 (Lumivero) was used for data analysis and management.

Ethical Considerations

This project was deemed quality improvement by the Trillium Health Partners Research Ethics Board and exempt from ethics board approval. Participants received an informational letter before completing the questionnaire and interview, outlining the study's purpose, potential benefits and risks of participation, and procedures for data deidentification and use. Informed consent was obtained from all participants before the questionnaire and interview. Interview participants received a CAD $50 (US $35) honorarium in the form of a gift card for their time.

Results

Participant Characteristics

In total, 428 individuals completed the questionnaire. After excluding, 167 responses that were incomplete (more than 50% of the questionnaire was blank) or from staff who were not health care providers but mistakenly believed they were eligible to participate, the final sample consisted of 261 individuals. Among the questionnaire participants, 44% (106/242) were nurses, 29% (70/242) were physicians, and 27% (65/242) were allied health professionals. In total, 15 health care providers participated in follow-up interviews, including 4 physicians, 6 nurses, and 5 allied health professionals. Participant characteristics are described in Table 1, and a summary of their perceptions of and experiences with MyChart are shown in Figure 1. In both the open-ended items on the questionnaire and in interviews, participants shared their experiences with and perspectives about the initial impacts of MyChart, focusing on patient care, workflow integration, and usability. Results are summarized below across common themes from the quantitative and qualitative data

Figure 1. Questionnaire participants' perceptions of the patient portal MyChart.

Patient Access to MyChart

Health care providers agreed or somewhat agreed that patients should have access to MyChart (215/258, 84%), as they perceived it to improve communication between patients and health care teams (168/255, 66%), and contribute to patient safety by increasing patient understanding of their own health and identifying errors (160/255, 62%). Among interview participants, those who strongly supported patient access to MyChart were often users of the tool themselves.

> *Obviously, you know, empowering patients with accessibility to their own information is really helpful and important. And, like, I have family members with chronic illness and it's very helpful for me to be able to just look at their results...* [Physician #2]

Participants indicated that certain patient populations may have difficulty with accessing and using MyChart, such as those who are uncomfortable using technology (166/182, 91%), have limited access to devices (129/182, 71%) and internet (127/182, 70%), and experience language barriers (132/182, 73%). Additional populations with potential barriers to using MyChart included geriatric patients, children aged 12 years or younger, and individuals with cognitive impairments.

Patient Access to Information Within MyChart

In this health system setting, MyChart features were made available to patients in a staged approach, where after-visit and discharge summaries, THP outpatient laboratory as well as diagnostic imaging reports, and appointment details were introduced as part of the initial implementation. E–check-in functionality and patient-entered questionnaires were phased sequentially over time. Health care providers had differing views on the staged approach of the release of information; while they tended to agree that it may have lessened upfront impacts on workflow and workload, there were varied perspectives about releasing additional information to patients in the future. Some advocated for releasing more test results and clinical notes, which was seen as enabling patients to share results with family members, understand their health, and seek second opinions.

> *More information should be available to the patient via MyChart - both inpatient and outpatient. it is important for patients to have access to their labs, clinical documentation, medications orders, as it gives them oversight into their care, opportunity to ask questions and catch errors or discrepancies. It gives them control over their health rather than providers dictating what should be done.* [Pharmacist #1]

Others voiced concerns that patients accessing results, images, and notes before health care encounters could heighten anxiety and create extra administrative work due to calls about "concerning results" and prompting expedited appointments. There were also concerns about patients viewing sensitive results (eg, diagnostic images) before discussing them with their healthcare provider or misinterpreting them.

> *But in terms of actually disclosing medical reports that are written in medical language with the intention of being a communication between medical providers, I think it results in unnecessary anxiety for patients frequently. I think there's certain types of patients that will review the details of their clinical imaging reports or pathology reports, clinical notes, and they will, you know, be highlighting things and freaking out about things. Sometimes totally inappropriately just due to their not being a typical intended recipient of that type of documentation. Sometimes appropriately if there could be bad news but instead of in the supportive, hopefully supportive environment of a doctor patient interaction, by themselves, alone in their house with maybe many days before they are actually going to be reviewing that with their provider.* [Physician 4]

To address concerns about patient anxiety, multiple participants proposed releasing test results and notes only after health care

XSL•FO
RenderX

encounters, which could allow patients to receive and interpret information in a supportive environment.

Impacts on Patient Care

When asked if MyChart allowed health care providers to provide better care, 42% (108/255) agreed or somewhat agreed, while 36% (94/258) were neutral. One nurse described that MyChart provided patients with comfort, allowing them to get secondary opinions or explanations if needed.

> *It gives them comfort. That's just sense I got. So, for some of the patients they just – they would ask, like, can I get this information, can I get this information. By having MyChart access they know that they could access at any time if they want to – like, if they want to talk to the family member or a family doctor or any other – anybody within, like, within their comfort level. Like, they want to share their information. They know that they could access it and then actually share medical charts. Instead of saying, oh, based on my memory this is what I was what I heard and what I told. Like, that's not the case now.* [Nurse #3]

While health care providers identified some benefits to patients having MyChart, there were also concerns. In total, 43% (107/251) of participants agreed or somewhat agreed that patient access to MyChart concerned them as patients could view notes about sensitive interactions, while 31% (77/251) felt neutral about this. Despite patient health information being available for patients to access via a request to the Health Records department, the increased access to notes caused some to express concern that allowing patients to view notes that they may not agree with or that describe challenging interactions could have a negative impact on patient-provider relationships.

> *And so I've had them say, like, you know, can you correct this from this note [discharge summary], or I read this and I disagree with this. Or I've even had patients sort of get a little bit kind of offended, I guess. Because, like, in the mental status exam, for example, if you can say, like, poor insight into illness or having delusions of grandiosity so they could read that and then they come back and they're a little bit sort of dysregulated because of that.* [Nurse Practitioner #1]

Although clinical notes were limited to just discharge summaries, some perceived negative impacts or raised concerns that allowing proxies to view certain records could cause negative consequences for patients.

> *We have something called an elder abuse screen which is, like, a piece of paper we fill out to follow a flowchart to determine what results should be taken in elder abuse. Like, should that be immediately available in my notes to a patient that an elder abuse screen was completed? Yes. But [...] The elder abuse screen is also used for people who are incapable. Right? Incapable in quotes. So, it would be their SDM [substitute decision maker] who would be accessing MyChart on their behalf. What if the SDM is the abuser and then they go and they access MyChart? And then they see that.* [Social Worker #1]

Workflow Integration

In an effort to limit clinician workload in a time of health human resource crisis, THP had intentionally limited impact on clinicians during the launch of MyChart, particularly through its staged approach to releasing MyChart features over time. However, this has led participants to report inadequate training and information on MyChart and its available functionalities (116/258, 45%). This also may have contributed to our findings that 22% (58/258) of participants agreed or somewhat agreed that MyChart made their work easier, and 42% (108/258) agreed or somewhat agreed that MyChart is a useful tool for providers, and 68% (173/254) agreed or somewhat agreed that MyChart had no impact on their workload. A lack of knowledge about MyChart, along with new responsibilities to promote signing up for MyChart, caused some concern among health care providers about workflow, workload, and changing documentation practices. These views may have also been attributable to the limited MyChart features offered at THP; for example, there was no need to respond to patient messages and health care providers were not activating MyChart accounts. While some providers were not aware that MyChart was being implemented in a staged approach, others agreed that this method eased the need to immediately incorporate it into clinical routines, especially when they may not be familiar with all of its features and functionalities. Some interview participants reported having to provide detailed explanations for clinically irrelevant information; while they acknowledged the benefit of patients being informed about their health, in-depth explanations can lead to extended encounters especially if patients have limited health literacy.

> *Because with all of that extra information most patients are not – don't have the health literacy to actually interpret the results or the test that they see. And so, you know, it can become challenging because they will ask questions about, you know, pertinent results that are contributing to the clinical picture, which is one thing, but then they also will often ask about minor changes or clinically relevant, you know, findings that we don't necessarily consider... Sometimes I feel like I'm teaching an introductory, like, medical school class and that's very burdensome when you have, like, a high volume of patients and you have – you know, sometimes these requests or these questions are coming from family who aren't even there physically, like, there, calling in remotely saying that they found something. So that's a challenge.* [Physician #2]

MyChart also changed workload by influencing clinical documentation practices. Among 253 participants, 45% (n=112) agreed or somewhat agreed that patients accessing MyChart motivated them to improve their clinical documentation to increase the accessibility of language for patients to read and understand. However, some expressed concerns about how adjusting their current documentation routine might impact workload in the future.

Though messaging between patients and providers had not been introduced as a MyChart feature in this health system, its

XSL•FO
RenderX

hypothetical implementation was an area of tension. A few providers were in favor of it, but most were opposed, fearing it would increase uncompensated time to their workload and disrupt their workflow. Some raised concerns about patient expectations for immediate responses and suggested a need for clear guidelines for the type and timeliness of communication that would be required through messaging.

> *There's pros and cons. So, the pro is, you know, as a patient you can – it's better access to care. It's better access to addressing any kind of issue or concern you may have, whether it be clarification about a prescription or an appointment or care that's being provided. But I can see from a healthcare professional's point of view where, you know, you might get inundated with, you know, these requests or emails or chats. And so, you know, what is the guideline in terms of, you know, what types of chats you should be receiving or what kind of information you can be sharing over the chat, whether it's secure. And what's sort of the guidelines in terms of when you're expected to respond to something.* [Nurse #1]

Discussion

Principal Results

In this study, 261 health care providers completed a questionnaire, and 15 shared their perspectives about and experiences with the initial impact of implementing the MyChart patient portal at a large community hospital. Our findings revealed a mixed response. While most health care providers were generally supportive of providing patients access to their health information, limited health care provider engagement and clear communication about the role of MyChart in care may have negatively impacted how health care providers perceived the tool. Those who were MyChart users themselves had more favorable views of it and, logically, understood more about how it can support patient care. However, some providers had concerns about the potential negative consequences of patient access to MyChart, including patient anxiety or misunderstandings from viewing sensitive notes, increased provider workload due to additional explanations, and accessibility challenges for patients with limited technology skills, internet access, or language barriers. We identified an opportunity to strengthen health care providers' understanding of how MyChart can be best integrated into their routines and the care they deliver; one unexpected and relatively simple way to achieve this could be to encourage them to access the portal themselves.

Comparison With Previous Work

Participants raised concerns about patients or proxies viewing notes or results for sensitive interactions or diagnoses, which could be misinterpreted and then negatively impact patient-provider relationships. This aligns with other studies, which identified concerns among health care providers about patients accessing mental health notes or pathology test results [25-28], and becoming overwhelmed, hurt, or surprised by the content. Studies have also reported worries of unauthorized portal access, for instance, by a curious spouse reading a patient's mental health notes detailing domestic abuse [25]. Concerns have also been raised about patients discovering new diagnoses from alerts on patient portals, leading to distress [28,29], which highlights the need for better communication about accessing sensitive information such as adding disclosures to alerts and notes. For instance, patients could be directed to indicate if they prefer to see results only after discussing with them with their health care team and opt out of viewing sensitive notes.

Interestingly, participants reported that MyChart improved patient-provider communication even in the absence of a secure messaging feature. This may possibly be due to both parties having clearer and more consistent access to patients' health information, allowing for more meaningful, informed, and productive conversations. Though secure messaging through portals is often desired by patients [30], this was an area of concern for many providers in our study. They feared it could increase their already-high workload, disrupt their workflow, and was not something they would be explicitly compensated for. Secure messaging has been a conflicting debate in the literature, with some studies demonstrating that it does not tend to impact health care provider workload [13,31,32], as it can reduce in-person visits and follow-up calls and help patients self-manage; however, other studies have found that it can increase indirect patient care activities [26,33,34].

Introducing patient portals requires organizations to take a thoughtful approach that considers potential positive benefits, potential harms, manageable workloads for staff, and evolving regulatory landscapes (eg, the Cures Act in the United States) [35]. Our institution followed a staged approach to releasing MyChart features, which reflected organizational capacity and early engagement with health care providers suggesting limited readiness for comprehensive features to be introduced all at once, likely related to high care volumes, limited resources and support for equipping health care providers to rapidly adopt and proficiently use MyChart, and ongoing challenges with retention of health human resources as well as burnout post the COVID-19 pandemic [36]. Participants in our study agreed this approach likely mitigated some initial challenges of implementing technology into clinical environments; as many other health systems also face similar challenges, our peers may benefit from a similar approach to align with capacity limits and available resources.

Providers in this study reported a limited awareness of what patients could access in MyChart, and expectations for how it should be incorporated into care routines. However, those who were MyChart users themselves often had more favorable attitudes toward MyChart and would likely be able to provide better support to patients as they navigate the tool. Our health system also serves the most diverse patient community in Canada with 52% of residents identifying as immigrants and 62% as visible minorities [10], which participants agreed can introduce challenges around language and accessibility barriers. Comprehensive support for both patients and providers to learn about and access patient portals can help address apprehension about them, and challenges with digital navigation, and encourage patients to access their full range of features [26,37].

RenderX

Strengths and Limitations

The use of a mixed methods approach, combining both qualitative and quantitative data, allowed for a holistic and deep evaluation of perspectives and experiences with MyChart during the first 6 months it was available to patients. This approach, coupled with a diverse participant pool representing various clinical settings, roles, ages, and experience levels, ensured a rich and nuanced understanding of the impact of MyChart.

Our study is limited by a relatively low response rate to the questionnaire, despite a broad communication cascade and long duration, but this may have been attributable to limited engagement with health care providers upon MyChart's launch. As a result, we were unable to interview participants from every clinical program in our health system to gain comprehensive perspectives about MyChart, as its use varies by clinical area; this may limit the transferability of our findings to areas where the portal is not widely used. However, our participants often represented clinical areas where MyChart is more frequently used by patients such as oncology and outpatient medicine. Our study was undertaken in the context of a staged release approach of portal features that followed the implementation of a hospital-wide digital health information system (Epic), so our findings may also not be transferable to health care systems using a different implementation strategy. Though community health care providers outside of tertiary care centers in our health system play important roles in delivering care, we did not include them in this study because MyChart was introduced in hospital settings only. Future studies will include their perspectives to understand how entire health systems interact with and support patient portals.

Conclusion and Recommendations

A number of recommendations for peer health systems flow from our findings. Given the number of participants who reported inadequate training and knowledge of MyChart, it is important to engage providers early in the process of implementing a patient portal. This can help to understand their readiness and capacity for introducing a new tool into care and create clear alignment about its purpose and expectations for how health care providers will use it. Encouraging providers to sign up for accounts themselves (when applicable) and providing ample resources to learn about and use patient portals can help introduce the portal into care and reduce the time providers may need to spend assisting patients with technical difficulties during health care encounters. Participants in our study shared their concerns about secure messaging, especially around the increase in workload. To address these concerns and manage the tension that may exist between patient priorities and provider capacity, it is recommended to invite both groups to share dialogue around shared expectations for the content and timeliness of secure messaging communication. In addition, allowing physicians to bill for time spent messaging patients [38,39] could mitigate the risk of resistance to this feature or burnout. Finally, to reduce the number of repetitive patient questions about bloodwork or imaging and enhance patient education, health care systems should implement a system to track the queries health care providers receive. By identifying common themes and areas of confusion, resources can then be added to the portal to address these questions, making it easier for both patients and health care providers.

Acknowledgments

Thank you to the Trillium Health Partners MyChart Project Executives: Dr Chris Hayes, Dr Joan Murphy, and Danielle Sanagan, and Steering Committee, Adam Gdyczynski, Raj Patel, Hassan Khurram, Marvelyn Oni, MyChart patient advisors, and pilot testers Drs. Katherine Enright, Ian Zelena, and Charles Lim for their support in conducting this study.

Data Availability

The data generated and analyzed during the current study are not publicly available. Participants did not consent to data sharing with individuals outside of the research team.

Abstract

Background: Many digital interventions for unhealthy alcohol use are based on personalized normative feedback (PNF) and personalized feedback on risks for health (PFR). The hypothesis is that PNF and PFR affect drinkers' perceptions of drinking norms and risks, resulting in changes in drinking behaviors. This study is a follow-up mediation analysis of the primary and secondary outcomes of a randomized controlled trial testing the effect of a smartphone-based intervention to reduce alcohol use.

Objective: This study aimed to investigate whether perceptions of drinking norms and risks mediated the effects of a smartphone-based intervention to reduce alcohol use.

Methods: A total of 1770 students from 4 higher education institutions in Switzerland (mean age 22.35, SD 3.07 years) who screened positive for unhealthy alcohol use were randomized to receive access to a smartphone app or to the no-intervention control condition. The smartphone app provided PNF and PFR. Outcomes were drinking volume (DV) in standard drinks per week and the number of heavy drinking days (HDDs) assessed at baseline and 6 months. Mediators were perceived drinking norms and perceived risks for health measured at baseline and 3 months. Parallel mediation analyses and moderated mediation analyses were conducted to test whether (1) the intervention effect was indirectly related to lower DV and HDDs at 6 months (adjusting for baseline values) through perceived drinking norms and perceived risks for health at 3 months (adjusting for baseline values) and (2) the indirect effects through perceived drinking norms differed between participants who overestimated or who did not overestimate other people's drinking at baseline.

Results: The intervention's total effects were significant (DV: b=–0.85, 95% bootstrap CI –1.49 to –0.25; HDD: b=–0.44, 95% bootstrap CI –0.72 to –0.16), indicating less drinking at 6 months in the intervention group than in the control group. The direct effects (ie, controlling for mediators) were significant though smaller (DV: b=–0.73, 95% bootstrap CI –1.33 to –0.16; HDD: b=–0.39, 95% bootstrap CI –0.66 to –0.12). For DV, the indirect effect was significant through perceived drinking norms (b=–0.12, 95% bootstrap CI –0.25 to –0.03). The indirect effects through perceived risk (for DV and HDD) and perceived drinking norms (for HDD) were not significant. Results of moderated mediation analyses showed that the indirect effects through perceived drinking norms were significant among participants overestimating other people's drinking (DV: b=–0.17, 95% bootstrap CI –0.32 to –0.05; HDD: b=–0.08, 95% bootstrap CI –0.15 to –0.01) but not significant among those not overestimating.

XSL•FO
RenderX

Conclusions: Perceived drinking norms, but not perceived risks, partially mediated the intervention's effect on alcohol use, confirming one of its hypothesized mechanisms of action. These findings lend support to using normative feedback interventions to discourage unhealthy alcohol use.

Introduction

Background

Unhealthy alcohol use is the highest risk factor for lowering young adults' disability-adjusted life years [1]. University students are particularly vulnerable to alcohol-related consequences [2-5] and thus constitute an appropriate target for selective prevention. Brief interventions (BIs) are one approach to reducing unhealthy alcohol use and its related consequences, and they are recommended by the World Health Organization [6], the United States Preventive Services Task Force [7], and the United Kingdom's National Institute for Health and Care Excellence [8]. The efficacy of BIs, administered using a variety of formats (ie, face-to-face, through the internet, on a computer, through a smartphone app), has been demonstrated among individuals not actively seeking treatment [9,10]. However, the mechanisms underlying the efficacy of BIs are still not completely understood, particularly with web- and smartphone-based BIs. Many of the digital interventions for unhealthy alcohol use that have been found effective were based on personalized normative feedback (PNF) and personalized feedback on risks for health (PFR) [11-13].

Personalized Normative Feedback and Personalized Feedback on Risks for Health in Brief Interventions

PNF is based on social norms theory, which posits that an individual's behavior is influenced by their perceptions and beliefs about what is considered normal behavior among other people [2,14-16]. Thus, an individual's alcohol consumption is impacted by their perceptions of other people's drinking habits. Previous studies have shown that there is a high prevalence of individuals who overestimate the amount that others drink and that those who overestimate other people's drinking typically consume more alcohol [17,18]. There are also indications that this relationship may be bidirectional, that is, the more an individual overestimates their peers' drinking behaviors, the more they drink; and the more an individual drinks, the more they overestimate their peers' drinking [19]. Therefore, providing accurate information about actual norms, using PNF, is expected to correct an individual's overestimations of other people's drinking and encourage them to reduce their alcohol use by adopting drinking behaviors more aligned with actual norms [20]. Digital and in-person BIs that aim to correct an individual's overestimations of other people's drinking (using PNF) are considered effective [13]. In BIs that include a PNF component, individuals are typically asked to provide information on their sex, age, personal alcohol consumption, and perceptions of their peers' alcohol consumption. The PNF then consists of a graphical comparison between the user's own alcohol use, their peers' alcohol use, and that of a reference group (eg, individuals of the same age and sex in the general population) [14,20,21]. It has been proposed that using more proximal normative reference groups (eg, gender-specific, age-specific, and group-specific) compared with more distal reference groups (eg, the general population) may enhance the efficacy of PNF [22]. However, this proposition has been challenged. For example, in a randomized controlled trial (RCT) among college students, LaBrie and colleagues [23] compared the efficacy of PNF with different levels of specificity of the reference group (ie, 7 groups with typical same-campus student as a reference with level of specificity based on a combination of gender, race, and Greek affiliation) with a typical same-campus student as a reference. Results indicated that participants receiving PNF with more specific reference groups showed less reduction in alcohol-related outcomes compared with those who received PNF referencing a typical student. In addition, other forms of PNF have been designed to improve motivation, engagement, and adherence. For instance, in 2 studies among college students, the addition of gamified elements (eg, a point-based reward system, norm visualization through visibly connected peers on Facebook [Meta], and elements of chance) was associated with greater reductions in both perceived peer drinking norms and personal alcohol use than standard PNF [24,25].

PFR is based on various theories related to health-protective behavior and emphasizes the significant motivational influence of perceived risk [26-29]. The desire to prevent or minimize negative health outcomes (perceived benefits) is thought to generate greater motivation for self-protection [30]. Consequently, PFR is anticipated to improve an individual's awareness of risks and motivation for self-protection and to result in reduced alcohol consumption or altered drinking patterns.

Thus, perceived drinking norms and perceived risks for health are expected to serve as mechanisms of action of PNF and PFR interventions and, therefore, they should be tested as mediators for the impact of such interventions on alcohol consumption [30,31]. The large number of RCTs showing the beneficial effects on alcohol outcomes of BIs incorporating PNF or PFR could be interpreted as indirect support for this assumption [23,32-35]. However, since most BIs comprise multiple components, including, but not limited to, PNF and PRF, these studies failed to formally test the mediation of interventions' effects through perceived norms and risks. Few studies have

XSL•FO
RenderX

directly investigated whether perceived norms mediated the effects of face-to-face [36-38] and digital [23,39-43] BIs on alcohol use. These studies were principally conducted among students [23,36-40,43], military personnel, or veterans [41,42]. They showed significant mediation through perceived drinking norms, although the results were not always consistent across outcomes. Furthermore, many of these studies failed to ensure the temporal ordering necessary between intervention, mediator, and outcome required for a mediation analysis (eg, studies by Borsari and Carey [36], Kulesza et al [37], Walters et al [39], and Pedersen et al [42]). Mediation occurs in a causal chain involving 2 causal associations, that is, the intervention influences the mediator and the mediator influences the outcomes, so the intervention must precede the mediator and the mediator must precede the outcome [44]. Concerning risk perception, only 1 study to date has, to the best of our knowledge, investigated whether changes in risk perception mediated the effect of BIs on alcohol use [41], but no significant mediation was observed.

This Study

We developed a smartphone app designed to reduce alcohol use among students reporting unhealthy alcohol use [45], and we tested its efficacy in an RCT involving university students reporting unhealthy alcohol use, identified by screening. Providing access to the app (vs not providing access) was associated with significantly fewer standard drinks consumed per week and heavy drinking days (HDDs) per month over the 12-month follow-up period [32]. This study aimed to test whether perceived drinking norms and perceived risks for health mediated the effects of providing access to the app. We hypothesized that perceived drinking norms and perceived risks for health at 3 months would partially mediate the BI's effects on alcohol use at 6 months, controlling for baseline measures. In addition, since PNF is thought to correct individuals' overestimations of other people's drinking, it should primarily affect the norms perception of individuals who overestimate other people's drinking. Thus, our secondary hypothesis was that mediation through norms perception would primarily occur among individuals who overestimate other people's drinking (ie, moderated mediation). To the best of our knowledge, this is the first study to assess moderated mediation in such a setting.

Methods

Overview

This manuscript adheres to the recommendations outlined in A Guideline for Reporting Mediation Analyses (AGReMA) [46]. This study was a secondary analysis of an RCT estimating the effects of providing access to a smartphone app to reduce alcohol use among university students with self-reported unhealthy alcohol use, identified by screening. The results of the primary analysis of this RCT were reported elsewhere [32] in accordance with the CONSORT (Consolidated Standards of Reporting Trials) reporting guidelines [47]. The only deviation from the planned mediation analysis published in the institutional review board–approved protocol is the use of the Mplus software (Muthén & Muthén) instead of SPSS (IBM Corp) with the process macro, although models are equivalent.

Recruitment and Sample

All participants were recruited in April 2021 at 4 higher education institutions in the Lausanne area in Switzerland (the University of Lausanne, the Swiss Federal Institute of Technology Lausanne, the Hospitality Business School Lausanne, and the University of Applied Sciences and Arts Western Switzerland's School of Health) and provided their written informed consent to participate. The study's procedures have been detailed elsewhere [11,32,45]. Each institution promoted the study through its official communication channels (eg, information screens and hallway posters) and student associations' websites and social media. Students were invited to visit the study's specially developed website, where they could complete an anonymous questionnaire assessing their eligibility to participate, that is, being a student at the moment of recruitment, being ≥18 years old, owning a smartphone, and screening positive for unhealthy alcohol use (defined as an Alcohol Use Disorders Identification Test–Consumption score ≥4 for males and ≥3 for females [48-50]). The sample size computation was done for the evaluation of intervention effects at 6 months on the primary outcome of the RCT [32], not for the evaluation of the mediation hypothesis. Of the 3714 students who completed the eligibility questionnaire, 2364 were eligible to participate. Baseline assessments were completed by 1770 students, who were subsequently included in the study and were directly randomized in the study website to either the intervention (n=884) or the control group (n=886). This procedure ensured a total concealment of allocation. Follow-up assessments were done electronically, ensuring blinding. Participants were followed up for 12 months until May 2022. This analysis used baseline, 3-month, and 6-month data. Follow-up rates were 96.4% (total: 1706/1770; intervention: 846/884; and control: 860/886) at 3 months and 95.9% (total: 1697/1770; intervention: 846/884; and control: n=851/886) at 6 months.

Intervention

The app's content was based on the existing literature [9,51-55], previous research involving digital interventions conducted by our group [56-60], and input from members of the target population [45]. Its development has been reported elsewhere [11,45]. Briefly, the app comprised 6 modules involving norms perception and risk perception elements.

First, personal feedback on self-reported alcohol consumption, including normative feedback, feedback on the calorific content of the reported consumption, and feedback on health risks. The user's reported alcohol consumption is compared with the alcohol consumption of people of the same sex and age in Switzerland, with an emphasis on the percentage of people drinking less than the user. This normative feedback is presented for the reported number of drinks per week and the frequency of heavy episodic drinking. Swiss population data were used to generate normative feedback based on the Swiss Health Survey [61] and Addiction Monitoring in Switzerland data [62]. The user also receives an indication of the risks associated with their drinking using specific examples (eg, risk of an accident or violence associated with heavy drinking occasions, risk of addiction, sleep disorders, and cancer associated with chronic

XSL•FO
RenderX

heavy drinking). The calorific content of the reported alcohol use is indicated (in kcal), and the total kcal is also presented in "hamburger equivalents" extrapolated to a 3-month period. At the end of the module, the user can choose to set themselves drinking limits by using a link to the goal-setting tool (ie, module 4).

Second, a blood alcohol content computation tool. This module provides a computed estimate of the blood alcohol content reached with the reported consumption and an indication of the risks associated with different levels of blood alcohol content (eg, "with a blood alcohol content of 1 g/L, the risk of a fatal accident is 7 times higher than for 0.5 g/L" and "altered judgement"). The module also computes how long it will take for the alcohol to be eliminated.

Third, a self-monitoring tool. Once the module is activated, the user is invited to report on their drinking daily. The drinking pattern is then presented to the user on a graph, with indications of the recommended drinking limits.

Fourth, a goal-setting tool. This module allows the user to set their drinking limits for 1, 2, 7, or 30 days. Users are then invited to report their drinking daily. They receive a badge when they drink at or below their self-determined drinking limits.

Fifth, a designated driver tool. This module allows user to take pictures of themselves and their friends. The app then randomly picks the picture of the designated sober driver.

Sixth, fact sheets. This module presents fact sheets on alcohol and health (ie, the effects of alcohol on the human body, diseases caused by alcohol, acute and long-term effects of alcohol use on health, addiction, and resources [available treatment options and contacts]). Participants in the intervention group were not given any limitations to their use of the app (they could use it as much or as little as they wished).

Measures

Follow-up assessments were completed 3 and 6 months after baseline. Email invitations containing a personalized link to the questionnaires were sent out to participants.

Outcomes

The primary (ie, weekly DV) and secondary (ie, number of HDDs) outcomes were prespecified in the research protocol [11]. Weekly DV was assessed using a quantity and frequency measure [63]. Drinking frequency was assessed using a question about the average number of days per week on which the individual had used alcohol in the past 30 days. Drinking quantity was evaluated with a question about the average number of standard drinks consumed on drinking days. Pictograms of Swiss standard drinks containing approximately 10-12 grams of pure alcohol were provided as a visual aid. Weekly DVs (ie, the mean number of standard drinks per week over the past 30 days) were the product of drinking frequency and drinking quantity. The number of HDDs was assessed by asking participants about the number of days they had drunk ≥5 drinks for men or ≥4 drinks for women over the past 30 days.

Mediators

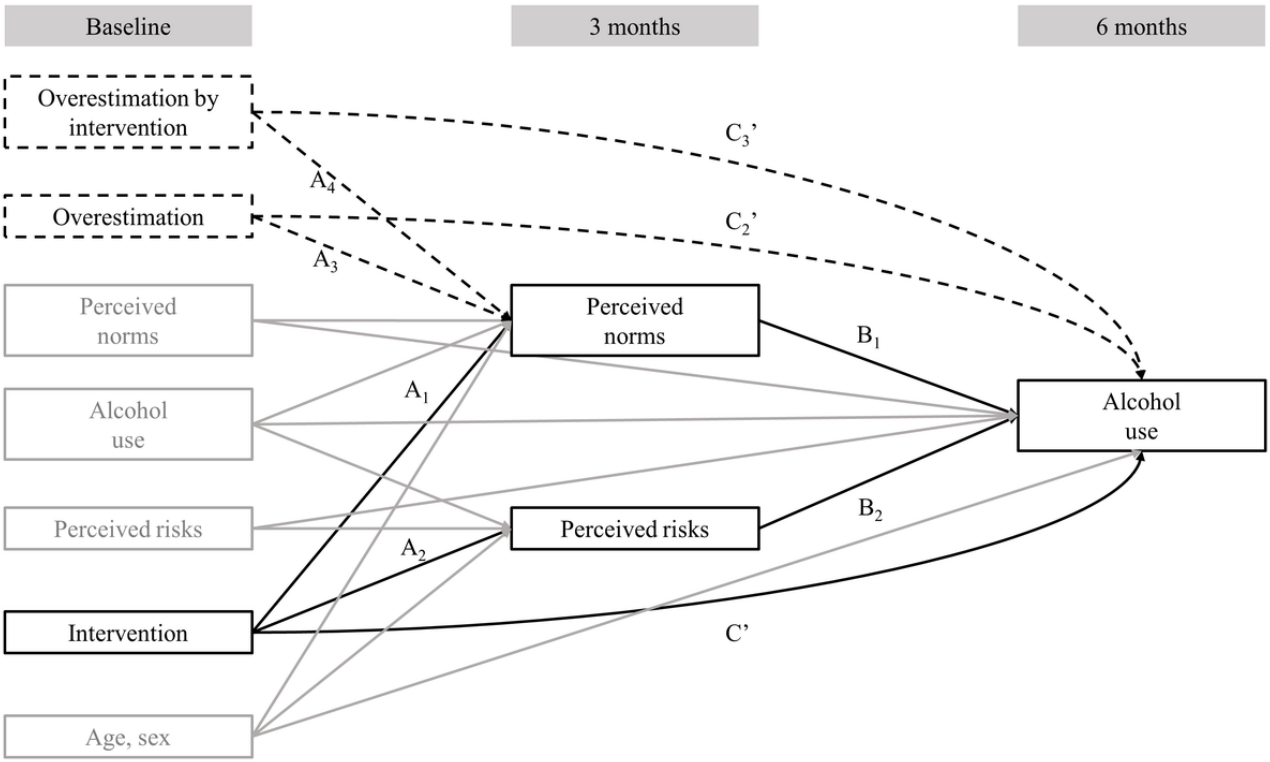
Perceived norms for weekly DV were assessed by asking participants to report their perceptions of the drinking quantity and frequency of a typical person of their age and sex. Perceived drinking norms were obtained by multiplying normative perceptions of drinking quantity and frequency. For HDDs, perceived norms were measured by asking participants how often a typical person of their age and sex drank 5 or more (for male) or 4 or more (for female) standard drinks on 1 occasion over a 30-day period. Perceived risks for health were assessed by asking participants to report the extent to which they believed that they would be personally at risk of being hurt or falling sick because of their drinking on a 10-point scale (1=no risk and 10=high risk).

Covariates

Covariates included age and sex, which were assessed at baseline.

Moderator

To determine whether participants overestimated other people's drinking at baseline, they were asked to estimate the percentage of people of their age and sex who drank more than they did (ie, a subjective estimation from 0% to 100%). Then, the objective percentage of people drinking more than the participant was estimated by comparing the participant's baseline DV with that of individuals in the Swiss population of the same age and sex, based on the Swiss Health Survey [61] and on Addiction Monitoring in Switzerland data [62]. Finally, the difference between the subjective and objective estimations of other people's DV was computed. Based on Bertholet et al [17], an overestimation of other people's drinking (coded 1) was defined as a difference between subjective and objective estimations of their DV of >5 percentage points, whereas no overestimation (coded 0) was defined as a difference of ≤5 percentage points.



Statistical Analyses

Descriptive statistics were calculated to characterize the sample in terms of age, sex, DV, HDDs, perceived DV norms, perceived HDD norms, perceived risks for health, and overestimation of other people's drinking. We conducted the mediation and moderated mediation analyses to test our hypotheses using Mplus software, version 8.3 [64]. The model tested is depicted in Figure 1. Parallel mediation analysis was used to test the hypotheses that the intervention effect was mediated through perceived drinking norms and perceived risks for health. Separate models were tested for each outcome (ie, DV and HDDs). The outcome at 6 months was regressed on the mediators (ie, perceived drinking norms and perceived risks for health at 3 months), the intervention (vs control), and the baseline values of the outcome and the mediators. The mediators were regressed on the intervention (vs control), their respective baseline values, and the baseline values of the outcomes. All associations were also adjusted for age and sex. This model assumes that intervention causally influences the mediators and that mediators causally influence the outcome. It enabled the estimation of the intervention's direct effects (ie, adjusted for the mediators) on alcohol use outcomes (path C') and the 2

XSL•FO
RenderX

specific indirect effects, that is, through perceived norms ($A_1 \times B_1$) and perceived risks ($A_2 \times B_2$) at 3 months. The intervention's total effect (C, ie, not adjusted for the mediators) is the sum of its direct and indirect effects ($C=C'+A_1 \times B_1+A_2 \times B_2$). If both the indirect and direct associations are significant, then there is evidence for partial mediation. In contrast, if the indirect association is significant and the direct association is 0 or close to 0, then there is evidence of full mediation. Missing values were handled using full information maximum likelihood. Bootstrapping with 10,000 resamples was used to estimate the 95% bootstrap CIs (95% CI) of the parameter estimates. We also computed the ratio of the indirect effects to the total effect as an indication of the indirect effect's size. As recommended by Hayes [65], this ratio was only computed when total effects were larger than indirect effects and of the same sign.

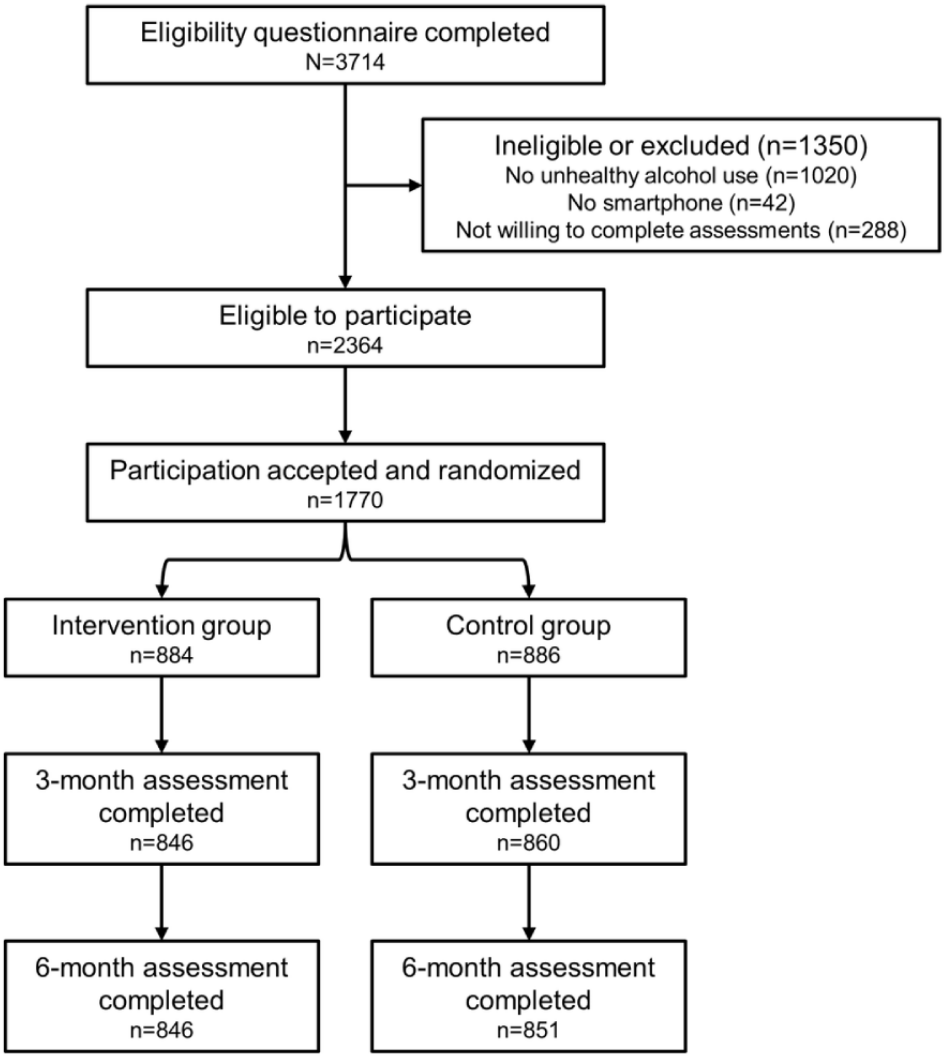
Figure 1. Schematic representation of the structural model of our brief intervention associated with alcohol use, both directly and indirectly through perceived norms and perceived risks at 3 months. Parallel mediation models included all the solid arrows. Moderated mediation models included all the solid and dashed arrows. Only the black arrows were of interest to compute the total, direct, and indirect effects. Gray arrows were only included for adjustment.

Moderated mediation was used to test the hypothesis that the intervention effect's mediation through perceived norms would differ between individuals who overestimated other people's drinking and individuals who did not overestimate, with mediation primarily expected to be among those individuals overestimating. The moderated mediation model is depicted in Figure 1. Compared with the parallel mediation model described above, the moderated mediation model also tested whether overestimating moderated the A_1 path (from intervention to perceived norms) and the direct path (C') from the intervention to the outcome. For this purpose, the overestimation variables and the interaction between intervention and overestimation were included in the model to predict drinking norms at 3 months and drinking outcomes at 6 months. The indirect effects of the intervention through perceived norms were estimated in the moderator's 2 categories (overestimation and no overestimation). The index of moderated mediation [66], corresponding to the absolute difference between the moderators' 2 categories' indirect effects, was also estimated. A sensitivity analysis was conducted using the same (moderated) mediation models on a restricted sample including all participants in the control group (n=886) and participants of the intervention group who accessed module 1 of the app, which included PNF and PFR (n=468). The results of this sensitivity analysis were similar to those of the main analysis. Coefficients were of a similar magnitude and the most significant coefficients in the main analysis remained significant in the sensitivity analysis, with a few exceptions due to lower statistical power. The details of the sensitivity analysis for mediation and moderated mediation models are reported in Tables S1 and S2 in Multimedia Appendix 1.

Ethical Considerations

The institutional review board protocol was approved by the Human Research Ethics Committee of the Canton of Vaud (number 2018-00560), registered in the ISRCTN registry (ISRCTN10007691), and published before the trial began [11]. The mediation analysis was planned in the Swiss National Science Foundation protocol and the institutional review board–approved protocol, whereas the moderated mediation analysis was not preplanned. All participants received information on the nature of the study, the procedures involved, the expected duration, the potential risks and benefits it may entail, and the financial compensation (gift certificates of up to

XSL•FO
RenderX



50 CHF, equivalent to approximately US $52). They were informed that study participation was voluntary and that they may withdraw from the study at any time without consequences. All participants provided written informed consent before their inclusion in the study. To ensure the confidentiality of data, all data collected on participants were identified with a randomly generated, unique participant identification number. Master lists of participant identification numbers and individually identifiable private information were stored in password-protected computers with restricted access. These lists were available only to senior research staff on this project. The linkage and the direct subject identifiers will be destroyed 10 years after study completion. Subject confidentiality was further ensured by using subject identification code numbers to correspond to treatment data in the computer files. The trial was monitored independently by Lausanne University Hospital's Clinical Trial Unit according to the International Council on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use Good Clinical Practice.

Results

Descriptive Characteristics

Figure 2 contains a CONSORT flow diagram. Participants' characteristics and alcohol use are reported in Table 1. The mean participant age was 22.35 (SD 3.07) years, and slightly more than half were female. At baseline, they reported a mean weekly DV of 8.59 (SD 8.18) standard drinks and 3.53 (SD 4.02) HDDs in the previous 30 days. Perceived drinking norms were slightly greater than participants' alcohol consumption, with a mean DV of 8.65 (SD 7.18) standard drinks and 3.67 (SD 2.75) HDDs. On a scale from 1 to 10, participants evaluated the risks to their health associated with their alcohol consumption as relatively low (mean 2.35, SD 1.55). About 78% (1375/1770) of participants overestimated the alcohol consumption of other people of their age and sex in the Swiss population.

Mediation Models

The results of our mediation models are reported in Table 2. Regarding DV, the intervention's total effect (C) was significant (b=–0.85, 95% CI –1.49 to –0.25), indicating a lower DV at 6 months in the intervention group than in the control group. The intervention's direct effect (C', ie, its effect adjusted for mediators) was also significant but smaller (b=–0.73, 95% CI –1.33 to –0.16). The intervention's indirect effect was significant through the drinking norms mediator (b=–0.12, 95% CI –0.25 to –0.03). The intervention was associated with lower estimations of drinking norms at 3 months (b=–0.80, 95% CI –1.36 to –0.22), and estimated drinking norms at 3 months were associated with drinking at 6 months (b=0.15, 95% CI 0.08 to 0.24). The intervention's indirect effect through estimated drinking norms at 3 months accounted for 14% (ratio of specific indirect effect/total effect=–0.12/–0.85) of the total effect. The intervention's indirect effect through risk perception was not significant (b=0.00; 95% CI –0.03 to 0.04), and neither was the association between the intervention and perceived risks at 3 months (b=0.02, 95% CI –0.11 to 0.15) or the association between perceived risks at 3 months and DV at 6 months (b=0.20, 95% CI –0.13 to 0.47).

The intervention's total effect (C) for HDDs was significant (b=–0.44, 95% CI –0.72 to –0.16), indicating fewer HDDs at 6 months in the intervention group than in the control group. The intervention's direct effect (C') was also significant but smaller (b=–0.39, 95% CI –0.66 to –0.12). However, the intervention's indirect effect through drinking norms at 3 months (b=–0.05, 95% CI –0.11 to 0.004) and its indirect effect through risk perception (b=0.00, 95% CI –0.01 to 0.02) were not significant.

[d]CI: bootstrap confidence interval.

[e]Coefficients are significant based on 95% CI.

Moderated Mediation Models

The results of our moderated mediation models, reported in Table 3 and Figure 3, showed that overestimations of other people's drinking moderated the association between the intervention and drinking norms at 3 months, in both the DV (b=–1.38, 95% CI –2.82 to –0.03) and HDDs (b=–0.63, 95% CI –1.24 to –0.05) models. The index of moderated mediation was also significant for both DV (b=–0.21, 95% CI –0.49 to –0.01) and HDDs (b=–0.12, 95% CI –0.25 to –0.01), indicating differences in the indirect effects between individuals who overestimated other people's drinking and those who did not. More specifically, the intervention's indirect effects on DV and HDDs at 6 months through drinking norms at 3 months was larger (as an absolute value) among individuals who overestimated other people's drinking (DV: b=–0.17, 95% CI –0.32 to –0.05; HDD: b=–0.08, 95% CI –0.15 to –0.01) than among those who did not (DV: b=0.04, 95% CI –0.14 to 0.26; HDD: b=0.05, 95% CI –0.05 to 0.15), and it was only significant among those who had overestimated. Among individuals who had overestimated other people's drinking, the indirect effect of the intervention on DV and HDDs through drinking norms accounted for 17% and 19% of the total effect, respectively.

Discussion

Principal Findings

This study's results showed that the effects of a smartphone-based intervention to reduce alcohol use were partially mediated by perceived drinking norms but not by its perceived risks. Specifically, the intervention was significantly associated with lower perceived drinking norms at 3 months, and perceived drinking norms at 3 months were associated with weekly DV at 6 months. The same pattern of association was observed for HDDs, although the indirect effect mediated by perceived drinking norms was not significant. This finding is in line with results from previous studies showing that perceived norms mediated the effects of face-to-face [36-38] and digital [39-43] BIs on alcohol use.

Furthermore, the intervention's indirect effects on weekly DV and HDDs at 6 months through perceived drinking norms at 3 months, were only significant among individuals who had overestimated other people's alcohol use. This finding is consistent with the theoretical bases of PNF, as it is primarily expected to influence an individual's drinking behaviors by correcting their overestimation of other people's drinking and encouraging them to adopt drinking behaviors that are more aligned with actual norms [20]. Thus, for individuals who did not overestimate other people's drinking, PNF is not expected to affect their perceptions of norms, which was consistently observed throughout this study.

XSL•FO
RenderX

Taken together, these results confirmed one of the hypothesized mechanisms of action of BIs [20]. They extended previous studies supporting the use of PNF in both internet-based [39-42] and face-to-face [36,37] BIs and lent support to its application in smartphone-based BIs to lower unhealthy alcohol use. PNF appeared to partially mediate the intervention's effects when individuals overestimated other people's drinking. As such, providing participants with information that their drinking was heavier than the norm had a conditional impact on those who misperceived their drinking with respect to other people's drinking. Nevertheless, we found no evidence of full mediation. Among individuals who overestimated other people's drinking, the mediation of perceived drinking norms accounted for 17% and 19% of the intervention's effect on DV and HDDs, respectively. Although this accounts for only a limited portion of the intervention's total effect, these results support the use of normative feedback interventions as an intervention option for secondary prevention interventions aiming at decreasing alcohol-related harm in the population. This type of digital intervention has the potential to be scaled up and reach a wide audience at a low cost, contributing to public health efforts in mitigating alcohol-related harm. It is among the NICE (National Institute for Health and Care Excellence) recommended options to address unhealthy alcohol use [67]. The remaining portion of the intervention's effect not explained by drinking norms leaves room for other mechanisms of action contained within the intervention. The app, developed previously, included other modules that may have played a role in the intervention's effects, such as setting drinking goals and monitoring one's own alcohol use [45], but their hypothesized mechanisms of action were not assessed or tested. Also, using the app may have led participants to reassess their alcohol use and their relationship with alcohol through other mechanisms not evaluated here. Assessment reactivity may also have exerted an effect on the participants in both study groups, but because the intervention group's participants had the ability to repeatedly assess their alcohol use, they may have been more disposed to changing their drinking behavior for this reason [68]. This warrants further studies to better understand the mechanisms of action of screening and BIs. Nonetheless, this type of intervention should be seen as one contributing piece in a comprehensive public health approach including, as recommended by the SAFER (Strengthen restrictions on alcohol availability; Advance and enforce drink driving countermeasures; Facilitate access to screening, brief interventions, and treatment; Enforce bans or comprehensive restrictions on alcohol advertising, sponsorship, and promotion; Raise prices on alcohol through excise taxes and pricing policies) initiative [69], contextual and structural prevention measures, such as restrictions on the availability and ban on advertising.

The lack of any mediation effect by perceived risks has to be interpreted in light of the study population. In line with results showing that risk perceptions for health related to alcohol use are lower in younger than in older adults [70], perceived risks (and likely actual risks) were low in our sample of young adults. Using the same question, the mean risk perception in our sample was approximately half of that reported in a North American sample of older participants reporting unhealthy drinking (mean age 37.9, SD 9.7 years) [71]. This suggests that young adults may be less concerned by the potential alcohol-related consequences on health than middle-aged and older adults because the potential consequences seem so far away. Thus, the role of perceived risks in BIs may depend on the age of the individuals involved. One alternative explanation for the lack of mediation by perceived risks is that digital interventions may not provide the same level of interaction, emotional engagement, and immediate clarification as face-to-face interventions, which can make PFR more impactful. In digital formats, the static nature of risk messages may reduce their perceived relevance and impact, making it harder to convey the seriousness of health risks compared with a more dynamic and responsive face-to-face setting. Further studies should replicate these analyses in other populations and explore interventions that deliver more dynamic and personalized risk feedback, such as using teleconsultations or adaptive messaging, to better engage users and enhance the perceived relevance of health risks.

Strengths and Limitations

This study had some limitations related to the use of self-reported measures, which can be susceptible to underreporting and social desirability bias, notably when norms are provided. Nonetheless, we used standardized measures, and the intervention's effects in the main trial were consistent for both the outcomes that provided us with normative feedback and the outcomes that did not [32]. The study was conducted among students, who may have been more able to deal with the complex cognitive process of comparing one's own drinking with other people's drinking, and better able to infer a percentage of people drinking more than oneself. Interventions with personalized feedback may be less effective in nonacademic settings [72]. Thus, these results need to be replicated in other settings. In addition, we used national drinking norms based on sex. Because of biological differences between the sexes in alcohol pharmacokinetics and alcohol-related risks and consequences [73], providing information based on sex is relevant. Nonetheless, some participants may consider gender norms more relevant to them and may not find sex norms adequate. As the perceived validity of norms is crucial to normative feedback being considered relevant, and as data on drinking norms by gender are currently lacking, this will likely be a challenge for future interventions. Furthermore, our sample of students with unhealthy drinking habits may be surrounded by individuals who consume more alcohol than those in the general population. As a result, our participants might have been skeptical of the information provided by PNF, which is based on nationally representative data for individuals of the same age and sex, as it may not reflect their personal experiences. Promising alternative approaches, such as using dynamic norms (as opposed to static norms) [74,75] or emphasizing deviant versus normative behaviors depending on the context and prevalence of the behavior [76], have been proposed. Evaluating their effectiveness in future interventions is warranted. The distribution of the HDD and DV outcomes, as well as perceived drinking norms, were right-skewed, which may violate the normality assumption of linear regression. To mitigate this issue, bootstrap resampling was used to provide accurate CIs without relying on parametric assumptions [77].

XSL•FO
RenderX

The study has some notable strengths. The mediation hypotheses were preplanned, and outcomes and mediators were assessed sequentially, ensuring proper temporal ordering so that the intervention occurred before the mediators, which acted before the outcomes. The mediators were also measured at baseline, allowing for the adjustment of baseline values. We were able to conduct a mediation analysis in an RCT that demonstrated the intervention's beneficial impact. Because of the nature of the mediators studied, they could be assessed in both groups with a limited risk of assessment reactivity.

Conclusions

This study's findings lend support to 1 of the 2 hypothesized mechanisms of action of the digital BI tested—the mechanism of PNF but not the mechanism of feedback on risks. This supports the use of PNF in similar interventions. Nonetheless, only a limited portion of the intervention's effects could be explained. Further research is therefore needed to identify other mechanisms of action of digital BIs.

Acknowledgments

This study was funded by Swiss National Science Foundation (SNSF) grant 176295. The SNSF had no involvement in the conduct of the study, the writing of the manuscript, or the decision to submit it for publication. We wish to thank the study participants, the research assistants who worked on the study (Stéphanie Perler, Alizée Dind, Lucie Escasain, Angeles Niembro Scaccianoce, Tajnja Vasileva, and Flavia Von Xylander), and Jean Szabo (netinfluence) for his work on the smartphone app and the study website.

Data Availability

The data analyzed in this study are available upon reasonable request to the corresponding author. Access will be granted following an approved data-sharing agreement and in compliance with ethical and institutional guidelines.

Conflicts of Interest

None declared.

Abstract

Background: Multimorbidity is a highly prevalent phenomenon whose presence causes a profound physical, psychological, and economic impact. It hinders help seeking, diagnosis, quality of care, and adherence to treatment, and it poses a significant dilemma for present-day health care systems.

Objective: This study aimed to assess the effectiveness of improved treatment as usual (iTAU) combined with a blended low-intensity psychological intervention delivered using information and communication technologies for the treatment of multimorbidity (depression and type 2 diabetes or low back pain) in primary care settings.

Methods: A 2-armed, parallel-group, superiority randomized controlled trial was designed for this study. Participants diagnosed with depression and either type 2 diabetes or low back pain (n=183) were randomized to “intervention + iTAU” (combining a face-to-face intervention with a supporting web-based program) or “iTAU” alone. The main outcome consisted of a standardized composite score to consider (1) severity of depressive symptoms and (2a) diabetes control or (2b) pain intensity and physical disability 3 months after the end of treatment as the primary end point. Differences between the groups were estimated using mixed effects linear regression models, and mediation evaluations were conducted using path analyses to evaluate the potential mechanistic role of positive and negative affectivity and openness to the future.

XSL•FO
RenderX

Results: At 3-month follow-up, the intervention + iTAU group (vs iTAU) exhibited greater reductions in composite multimorbidity score (B=–0.34, 95% CI –0.64 to –0.04; Hedges *g*=0.39) as well as in depression and negative affect and improvements in perceived health, positive affect, and openness to the future. Similar positive effects were observed after the intervention, including improvements in physical disability. No significant differences were found in glycosylated hemoglobin, pain intensity, or disability at 3-month follow-up (*P*=.60; *P*=.79; and *P*=.43, respectively). Path analyses revealed that the intervention had a significant impact on the primary outcome, mediated by both positive and negative affect (positive affect: indirect effect=–0.15, bootstrapped 95% CI –0.28 to –0.03; negative affect: indirect effect=–0.14, bootstrapped 95% CI –0.28 to –0.02).

Conclusions: This study supports the efficacy of a low-intensity psychological intervention applied in a blended format on multimorbidity in primary care. It justifies the exploration of the conceptualization of depression in type 2 diabetes as well as the analysis of the implementation of such interventions in routine clinical practice.

Introduction

Background

Multimorbidity (ie, the presence of ≥2 chronic medical conditions) is a highly prevalent phenomenon [1-4] that affects 1 in 3 adults [5] and has been increasing in recent decades [6-9]. Its presence has a significant physical, psychological, and economic impact and hinders help seeking, diagnosis, the quality of care received, and adherence to treatment [10-14]. Multimorbidity studies conducted in Spain confirm that mental illnesses, particularly major depression, negatively impact quality of life and disability [15,16]. Comorbidity between depression and chronic medical conditions is one of the leading global public health priorities [17]. Although hypertension is very prevalent [15], the most disabling chronic medical conditions are osteoarticular diseases (especially chronic pain), diabetes, and cerebral infarction [15,16]. This study focuses on 2 physical conditions that are comorbid with depression and that involve the greatest disability, loss in quality of life, and higher health care costs: diabetes and chronic pain.

Despite the high prevalence of multimorbidity worldwide, with its consequent demand for care and important health and economic consequences [18], much work remains to be done. Multimorbidity interventions pose a challenge for present-day health care systems [19]. As pointed out by a previous meta-analysis, it is difficult to improve outcomes in people with multimorbidity, although interventions oriented toward depression or specific difficulties and risk factors are promising [17]. There is consensus on the need for a comprehensive assessment to identify patients with multimorbidity who are at risk for negative health outcomes and to simultaneously treat mental and physical comorbidities to prevent functional limitations and future deterioration [20-24]. A comprehensive approach is recommended, addressing not only the medical conditions but also the social, cognitive, and functional issues faced by these patients, as well as a stepped and personalized approach, with therapeutic goals being collaboratively negotiated and regularly re-evaluated throughout the process, for example, by applying the Ariadne principles [22,25]. Patient-oriented approaches, interventions to support self-management, and training for health care professionals appear to be the most frequent elements of interventions with the potential to have a positive impact on patients with multimorbidity [26].

Interventions involving the use of information and communication technologies (ICTs) have been suggested as a promising resource for the provision of adequate and timely support for the self-management of multimorbidity [27-29]. Several studies have demonstrated the effectiveness of personalized, ICT-based interventions for treating depression [30]. However, their effectiveness and cost-effectiveness have not been assessed within a multimorbidity framework. We use the term multimorbidity not only to refer to a specific population of patients but also to the way they are approached and treated [31-33]. Studies focusing on comorbidity deal with only one priority condition over another, instead of addressing multimorbidity [34,35]. As a result, unlike studies using a multimorbidity approach, such as this study, they neglect the bidirectional relationship between the different conditions present and their role or influence on the course of the total index disease. Such approaches, such as using comorbidity, contradict the general recommendation of managing all of a patient's conditions simultaneously to prevent functional limitations and subsequent decline. The comorbidity concept is useful in secondary and tertiary care settings, while multimorbidity is more useful in primary care (PC) [33].

Objectives

In this context, this study aimed to evaluate the effectiveness of a blended low-intensity psychological intervention delivered via ICTs for the treatment of multimorbidity (including depression plus either type 2 diabetes or low back pain) in PC settings. We hypothesized that the improved treatment as usual (iTAU) intervention, enhanced by the delivery of ICT-based, low-intensity psychological therapy, would be more effective for ameliorating multimorbidity symptoms in PC compared to a group receiving only iTAU at 3 months after completion of the program.

XSL•FO
RenderX

Methods

Study Design

This was a parallel-group, superiority randomized controlled trial (RCT) in which patients receiving treatment as usual by their general practitioners (GPs) were randomized to receive either (1) iTAU or (2) the same iTAU combined with a blended low-intensity internet-delivered psychological intervention, which comprised 2 individual face-to-face sessions and 6 individual web-based therapeutic modules. Upon implementation of the protocol and commencement of the RCT, and ultimately due to the outbreak of the COVID-19 pandemic, the RCT management group was compelled to make several changes to the original study protocol [36]. Three major changes were made to the original protocol [36], all of which were discussed and agreed upon by the trial management group before their implementation and were approved by the Research Ethics Committee of the Autonomous Community of Aragon (CEICA; PI16/0259). Changes were made to (1) the number of participants recruited, (2) the time point measurements, and (3) the mechanistic outcome measures. These changes are addressed in the corresponding sections.

Participants and Procedure

Participants were recruited at PC health centers of the 3 Spanish autonomous communities participating in this study (Andalusia, Aragon, and the Balearic Islands). The inclusion criteria were as follows: (1) minimum age of 18 years; (2) *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* diagnosis of major depression or persistent depressive disorder, of mild or moderate severity, expressed as a Patient Health Questionnaire-9 (PHQ-9) score <14; (3) duration of depressive symptoms of ≥2 months; (4) diagnosis of (a) type 2 diabetes (diagnosis according to criteria of the American Diabetes Association [ADA] [37]) or (b) low back pain (diagnosis of nonspecific chronic low back pain according to the definition established by the European Cooperation in Science and Technology B-13 clinical practice guidelines [38] with a duration of at least 6 months); (5) possession of and ability to use a computer, an internet connection, and a mobile phone; (6) ability to understand oral and written Spanish; and (7) willingness to participate in the study and signing the corresponding informed consent form. The following exclusion criteria were applied: (1) any diagnosis of a disease that might affect the central nervous system (eg, brain condition, traumatic brain injury, or dementia); (2) other psychiatric diagnoses or acute mental illness (eg, substance dependence or abuse, history of schizophrenia or other psychotic disorders, or eating disorders), except for anxiety disorder or personality disorders; (3) any medical, infectious, or degenerative disease that might affect mood; (4) presence of delusional ideas or hallucinations, whether consistent with mood; and (5) suicide risk.

The protocol [36] initially stated that this study would require 63 participants in each arm to detect an expected medium effect size on multimorbidity symptoms [39,40]. Nevertheless, to provide enough statistical power to compare the participants receiving psychological therapy versus those only receiving iTAU, considering the comorbid disease that manifested in conjunction with depression (ie, type 2 diabetes or low back pain), 4 possible subgroups were secondarily established, resulting in a total of 252 participants. In addition, an experimental mortality of approximately 15% was expected [41], which meant that the required sample size was initially estimated at approximately 300 participants. However, challenges arose during the trial setup process in recruiting patients with type 2 diabetes. Specifically, most patients with type 2 diabetes were older adults who lacked access to the internet or email and did not possess the basic computer skills needed to participate in the study. This considerably slowed down the recruitment phase of the trial. The focus on type 2 diabetes was originally decided because it is the most common type of diabetes (approximately 95%) and has a more prevalent association with major depressive disorder, and it has been more widely studied than other types of diabetes [42,43]. However, given that this type of diabetes normally develops at a more advanced age and its risk increases with age, patients with type 2 diabetes were much less inclined to use ICTs and thus showed greater reluctance to participate in this study. After serious consideration, it was decided that the secondary comparison by comorbid disease subgroup would be omitted. A new sample size calculation was then performed that considered each trial arm as a whole entity.

For this purpose, we retained the possibility of detecting a similar intermediate effect size on multimorbidity symptoms to test whether the trend in changes differed between the intervention and control groups. This criterion was considered clinically important in previous research [39,40]. We maintained a statistical power (1–β) of 0.80, a significance level of 5%, and a 1:1 allocation ratio. However, due to the previously mentioned recruitment challenges, we assumed a 1:2 ratio between participants with depression and type 2 diabetes compared to those with depression and low back pain in each group. On the basis of the “time×group” interaction in a general linear repeated measures (RMs) design with Greenhouse-Geisser correction [44], and considering a correlation that decreases monotonically with the time gap between RMs, a base correlation of 0.5, and a decay rate of 0.3, along with the expected 15% mortality, we estimated that a total of 180 participants would be needed. This includes 90 participants in each group, with approximately 30 patients with comorbid depression and type 2 diabetes and 60 patients with comorbid depression and low back pain.

Patients were recruited by GPs working in PC centers of the previously mentioned Spanish autonomous communities, who subsequently sent the referral and consent forms of potential participants to the evaluating investigator. The evaluating investigator then contacted the participants to schedule the screening assessments and recorded the psychological and biological variables to determine their inclusion. Randomization was performed in blocks of patients based on the PC center and comorbid disease (ie, type 2 diabetes or low back pain). An independent researcher unrelated to the research team generated the individual randomization list using a randomization software. A researcher from the research team not involved in any other project-related task, together with an independent GP, performed data monitoring tasks. For further information regarding masking and procedures, refer to the protocol by

XSL•FO
RenderX

Monreal-Bartolomé et al [36]. Participants gave their consent for inclusion before learning which treatment they were assigned to and were allowed to withdraw from the study at any time.

Interventions

iTAU at PC Level

All the patients included in this study (both those in the control group and those included in the intervention group) were given their usual treatment by their GPs in PC. This treatment is described as improved because the participating GPs received a training program based on the widely used Spanish guidelines for the treatment of depression in PC, which are based on the National Institute of Health and Care Excellence guidelines [45].

Blended Low-Intensity Internet-Delivered Psychological Program

The blended, low-intensity, internet-delivered psychological program was received only by the intervention group. It consisted of 2 face-to-face individual sessions and 6 web-based individual and interactive therapeutic modules. The web-based therapeutic modules were oriented to work on different psychological techniques and therapeutic strategies that have demonstrated their efficacy for treating depression, diabetes, and chronic low back pain, including motivational techniques, psychoeducation on depression and healthy lifestyle, behavioral activation, positive psychology, and mindfulness-based components [46-55]. These modules were supported by multimedia materials (eg, videos and audios) and had an approximate duration of 60 minutes each.

The content of the program is summarized in Tables 1 and 2. The structure of the modules consistently followed the same pattern [36] and concluded with suggested assignments to enable the material covered to be practiced. Before the commencement of each module, the participants were prompted to confirm their completion of the recommended assignments, and they received a response either congratulating them for finishing the tasks or encouraging them to do so. Completing these assignments is considered crucial for consolidating the knowledge acquired in the program and for translating the strategies of the program into skills. To improve engagement, after a period of inactivity on the software (which was scheduled according to the preferences of the patient), users received an email reminder to continue completing the modules. The program was designed to last between 8 and 12 weeks.

XSL•FO
RenderX

Table 1. Overview of the program modules.

Module or session	Interventions	Aims and contents
Face-to-face session 1 + M0[a] (program presentation)	Motivational techniques	To increase participant adherence to face-to-face sessions and assignments. To present the web-based program and train the patients in the procedure and to log in and use it on their home computers.
M1: understanding emotional issues in medical illnesses	Psychoeducation on depression	To develop a new attitude, understanding problems and difficulties as something inherent to daily life, and seeing them as opportunities for learning and growth. The impact of depression on the quality of life and functional capacity of patients as well as on the prognosis of chronic diseases (such as diabetes and chronic pain) was described. In addition, specific techniques and useful and practical tips to reduce stress in daily life were explained.
M2: healthy lifestyle habits and diabetes or chronic pain	Education, information, practical exercises, and specific techniques on how to build and maintain a healthy lifestyle	To work on the healthy lifestyle component, including physical activity, diet, good sleep (relating it to the physical conditions they experience, such as diabetes and chronic pain), and the development of a social support network.
M3: learning how to live	Behavioral activation	To learn to establish and maintain an appropriate level of activity and involvement with life and to schedule activities (especially meaningful ones) and incorporate them into their routine. It is explained that the abandonment of activities that occurs when there is discomfort is not beneficial, but rather worsens the problems. The program also emphasizes the role of activity in mood regulation and physical well-being, highlighting the importance of staying active and engaging in activities that are meaningful, satisfying, and aligned with their values.
M4: life satisfaction	Positive psychology	To recognize the importance of positive emotions and learn strategies that create positive experiences, encouraging participation in enjoyable and meaningful activities, social interaction, improving mood, and supporting effective management of diabetes and chronic pain.
M5: mindfulness and self-compassion	Components of MBCT[b] and some basic elements of self-compassion	To establish a regular formal practice of mindfulness and self-compassion as well as a regular informal practice. This module includes components of MBCT and MBSR[c], which have shown positive and promising results in patients with depression, but also diabetes, chronic pain, and multimorbidity [54,56,57]. The section on distancing thoughts to reduce discomfort is particularly important as it allows patients to differentiate between primary and secondary diseases and the causes of each.
Face-to-face session 2	Review of the modules already completed and practice	This semistructured session includes the following objectives: (1) resolution of doubts; (2) performing some of the most important practices, also considering the preferences of each patient (3) emphasis on the continuous practice of the strategies learned; and (4) farewell and completion of the intervention.
M6: So, what happens next?	Relapse prevention and maintenance	To reinforce the strategies learned during the program, encourage participants to continue practicing these strategies throughout the follow-up period and teach them how to identify and cope with future high-risk situations related to depression, diabetes, or chronic pain.

[a]M1, M2, M3, etc, refers to module numbers.

[b]MBCT: mindfulness-based cognitive therapy.

[c]MBSR: mindfulness-bases stress reduction.

Table 2. Overview of the program transversal tools.

Transversal tools	Aims and contents
Behavioral activation diary	This tool was designed to focus the attention of the patients to the activities they perform daily; what they spend their time doing; and how this influences their mood, medical condition, and coping ability.
Calendar	This tool provides patients with written information regarding their progress throughout the program.
How am I	This is a tool that provides patients with visual feedback regarding their evolution throughout the program in terms of both their activity level and the intensity of pain as well as their positive (excited, energetic, vital, etc) and negative (upset, fearful, stressed, grumpy, tense, etc) emotionality.

XSL•FO

Measures

Overview

During this study, a modification was made to the time point measurements. The initial protocol originally stated [36] that 4 time points would be taken (ie, baseline, posttreatment, 3-month follow-up, and 6-month follow-up), with the last measurement being the primary end point. However, the outbreak of the COVID-19 pandemic in 2020 severely affected life in Spain. As a nationwide lockdown was declared in March 2020, this resulted in PC centers being closed to the public. The COVID-19 pandemic impacted Spanish PC centers, health care professionals, patients, and the general population in various ways—emotionally, socially, and ultimately, in terms of the health care services provided and received. With regard to this RCT, the COVID-19 pandemic outbreak coincided with the final phase of the study, immediately before the last follow-up measurement. Consequently, we had completed the initial baseline measurement as well as delivery of the intervention, postintervention measurement, and the 3-month follow-up measurement, with the 6-month follow-up measurement yet to be conducted. Thus, the most significant impact of the COVID-19 pandemic was on data collection for the primary outcome at 6 months. Several possibilities were considered, although they all pointed to the measurements being seriously compromised in terms of data collection and quality (eg, uncertainty about when PC centers might reopen and social distancing issues). As a result, the feasibility, validity, and accuracy of the estimates—along with the ability to generalize the study results beyond the specific circumstances faced by the Spanish population during the COVID-19 pandemic—were called into question. Therefore, it was decided that the primary end point would be changed from 6-month follow-up to 3-month follow-up after treatment, which was a measure that remained unaffected by the complex and unusual circumstances brought about by the COVID-19 pandemic. Ultimately, the difficult situation at the time prevented us from performing the 6-month follow-up measurement.

Sociodemographic Data

The following sociodemographic variables were collected at baseline: self-identified sex, age, marital status, education, employment, and income.

Main Outcome

In line with previous RCTs [58-60], the main outcome consisted of a composite score that considered (1) severity of depressive symptoms and (2a) diabetes control or (2b) pain intensity and physical disability.

The severity of depressive symptoms was measured using the PHQ-9 [61,62]. The PHQ-9 consists of 9 questions that correspond to the criteria for diagnosing major depressive disorder in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*. Respondents rate the frequency of their experiences over the past 2 weeks, ranging from “not at all” to “nearly every day.” The PHQ-9 covers different aspects of depression, including mood, energy levels, sleep, appetite, and concentration. Scores for each question are added up to provide an overall severity score (range 0-27). These scores are categorized according to the severity of depression: minimal or mild depressive symptoms (0-10), mild (10-14), moderate (15-19), and severe (20-27) [63]. The Spanish version of the PHQ-9 has demonstrated adequate psychometric properties [61,62].

Diabetes control was measured using glycated hemoglobin (HbA_{1c}). HbA_{1c} is a vital tool for effective diabetes management. It represents the proportion of hemoglobin in the blood that has bound to glucose over an extended period, typically 2 to 3 months. Regular measurement of HbA_{1c} allows tracking progress over time and evaluating whether lifestyle changes or therapy are having an effect. The ADA has defined the following 3 cutoff points: ≤5.6% (nondiabetes), between 5.7% and 6.4% (prediabetes), and ≥6.5% (compatible with a diagnosis of diabetes) [64]. Likewise, the ADA maintains a level of HbA_{1c} ≤7% as the goal for the treatment of patients with diabetes.

Pain intensity and physical disability were assessed using the Faces Pain Scale-Revised (FPS-R) [65] and the Roland-Morris Disability Questionnaire (RMDQ) [66], respectively. The FPS-R is a self-report visual measure in which the patient chooses the face that best represents the level of pain being experienced, with the allocation of a score of 0, 2, 4, 6, 8, or 10, where 0=“no pain” and 10=“very much pain.” The RMDQ was designed to reliably determine the level of physical disability (ie, the limitation in the performance of daily activities) resulting from nonspecific low back pain. It ranges between 0 (absence of disability for back pain) and 24 (maximum possible disability). A change in the score on this scale is clinically significant if it is ≥2 [66-68]. The Spanish version of the RMDQ has demonstrated adequate psychometric properties [66].

The composite score was obtained by combining these components after weights were assigned to them. For (2a), weightage of 50% was assigned both to the severity of depressive symptoms and diabetes control. For (2b), first, the same weightage of 50% was assigned to pain intensity and physical disability (to obtain a composite, including both), and, second, to the severity of depressive symptoms and pain (which included the previous pain measure of intensity and physical disability). These equal weights were added together to yield a standardized composite score that reflected the combination of the 3 components mentioned earlier. This composite score provides a comprehensive measure of comorbidity that considers both depressive symptoms and either diabetes control or pain intensity and physical disability in a single metric.

Secondary and Mechanistic Outcomes

Perceived health status was assessed as a secondary outcome using the 12-item Short Form Survey (SF-12) [69]. The SF-12 questionnaire is widely used in both clinical and research settings. A total score is calculated after coding and transforming the items that range from 0 (worst possible health status) to 100 (best possible health status) [70]. The SF-12 has demonstrated appropriate psychometric qualities [71,72] and has been validated in Spanish [73].

As a new addition to the protocol, it was decided that a measure of affectivity (ie, positive and negative affect) would be added as a potential mechanistic variable. The rationale for this was

XSL•FO
RenderX

to be able to evaluate the potential effects of changes in affectivity on promoting better outcomes. For this purpose, the Positive and Negative Affect Schedule (PANAS) was used [74,75]. This self-report measure consists of 2 subscales: positive and negative affect. Each of the subscales includes 10 adjectives, which must be rated on a scale ranging from 1="not at all or very slightly" to 5="very much," depending on the degree to which each adjective describes the state of mind in which participants generally find themselves. The maximum score is 50 for each of the subscales. This scale has shown good psychometric properties [74-76].

Finally, we used the Openness to the Future Scale (OFS) [77] to specifically measure positive affectivity toward the future as a potential mechanism. This variable can be an indicator of psychological adjustment and a protective factor for mental health. The OFS is a self-reported questionnaire composed of 10 items that are scored on a scale from 1 ("strongly disagree") to 5 ("strongly agree"). A total openness to the future score is obtained by summing the scores of all items (after reversing item 6). The OFS has shown good psychometric properties in the Spanish population [77].

Data Analyses

Data were analyzed using Stata V.18.0 statistical software [78]. First, sociodemographic and outcome descriptive data at baseline (ie, preintervention) were analyzed using frequencies (percentages), medians (IQR), and means (SD), according to their level of measurement and statistical distribution. We evaluated the success of randomization by visual inspection.

The primary analysis consisted of a comparison between the intervention + iTAU and iTAU groups at a 3-month follow-up after the intervention ended, considering the main outcome as a continuous variable. The main outcome was a composite score [36] that included the following: (1) depressive symptom severity using the PHQ-9 [61] and (2a) control of diabetes measured by HbA_{1c} or (3b) pain intensity using the FPS-R [65] and physical disability using the RMDQ [66]. The composite score was weighted to give a continuous standardized aggregate score. The primary analysis was performed using an RM design on a modified intention-to-treat (ITT) basis, that is, we analyzed complete cases due to the high proportion of missingness and explored patterns of missing data. We used multilevel linear mixed regression models with the restricted maximum likelihood method for the estimation of parameters, controlling for age and sex as covariates. The "treatment-by-time" interaction was calculated to determine possible differences between the study arms. The slope coefficient (B), representing the between-group adjusted mean difference change (ie, the interaction term), and its 95% CI were calculated (within-group adjusted mean difference changes and 95% CIs are also provided). Hedges *g*, as an effect size measure of between-group differences, was calculated from the raw data, with Hedges g=0.2 (small effect), Hedges g=0.5 (intermediate effect), and $g \geq 0.8$ (large effect) [79]. We used a 2-sided test with a .05 significance level.

The same analytical approach was used to perform secondary analyses for the main outcome at postintervention as well as for the components of the composite score and for the secondary and mechanistic outcomes at postintervention and 3-month follow-up. We corrected for multiple comparisons by adjusting the significance threshold based on the number of comparisons and the rank of the *P* value according to the Benjamini-Hochberg procedure [80].

Additional post hoc sensitivity analyses were also conducted using complier average causal effect (CACE) or instrumental variable (IV) methods [81] to further investigate the impact of compliance with the program on the composite (primary outcome) at postintervention and at 3-month follow-up, while accounting for potential hidden confounding relationships. A participant in the intervention + iTAU arm was considered a complier if they attended the 2 face-to-face sessions and completed the 6 web-based modules. For this purpose, a 2-stage least squares IV approach was used. In the first stage of regression, marital status, employment, and diagnosis were included as predictors of compliance. In the second stage of regression, age, sex, and the composite at preintervention were introduced as predictors of the outcome at postintervention or 3-month follow-up. The allocated group was used as an IV to define compliance. Results are presented in terms of unstandardized regression coefficients, along with their corresponding 95% CI and *P* values.

The role of positive affect, negative affect, and openness to the future as mediators of improvements in the main outcome was explored. For this purpose, (1) the primary outcome at follow-up was considered the dependent variable; (2) pre-post differential scores of positive affect, negative affect, and openness to the future were calculated and included as process variables; and (3) the group condition (with 2 possibilities: intervention + iTAU vs iTAU) was considered the independent variable. Models included the main outcome at preintervention, age, and sex as covariates. The mediating analyses were conducted using path analyses for continuous dependent variables. Standardized regression coefficients for bootstrapped indirect effects were estimated, along with their 95% CIs based on 10,000 bootstrapped samples. A significant mediating effect was considered when the 95% CI did not include zero [82].

Ethical Considerations

This study was approved by the research ethics committee of each of the autonomous communities involved (CEICA Aragon: PI16/0259, CEI Balearic Islands: IB 3402/17 PI, and the Regional Ethics and Research Committee of the province of Malaga: 03/2017 ICPS 2) and was designed in accordance with the ethical standards laid down in the Declaration of Helsinki and its later amendments. Modifications to the published protocol [36] were approved by the research ethics committee of the autonomous community corresponding to the leading group (CEICA Aragon, PI16/0259). Written informed consent was obtained before screening, and exclusion criteria were applied afterward. As this study involved the use of the internet, AES strategies for data encryption and personal password use were implemented to ensure the protection of personal information. The data were treated anonymously and confidentially and were used solely for the purposes of the study. Study participants did not receive any compensation for their participation, other than receiving improved treatment for their condition.

Results

Flow, Baseline Characteristics, and Compliance

As shown in Figure 1, after excluding 112 (37.9%) participants (who did not meet the inclusion criteria) from the initial 295, the remaining 183 (62.1%) individuals were randomly assigned to 1 of the 2 experimental conditions (intervention + iTAU: n=93, 50.8%; iTAU: n=90, 49.2%). The participants were mostly women (132/183, 72.1%) with a mean age of 51.36 (SD 11.3) years, and there were no important differences in either sociodemographic or clinical characteristics between the 2 arms that might suggest prognostic strength (Table 3). In line with the CONSORT (Consolidated Standards of Reporting Trials) guidelines for reporting parallel-group RCTs and following the recommendation to avoid conducting probability tests on potential baseline differences that may have occurred by chance due to random assignment, we did not perform such hypothesis testing. This type of testing is unnecessary because it assesses the likelihood that observed baseline differences happened by chance, and as random assignment has already been performed, this is already understood. Instead, we based our comparisons of sociodemographic and clinical data at baseline on the size of potential chance imbalances and their prognostic relevance [83,84]. In this regard, there were no significant differences in sociodemographic or clinical characteristics between the two groups that could suggest prognostic strength (Table 2). Therefore, no additional covariates were included in the subsequent analytical models beyond those prespecified in the protocol, namely, age and sex.

Figure 1. Participant flow diagram. Numbers at posttreatment and follow-up evaluations reflect those cases in which at least 1 of the variables that make up the composite multimorbidity main outcome measure were obtained. iTAU: improved treatment as usual.

[a]iTAU: improved treatment as usual.

[b]Marital status, place of residence, education, and employment: 1 missing in the intervention arm.

[c]Income: 15 missing in the intervention arm, and 9 missing in the control arm.

[d]NSAID: nonsteroidal anti-inflammatory drug.

[e]PHQ-9: Patient Health Questionnaire-9.

[f]RMDQ: Rolland-Morris Disability Questionnaire.

[g]FPS-R: Faces Pain Scale-Revised

[h]HbA_{1c}: glycosylated hemoglobin.

[i]SF-12: 12-item Short Form Survey.

[j]PANAS-positive: Positive and Negative Affect Scale.

[k]OFS: Openness to the Future Scale.

On average, the PHQ-9 indicated moderate levels of depression (mean 14.18, SD 5.55) in the total sample, the RMDQ suggested a dysfunctional low back pain status (mean 13.93, SD 5.82) in the subgroup with low back pain, and the HbA_{1c} value confirmed the presence of diabetes (mean 7.09, SD 1.51) in the type 2 diabetes subgroup. More than half of the sample (107/183, 58.5%) was taking analgesics, which was the most common medication. In total, 95% (89/93) of the participants in the intervention + iTAU arm attended the first face-to-face session, and 63% (59/93) of the participants attended the second face-to-face session. The median (IQR) number of modules attended in the intervention arm was 4 (out of 7), with a mean of 4.02 (SD 2.75). Postintervention retention rates in the primary outcome (ie, composite score) were 37% (35/93) in the intervention + iTAU arm and 54% (49/90) in the iTAU arm, with rates of 49% (46/93) and 55% (50/90), respectively, at follow-up. At the 3-month follow-up (primary end point), higher age, being separated or divorced, and having a diabetes diagnosis (as well as taking antidiabetics and insulin) were significantly associated with a higher probability of attrition. On the other hand, being employed, engaging in household chores, being on sick leave, and taking analgesics and antiepileptics were significantly associated with a lower probability of study attrition (Multimedia Appendix 1).

Effects on Primary and Secondary Outcomes at Primary End Point

The study outcomes are reported by trial arm status at postintervention (Multimedia Appendix 2) and 3-month follow-up (Table 4). At 3-month follow-up (primary end point), the within-group analyses of the intervention + iTAU group based on a modified ITT basis revealed significant improvements in the composite score (main outcome) as well as in depression (PHQ-9), perceived health status (SF-12), positive affect (PANAS-positive), negative affect (PANAS-negative), and openness to the future (OFS; Table 4). However, there were no significant effects on HbA_{1c} or pain intensity and disability (RMDQ and FPS-R). At 3-month follow-up, the within-group analyses of the iTAU group based on a modified ITT basis showed no significant effects in any of the outcomes (Table 4). At 3-month follow-up, there was evidence that the intervention + iTAU group achieved a significantly greater reduction in the composite score (main outcome) compared to iTAU (B=–0.34, 95% CI –0.64 to –0.04),

XSL•FO
RenderX

with small-to-medium effects (Hedges *g*=–0.39). Furthermore, compared to iTAU, the intervention + iTAU group showed greater reductions in depression (PHQ-9: B=–3.92, 95% CI –5.70 to –2.15) and negative affect (PANAS-negative: B=–3.67, 95% CI –6.63 to –0.71) and greater improvements in perceived health status (SF-12: B=9.04, 95% CI 3.21-14.87), positive affect (PANAS-positive: B=4.73, 95% CI 2.01-7.45), and openness to the future (OFS: (B=4.73, 95% CI 2.01-7.45), with small-to-large effects (Hedges *g* ranging from 0.36 to 1.13 in absolute value). However, no significant differences in HbA_{1c} or pain intensity and disability (RMDQ and FPS-R) were identified in the comparison between the intervention + iTAU group and the iTAU group at 3-month follow-up.

Effects on Primary and Secondary Outcomes at Secondary End Point

At postintervention, the within-group analyses of the intervention + iTAU group based on a modified ITT basis revealed significant improvements in the composite score (main outcome) as well as in depression (PHQ-9), pain intensity (RMDQ), HbA_{1c}, perceived health status (SF-12), positive affect (PANAS-positive), negative affect (PANAS-negative), and openness to the future (OFS); however, there were no significant effects on pain disability (FPS-R; Multimedia Appendix 2). At postintervention, the within-group analyses of the iTAU group based on a modified ITT basis showed a significant worsening in the composite score (main outcome); however, there were no other significant effects (Multimedia Appendix 2). At postintervention, there was evidence that the intervention + iTAU group achieved a significantly greater reduction in the composite score (main outcome) compared to iTAU (B=–0.63, 95% CI –0.94 to –0.31), with large effects (Hedges *g*=–0.85). Furthermore, the intervention + iTAU group also showed greater reductions in depression (PHQ-9: B=–5.02, 95% CI –6.77 to –3.26), low back pain disability (RMDQ: B=–2.28, 95% CI –4.10 to –0.46), and negative affect (PANAS-negative: B=–5.52, 95% CI –8.45 to –2.60) and greater improvements in perceived health status (SF-12: B=13.55, 95% CI 7.77-19.33), positive affect (PANAS-positive: B=5.25, 95% CI 2.56-7.93), and openness to the future (OFS: B=3.16, 95% CI 0.64-5.67), with small-to-large effects (Hedges *g* ranging from 0.38 to 0.88 in absolute value). However, no significant differences in HbA_{1c} and pain intensity (FPS-R) were identified in the comparison between the intervention + iTAU group and the iTAU group at postintervention.

Effect of Compliance With the Program

The results of the CACE or IV analyses represent an estimation of the intervention effect among the subpopulation of compliers in the intervention arm, compared to those in the control arm who would have complied with the intervention had they been offered it. The CACE or IV analyses indicated evidence of a relationship between the completion of the program and the composite score (main outcome) at postintervention (B=–1.04, 95% CI –1.56 to –0.52; *P*<.001). These analyses also showed evidence of a relationship between the completion of the program and the composite (main outcome) at 3-month follow-up (B=–0.54, 95% CI –1.01 to –0.07; *P*=.03).

Analysis of Mediating Variables

The results of the path analyses on the primary outcome (composite score) are detailed in Table 5, where the independent variable is the group condition (intervention + iTAU vs iTAU). Three models controlled for the main outcome at baseline, age, and gender were tested (ie, positive affect, negative affect, and openness to the future as potential mediators of the effect of the intervention on the outcome); however, only positive affect and negative affect showed a significant indirect effect (positive affect: ab=–0.15, bootstrapped 95% CI –0.28 to –0.03 and negative affect: ab=–0.14, bootstrapped 95% CI –0.28 to –0.02). After controlling for the mediators, the direct effect (path c) of the intervention was significant and of the same sign as the indirect effects in both models, suggesting a “complementary mediation.”

XSL•FO

	c′	–0.54	.001			
	c	–0.48	.003			

[a]The dependent variable (main outcome) is the composite score at 3-month follow-up.

[b]The potential mediators, highlighted in italics (positive affect, negative affect, and openness to the future), were based on pre-post change scores.

[c]R^2: variance explained by regression models.

[d]Path coefficients are (standardized) ordinary least squares–based regression coefficients.

[e]Coefficient: (standardized) slope.

[f]*P* value related to *t* test.

[g]The product of "ab" is the bootstrapped indirect effect using 10,000 samples.

[h]It is the 95% CI of the bootstrapped indirect effect using 10,000 samples.

[i]a: the direct path between the independent variable and the mediator.

[j]b: the direct path between the mediator and the outcome.

[k]c′: total effects.

[l]c: direct effect of the independent variable on the dependent variable after adjustment for mediating effects.

Discussion

Principal Findings

The main aim of this trial was to evaluate the effectiveness of a low-intensity psychotherapy program (intervention + iTAU) applied in a hybrid form with face-to-face and internet-based sessions (ie, blended), for the treatment of multimorbidity between mild to moderate severity depression and either type 2 diabetes or chronic low back pain in PC, compared to a group that only received iTAU. It was observed that the intervention + iTAU group achieved a significantly greater reduction in the composite score (main outcome) compared to iTAU, with large effects at postintervention and small-to-medium effects at follow-up. In addition, compared to iTAU, the intervention + iTAU group showed greater reductions in depressive symptomatology, low back pain disability, and negative affect at postintervention, although not at follow-up, where only reductions in depression and negative affect were maintained. On the other hand, greater improvements in perceived health, positive affect, and openness to the future were observed in the intervention + iTAU group versus iTAU, with small-to-large effects at both time points. However, no significant differences in HbA_{1c} or pain intensity were identified in the comparison between the intervention + iTAU group and the iTAU, either at postintervention or 3-month follow-up.

Comparison to Prior Work

These results align with previous literature, indicating the effectiveness of psychological intervention programs for multimorbidity in improving depressive symptomatology, whether delivered face-to-face or through ICTs

XSL•FO
RenderX

[20,35,49,51,52,85-95]. With regard to pain, the few studies that tested psychotherapy tools delivered via ICTs in these patients showed varying results [96]. While some studies achieved improvements in either disability and pain intensity, or both [92,97-99], others achieved no or only partial improvement in these variables [93,100-103]. Differences in the results may be attributed to the significant heterogeneity among these studies, such as variations in the type of intervention, the presence of pain comorbidities, the measurement instruments used, and the existence of comorbid depression. Among the studies that specifically had chronic low back pain and depression as inclusion criteria and were conducted entirely through ICTs, improvements in pain intensity or associated disability were not observed 6 months after randomization [99,102]. However, one of them did show improvements postintervention [99]. It is possible that pain intensity, being a variable that is difficult to modify, exhibits effects that are lost earlier, and this was evident in both cases, although the loss occurred in the medium term. As far as we know, there are no studies applying blended psychotherapy in patients with chronic pain and depression. Therefore, reaching a solid conclusion in this regard is challenging, highlighting the need for further studies in this field.

Our results present a contrast with findings from other studies that used psychological interventions in patients with diabetes and depression [57,104-109]. In those studies, both cognitive behavioral therapy and interventions incorporating mindfulness and self-compassion components appeared effective in glycemic control. However, it is worth noting that these interventions were primarily delivered in a face-to-face design. In studies where interventions were applied via the internet or telephone, improvements in glycemic control were not achieved [35,90,91,94,110-113]. Thus, the method of implementing the intervention could play a decisive role. Given that our intervention was blended, such effects might have been mitigated. This could also be associated with the small sample size (resulting in reduced statistical power) achieved when recruiting patients with diabetes, along with the limited follow-up time (3 months). The HbA_{1c} variable represents the proportion of hemoglobin in the blood that has bound to glucose over an extended period. Therefore, a more extended follow-up time may be necessary to observe significant results, as demonstrated by Hoyo et al [114], where HbA_{1c} levels continued to decrease at 12- and 18-month follow-ups.

With regard to the observed improvements in perceived health, the use of a blended model rather than a solely web-based approach may have led these improvements to stand out, particularly in comparison to other nonblended studies [90,110]. In those studies, only some of the dimensions of perceived health showed improvement, or improvements were not achieved at the intragroup level. A study that applied a face-to-face mindfulness-based cognitive therapy (MBCT) intervention in patients with diabetes and low levels of emotional well-being found that MBCT was more effective for improving perceived health than the waitlist control group [115]. Conversely, in the case of pain, a previous face-to-face delivered study that compared cognitive behavioral therapy, mindfulness-based stress reduction, and a waiting list showed improvements in perceived mental health only [116].

In the case of improvements in negative and positive affect, a situation similar to that observed for the previous variables arose, with varied results across different studies [93,117,118] Those studies exhibit considerable heterogeneity, differing in crucial characteristics such as the type of intervention, delivery method (eg, face-to-face, telephone, and web-based vs mixed), and the nature of the medical conditions. This heterogeneity makes it challenging to compare them with each other and with this study. Our results underscore the crucial role of affect, both positive and negative, as potential mediators in the functioning of the intervention, influencing improvements in the composite main outcome. Understanding how affective states mediate the impact of the intervention is pivotal for tailoring and optimizing future treatment developments. This finding emphasizes the need for interventions that consider the affective dimension, not only addressing the negative valence of depressive symptoms but also enhancing positive emotional experiences. While this study contributes to this understanding, it is noteworthy that similar results were found when using MBCT to reduce the risk of relapse or recurrence in major depressive disorder [119].

Finally, improvements in openness to the future could not be compared with any previous studies due to the novelty of the construct [77]. It is interesting to understand the positive future expectations of patients both before and after receiving an intervention for any health problem. Specifically, the measure used in this study incorporates different aspects, such as the positive illusion of control, the active process of accepting future scenarios, and the confidence and commitment in one's ability to plan for desired outcomes and to cope with adversity. Nevertheless, this variable did not show any potential mediating effects on the main composite score.

Strengths and Limitations

This is the first study to use blended models involving ICTs in the treatment of multimorbidity. It focused on a particularly prevalent, disabling, and challenging condition in clinical practice, multimorbidity between depression and type 2 diabetes or chronic low back pain. Furthermore, an evidence-based design and intervention were proposed, adhering to the recommendations of major clinical guidelines and previous research. The intervention specifically targeted risk factors, such as depression, and addressed functional difficulties. It was centered on patients and their specific needs, offering support for self-management, adopting a comprehensive and personalized approach, and incorporating therapeutic objectives negotiated and reassessed throughout the process in accordance with the principles by Ariadne [22].

However, the study has significant limitations. First, a notable challenge was the high attrition rate, which impacted the statistical power of this study. Recruitment and retention difficulties in RCTs targeting comorbid physical and mental illnesses have been documented in prior studies [120,121], and specific details of this study will be discussed in a forthcoming publication focused on implementation. Nevertheless, it is important to highlight that, in line with the earlier recruitment

XSL•FO
RenderX

challenges, dropouts were more prevalent among older patients and those with type 2 diabetes. This trend might be attributed to challenges in managing the use of internet and email and the acquisition of the basic computer skills required for active participation. Similar observations were made in a study by Clarke et al [35] focusing on patients with type 2 diabetes and depression. This study reported higher attrition and mean age compared to other ICT-delivered interventions in chronic low back pain and depression [99,102] and diabetes and depression [90,91]. It is noteworthy that the latter studies also included type 1 diabetes, contributing to differences in the age distribution of participants. There is also a proposal that patients with diabetes and mild depression might perceive low mood as a feature of their diabetes rather than a separate condition to be treated, potentially influencing treatment adherence and completion [122]. As suggested by other authors [35], further exploration of the conceptualization of depression in type 2 diabetes and its impact on program uptake and the benefit of treatment is recommended. Regardless, the low recruitment and retention rate in this study, particularly for older patients with diabetes owing to their lack of basic computer skills, could affect the generalizability of the results. Second, similar to many clinical trials, this study faced disruptions due to the COVID-19 pandemic [123], preventing the implementation of necessary follow-up measures, particularly for patients with diabetes. Given their heightened vulnerability to the virus, this situation led to the loss of valuable follow-up data. Trials that stop earlier for reasons independent of trial findings are unlikely to introduce bias because of their premature termination [124]; however, changing the primary end point from a 6-month follow-up to a 3-month follow-up in response to the challenges posed by the COVID-19 pandemic offers a different time perspective than originally proposed. We lack information on the effect sizes at 6 months, and the true effect size may vary between the 3-month and 6-month time points. In this sense, future research might benefit from the inclusion of longer follow-up periods. Third, we observed a varying proportion of losses between the intervention and control groups postintervention, although this effect disappeared at the subsequent primary end point. Similar effects were noted in prior studies [35,90,91,102,111] and could be attributed to some extent to the control groups being wait-listed, leading participants to initially complete the assessment and refrain from dropping out in anticipation of receiving the intervention at a later point. Although modified ITT and CACE or IV approaches provided useful insights into the impact of treatment on those who completed the study and on those who completed the treatment, we must not overlook this potential attrition bias and the possible limitation when generalizing the results to the entire population, where adherence can be variable. Nevertheless, the fact that the effect of the losses disappears at the primary end point indicates that the initial bias was not significant in the long term. A more comprehensive consideration of these implementation aspects will be presented in a subsequent paper. Finally, we did not measure other diseases besides depression, diabetes, and chronic pain; therefore, we are unaware of how the program might work with other potentially present conditions. Future studies should take into account a wider range of potential disorders among the participating patients.

Conclusions

This study supports the efficacy of a low-intensity psychological intervention applied in a blended form for multimorbidity in PC. Promising outcomes are particularly noted in the psychological dimension, showing improvements in depression, perceived health, positive and negative affect, and openness to the future. However, the findings in the physical dimension are mixed, indicating variable results in pain and disability reduction, promising results in short-term disability reduction, and no improvements in diabetes control. We encourage further research to validate the findings of this study, including the exploration of subgroups that could not be adequately examined due to the discussed limitations. In addition, we advocate an exploration of the conceptualization of depression in type 2 diabetes to shed light on its effects on adherence indicators, acceptance, and the efficacy of psychological interventions in these patients. Analyzing the implementation of such interventions in routine clinical practice is also warranted.

Acknowledgments

JM-M has a ‘Miguel Servet’ research contract from the ISCIII (CP21/00080), he was funded by mobility grants during the project duration (MV22/00022, CAS22/00436) and he is grateful to the Department of Psychiatry at the University of Oxford, UK, and to the Spanish CIBER of Epidemiology and Public Health (CIBERESP CB22/02/00052; ISCIII) for their support. AM-B has a Margarita Salas postdoctoral fellowship at the University of Zaragoza, which is funded by the NextGeneration European Union. This research was supported by Carlos III Health Institute (ISCIII) of the Spanish Ministry of Economy and Competitiveness (PI16/00962; FI17/00180), and with group funds the Research Network on Chronicity, Primary Care and Health Promotion (RICAPPS, RD21/0016/0005) that is part of the Results-Oriented Cooperative Research Networks in Health (RICORS) (Carlos III Health Institute), funded by the European Union “NextGeneration EU/PRTR” funds. The funding body had no involvement in the study design, data collection, analysis, interpretation of the data, or manuscript writing. The funding entity audited the trial execution.

Authors' Contributions

JG-C conceptualized and designed the study. AM-B and JM-M developed the statistical analysis plan and wrote the first draft. FM, CB and RMB verified the analytical methods. AG-P was responsible for training clinicians on the programme content and web-based application aspects throughout the clinical trial. The web-based therapeutic modules were designed and developed by AG-P. JG-C coordinated the study in Aragon, MG in the Balearic Islands and FM in Andalusia. YL-D-H and AM-B were involved in the execution of the project and were responsible for data collection in Aragon, AC and MAP-A in the Balearic Islands and MMH and EV in Andalusia. JM-M performed all the statistical analyses. AM-B and JM-M wrote the first draft of the manuscript. All authors contributed to the final version of the manuscript. JG-C, MG, FM and AG-P obtained funding and supervised all steps. All authors have read and accepted the published version of the manuscript.

Abstract

Background: Adherence to healthy behaviors initiated or adapted during cardiac rehabilitation (CR) remains a significant challenge, with few patients meeting guideline standards for secondary prevention. The use of mobile health (mHealth) interventions has been proposed as a potential solution to improve adherence to healthy behaviors after CR. In particular, app-based interventions have shown promise due to their ability to provide monitoring and feedback anytime and anywhere. Growing evidence supports the use of apps in post-CR settings to enhance adherence. In 2020, we demonstrated that individualized follow-up via an app increased adherence to healthy behaviors 1 year after CR. However, it remains uncertain whether these effects persist once the follow-up is discontinued.

Objective: This study aims to evaluate the long-term effects of individualized follow-up using an app, assessed 4 years after the intervention.

Methods: A single-blinded multicenter randomized controlled trial was conducted. Patients were recruited from 2 CR centers in eastern Norway. The intervention group (IG) received individualized follow-up through an app for 1 year, while the control group (CG) received usual care. After the 1-year follow-up, the app-based follow-up was discontinued for the IG, and both groups were encouraged to maintain or improve their healthy behaviors based on their individual risk profiles. The primary outcome was the difference in peak oxygen uptake (VO_{2peak}). The secondary outcomes included exercise performance, body weight, blood pressure, lipid profile, exercise habits, health-related quality of life, health status, cardiac events, and physical activity. Linear mixed models for repeated measurements were used to analyze differences between groups. All tests were 2-sided, and *P* values ≤0.05 were considered statistically significant.

Results: At the 5-year follow-up, 101 out of the initial 113 randomized participants were reassessed. Intention-to-treat analyses, using a mixed model for repeated measurements, revealed a statistically significant difference (*P*=.04) in exercise habits in favor of the IG, with a mean difference of 0.67 (95% CI 0.04-1.29) exercise sessions per week. Statistically significant differences were

XSL•FO
RenderX

also observed in triglycerides (mean difference 0.40, 95% CI 0.00-0.79 mmol/l, *P*=.048) and walking (*P*=.03), but these were in favor of the CG. No differences were found between the groups for other evaluated outcomes.

Conclusions: Most of the benefits derived from the app-based follow-up diminished by 4 years after the intervention. Although the IG reported statistically significantly higher levels of exercise, this did not translate into improved VO_{2peak} or exercise performance. Our study highlights the need for follow-up from health care providers to enhance adherence to healthy behaviors in the long term following CR.

KEYWORDS

mHealth; cardiac rehabilitation; mobile phone app; smartphone; lifestyle

Introduction

The beneficial effects of comprehensive cardiac rehabilitation (CR) have been well established, and for the past decade, CR has carried a class IA recommendation in the European guidelines on cardiovascular disease [1,2]. The overarching goal of CR and secondary prevention is to prevent subsequent cardiac events [1]. Achieving this goal relies heavily on adherence to healthy behavior [1,3]. However, maintaining healthy behavior initiated or adapted during CR is challenging for most patients, resulting in only a small proportion achieving the guideline standards for secondary prevention [3-5]. Accordingly, the long-term (≥1 year) outcomes of CR are poor, and evaluations of CR with follow-ups exceeding 1 year are sparse.

The recently published statement from the European Association of Preventive Cardiology on optimizing adherence in the secondary prevention of cardiovascular disease [3] recommends mobile health (mHealth) interventions to address challenges related to adherence to healthy behavior after CR. mHealth was defined by the World Health Organization in 2011 as "medical and public health practice supported by mobile devices, such as mobile phones, patient monitoring devices, personal digital assistants, and other wireless devices" [6]. It includes the use of mobile phones for calls, short messaging, and more advanced functionalities, such as apps that utilize packet radio service, 3G and 4G systems, global positioning systems, and Bluetooth technology for medical and public health practice [6]. The use of apps was suggested early as particularly promising, as it enables monitoring and providing feedback to patients from anywhere, at any time [7]. Despite rapid advancements in the mHealth research field, only a few studies have investigated whether app use can support adherence to lifestyle changes after completing CR. Duscha and colleagues [8] conducted a randomized controlled trial to evaluate the impact of an mHealth intervention, including an app, on exercise capacity (peak oxygen uptake [VO_{2peak}]) after CR [8]. Among 32 patients randomized, they observed a significant increase in absolute VO_{2peak} at the 12-week follow-up. The TeleCare study (n=122) investigated the effects of telemonitoring (smartphone and Bluetooth heart rate monitor belt) and telecoaching (monthly calls over 6 months) compared with usual care on VO_{2peak} and other cardiovascular risk factors [9]. In addition to assessing patients at the 6-month follow-up at the end of the intervention, they re-evaluated them 6 months after the intervention (12 months after CR) [9]. No significant differences were observed between the groups at either follow-up [9].

In 2020, we demonstrated that individualized follow-up for 1 year using an app improved adherence to healthy behaviors after CR [10]. In this study, 113 patients were randomly assigned to individualized follow-up enabled by an app or to a control group (CG) receiving usual care. At the 1-year follow-up, there was a statistically significant difference between the groups, favoring the intervention group (IG), in VO_{2peak} (ml/kg/minute), exercise performance, exercise habits, and self-perceived goal achievement [10]. At the 1-year follow-up, the individualized follow-up ceased, and both the CG and the IG were encouraged to maintain or improve their healthy behaviors based on their individual risk profiles. To the best of the authors' knowledge, our study was the first to evaluate the effect of an app over an entire year in a post-CR setting. However, no research to date has investigated the long-term effects of successful mHealth interventions beyond 1 year after app use is discontinued. Therefore, the primary aim of this study was to examine whether the improvement in VO_{2peak} observed after 1 year [10] was maintained 4 years after the intervention. Similarly, as secondary outcomes, we aimed to evaluate exercise performance, body weight, resting blood pressure, lipid profile, exercise habits, health-related quality of life (HRQL), health status, cardiac events, and level of physical activity.

Methods

Design

We conducted a single-blinded, randomized controlled trial with 2 arms. Patients were allocated to either the CG or the IG in a 1:1 ratio using a computer-generated, permuted block randomization scheme. The randomization was stratified by the CR program. A statistician (AHP) performed the randomization and sent the schemes to one of the coauthors (BBN), who prepared sealed envelopes. The first author, who also recruited the patients and conducted baseline assessments, brought the sealed envelopes to the baseline assessments. The envelopes were opened immediately after each baseline assessment, and patients were informed of their group allocation. The IG received individualized follow-up through an app for 1 year, while the CG received usual care, which included

XSL•FO
RenderX

recommendations to maintain or further improve their lifestyle. Reporting adhered to the CONSORT (Consolidated Standards of Reporting Trials) 2010 statement [11].

Setting and Participants

Patients were recruited from 2 CR centers in the eastern part of Norway. One center offers 1- and 4-week inpatient CR programs, while the other provides a 12-week outpatient CR program. The 12-week outpatient rehabilitation program includes exercise and education sessions 3 times a week, along with personalized support based on patients' needs, such as medication optimization, psychological counseling, dietary advice, and assistance with smoking cessation. This program has previously been evaluated and shown to improve exercise capacity and quality of life [12]. The 1- and 4-week residential programs had the same content as the 12-week outpatient program. However, the 4-week residential program provided patients with more time to adapt to lifestyle changes and learn about their condition compared with the 1-week program. The 4-week residential program has previously been reported as standard care [13]. Cardiologists, physiotherapists, dietitians, psychologists, and nurses were part of the health care team in all CR programs. Patients were recruited from 3 different CR programs, with randomization stratified accordingly. Approximately one-third of the patients were recruited from each program. Patients attending these CR programs are referred by a physician for various forms of heart disease, with coronary artery disease (CAD) being the most common reason for referral.

During participation in CR, all patients received oral information about the study from the first author (PL). Patients who met the inclusion criteria and were willing and able to participate were scheduled for a baseline assessment. Baseline assessments were conducted after a cardiopulmonary exercise test (CPET), during which patients were screened for exclusion criteria. As previously described [10,14], inclusion criteria included patients completing one of the CR programs, aged ≥40 years, ownership and use of an Android (Google LLC/Alphabet Inc.) or Apple (Apple Inc.) smartphone, and the ability to read and understand Norwegian or English. Exclusion criteria included ischemia or arrhythmias identified during CPET that imposed restrictions equivalent to <80% of maximal heart rate or a Borg scale (6-20) score [15] <15 during exercise. Patients with muscular or skeletal disorders that significantly affected exercise capacity more than their heart disease were excluded. Additionally, patients with severe malignant diseases (ie, advanced cancer) that had a greater impact on life expectancy than their heart disease were also excluded.

Recruitment for the 5-year follow-up was conducted by sending email and SMS text messages to all patients included in the original study [10]. The mail included written information about this study and an appointment for the 5-year follow-up, sent 4-6 weeks before the scheduled appointment. Patients were encouraged to confirm their willingness to participate and notify the first author if they planned to attend. Efforts were made to accommodate each patient's schedule.

Intervention Group

After the baseline assessment, patients randomly assigned to the IG were given access to an app and trained on how to use it. The app allowed users to create and set goals, with tasks and automatic reminders. A detailed description of the intervention is provided elsewhere [10,14]. Following the baseline assessment, the app was personalized with each patient's goals and tasks for the upcoming year. Patients could choose when and how often they wanted reminders for their tasks. Additionally, they could use the app for reflections or notes related to a specific goal and directly communicate any questions to the supervisor. The supervisor had access to an administrator interface, which allowed them to monitor each patient. The interface also enabled the supervisor to send short motivational messages (maximum 112 characters) directly to each patient through the app.

Patients in the IG received comprehensive individualized feedback based on their goals, completed tasks, pending tasks, and any notes they had written. This feedback was provided weekly for the first 12 weeks and monthly for the remainder of the year. Additionally, all patients received 1-3 short individualized motivational messages per week throughout the year. The supervisor, a specialized physiotherapist in this study, provided all feedback and motivational messages to the patients in the IG. Questions submitted to the supervisor were answered within 2 working days. This individualized follow-up continued until the 1-year follow-up assessment. After the 1-year follow-up, the app was removed from the patients' smartphones, and the follow-up was discontinued. At this point, patients were encouraged to maintain or improve their healthy behaviors based on their individual risk profiles.

Control Group

Patients allocated to the CG received usual care, which included visits to their general practitioner and cardiologist as needed. After the baseline assessment, they were encouraged to maintain or improve healthy behaviors based on their individual needs and goals. The same encouragement was provided at the 1-year follow-up assessment.

Outcomes and Assessments

Assessment Protocol and Outcome Measures Over a 5-Year Follow-Up Period

Assessments were performed at baseline (post-CR), after 1 year, and after 5 years at the same CR center where the patient was recruited. During the baseline assessment, demographic data were collected. The primary outcome was VO_{2peak}. Secondary outcomes at the 1- and 5-year follow-ups included exercise performance (time to exhaustion, peak incline, and peak velocity), body weight, resting blood pressure, lipid profile, exercise habits, HRQL, and health status. Additionally, at the 5-year follow-up, new cardiac events and levels of physical activity were assessed. Test personnel measuring the primary outcome were blinded to group allocation. Data collection was organized and conducted by the same person at all follow-ups, and the same test personnel led the tests at all 3 assessments.

XSL•FO
RenderX

Peak Oxygen Uptake and Exercise Performance

To ensure eligibility for the study, all patients performed a CPET before entering the study and at all follow-up times (1 and 5 years). The test was used to determine VO_{2peak} and exercise performance and is described in detail elsewhere [10,14]. Briefly, 2 standardized protocols were created: a walking protocol and a running protocol. Experienced test personnel selected the most suitable protocol for each patient, and the same protocol was used for all 3 tests. During all tests, patients were strongly encouraged to exercise to exhaustion; the Borg scale (6–20) [15] was used to assess perceived exertion, and VO_{2peak} was taken as the highest 30-second VO_2 measurement. In case of suspected submaximal effort, the test was repeated. Exercise performance was evaluated by time to exhaustion (seconds), peak incline (%), and peak velocity (km/hour). All CPETs were performed with continuous 12-lead electrocardiogram monitoring. Pulmonary ventilation and gases (oxygen and carbon dioxide) were recorded breath-by-breath using a Vyntus CPX metabolic analyzer (Vyaire Medical) at 1 of the CR centers. At the other CR center, pulmonary ventilation and gases were analyzed using a Schiller Ganshorn ergo-spirometry system (Schiller AB) at baseline, and with a Vyntus CPX (Customed) at the 1- and 5-year follow-ups. Patients were instructed to take medication and eat and drink as usual before all tests.

Body Weight

Body weight was measured without shoes and while wearing exercise clothes before the CPET at all assessments. Efforts were made to use the same equipment for all measurements.

Blood Pressure

Blood pressure was measured manually before the CPET. Patients were instructed to relax in a chair for a minimum of 3-5 minutes before the measurements were taken. Three measurements were performed, preferably on the left arm, and the lowest recorded value was used.

Lipid Profile

Venous blood was drawn using standard local procedures at the general practitioner's clinic within 4 weeks before each assessment. Patients were instructed to fast overnight before providing blood samples. Data were collected on low-density lipoprotein (LDL)-cholesterol, high-density lipoprotein (HDL)-cholesterol, total cholesterol, and triglycerides. Patients were required to bring the results to the assessment points.

Exercise Habits

At all assessments, patients were asked about their exercise habits. Exercise habits were defined as the average number of exercise sessions per week over the past year. An exercise session was further defined as a structured activity lasting at least 30 minutes, during which the individual became both sweaty and breathless and felt the need to shower afterward.

Health-Related Quality of Life

HRQL was assessed using the HeartQoL questionnaire, a disease-specific HRQL tool comprising 14 questions [16]. This questionnaire is both valid and reliable in patients referred to CR [17-21]. It includes 2 subscales: a physical HRQL subscale (10 items) and an emotional HRQL subscale (4 items) [16]. The combination of these subscales provides a global scale score [16]. Scores range from 0 to 3, with higher scores indicating better HRQL.

Health Status

Health status was assessed using the EQ-5D questionnaire, which consists of 5 questions [22]. Each question addresses a different dimension of health status: mobility, self-care, usual activities, pain/discomfort, and anxiety/depression [22]. Each question offers 5 response options, with a score of 1 indicating the best possible outcome and a score of 5 indicating the worst [22]. The EQ-5D also includes an overall health question (EQ Visual Analog Scale), which is answered on a Likert scale ranging from 0 to 100, where 0 represents the worst possible health and 100 represents the best possible health [22].

Cardiac Events

At the 5-year follow-up, new cardiac events were assessed. Patients were asked if they had experienced any cardiac events, with follow-up questions posed as needed. New cardiac events were defined as documented acute coronary syndrome, newly diagnosed CAD, valve surgery, survival of cardiac arrest, or atrial fibrillation (AF). Additionally, it was noted whether patients had undergone coronary angiography, percutaneous coronary intervention, or coronary artery bypass grafting, as well as any other cardiac-related incidents.

Physical Activity

At the 5-year follow-up, physical activity was assessed using the short version of the International Physical Activity Questionnaire (IPAQ). This questionnaire was designed as a tool for cross-national assessment of physical activity [23]. Both long and short versions of the IPAQ are available, and 2 reference periods can be evaluated: the "last 7 days" or a "usual week" [23]. In this study, the "last 7 days" reference period was used. The short version of the IPAQ provides information on time spent walking, as well as engaging in moderate-intensity and vigorous-intensity activities [23]. The instrument has been shown to have sufficient validity and reliability within a Norwegian population [24]. IPAQ data were reported following the recommendations outlined in the user manual [23].

Sample Size

The sample size was calculated based on the primary outcome, assuming a clinically significant difference in relative VO_{2peak} between groups of 3.5 ml/kg/minute [25-27]. Using data from a previously conducted feasibility study [28], the SD was estimated to be 6 ml/kg/minute. With a power of 80% and a significance level of .05, the required sample size was determined to be 47 patients per group. To account for a 20% dropout rate at the 1-year follow-up, we aimed to include a total of 113 patients.

Statistical Analysis

IBM SPSS Statistics (version 29) and Stata (version 18; StataCorp LLC) were used for statistical analysis. Continuous, normally distributed baseline data were analyzed using an independent *t* test to assess differences between groups, while

XSL•FO
RenderX

the Pearson chi-square test was used for categorical data. Baseline differences between participants with and without 5-year outcome data were analyzed using the same statistical tests. Missing data were assessed according to established strategies for handling missing data in clinical trials [29]. Differences between groups in primary and secondary outcomes were evaluated using a mixed model for repeated measurements. This model included a random intercept of the patient, as well as group, follow-up time, the interaction between group and follow-up time, and the baseline outcome measure as fixed effects. The Mann-Whitney *U* test was used to analyze differences between groups in IPAQ data at the 5-year follow-up. Independent *t* tests and Pearson chi-square tests were used to assess differences between participants with and without 5-year primary outcome data. This analysis was conducted to determine whether imputation of missing values was necessary, in accordance with strategies for managing missing data in clinical trials [29]. All analyses were performed on an intention-to-treat basis, and all tests were 2-sided. Data are presented as mean (SD) unless otherwise specified. A *P* value <.05 was considered statistically significant.

Ethical Considerations

The Regional Committee for Medical and Health Research Ethics (South-East, ID: 2016-1476) approved the study protocol, and the study was conducted in accordance with the Declaration of Helsinki. An updated study protocol for this follow-up study was submitted and approved. All patients provided written, informed consent before inclusion in the study. The study data reported in this manuscript are anonymous. The original and updated study protocols were registered on ClinicalTrials.gov with the IDs NCT03174106 and NCT05697120, respectively. The study protocol and 1-year results have been previously published [10,14].

Results

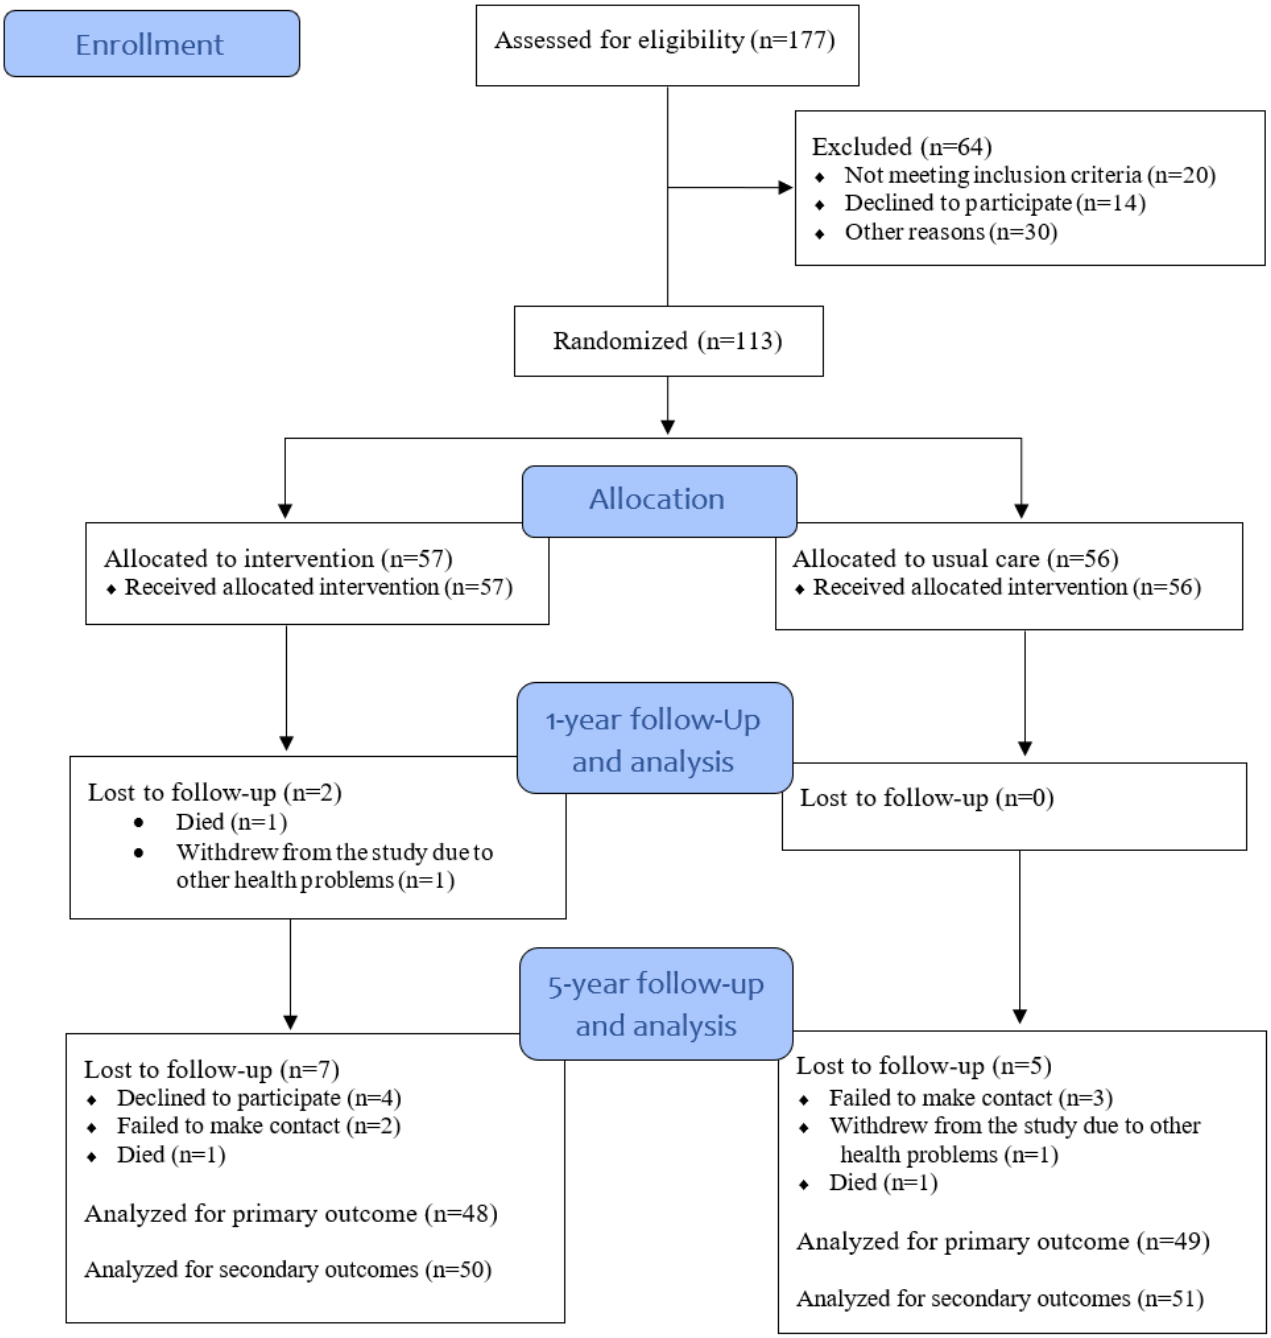
A total of 177 patients were screened for eligibility at 2 CR centers between October 2017 and June 2018, of whom 113 were included and randomized to the IG or CG (see Figure 1). The 5-year follow-up was completed in September 2023, with a total of 101 patients assessed. In the IG, 2 patients were unable to perform the CPET due to advanced cancer and complex musculoskeletal disorders. In the CG, 2 patients were unable to perform the CPET due to complex musculoskeletal and mental health disorders. This left 97 patients (85.8%) available for analysis of the primary outcome and 101 patients (89.4%) for secondary outcomes (Figure 1).

There were no differences in baseline characteristics between participants with missing data at the 5-year follow-up and those without missing data. Missing data were assumed to be completely at random, as they were not related to any observed or unobserved variables [29]. Consequently, imputation of missing data was not performed [29].

No statistically significant differences in baseline characteristics were observed between the IG and CG (Table 1). Additionally, there were no differences between the groups in changes in medication from baseline to the 1-year follow-up [10] or at the 5-year follow-up.

At the 5-year follow-up, no statistically significant difference (*P*=.69) in VO_{2peak} was observed between the groups. Other outcomes evaluated at the 5-year follow-up are presented in Table 2. A statistically significant difference was found in exercise habits (*P*=.04), favoring the IG, and in triglycerides, *P*=.048), favoring the CG. No statistically significant differences were observed between the CG and IG for any other outcomes (Table 2).

The distribution of EQ-5D scores at baseline, 1-year follow-up, and 5-year follow-up is presented in Multimedia Appendix 1.



During the 1-year follow-up period, 11 patients experienced a new cardiac event (5 in the CG and 6 in the IG). Of these, 6 were cases of recurrent or new CAD (3 in the CG and 3 in the IG), and 4 were cases of AF (2 in the CG and 2 in the IG). Between the 1- and 5-year follow-ups, 21 patients experienced a new cardiac event, including 11 in the CG and 10 in the IG. Of these events, 9 were cases of recurrent or new CAD (8 in the CG and 1 in the IG), 5 were cases of AF (2 in the CG and 3 in the IG), 1 patient in the IG underwent valve surgery, and another survived a cardiac arrest (IG). Additionally, 2 patients in the IG underwent angiography, and 3 patients experienced other heart-related events (1 in the CG and 2 in the IG).

During the first year after CR, 49 patients experienced different kinds of diseases or health problems that affected their ability to adhere to a healthy behavior for 4 weeks or more. This included musculoskeletal disorders (n=34), pulmonary diseases (n=2), diseases in other organs (n=8), complex pain (n=2), and other disorders (n=3). The IG reported statistically significant (*P*<.001) more health problems compared with the CG the first year after CR. From the 1-year follow-up to the 5-year follow-up, 54 patients reported challenges with diseases or health problems, including cancer (n=6), serious COVID-19 (n=2), musculoskeletal disorders (n=30), psychological stress (n=11), and other conditions (n=5). There were no statistically significant differences (*P*=.32) between the IG and CG at a 5-year follow-up regarding diseases or health problems that impacted the ability to adhere to healthy behaviors.

At the 5-year follow-up, the CG reported walking significantly more (MET-minutes/week) than the IG, as assessed by the IPAQ (*P*=.03). There were no statistically significant differences between the groups in any other physical activity domains evaluated by the IPAQ (moderate MET-minutes/week, *P*=.69; vigorous MET-minutes/week, *P*=.20; and total MET-minutes/week, *P*=.64).

[a]Mean difference is calculated as intervention – control.

[b]*P*<.05 between groups.

[c]HeartQoL: disease-specific Health-Related Quality of Life Questionnaire (scored from 0 to 3), which comprises 3 domains (physical, emotional, and global quality of life).

[d]The overall health status was measured using the Visual Analog Scale (0-100) in the EQ-5D questionnaire.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to evaluate the long-term effects of individualized follow-up using an app during the first year after CR. Our primary finding indicates that the beneficial effects on VO_{2peak} and exercise performance observed 1 year after CR [10] had diminished 4 years after the intervention. For the primary outcome (VO_{2peak}), we maintained adequate statistical power to detect a true difference between the groups at the 5-year follow-up. However, the results for secondary outcomes should be interpreted with caution.

Numerous factors may explain why the effects observed after 1 year of individualized follow-up [10] were no longer present at the 5-year follow-up, and we can only speculate whether these effects might have been sustained if the follow-up had continued. We believe the relationship between the supervisor and the patients in our study played a pivotal role in fostering the successful adherence to healthy behaviors observed 1 year after CR [10]. This was also highlighted by the patients in a qualitative study investigating their experiences with the follow-up provided [30]. The patients emphasized that the supervisor, the person behind the app, was the most significant factor in promoting adherence to healthy behavior [30]. Successful adherence in the context of cardiovascular risk reduction is often attributed to an ongoing, collaborative relationship between the health care provider and the patient [31]. The idea that close monitoring or follow-up can enhance adherence is widely recognized [1,3]; however, only a few studies have demonstrated this in real-world settings. In our study, follow-up was discontinued after 1 year, and the observed effects appeared to diminish over time. The app-based follow-up provided to the IG during the first year after CR in this study was grounded in the Transtheoretical Model, also known as the Stages of Change Model [32]. According to this model, health behavior change involves 6 stages: precontemplation, contemplation, preparation, action, maintenance, and termination. The model emphasizes that behavior change is a process that takes time and is not linear. For example, patients in the maintenance stage may quickly regress to the preparation

XSL•FO
RenderX

stage after CR due to factors such as a new cardiac event or other diseases or health problems that challenge their ability to maintain healthy behaviors. The need for support varies across different stages and should be tailored to increase the likelihood of successful behavior change [32]. Our findings suggest that reaching the termination phase—where individuals are confident they will never revert to their previous unhealthy behaviors and require minimal support [32]—is unlikely to be achieved within a 1-year follow-up period. Whether it would be possible with extended follow-up beyond 1 year remains an open question.

Patients in the IG reported exercising significantly more than those in the CG at the 5-year follow-up. However, there were no statistically significant differences between the groups in variables that reflect the effects of exercise (eg, VO_{2peak} and exercise performance). Notably, the difference in exercise habits between the groups at 5 years was similar to that observed at the 1-year follow-up. A plausible explanation for the lack of differences in VO_{2peak} and exercise performance at the 5-year follow-up, despite the IG reporting higher levels of exercise, could be the lower intensity or shorter duration of exercise sessions after the individualized follow-up was discontinued. As expressed by the patients in the IG [30], the individualized follow-up during the first year after CR provided more structure and focus to their exercise sessions than they were able to achieve on their own. Based on IPAQ data, the CG and IG appear to be equally physically active at the 5-year follow-up, although the CG reported significantly higher levels of walking METs compared with the IG. The IG reported higher levels of physical activity at both moderate and vigorous intensities than the CG, which may correspond to the significant difference observed in exercise habits, although differences observed in moderate and vigorous intensities were not statistically significant. Additionally, there was a statistically significant difference in triglycerides at the 5-year follow-up, favoring the CG. However, the uncertainty regarding the clinical relevance of the observed difference renders the result insignificant, and, on average, both groups remained within normal ranges [33].

For other metabolic risk factors, there were no statistically significant differences between the groups. The mean difference in body weight between the IG and CG at the 5-year follow-up was >1 kg. Although this difference did not reach statistical significance, we believe it is noteworthy, as each kilogram of weight gain has been shown to increase the risk of type 2 diabetes mellitus by 7.3% [34]. This suggests there may be a clinically relevant difference in body weight favoring the IG. However, given a minimal clinically important difference in body weight of 1 kg and an SD of 17 kg (based on our sample), more than 4500 patients would be required in each group to achieve 80% statistical power at a 5% significance level. Another noteworthy finding, although not statistically significant, is the LDL-cholesterol levels. The mean LDL-cholesterol at the 5-year follow-up was 2.3 mmol/l in the CG and 2.1 mmol/l in the IG. Given that the sample includes patients both with and without CAD, these levels are not alarming. When examining LDL-cholesterol specifically for those with CAD or acute coronary syndrome as the referral cause, the mean LDL-cholesterol levels at 5 years were 1.70 (SD 0.62) mmol/l in the CG and 1.88 (SD 0.62) mmol/l in the IG. The elevated LDL-cholesterol levels observed appear to be a common finding in studies evaluating maintenance programs after CR [35-38]. A reasonable explanation for this trend is that these post-CR programs [35-38] primarily focus on exercise rather than specifically addressing metabolic risk factors such as LDL-cholesterol and body weight. When comparing our results regarding LDL-cholesterol with a cross-sectional study by Peersen and colleagues (n=1127) [4], our sample at the 5-year follow-up is slightly better than their sample, with a mean LDL-cholesterol of 2.02 mmol/l 2-36 months (median 16 months) after a cardiac event. However, it is important to note that treatment targets for LDL-cholesterol have changed from <1.8 mmol/l to <1.4 mmol/l [39] since the completion of the intervention in this study. This indicates that there remains a need to optimize lipid management after CR. For the most part, lipid management after CR is handled by patients' general practitioners. For decades, studies on lipid profiles following a cardiac event or CR have shown that few patients meet the guidelines for secondary prevention. This raises the timely question of whether this responsibility should be prioritized more by general practitioners or shifted back to the specialist health service. Consistent with the 1-year follow-up results [10], there were no statistically significant differences between the groups in HRQL at the 5-year follow-up. Nevertheless, it is encouraging that HRQL in our sample remained at a high level. This is particularly important, as reduced HRQL has been associated with an increased incidence of depression and anxiety [40,41], both of which are well-established psychosocial risk factors for poor prognosis in patients with cardiovascular disease [2]. Compared with the reference values for HeartQoL from the EUROASPIRE IV survey (EUROpean Action on Secondary and Primary prevention through Intervention to Reduce Events), our sample demonstrated higher scores in the global domain as well as the physical and emotional HRQL domains at both follow-up points [18].

Strengths and Limitations

A key strength of our study is the low dropout rate at both the 1- and 5-year follow-ups. Additionally, patients were recruited from 3 different CR programs, and the use of broad inclusion criteria further strengthens the generalizability of our findings. Our goal was to make the results applicable to the wider population of cardiac patients participating in CR. Given that CR programs vary widely both across and within countries, we included patients from 3 distinct CR programs delivered in different settings (residential and outpatient) and with varying durations (1, 4, and 12 weeks). Because of the uncertainty regarding whether adherence to healthy behaviors after CR is influenced by the type of CR program, randomization was stratified based on the specific CR program. By including all medically stable patients with cardiac diseases, we were able to capture a representative sample of a typical CR population. However, this broad inclusion criterion also posed challenges in reporting some outcomes, particularly metabolic risk factors. For example, patients treated for valve disease may not necessarily be advised to reduce LDL-cholesterol levels or body weight. To address this, descriptive statistics on subgroups and the clinical relevance of these outcomes have been provided. We believe that different subgroups of patients completing CR

XSL•FO
RenderX

may derive varying benefits from the intervention. To explore this further, future studies could consider narrowing the inclusion criteria or significantly increasing the sample size to enable systematic subgroup analyses.

Conclusion and Implications

This study demonstrates that the beneficial and clinically important effects of a 1-year individualized follow-up via an app post-CR [10] had ceased by 4 years after the intervention. Despite the growing emphasis on addressing challenges related to adherence to healthy behavior and the use of technology in international research strategies [6,42,43], as well as in key public policies, we believe that significant work remains before mHealth can be fully implemented in this context. However, our findings on feasibility [28], 1-year follow-up outcomes [10], patients' experiences [30], and the results presented in this study can provide valuable guidance for developing an implementation strategy for mHealth interventions aimed at promoting adherence to healthy behaviors in the post-CR setting. Before developing such a strategy, it is essential to conduct a comprehensive investigation into the potential barriers and facilitators associated with its implementation, involving all relevant stakeholders. To fully understand the multifaceted challenges of adherence to healthy behavior after CR, this investigation must include input from policy makers, CR program managers, health care professionals, and, most importantly, patients—both those struggling with adherence and those who have successfully maintained adherence to secondary prevention recommendations over the years.

Acknowledgments

This project was made possible through the support of the Dam Foundation. We extend our heartfelt gratitude to the Norwegian Institute of Sports Medicine (NIMI), Volvat, and Lovisenberg Rehabilitation AS (formerly the National Association for Pulmonary and Cardiac Disease) for allowing us to recruit patients from their CR centers. We also thank M4Influence for providing access to their software solutions during the intervention period. This project is funded by Foundation Dam (grant 326568).

Data Availability

The data sets generated and analyzed during this study are not publicly available due to the consent provided by the participants. However, they may be made available from the corresponding author upon reasonable request.

Abstract

Background: Cognitive impairment is an important public health challenge among older adults, particularly in long-term care facilities (LTCFs), where prevalence is higher due to staffing shortages, limited resources, and difficulty maintaining structured exercise programs. Furthermore, older adults often lose interest in repetitive interventions. The exergame "WarioWare: Move It!" (Nintendo) offers a novel solution by combining aerobic exercise, motor coordination, balance training, and cognitive engagement into an immersive experience.

Objective: This study aimed to assess the clinical efficacy of an exergame-based training program delivered via "WarioWare: Move It!" in improving physical flexibility, joint range of motion, motor coordination, hand dexterity, and cognitive function in older adults living in LTCFs.

Methods: The training program was conducted across multiple rural LTCFs in Shanxi Province, China. Participants were randomly assigned to the intervention or control group. The intervention protocol encompassed two 60-minute sessions per week over 12 weeks, using motion-sensing exercises such as waving, jumping, arm swinging, rotational movements, and object-mimicking postures with Joy-Con controllers. Primary outcome measures were derived through clinical tests, including the sit and reach test, shoulder flexibility test, trunk rotation flexibility test, shoulder and elbow range of motion, figure-of-8 walk test, standing balance test, hand dexterity test, and cognitive function tests. Statistical analysis was performed using mixed ANOVA, with time as the within-participant factor and intervention group as the between-participant factor, to assess the training effects on the various outcome measures.

Results: A total of 232 participants were recruited, including 32 (13.8%) patients with mild dementia, 18 (7.8%) with moderate dementia, and 182 (78.4%) with mild cognitive impairment, all of whom completed the study. The mixed ANOVA revealed significant group × time interactions across multiple physical flexibility assessments, including the remaining distance between the hands and toes during the forward bend ($F_{2,156}$=8.484; P<.001; η^2=0.098), the distance between the hands clasped behind the back ($F_{2,156}$=3.666; P=.04; η^2=0.045), and the angle formed by trunk rotation to the left and right ($F_{2,156}$=17.353; P<.001; η^2=0.182). Significant group × time interactions also emerged for shoulder joint forward flexion ($F_{2,156}$=17.655; P<.001; η^2=0.185), abduction ($F_{2,156}$=6.281; P=.004; η^2=0.075), and elbow flexion ($F_{2,156}$=3.298; P=.049; η^2=0.041). In addition, the time to complete the figure-of-8 walk test ($F_{2,156}$=11.846; P<.001; η^2=0.132) and the number of blocks moved within 1 minute ($F_{2,156}$=4.016;

XSL•FO
RenderX

P=.02; η^2=0.049) showed significant interactions. Finally, all scale-based measures exhibited statistically significant group × time interactions (all P values <.001).

Conclusions: The "WarioWare: Move It!" intervention significantly improved physical flexibility, joint range of motion, motor coordination, hand dexterity, and cognitive function among older adults with mild cognitive impairment or dementia residing in rural LTCFs. The intervention offers an innovative and feasible approach for promoting the health of older adults in resource-limited settings, demonstrating its potential for widespread application in diverse low-resource environments.

Trial Registration: ClinicalTrials.gov NCT06717971; https://clinicaltrials.gov/study/NCT06717971

exergame; mild cognitive impairment; dementia; long-term care facilities; multicomponent training

Introduction

Background

Mild cognitive impairment (MCI) and dementia exhibit high prevalence rates among the global older adult population, with new cases projected to increase due to population aging [1,2]. MCI is considered an intermediary stage between age-related cognitive decline and dementia, with studies indicating that approximately 5% to 13% of individuals with MCI progress to dementia each year [3]. The progression is influenced by multiple risk factors, including age, family history, and lifestyle choices, underscoring the critical importance of early intervention and preventive strategies in reducing the incidence of dementia. Dementia, a neurodegenerative disorder with multifactorial etiology, is characterized by the progressive degeneration of brain neurons, resulting in cognitive deficits across several domains, such as complex attention, memory, learning ability, perceptual motor skills, social cognition, and language ability [4]. Due to its multifactorial nature, no effective cure for dementia currently exists, which not only leads to a significant decline in patients' quality of life but also imposes a substantial economic and social burden on families, caregivers, and health care systems [5]. Consequently, early prevention of dementia and maintenance of cognitive function are of particular importance in the older adult population.

In recent years, exergaming, an innovative intervention that integrates physical activity with gaming, has increasingly been introduced into training and rehabilitation programs for the older adult population [6,7]. By combining interactive experiences with immersive virtual environments, exergames encourage active participation among older adults, enhancing cognitive function while alleviating the monotony of traditional exercise forms. Studies indicate that many commercial gaming systems (such as Wii and Kinect) and custom-developed virtual reality games significantly stimulate cognitive abilities, especially in improving memory, attention, and executive function [8,9].

Globally, exergames have garnered significant attention as a promising approach to promoting healthy aging and addressing age-related cognitive and physical decline. Studies conducted across various countries have explored the potential of exergames to combat cognitive impairments, reporting improvements in cognitive and physical health as well as increased enjoyment and motivation among older adults in North America, Europe, and Asia [10-12]. For instance, Kannan et al [13] focused on integrating exergames into community programs and long-term care facilities (LTCFs), demonstrating their effectiveness in enhancing physical functions such as dynamic balance, gait performance, and muscle strength among community-dwelling older adults with reduced physical capacity. Similarly, Chan et al [14] highlighted the role of gamified interventions in fostering social interaction and alleviating feelings of loneliness among older adults, underscoring their cultural adaptability across different social contexts. In Asia, where aging populations are rapidly growing, researchers have developed culturally tailored exergame systems that incorporate traditional activities and movements to enhance their relevance and adherence for older users [15,16].

Moreover, exergames address common barriers to physical activity, such as adverse weather conditions, limited mobility, and geographic isolation, making them particularly valuable in regions with resource constraints or limited access to recreational facilities. These challenges are especially pronounced in rural LTCFs, where cultural attitudes toward exercise often regard physical activity as unnecessary for older adults, and social norms prioritize labor-intensive activities over structured exercise programs. In addition, logistical barriers such as transportation challenges, linguistic diversity, and lack of familiarity with digital technologies hinder the implementation of innovative interventions such as exergames [17,18]. Coupled with the higher prevalence of social isolation in rural settings, these factors necessitate tailored, accessible, and engaging solutions to promote physical and cognitive health among older adults. As global efforts continue to expand the application of exergames in diverse settings, they demonstrate considerable potential for improving the quality of life among older adults, regardless of cultural or socioeconomic contexts.

Despite the promising outcomes of exergaming for older urban populations, its adoption in rural LTCFs remains challenging due to limited health care and social resources [19]. In these settings, shortages of trained caregivers and limited equipment hinder the effective implementation of structured exercise programs, limiting older adults' access to sustained, systematic rehabilitation. In addition, older adults often experience boredom with repetitive exercise routines. They may lack intrinsic motivation, especially when deprived of novel experiences, which can diminish interest and compromise the long-term effectiveness of training [20]. Therefore, exploring and evaluating exergaming systems that are feasible for rural LTCFs

XSL•FO
RenderX

and capable of fostering high engagement could serve as a viable approach to enhancing cognitive and physical health among older adults in these communities.

Objectives

Despite the demonstrated clinical benefits of exergames for community-dwelling older adults [6,21], their effectiveness within LTCFs remains insufficiently explored. Current research primarily focuses on improvements in health-related quality of life, cognitive function, and overall functional status [12,22,23], with relatively few assessments targeting specific physical functions, such as flexibility, joint mobility, motor coordination, and hand dexterity. However, these physical capabilities are crucial for the independence of older adults. For instance, limited flexibility can hinder daily activities, directly impacting self-care abilities and increasing dependency on others [24,25]. A reduction in joint mobility is often associated with joint stiffness and pain, restricting the range of motion and diminishing overall physical function, and limiting the living space and activity radius of older adults [26]. Motor coordination is critical in balance maintenance and complex movements, where diminished coordination heightens the risk of falls [27]. Falls can have severe consequences for older adults, including fractures, prolonged immobility, or even accelerated frailty, substantially reducing the quality of life [28-30]. Hand dexterity also underpins the self-sufficiency of older adults. Loss of fine motor skills, such as gripping, pinching, and writing, can restrict their ability to perform daily tasks and participate socially, potentially leading to psychological distress [31].

The Nintendo exergame “WarioWare: Move It!” integrates 12 distinct movement modes, offering not only aerobic, coordination, and balance training but also cognitive exercises that engage memory, attention, and logical reasoning. The game’s difficulty can be flexibly adjusted to match users’ needs, ensuring optimal training effects at appropriate challenge levels. Despite its evident potential, comprehensive empirical studies are still required to substantiate its benefits fully. Therefore, this study conducted a 12-week longitudinal user study to examine the feasibility and potential clinical utility of “WarioWare: Move It!” for older adult populations in rural LTCFs. Furthermore, this research provides valuable insights and references for older adult rehabilitation professionals and human-computer interaction researchers interested in designing exergame-based interventions for the care of older adults.

Methods

Ethical Considerations

This study was conducted in accordance with the Helsinki Declaration and received approval from the Biomedical Ethics Review Committee of Taiyuan University of Technology (20230641). The study design adheres to the 2013 SPIRIT statement for randomized controlled trials and the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines (Multimedia Appendix 1), and it has been registered on ClinicalTrials.gov (NCT06717971). Before submitting the written informed consent, participants were informed of potential risks, including minor muscle discomfort or fatigue. They were also made aware that participation was voluntary and that they could withdraw at any time without penalty. All participants provided written informed consent, and eligible participants received a US $10 compensation.

Participants

In this study, we recruited 232 participants (n=32, 13.8% patients with mild dementia; n=18, 7.8% with moderate dementia; and n=182, 78.4% with MCI) from LTCFs, such as rural daycare centers and nursing homes in Shanxi Province, China. Participant selection followed a purposive sampling method [32], with the entire recruitment process rigorously supervised by experienced neurologists. Caregivers and facility staff were not involved in the participant selection process to avoid potential bias. Inclusion criteria were as follows: (1) normal or corrected-to-normal hearing and vision; (2) age >65 years; (3) residence in an older adult care facility or a minimum stay of 1 month in such a facility; (4) completion of the Global Deterioration Scale (GDS), the Chinese version of the Mini-Mental State Examination (MMSE), and the Chinese version of the Montreal Cognitive Assessment (MoCA), with the capacity to communicate effectively; (5) ability to engage in moderate physical activity without physical disability; (6) absence of severe depressive symptoms or other neurological disorders (eg, stroke, dizziness, and epilepsy); (7) absence of chronic conditions significantly affecting mobility (eg, advanced arthritis, severe osteoporosis, or recent fractures); and (8) provision of informed consent by the participant or their guardian.

All participants underwent comprehensive medical evaluations conducted by experienced neurologists, including a thorough medical history, physical examination, neuroimaging studies (either brain magnetic resonance imaging or computed tomography), and cognitive function assessments. Neurologists assessed participants’ cognitive function using the GDS score, classifying the severity of dementia symptoms accordingly. Among the participants with dementia, the average GDS score was 3.7 (SD 0.75), with an average duration of dementia symptoms spanning 3.15 (SD 0.8) years. Cognitive function in the 182 patients with MCI was evaluated using the MoCA, with scores consistently <26. Furthermore, neuroimaging revealed no other structural abnormalities in any participant that could contribute to cognitive impairment. Table 1 summarizes the clinical and demographic characteristics of participants allocated to the intervention and control groups.

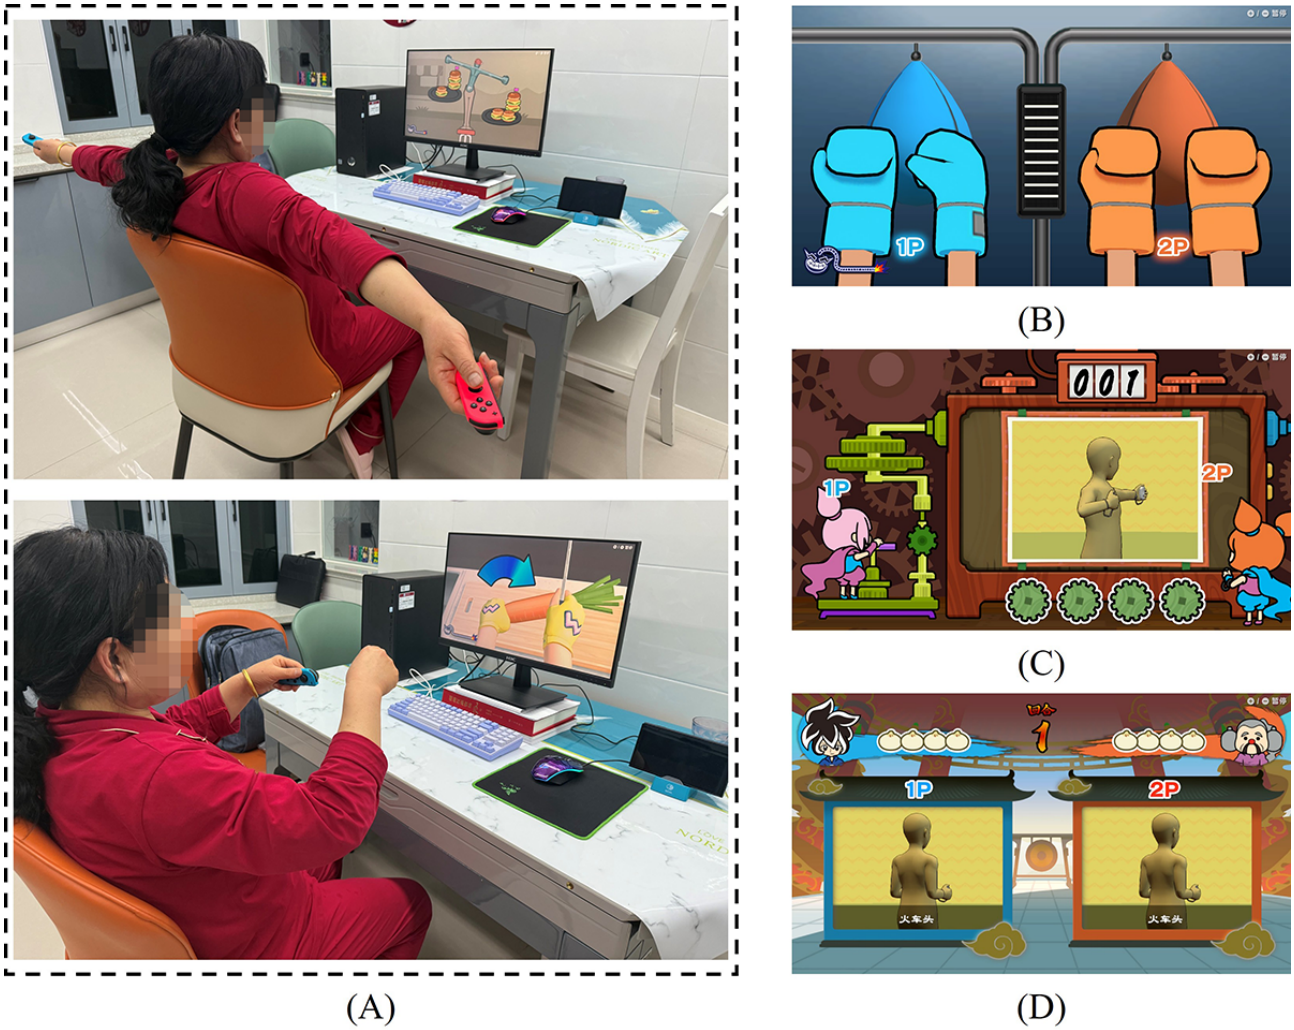
No	54 (46.6)	56 (48.3)	
Years of education, mean (SD)	6.53 (3.037)	6.31 (2.994)	.57
Hours of sleep, mean (SD)	6.44 (1.239)	6.42 (1.259)	.92
Years of smart device use, mean (SD)	4.59 (1.658)	4.35 (1.741)	.28

Randomization and Blinding

To eliminate selection bias, enhance the internal validity of the research findings, and ensure scientific rigor and reliability, this study used a stringent randomized grouping method to assign participants to either the intervention or control group. The randomization process followed the following strict steps:

- All eligible participants were assigned a unique identification number to maintain anonymity.
- Identification numbers were recorded on slips of paper, which were then sealed in opaque envelopes to ensure a double-anonymized grouping process.
- The numbered envelopes were placed in an opaque container and thoroughly mixed to guarantee complete randomness in selection.
- Researchers wore blindfolds to prevent prior knowledge of envelope contents and randomly drew a single envelope.
- The selection process was repeated until 116 envelopes were chosen to form the intervention group, with the remaining participants allocated to the control group.



After random assignment at a 1:1 ratio, the intervention group received a 12-week training regimen, while the control group continued with standard care provided by LTCFs. Both groups maintained equivalent activity durations.

Intervention Group Training Program

The training program for the intervention group used the Nintendo Switch exergame “WarioWare: Move It,” as depicted in Figure 1. Participants engaged with the game through Joy-Con controllers, completing rapid microgames designed to meet specific movement-oriented objectives. Each game session lasted approximately 5 seconds, requiring participants to quickly adapt to various physical actions and postures, such as waving, jumping, swinging arms, rotating, and mimicking object movements. The game’s interactive design fosters an engaging experience that promotes physical coordination, reaction speed, upper and lower limb strength, and hand-eye coordination through diverse movement patterns. Switching between tasks compels players to swiftly adjust to varying motion demands, enhancing physical agility while strengthening attention shifting and quick decision-making skills.

XSL•FO
RenderX

Figure 1. Training scenarios and gameplay modes of the Nintendo Switch "WarioWare: Move It" exergame: (A) a participant engaging in a gameplay scenario, (B) competitive mode, (C) cooperative mode, and (D) versus mode.

Furthermore, to enhance both engagement and safety, the intervention program was supported by trained staff responsible for providing tailored assistance to participants throughout the training. Before the intervention, all staff members received comprehensive training in using both the Nintendo Switch console and the game mechanics of "WarioWare: Move It!." The training included familiarization with the game's functionality, understanding how to adapt the tasks to meet participants' physical and cognitive needs, and recognizing when to modify the intensity or duration of tasks. Staff were also trained to monitor participants' physical and cognitive responses, offer guidance as needed, and adjust the game's parameters based on individual performance.

The training program was administered twice weekly, with each session lasting 60 minutes over 12 weeks. Each session comprised three 15-minute gaming segments interspersed with 1- to 5-minute rest periods to sustain participant engagement and mitigate mental fatigue. Before the intervention, all participants attended a 30-minute orientation session to familiarize themselves with the Nintendo Switch console, the game mechanics of "WarioWare: Move It!," and the use of Joy-Con controllers. During training, staff provided tailored support and dynamically adjusted program parameters based on individual performance, modifying task content, intensity, duration, and physical demands as necessary.

Control Group Standard Care Program

The standard care program for the control group is grounded in routine practices of LTCFs, aiming to sustain and enhance the physical and mental well-being of older adult residents through structured group activities. These activities encompass tailored fitness exercises, horticultural therapy, and sedentary group engagements for older adults. The fitness exercises are adapted to meet the varying physical conditions of participants, ensuring a safe and comfortable environment that promotes moderate physical activity. Horticultural therapy involves hands-on planting and tending to plants, stimulating the senses, and fostering emotional regulation, contributing to improved psychological health. Sedentary activities, such as tabletop games, emphasize social interaction and cognitive maintenance by promoting a relaxed social environment that helps participants remain cognitively engaged. A professional therapist leads each session to ensure that participants receive adequate guidance and support throughout the activities. The program is conducted twice a week, with each session lasting 60 minutes over 12 weeks.

XSL•FO
RenderX

Outcomes Measured

All participants underwent 3 assessments at distinct time points. The initial assessment occurred at baseline before randomization. Subsequent evaluations were conducted at the end of 12 weeks (posttest) and 6 months after the intervention concluded. The primary outcomes of this study focus on detecting intervention effects using indicators related to physical flexibility, joint range of motion, motor coordination, hand dexterity, and cognitive abilities.

In this study, physical flexibility assessments involve several standardized tests. First, the sit and reach test measures the participant's ability to stretch forward while seated with legs extended and heels fixed [33,34]. The farthest distance reached with outstretched hands toward the toes is recorded, with the gap between the fingertips and toes serving as the flexibility index. The shoulder flexibility test assesses flexibility by measuring the distance between the hands when clasped behind the back [35,36]. Participants with higher flexibility achieve either easy hand clasping or shorter hand-to-hand distance. The trunk rotation flexibility test requires participants to stand with feet together and arms extended forward, rotating the torso left and right around the waist [37]. The maximum angle reached on each side indicates flexibility, with more prominent angles signifying greater flexibility.

The joint range of motion reflects the extent of freedom a joint possesses within a specified range of movement. Observing changes in the range of motion across different directions in the intervention group makes it possible to determine whether significant improvements occur in particular directions (eg, flexion or internal rotation), thus providing targeted feedback for the intervention. This study's joint range of motion assessments include shoulder and elbow range of motion tests. The shoulder range of motion test measures the maximum range in 4 directions (eg, flexion, extension, abduction, and adduction) [38,39]. In contrast, the elbow range of motion test assesses the degree of elbow flexion [40].

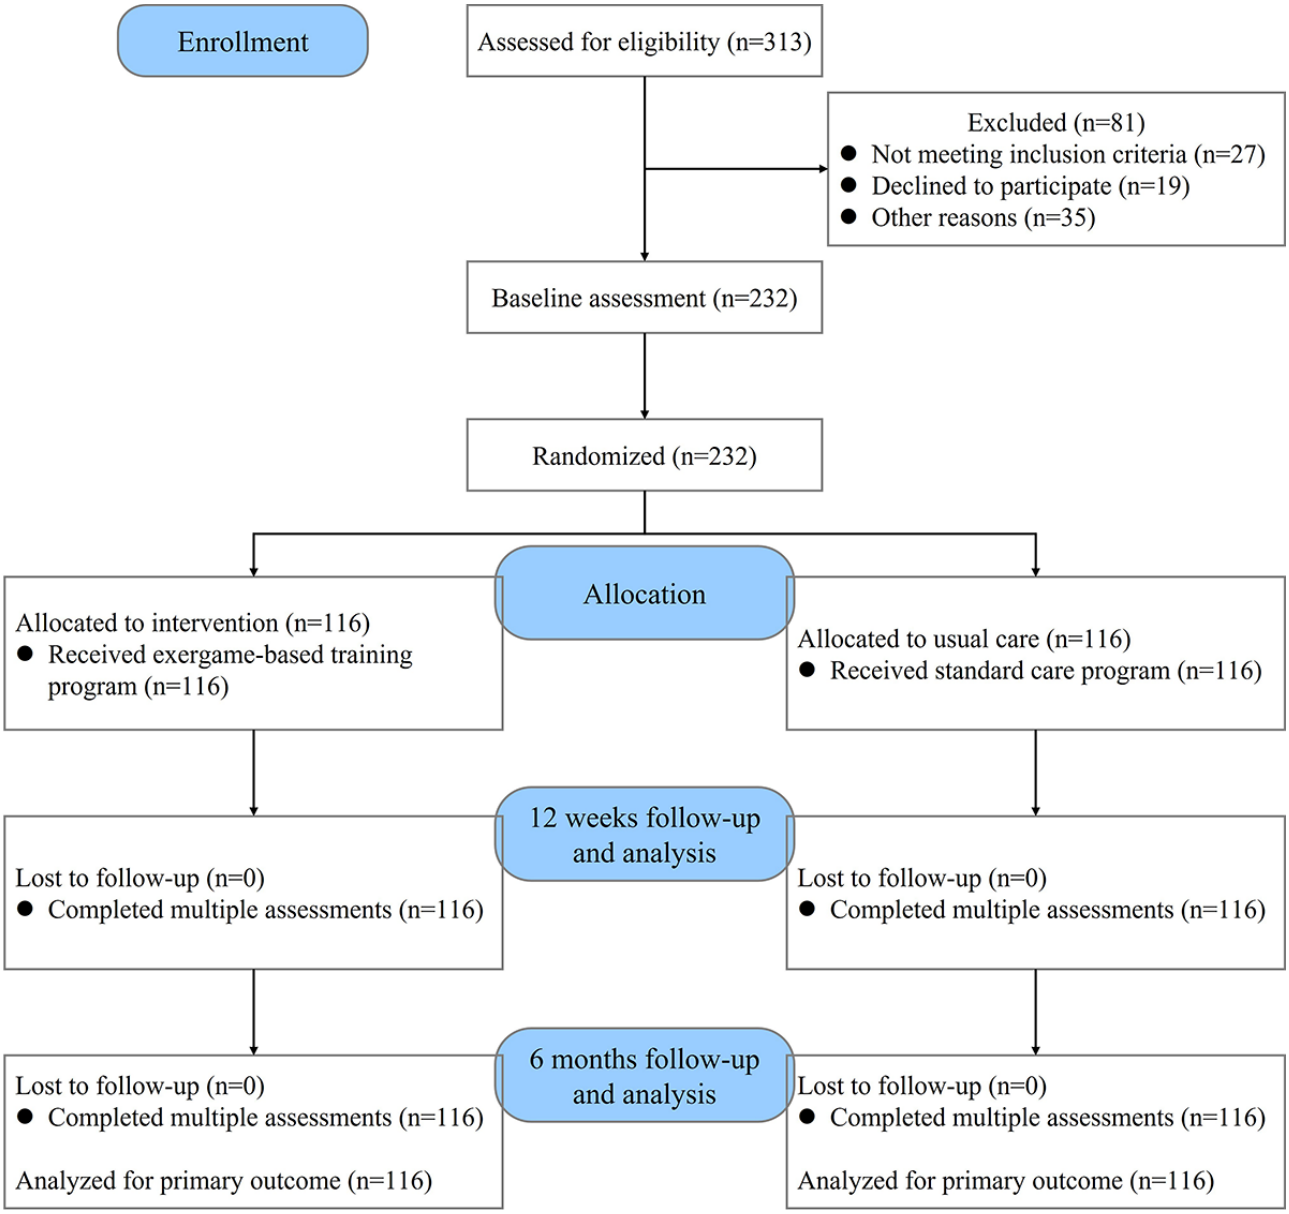
In addition, this study evaluates motor coordination, defined as the body's ability to synchronize various parts during complex physical tasks. The assessment methods include the figure-of-8 walk [41,42] and standing balance test [43,44]. In the figure-of-8 walk test, participants are instructed to walk in a figure-of-8 pattern around 2 markers placed on the ground, covering a total distance of 10 m. The time taken to complete this task is recorded as a measure of coordination. The standing balance test requires participants to stand with their feet together and their eyes closed, aiming to maintain balance, with the duration of balance maintained being measured as an indicator of stability.

Similarly, hand dexterity reflects an individual's coordination, agility, and reaction speed in performing fine motor tasks, particularly when required to complete repetitive, high-precision tasks within a limited time frame. Hand dexterity was assessed using the box block test [45,46], where participants were instructed to use their dominant hand to transfer blocks from one compartment to another within a wooden box over 60 seconds, recording the total number of transfers completed within the specified time. Finally, cognitive function was evaluated using the Cognitive Abilities Screening Instrument (CASI) [47] as well as the Chinese versions of the MMSE [48] and MoCA scales [49]. Detailed measurement procedures are provided in Multimedia Appendix 2.

Statistical Analysis

Statistical analysis was conducted using SPSS for Windows (version 21.0; IBM Corp). Continuous variables were represented by means and SDs, while categorical variables were expressed as frequencies and percentages. Before each analysis, normality and homogeneity of variance were preliminarily assessed. For variables conforming to a normal distribution, we applied 2-tailed *t* tests for continuous variables and chi-square tests for categorical variables to determine the significance of differences between groups. The statistical significance level for all tests was set at $P<.05$.

To assess the impact of the intervention on outcomes across different time points, we performed a mixed ANOVA, with time as a within- participant factor and the nature of the intervention as a between-participant factor. Effect sizes were calculated using η^2, which ranges from 0 to 1, to quantify the strength of the intervention's influence. Generally, higher η^2 values indicate a more significant proportion of variance in the dependent variable explained by the intervention, thus reflecting a more substantial intervention effect. For any significant interactions or main effects, Bonferroni correction was used for post hoc evaluations.



Results

Baseline Performance of the Intervention and Control Groups

In this study, a total of 313 participants were screened for eligibility at LTCFs, including rural daycare centers and nursing homes. Of these, 232 participants were included and randomly assigned to either the intervention group (n=116) or the control group (n=116) (Figure 2). Notably, no dropouts occurred during the 12-week intervention period or the 6-month follow-up after the intervention.

XSL•FO
RenderX

Figure 2. CONSORT (Consolidated Standards of Reporting Trials) flow diagram.

This study assessed baseline performance for both the intervention and control groups before the intervention began. The evaluation covered multiple domains, including physical flexibility, joint mobility, balance, coordination, and cognitive abilities. As presented in Multimedia Appendix 3, no significant differences were observed between the 2 groups across these various assessments (P>.05), indicating that participants exhibited relatively comparable physical function and cognitive status before the intervention.

Comparison of Physical Function Outcomes Between Intervention and Control Groups

As detailed in Multimedia Appendix 3, the sit and reach test results indicated a significant reduction in the distance between participants' hands and toes over time ($F_{2,78}$=35.682; P<.001). A significant group × time interaction effect was also observed ($F_{2,156}$=8.484; P<.001), demonstrating the intervention group exhibited a markedly more significant flexibility improvement than the control group. A similar trend was observed in the shoulder flexibility test, where the distance between participants' hands positioned behind the back showed a significant time effect ($F_{2,78}$=16.511; P<.001) and a significant group × time interaction effect ($F_{2,156}$=3.666; P=.04). In addition, in the trunk rotation flexibility test, the intervention group exhibited a significant increase in rotational range, with a significant interaction effect ($F_{2,156}$=17.353; P<.001) and a moderate-to-small effect size (η^2=0.182). Post hoc analysis demonstrated that physical flexibility indicators in the intervention group showed substantial improvement from baseline to the end of the intervention and remained consistently enhanced up to 6 months post intervention, indicating the durability and stability of the intervention effects.

Furthermore, the joint range of motion was assessed by comparing participants' maximal range of motion in 4 directions (eg, shoulder flexion, extension, abduction, and adduction). The results indicated a significant increase over time in shoulder flexion ($F_{2,78}$=36.315; P<.001) and abduction ($F_{2,78}$=4.499; P=.02) among participants. Further analysis revealed a

XSL•FO
RenderX

significant group × time interaction effect, with participants receiving the intervention demonstrating more pronounced improvements in shoulder flexion ($F_{2,156}$=17.655; P<.001) and abduction ($F_{2,156}$=6.281, P=.004), suggesting a positive impact of the intervention on enhancing range of motion in specific directions. In addition, the elbow range of motion test showed a significant increase in elbow flexion over time ($F_{2,78}$=9.261; P<.001), along with a significant group × time interaction effect ($F_{2,156}$=17.353; P<.001) and a small effect size (η^2=0.041). These effects may be related to the nature of the intervention tasks (eg, simulated swimming, skiing, and flying), emphasizing shoulder flexion, abduction, and elbow flexion, thereby enhancing the range of motion more substantially in these directions.

Subsequently, in the assessment of motor coordination, the figure-of-8 walk and standing balance test were used to evaluate participants' functional performance based on time metrics. The figure-of-8 walk test measured walking coordination by recording completion time, with shorter times indicating better coordination. The standing balance test assessed static balance ability by recording how participants could maintain balance while standing with their eyes closed, with longer durations indicating better balance. Post hoc analysis revealed a significant time effect in the completion time of the figure-of-8 walk test ($F_{2,78}$=36.038; P<.001) as well as a significant group × time interaction effect ($F_{2,156}$=11.846; P<.001), suggesting that the intervention group showed a notably more significant improvement in walking speed and motor coordination than the control group. Similarly, the results from the standing balance test demonstrated a significant increase over time in participants' balance duration with eyes closed ($F_{2,78}$=9.059; P<.001), indicating a positive impact of the intervention on static balance ability.

Finally, the box block test, used to assess hand dexterity, revealed a significant increase in the number of blocks transferred by participants within 1 minute over time ($F_{2,78}$=18.648; P<.001). In addition, a significant group × time interaction effect was observed ($F_{2,156}$=4.016; P=.02), indicating that the intervention group demonstrated a substantially greater improvement in hand dexterity than the control group.

Comparison of Cognitive Function Outcomes Between Intervention and Control Groups

This study assessed cognitive function by examining changes in performance on cognitive scales (eg, CASI, MMSE, and MoCA) between the intervention and control groups, as shown in Multimedia Appendix 3. In the CASI assessment, participants' scores significantly increased over time ($F_{2,78}$=21.427; P<.001), with a notable group × time interaction effect ($F_{2,156}$=13.226; P<.001), suggesting a positive impact of the intervention on cognitive function. A similar pattern was observed in both the MMSE and MoCA assessments. For the MMSE, scores significantly improved over time, with a strong time effect ($F_{2,78}$=94.552; P<.001) and a significant group × time interaction effect ($F_{2,156}$=53.244; P<.001), supporting the pronounced cognitive improvement within the intervention group. Likewise, MoCA scores demonstrated a significant time effect ($F_{2,78}$=52.563; P<.001) and a group × time interaction effect ($F_{2,156}$=15.882; P<.001), reinforcing the intervention's effectiveness in enhancing various aspects of cognitive function. Notably, the effect sizes (η^2) for the group × time interaction effects across the 3 scales were 0.145 for CASI, 0.406 for MMSE, and 0.169 for MoCA. The relatively larger effect size for MMSE suggests its higher sensitivity in detecting the intervention's impact on cognitive outcomes.

Discussion

Advantages of "WarioWare: Move It!" in Physical and Cognitive Rehabilitation for Older Adults

To our knowledge, this is the first study to evaluate the clinical efficacy of an exergame intervention on a range of functional outcomes, including physical flexibility, joint mobility, motor coordination, hand dexterity, and cognitive status. "WarioWare: Move It!" integrates elements of aerobic exercise, physical coordination, balance training, and cognitive engagement into a motion-based game, with real-time feedback mechanisms to enhance the experience. The immersive setting encourages active participation among older adults, which is particularly valuable in LTCFs in rural areas, where limited medical and social resources make it challenging to implement structured exercise programs. Therefore, we explored the application value of "WarioWare: Move It!" in systematic rehabilitation, focusing on its feasibility in improving older adults' participation and promoting functional recovery. The findings reveal that the older adult participants in LTCFs who received the "WarioWare: Move It!" intervention showed significantly improved flexibility, joint mobility, hand dexterity, and cognitive function compared to a standard care control group. It highlights the potential of "WarioWare: Move It!" as an innovative therapeutic strategy, offering an accessible and well-accepted rehabilitation approach that may help mitigate age-related declines in physical function within long-term care settings.

In addition, this study innovatively incorporates "WarioWare: Move It!" into the design of a motion-based intervention program for older adults. Similar to other exergames, it uses role-playing game mechanics and immersive scene design to foster participant engagement through a playful approach [50,51]. The program offers visual feedback (via screen display) and tactile feedback (through the Joy-Con controller) while incorporating diverse movement postures and randomly varied actions, thus extending beyond traditional exergames limited to fingertip control. Notably, "WarioWare: Move It!" presents a multicomponent training scheme that combines aerobic exercise, body coordination, balance training, and cognitive stimulation to enhance participants' cardiorespiratory endurance, balance, flexibility, and cognitive functions. Prior studies have demonstrated that such multicomponent exergaming provides substantial benefits to physical and cognitive functions in community-dwelling older adults due to its accessibility, cost-effectiveness, and time efficiency, earning broad acceptance [52-54]. Consistent with these findings, this study observed that "WarioWare: Move It!" led to marked improvements in participants' physical abilities (eg, coordination, balance, and

XSL•FO
RenderX

flexibility) and cognitive capacities (eg, executive function, attention, and memory).

One unique aspect of the exergame provided by "WarioWare: Move It!" lies in its ability to automatically set an initial difficulty level at each stage and progressively adjust this based on the player's performance. As players become more familiar with specific game scenarios and movement patterns, the system increases the challenge by gradually increasing the frequency and diversity of the required actions, thus prompting players to achieve efficient coordination between body and mind within a short time frame. Such dynamic adaptability enhances the game's appeal and imposes higher demands on participants' reaction speed, coordination, and focus.

Another fascinating aspect of "WarioWare: Move It!" is its thoughtful inclusion of 3 distinct multiplayer modes, each tailored to meet the preferences of different types of players. In addition to a robust single-player training mode, the game introduces competitive, cooperative, and duel modes to enrich social interactions and enhance player engagement and immersion. First, the competitive mode enables players to compete in specific tasks, with victory determined by scoring or task completion speed, fostering a sense of challenge and achievement. Next, the cooperative mode emphasizes teamwork, encouraging players to complete tasks together, thus strengthening team dynamics and promoting social cohesion. Then, the duel mode focuses on direct player versus player confrontations, offering immediate feedback and creating an intense, engaging battle experience. Overall, these multiplayer interaction modes diversify the game's social and interactive dimensions and offer varied engagement pathways for different player types, thereby boosting player loyalty and satisfaction.

Finally, while this study focused on LTCFs, the intervention's design also makes it feasible for implementation in non-LTCF rural environments. The equipment requirements for "WarioWare: Move It!"—a Joy-Con controller and a screen—are minimal, allowing for adaptation in community centers, individual homes, or other communal spaces. With proper training, family members or community volunteers could facilitate the sessions, alleviating the need for professional caregivers. Moreover, the intervention's engaging and intuitive gameplay makes it accessible even for individuals unfamiliar with gaming technology. Expanding such interventions beyond LTCFs could significantly enhance access to physical and cognitive rehabilitation for older adults in resource-limited settings, promoting healthier aging outcomes across diverse rural populations.

Implications of Multidimensional Improvements in Functional Performance Among Older Adults

In this study, we investigated whether early improvement trends in body coordination and flexibility could be identified in older adults during training. Age-related declines in muscle elasticity and neuromuscular control typically negatively affect coordination and flexibility in older adults [55]. Unlike younger individuals, older adults tend to benefit from training primarily through adaptive changes in the neuromuscular system, improving motor control, postural stability, and coordination, rather than relying solely on muscle hypertrophy or strength gains [56,57]. Our findings indicated that after the 12-week training period, the remaining distance between the fingertips and toes during the sit and reach test as well as the distance between the hands during the shoulder flexibility test were significantly reduced, indicating a positive effect of the intervention on enhancing both lower and upper limb flexibility. In addition, the trunk rotation angle in both directions significantly increased, further demonstrating the improvement in trunk rotation capacity and overall coordination. Although short-term enhancements in muscle mass may be challenging to detect, neuromuscular adaptations have already positively impacted functional performance in the early stages. In other words, through dynamic contextualized training, older adults experienced enhanced neuromuscular control and motor flexibility, leading to faster, observable improvements in coordination and flexibility.

We also observed a significant improvement in participants' range of motion in specific directions of the shoulder joint, such as flexion and abduction. These movements are crucial for many daily activities, such as dressing and reaching, and their enhancement directly impacts functional performance and independence in older adults' everyday lives [58]. The direction-specific improvement is primarily attributed to the contextualized exercises embedded within the intervention (eg, swimming, flying, and skiing simulations), emphasizing functional relevance and practical application, thereby fostering adaptations in the associated muscle groups and neuromuscular pathways. In addition, the range of motion in elbow joint demonstrated a significant group × time interaction effect in flexion angle, reflecting the rapid adaptability of the neuromuscular system during the short-term intervention. Compared to muscle hypertrophy, older adults are more likely to improve motor control and joint flexibility through neuromuscular adaptations in the short term [25,59], leading to prioritized enhancements in specific directions for the shoulder and elbow joints.

Although the gamified intervention in this study primarily targeted upper limb and trunk movements, a significant increase in walking speed was also observed, indicating the potential benefits of diverse game-based training for gait-related abilities. Walking involves coordinated lower limb and trunk movements, gait control, balance adjustment, and core stability [60,61]. In this study, game interventions (eg, racing, skiing, flying, and archery) not only required upper limb and trunk movements but also challenged balance and center of gravity control through dynamic postures (eg, leaning forward, reaching forward, and lateral shifting). The multifaceted posture control and center of gravity shifting training facilitated improvements in postural stability, balance perception, and neuromuscular coordination, ultimately enhancing gait performance. Moreover, the intervention group significantly reduced completion time for the figure-of-8 walk test, indicating improved stability and turn control during dynamic gait tasks. Similarly, increased duration in the standing balance test reflects improved balance, suggesting that the intervention significantly enhanced participants' neuromuscular control in dynamic and balance tasks. Although the training did not directly target lower limb gait, the center of gravity adjustments, posture transitions, and

XSL•FO
RenderX

full-body coordination exercises embedded within the games significantly improved gait performance.

The intervention program demonstrated significant efficacy in enhancing fine motor control and flexibility of the hands. During the intervention, participants performed hand movement tasks with the Joy-Con controller, such as simulating a tug-of-war, making rock-paper-scissors gestures, and quickly catching a flying disc. These tasks required precise hand adjustments across various contexts, emphasizing independent finger movement and wrist flexibility. In addition, the intervention group showed a notable increase in the number of blocks transferred within 1 minute, alongside a significant group × time interaction effect. This contextualized hand movement training facilitated improvements in fine finger control and wrist flexibility among older adults, with implications for daily tasks requiring fine motor skills, such as grasping objects, handling utensils, and using tools [62].

Finally, this study observed significant improvements in participants' cognitive performance across various assessment tools (eg, CASI, MMSE, and MoCA). Existing research indicates that gamified interventions have a therapeutic impact on the cognitive functions of older adults [63,64]. In this study, the gamified environment provided multidimensional stimulation through visual, auditory, and tactile cues, along with task-based prompts and real-time feedback, consistently presenting participants with spatial and logical challenges. Immersion in such virtual scenarios contributed not only to attentional recovery and stress reduction but also played a positive role in cognitive rehabilitation and enhancement [65]. Moreover, the nature of gamified training, which requires participants to make quick decisions in dynamic scenarios, stimulated executive functioning and response capabilities [66]. Notably, the design features of "WarioWare: Move It!" integrated aerobic exercise, coordination, and balance training alongside cognitive tasks involving memory, attention, and logical reasoning. These multilayered cognitive stimulations created a comprehensive training environment, promoting broad activation of brain functions. Therefore, the notable improvements observed in brain health assessments postintervention were anticipated, highlighting the significant role of gamified interventions in cognitive rehabilitation and enhancement for older adults.

Insights for Rehabilitation Professionals and Human-Computer Interaction Researchers in Older Adult Care

This study offers a new perspective for rehabilitation professionals working with older adult populations, focusing on three key areas: (1) integrating multicomponent cognitive training with physical function restoration—"WarioWare: Move It!" effectively combines aerobic exercise, body coordination, balance, and cognitive stimulation within a structured platform that facilitates multifunctional training through various interactive physical movements—and (2) enhancing adherence through practicality and enjoyment—by integrating intuitive visual feedback, goal achievement mechanisms, immersive scenarios, real-time feedback, and progressively challenging tasks, WarioWare: Move It! Fosters a sense of accomplishment and interactive enjoyment, reinforcing experiential learning and significantly improving adherence—and (3) Practical application of targeted physical function training—through contextualized and interactive movement design, "WarioWare: Move It!" incorporates actions frequently performed in daily life (eg, shoulder flexion and abduction, gait balance, and hand movements) within gameplay to enhance specific physical functions (eg, joint mobility and flexibility).

This study offers valuable insights for researchers in the human-computer interaction field, specifically in designing older adult–friendly interactive systems. Specifically, it highlights three key areas: (1) dynamic adaptive design for older adult–friendly interventions—the dynamic adaptability of the system in "WarioWare: Move It!" gradually guides participants toward higher levels of physical and cognitive demands, facilitating synchronized improvements in both domains within a safe and comfortable experience; (2) multisensory feedback and enhanced interaction—the Intervention successfully integrates multisensory stimulation through visual, auditory, and tactile feedback, enhancing the immersive experience and improving the brain's responsiveness through multimodal input; and (3) rehabilitation benefits of multiple social interaction modes—the social interaction modes within the exergames, including competition (which stimulates participants' achievement motivation), cooperation (which strengthens teamwork awareness), and versus challenges (which foster quick decision-making and response skills), not only enrich the social experience but also meet the psychological and emotional needs of older adults, thus enhancing rehabilitation outcomes.

Limitations and Future Work

Our study has several limitations. First, although the sample size exceeds the requirements for statistical analysis, it remains relatively small. Second, although the exergames have positively affected specific physical and cognitive functions, they cannot fully replace traditional rehabilitation methods (eg, physical or cognitive behavioral therapy). Future intervention designs could consider integrating exergames with conventional rehabilitation techniques, creating a more diversified and comprehensive rehabilitation plan to meet the broader needs of older adults. Third, the social interaction features of "WarioWare: Move It!" (eg, competition, cooperation, and rivalry) enhance rehabilitation outcomes. However, preferences for competition or collaborative modes may vary among older adults, particularly those who are more introverted or have lower social engagement, making these modes less appealing to some individuals. Future game iterations could incorporate personalized social interaction options to ensure each participant receives an optimal experience, boosting engagement. Fourth, although this study focused on older adults, differences in age, stage of cognitive impairment, and the specific needs of different age groups may warrant further investigation to understand the broader applicability of the intervention.

Conclusions

The "WarioWare: Move It!" training program significantly improves physical flexibility, joint range of motion, motor coordination, hand dexterity, and cognitive function among older adults in rural LTCFs. For patients with MCI or dementia, this intervention not only aids in delaying functional decline

XSL•FO
RenderX

but also enhances cognitive function and quality of daily living through multisensory stimulation and dynamic physical engagement. Furthermore, the incorporation of exergames marks an innovative shift in older adult care models, offering a novel, low-demand intervention method that effectively addresses the shortcomings of traditional care approaches. These findings support the integration of exergames into routine care practices and provide a viable, technology-driven solution to address the challenges of aging health in institutional care settings worldwide.

Abstract

Background: Unguided internet-based cognitive behavioral therapy (ICBT) has been proven effective for major depressive disorder (MDD). However, few studies have examined its cost-effectiveness in low-resource countries and under nonspecialist routine care.

Objective: This study aimed to evaluate the short- and long-term cost utility of unguided ICBT compared to a waitlist control for persons with MDD from the perspectives of society and the health care system.

Methods: This analysis was implemented alongside an 8-week 2-arm randomized controlled trial with a 12-month follow-up period conducted in Shenzhen, China. Outcomes including cost and health utility were collected at the pretreatment and posttreatment time points and 3, 6, and 12 months after the intervention. Direct medical costs and indirect costs were prospectively collected using the hospital information system and the Sheehan Disability Scale. Health outcomes were measured using the Chinese version of the Short-Form Six-Dimension health index. The primary outcome was incremental cost utility ratio (ICUR) expressed as the difference in costs between 2 therapies by the difference in quality-adjusted life years (QALYs). The seemingly unrelated regression model and the bootstrap method were performed to estimate adjusted ICURs. Cost-effectiveness planes and cost-effectiveness acceptability curves were used to demonstrate uncertainty. A series of scenario analyses were conducted to verify the robustness of base-case results.

Results: In total, 244 participants with MDD were randomly allocated to the ICBT (n=122, 50%) or waitlist control (n=122, 50%) groups. At the pretreatment time point, no statistically significant difference was observed in direct medical cost (*P*=.41), indirect cost (*P*=.10), or health utility (*P*=.11) between the 2 groups. In the base-case analysis, the ICBT group reported higher direct medical costs and better quality of life but lower total costs at the posttreatment time point. The adjusted ICURs at the posttreatment time point were CN ¥–194,720.38 (US $–26,551.50; 95% CI CN ¥–198,766.78 to CN ¥–190,673.98 [US $–27,103.20 to US $–25,999.70]) and CN ¥49,700.33 (US $6776.99; 95% CI CN ¥46,626.34-CN ¥52,774.31 [US $6357.83-$7196.15]) per

XSL•FO
RenderX

QALY from the societal and health care system perspectives, respectively, with a probability of unguided ICBT being cost-effective of 75.93% and 54.4%, respectively, if the willingness to pay was set at 1 time the per-capita gross domestic product. In the scenario analyses, the probabilities increased to 76.85% and 77.61%, respectively, indicating the potential of ICBT to be cost-effective over the long term.

Conclusions: Unguided ICBT is a cost-effective treatment for MDD. This intervention not only helps patients with MDD improve clinically but also generates societal savings. These findings provide health economic evidence for a potential scalable MDD treatment method in low- and middle-income countries.

Introduction

Background

Major depressive disorder (MDD) is a highly prevalent mental disorder estimated to affect 332 million people worldwide in 2021 [1]. MDD is associated with significant impairment of health-related quality of life (HRQoL) [2], substantial health care use [3], and huge societal impacts on employment and productivity [4,5]. Now, MDD is ranked as the second leading cause of global nonfatal disability [1], and MDD-attributed lost productivity costs the global economy US $1 trillion annually [6]. Effective, scalable, and cost-effective therapies are needed to reduce the disease burden caused by MDD [7].

Despite the availability of effective first-line treatments involving psychotherapies and pharmacotherapies for MDD [8], the treatment gap is still large [9,10]. Individuals with MDD are faced with a series of barriers to treatment, including social discrimination, stigma, health care costs, and a shortage of specialists [11,12], especially in low-resource settings such as China [13]. Unguided internet-based cognitive behavioral therapy (ICBT), a form of cognitive behavioral therapy delivered through the internet without therapeutic support [14], has the attributes of privacy, accessibility, flexibility, and ease of implementation with constrained health care resources and personnel [15,16]. It has been gradually applied for the treatment of MDD. Existing research across low-, middle-, and high-income countries has demonstrated the effectiveness of unguided ICBT for MDD in comparison with usual care [11,17-20]. In China, our team has also developed an unguided ICBT course for MDD, and its efficacy has been confirmed through a randomized controlled trial (RCT) [21].

In contrast with the well-established evidence of effectiveness, the cost-effectiveness of unguided ICBT for MDD remains relatively under-studied [22-30]. There is an increasing demand for economic evidence to optimize resource allocation and scale up the implementation of unguided ICBT in different contexts [31]. However, existing trial-based economic evaluations are mostly conducted in high-income countries and adopt a single perspective (societal or health care system perspective), and the results are inconclusive [32-34]. Previous cost utility analyses (CUAs) conducted from the perspective of the health care system over a long-term follow-up period (1-2 years) have reported that unguided ICBT had lower probability of being more cost-effective in comparison with usual care at setting values of willingness to pay (WTP), with the probability of unguided ICBT being cost-effective ranging from 3.8% to 41.7% [26-28,30]. In the case of those adopting the societal perspective, the findings have been mixed, and the supportive evidence has had some uncertainties [22-25,29,30]. Holst et al [30] conducted a CUA of unguided ICBT compared with usual care among participants with mild to moderate depression in Sweden and found that no firm conclusions could be drawn under a range of assumed WTP. In the Netherlands, all CUA analyses have reported positive results and suggested the economic merits of unguided ICBT compared to usual care, with the likelihood of the former being cost-effective being 52%, 65%, and 62% [23-25]. In addition, another 2 evaluations conducted in the United Kingdom and Spain demonstrated that unguided ICBT was the dominant treatment option in comparison with usual care [22,29]. Considering the large heterogeneity in current research, the generalizability and external validity of the cost-effectiveness conclusions require more research in different settings under economic guidance. To our knowledge, no study has reported the cost-effectiveness of unguided ICBT for MDD in China. It is necessary to extend the analysis to China and account for both the societal and health care system perspectives to provide decision-making evidence for the optimization and allocation of the limited health care resources.

Objectives

Therefore, this study aimed to comprehensively assess the short- and long-term cost utility of unguided ICBT among persons with MDD in China from the perspectives of society and the health care system.

Methods

Study Design

This economic evaluation was conducted prospectively alongside an 8-week pragmatic, unblinded, 2-arm RCT with a follow-up period of 12 months and was conducted from the perspectives of society and the Chinese health care system. The time horizon was in line with that of the RCT from baseline to 12 months after treatment. Participants were randomly allocated to the ICBT (ICBT plus usual care) or waitlist control (usual

XSL•FO
RenderX

care) groups at a ratio of 1:1. The detailed study design and procedures have been described in a published paper [21].

Ethical Considerations

This RCT was registered with the Chinese Clinical Trial Registry (ChiCTR2100046425) and obtained ethics approval from the Ethics Review Committee of Shenzhen Nanshan Center for Chronic Disease Control (ll20210012) in line with the standards stipulated in the Declaration of Helsinki. The CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist was used to guide and report the RCT [35]. In addition, the Consolidated Health Economic Evaluation Reporting Standards were applied to conduct and guide the economic evaluation [36]. All participants provided written informed consent, including for the use of their data for secondary analyses. The data used for the analyses were deidentified to protect the privacy of the participants. For those who completed the trial, financial incentives in the form of small amounts of electronic cash (CN ¥50 [US $6.82]) were distributed.

Study Participants

In this study, participants were recruited from the Department of Depressive Disorder, Shenzhen Kangning Hospital, and the Department of Psychiatry, Shenzhen Nanshan Center for Chronic Disease Control, between August 2021 and December 2022. To be eligible for this study, participants had to meet the following inclusion criteria: (1) age 18 to 60 years; (2) a positive screening result on the Patient Health Questionnaire–9 (PHQ-9) of ≥5 [37]; (3) a diagnosis of MDD through the Mini-International Neuropsychiatric Interview [38] through the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition*; (4) access to internet-connected mobile devices; (5) lack of any other psychotherapy or physical therapy currently; (6) no changes in condition during the previous month (eg, patients with antidepressant use did not change the dosage); and (7) informed consent. The exclusion criteria were (1) neurological illness (eg, traumatic brain injury or functional impairment); (2) a moderate to high risk of suicide; (3) alcohol abuse or substance use disorder; (4) pregnancy or breastfeeding; and (5) diagnosis of a severe physical disease, psychosis, or bipolar disorder. Eligible participants were asked to complete the baseline assessment, including sociodemographic information (eg, age, sex, and ethnicity), clinical history (eg, antidepressant use and history of psychopathology), lifestyle (eg, smoking and drinking), and baseline clinical symptoms (measured using the PHQ-9, Generalized Anxiety Disorder–7, and Kessler Psychological Distress Scale).

Intervention

Participants in the ICBT group were provided with an ICBT course for 8 weeks in addition to usual care. Each participant was assigned an account number and corresponding password after the pretreatment instruction and training for use. The ICBT course is called Morning Mood; is embedded in the WeChat mini program; and can be accessed via smartphones, tablets, and computers. The course was grounded in cognitive behavioral therapy principles aiming at teaching emotional regulation skills and cognitive restructuring. In total, there are seven 30-minute modules. The detailed contents and corresponding screenshots are shown in Multimedia Appendix 1. Participants were required to complete 1 module per week. Technical support and reminder services via telephone call and SMS text messaging were provided by trained nonspecialists (ie, lay health workers, nurses, and social workers) throughout the intervention and follow-up periods to promote participant engagement. However, no therapeutic guidance was offered to them, and thus, this treatment was defined as an unguided ICBT course.

Participants in the waitlist control group were on a waiting list for ICBT and did not receive any additional specific interventions. However, individuals' usual treatment was maintained during the 8-week control period. After 8 weeks, the participants in the control arm completed the observation phase and began to receive the ICBT treatment.

Health Outcomes

The primary health outcome was quality-adjusted life years (QALYs), estimated using the Simplified Chinese version of the Short-Form Six-Dimension (SF-6D) health index, which is demonstrated to have good validity among the Chinese population, including individuals with mental health problems [39,40]. The SF-6D is one of the most widely used preference-based HRQoL instruments [41] and has been recommended by many national guidelines of economic evaluations for the calculation of QALYs [42]. The SF-6D defines the health state through the following 6 dimensions: physical functioning, role limitation, social functioning, pain, mental health, and vitality [43]. The SF-6D responses were converted to health utility on the QALY scale from 0 (death) to 1 (full health) using the Chinese value set for the SF-6D [44], with a value of <0 indicating a worse health condition than death. The SF-6D was administered at baseline; the posttreatment time point; and the 3-, 6-, and 12-month follow-ups. Subsequently, QALYs were derived by multiplying time in a particular health state by its health utility using the area under the curve method [45], with 1 QALY indicating 1 life year in perfect health. The adjusted QALY for CUA was calculated using the regression model mentioned in later sections.

Cost Analyses

Costs were calculated from the societal and health care system perspectives using individual-level data collected for the following periods: 3 months before randomization, from randomization to the posttreatment time point (3 months), from the posttreatment time point to the 3-month follow-up, from the 3- to the 6-month follow-up, and from the 6- to the 12-month follow-up. In total, 3 main categories of costs were identified: intervention costs, health care costs, and societal costs attributed to lost or declined productivity. The health care system perspective accounts for all the costs directly associated with health care services [46], and thus, intervention costs and health care costs are included within this perspective. As the societal perspective is the broadest perspective comprising all health care–related costs and productivity costs [46], all 3 costs are considered within this perspective.

XSL•FO
RenderX

Intervention costs refer to the expenses associated with the intervention administered. For the ICBT group, the intervention costs comprised the costs of development and maintenance of Morning Mood, implementation support, and personnel training. On the basis of the practical operation, we estimated that the costs were CN ¥545 (US $74.31) per participant. For the waitlist control group, the intervention costs were CN ¥0 per participant.

Health care costs, also called direct medical costs, comprise expenses generated from health care resource use, including but not limited to diagnostic tests, examinations, medications, and other treatments. In this study, direct medical costs were retrieved from the Shenzhen Hospital information system at the individual patient level and calculated using the bottom-up method [47].

Societal costs, also known as indirect costs, are the quantified economic value of lost and declined productivity attributed to MDD. The Sheehan Disability Scale (SDS) was applied to measure days of lost and declined productivity through the following items: “On how many days in the last week did your symptoms cause you to miss school or work or leave you unable to carry out your normal daily responsibilities” and “On how many days in the last week did you feel so impaired by your symptoms, that even though you went to school or work, your productivity was reduced” [48]. Previous research has converted absenteeism and presenteeism into monetary units in populations with mental health conditions [49]. Thus, this study also applied the human capital approach for the estimation [50]. Specifically, loss of productivity was calculated using days of lost productivity multiplied by the monthly average wage in Shenzhen [51]. For declined productivity, a weighting coefficient of 42.98% was used for the adjustment [49].

All costs were collected alongside the RCT and were measured in 2022 Chinese yuan. The baseline costs were identified as costs incurred during the 3 months before the individuals’ time of enrollment and were used to control for baseline differences.

Statistical Analysis

Baseline characteristics and outcome measures were described by group and by phase with continuous variables using mean, SD, and frequency for categorical variables. Mann-Whitney *U* tests, 2-tailed *t* tests, and chi-square tests were used to investigate the differences in baseline characteristics and outcomes between the 2 arms. Estimates of the difference between groups in health utility scores were derived at each time point with 95% CIs and *P* values. Statistical significance was determined when the *P* value was <.05.

Missing data were imputed using the multiple imputation by chained equations package in R (version 4.2.2; R Foundation for Statistical Computing) under the assumption of data being missing at random [52,53]. There is compelling evidence that multiple imputation and bootstrapping are robust resampling approaches for dealing with skewed and missing data in cost-effectiveness trials [54]. The predictive mean matching method in multiple imputation by chained equations was adopted for imputation, which matched the missing value to the observed value with the closest predicted mean, with the advantage of preserving data distribution and avoiding values lying outside the bounds for each variable [55]. A total of 5 imputed datasets were generated and used for analysis as previous studies have suggested that 3 to 5 imputed datasets were sufficient to provide adequate estimates [56]. The rules by Rubin [57] were used to pool the results, involving the estimates, SEs, and 95% CIs. Health utility and costs at the posttreatment time point and every follow-up time point were imputed based on age, gender, antidepressant use, baseline values (utility and cost), and values from the previous or next measurement time point [26].

Economic Evaluation

The CUA was conducted from the perspectives of society and the health care system for 8 weeks, 3 months, 6 months, and 12 months, not accounting for the discount rate for cost and QALYs. Both the complete-case (CC) and intention-to-treat (ITT) samples were considered. Seemingly unrelated regression was conducted to estimate the total costs, QALYs, and corresponding differences (incremental differences in costs and QALYs between the 2 arms) while adjusting for baseline values and other covariates and considering the correlation between costs and QALYs, with the coefficients of the treatment group (reference: waitlist control group) in 2 separate regression models representing the cost and effect differences [58]. Total costs were adjusted for baseline costs, age, gender, and antidepressant use [59]. QALYs were adjusted for baseline utility, age, gender, and antidepressant use [59,60]. Incremental cost utility ratios (ICURs) were calculated using the incremental difference in costs divided by the incremental difference in QALYs between the 2 arms. Nonparametric bootstrapping methods were performed to account for the uncertainty surrounding the estimates of cost, QALYs, and ICURs. Cost-effectiveness planes and cost-effectiveness acceptability curves (CEACs) were applied to demonstrate the uncertainty of the results [61]. In this study, the WTP threshold (ie, the amount that people are willing to pay for 1 year lived in full health state) was set at 1.5 times the per-capita gross domestic product per QALY [62], with a range from 1 to 3 times the per-capita gross domestic product (CN ¥80,976 to CN ¥242,928 [US $11,041.60 to $33,124.90]) according to the Chinese guideline for health economics [63]. Standard decision rules were used to determine whether the ICBT was cost-effective compared to the waitlist control [58].

Base-case cost-effectiveness analysis was conducted using data collected at the posttreatment time point (ie, 8 weeks). Sensitivity analyses were implemented through a series of scenario analyses using data collected at the follow-up time points. The aforementioned analyses also assessed whether the results remained consistent after adjusting for baseline differences and adopting different analysis datasets. To explore the long-term cost utility of ICBT, extrapolation analyses across various time horizons (3-, 6-, and 12-month follow-ups) for the waitlist control group were conducted as no follow-up data were available for that group. For each time point, data extrapolation for the control group was applied based on the predicted model formulated from cost and utility data in the ICBT group. Detailed operations and practical rationality have been clearly described in a published article [64]. All analyses were conducted using R (version 4.2.2) and Stata (version 17.0; StataCorp).

Results

Overview

Between August 2021 and December 2022, a total of 291 persons with MDD were recruited. Of these 291 participants, 33 (11.3%) either refused to participate or lost contact, 13 (4.5%) did not meet the inclusion criteria, and 1 (0.3%) met the exclusion criteria. Finally, a total of 244 eligible participants with baseline information and who provided informed consent were enrolled, with 122 (50%) participants allocated to each group. In the ICBT group, a downward trend was observed in completion rates, with the highest rate at 8 weeks (93/122, 76.2%) and the lowest rate at the 12-month follow-up (86/122, 70.5%). For the waitlist control group, a high completion rate was reported, with 94.3% (115/122) of the participants completing the posttreatment assessment. A detailed account of the study population and participant flow is shown in Figure 1.

Figure 1. Flowchart of participants. ICBT: internet-based cognitive behavioral therapy.

Baseline Characteristics

Table 1 shows the baseline characteristics of the participants by treatment group. The mean age was 28.3 (SD 7.0) years, and the female-to-male participant ratio was 3:1. Most of the sample (224/240, 93.3%) was of Han ethnicity. Most of the participants were well educated, with 82.2% (199/242) having received education above the undergraduate level. A total of 69.8% (169/242) of the participants were employed. More than half of the participants were experiencing their first episode of MDD (144/239, 60.3%) and were not receiving antidepressant treatment (127/244, 52%). The mean scores on the PHQ-9, Generalized Anxiety Disorder–7, SDS, and Kessler Psychological Distress Scale at baseline were 13.9 (SD 5.2), 10.5 (SD 4.7), 17.7 (SD 7.0), and 29.7 (SD 9.0), respectively. There were substantial differences in baseline characteristics between the ICBT and waitlist control groups except for the SDS scale scores. The mean SDS scores in the ICBT group were significantly higher than those in the control group (18.8, SD 7.0 vs 16.7, SD 6.8; *P*=.02), indicating that participants in the ICBT group had worse social functioning.

Health Outcome

Table 2 provides the completion rates of the SF-6D scale and the converted health utility scores. At baseline, the mean utility of the ICBT group was lower than that of the control group (0.5190, SD 0.2286 vs 0.5625, SD 0.1949); however, the difference was not statistically significant (*P*=.11). After the 8-week intervention, increases in the average utility scores were observed in both groups (0.6002, SD 0.2285 vs 0.6012, SD 0.2149; *P*=.98), with completion rates of 73% (89/122) and 94.3% (115/122), respectively. The ICBT group demonstrated continuous improvement in health utility scores over the 6-month follow-up period, with a slight decline at 12 months. The highest health utility score of 0.6240 in the ICBT group was observed at the 6-month follow-up.

Multimedia Appendix 2 shows the health utility scores and subsequent QALY estimations in the ITT sample. In the ICBT group, the mean QALY gains were 0.1414 (SE 0.0021), 0.2952 (SE 0.0041), 0.4539 (SE 0.0059), and 0.7765 (SE 0.0096) at the posttreatment time point (ie, 8 weeks) and the 3-, 6-, and 12-month follow-up time points, respectively. In the control group, the average QALYs at the same time points were 0.1463 (SE 0.0019), 0.3000 (SE 0.0038), 0.4598 (SE 0.0053), and 0.7839 (SE 0.0080), respectively. There was no significant difference in QALYs between groups at any time point. Both the CC and ITT analyses suggested sustained improvement in health utility in the ICBT group over 12 months and in the waitlist control group over 8 weeks.

Table 2. Health utility measured using the Short-Form Six-Dimension health index by time point in the complete-case analysis.

Costs

Table 3 shows the costs of different components and aggregated costs in the CC analysis by trial arm. At all time points, indirect costs were the major contributor to the total costs. The cost of antidepressants constituted the primary component of direct medical costs. At the pretreatment time point (ie, baseline), the average direct medical costs in the ICBT and control groups

XSL•FO
RenderX

were CN ¥6588.70 (US $898.42; SD CN ¥14,093.70 [US $1921.77]) and CN ¥5861.70 (US $799.28; SD CN ¥10,198.60 [US $1390.65]), respectively. Indirect costs approximately amounted to CN ¥22,225.90 (US $3030.66; SD CN ¥16,225.30 [US $2212.43]) in the ICBT group and CN ¥18,853.10 (US $2570.75; SD CN ¥16,197.50 [US $2208.64]) in the control group. However, both lacked statistical significance. After the 8-week intervention, both the direct medical costs and indirect costs decreased in both groups. The ICBT group reported statistically significantly higher indirect costs than those in the waitlist control group (P=.01).

Multimedia Appendix 3 shows the results of the cost analysis in the ITT sample. Both groups revealed a decreasing trend in direct medical costs and indirect costs during the posttreatment and follow-up periods. For patients in the ICBT group, the declining trend was sustained throughout the follow-up period.

Table 3. Average costs per participant (in Chinese yuan) by trial arm for the complete-case analysis at the pre- and posttreatment time points.

Time point	ICBT[b] (n=122)		Waitlist (n=122)		*P* value[a]
	Resource users, n (%)	Costs (CN ¥), mean (SD)	Resource users, n (%)	Costs (CN ¥), mean (SD)	
Pretreatment

Economic Evaluations

The adjusted mean costs and QALYs (bootstrapped SEs and 95% CIs) by seemingly unrelated regression in base-case analysis and scenario analyses for this health economic evaluation from the perspectives of society and the health care system in the CC and ITT samples are shown in Multimedia Appendices 4 and 5. In most scenarios, the adjusted costs and QALYs were not statistically significantly different between the 2 groups. The corresponding results of the incremental cost-effectiveness analysis are shown in Table 4.

[a]The scenario analysis represents a scenario whereby the waitlist control participants' health-related quality of life and care costs after 8 weeks up to 12 months followed the same trend observed in the intervention group; therefore, the difference in costs and quality-adjusted life years is based on the observed values for the intervention group at each time point, but predicted values were obtained using regression analysis for the waitlist control group, the regression model for which is described in the Methods section.

[b]Difference in mean values between trial arms.

[c]bSE: bootstrapped SE.

[d]QALY: quality-adjusted life year.

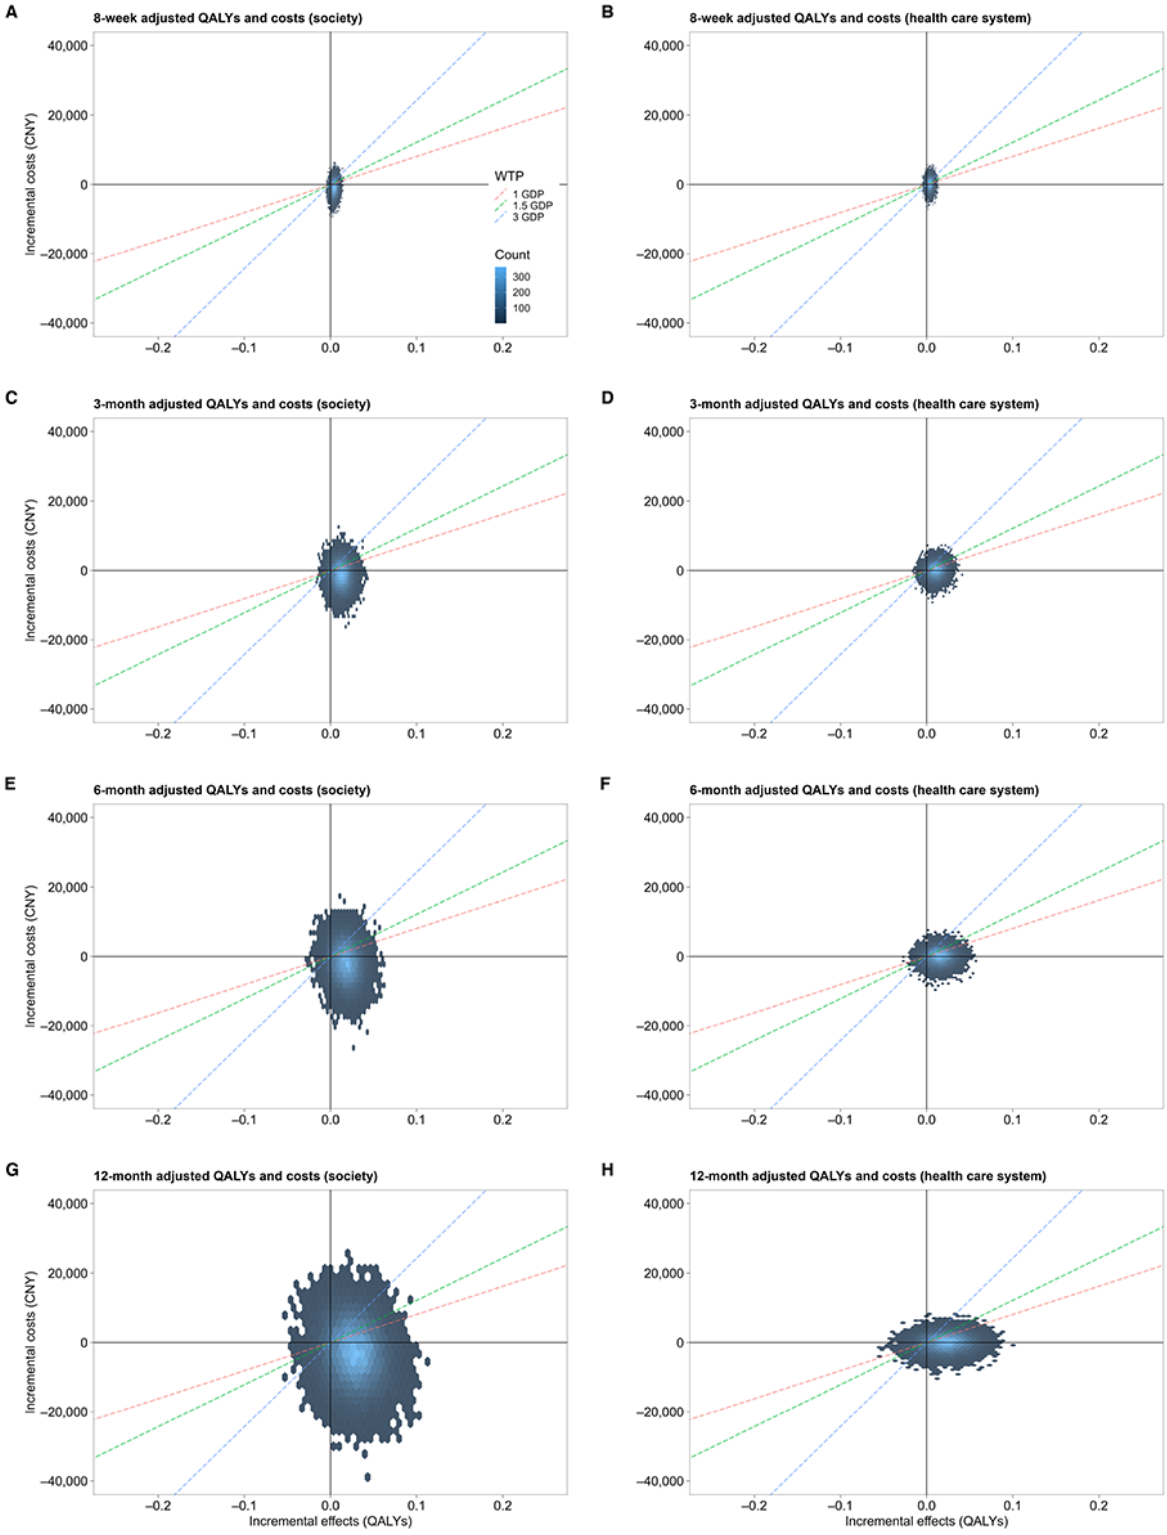
[e]ICUR: incremental cost utility ratio.

[f]Probability of being cost-effective.

[g]GDP: gross domestic product.

[h]Willingness to pay 1 time the per-capita GDP.

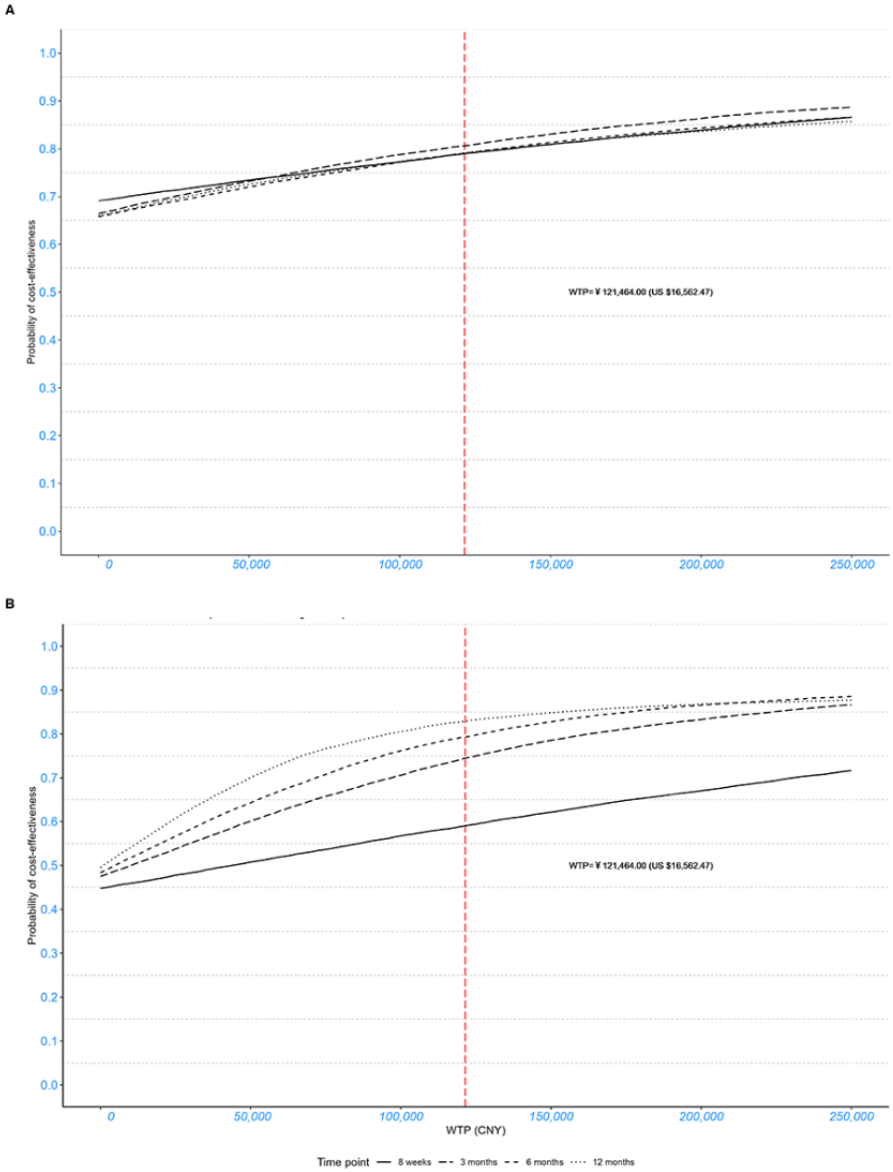
[i]Willingness to pay 3 times the per-capita GDP.



From the perspective of society, the adjusted incremental costs (CN ¥−899.45 [US $–122.65]) and QALYs (0.0046) resulted in an ICUR of CN ¥−194,720.38 (US $–26,551.50) per QALY in the base-case analysis, which was much lower than the setting WTP threshold. This dominant ICUR indicates that ICBT is more cost-effective compared to the waitlist control from the societal perspective. The cost-effectiveness plane and CEAC, generated based on 5000 bootstrapping replications, further illustrated the robustness of the point estimates. Specifically, 29.84% of replications fell within the northeast quadrant (more

XSL•FO
RenderX

expensive and more effective), and 65.82% fell within the southeast quadrant (less expensive and more effective; Figure 2). The probability of ICBT being cost-effective at the setting WTP ranged from 75.93% to 86.24% and showed an upward trend with the increase in WTP (Figure 3).



Similarly, analysis from the perspective of the health care system indicated that ICBT was more cost-effective than the waitlist control, with an ICUR of CN ¥49,700.33 (US $6776.99) per QALY and probabilities of ICBT being cost-effective ranging from 54.4% to 71.03%. Notwithstanding the aforementioned observation, no cost-saving effect for the health care system was observed.

Figure 2. Cost-effectiveness planes showing the difference in baseline-adjusted incremental quality-adjusted life years (QALYs; x-axis) and incremental costs (y-axis) of 5000 bootstrapping samples between trial arms across 8 weeks and 3, 6, and 12 months. (A,C,E,G): society; (B,D,F,H): health care system. CNY: Chinese yuan; GDP: gross domestic product; WTP: willingness to pay.

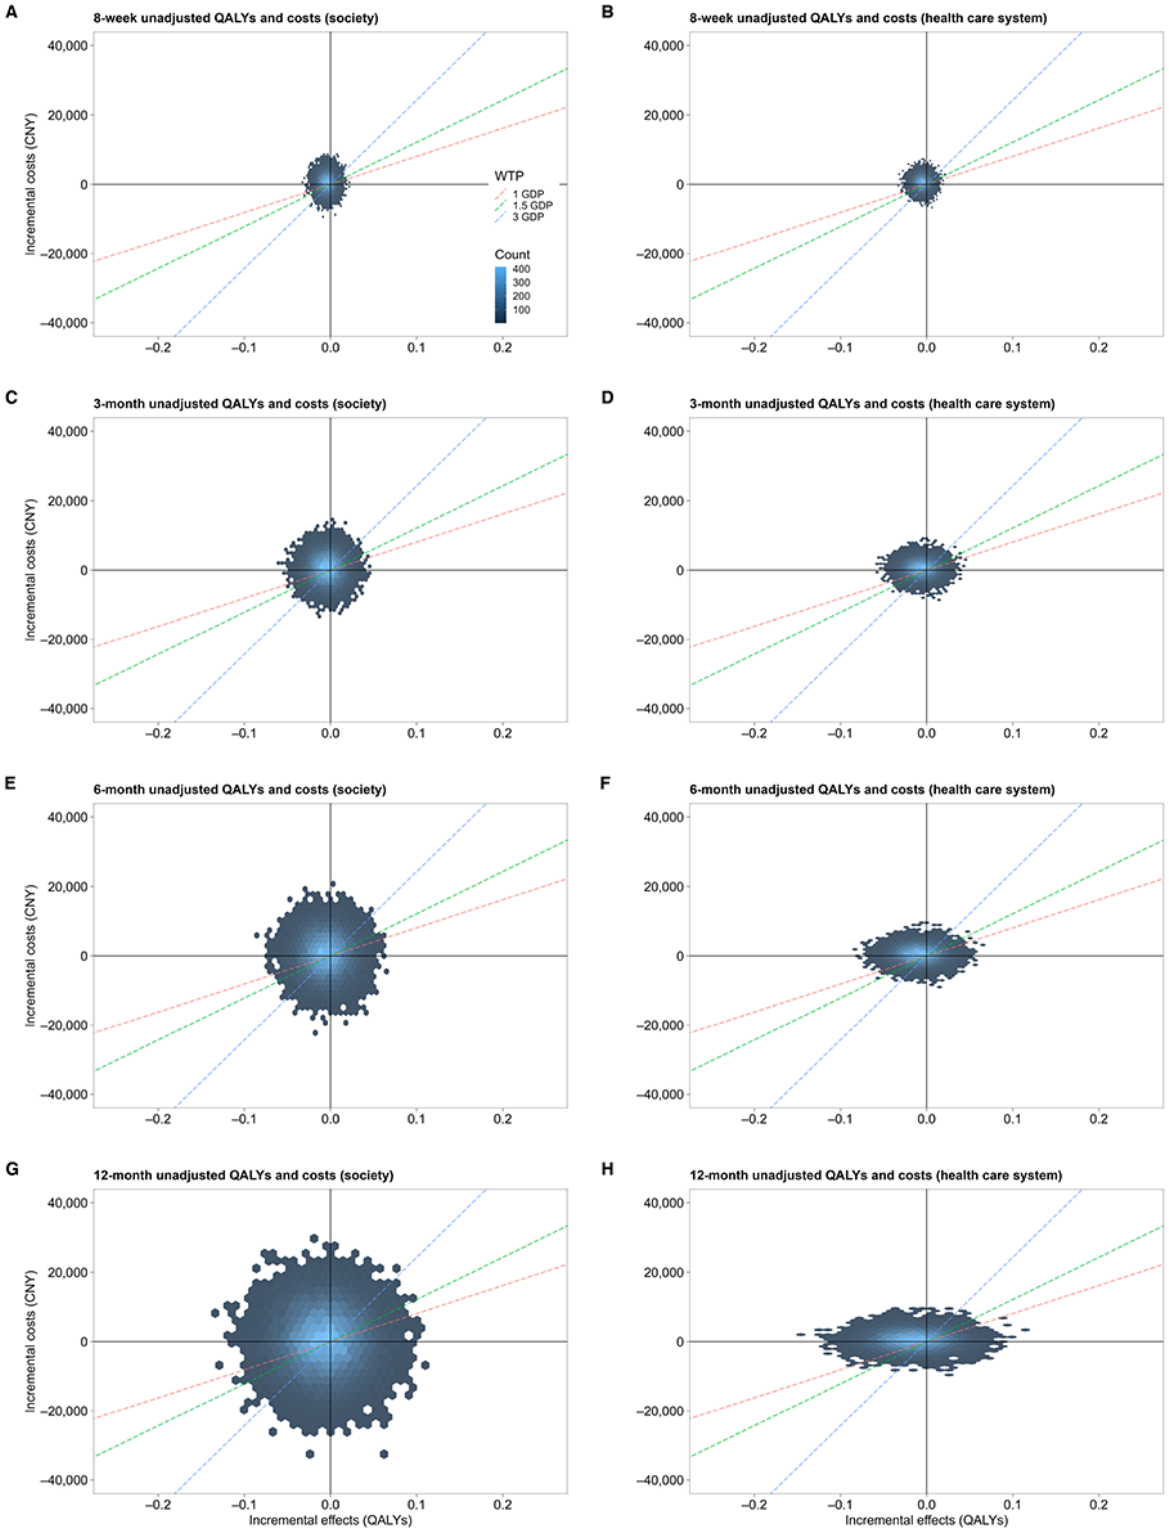
Figure 3. Cost-effectiveness acceptability curves representing the probability of cost-effectiveness of internet-based cognitive behavioral therapy (ICBT) relative to the waitlist control over 8 weeks and 3, 6, and 12 months (baseline-adjusted). (A) ICBT versus waitlist (society); (B) ICBT versus waitlist (health care system). CNY: Chinese yuan; WTP: willingness to pay.



Sensitivity Analysis

Sensitivity analyses were conducted by varying follow-up duration (3-, 6-, and 12-month follow-ups) through subsequent scenario analyses. Figures 2 and 3 show the cost-effectiveness planes and CEACs, respectively, at different time points from the societal and health care system perspectives for comparison. From the societal perspective, the results similarly indicated lower costs but higher QALYs for participants in the ICBT group, with an 88.46% probability of ICBT being cost-effective, suggesting the long-term health and economic value of ICBT. In addition, from the health care system perspective, no cost-saving effect was observed. Higher direct medical costs and QALYs were observed in the ICBT group, with the probability of ICBT being cost-effective reaching 88.34%.

When the baseline values were not adjusted, the ICBT and waitlist control groups showed no difference in terms of cost utility at all time points (Figures 4 and 5). The economic evaluation is reported following the Consolidated Health Economic Evaluation Reporting Standards 2022 checklist, which is presented in Multimedia Appendix 6.

Discussion

Principal Findings

This study aimed to evaluate the short- and long-term cost-effectiveness of unguided ICBT compared to a waitlist control for MDD in China. The base-case findings of this CUA showed that the ICBT intervention was more cost-effective for persons with MDD compared to the waitlist control over 8 weeks from the perspectives of society and the health care system. Sensitivity analyses further confirmed the results by changing the data analysis set (ie, CC and ITT samples), study period (ie, 3-, 6-, and 12-month follow-ups), and whether baseline conditions were adjusted for. To the best of our knowledge, this is the first cost-effectiveness study on unguided ICBT for MDD in China, contributing to the research gap in low- and middle-income countries and providing economic evidence for policy makers to rationally allocate limited health resources.

Previous Studies

From the perspective of society, the incremental cost per QALY gain was CN ¥−194,720.38 (US $–26,551.50), which implied that the ICBT intervention was associated with higher improvement in HRQoL at lower costs, with the probability of ICBT being cost-effective ranging from 75.32% to 88.46% at the setting WTP thresholds. These findings were consistent with those of most previous research conducted in high-income countries demonstrating the cost utility of unguided ICBT for MDD [22-25,29]. Among them, one study also suggested the clinical and cost-saving effect of unguided ICBT [29], with other studies reporting more effectiveness at higher costs [22-25]. This might be owing to the different depression severity in the recruited study participants. It has been indicated that unguided ICBT is more suitable for mild depression [17]. Individuals with milder depressive symptoms are likely to benefit more from ICBT treatment, with greater responsiveness and more substantial health improvements. As a result, their

XSL•FO
RenderX

social functions improve, enabling them to engage in daily activities and return to work and leading to decreased societal costs. However, a study with a small sample size conducted in Sweden reported that no firm conclusions could be drawn on the cost-effectiveness of unguided ICBT [30].

From the health care system perspective, the findings that unguided ICBT was more cost-effective than usual care (ICUR: CN ¥49,700.33 [US $6776.99]; range of probability of ICBT being cost-effective at the given WTP 54.4%-88.34%) were contrary to those of most previous cost-effectiveness studies [26-28,30]. The following different settings might explain the discrepancy: the different instruments used for the measurement of HRQoL (EQ-5D in previous studies and SF-6D in this study), varied baseline symptom severity (PHQ-9≥10 in previous studies and PHQ-9≥5 in this study), and diverse health care use patterns in different health care systems. It is assumed that persons with mild symptoms are more likely to benefit from unguided ICBT [17]. In addition, the SF-6D is more sensitive to changes in mental health, and thus, minor improvements could be captured [65]. Previous research has reported that the conclusions on cost-effectiveness were the opposite when QALYs were estimated using the EQ-5D-3L or the SF-6D [26,28]. When using the SF-6D, ICBT appeared to dominate usual care (lower mean costs and higher QALYs), whereas in our study, ICBT exhibited greater health effects at higher costs. A possible explanation could be the variations in mental health care–seeking behaviors in different contexts. In China, individuals are less likely to approach mental health care due to stigma [66]. However, the ICBT course helps people with MDD transform their inappropriate or negative thought patterns to promote health care use [67]. Hence, the costs of health care in the ICBT group appeared higher than those of the waitlist control group in our analysis. This, in turn, explains the results from the societal perspective. It is plausible that increased patient investment in mental health care and service yields improved social functioning. Consequently, reduced days of lost or decreased productivity and indirect costs associated with cost savings were observed [22,68]. It is worth mentioning that these results should be interpreted with caution and need to be confirmed by further powered studies in different contexts.

The robustness of the results of the base-case analysis was verified through different sensitivity analyses. Scenario analyses over the 3-, 6-, and 12-month follow-ups all suggested higher likelihoods of ICBT being cost-effective, aligning with previous studies and confirming the long-term cost-effectiveness of ICBT [22-25,29]. It is important to note that adjustment for differences in baseline costs and QALYs leads to slightly different results compared to those obtained without baseline correction. At lower levels of WTP, ICBT showed an even chance of being cost-effective in both baseline-adjusted and nonadjusted analyses. However, with the increase in WTP, the opposite conclusion was drawn in the choice between the 2 treatments in terms of cost utility. One plausible explanation is that the effect of the intervention on utility was mild and the differences between the intervention and control group in costs and QALYs were relatively minor [28]. It was assumed that the baseline utility and costs were strongly correlated with the subsequent estimates, potentially leading to different outcomes when not adjusting for baseline variables [24]. It was argued that, in the economic evaluation, controlling for baseline utility and costs should be necessary [60].

Despite the positive outcomes of the economic evaluation, the results suggest that there was no statistically significant difference in HRQoL (subsequent QALYs) and cost estimates between the 2 groups at most time points, which is consistent with the findings of previous economic evaluations [23-25,29,69]. It has been reported that the between-group (ICBT vs control) effect size of HRQoL is small and a longer duration is required to capture meaningful observations [17-19,70]. In this study, the sample size was calculated based on detecting the medium effect size on depressive symptoms between the 2 groups, and thus, the statistical power might not be sufficient to detect statistical differences in HRQoL. Moreover, a systematic review aimed at addressing the effectiveness of ICBT on HRQoL also found that adults with more severe depressive symptoms were more likely to achieve greater HRQoL improvements and therapeutic guidance could further enhance the effect on HRQoL [71]. Hence, this lack of statistically significant differences in HRQoL and cost estimates between the 2 groups might be partly explained by the mild symptoms (mean PHQ-9 score 13.9, SD 5.2) experienced by the participants and the unguided ICBT intervention in this study. Another possible explanation was that the measurement tool for HRQoL lacked sensitivity to minor changes in this patient group [28,72]. Regarding costs, an economic evaluation of unguided ICBT conducted among 1013 participants with mild to moderate depression severity suggested that the total costs at 6 months after enrollment did not significantly differ between the intervention and control groups [69]. Given the high variability of costs [73], research with larger sample sizes and longer time frames may be needed to detect statistically significant differences.

There were several strengths to this study. First, this economic evaluation was carried out and reported following international economic evaluation guidelines. Moreover, the outcome data were collected alongside a pragmatic RCT. Therefore, the validity and reliability of the data were guaranteed. Second, in the recording of direct medical costs, the hospital information system was used to collect data at an individual level. Hence, recall bias was reduced to some extent compared with self-reported data. In addition, the self-developed ICBT courses were embedded in the WeChat mini program, one of the most popular platforms among the Chinese population, which led to a high retention rate. Under the support of nonspecialists, the retention rate in the waitlist control group was also maintained at a high level. Thus, the changes in clinical effectiveness and quality of life might reflect the real effect of the intervention. Fourth, the implementation of our intervention was executed by nonprofessional personnel, such as primary health care workers, which was in line with practical operations in routine care, indicating that the results had good features of scalability in the current medical environment.

Limitations

Nonetheless, this study has some limitations. The primary limitation was the short-term follow-up period in the control

XSL•FO
RenderX

group due to ethical considerations. Consequently, given the time-dependent nature of QALYs, the potential lag effect of ICBT, and the results reported in previous studies, rigorous statistical extrapolations on costs and QALYs were made for the control group with the assumption that the trends in costs and QALYs were the same in the intervention and control arms. Scenario analysis was conducted based on predicated data, suggesting that the long-term cost-effectiveness results should be interpreted with caution. It is likely that ICBT is more cost-effective in a longer follow-up period. Further studies under longer time frames extending the follow-up periods or adopting strong modeling assumptions would be useful. Second, although the sample size in this RCT had sufficient statistical power to detect clinically significant improvements in depression, it did not necessarily have the statistical power to detect differences in cost and utility due to the high variability of costs and the small effect of ICBT on HRQoL. Replications with large sample sizes are needed to explore differences in costs and cost utility. In addition, identifying individuals who benefit from the ICBT course and those who are at risk of not responding and adopting tailored interventions is likely to be an important way to improve the cost-effectiveness of ICBT. However, these results need to be confirmed by more research in different subsamples. Third, as direct nonmedical cost data were unavailable, only direct medical and indirect costs were included in this analysis. The aforementioned limitation might potentially underestimate the overall total economic burden and affect the conclusions. In future studies of economic evaluations on ICBT, a comprehensive assessment of the economic burden of participants will be of significance. Fourth, in this study, female participants accounted for 75% (183/244) of the total participants, and most participants (199/242, 82.2%) were well educated, which affects the extrapolation at the population level. Future interested researchers may need to take account of the representativeness of the samples. Fifth, this study only included participants who had access to digital devices and, thus, might have excluded socioeconomically marginal populations and could raise ethical issues [74,75]. It is not clear whether addressing digital divides and ensuring equitable access (eg, providing loaner electronic devices and internet connection) would influence the extant results. This remains open for further exploration. Sixth, despite the existing evidence on effectiveness and cost-effectiveness, the use of personal data, including data privacy and participant autonomy, should be considered before the massive scale-up of ICBT [76,77].

Conclusions

In comparison with the waitlist control, unguided ICBT is more cost-effective for MDD from both the health care system and societal perspectives in China. This intervention not only helps patients with MDD improve clinically but also generates societal savings. These findings suggest that unguided ICBT has broad application prospects in low-resource countries such as China and can serve to allow scalable resource access to MDD care for low- and middle-income countries.

Acknowledgments

The authors thank all the participants of the study. The Depression Cohort in China is conducted by Sun Yat-sen University and the Shenzhen Nanshan Center for Chronic Disease Control in Shenzhen, China. This work was supported by the National Natural Science Foundation of China (81761128030). No generative artificial intelligence was used in this manuscript.

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

All authors conceptualized and designed the trial. WZ, YC, Y Liu, Y Liao, H Zhang, CG, and JH conducted the trial and follow-up. WZ, HW, H Zhao, Y Li, GS, and WW collected and prepared the data. WZ and YC analyzed and interpreted the patient data and were major contributors to writing the manuscript. WW, GHL, and RSM polished and revised the manuscript. XH and LC offered administrative, technical, and material support for the implementation of the trial. XH and CL provided supervision for the entire trial. CL obtained the funding for the trial. All authors read and approved the final manuscript.

Conflicts of Interest

RSM has received research grant support from the Canadian Institutes of Health Research, the Global Alliance for Chronic Diseases, the National Natural Science Foundation of China, and the Milken Institute and speaker and consultation fees from Lundbeck, Janssen, Alkermes, Neumora Therapeutics, Boehringer Ingelheim, Sage Therapeutics, Biogen, Mitsubishi Tanabe Pharma Corporation, Purdue Pharma, Pfizer, Otsuka, Takeda, Neurocrine Biosciences, NeuraWell, Sunovion, Bausch Health, Axsome Therapeutics, Novo Nordisk, Kris Pharma, Sanofi, Eisai, Intra-Cellular Therapies, NewBridge Pharmaceuticals, Viatris, AbbVie, and Atai Life Sciences. RSM is the chief executive officer of Braxia Scientific. All other authors declare no other conflicts of interest.

Abstract

Background: Patients and families who have experienced delirium may seek information about delirium online, but the quality and reliability of online delirium-related websites are unknown.

Objective: This study aimed to identify and evaluate online delirium-related websites that could be used for patient and family education.

Methods: We searched Microsoft Bing, Google, and Yahoo using the keywords “delirium” and the misspelled “delerium” to identify delirium-related websites created to inform patients, families, and members of the public about delirium. The quality of identified delirium-related website content was evaluated by 2 authors using the validated DISCERN tool and the *JAMA* (*Journal of the American Medical Association*) benchmark criteria. Readability was assessed with the Simple Measure of Gobbledygook, the Flesch Reading Ease score, and the Flesch Kincaid grade level. Each piece of website content was assessed for its delirium-related information using a checklist of items co-designed by a working group, which included patients, families, researchers, and clinicians.

Results: We identified 106 websites targeted toward patients and families, with most hospital-affiliated (21/106, 20%) from commercial websites (20/106, 19%), government-affiliated organizations (19/106, 18%), or from a foundation or advocacy group (16/106, 15%). The median time since the last content update was 3 (IQR 2-5) years. Most websites’ content (101/106, 95%) was written at a reading level higher than the recommended grade 6 level. The median DISCERN total score was 42 (IQR 33-50), with scores ranging from 20 (very poor quality) to 78 (excellent quality). The median delirium-related content score was 8 (IQR 6-9), with scores ranging from 1 to 12. Many websites lacked information on the short- and long-term outcomes of delirium as well as how common it is. The median *JAMA* benchmark score was 1 (IQR 1-3), indicating the quality of the websites’ content had poor transparency.

Conclusions: We identified high-quality websites that could be used to educate patients, families, or the public about delirium. While most delirium-related website content generally meets quality standards based on DISCERN and JAMA benchmark criteria, high scores do not always ensure patient and family-friendliness. Many of the top-rated delirium content were text-heavy and complex in layout, which could be overwhelming for users seeking clear, concise information. Future efforts should prioritize the development of websites with patients and families, considering usability, accessibility, and cultural relevance to ensure they are truly effective for delirium education.

Introduction

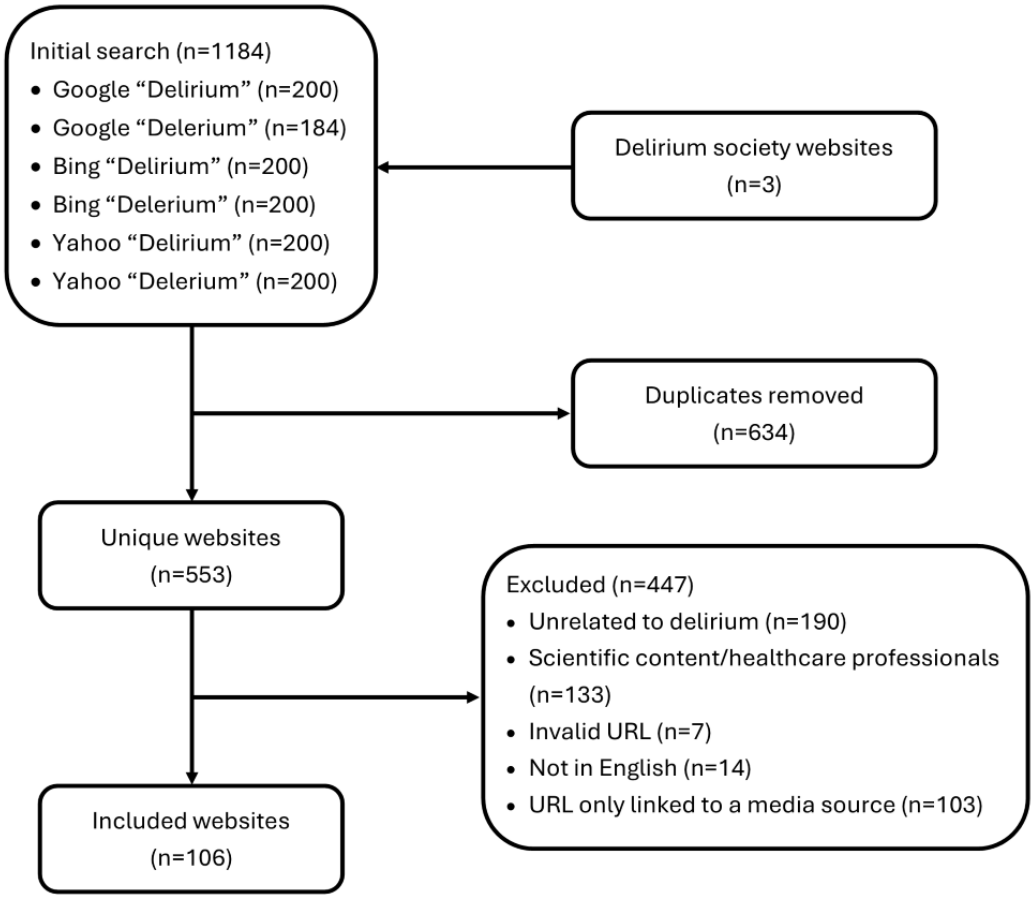
Delirium is a common, potentially preventable medical condition characterized by an acute onset of inattention, altered level of consciousness, or disorganized thinking. Delirium is the most common hospital-acquired complication [1-3], with greater prevalence in older adults (≥70 years of age) [1] and critically ill adults and children [2,4-7]. Emerging literature consistently highlights the negative impacts of delirium on patients (eg, increased risk of morbidity and mortality) [5,8,9] and families (eg, symptoms of distress, helplessness, and anxiety) [10-16]. Despite its prevalence and negative outcomes, delirium remains poorly recognized and is often missed by health care providers [17-19].

Families at the bedside may be important partners in delirium prevention, detection, and management. They are well-positioned to notice subtle changes in their loved one's cognition and behavior from their prehospitalized levels and help to identify symptoms of delirium [20-23]. However, there are challenges to building effective partnerships between families and the health care team. First, families require delirium knowledge to participate in delirium care [24,25]. The literature indicates that not all health care providers engage in this aspect of patient care [26,27]. Time constraints and lack of access to sufficient educational materials limit the ability of health care providers to deliver health education on delirium [28]. Even when health care providers discuss delirium with patients and their families, the qualitative literature suggests gaps in understanding and unmet delirium information needs [29-31], which may prompt patients or families to independently seek out their own sources of delirium information.

A recent study found that families of patients admitted to an intensive care unit (ICU) had a self-reported low level of delirium knowledge and learned about delirium by searching the term online [32]. A separate study indicated families preferred obtaining delirium-related information through internet sources [24]. As families self-report accessing delirium information online, high-quality online delirium information may be one way to improve patient, family, and the public's understanding of delirium, which can, in turn, empower them to participate in delirium prevention, detection, and management [33].

Over 10 million Americans access the internet for health information per day [34]. Recent studies report that health-related information on websites is often inaccurate, biased, misleading, or outdated [35-41]. Information about delirium is widely available on the internet, but, as with other health information on the internet, the information may be low-quality and inconsistent across sources. It is unknown if the websites of patients, families, and the public access to delirium information contain reliable, accurate, and up-to-date information.

The increasing availability of websites related to delirium is likely reflective of the creation of delirium societies or associations (American Delirium Society, European Delirium Association, and Australasian Delirium Association), World Delirium Awareness Day (established in 2017), and an increase in the implementation of regular delirium screening in hospitals [42,43]. The purpose of our study was to evaluate delirium website content based on readability, quality, and key content areas to identify high-quality delirium-related website content that could be used for patient, family, and public delirium education.



Methods

Website Search

We searched the top 3 most used search engines: Microsoft Bing [44], Google [45], and Yahoo [46-48] using the keywords "delirium" and misspelled "delerium" [49] to ensure comprehensive coverage of websites addressing the topic. "Delirium" is the primary and widely recognized term in both clinical and public domains, allowing us to retrieve the most relevant content. Including the misspelling "delerium" accounted for potential variations in user input, helping to capture additional website content that might not be optimized for the correct spelling. We disabled location identifiers, conducted the searches using a newly launched incognito or private window, and cleared cookies before each search to ensure search results were not influenced by precise geographic location or search history. We collected the top 200 search results from each search engine to capture the most relevant and widely accessed websites while maintaining consistency across engines. Search engines, such as Microsoft Bing, Google, and Yahoo, use sophisticated algorithms to rank search results based on factors such as relevance to keywords searched, content quality, and user engagement. In this study, while acknowledging that search results are typically personalized and may vary for each user based on factors such as location, search history, and preferences, for the purposes of analysis, we assumed that all users received the same search results. After removing duplicates, we excluded websites if they met any of the following exclusion criteria: (1) does not provide information on delirium, (2) written in a language other than English, (3) retrieved URL linked to a media source, (eg, YouTube channel or podcast), (4) retrieved URL targeted researchers or health care providers (eg, research articles), or (5) retrieved URL linked to a website that produced an error message, or content not available without a subscription. Despite disabling location identifiers, it is possible that search engine algorithms used IP addresses or language settings and identified the delirium association that is most closely associated with our location (ie, the American Delirium Society). As such, we also evaluated the website of the delirium association (European Delirium Association), which was not identified by the search (Figure 1).

XSL•FO
RenderX

Figure 1. Flowchart illustrating the process of selecting websites for quality analysis.

Website Quality

A team of patients, families, researchers, and health care providers (herein referred to as reviewers) evaluated delirium website content. The quality of website content was determined using the validated DISCERN tool (Multimedia Appendix 1) and the *JAMA* (*Journal of the American Medical Association*) benchmark criteria (Multimedia Appendix 2). DISCERN is a standardized set of criteria developed to evaluate the transparency, quality, and reliability of health information written for the public [50,51]. The DISCERN instrument has 16 questions. Each question can be scored from 1 (definite no) to 5 (definite yes). The total score can range from 16-80, wherein scores can be interpreted as excellent (63-75 points), good (51-62 points), fair (39-50 points), poor (27-38 points), and very poor (16-26 points) quality [52]. Two reviewers independently and in duplicate evaluated each website using the DISCERN instrument. DISCERN scores that differed by 5 points or more between the two reviewers were scored again by a third reviewer. The mean of all reviewers was taken as the final DISCERN score for each website. JAMA benchmark criteria include 4 standards of credible information sources: authorship (affiliations and credentials), attribution (references, sources, and copyright), disclosure (conflicts of interests), and currency (when content is posted and updated) [53]. Scores range from 0 to 4, with a score of 4 indicating the website is a credible source. Two reviewers independently and in duplicate assigned scores for each item in the JAMA benchmark criteria to indicate if it was present (score=1) or absent (score=0). Disagreements in scoring were resolved through discussion or the inclusion of a third reviewer.

Delirium-Related Content

There are no published guidelines for evaluating delirium education materials. To evaluate the quality of content from each website, a working group of patient partners (past ICU patients and families who are members of our research team), delirium researchers, and clinicians identified seven key points that patients, families, and the public would want to know about delirium: (1) the definition of delirium (must align with definition from the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* Fifth Edition]) [54], the American Delirium Society, European Delirium Association, or Australasian Delirium Association [55-57]; Multimedia Appendix 3); (2) delirium risk factors [5]; (3) short and long-term outcomes of delirium [5]; (4) signs and symptoms of delirium [5,58]; (5) information to differentiate between delirium and dementia [59]; (6) delirium prevalence; and (7) strategies to prevent and manage delirium [13,15]. The DISCERN criteria evaluate treatment choices, so only items 1-6 (of 7) were evaluated. Two reviewers evaluated the websites independently and in duplicate to determine if the site provided complete and accurate information in these 6 areas (Multimedia Appendix 3**).** Each item was scored to be present (score=2), somewhat present (ie, incorrect or incomplete information, score=1), or absent (score=0). Scores could range from 0 to 12, with a higher score indicating the website had more sufficient delirium content.

XSL•FO
RenderX

Disagreements in scoring were resolved through discussion or the inclusion of a third reviewer.

Readability

The level of difficulty of the reading material of each website was scored using the Simple Measure of Gobbledygook (SMOG) formula [60], the Flesch Reading Ease score [61], and the Flesch Kincaid grade level [62]. These scores are credible tools that are widely used to evaluate readability [63]. The included websites were evaluated if they were written at the American Medical Association and National Institutes of Health recommendation of a grade 6 reading level [64,65].

Data Extraction and Analyses

A standardized data extraction template was created and piloted to ensure reviewers understood how to evaluate the quality, content, and readability of each website. The template included detailed column headers to ensure each website was scored the same way (eg, guidelines for rating each DISCERN question). We also collected the following variables for each website: URL or website address, date the website was created, country, free text description of the website, website creators, and patient population or clinical setting targeted. We mapped the included websites onto the patient engagement framework that described patient engagement as inform (provision of education), activate (prompts action), or collaborate (encouraging interaction with health care providers) [3]. To ensure consistency in evaluations, all reviewers underwent comprehensive training. All reviewers read the DISCERN handbook and the study protocol, which described how to evaluate the quality, content, and readability of each website. All reviewers met to go through the evaluation criteria and to evaluate one website together. We then conducted a calibration exercise wherein all reviewers independently evaluated the same 5 randomly selected websites. We met to discuss discrepancies and reached a consensus on the overall quality of the 5 websites. The remaining websites were evaluated independently and in duplicate. Quality checks were conducted at regular intervals to verify that the criteria were being interpreted and applied consistently. Reviewers met regularly to discuss progress and address any uncertainties or discrepancies identified by the quality checks.

Website scores were summarized descriptively using counts and percentages, mean (SD), or median (IQR). The Kruskal-Wallis test was used to evaluate website scores between website categories (eg, foundation or advocacy group, government, hospital, and academic institution). Statistical analyses were performed in Stata/MP (version 14.2; StataCorp LLC). A *P* value of <.05 was considered significant. We compiled the top 10 websites based on the highest weighted combined quality score. Each score-delirium-related content, readability, DISCERN, and *JAMA* benchmark was normalized using observed (readability only) or possible score ranges. Readability was reverse-scaled because a lower score is better. We weighted readability, delirium-related content, and DISCERN at 30% each, and *JAMA* benchmark criteria (website content transparency) at 10%. These weightings, determined by the working group, were used to calculate a final weighted score, where a higher score indicated higher quality.

Ethical Considerations

As the study did not involve human participants or human biological materials, the study was deemed exempt from the ethics board approval process. This study relied on publicly available data and therefore, ethics approval was not needed for this study as per the University of Calgary Conjoint Health Research Ethics Board guidelines [66].

Results

Website Search

On November 21, 2024, we searched Bing, Google, and Yahoo and removed duplicates and URLs that did not meet inclusion criteria; we identified 106 websites targeted toward patients, families, and the public. This included private or public hospitals (eg, Mayo Clinic: 21/106, 20%), commercial websites (eg, Merck: 20/106, 19%), and websites affiliated with a foundation or advocacy group (eg, American Delirium Society: 16/106, 15%). A description of each website is in Multimedia Appendix 4. Over half of the included URLs (62/106, 58%) used all 3 engagement strategies: inform (eg, delirium information), activate (eg, how to prevent or manage delirium), and collaborate (eg, when or how to talk with a health care provider about delirium). A total of 17 websites (16%) used inform strategies only, and 22 websites (21%) used both inform and activate engagement strategies. Of the 82 (77%) websites that reported a date when the website was posted or updated, the median time since the last update was 3 (IQR 2-5) years.

Website Content Quality

The median DISCERN score was 42 (IQR 33-50), representing fair quality. The quality ranged from 20 (very poor quality) to 78 (excellent quality). Many websites did not include a list of the sources used to compile the information on the website, refer to areas of uncertainty (eg, delirium may be missed or difficult to identify, no guideline-recommended pharmacological treatments for delirium), nor describe risks of each treatment (eg, antipsychotics if used for severe agitation). Several websites shared information that was not backed by a current evidence synthesis [5] or available guidelines [13,15]. This included claims that antipsychotics were the first line of treatment for delirium without discussion of their risk of prolonging or exacerbating delirium symptoms. Many websites mention antipsychotics as a means to manage the symptoms of delirium, such as agitation, which is a safety concern (supported by recent guidelines) [13,15]. DISCERN scores were significantly different between website categories (ie, academic, commercial, foundation or advocacy group, etc).

The median JAMA score was 1 (IQR 1-3), with 17/106 websites (16%) scoring 0, which indicates most websites lacked transparency. In particular, most websites did not list authors or contributors, their affiliations, and relevant credentials (67/106, 63%) nor included references and sources for all content (65/106, 61%). JAMA scores were not significantly different between website categories (ie, academic, commercial, foundation or advocacy group, etc). The median scores for delirium website transparency can be seen in Table 1.

XSL•FO
RenderX

Table 1. Comparison of the median DISCERN, Journal of the American Medical Association (JAMA) benchmark score, and weighted quality scores across website categories.

Website category	Websites, n (%)	DISCERN score (range 16-80), median (IQR)	JAMA benchmark score (range 0-4), median (IQR)	Weighted quality score (range 0-100), median (IQR)
Hospital affiliated	21 (19.8)	37.5 (32-44.5)	1 (0.8-3)	55.9 (52.4-59.4)
Commercial	20 (18.9)	44.5 (34.5-52.3)	3 (2-4)	57.4 (49.4-66.6)
Government	19 (17.9)	42 (32.5-51.5)	1 (1-2)	54.5 (47-64.3)
Foundation or advocacy organization	16 (15)	46.5(42.5-50.3)	1 (0-1.3)	58.4 (55.7-65.7)
Regional health authority	14 (13.2)	32.5 (27.3-40.5)	1 (1-1.8)	49.4 (46.1-56.2)
Academic	6 (5.7)	52.5 (50-57.3)	1.5 (1-2)	64.4 (60.2-70.2)
General reference or educational resource	6 (5.7)	40.5 (32.8-55)	2.5 (2-3)	54.3 (52.5-63.5)
Professional organization	4 (3.8)	34.0 (33-38)	1.5 (1-2)	50.1 (41.3-57.4)

Delirium-Related Content

The median score for delirium-related content was 8 (IQR 6-9). Nearly half of the websites included a complete definition of delirium (77/106, 73%). Website evaluators rated several websites (26/106, 25%) to have a somewhat correct definition of delirium (eg, missing items from the *DSM-5* or delirium society definitions of delirium). A majority of the websites (77/106, 73%) included predisposing (eg, age and dementia) and precipitating delirium risk factors (eg, surgery and dehydration) that are consistent with available evidence [5]. Websites that reported somewhat correct delirium risk factors (23/106, 22%) reported incomplete or inaccurate risk factors. These websites either focused solely on predisposing or precipitating factors, overlooked key groups like infants and young children, or included risk factors not widely associated with delirium in the literature (eg, male sex). Most websites (83/106, 78%) included the signs and symptoms of delirium. Those websites that somewhat described the signs and symptoms of delirium (19/106, 18%) often missed a hallmark of delirium (eg, inattention, acute onset, fluctuating course, or disorganized thinking). Many websites did not include short and long-term outcomes associated with delirium (54/106, 51%). This included not describing delirium as a risk factor for dementia or the association between delirium and risk for long-term cognitive decline. Many websites did not describe the prevalence of delirium (41/106, 39%) or vaguely described its prevalence (eg, “common;” 31/106, 29%). Half of the websites stated that there was a difference between dementia and delirium (54/106, 51%). Out of these 54 websites, 43 (80%) described in detail how dementia and delirium differed. Table 2 shows the mean scores for delirium content.

Table 2. Comparison of the mean delirium content scores across website categories.

Website category	Website, n (%)	Delirium content[a]					
		Delirium definition, mean (SD)	Risk factors and causes, mean (SD)	Short- and long-term outcomes, mean (SD)	Signs and symptoms, mean (SD)	Differences between delirium and dementia, mean (SD)	Delirium prevalence, mean (SD)
Hospital affiliated	21 (19.8)	1.6 (0.6)	1.5 (0.6)	0.7 (0.7)	1.6 (0.5)	0.6 (0.9)	0.9 (0.8)
Commercial	20 (18.9)	1.6 (0.5)	1.9 (0.4)	0.7 (0.9)	1.9 (0.5)	1.2 (0.9)	1 (0.9)
Government	19 (17.9)	1.9 (0.4)	1.9 (0.3)	0.5 (0.7)	1.9 (0.2)	0.9 (1.0)	0.8 (0.9)
Foundation or advocacy organization	16 (15)	1.8 (0.4)	1.7 (0.5)	0.9 (0.9)	1.9 (0.2)	1.3 (0.8)	0.8 (0.7)
Regional health authority	14 (13.2)	1.9 (0.3)	1.4 (0.8)	0.7 (0.8)	1.6 (0.6)	0.8 (0.9)	0.8 (0.9)
Academic	6 (5.7)	2 (0)	1.5 (0.5)	1.2 (0.7)	2 (0)	1.2 (0.9)	1.7 (0.5)
General reference or educational resource	6 (5.7)	1.3 (0.7)	1.7 (0.7)	1.3 (0.9)	1.3 (0.7)	0.7 (0.9)	1.3 (0.7)
Professional organization	4 (3.8)	1.3 (0.4)	1.5 (0.9)	0.3 (0.4)	1.3 (0.8)	0.5 (0.9)	1 (0.7)

[a]For all criteria, the minimum possible score=0, maximum=2.

Readability

The median SMOG readability score was a grade 15 (IQR 13-17, range 10-22) level. The median Flesch Kincaid Reading Level score was a grade 10 (IQR 9-12, range 5-21) level. The median Flesch Reading Ease score was 47 (IQR 38-56; range 0-80.7), indicating the websites are difficult to read for most of the

XSL•FO
RenderX

population. Of the 106 websites, 5 (5%) were written at a reading level equal to or lower than grade 6.

Top 10 Websites for Patient, Family, and Public Information on Delirium

The median for the weighted quality score for websites was 56.1 (IQR 49.3-65.5, range 28.8-84.1). Based on the normalized and weighted evaluation criteria, the top 10 websites for delirium for patient and family education are summarized in Table 3. The Mayo Clinic website, which appeared as the top result for Google and Yahoo "delirium" searches, ranked 15th overall based on weighted scores for quality, content, and readability, with an overall weighted score similar to the top 10 websites (69.8). In contrast, one of the websites listed among the top 10 search results ranked 83rd overall due to incomplete and low-quality information such as inaccurate claims (eg, counseling as a method to address disorientation, male sex as a risk factor, and a section on "confusion."). The Wikipedia entry on delirium was in the first 10 results of Microsoft Bing (3rd), Google (5th), and Yahoo (4th). However, it had an overall weighted score of 54.8 due to its poor readability. Weighted quality scores were not significantly different between website categories (ie, academic, commercial, foundation or advocacy group, etc).

Table 3. The top 10 websites ranked by weighted, combined quality, delirium content, and readability scores.

Website[a]	Position in the Bing, Google, and Yahoo search			DISCERN score (range 16-80)	Flesh Kincaid Grade Level	Delirium content score (range 0-12)	Composite weighted score (rank)

Discussion

Principal Findings

Delirium websites are one source of delirium education to prepare families to partner with delirium prevention, detection, and management. This study reports on the quality, content, and readability of websites with delirium information for patients, families, and the public. Overall, our findings suggest the quality of delirium-related website content is fair, with many websites lacking credibility and transparency. The American Medical Association and National Institutes of Health recommend that patient education materials be written at a grade 6 reading level [64,65], but nearly all websites (100/106, 95%) were written at higher than a grade 6 reading level. Furthermore, websites that families may encounter when looking for information about delirium may include incomplete information about delirium, overlook key groups such as infants or young children, or provide outdated or inaccurate information. This study identified the 10 best websites that patients, families, and clinicians can refer to, to find information about delirium.

It is crucial that high-quality and easily understandable websites on delirium are available to patients, families, and the public for several reasons. First, delirium is a common and serious medical condition that can be confusing and frightening for patients and families [4,10-13,77,78]. This may prompt families to search for delirium on the internet. Clear and concise information will help families to better understand delirium, its causes, signs, and prevention or management options. Second, countries and organizations promote engaging families with patient care [16,23,79]. To be active participants in delirium care, families must be provided with delirium education. Accessible health information can empower patients and families to participate in delirium prevention, detection, and management [20,80] and seek medical attention when necessary. Like any family engagement intervention, not all families may want to participate in delirium care, and they have reported that one of their preferential ways to receive information is through the internet. As such, websites should offer information that informs (providing information on delirium), activates (encouraging families to prevent and manage delirium), and collaborates (preparing families to discuss delirium with health care teams) with families to cater to a broad audience with varying information needs.

To improve the quality of delirium websites, it is essential to identify common deficiencies among them. A majority of the included websites did not provide proper citations for the information used in the website content. Including sources on websites benefits readers by fostering credibility, transparency,

XSL•FO
RenderX

and accountability of the website information and enables readers to access additional delirium resources. Most websites (100/106, 95%) were written above the recommended grade 6 level. It is important that health information is presented in a manner that is accessible to its target so that the information is not misinterpreted and to enable the reader to make informed decisions about their health. Other studies evaluating the quality of health information on websites also report that health information is not written at an appropriate reading level [81-85]. While website creators can modify their content to meet the grade 6 recommendation, the best practice would be to codevelop websites with patients, families, and the public. Websites should also include the following delirium-related content: (1) the definition of delirium (from the *DSM-5* [54] or from delirium societies or associations) [55-57], (2) delirium risk factors [5], (3) short and long-term outcomes of delirium [5], (4) signs and symptoms of delirium [54,58], (5) information to differentiate between delirium and dementia [59], (6) delirium prevalence [1,2,4-7], and (7) strategies to prevent and manage delirium [13,15]. With more people using the internet to access health information, it is imperative that website developers follow the above guidance to ensure websites include the highest quality and readable delirium information for patients, families, and the public.

This study has several implications for practice. First, there is a need for families to be integrated as partners in delirium care [86]. An important first step is to provide families with delirium information to prepare them to participate in delirium prevention, detection, and management. However, staff often lack the time to provide comprehensive delirium education to families due to heavy workloads and clinical responsibilities. Health care providers can leverage this curated list of websites to supplement delirium information provided to patients and families. By directing families to these websites, they can ensure families are consulting the highest quality and most reliable delirium information currently available on the internet. Second, it is clear that higher-quality delirium websites with plain language are needed. This can be accomplished by hospital organizations or delirium societies creating their own delirium education materials. Hospitals can leverage the set of criteria (ie, DISCERN, JAMA benchmark, readability measures, and delirium content) when adapting or creating delirium-related materials on their websites. Furthermore, there remains a need for policymakers to prioritize the importance of digital health literacy. This might include initiatives to enhance how people navigate health information on websites. This might also include advocating for high-quality educational resources.

Strengths and Limitations

There are several strengths and limitations that should be considered in this study. To our knowledge, this is the first study to identify and evaluate websites on delirium that could be used for patient and family education. Delirium websites were identified using the top 3 most used search engines (Bing, Google, and Yahoo). Finally, all study activities included patient and family partners. Despite these strengths, there are several limitations that should be considered. First, the search strategy consisted of only 2 search terms: delirium and the most commonly misspelled form of delirium (delerium). It is possible that patients, families, and the public may use other terms to search for delirium information, and, as such, some websites may have been missed. Second, the search was performed in Canada. Despite disabling location services, which limited the extent to which the search engines can use our location, other aspects of our location may have been inferred based on our IP address or language settings. For this reason, and that our team was proficient in English, we only included websites written in English. As such, the results of this study may not be generalizable to people who do not speak English. To attain a more comprehensive understanding of delirium-related websites in languages other than English, further research is warranted. This should include other prominent search engines with significant market shares (eg, Yandex, Baidu, Petal Search, and DuckDuckGo) and collaborative efforts with researchers from diverse linguistic backgrounds and countries. Third, the analysis of the websites was limited to what was reported, which may not have comprehensively captured the development of the website. This may include if websites used credible sources or delirium experts to compile the websites but did not cite the sources or identify the delirium experts. Finally, the tool that was used to evaluate delirium content has not been externally validated, as it was developed specifically for this study. Finally, while DISCERN, JAMA benchmark, delirium content, and readability tools are robust for assessing quality and transparency, they focus on structural elements rather than usability or accessibility for patients and families. Websites with high scores often had dense information or busy layouts that may overwhelm patients or families seeking concise and accessible information. These metrics do not account for patient or family experience, engagement, or cultural relevance, which are critical for effective patient and family education.

Conclusion

This study suggests delirium websites for the public are of fair quality. Inadequacies in evaluated websites, such as lack of transparency, incomplete delirium information, and poor readability, should be addressed when updating current or creating new delirium websites aimed at patients, families, or the public. Following the outlined standards for quality, delirium content, and readability will ensure high-quality, transparent, and accessible delirium information for patients, families, and the public.

Acknowledgments

The authors would like to thank Kira Makuk and Thérèse Poulin for their help with conducting the Bing, Yahoo, and Google searches and piloting the delirium website evaluation. This work is funded by the Canadian Institutes of Health Research Transitions in Care Team Grant (grant 423947). The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the manuscript.

Abstract

Background: The phenomenon of procrastination refers to an individual's conscious decision to postpone the completion of tasks despite being aware of its adverse consequences in the future. Extant research in this field shows that procrastination is associated with increased levels of anxiety and stress and the likelihood of developing depression and calls for the development of suitable interventions that support individuals in making lasting positive changes to their procrastination behaviors. In parallel, practice has produced a plethora of behavior change support systems (BCSSs) that aim to provide a low-threshold, accessible alternative to in-person therapeutic approaches. Most of these BCSSs can be considered motivational BCSSs that combine functional, utilitarian components with hedonic and eudaimonic design elements to empower self-treatment. Although early studies have suggested the potential benefits of such BCSSs, research on understanding their specific design characteristics and support of individuals in self-treating procrastination is still in its infancy.

Objective: In response to this gap between practice and research, we aimed to analyze and systemize the multitude of practical design efforts in motivational BCSSs for the self-treatment of procrastination and identify the main design archetypes that have emerged.

Methods: We conducted a 3-step research approach. First, we identified 127 behavior change support apps for procrastination through a systematic screening process in the German and US Apple App Store and Google Play Store. Second, we systematically coded the identified apps in terms of the behavior change techniques targeted by their functional design and hedonic or eudaimonic design elements. Third, we conducted a 2-step cluster analysis to identify archetypes of motivational design in behavior change support apps to combat procrastination.

Results: A variety of motivational designs have been developed and implemented in practice, and our analysis identified five main archetypes: (1) structured progress monitor, (2) self-improvement guide, (3) productivity adventure, (4) emotional wellness coach, and (5) social focus companion. The identified archetypes target different psychological determinants of procrastination and successfully use a variety of hedonic and eudaimonic design elements that extend beyond the current state of research.

Conclusions: The results of our study provide a foundation for future research endeavors that aim to examine the comparative effects of motivational design archetypes and develop more effective interventions tailored to individual needs. For practitioners, the findings reveal the contemporary design space of motivational BCSSs to support the self-treatment of procrastination and may serve as blueprints that can guide the design of future systems. For individuals seeking support and health professionals treating procrastination, our study systemizes the landscape of apps, thereby facilitating the selection of one that best aligns with the patient's individual needs.

Introduction

Motivation

Procrastination, an irrational and malicious behavioral pattern defined as the intentional delay of important or necessary tasks despite knowing the negative consequences [1], affects nearly one-fifth of adults worldwide [2,3]. Despite the phenomenon often being described with a bit of humor, as evidenced by a popular Technology, Entertainment, Design Talk [4], it poses a serious threat to mental and physical health. Studies have demonstrated that procrastination can cause stress, depression, and anxiety [5-7], as well as raise the risk of cardiovascular diseases and hypertension [8]. Overall, those affected by procrastination experience a concerning risk of a decline in life quality [9].

Correspondingly, medical research has engaged in numerous treatment directions to help and support those affected [10,11]. Acknowledging that procrastination primarily results from a failure of self-regulation [2], which is influenced by both situational (eg, task characteristics, expected outcome, and delay) and motivational (eg, self-efficacy, self-belief, and impulsiveness) determinants [12], cognitive and behavioral interventions as well as their combination in cognitive behavioral therapy promise to be most successful [10,13-15]. However, traditional treatment of procrastination still suffers from low attendance and adherence rates compared to the amount of people affected [16]. In this regard, digitally supported treatment of procrastination using behavior change support systems (BCSSs) has gained attention as a low-threshold, accessible alternative to in-person therapeutic approaches [11,14,17].

BCSSs are systems "with psychological and behavioral outcomes designed to form, alter or reinforce attitudes, behaviors or an act of complying without using coercion or deception" [18]. They have been demonstrated to help restructure malicious behaviors that pose health threats [19], such as obesity [20-22], lack of physical activity [23,24], unhealthy nutrition [25-27], or smoking [28-30]. Through various behavior change techniques (BCTs) that target situational and motivational behavior determinants, such as goal setting and self-monitoring, context restructuring, reframing of beliefs, or the illustration of behavioral consequences [31], BCSSs can support a stepwise transition from health-threatening behaviors to novel behavior patterns and habits [32]. A recent review of primary studies in the field of BCSSs for procrastination [17] demonstrates that such BCSSs can evidently help raise awareness of distractions [33-35], reduce procrastination behaviors [34,36,37], and increase self-efficacy [37-39].

While these studies are still often tied to augmenting traditional cognitive behavioral therapy with digital applications under medical guidance, it is only in the last few years that BCSSs with motivational design approaches for the successful self-treatment of procrastination have gained traction [17]. This development can be attributed to the emerging research trend of motivational information systems (ISs) [40,41], which combine functional, utilitarian components (such as support in planning and goal setting) with hedonic (referring to a sense of pleasure [42]) and eudaimonic (referring to a sense of meaningfulness [42]) design elements. The latter aim to evoke positive experiences in using the system and performing the target behavior, such as joy, excitement, or curiosity, and satisfy motivational needs [40,41]. Initial studies show that motivational BCSSs for procrastination that combine educational content about procrastination stimuli with quiz and achievement mechanics can significantly reduce procrastination in unguided self-treatment [43]. Moreover, gameful storytelling in task planning and work on tasks can enhance feelings of self-control [44].

Research on motivational BCSSs for low-threshold and accessible self-treatment of procrastination is still nascent, but practical efforts have produced a plethora of (primarily mobile) apps that use motivational design approaches to support people in handling procrastination behaviors [44]. These include gamified task management platforms that integrate narrative design [45]; artificial companions that provide approval and help with planning and self-reflection [46]; and digital tools that use focus timers, unlockable collectibles, and team focus sessions [47], with several apps exceeding a million downloads. In this regard, there is great potential for research on motivational BCSSs for procrastination to build on and learn from these practical efforts [17] and investigate how different motivational design approaches affect the procrastination process as a basis to develop targeted recommendations for individuals seeking support in dealing with procrastination.

In this context, previous research has demonstrated that effectively designing health BCSSs requires not only experimenting with different BCTs that, in untargeted combinations, can cause counteracting mechanisms and result in highly ineffective solutions [48]. Rather, to provide an informed foundation for both researchers and designers on how to successfully approach the problem of procrastination with motivational BCSSs, it is crucial to identify and characterize commensurate combinations of BCTs and take account of their underlying theoretical mechanisms [48]. To this end, identifying the main *archetypes* of design that have emerged to target situational and motivational determinants of procrastination in practical applications is particularly valuable. Design archetypes represent a practice-oriented perspective on design knowledge that *abstracts* from single applications, which might sometimes combine BCTs randomly, to identify industry best practices. Thus, design archetypes can be regarded as complementary to conceptual, theory-driven design knowledge (eg, design principles and frameworks) in guiding developers when

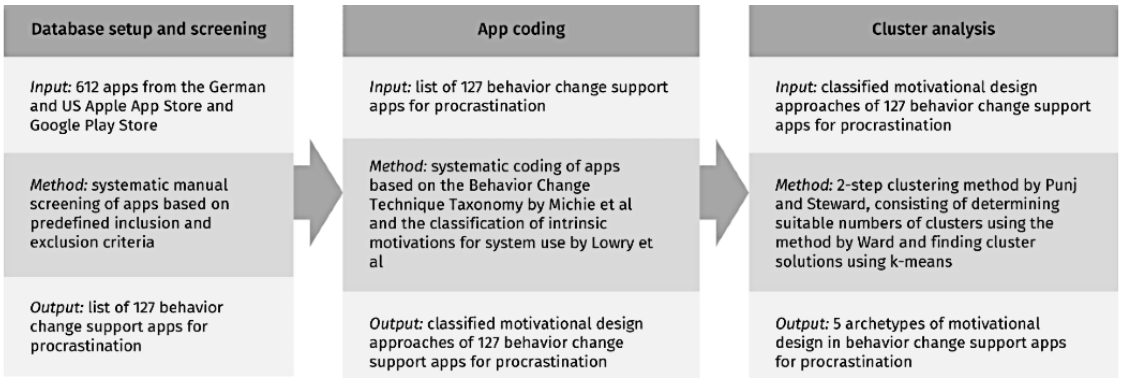
XSL•FO
RenderX

designing and implementing motivational BCSSs by offering prescriptions for effective design [49]. For researchers, knowledge about design archetypes further serves as a feedback mechanism that shows whether and, if so, how research insights have been transferred to real-world systems and where gaps between research and practice remain [50].

Objectives

This study aimed to provide this foundation for both future research in investigating motivational BCSSs to combat procrastination and further practical efforts to design and select motivational BCSSs for self-treating procrastination by answering the following research question: *what are prevalent archetypes of motivational design in behavior change support apps for procrastination?*

To answer this research question, in line with previous studies that have systematized design in (mobile) health apps [50-52], we adopted a systematic screening and coding approach that built on the recognized Behavior Change Technique Taxonomy (BCTT) by Michie et al [53] and the intrinsic motivations for system use classification by Lowry et al [54] to form the basis for a 2-step cluster analysis according to Punj and Stewart [55]. Thereby, we identified clusters of motivational design approaches in prevailing motivational BCSSs for procrastination and then discussed the archetypes of motivational design characteristics for each identified cluster.



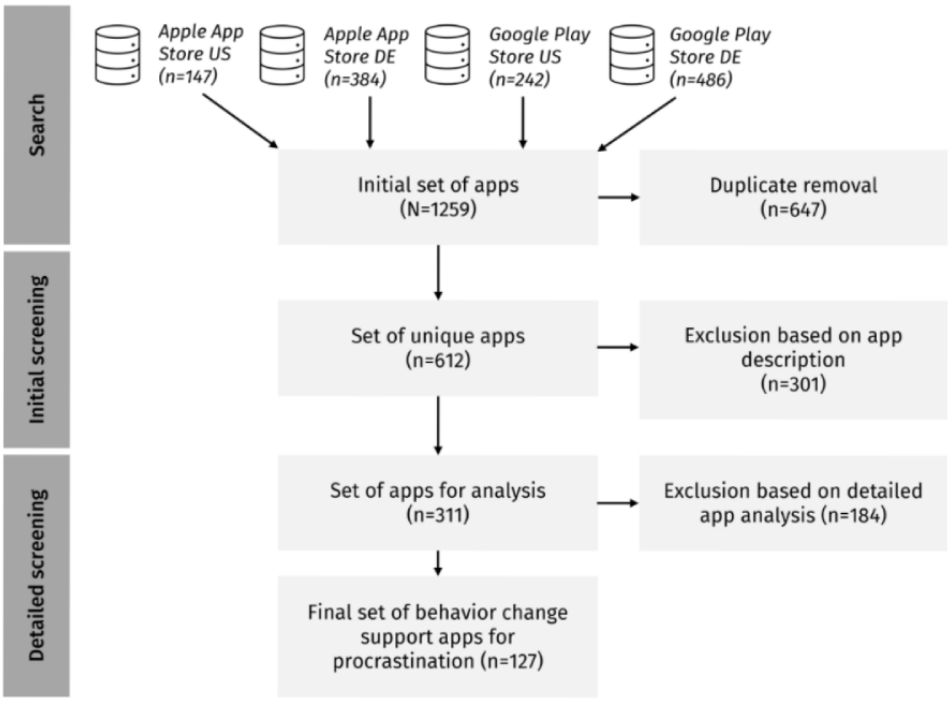
Consequently, our study systematically classified motivational design approaches in BCSSs to combat procrastination, providing 3 main contributions to research and practice. First, it constitutes the basis for future research efforts to investigate the comparative effects of motivational design archetypes on various situational and motivational determinants of procrastination, possibly paving the way for more targeted and individualized self-treatment recommendations through motivational BCSSs depending on the individual problem profile [1,56,57]. Second, it represents blueprints of design opportunities for developers of BCSSs to support the self-treatment of procrastination using motivational design approaches that increase system use and counteract dropout rates, a problem known from health-related digital applications [58]. Finally, it systemizes the plethora of available apps for both health professionals and individuals seeking support in handling procrastination as a basis to decide on a design archetype that best suits the patient's or individual's needs and preferences, thereby potentially increasing treatment adherence and counteracting the severe mental and physical health consequences of ongoing procrastination.

Methods

Overview

To answer our research question, we followed a systematic screening and coding approach of existing mobile apps, complemented by a 2-step cluster analysis [55] informed by previous work that has conducted archetype analyses of health-related apps and platforms [50-52]. Accordingly, our research method consisted of 3 main steps: database setup and screening, app coding, and cluster analysis (Figure 1 [50-55]).

Figure 1. Overview of the 3 research steps, applied research methods, and outputs of the methods.



Database Setup and Screening

To set up the database of pertinent behavior change support apps to combat procrastination, we followed a systematic search strategy in the German and US Apple App Store and Google Play Store. The reason why we opted for these 2 platforms is that they represent the 2 largest app stores for iOS- and Android-based mobile phones, with the Google Play Store recording >110 billion app downloads and the Apple App Store reporting approximately 35 billion app downloads in 2023 [59]. Moreover, the United States is the most significant Western mobile app market in terms of downloads and consumer spending on mobile devices [60], and Germany represents the largest mobile app market in the European Union [61]. We searched for apps related to the terms "procrastination" or "Prokrastination" (the German equivalent) in March 2024, leading to an initial set of 1259 apps (Figure 2).

After removing duplicates, of the 1259 apps, 612 (48.61%) unique apps remained for the initial screening. Thus, we screened the descriptions of these 612 apps in the Apple App Store and Google Play Store against our predefined inclusion and exclusion criteria, listed in Textbox 1.

XSL•FO
RenderX

Figure 2. Overview of the app screening and selection process. DE: Germany; US: United States.

Textbox 1. Inclusion and exclusion criteria for the screening and selection process.

Inclusion criteria

- Topicality: maintained apps with regular updates
- Access: free apps
- Language: English or German
- Content focus: explicit focus on the problem of procrastination at work or in daily life
- App design: motivational behavior change support system with both functional and hedonic or eudaimonic design aspects according to the classification of intrinsic motivations for system use by Lowry et al [54]

Exclusion criteria

- Topicality: outdated apps flagged as not maintained anymore
- Access: paid apps and paywalls after installation
- Language: other languages
- Content focus: lack of focus on procrastination (eg, household organizers; microlearning apps; time-tracking apps for client projects; team planners; general meditation apps; general habit trackers; mood trackers; and treatment apps for other mental health issues such as attention-deficit/hyperactivity disorder, depression, or anxiety)
- App design: purely functional, utilitarian app design without hedonic design aspects

Specifically, concerning their topicality, we excluded apps flagged as not maintained by the app stores. We also excluded paid apps that were not accessible without upfront payment as we wanted to focus on apps that are readily accessible to a broad audience of people affected by procrastination without posing a payment hurdle that might inhibit their benefit compared to traditional treatment approaches. Moreover, we excluded apps that were in languages other than English or German (eg, Chinese or Russian). In terms of their content and focus, we explicitly searched for apps that targeted procrastination of individuals at work or in daily life by providing specific utilitarian functionalities or content to approach procrastination (ie, the postponement of important or necessary tasks) on a cognitive (eg, specific learning or reflection content or guidance related to procrastination) or behavioral (eg, features to engage in goal and task planning or organization or focused work) level. Conversely, we excluded apps that were not focused on this problem, such as microlearning apps and general meditation apps (with content entirely unrelated to procrastination); household organizers; time-tracking apps for client projects or team planners (focused on organizing multiple people instead of supporting individuals); mood trackers and general habit trackers (without any content or functionalities related to specific tasks); or treatment apps for other mental health problems such as attention-deficit/hyperactivity disorder, depression, or anxiety (that were not suitable for individuals without pathological

XSL•FO
RenderX

mental health issues). Moreover, as we focused on motivational BCSSs that are characterized by functional, utilitarian, and hedonic or eudaimonic design aspects [40,41], we excluded apps without any visible hedonic or eudaimonic design approaches, such as purely functional to-do lists, calendars, timers, or app blockers.

As a result of the initial screening process, of the 612 apps, 311 (50.8%) remained for the subsequent detailed analysis. In this step, we downloaded all the apps on an iPhone 15 Pro (for iOS apps) and a Google Pixel 4a (for Android apps) and analyzed their functionalities in detail against the predefined inclusion and exclusion criteria. During this step, we excluded an additional 59.2% (184/311) of the apps because they did not meet the inclusion criteria. Specifically, of the 184 apps, 34 (18.5%) were excluded because they had a paywall for use after installation (n=32, 94%) or could be accessed only via invitation (n=2, 6%); 16 (8.7%) were excluded because they were not usable (ie, they had been either removed from the app stores between screening in March 2024 and analysis in May 2024, n=6, 38%, or were buggy so that the main functionalities could not be used, n=10, 62%); 3 (1.6%) were excluded because they were only available in Turkish, French, or Chinese; 70 (38%) were excluded because they were not focused on the problem of procrastination; and 51 (27.7%) were excluded because they did not exhibit any hedonic design approaches. To decide whether an app entailed hedonic or eudaimonic design approaches, we juxtaposed them with our codebook based on the classification of intrinsic motivations for system use by Lowry et al [54] (Table 1) and excluded those apps that did not provide hedonic or eudaimonic features to evoke any of these defined motivations.

Table 1. Codebook of hedonic and eudaimonic design aspects based on the classification by Lowry et al [54].

Design aspect (based on the classification by Lowry et al [54])	Definition based on the Cambridge Dictionary	Exemplary design features (added after intercoder agreement check)
Fun and enjoyment	Experience of playfulness or pleasure	Mini games, role-play, digital companions, juicy animations and sounds, or shuffling or chance
Escapism	Experience of escaping pressures and avoiding an unpleasant or boring life	Fantasy, reframing, or virtual reality
Challenge	Experience of being faced with something that requires mental or physical effort and tests one's ability	Quests or daily challenges, leaderboards, or levels
Immersion	Experience of becoming completely involved in an environment or action	Story or narrative, nature sounds, or meditations
Curiosity	Experience of being eager to know or learn about something or encountering something interesting, rare, or unusual	Counterintuitive behavior or surprising events
Discovery	Experience of finding information, places, or objects that one did not know about before	Easter eggs, skill paths, unlockable content, or new content
Self-expression	Experience of expressing one's personality, emotions, or ideas	Personal profile, personal journal, or customization of an avatar
Knowledge expansion and self-development	Experience of learning, growing, changing, or advancing through one's own efforts	Skill trees, quizzes, comparison to past behavior, or self-reflection
Freedom and autonomy	Experience of being allowed to do, say, and think what one wants and make one's own decisions without being controlled or limited by anyone else	Choices, customization and configuration, or multiple paths and options
Companionship	Experience of enjoyment in spending time with other people or being bound with others that share similarities	Collaboration partner, social feed, digital coffee, or community
Approval	Experience of receiving positive opinions, being accepted, or being positively reinforced for one's actions	Motivational messages, positive feedback, likes and comments, or badges
Meaning	Experience of importance or value in an action or outcome	Narrative, coupling actions with benefits for others, altruism, or gifting

To ensure the reliability of our exclusion process, 3 authors took part in the detailed screening. One of them was a postdoctoral researcher in motivational ISs with 5 years of research experience in the field of BCSSs and motivational design, who set up the inclusion and exclusion criteria, defined the codebook, and led the screening and selection process. The 2 others were junior researchers with backgrounds in organizational psychology and business pedagogy. To ensure reliability, an intercoder agreement check was carried out after 40.2% (125/311) of the apps were analyzed. A total of 20% (25/125) of the analyzed sample was randomly selected and additionally analyzed by one of the other authors (specifically, the apps analyzed by the junior researchers were subjected to intercoder checking by the postdoctoral researcher, and the apps analyzed by the postdoctoral researcher were equally divided and checked by the 2 junior researchers). The intercoder agreement rate for inclusion and exclusion was 96% (κ=0.92), indicating nearly perfect agreement [62]. Any conflicts were resolved in a joint discussion, and the 3 authors progressed with the remaining apps. As a result, 127 apps remained as the final

XSL•FO
RenderX

set of behavior change support apps for procrastination for the following research step. The complete list of included and excluded apps can be found in Multimedia Appendix 1.

App Coding

For our app coding as a basis to identify motivational design archetypes, we opted for 2 existing classifications to code the utilitarian, functional design aspects and the hedonic or eudaimonic design aspects of the apps, which are both crucial for motivational ISs [40,41].

Regarding the functional design, we used the BCTT by Michie et al [53]. Michie et al [53] developed a taxonomy of 93 different BCTs organized in 16 hierarchical clusters: *goals and planning*, *feedback and monitoring*, *social support*, *shaping knowledge*, *natural consequences*, *comparison of behavior*, *associations*, *repetition and substitution*, *comparison of outcomes*, *rewards and threats*, *regulation*, *antecedents*, *identity*, *scheduled consequences*, *self-belief*, and *covert learning* [63]. The BCTT has proven its reliability and validity [31] and has already been widely used in studies to classify health applications and digital health interventions [19,64-68]. While alternative taxonomies for classifying design in BCSSs exist, such as the persuasive system design (PSD) model [69], which has also been extensively applied in research on health BCSSs [70,71], we decided to build on the BCTT for 2 reasons. First, unlike the PSD model, it incorporates cognitive techniques such as identity and self-belief. Given that previous IS research in the field of motivational BCSSs for self-treating procrastination has largely disregarded the use of cognitive techniques [17], it is all the more important to analyze whether such approaches have been incorporated into the practical design of motivational BCSSs. Second, PSD incorporates principles that are on the cusp of being considered utilitarian, such as liking (which refers to the aesthetic experience and, thus, is related to the hedonic experience of enjoyment [41]) or competition and praise (which can be considered hedonic elements aiming to evoke experiences of challenge and approval [54]). However, it does not encompass the full range of hedonic and eudaimonic aspects that could be included in apps, such as immersion, curiosity, or discovery [54]. Accordingly, we chose to use the BCTT as a taxonomy to classify the functional design of the analyzed apps complemented by a second classification explicitly targeting the hedonic and eudaimonic aspects of the apps. Consequently, for our analysis, we coded the apps based on the 16 overarching clusters of the BCTT; for example, an app was coded as meeting the BCT cluster *self-belief* if it provided functionalities for (1) verbal persuasion about capability, (2) mental rehearsal of successful performance, (3) focus on past success, or (4) self-talk, whereby the detailed definitions and examples for each BCT provided by the BCTT [63] served as our codebook.

In terms of the hedonic and eudaimonic design aspects of the apps [41], we opted for the classification of intrinsic motivations for system use provided by Lowry et al [54]. In their study, Lowry et al [54] list 11 intrinsic motivations for hedonic IS use based on a review of the IS literature: *fun and enjoyment*, *escaping pressures*, *challenge*, *immersion*, *curiosity*, *discovery*, *self-expression*, *obtaining knowledge*, *experiencing autonomy/freedom*, *peer companionship*, and *approval* [54]. According to their hedonic-motivation system adoption model, which has been extensively used to evaluate motivational BCSSs in the health domain [72-75], these hedonic motivations are pivotal to the adoption and continued use of systems that target hedonic experiences [54]. We defined each of these intrinsic motivations based on the Cambridge Dictionary and added *meaning* (ie, a sense of experiencing importance or value in an action [76]) as the 12th dimension to reflect the eudaimonic aspect of motivational ISs [40]. During the coding process, an app was coded to meet a specific dimension if it provided functionalities to evoke the described hedonic or eudaimonic experience (eg, of fun or challenge; Table 1).

In total, 3 authors performed the coding independently. Each app was downloaded, tested, and used to experience all features and functionalities. In this regard, we used each app intensively upon installation (ie, we clicked on all menu items, buttons, and learning content and used all available functionalities on the app to experience whether completing tasks or using features on the app resulted in system feedback or progress), and if the app included progression mechanics to unlock new features or notification and reminder mechanics, we also used the apps for several days to code all their features that might become visible over time. To ensure reliability in the coding process, we performed an intercoder agreement check after coding 30% of the apps, again randomly selecting 25 apps for intercoder checks and dividing the intercoder checks in a similar way to that for the screening check (ie, the apps coded by the junior researchers were subjected to intercoder checking by the postdoctoral researcher, and the apps coded by the postdoctoral researcher were equally divided and checked by the 2 junior researchers). The intercoder agreement rate ranged between 50% and 100% for the BCTs (with a mean agreement rate of 84%, SD 14%) and between 67% and 92% for the hedonic and eudaimonic design aspects (with a mean agreement rate of 82%, SD 6%), indicating good agreement [62]. As a result of the joint discussion, we streamlined our understanding of the BCTs (eg, defining that the social support technique only refers to support from other human beings and not from artificial agents on the app) and enlarged our codebook of hedonic and eudaimonic design aspects based on exemplary design features (Table 1) before progressing with the coding process. The final list of the 127 coded apps can be found in Multimedia Appendix 1.

Cluster Analysis

We used cluster analysis to derive meaningful archetypes of app designs in the third step of our methodology. To do so, we followed the 2-step clustering approach proposed by Punj and Stewart [55] for 2 main reasons. First, this approach combines hierarchical clustering with iterative partitioning algorithms, thereby attempting to overcome the respective weaknesses of both approaches (eg, many partitioning algorithms, such as k-means, perform better than hierarchical algorithms but require an a priori definition of the number of clusters). Second, this methodology has been successfully applied to similar clustering tasks and has been shown to be useful for identifying design archetypes in various contexts [50,51,77].

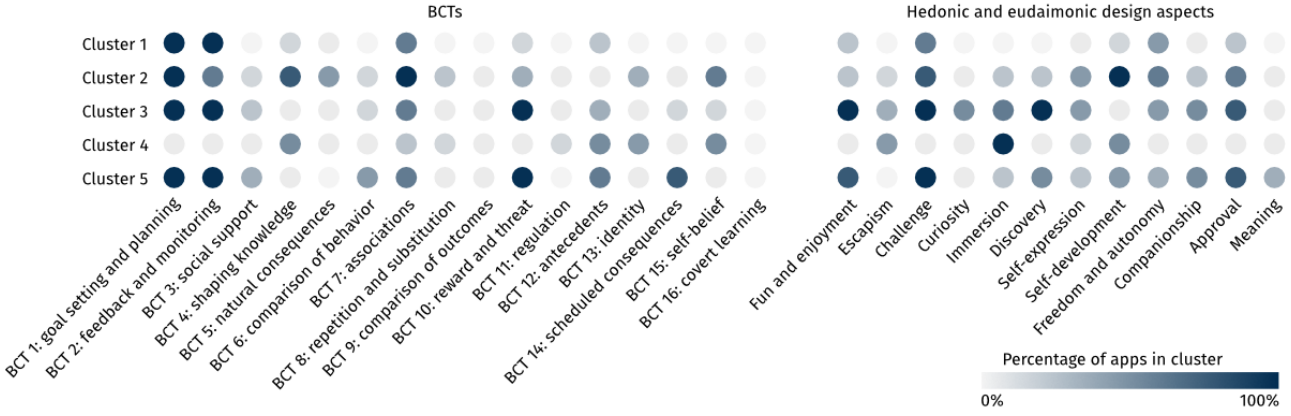
In line with the approach by Punj and Stewart [55], our clustering analysis included 2 steps. In the first step, we used

XSL•FO
RenderX

the method by Ward as a hierarchical clustering method to determine preliminary solutions and identify potential candidate numbers of clusters. Our coding included only binary data (ie, a design aspect, meaning each of the 16 BCT clusters of the BCTT [53] and each of the 12 hedonic or eudaimonic design aspects based on the classification by Lowry et al [54], is either present or absent). Thus, we chose the Euclidean squared distance as the similarity measure [50]. The dendrogram resulting from applying the method by Ward to our dataset indicated that 2 to 5, 7, 9, 11, and 12 were suitable candidate numbers of clusters. By examining the scree plot using the elbow rule [78], we narrowed down our selection to the 2-, 4-, 5-, 7-, 9-, or 12-cluster solution. On the basis of these candidate numbers, we conducted k-means clustering as an iterative partitioning algorithm. The 7-, 9-, and 12-cluster solutions produced by k-means all contained clusters with only 4 or even fewer apps, making reasonable interpretation of these solutions difficult. To decide on one of the remaining cluster solutions, 2 researchers manually compared their explanatory power by investigating differences and similarities in the BCTs and hedonic and eudaimonic design aspects included in our coding. First, we decided against the 2-cluster solution because the clusters were too heterogeneous in design aspects, making it impossible for us to derive meaningful interpretations. This left us with the 4- and 5-cluster solutions as candidates. After carefully analyzing both cluster solutions, we concluded that they were similar in many aspects but that one of the clusters in the 4-cluster solution was further divided into 2 distinct and informative clusters within the 5-cluster solution. Thus, we decided that the 5-cluster solution had the highest explanatory power and was the most suitable for deriving meaningful archetypes within this study. The cluster analysis results and the cluster solutions are included in Multimedia Appendix 2.

Results

Overview



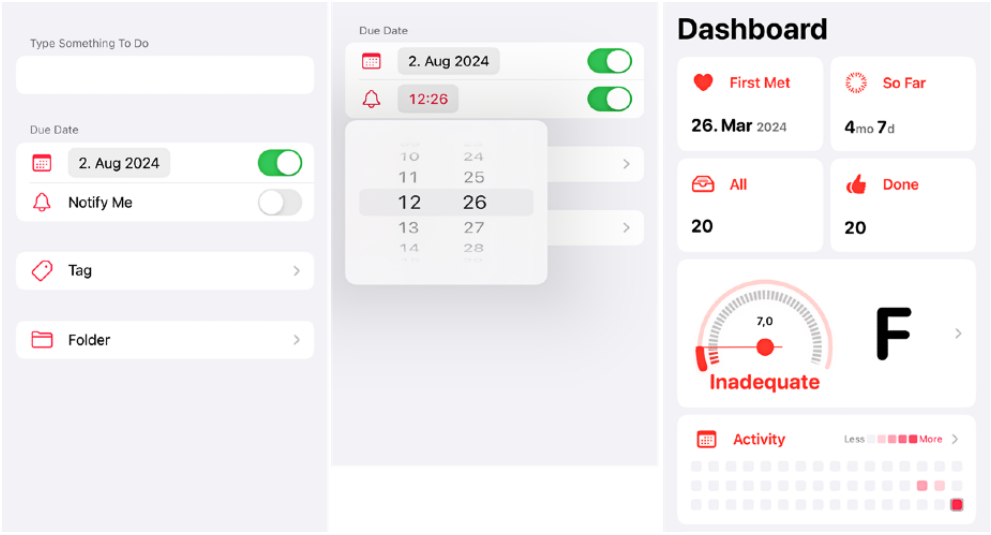
The final apps (N=127) that we included were fairly homogeneous regarding their categories, with most (n=122, 96.1%) categorized as productivity apps. In addition, 1.6% (n=2) were listed as lifestyle apps, 1.6% (n=2) were labeled as health and fitness apps, and 0.8% (n=1) were subsumed under the category of education, suggesting that, from a developer's perspective, apps that support behavior change to combat procrastination are seen as primarily organizational tools rather than mental health support apps. Overall, the analyzed apps were well rated (mean 4.39, SD 0.48 stars), with 1.6% (n=2) of the apps with a rating <3 stars, 11.8% (n=15) with a rating between 3 and 4 stars, 23.6% (n=30) with a rating between 4 and 4.4 stars, 36.2% (n=46) with a rating between 4.5 and 4.9 stars, and 7.9% (n=10) with a rating of a full 5 stars. A total of 18.9% (n=24) of the apps that we included had not been rated at the time of analysis.

Archetypes of Motivational Design in Behavior Change Support Apps to Combat Procrastination

Overview

Through our cluster analysis, we identified 5 distinct clusters of motivational behavior change apps to combat procrastination, which subsume a different number of apps. Specifically, cluster 1 was the largest cluster, with 51.2% (n=65) of the 127 apps, followed by cluster 2 and cluster 5, with 15.7% (n=20) of the apps each. Cluster 3 contained 10.2% (n=13) of the apps, and the smallest cluster, cluster 4, comprised 7.1% (n=9) of the apps. The apps in the clusters were rated fairly equally (mean 4.33, SD 0.55 stars for cluster 1; mean 4.30, SD 0.45 stars for cluster 2; mean 4.44, SD 0.31 stars for cluster 3; mean 4.42, SD 0.34 stars for cluster 4; and mean 4.55, SD 0.33 stars for cluster 5), with the apps in clusters 1 and 2 having the least positive ratings and the apps in cluster 5 having the most positive ratings. The clusters differed considerably in the BCTs and the hedonic and eudaimonic design aspects implemented in the contained apps (Figure 3). From the profiles of the clusters in terms of their motivational design, we can derive a motivational design *archetype* (ie, an abstract representation of a cluster), which helps understand how the clusters differ from each other. In the following sections, we will explain the 5 motivational design archetypes represented by the 5 clusters we found.

Figure 3. Graphical overview of the different clusters and the percentage of apps in each cluster that target specific behavior change techniques (BCTs; through functional design) and hedonic and eudaimonic design aspects.

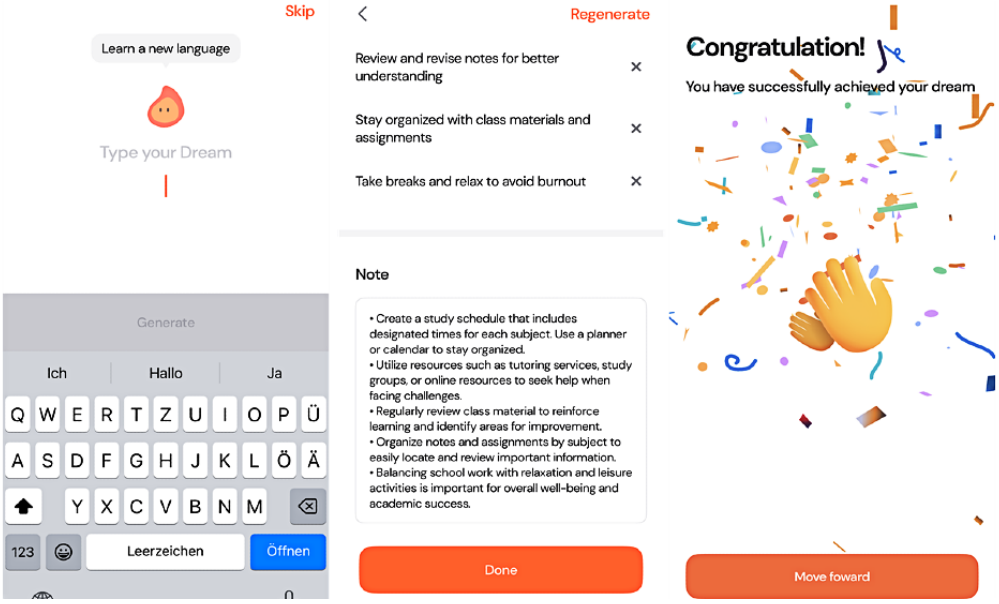


XSL•FO
RenderX

Archetype 1: Structured Progress Monitor

Archetype 1 represents an app used predominantly for managing personal tasks, goals, or habits. To establish goals and develop a plan of action (BCT 1), users can set tasks with a high degree of efficiency and ease. Furthermore, they can stipulate precise time frames for completion, the frequency of repetition, and the time of day at which the task is to be carried out. As a means of prompting users to engage with the app (BCT 7), notifications are sent to remind them to follow their task lists. The provision of detailed statistics and graphics for self-monitoring (BCT 2) represents a further key feature of the *structured progress monitor*. The visualization of one's development, presented in the form of progress bars, grades, badges, points, or streaks, illustrates past achievements and the individual capacity to complete tasks successfully. These mechanisms elicit a sense of challenge in the user, prompting them to sustain the desired behavior and, consequently, adhere to the established goals over time. They represent the primary hedonic design aspect of the *structured progress monitor*, distinguished by a transparent and uncluttered design devoid of any significant hedonic or eudaimonic elements beyond the element of challenge. Consequently, it can be characterized as a primarily functional assistance system. An example of the *structured progress monitor* is the Noverdue app [79]. Figure 4 [79] illustrates how individuals can create tasks with notifications and due dates (Figure 4A [79]); personalize the reminder function (Figure 4B [79]); and self-monitor their progress on a dashboard that provides a rating, thereby challenging the users to improve their performance (Figure 4C [79]).

Figure 4. Noverdue as an exemplary app of the structured progress monitor archetype, with (A) the customizable creation of tasks, (B) the reminder function, and (C) the dashboard visualizing personal progress.



Archetype 2: Self-Improvement Guide

Archetype 2 provides the means to restructure detrimental behaviors and introduce novel habits (BCT 1) within one's personal life. An artificial intelligence (AI)–powered chatbot offers tailored assistance and guidance (BCT 4) on overcoming obstacles and navigating questions regarding habit implementation while emphasizing the positive consequences of behavior change (BCT 5), for example, for personal well-being. This key mechanic is complemented by functionalities to track (BCT 2) and repeat (BCT 8) new habits and receive personalized reminders (BCT 7). In-app journaling encourages introspective reflection on one's behavior, facilitating the development of self-belief (BCT 15). Consequently, the *self-improvement guide* assists users in articulating their desired personal development and provides guidance on how to achieve these life goals through the use of a digital companion, which offers continuous approval for positive self-development. The elicited feeling of self-development, in conjunction with challenge-oriented elements such as streaks, serves as the primary hedonic and eudaimonic mechanism that facilitates users' maintenance of new habits. An illustrative example of the *self-improvement guide* is Dreamfora [46]. Figure 5 [46] illustrates how users can establish new, overarching objectives and dreams that they aspire to attain through self-development (Figure 5A [46]). The figure also depicts how the AI chatbot dispenses knowledge and assistance regarding forming new habits (Figure 5B [46]), thereby facilitating the achievement of the aforementioned life goals. Furthermore, it demonstrates how users receive ongoing approval for their successful actions (Figure 5C [46]).

XSL•FO
RenderX

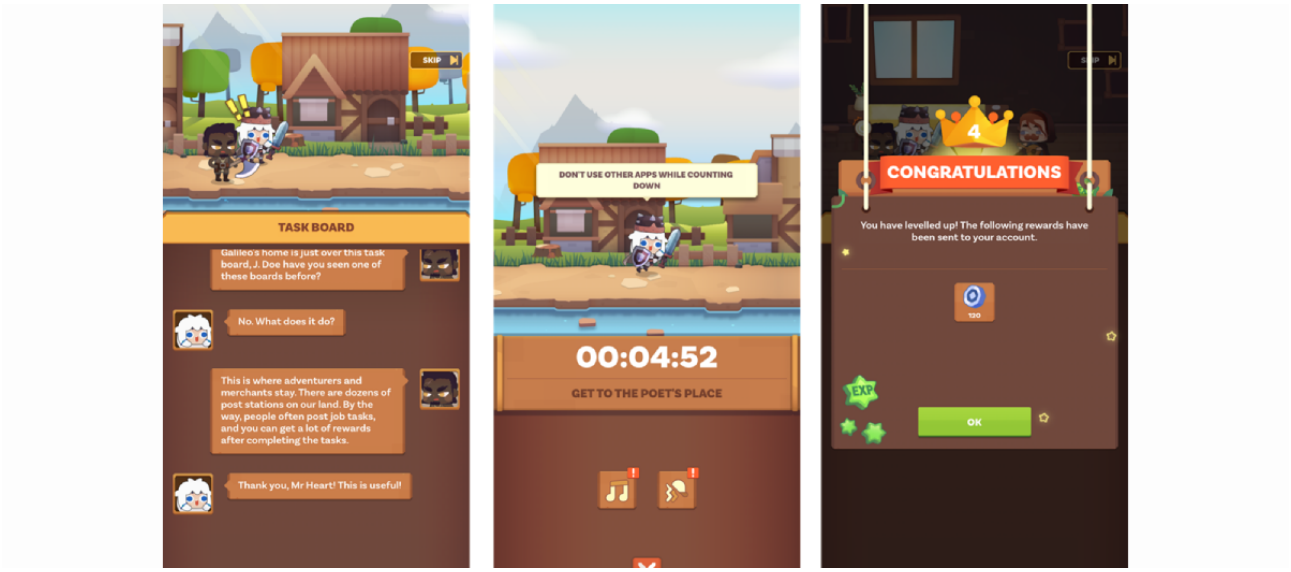


Figure 5. Dreamfora as an exemplary app of the self-improvement guide archetype, with (A) opportunities to define long-term goals and dreams, (B) the artificial intelligence assistance that breaks them down into tangible tasks and explains their relevance, and (C) ongoing approval for successful actions.

Archetype 3: Productivity Adventure

Archetype 3 is distinguished by its comprehensive hedonic and eudaimonic design. Playfully designed storylines, mini games, unlockable levels, and customizable characters elicit feelings of enjoyment, challenge, curiosity, discovery, and self-expression among app users. By transforming the mundane and occasionally onerous task completion into a digital experience, the seriousness associated with task fulfillment is diminished. Digital characters that accompany the individual in the digital journal facilitate this process by offering a sense of companionship and providing approval. As a foundation for digital progression, the productivity adventure is predicated on 5 principal BCTs: the user defines their to-dos (BCT 1) and monitors the completion of these tasks in a step-by-step manner (BCT 2), aided by a timer that schedules focus sessions (BCT 12) and notifies upon successful completion (BCT 7). Should the user maintain their focus for the requisite period, the app will instantaneously reward them with, for example, the ability to access a new level (BCT 10). An example of this archetype is the Focus Quest app [80]. Figure 6 [80] illustrates the integration of goals and task fulfillment into a fictional storyline in interaction with a digital character (Figure 6A [80]), which challenges the user to maintain focus for a designated period (Figure 6B [80]) to obtain digital rewards and progress in the story (Figure 6C [80]).

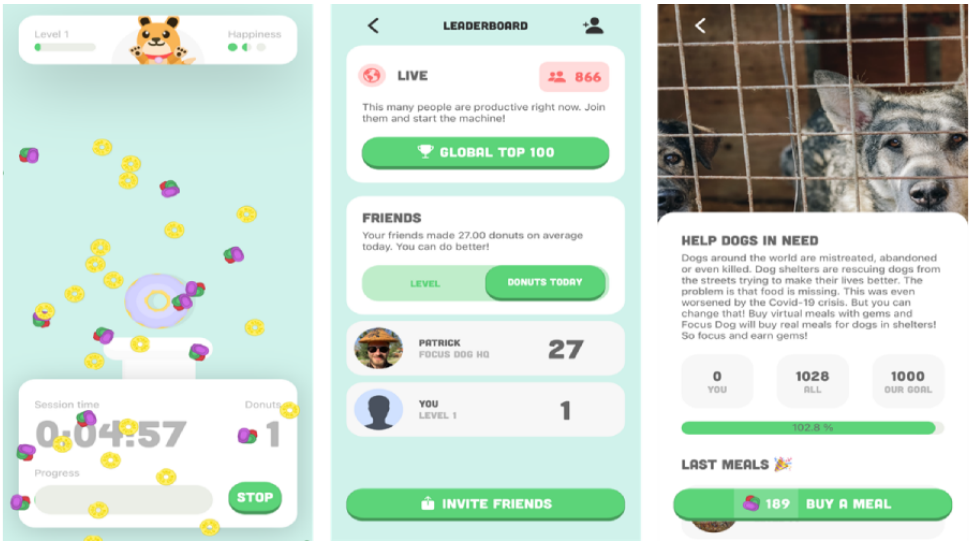
Archetype 4: Emotional Wellness Coach

Archetype 4 represents an app that furnishes users with a variety of content, including quotes, images, videos, and audio material, with the objective of enhancing motivation and emotional regulation, particularly in the context of perceived pressure. Positive affirmations, relaxing audio sessions, and motivational speeches by role models reinforce the user's self-belief (BCT 15) and cultivate a positive outlook on one's future identity (BCT 13). In terms of hedonic and eudaimonic design, the *emotional wellness coach* contributes to the attainment of a positive state of mind in which the user can escape the stressful reality and immerse themselves in meditative sessions, thereby preparing themselves mentally for pursuing their goals. This ultimately facilitates the process of intense cognitive self-development. An app that exemplifies the *emotional wellness coach* is Greatness [81], depicted in Figure 7 [81]. Individuals may select from an array of productivity- and well-being–oriented meditation programs (Figure 7A [81]). These programs comprise distinct coaching sessions to foster motivation and promote emotional well-being (Figure 7B [81]). Moreover, the app provides guidance and facilitates mental preparation and rehearsal through immersive meditation exercises (Figure 7C [81]).

Figure 7. Greatness as an exemplary app of the emotional wellness coach archetype, with (A) a variety of meditation programs to choose from, (B) coaching sessions on motivation and emotional well-being, and (C) immersive meditation exercises.



Archetype 5: Social Focus Companion

The primary operational mechanism of archetype 5 is a focus timer that inhibits the use of alternative apps and external distractions, thereby facilitating the control of environmental stimuli (BCT 12). The user establishes their to-dos along with an intended time interval (BCT 1). Upon the expiration of the designated time and the maintenance of focus, the user is granted the aforementioned scheduled rewards. Conversely, upon the occurrence of a distraction, the user is subjected to a digital penalty (BCTs 10 and 14). The primary hedonic design element is an in-app character situated in a playful and enjoyable environment. This character is developed and behaves in accordance with the user's focus sessions. That is, it either progresses and flourishes through the digital rewards or suffers from the digital penalties. This dynamic challenges the user to complete focus sessions for the benefit of their digital companion. In this regard, the digital entity also offers feedback (BCT 2) indicating approval for successful work. Furthermore, in contrast to the other archetypes, the *social focus companion* allows for interaction with other users, facilitating social support in focusing together (BCT 3) and comparison with the behavior of others (BCT 6), fostering a feeling of companionship. While unlocking novel rewards also elicits a feeling of discovery, a distinctive eudaimonic feature of the *social focus companion* is the altruistic benefit of one's behavior, evoking a sense of meaning. By adhering to the designated focus time, one not only rewards the character within the app but also achieves a positive impact outside the app. The exemplary app of the *social focus companion*, named *Focus Dog: The Productivity Timer* [82] (Figure 8 [82]), features a fictional dog that requires nourishment, which can be obtained by unlocking donuts through the use of coins (Figure 8A [82]). Individuals are rewarded with coins for maintaining focus, and users can compare their performance on a ranking list (Figure 8B [82]). Furthermore, in addition to benefiting the fictional dog, the coins can be used to purchase meals for canines in need (Figure 8C [82]).

Discussion

Principal Findings

Overview

Our study sheds a novel light on how practice has approached the design and implementation of motivational BCSSs for the unguided self-treatment of procrastination as a low-threshold alternative to professional medical treatment programs for those affected. Generally, while research on motivational BCSSs for procrastination is still nascent [17], we can observe that practice has already produced a plethora of behavior change support apps with various behavior change support techniques and hedonic or eudaimonic design aspects implemented to both provide functional support and elicit positive experiences in managing procrastination. In response to our research question, we identified 5 archetypes of motivational design in prevalent apps: the *structured progress monitor*, the *self-improvement guide*, the *productivity adventure*, the *emotional wellness coach*, and the *social focus companion*. In reflecting on our results, we can discuss 3 main observations that entail important implications for future research and practice in the field.

Observation 1: The Relationship Between Motivational Design Archetypes and Psychological Determinants of Procrastination

Upon juxtaposing the identified archetypes of motivational design with procrastination theory, it becomes evident that the designs appear to target different determinants of procrastination, specifically, outcome expectancies, outcome value, delay, and impulsiveness [2,12].

In particular, the *structured progress monitor* and the *productivity adventure* both appear to target primarily outcome value, that is, the desirability of a task or activity for an individual [2,12], and delay, which is a temporal indicator of the proximity of the outcome value's realization [2,12]. In this regard, the *structured progress monitor* emphasizes task organization, self-monitoring, and the illustration of progress and self-development. From a theoretical perspective, the organization and planning of tasks (as a form of goal setting [83]) and adherence to a self-set schedule as a self-regulatory technique [2] affect procrastination through 2 mechanisms: temporal discounting and diminishing returns [12]. Specifically, this implies that the successful completion of each individual task that arises from a divided overall objective provides a similar level of satisfaction concerning the need for competence [84] to that for the entire project. Consequently, the overall outcome value accumulates as a determining factor in procrastination [12]. Simultaneously, individual tasks are more proximal than a distant deadline for an overall project, which reduces delay and, thereby, enhances the power of the accumulated outcome value [12]. The *productivity adventure*, similarly to the *structured progress monitor*, appears to seek to enhance the perceived outcome value of a task or action, albeit through a markedly different approach. By advancing in a narrative, obtaining digital rewards for completing tasks and focus sessions, and stimulating individuals' curiosity and desire for exploration and discovery with unexpected events and unlockable paths and content, the archetype—in addition to merely subdividing a goal and illustrating progress—reframes task values by offering rewards and digital progress, thereby reducing task aversiveness [2]. Task unpleasantness and a lack of interest or boredom have been identified as reliable determinants of procrastination [10], reducing outcome value. Conversely, the satisfaction of autonomy needs through opportunities for exploration and discovery of a story or narrative [85] has been shown to counteract procrastination [86,87]. In addition, from a behavioral perspective, immediate (digital) rewards provide timely reinforcement of behavior [88-90], thereby reducing the delay of outcome value, particularly for individuals who are prone to immediate gratification [90].

In contrast, the *self-improvement guide* and the *emotional wellness coach* primarily aim to target outcome expectancies, that is, the conviction that a task can be completed successfully [2,12]. In this context, the *self-improvement guide* emphasizes the education of individuals regarding the consequences of procrastination and the means to counteract it. It provides

XSL•FO
RenderX

support and approval for self-reflection, personal development, and the establishment of self-belief, thereby enabling those affected by procrastination to realize new habits (ie, behavioral routines vital in inhibiting procrastination [2,10]). From a theoretical perspective, research has emphasized that irrational beliefs, unrealistic expectations, and low self-esteem present critical risk factors for procrastination and a phenomenon called self-handicapping [10], which is defined as engagement in unrelated activities or tasks that are likely to fail [91]. The resolution of such cognitive barriers and the reinforcement of self-efficacy represent a crucial element in forming outcome expectancies [92]. In turn, this fosters a reduction in procrastination behaviors [12]. In a similar albeit different manner, the *emotional wellness coach* uses a cognitive approach to procrastination, eschewing the behavioral elements present in the other archetypes. This approach is centered on enhancing self-belief and identity through immersive formats and meditation while mitigating the pressure experienced by individuals. In this regard, procrastination theory demonstrates that pressure and stress resulting from perfectionism and fear of failure promote procrastination as a separate factor from self-esteem and self-efficacy [2,15]. The cognitive restructuring of perfectionist beliefs and mental contrasting sessions that highlight the steps necessary to achieve the goal rather than remaining in a passive mental state have been demonstrated to be effective therapeutic approaches to this problem [10]. These approaches are implemented in the emotional wellness coach as digital coaches or role models.

Finally, the *social focus companion* is primarily concerned with reducing distractibility and enhancing stimulus control. That is to say, it is focused on volitional rather than motivational factors [1]. Both are essential for strengthening self-control [2,92] and reducing impulsiveness, which is defined as a preference for short-term outcomes over future rewards [90] and presents a key determinant of procrastination [12]. To this end, the primary functionalities of the *social focus companion* are focus timers that mitigate distractions coupled with scheduled digital incentives and penalties for successful or unsuccessful focus sessions, respectively. These sessions are enhanced with playful environments, digital companions or assets, and linking of in-app achievements to meaningful additional outcomes. Moreover, the social comparison and support mechanisms inherent to the *social focus companion* reinforce the normative influence to focus on the task, which in turn reduces impulsiveness even further [14]. In addition, through a process known as *fusing*, immediate social gratification increases the perceived value of the outcome [2,10].

In summary, it can be observed that the *self-improvement guide* and the *emotional wellness coach* primarily target outcome expectancies as determinants of procrastination, whether through the enhancement of self-efficacy and self-belief or the reduction of perfectionism and pressure. The *structured progress monitor* and the *productivity adventure*, in turn, primarily seek to enhance outcome value by subdividing goals or reducing task aversiveness and decreasing delay through temporal discounting and immediate reinforcement. Finally, the *social focus companion* is concerned with reducing impulsiveness through stimulus control and normative influence. Therefore, from a procrastination theory perspective, the 5 archetypes address all the primary factors that contribute to procrastination [2,12].

Observation 2: BCTs in Motivational BCSSs for Procrastination Compared to Traditional Treatment Strategies

Research has suggested that BCSSs may provide an efficacious and low-threshold alternative to traditional therapeutic treatments for procrastination [11,14,17]. In this regard, it has been demonstrated that studies on BCSSs for procrastination rely heavily on behavioral treatment strategies, including self-supervision, planning and prioritization, time management, and goal setting [17]. However, cognitive approaches appear to be underrepresented and are predominantly used as an extension of cognitive behavioral therapy with professional guidance [17], also referred to as internet-based cognitive behavioral therapy [39,93,94]. Consequently, they are not yet widely regarded as a stand-alone self-treatment option. Our analysis of practical approaches to BCSSs to combat procrastination similarly demonstrates an emphasis on behavioral strategies, most importantly goal setting and planning (BCT 1), feedback and monitoring (BCT 2), and associations and cues (BCT 7). In this context, it is noteworthy that several archetypes, particularly the *productivity adventure* and the *social focus companion* but also the *emotional wellness coach*, incorporate functionalities to alter the natural environment and avoid distractions, targeting antecedents (BCT 12), whereas research has thus far primarily overlooked the potential of stimulus control, or volitional influences, in self-treatment BCSSs [17].

Furthermore, it can be observed that both the *self-improvement guide* and the *emotional wellness coach* use cognitive strategies, specifically knowledge shaping (BCT 4), identity building (BCT 13), and self-belief strengthening (BCT 15), through the use of predefined information and meditation sessions conducted by coaches or through AI companions that generate personalized recommendations based on the individual's goals, challenges, and reflections. Although intelligent conversational agents can serve as a valuable alternative for individual coaching in other health care areas [95-97], their potential in research on BCSSs for procrastination remains unexplored [17,98]. Our analysis demonstrates that practice has already taken the initiative to use such approaches, which can potentially enable the tailoring of cognitive strategies to individuals and their specific problem profiles [1,56,57] for the purpose of self-treating procrastination. Scholars are encouraged to build on these implementations to further explore their potential for the personalized treatment of procrastination.

Nevertheless, when considering the therapeutic treatment of procrastination, it becomes evident that the prevailing self-treatment archetypes lack the incorporation of other cognitively oriented BCTs that have been demonstrated to exert a beneficial influence on procrastination. These include the comparison of outcomes through the reflection on the advantages and disadvantages of the behavior in question as well as the visualization of prospective outcomes (BCT 9) and emotional regulation (BCT 13) [99,100]. It remains unclear whether nonhuman artificial agents can entirely supplant

XSL•FO
RenderX

therapeutic guidance, particularly regarding emotional regulation, which necessitates a personal bond [101] that is frequently impeded by cognitive and emotional barriers in the context of artificial systems [102,103]. Furthermore, medical research has demonstrated that group treatment and social strategies, including social support (BCT 3), comparison of behavior (BCT 6), and covert learning from others' experiences (BCT 16), are more effective in treating procrastination than individual approaches [104]. In this regard, existing research efforts [17], as well as our identified practical archetypes, still demonstrate considerable potential for harnessing the power of social support. While the *social focus companion* notably uses joint focus sessions as a form of common goal setting and at least enables social comparison on ranking lists, such mechanics are primarily competitive [105] and oriented toward normative pressure that can evoke feelings of guilt or shame [106] rather than being socially supportive, as in the form of group counseling sessions and mutual exchange about the challenges and personal experiences with procrastination [107]. The combination of cognitive reflection and self-belief strategies with social support and covert learning may prove an effective approach to the self-treatment of procrastination. In particular, this approach may offer significant benefits for individuals facing challenges related to false expectations, irrational beliefs, low self-esteem, and other stable dispositions that require intensive cognitive restructuring [10] rather than behavioral support for task organization and stimulus control.

Observation 3: Hedonic and Eudaimonic Design of Motivational BCSSs for Procrastination

With regard to hedonic and eudaimonic design aspects of motivational design archetypes, it is evident that dominant designs are either centered on digital environments that are designed for enjoyment, featuring fictional characters and stories that foster discovery and provide a sense of approval (the *productivity adventure* and the *social focus companion*), or on providing means for users to escape pressures, engage in meditation, and support their self-development (the *self-improvement guide* and the *emotional wellness coach*). It is noteworthy that practice has used a more diverse array of hedonic and eudaimonic design elements than research efforts in the field of motivational BCSSs for procrastination, which have primarily focused on challenge-oriented elements such as points [43,108,109] and badges [109,110], similarly to the *structured progress monitor* [17]. Furthermore, in comparison to most existing works on motivational BCSSs for other health dimensions beyond procrastination, such as physical activity [23,50] or therapy adherence [111], our identified practical archetypes extend beyond the use of challenge-oriented elements commonly observed in classic gamification [112]. They incorporate exploration, narrative design, and immersive elements, which have been recently proposed by research on motivational BCSSs to enhance the hedonic and eudaimonic experience effects beyond those typically associated with challenge-oriented approaches [113,114].

However, when considered together with the treatment strategies, cognitive approaches appear to be at odds with fictional environments and narratives in the identified archetypes. Thus far, motivational design archetypes seem to be focused on either using playful reframing to enhance hedonic and eudaimonic experiences during behavioral strategies or on fostering feelings of self-development and escapism from pressures during cognitive strategies. The latter naturally focus on real-life problems and the individual rather than a fictional story. In this regard, research on motivational BCSSs in other areas indicates that narrative design can be effectively combined with self-reflection exercises, which may enhance the beneficial hedonic and eudaimonic experiences elicited by both approaches [115-117].

Furthermore, novel motivational BCSSs that extend beyond the smartphone technology examined in this study, such as virtual reality applications, may offer even greater potential to integrate immersive narratives with cognitive treatment approaches, a relaxing environment, and feelings of actual self-development [118,119]. While those developments are still in their infancy, both research and practice can benefit from exploring such novel technological advancements in designing effective motivational BCSSs for procrastination.

Implications

The principal findings of our study have significant implications for further research and practice. From a research perspective, our findings identified 5 main archetypes of motivational design in BCSSs for procrastination. These archetypes constitute a novel perspective on design knowledge for motivational BCSSs that abstracts from single, potentially ineffective real-world systems [48] and describes industry best practices that have prevailed in the design of motivational BCSSs for procrastination. For researchers, these archetypes provide a unique opportunity to obtain a holistic picture of how BCTs and hedonic and eudaimonic design elements have predominantly been instantiated in apps for procrastination. Researchers may juxtapose these findings with their own research endeavors, thereby potentially identify mismatches between current research foci and industry best practices. Consequently, they may discover new research opportunities or necessities to reallocate resources toward investigating the archetypal design configurations as possibly promising combinations of BCTs and motivational design that extend beyond the predominant focus on behavioral approaches [17].

Moreover, our observations indicate that the different motivational design archetypes may be suitable for targeting different determinants of procrastination [12]. Specifically, we found that apps in the *self-improvement guide* or *emotional wellness coach* archetypes primarily target outcome expectancies, whereas the *structured progress monitor* and *productivity adventure* seek to enhance outcome value and the *social focus companion* focuses on reducing impulsiveness [12]. While the archetypes were identified based on apps in the US and German markets and, therefore, predominantly reflect Western design approaches to target procrastination, research indicates that the primary determinants of procrastination, such as outcome expectancies, task aversiveness, and impulsiveness or self-control, are applicable and relevant across cultural contexts that are different from the Western one, including those of countries such as China, India, Israel, and Turkey [120-123]. Consequently, our design archetypes constitute a valuable

XSL•FO
RenderX

foundation for further research, not only within the Western cultural context but, more broadly, to explore the potential of BCSSs as a low-threshold self-treatment approach for the global phenomenon of procrastination [2,3] across cultures. For example, given that individuals differ in their procrastination profiles and which of the determinants pose the most significant problem for them [1,56,57], there is great potential to examine how these motivational BCSS archetypes can serve as the basis for targeted self-treatment strategies for different individuals. The existing research has already called for implementing more individualized treatment strategies for procrastination [1,44]. Concurrently, the extant motivational BCSS research has demonstrated that, in addition to the treatment approach, individuals also express preferences for various hedonic and eudaimonic design elements that have the potential to influence their experiential impact [124-126]. Our findings provide a foundation for further research into how the different motivational design archetypes, in terms of both their treatment focus (behavioral, cognitive, or a combination) and their hedonic and eudaimonic design approaches, affect individuals with varying procrastination problem profiles, dispositions, situational contexts, and motivational preferences. In this way, targeted recommendations can be developed for individuals affected by procrastination.

Furthermore, our 5 motivational design archetypes present a blueprint for the effective practical development of BCSSs for procrastination. By demonstrating how designers can use and combine hedonic and eudaimonic design elements to enhance the efficacy of behavioral and cognitive BCTs in digital applications [40,41] while concurrently addressing dropout rates [58] and how designers can build on our archetypes as established configurations of design elements [49] rather than experimenting with inefficient combinations of BCTs [48], our study paves the way for an even more diverse array of motivational BCSSs to combat procrastination. Potential avenues for exploration include the integration of AI-based conversational agent approaches to enhance cognitive treatment strategies [95-98] and the use of virtual reality technology to unify cognitive and behavioral treatment and playful and narrative designs [127] with the objective of enhancing both the functional and experiential aspects of motivational BCSSs for procrastination. From the perspective of health professionals and affected individuals, our findings provide a basis for selecting a motivational design archetype that best suits the patient's or individual's challenges, needs, and preferences. Once this has been done, a suitable, existing app can be chosen from the results of our systematic cluster analysis. Consequently, our study provides a foundation for potentially enhancing the treatment adherence of individuals seeking mobile apps to assist them in addressing procrastination (as opposed to, eg, experiencing frustration due to the absence of effects from attempting to use an emotional wellness coach when the primary issue lies in stimulus control and distractibility). Therefore, ultimately, our findings assist in counteracting the significant mental and physical health consequences associated with procrastination [5-9].

Limitations and Future Research

It is essential to consider some critical limitations in interpreting the findings of this study, which have their roots in the methodological choices made.

First, we restricted our examination of motivational BCSSs against procrastination to smartphone-based apps. Despite this decision, our search and screening process demonstrates that we identified a multitude of motivational behavior change apps for procrastination. However, we recognize that there are other motivational BCSSs for the self-treatment of procrastination that rely on alternative technology, such as web applications [128], which were excluded from our cluster analysis. Furthermore, while the Apple App Store and the Google Play Store represent the 2 largest app stores for iOS- and Android-based mobile phones, there are other app stores for Android-based mobile phones, such as the Microsoft Store, that were not included in our search. Similarly, it is crucial to acknowledge that user settings, filters, and preferences in app store searches may impact the results obtained by entering identical search terms on disparate devices. Consequently, some users may not be able to access all the apps that we screened for use on their smartphones. In addition, it should be noted that our search and screening were limited to German or English search terms and apps because the United States is the most significant Western mobile app market in terms of app downloads and consumer spending on mobile devices [60] and Germany represents the largest mobile app market in the European Union [61]. As a result, it is possible that we overlooked valuable apps that were designed for the Chinese market and only accessible and functional with Chinese-language proficiency.

Furthermore, while our attention was directed toward motivational BCSSs due to their hedonic and eudaimonic design characteristics that can augment positive experiences [40,41] and, in turn, potentially increase self-treatment adherence, it is important to recognize that, within the realm of research, numerous BCSSs aimed at combating procrastination have demonstrated efficacy despite not relying on hedonic or eudaimonic design [17]. In this regard, our archetype analysis provides a foundation upon which the effects of different motivational design approaches can be investigated; however, it does not provide insights regarding their effectiveness itself. It is recommended that future research be conducted to build on this open avenue and explore the distinct effects of different motivational design archetypes compared to merely functional BCSSs for procrastination.

Ultimately, in recognizing that most studies in the domain of BCSSs for procrastination that rely on cognitive behavioral treatment strategies use BCSSs to augment existing therapeutic guidance [17], we restricted our cluster analysis to exclusively self-treatment motivational BCSSs, omitting the inclusion of therapeutic guidance. Although our objective was to concentrate on apps that have the potential to be low-threshold alternatives to therapeutic treatment [11,14], it is important to acknowledge that professional assistance may be essential and irreplaceable for individuals who are already experiencing serious mental and physical health consequences of procrastination. In such

XSL•FO
RenderX

cases, it could even be irresponsible to provide them with a stand-alone solution that is not designed as a medical product. Consequently, an avenue for future research in the treatment of procrastination is the analysis of the design opportunities for hybrid apps that provide hedonic and eudaimonic experiences while simultaneously integrating professional therapeutic guidance.

Conclusions

Although procrastination represents a significant self-regulatory failure with the potential to cause adverse mental and physical health consequences, the rate of adherence to professional therapies remains low, particularly in light of the considerable number of individuals affected. Specific forms of BCSSs, namely, motivational BCSSs that elicit positive experiences through hedonic and eudaimonic design elements, have been proposed as a promising self-treatment alternative for individuals struggling with procrastination. However, research on the design and effects of such systems is still in its infancy. Conversely, a multitude of motivational behavior change support apps designed to facilitate behavior change and overcome procrastination have already been developed and implemented in practice. To analyze these practical developments, a systematic review and cluster analysis of prevalent smartphone apps was conducted, resulting in the identification of 5 motivational design archetypes. Upon critical discussion, these archetypes appeared to target different psychological determinants of procrastination and successfully use a variety of hedonic and eudaimonic design elements that extend beyond the current state of research. Nevertheless, further investigation is warranted to ascertain how hedonic and eudaimonic design can be more effectively integrated with cognitive BCTs and how social support mechanisms that have demonstrated efficacy in traditional procrastination treatment can be elicited through motivational BCSSs.

Abstract

Background: Perinatal maternal mental health problems, such as depression and anxiety, are highly prevalent during pregnancy and post partum. Electronic mindfulness-based interventions (eMBIs) are a promising treatment option, which can be provided in a low-threshold, cost-effective manner. However, research underscores the fact that face-to-face coaching sessions are more effective than solely digital methods. A blended care approach (eMBI with direct face-to-face coaching) could amplify the therapeutic impact on maternal mental health and weight gain during the perinatal period.

Objective: We investigated whether combining an eMBI intervention with face-to-face personal support significantly improves maternal mental health, and whether the intervention can influence weight gain in affected women during pregnancy.

Methods: A community-based sample of 460 pregnant women with a singleton pregnancy who screened positive for depression was enrolled in a multicenter randomized controlled trial (RCT) including the University Hospitals of Heidelberg and Tübingen as well as more than 200 gynecological practices within the state of Baden-Württemberg in Germany between February 2019 and October 2020. Participating women were randomized 1:1 to the control group (CG) or intervention group (IG) that received access to an 8-week pregnancy-adapted eMBI between the 29th and 36th gestational week. In a subanalysis, we grouped participants in those receiving only the initial face-to-face coaching session at recruitment (no personal coaching) and those with ≥2 personal coaching sessions. Primary outcome measures were severity of depressive symptoms using the Edinburgh Postnatal Depression Scale, anxiety using the State-Trait Anxiety Inventory, the Pregnancy-Related Anxiety Questionnaire, the Freiburg Mindfulness Inventory, and the Patient Health Questionnaire; secondary outcome measure, BMI.

Results: In the final sample, 137 CG women and 102 IG women received only one coaching session, whereas 37 CG women and 40 IG women received at least 2 (mean 2.3, SD 0.7) coaching sessions. The analyses were adjusted for significant confounders. The IG's mindfulness scores increased significantly ($F_{1.873,344.619}$=4.560, P=.01, η^2=0.024, ω^2=0.012) regardless of coaching frequency. Both general anxiety ($F_{12,129}$=2.361, P=.01, η^2=0.0180, ω^2=0.100) and depression symptoms ($F_{4.758,\ 699.423}$=3.033,

XSL•FO
RenderX

P=.01, η^2=0.020, ω^2=0.009) were significantly lower in the group that received ≥2 coaching sessions than in the no-personal-coaching group. In the group receiving ≥2 coaching sessions, BMI generally was lower in the IG than in the CG ($F_{3.555,444.416}$=4.732, P=.002, η^2=0.036, ω^2=0.013).

Conclusions: Adding a minimal amount of PC to the digital eMBI increased mindfulness and decreased birth-related anxiety, symptoms of depression, and anxiety in at-risk pregnant women. Favorable effects on gestational weight gain were found in the respective IGs, the strongest effect being within the PC group. This blended digital health approach amplifies the effectiveness of the digital intervention.

Introduction

During the perinatal period, pregnant women face an elevated risk of developing anxiety and depressive disorders. While prenatal depression affects 10%-25% of pregnant women [1], up to one-third experience depression and anxiety disorders after delivery [2,3].

The etiology of these disorders is multifactorial, ranging from obstetrical, high-risk pregnancies and psychological distress to the manifestation of previous depression or anxiety disorders [4]. Once present, perinatal mental disorders can, in turn, lead to pregnancy complications, sleep disturbances, suicidal tendencies, high-risk behavior, and overall poor maternal health-related quality of life [5-7]. Moreover, maternal anxiety and depression increase the risk of preterm birth and newborn low birth weight and have a negative impact on infant behavioral, motor, and cognitive development [8,9].

Psychological distress, in turn, is associated with greater gestational weight gain (GWG) during pregnancy and a higher risk for impaired insulin resistance, potentially resulting in adverse outcomes for both mother and child [10]. As women are at higher risk for gestational diabetes, cesarean section, large-for-gestational-age fetal growth, and postpartum weight retention, prevention at this stage is crucial [11]. As excessive GWG can be found in approximately 50% of all pregnancies, thus presenting a major global health burden, prenatal lifestyle interventions and prevention measures are warranted [12].

Meanwhile, digital interventions such as mindfulness approaches have proven to be helpful in supporting pregnant women with mental health symptoms and in preventing excessive weight gain [13]. We recently demonstrated the beneficial effects of an electronic mindfulness-based intervention (eMBI) in a randomized controlled clinical trial (RCT) [14] with an 8-week digitally guided intervention. The intervention significantly increased maternal mindfulness and significantly decreased birth-related anxiety. However, while the intervention significantly impacted the prevalence of postpartum depressiveness, symptoms of depression and general anxiety were not significantly reduced during the intervention. Comparable outcomes in diminishing maternal distress have been highlighted in previous research as well [15]. Lönneberg et al [16] conducted an RCT to evaluate the effects of a face-to-face mindfulness program (Mindfulness-Based Childbirth and Parenting Program) on stress, depression, and mood of pregnant women. Integrating perinatal health insights with mindfulness exercises, the program yielded promising results: participants reported fewer depressive symptoms, diminished stress levels, an increased sense of mindfulness, and a positive state of mind after completing the program.

However, this literature is sparse regarding the prevention of glucose intolerance. Research has shown favorable effects of a personal mindfulness intervention in improving perinatal stress and maternal weight gain, though without reaching significance [10].

While digital interventions have proven useful, we questioned whether their effectiveness could be optimized by combining eMBI with a minimum of personal support, such as face-to-face interventions, in a blended care model. Digital health care interventions have generally shown high acceptability rates and represent far-reaching, relatively cost-effective methods to support health care on a low-threshold basis [17]. However, despite the considerable growth of digital interventions in the last decade, previous research has shown that such interventions tend to lack sensitivity and may not adequately meet individual needs [18]. Therefore, flexible solutions are warranted, and ongoing studies are increasingly focusing on blended digital health solutions with human support in order to enhance patient engagement and satisfaction [19]. Favorable results in combining conventional digital tools with a human touch, which has been identified as a key component, were demonstrated in an RCT focusing on the promotion of healthy GWG [20]. In line with this, Chiauzzi and Newell [19] assert that flexible use of apps based on a tailored strategy is more appropriate than reliance on the app alone. Therefore, adding personal support to digital mindfulness programs may increase their positive outcome. As digital-only methods frequently underperform compared to face-to-face approaches in addressing depression, general anxiety, and GWG, adding a personal touch seems imperative.

Personal coaching (PC) through smartphones or video may improve the mental health of pregnant women, fostering deeper interactions, on the one hand, and facilitating health-focused

XSL•FO
RenderX

conversations with health care personnel, on the other. Building on this premise, we aimed to extend previous research by comparing 2 different clinical approaches, that is, eMBI and PC. Expanding upon our previous RCT, we investigated the combined efficacy of personal support and coaching with an electronic mindfulness program in this study, specifically examining its effects on depression and anxiety as well as on maternal weight gain as a secondary outcome in pregnant women.

Methods

Patients

Participating centers were the university hospitals of Heidelberg and Tübingen, along with over 200 gynecological practices in the state of Baden-Wuerttemberg, Germany, as detailed in our previous publication [14]. Briefly, we screened 5299 pregnant women using the Edinburgh Postnatal Depression Scale (EPDS) between February 2019 and October 2020. Those scoring above 9 were enlisted to participate in an 8-week eMBI from their 29th to 36th gestational weeks. Demographic and psychometric data were collected before, during, and up to 6 months after the intervention and compared with the control group (CG).

For this subanalysis, we compared participants who received more than one face-to-face coaching session during the study period (personal coaching group [PC group]), with participants who received only the first mandatory session (no personal coaching [NPC group]). The effect of PC on psychometric parameters was evaluated in the intervention groups (IG) and CGs. The clinical study phase was conducted over a 2-year period between January 1, 2019, and December 31, 2020. The individual study period was 13 months.

Ethical Considerations

The study was approved by the ethics committees of the Medical Faculties of the Universities of Heidelberg (S-744/2018) and Tübingen (952/2018BO2) and was conducted in accordance with the ethical standards of the Declaration of Helsinki. All personal data were collected in accordance with the principles of confidentiality and the European General Data Protection Regulation (EU-GDPR). All participants provided a signed written consent and received €100 (roughly US $102) each as financial compensation. The study participants had the right to request information about the personal data collected from them. Participation in the study was voluntary after all study content and objectives had been declared and written consent had been given and could be withdrawn at any time without any disadvantages for the patient. Patient data and clinical data are recorded pseudonymously and stored centrally in the eCRF. This study follows the CONSORT (Consolidated Standards of Reporting Trials) statement (Multimedia Appendix 1) and the SPIRIT (Standard Protocol Items: Recommendations for Intervention Trials) guidelines [21]. The study was registered with the German Clinical Trials Registry (DRKS00017210).

Interventions

Expectant mothers were randomized 1:1 to the IG, where they were granted access to eMBI (IG=eMBI), or the CG, which received standard care, including an initial psychological session (CG=treatment as usual [TAU]). The eMBI, starting at 29 weeks gestation, consisted of eight weekly 45-minute sessions. These sessions provided psychoeducational and obstetrical content, along with pregnancy-adapted mindfulness exercises. Both groups completed digital questionnaires on a regular basis: every 2 weeks during the intervention (T1-T5) period and at 1 and 5 months post partum (T6 and T7). Before randomization, all women participated in a mandatory psychological assessment. Enhanced personalized care encompassed the telephone availability of supervised and professionally trained providers and access to psychological support when needed.

The eMBI was developed by a multidisciplinary team that included gynecologists, psychologists, and midwives. The questionnaires assessed sociodemographic and medical data, physiological measures, and self-reported data on maternal mental health. In addition, each participating woman had weekly access to a self-developed digital pregnancy guide with educational and validated medical content focused on pregnancy and childbirth. The modules included for example the following topics: fears and worries about birth or parenting, coping with stress, birth-related pain control, and outlook puerperium.

Primary Outcome Measures

The EPDS

The EPDS, originally developed in 1998 by Cox et al [22] and translated into German by Bergant et al [23], is a 10-item self-rating scale that assesses depressive symptoms in the peripartum. The EPDS has proven to be a valid and sensitive instrument for predicting depressive disorders not only in the postnatal period but also prenatally [24]. The most commonly used cut-off score of 9 (EPDS>9) has shown a sensitivity of 0.96 and a specificity of 1.00 [25].

State-Trait Anxiety Inventory

Perinatal anxiety was measured using the German version of the State-Trait Anxiety Inventory (STAI) during the perinatal period. The questionnaire consists of two scales: The STAI-S (state scale) assesses anxiety as a temporary condition, encompassing feelings of tension, nervousness, and worry, whereas the STAI-T (trait scale) refers to dispositional anxiety over time. The sum, ranging from 20 to 80, indicates the level of situational and dispositional anxiety [26].

Pregnancy-Related Anxiety Questionnaire–Revised

The Pregnancy-Related Anxiety Questionnaire–Revised (PRAQ-R) is an abbreviated 10-item self-report measure of pregnancy and childbirth anxiety and is a valid predictor of birth and childhood outcomes [27-29]. Items include fear of childbirth, concerns about bearing a physically or mentally handicapped child, and concerns about one's appearance [30].

Secondary Outcomes

Freiburg Mindfulness Inventory

The Freiburg Mindfulness Inventory (FMI-14, also known as FFA-14) was developed according to the Buddhist rules of life. It defines mindfulness as the tendency to act in a mindful way, measured as a personal characteristic [31,32]. We used the

XSL•FO
RenderX

abbreviated German version consisting of 14 Likert-scale (1-4) items [33].

Patient Health Questionnaire

The Patient Health Questionnaire (PHQ-D), tailored for the practical screening of mental disorders in primary care, directly measures the diagnostic criteria of the *DSM-IV* (*Diagnostic and Statistical Manual of Mental Disorders* [Fourth Edition]) [34]. It has been shown to be a valid and well-accepted self-rating instrument for use in research and clinical practice, also in its German rendition [35]. The PHQ-D measures the following scales with 78 items: somatoform, depressive, anxiety, eating disorders, and alcohol abuse. It also includes items on psychosocial functioning, stress experiences, and critical life events.

BMI

Participants responded to items about body height and weight. Weight was assessed at all time points. In addition, at T1, weight before pregnancy was assessed retrospectively (T0). Thus, we were able to compute the BMI for 8 time points according to the respective formula:

Statistical Analysis Plan

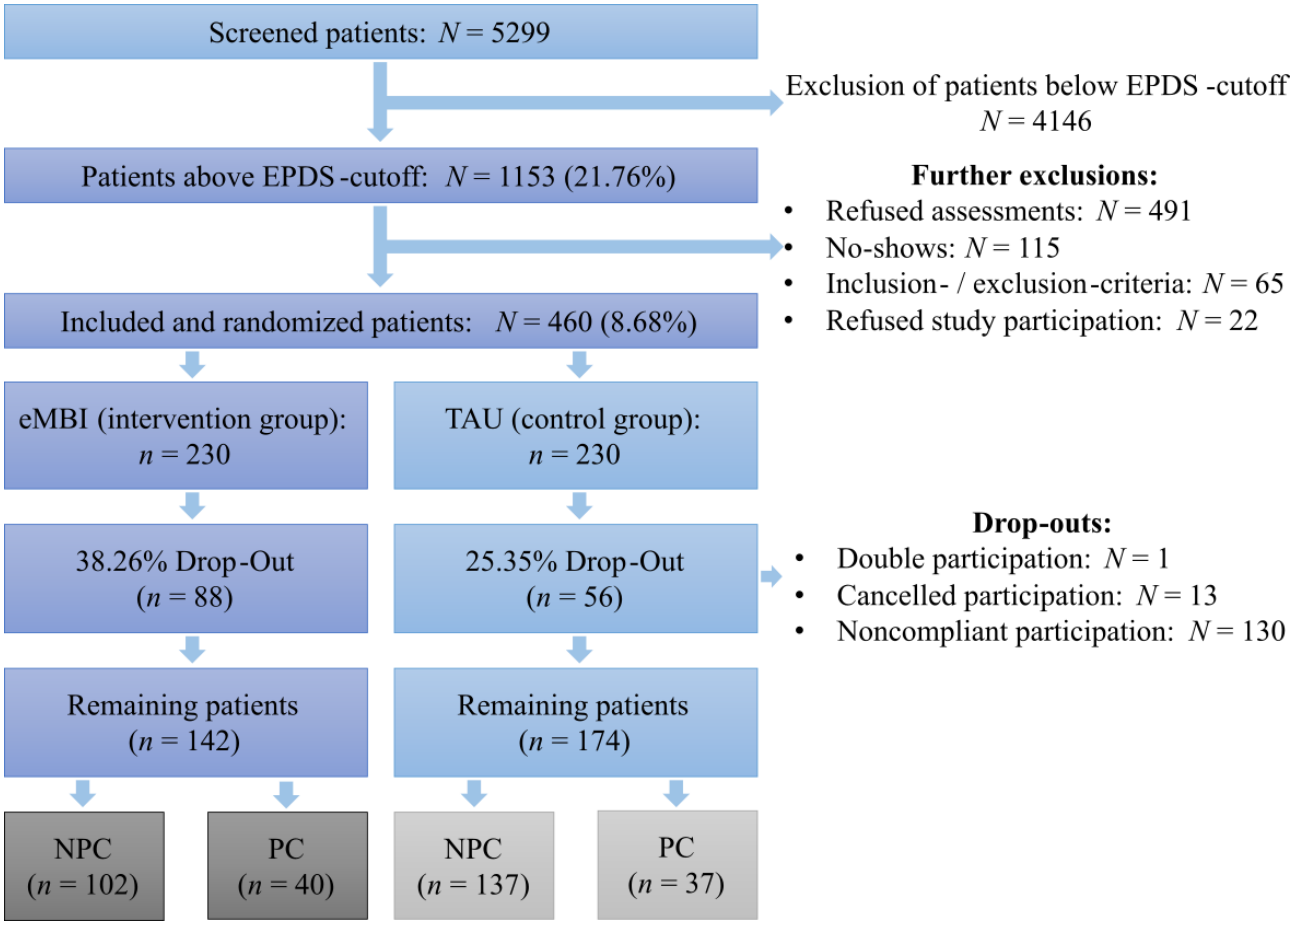
All analyses were conducted using SPSS Statistics for Windows (version 29.0.0.0-241; IBM Corp). Little's Missing-completely-at-random test was used to ensure that missing data due to dropouts and missing values were valid for our analyses [36] Moreover, the groups were tested for comparability regarding sociodemographic and medical third variables by means of *t* tests, Mann-Whitney *U* tests and chi-square tests. If differences were significant, the respective variables were analyzed for associations with the outcome variables and included as covariates.

The manipulation check (analyses regarding mindfulness as indexed by the FFA-14 scores) as well as the primary and secondary analyses were conducted using (multivariate) ANOVA with repeated measurements corrected for significant confounders. Mauchly's sphericity test was used to determine whether the sphericity assumption had been violated. If significant, repeated measures *df*s were corrected using Huynh–Feldt or Greenhouse-Geisser correction, depending on the degree of violation. Due to the exploratory nature of the current analyses, the critical, local α-errors were not adjusted and set to a conventional level of α_{local}=.05. Partial η^2 and ω^2 are used as effect sizes. These are sample-based and population-based estimators of explained variances, respectively. According to Cohen [37], η^2/ω^2=0.01 represents small, η^2/ω^2=0.06 represents medium, and η^2/ω^2=0.14 represents large effects. Dunn's multiple comparison procedure [38] was performed as a post hoc test for significant effects relevant to the hypotheses. This procedure results in a minimum significant difference (ψ).

The final sample consisted of 460 participants. However, due to dropouts and further missing values, the number of valid cases varies. Post hoc power calculations (calculated with G*Power; version 3.1.9.7) [39,40] for nonsignificant results are reported in the results section. However, in our ANOVAs, mainly, the power was virtually 1–β=1.0 for large (*f*=0.40) within- and between-subject effects as well as for medium-sized within-subject effects (*f*=0.25).

Main and interaction effects are not reported or interpreted in detail if the respective factors are significantly interacting with additional factors. Also, the main effects of confounders are not reported and interpreted in detail.

Results



Descriptive Characteristics

The flow chart is presented in Figure 1. Results of the Missing-completely-at-random test were not significant ($\chi^2_{25,073}$=25,104.7, *P*=.44). All sociodemographic characteristics and tests on comparability are demonstrated in Tables 1 and 2. The IG and the CG statistically significantly differed regarding the PHQ score, the number of children at home, and the educational level (refer to Table 1): the IG scored lower in the PHQ stress evaluation, had more children at home, and had a lower educational level than the CG. There were no significant differences between the NPC and the PC groups (refer to Table 2).

The potential confounders identified were correlated with the outcome variables: The PHQ stress evaluation was significantly associated with every outcome at every measurement point, except the BMI. The associations (*r*) ranged between 0.201 and 0.479 (*P*<.001), showing the highest association with the STAI-T at T6 and the lowest association with the PRAQ-R at T5. The numbers of children at home were significantly associated with the FFA-14, the STAI-S, and STAI-T, as well as the PRAQ-R (ρ ranging between–0.241 and 0.173) for the highest positive association with the STAI-S at T1 and the highest negative association with the PRAQ-R at T1 (levels of significance [*P*] ranging between <.001 and .048). The level of education was significantly associated with the EPDS, STAI-S, and STAI-T, and the BMI (ρ ranging between–0.346 and –0.122) for the highest negative association with the BMI at T4 and the lowest negative association with the EPDS at T1 (levels of significance [*P*] ranging between <.001 and .04). Consequently, we controlled these variables as covariates in the respective analyses. Descriptive statistics of outcome measures are shown in Table 3.

[a]FFA-14: Freiburg Mindfulness Inventory.

Manipulation Check (FFA-14)

As covariates a 2 (group) × 2 (coaching) × 3 (time) ANOVA with PHQ stress evaluation and the number of children at home were used. The assumption on sphericity was significantly violated (P<.001) and thus Huynh-Feldt correction was applied (ε=.936). There was a significant main effect of time (P<.001).

Moreover, a significant interaction effect was observed between group and time ($F_{1.873,344.619}$=4.560, P=.01, η^2=0.024, ω^2=0.012). Dunn's post hoc test (Ψ_{Dunn}=1.9) revealed a significant increase from T1 to T5 and T7 for the IG, but also an increase from T1 and T5 to T7 for the CG. However, the IG score is significantly higher than the CG score at T5. In addition, there was a significant interaction effect between coaching and time ($F_{1.873,344.619}$=4.585, P=.01, η^2=0.024, ω^2=0.012). Dunn's post hoc test (Ψ_{Dunn}=2.4) revealed a significant increase from T1 to T5 and T7 but only for the PC group (refer to Figure 2).

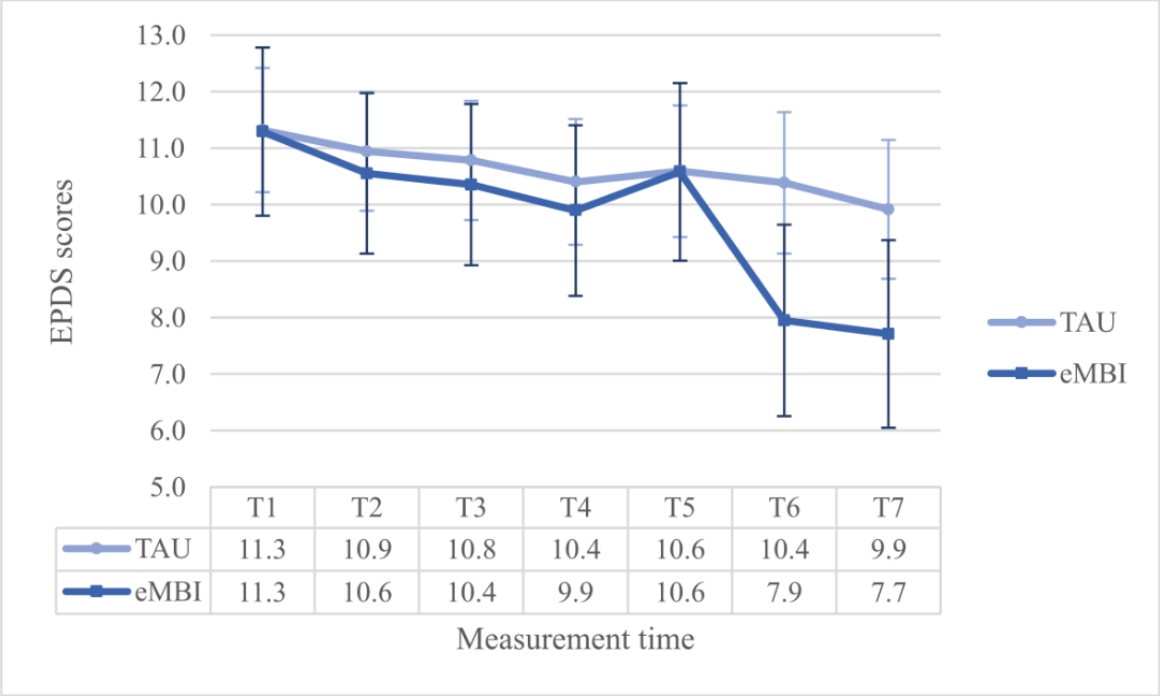
Figure 2. Interaction effect between coaching and time regarding FFA-14 scores. GW: gestational week; T1: 28th GW; T5=36th GW; T7=5 months postpartum; NPC: no personal coaching; PC: personal coaching.

Furthermore, a significant main effect of the PHQ stress evaluation was observed. There were no other significant main (P≥.14) or interaction effects (P≥.09).

We calculated a power of 1–β=.927 for medium-sized between-subject effects and 1–β=.816 for small within-subject effects (f=0.10). Only small between-subject effects cannot be ruled out sufficiently with 1–β=0.232.

Symptoms of Depression According to EPDS

As covariates a 2 (group) × 2 (coaching) × 7 (time) ANOVA with PHQ stress evaluations and the highest school educational level were used. The assumption on sphericity was significantly violated (P<.001) and thus Huynh-Feldt correction was applied (ε=.793).



We found significant main effects of the PHQ stress evaluation (P<.001) and maternal education (P=.01). Moreover, the main effect of the group was significant ($F_{1,147}$=7.845, P=.006, η^2=0.051, ω^2=0.04), revealing a generally lower EPDS score for the IG (mean 9.3, SE 0.5) than for the CG (mean 11.2, SE 0.4).

The coaching time—interaction effect was significant, too (P=.04). Most importantly, this interaction term was enriched by a significant 3-way interaction term ($F_{4.758,699.423}$=3.033, P=.01, η^2=0.020, ω^2=0.009): Dunn's post hoc test (Ψ_{Dunn}=4.1) revealed significant differences at T4 and T5 between the IG and the CG, but only in the PC group (Figures 3 and 4).

Findings were nonsignificant for all other between- (P≥.12) and within-subject effects (P≥.07). The power was 1–β=0.983 for medium-sized (f=0.40) between-subject effects. Only small within-subject and between-subject effects (f=0.10) cannot be ruled out sufficiently with 1–β=.590 and 1–β=.313.

	T1	T2	T3	T4	T5	T6	T7
TAU	13.0	12.7	13.0	13.0	11.5	10.1	9.2
eMBI	12.7	10.7	9.8	7.3	6.3	6.9	8.2

General Anxiety According to the STAI

As covariates a 2 (group) 2 (coaching) 7 (time) MANOVA with PHQ stress evaluations, the number of children at home, and the highest educational level were used. There was a significant main effect of PHQ stress evaluation (P<.001). Moreover, a significant main effect of group was observed (P=.04), which was enriched by a significant 2-way interaction term between group and time (P=.01) as well as a significant 3-way interaction term ($F_{12,129}$=2.361, P=.01, η^2=0.0180, ω^2=0.100).

Findings were nonsignificant for all other between- (P≥.29) and within-subject effects (P≥.23). The power was 1–β=.920 for medium-sized (f=0.40) within- and .981 for medium-sized between-subject effects. Only small within-subject and between-subject effects (f=0.10) cannot be ruled out sufficiently with 1–β=0.175 and 1–β=0.307. Therefore, we calculated two

2 (group) 2 (coaching) 7 (time) post hoc ANOVAs (one for each STAI-measure) with PHQ stress evaluations, the number of children at home, and the highest educational level as covariates.

State Anxiety According to the STAI-S

The assumption on sphericity was significantly violated (P<.001) and thus Huynh-Feldt correction was applied (ε=.817). A significant main effect of the PHQ stress evaluation was observed (P<.001). Moreover, there was a significant main effect of the group (P<.05).

However, there was a significant interaction effect between group and time (P=.01), which was enriched by a significant 3-way interaction term ($F_{4.902,686.330}$=4.422, P=.001, η^2=0.031, ω^2=0.016): Dunn's post hoc test (Ψ_{Dunn}=8.8) revealed significant differences between the IG and the CG at T3, T4, and T5, but only in the PC group (Figures 5 and 6).

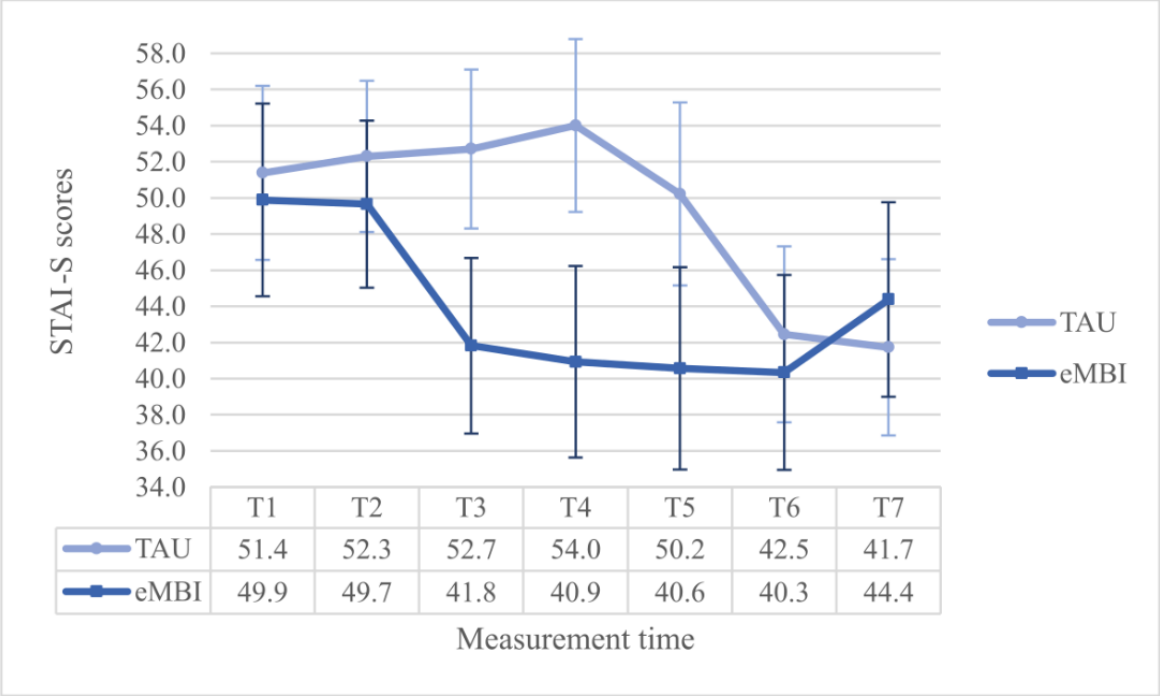

Figure 5. Group x time-interaction effect regarding STAI-S scores for the NPC group. GW: gestational week; PP: postpartum; T1: 28th GW; T2: 30th GW; T3: 32nd GW; T4: 34th GW; T5 = 36th GW; T6: 1 month PP; T7: 5 months PP; TAU: treatment as usual; eMBI: electronic mindfulness-based intervention.

Trait Anxiety According to the STAI-T

The assumption on sphericity was significantly violated (P<.001) and thus Greenhouse-Geisser correction was applied (ε=.691). A significant main effect of the PHQ stress evaluations was observed (P<.001).

Moreover, there was a significant interaction effect between group and time (P=.02). However, this interaction term was enriched by a significant 3-way interaction term ($F_{4.902,686.330}$=4.689, P=.001, η^2=0.032, ω^2=0.015): the Dunn post hoc test (Ψ_{Dunn}=8.0) revealed significant differences between the IG and the CG at T4 and T5, but only in the PC group (Figures 7 and 8).

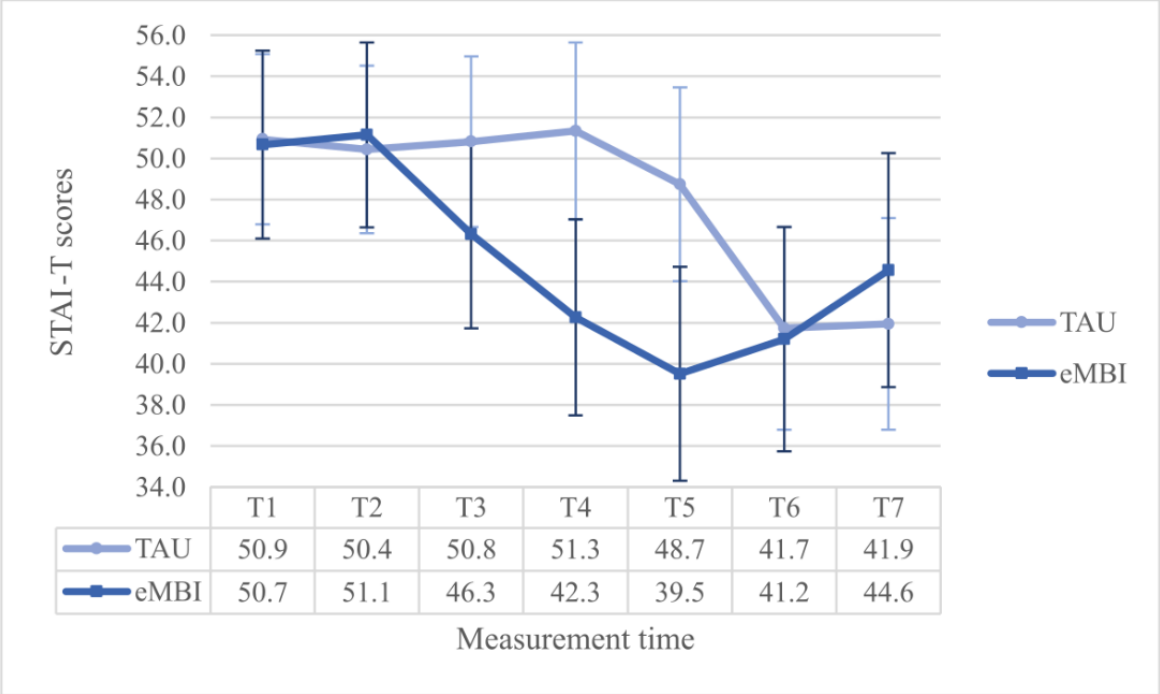

Figure 7. Group x time-interaction effect regarding STAI-T scores for the NPC group. eMBI: electronic mindfulness-based intervention; GW: gestational week; PP: postpartum; T1: 28th GW; T2: 30th GW; T3: 32nd GW; T4: 34th GW; T5: 36th GW; T6: 1 month PP; T7: 5 months PP; TAU: treatment as usual.

	T1	T2	T3	T4	T5	T6	T7

Figure 8. Group x time-interaction effect regarding STAI-T scores for the PC group. eMBI: electronic mindfulness-based intervention; GW: gestational week; PP: postpartum; T1: 28th GW; T2: 30th GW; T3: 32nd GW; T4: 34th GW; T5: 36th GW; T6: 1 month PP; T7: 5 months PP; TAU: treatment as usual.

Pregnancy-Related Anxiety According to the PRAQ-R

As covariates a 2 (group) 2 (coaching) 5 (time) ANOVA with PHQ stress evaluation and number of children were used. Huynh-Feldt correction was applied (ε=.812) as the assumption on sphericity was significantly violated (P<.001). We found significant main effects of the PHQ stress evaluation (P<.001) and number of children (P<.001).

No other significant differences were found between- (P≥.10) or within-subject effects (P≥.14). In this analysis, the power was additionally virtually 1–β=.998 for small within-subject effects (f=0.10). Furthermore, it was 1–β=0.959 for medium-sized between-subject effects (f=0.25). Only small between-subject effects cannot be ruled out sufficiently with 1–β=0.264.

BMI

As a covariate a 2 (group) × 2 (coaching) × 8 (time) – ANOVA with the highest school educational level was used. The assumption on sphericity was significantly violated (P<.001) and thus Greenhouse-Geisser correction was applied (ε=.508). There was a significant main effect of time (P<.001).

The group × time--interaction effect was significant, too (P=.04). Most importantly, this interaction term was enriched by a significant three-way-interaction term ($F_{3.555,\ 444.416}$=4.732, P=.002, η^2=0.036, ω^2=0.013): the Dunn post hoc test (Ψ_{Dunn}=1.5) revealed significant differences at all assessments between the IG and the CG in the NPC group and at all assessments except T0 in the PC group. In the PC group, the IG generally reports a lower BMI than the CG. However, in the NPC group, it is the opposite (Figures 9 and 10).

Moreover, we found a significant main effect of maternal education (P=.01). Furthermore, there was a significant interaction effect between the groups with or without coaching (P=.01), however, as there was a significant 3-way interaction term as reported above, we did not further investigate this interaction effect.

Findings were nonsignificant for all other between- (P≥.57) and within-subject effects (P≥.19). In this analysis, the power for even small within-subject effects (f=0.10) was virtually 1. The power was 1–β=0.983 for large (f=0.40) between-subject effects. Medium-sized (f=0.25) and small between-subject effects cannot be ruled out sufficiently with 1–β=.680, 1–β=.142.

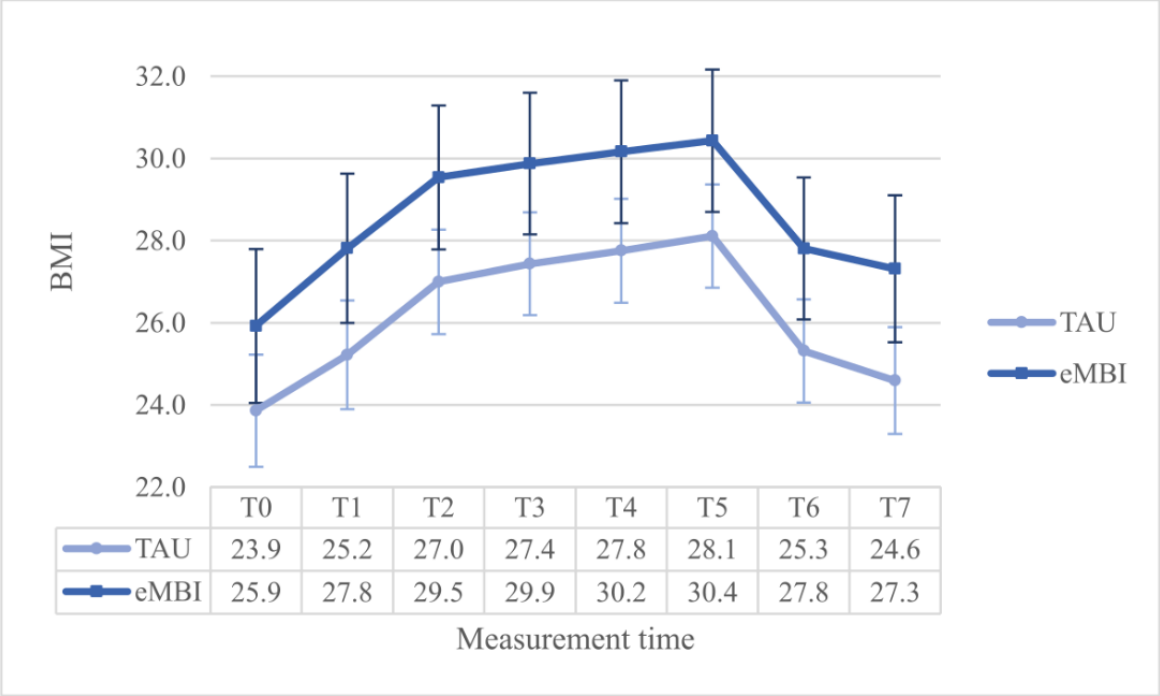

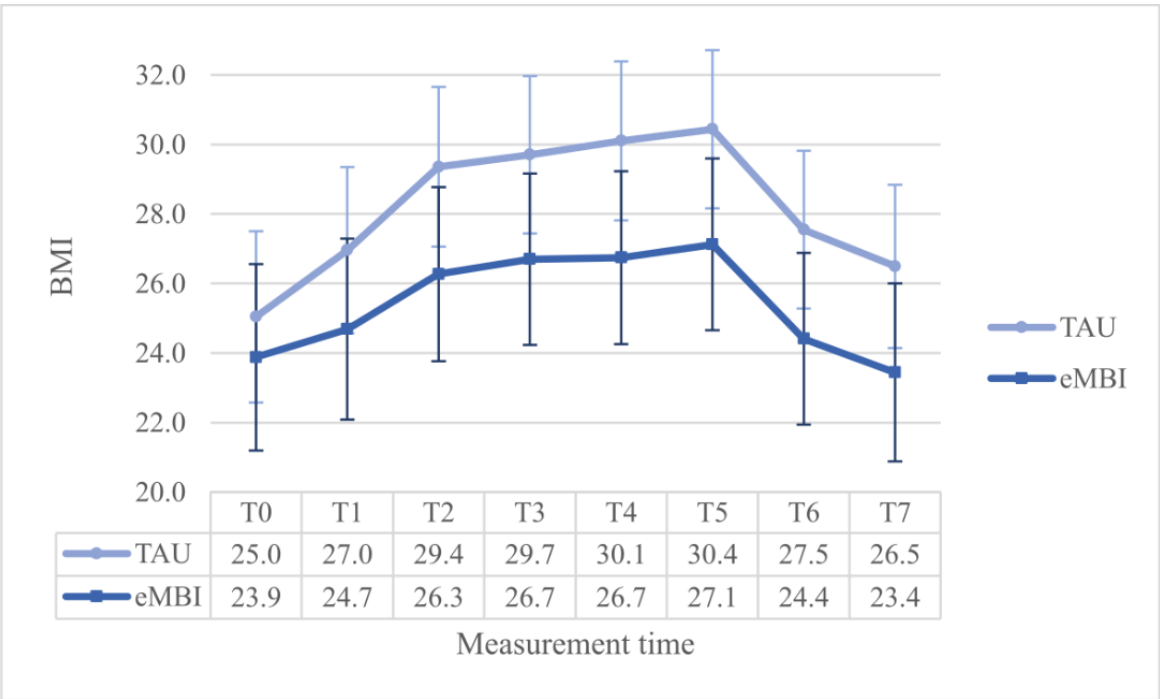

Figure 10. Group x time-interaction effect regarding BMI for the PC group. eMBI: electronic mindfulness-based intervention; GW: gestational week; PP: postpartum; T0: before pregnancy; T1: 28th GW; T2: 30th GW; T3: 32nd GW; T4: 34th GW; T5: 36th GW; T6: 1 month PP; T7: 5 months PP; TAU: treatment as usual.

Discussion

Principal Findings

The aim of the present RCT subanalysis was to examine the effectiveness of a mindfulness-based blended care approach on maternal depression, anxiety, pregnancy- or birth-related anxiety, as well as weight control. Our results show that the eMBI alone has the potential to significantly improve birth- and pregnancy-related anxiety and mindfulness, with long-lasting effects up to 5 months after delivery. However, combining the eMBI with 2.3 PC sessions on average also significantly reduced state and trait anxiety and depression already during pregnancy and, as a side effect, revealed a significant positive influence on maternal BMI. These results favor blended care models combining digital interventions with a minimal amount of personal support by demonstrating the significant effectiveness

XSL•FO
RenderX

on perinatal mental health as well as on GWG during pregnancy and the postpartum period. Regarding maternal weight gain, pregnant women in the IG combined with PC generally reported a significantly lower BMI than women in the CG.

Comparison to Previous Work

The observation that a mindfulness intervention improves the mental health and well-being of pregnant mothers is consistent with findings from previous studies [13,16]. Looking deeper, studies using a mere digital approach often failed to find a benefit of such interventions for psychological distress while face-to-face interventions usually did [41,42]. On the other hand, programs that can be delivered digitally, such as the eMBI program used in our study, appear to be particularly beneficial for a high retention rate [43,44]. Therefore, the results of this subanalysis support the hypothesis that the failure of digital interventions to show effectiveness in lowering depression and general anxiety in contrast to face-to-face interventions might suggest that, in order to positively impact general mental health, a small personal component needs to be added, whereas the positive effects on birth anxiety can be achieved digitally [45]. Therefore, the results of the present study emphasize the importance of personal support in reducing depressive and anxiety symptoms as well as GWG, as these symptoms decreased significantly when participants had 2 or 3 PC sessions on average. In line with this, Bright et al [46] demonstrated the positive effect of interpersonal psychotherapy on maternal well-being during the perinatal period. Favorable findings that support the superiority of a blended care approach compared to a mere digital intervention have been recently published by Martin-Key et al [47] within in the framework of an anonymous online survey in the United Kingdom. Overall, 38% of 829 participating women showed a preference for a blended care approach in order to assess perinatal mental health, whereas only 12% preferred a digital-only consultation [47].

Regarding gestational weight gain and maternal BMI as secondary outcome measures, our results support the hypothesis that digital mindfulness interventions have the potential to positively influence health behaviors including stress and weight management during pregnancy [48]. In particular blended care approaches seem to be effective in providing health-promoting lifestyle modifications and complementing traditional diet and exercise programs [49]. However, in contrast to our study previous ones have not been generated as part of randomized-controlled trials and should be interpreted with caution. Furthermore, differing from previous research, the impact of PC in addition to eMBI on maternal BMI even reached significance in the present sub-analysis of our RCT [48]. However, the number of high-quality and large-scale studies is scarce so far and further research, preferably in the form of an RCT, should be conducted in the future to investigate the feasibility and cost-effectiveness of implementing digital tools into standard clinical routine.

In terms of the respective demographic characteristics results showed that the level of education was significantly associated with the EPDS, STAI-S and STAI-T, and the BMI. According to the current status of the literature former studies find that lower educational levels and socioeconomic status are associated with higher prepregnancy BMI and a higher rate of excessive gestational weight gain [50]. Vice versa, education often correlates not only with socioeconomic status but also with the pursuit of a health-promoting lifestyle [51]. Further negative associations on a significant level have been found between perinatal depression and anxiety on the one hand and educational level on the other hand. The bidirectional association between educational attainment and maternal mental health has been published before [52,53].

Thus, our study results support the use of a blended care approach not only regarding mental health but also in order to promote healthy lifestyle habits and should be taken into account while implementing digital intervention tools into clinical routine. In contrast to previous research, our study results were generated as part of an RCT contributing to good validity and reliability.

Strengths and Limitations

Our study has the potential to provide high-quality implementation knowledge of a complex mHealth eMBI and coaching intervention for the perinatal period. Being the largest trial across Europe with screening numbers of more than 5000 pregnant women, the Mind: Pregnancy study has the potential to provide high-quality data on the effectiveness of digital eMBI and coaching interventions for preventive and alternative treatment of perinatal mental health problems. Indeed, the results of this evaluation yield important findings that will potentially support the improved health of women and children. The main strength of our study lies in its prospective, longitudinal design with a follow-up period of up to 5 months after childbirth and the inclusion of a CG. The intervention and the peripartum assessments were provided as part of an app and are thus easily and universally applicable and cost-effective. Another strength of our study is that mental health was examined according to a multidimensional approach based on DSM or ICD criteria. In addition, a broad range of confounders were considered.

However, the applicability of the study is limited by several factors that should be considered. First, PC was provided on an as-needed basis during the 8-week intervention period and not in a standardized way, making it difficult to identify a best practice guideline for optimal outcomes. Second, the number of sessions varied, and it remains unclear at what point in the last trimester PC might be most effective in improving mental health. This should be the subject of further research based on the findings of this study. Third, in these analyses, the power to detect in particular small between-subject effects was low. Finally, but not least, the number of observations varies between subgroups. Thus, the results of the interaction terms should be interpreted with caution and should be evaluated in further research. If applicable, a standardized personal component with a fixed amount of sessions should be implemented to improve the validity and reliability of the study findings.

In order to further prove the effect on maternal weight gain, it would be interesting to evaluate the development of the BMI with similar baseline characteristics.

Despite the limitations, our study presents evidence that a blended care approach is potentially highly effective not only

XSL•FO
RenderX

in optimizing perinatal mental health but also in affecting maternal weight gain as a synergistic effect. Due to the increasing accessibility of digital interventions, widespread implementation of these interventions should be encouraged.

Conclusion

In conclusion, our results provide evidence that a blended care model combining digital with a small amount of personal care can potentiate the effect of eMBIs on depressive symptoms and general anxiety with lasting effects up to several months postpartum and can significantly influence maternal BMI. This intervention is a low-cost, easy-to-use intervention for pregnant women to improve their well-being and mental health. However, especially in light of the ongoing digitalization in medical care, it is essential to investigate the potential of individualized, personalized care in everyday clinical practice.

Abstract

Background: Regular exercise may counteract obesity-related health risks, but adherence is low among individuals with obesity. Personal trainers may positively influence exercise behavior by providing motivational support. Individuals who receive regular exercise coaching are more likely to adhere to their exercise routine, compared with those who exercise individually. However, investing in personalized exercise guidance, such as a personal trainer, can be expensive for the individual. Thus, integrating web-based coaching could be a more economically sustainable option, offering both flexibility and reduced costs compared with in-person coaching only. Yet, research is needed to assess the effect of hybrid models in improving psychosocial factors among women with obesity.

Objective: This 20-week, pragmatic randomized controlled trial aimed to investigate the effect of weekly in-person coaching compared with 2 combinations of in-person and web-based coaching on 5 psychosocial factors in women with obesity (BMI ≥30 kg/m^2).

Methods: Participants were invited through Facebook and Instagram advertisements posted by various fitness clubs across rural and urban locations in Norway (7 different counties and 12 different municipalities). Women with low activity (n=188; <150 minutes of moderate-intensity physical activity/week; 42.7, SD 10.5 years; mean BMI of 35.1, SD 6.9 kg/m^2) were allocated into 3 groups of in-person coaching—weekly (n=47), twice weekly (n=47), and once monthly (n=47)—and as controls (n=47). Those with twice weekly and once monthly in-person coaching received web-based coaching of 15 minutes during weeks without in-person coaching. Data included background variables, motivation (Behavioral Regulation in Exercise Questionnaire-2), barriers, self-efficacy (The Self-Efficacy Survey), social support (Social Support Questionnaire), and health-related quality of life (36-Item Short Form Health Survey [SF-36]).

Results: A total of 120 (64%) out of 188 participants completed baseline and postintervention assessments. A minor difference was observed in one item of the SF-36, where all intervention groups reported a greater "change in health last year" than the control group (mean difference: 14.2-17.1, 95% CI 2.04-29.5; g=0.79-1.14; P≤.01). No other effects were found on the selected psychosocial factors. It should be noted that controls reported higher intrinsic motivational regulation at baseline than intervention groups (mean difference: 0.43-0.93; P≤.05). All intervention arms exercised more frequently than controls (mean difference: 1.1-1.5; P≤.001), with no differences in weekly exercise frequency between the 3 intervention arms (P=.30).

Conclusions: We found no effects on motivation, barriers, self-efficacy, perceived social support, or other health domains compared with controls. All intervention groups reported a slight improvement in self-perceived health in 1 of the 8 subscales of the SF-36. Combined in-person and web-based coaching may give a minor improvement in self-perceived health in women with obesity. However, the lack of impact on motivation, barriers, and self-efficacy warrants further research.

Introduction

Obesity (BMI ≥30 kg/m^2) is a major global health challenge, significantly economically burdening the health care and welfare systems [1,2]. Worldwide, the obesity rate has nearly tripled in the past 35 years, and it is estimated that 1 billion adults will have obesity in 2030 [3-5]. It affects women more than men, with 1 in 5 women and 1 in 7 men living with obesity [5,6]. Obesity increases the risk of noncommunicable diseases, such as cardiovascular disease, metabolic disease, and type 2 diabetes [7-11]. It is also negatively associated with mental health conditions, including anxiety, personality disorders, binge eating, and schizophrenia [12].

Structured exercise programs have become a key element in obesity management worldwide, offering benefits for both physiological and psychological well-being [13-15]. Regular exercise can mitigate obesity-related health risks and is widely recommended, along with diet advice and behavioral strategies, as part of a comprehensive treatment strategy [9,11,16-18]. The feasibility of these programs is frequently challenged by barriers such as time constraints, logistical issues, and accessibility, particularly for women with obesity [13,14]. In addition, the complexity of implementing lifestyle changes often results in low adherence rates, which limits the associated health benefits [19,20]. This challenge is further compounded by the fact that individuals with obesity tend to be more sedentary and less active than those of normal weight, and women are less likely than men (32% versus 23%) to meet physical activity recommendations (150 to 300 minutes of moderate-intensity or 75 to 150 minutes of vigorous-intensity physical activity per week) [21-24].

Low levels of motivation, limited strategies to overcome barriers, lack of self-efficacy, inadequate social support, and poor physical or mental health negatively impact an individual's ability to maintain regular exercise [19,25-28]. Exercise coaching may positively influence these factors by fostering autonomy (eg, offering choices and alternatives), building competence (eg, providing positive feedback and promoting skill development), and improving relatedness (eg, offering emotional support) [28-31]. As a result, these elements collectively have the potential to improve adherence to exercise [28,32-34]. Randomized controlled trials (RCTs) have shown that personal trainers help clients adhere more consistently to exercise by equipping them with strategies to overcome barriers, fostering a sense of community, and enhancing self-efficacy through knowledge and confidence building [31,32,35-37].

Further, perceived social support has been shown to encourage regular participation in exercise, particularly among women rather than men [25,38,39]. In addition, obesity is often associated with lower self-perceived health, and individuals who perceive their health as poor may face physical limitations that hinder participation in regular exercise [27,40]. A personal trainer can develop customized exercise programs that address these physical limitations, helping clients overcome barriers and ultimately improve their perceived health-related quality of life [41,42].

Although individuals with obesity might acknowledge the benefits of personal trainers in providing exercise motivation and support, their use is often limited by barriers such as accessibility, time constraints, socioeconomic resources, and cost concerns [43-45]. The high cost of hiring a personal trainer also often limits the frequency of follow-up sessions. Mobile exercise apps have emerged as a popular and accessible alternative [14]. When used in conjunction with or as an extension of qualified exercise professionals, mobile apps may enhance exercise adherence [14]. Hence, integrating web-based coaching is an attractive alternative due to its cost-effectiveness and accessibility. Web-based coaching offers flexibility and lower costs compared with in-person coaching [46,47], while in-person coaching provides unique advantages, such as fostering deeper personal relationships that may be vital for sustained exercise adherence. Consequently, hybrid models combining in-person and web-based coaching have gained popularity, as they provide the flexibility and convenience of web-based coaching with the direct interaction and personalized feedback of in-person coaching. These models show potential for promoting behavior change by meeting a wider range of client needs. However, the effectiveness of such combined approaches, particularly for women with obesity, requires further investigation [46,47]. Hence, further research is needed to evaluate the potential of hybrid models in addressing key psychosocial factors to exercise adherence, particularly for women with obesity. While these models are promising in combining accessibility with personalized support, their ability to positively influence motivation, barriers, self-efficacy, social support, and health-related quality of life remains unclear. In addition, to provide a "real-life" approach, weekly in-person coaching is needed as a comparison group, as it represents the most common mode of in-person coaching among clients [48]. Understanding how such hybrid models can optimize psychosocial outcomes in this population is crucial for developing effective and sustainable interventions.

In women with obesity, our 20-week, 4-armed, pragmatic RCT aimed to investigate the effects of weekly in-person coaching compared with 2 different combinations of in-person and web-based coaching on motivation, barriers, self-efficacy, social support, and health-related quality of life.

Methods

Overview

This 20-week, 4-armed, pragmatic RCT's primary outcomes were exercise adherence, aerobic capacity, and muscular strength. Hence, this study presents a secondary analysis of the intervention's effect on perceived motivation, barriers to exercise, self-efficacy, social support, and health-related quality of life.

Participants were invited through Facebook and Instagram advertisements posted by various fitness clubs across rural and urban locations in Norway (7 different counties and 12 different municipalities). The recruitment was ongoing in February 2023, with eligible participants enrolled continuously. Unfortunately, data on the total number of interested participants were not collected. The inclusion criteria were BMI ≥30 kg/m^2, aged 18 to 65 years, no membership in a fitness club 6 months before recruitment, being classified as low activity (<150 minutes of moderate-intensity or 75 minutes of vigorous-intensity physical activity per week), Norwegian speaking, and having a smartphone. Exclusion criteria were chronic disease or injuries (eg, severe hypertension 180/110 mm Hg, heart disease, lung disease, or functional impairment) that hindered participation in exercise and planned leave during the intervention period. To ensure that none of the participants had any contraindications for exercise, all participants underwent a general health screening by their general practitioner.

A total of 188 participants were included, and informed consent was signed to participate. A blinded statistician performed random allocation (1:1:1:1) following a simple computer-based randomization program (R for Windows, version 4.2.2; R Foundation for Statistical Computing), and the participants were allocated to (1) once a week (in-person exercise coaching 100% [IP100], n=47), (2) twice a month (in-person exercise coaching 50% [IP50], n=47), or (3) once a month (in-person exercise coaching 25% [IP25], n=47) in-person coaching, or as controls (n=47). The intervention groups were provided the same weekly frequency of follow-up, but in IP50 and IP25, a total of 50% (2/4) and 75% (3/4) of the follow-up sessions were replaced with 15-minute digital sessions, respectively. An overview of intervention arms is shown in Textbox 1.

Textbox 1. Overview of intervention arms in this 20-week, pragmatic randomized controlled trial.

In-person exercise coaching 100% (IP100)

- One weekly in-person exercise coaching.
- A total of 20 hours of in-person coaching.
- Access to the ABEL-app (Abel Technologies AS) including individual exercise programs, progress charts, nutritional advice, and motivational notices.
- 20 weeks fitness club membership.

In-person exercise coaching 50% (IP50)

- Two monthly in-person exercise coaching and 15 minutes of web-based coaching during weeks without in-person coaching.
- Total of 10 hours of in-person coaching during the intervention.
- Access to the ABEL-app including individual exercise programs, progress charts, nutritional advice, and motivational notices.
- 20 weeks fitness club membership.

In-person exercise coaching 25% (IP25)

- One monthly in-person exercise coaching and 15 minutes of web-based coaching during weeks without in-person coaching.
- Total of 5 hours of in-person coaching during the intervention.
- Access to the ABEL-app including individual exercise programs, progress charts, nutritional advice, and motivational notices.
- 20 weeks fitness club membership.

Control group

- Was asked to continue with normal life.
- Received the "Norwegian Directorate of Health's" recommendations for physical activity and nutrition.
- Access to the ABEL-app to register physical activity and exercise, but were not provided with individual exercise programs, nutritional advice, and motivational notices.

A total of 23 exercise professionals, all employed as personal trainers, were recruited to provide follow-up for study participants. Trainers needed at least 3 years of part-time experience and to have led at least 80 exercise sessions/month recently. Of the 23 trainers, 10 had acquired certification as personal trainers, 8 held relevant bachelor's or master's degrees in fields such as exercise science or physiotherapy, and 5 had bachelor's or master's degrees in health and social care education. The trainers were instructed to follow up with each participant and create customized weekly exercise programs

XSL•FO
RenderX

based on their needs. They also offered lifestyle advice, such as coaching in maintaining a healthy diet. Our study design did not allow for further masking of study participants or the personal trainers.

Measures

Overview

A standardized electronic survey was used to obtain information about exercise motivation, barriers to exercise, self-efficacy, social support, and health-related quality of life, as well as background variables (body weight and height, age, education, household income, and occupation). The survey took approximately 20 minutes to complete, with all questions being close ended. Of the 188 participants, 120 (64%) participants completed the questionnaire at both baseline and after 20 weeks (postintervention) and were included in the current analysis.

Exercise Motivation

The measurement of exercise motivation was based on a Norwegian version of the validated Behavioral Regulation in Exercise Questionnaire-2 (BREQ-2) [49], assessing the stages of the self-determination continuum of motivation. The BREQ-2 comprises 5 subscales, with a total of 19 statements. For each statement, the participants rated the significance of each statement as a personal motive to engage, or not engage in exercise, on a 5-point scale (from "0 not true for me" to "4 very true for me"). A sum score (from 0 to 4) for each subscale was calculated by adding scores from each statement, divided by the number of statements. The BREQ-2 has good internal consistency for all 5 subscales (Cronbach α >0.7) [49,50]. In our study, Cronbach α values for the 5 subscales were as follows: 0.81 and 0.87 (intrinsic regulation), 0.69 and 0.80 (identified regulation), 0.73 and 0.80 (introjected regulation), 0.83 and 0.81 (external regulation), and 0.82 and 0.79 (amotivation) for before and after the intervention, respectively.

Barriers to Exercise

Barriers to exercise were assessed based on factors identified in a large-scale study among the Norwegian adult population [51] and a previous study among fitness club members [52]. The questionnaire section contained 18 barriers categorized into 4 subscales. The participants rated how limiting they perceived each barrier to be on a 3-point scale, ranging from "1 not important to me" to "3 very important to me." By adding the score from each barrier divided by the number of statements, a sum score (from 1 to 3) for each subscale was calculated. The barrier subscales in the previous large-scale Norwegian study [51] have been shown to have Cronbach α values above 0.70 for the practical, health-related, and affective-cognitive subscales, but lower for the priority subscale. In this study, Cronbach α values for the 4 subscales were as follows: 0.53 and 0.50 (priority), 0.46 and 0.51 (practical), 0.22 and 0.39 (health-related), and 0.61 and 0.63 (affective-cognitive) for before and after the intervention, respectively. As expected, Cronbach α was lowest for subscales with the fewest items, and these subscales should be interpreted with care. Internal consistency of the whole barrier questionnaire was higher, as determined by Cronbach α as follows: 0.66 at baseline and 0.72 at posttest.

Self-Efficacy

An abbreviated and validated version of the Self-Efficacy Survey, comprising 2 subscales and a total of 12 statements, was used to measure self-efficacy for exercise [53]. The participants rated each statement on a 5-point scale (from "1 I know I cannot" to "5 I know I can") in how confident they were to increase or continue with regular exercise under a wide range of conditions. For each subscale, a sum score (from 1 to 5) was calculated by adding the scores of each statement, divided by the number of statements. The Self-Efficacy Survey has been shown to have good test-retest reliability and internal consistency [53]. In our study, Cronbach α values for the 2 subscales were as follows: 0.89 and 0.90 ("sticking to it"), and 0.63 and 0.55 ("making time for exercise") for before and after the intervention, respectively. Cronbach α was lowest for the subscale with 4 items and this subscale should be interpreted with care. The internal consistency of the entire Self-Efficacy Survey was high, as determined by the Cronbach α are as follows: 0.80 at baseline and 0.90 at posttest.

Social Support

Social support for exercise was based on a validated survey developed by Sallis et al [54], consisting of 13 statements. The participants rated each statement on a 5-point scale, ranging from "1 none" to "5 very often," in how often their family or friends had been supportive of them exercising. A total social support score was calculated (from 13 to 65) by adding the scores from each of the statements, where higher scores demonstrated greater social support for exercise. The 2 sections (family and friends) were merged. The original survey has been shown to have acceptable test-retest reliability and internal consistency [54]. In our study, Cronbach α values for the 13 statements concerning social support were 0.83 and 0.87 at baseline and posttest.

Health-Related Quality of Life

The 36-Item Short Form Health Survey (SF-36) was used to measure subjective evaluations of health-related quality of life. The questionnaire encompasses 8 health-related subscales with 2 to 10 questions or statements and a single item that provides an indication of perceived change in health last year. Each set of response options is designed to quantify the intensity of the participant's feelings or limitations of health and well-being [55]. As recommended, we precoded all items on a 0 to 100 range with a high score presenting a more favorable health state. A sum score for each subscale was then calculated by adding scores from each statement, divided by the number of statements. A Norwegian version of SF-36 has been shown to have good internal consistency for all subscales (Cronbach α >0.80) [56]. In our study, Cronbach α values for the 8 subscales pre/post was as follows: 0.84 and 0.85 ("physical functioning"), 0.84 and 0.90 ("role limitations due to physical health"), 0.84 and 0.86 ("role limitations due to emotional problems"), 0.85 and 0.19 (energy/fatigue), 0.71 and 0.31 ("emotional well-being"), 0.76 and 0.71 ("social functioning"), 0.88 and 0.82 (pain), and 0.71 and 0.79 ("general health") for before and after the intervention, respectively. The internal consistency of the entire questionnaire section was high, as determined by

XSL•FO
RenderX

Cronbach α, were as follows: 0.91 at baseline and 0.93 at posttest.

Participation in Exercise and Physical Activity

Data on exercise and physical activity participation were collected using the ABEL app (Abel Technologies AS). Information, including type of activity, intensity, duration, and frequency, was recorded by participants during individual sessions and by personal trainers during follow-up sessions.

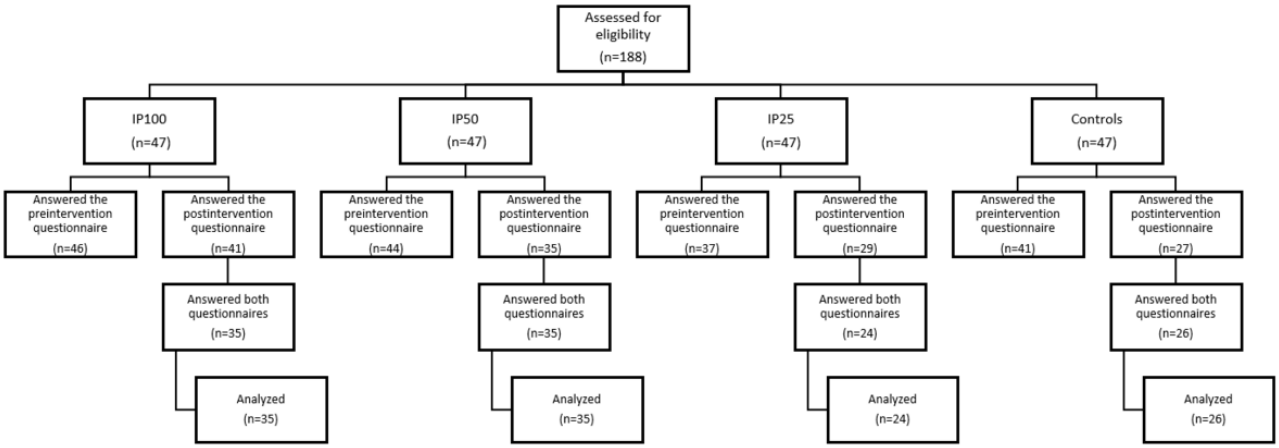
Statistical Analysis

The analyses were performed with SPSS statistics (version 28; IBM Corporation), following a predefined analysis plan and before unmasking the intervention arms. The normal distribution of the data was assessed with the Shapiro-Wilk test. We used appropriate statistical tests to compare baseline characteristics between the current sample and those who dropped out, as well as to identify differences between groups. These included a chi-square test, an independent 2-tailed *t* test, or a 1-way ANOVA, as dictated by the data. Postintervention, group comparisons were done using a 1-way ANOVA with Bonferroni post hoc comparisons. We also calculated Hedges *g* effect size, with values around 0.2, 0.5, and 0.8 interpreted as weak, medium, and strong effect sizes, respectively. Data are presented as mean (SD), numbers (%), mean changes, mean differences, 95% CI, effect sizes, and *P* value. The level of statistical significance was set at $P \leq .05$ and adjusted as appropriate for the 1-way ANOVA and Bonferroni post hoc comparison ($P \leq .01$).

In this study, targeting a specific population of women with obesity who have low activity presented challenges in accurately estimating attrition rates due to limited comparable data. Given the lack of reliable data on expected dropout rates within this demographic, the research group assumed recruitment of 200 participants was appropriate.

Ethical Considerations

The study was conducted following the ethical standards of the Helsinki Declaration (as revised in 2000) and relevant national and institutional guidelines. All participants provided written informed consent after receiving detailed study information, including their rights to withdraw at any time without consequence. The study was reviewed by the Regional Committee for Medical and Health Research Ethics (REK 2022/552476), which determined that, under the Act on Medical and Health Research (the Health Research Act 2008), full review by the Regional Committee for Medical and Health Research Ethics was not required. Ethical approval was granted by the Norwegian School of Sports Sciences Ethical Committee (Applications number 262). The study was also registered with the Norwegian Social Science Data Service (Sikt 104437) and ClinicalTrials.gov (NCT05792657).



To protect participant privacy, no identifying information was collected or published. Participants in the intervention arms received regular follow-ups by a personal trainer, while all study groups, including the control group, had access to a fitness club and an exercise app (ABEL Technologies). No financial compensation was provided to participants.

Results

A total of 120 (64%) out of 188 participants completed baseline and postintervention assessments (IP100: n=35; IP50: n=35; IP25: n=24; and controls: n=26). The flow of the participants is shown in Figure 1. Mean age of the participants collapsed was 42.7 (SD 10.5) years and the mean BMI was 35.1 (SD 6.9) kg/m^2. There were no differences between the 4 groups in age, body weight, education, or household income at baseline (all $P>.05$; Table 1). In terms of BMI, participants in the control group had a higher mean BMI (35.8, SD 5.8 kg/m^2) than those allocated to IP100 (32.8, SD 2.6 kg/m^2; $P=.02$). There were no significant differences between the current sample and study dropouts in background characteristics at baseline (data not shown).

Weekly exercise frequency over the 20-week intervention was as follows: 2.0 (SD 1.3) days/week (IP100), 2.4 (SD 1.5) days/week (IP50), 2.2 (SD 1.6) days/week (IP25), and 0.9 (SD 1.6) days/week (controls). We found no differences in weekly exercise frequency between the 3 intervention arms ($P=.30$); however, all intervention arms exercised more frequently than controls ($P \leq .001$).

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flowchart of the participants. IP100: in-person exercise coaching 100%; IP25: in-person exercise coaching 25%; IP50: in-person exercise coaching 50%.

[a]IP100: in-person exercise coaching 100%.

[b]IP50: in-person exercise coaching 50%.

[c]IP25: in-person exercise coaching 25%.

At baseline, we found that the control group scored higher on intrinsic motivational regulation than the 3 intervention groups (mean difference: 0.4-0.9; $P \leq .05$). After the intervention, we found a between groups difference in 1 of the 8 health-related subscales for the SF-36. All intervention groups reported a greater improvement in self-perceived health in 1 of the 8 subscales of SF-36 (SF-36 domain: change in health from 1 year ago), than controls (IP100: 81.4, SD 17.5, g=0.82, P=.007; IP50: 80.9, SD 17.5, g=0.79, P=.01; IP25: 84.4, SD 12.4] g=1.14, P=.002; and controls: 66.7, SD 15.9; Table 2). No other intervention effects were found (Table 3).

Discussion

Principal Findings

This pragmatic RCT investigated the effectiveness of weekly in-person coaching compared with 2 different combinations of in-person and web-based coaching on motivation, barriers, self-efficacy, social support, and health-related quality of life among women with obesity. While no intervention effects were detected for most of the measured variables, a slight improvement was reported in self-perceived health in 1 of the 8 subscales of the SF-36. This improvement was consistent across all intervention groups when compared with the control group from before to after the intervention. However, it is important to note that the observed difference was limited to a single subscale of the SF-36, indicating that the interventions had only a minimal impact on overall health-related quality of life.

The improvement in the "change in health" subscale of the SF-36 across all intervention groups suggests that combining in-person and web-based exercise coaching may contribute to enhanced self-perceived health among women with obesity. This is consistent with a previous RCT involving 143 inactive women with excess body weight, which found that those who received in-person exercise coaching by a personal trainer reported improved self-perceived health after 12 weeks of intervention [42]. Interestingly, this RCT also found that those who exercised alone reported better self-perceived health compared with the control group [42]. This may be due to the fact that regular physical activity, even at low levels (≥1 day/week), has been shown to improve self-perceived health [57]. In a previous longitudinal prospective study among novice exercisers in a fitness club setting, regular exercise in the fitness club (≥2 days/week) was associated with high self-perceived health (odds ratio 3.53, 95% CI 1.60-7.82; *P*=.002) [58]. Therefore, regular exercise itself may improve self-perceived health, emphasizing exercise as a key factor in overall well-being. Although the use of a personal trainer may not directly influence self-perceived health, it seems to bolster exercise adherence, thus supporting long-term health benefits. This appears to be consistent regardless of in-person or web-based coaching, as we did not find differences in exercise frequency between the 3 intervention groups. However, since this improvement in our study was limited to just 1 of the 8 subscales of the SF-36, further research is necessary to determine whether this represents a true and clinically significant effect.

The intervention did not demonstrate significant effects on exercise motivation, which may be explained by several factors. One key factor is the baseline differences in intrinsic motivational regulation between the control group and the intervention arms, with the control group having higher intrinsic motivation at baseline. This disparity may have created a ceiling effect, limiting further improvements in motivation both within and between groups. However, all groups scored between 1.7 and 2.6 on the 5-point scale, indicating room for improvement, irrespective of the initial differences. In addition, variations in the coaching approaches of the personal trainers, which were not controlled for in this study, could influence exercise motivation. According to self-determination theory (SDT), interactions between the personal trainer and the client may enhance motivation for exercise by satisfying the basic psychological needs (autonomy, competence, and relatedness) [59]. Personal trainers who adopt a need-supportive coaching approach, such as providing meaningful choices, acknowledging client feelings, and offering constructive feedback, may foster these needs and thereby improve exercise motivation [30]. For instance, one study investigating the effects of an SDT-based physical activity program among adults with obesity (BMI ≥40 kg/m^2) found that perceived autonomy support and the satisfaction of basic psychological were positively associated with increases in autonomous motivation and negatively associated with controlled motivation and amotivation [60]. On the other hand, certain coaching approaches, which include elements like guilt-inducing language or not fully considering the clients' preferences, may inadvertently impact these psychological needs and reduce motivation [30].

By offering scheduled appointments, free follow-up sessions, and access to exercise equipment, the intervention effectively minimized many logistical and financial barriers to exercise. However, we found no changes in exercise barriers, with all intervention groups reporting high scores on barriers such as "priority" (lack of time and energy) after the intervention. These findings are consistent with previous studies [52,61-63], suggesting reducing logistical obstacles alone may not be sufficient to overcome exercise barriers. This highlights the importance of addressing more individual factors, such as personal priorities and attitudes toward exercise. Overcoming these barriers likely requires coaching strategies that go beyond logistical support to include more personalized approaches tailored to each individual's needs and circumstances [64,65].

The lack of effect on self-efficacy in our study is in line with 2 previous RCTs, which reported no differences between in-person and phone-based exercise coaching [66,67]. While one cross-sectional study found an association between in-person coaching and improvement in self-efficacy compared with web-based coaching [68], this was not reflected in our results.

XSL•FO
RenderX

One potential explanation for the varying results could be the high baseline self-efficacy scores across all groups, indicating that participants who already had high self-efficacy may have had limited room for further improvement [31,37]. Nevertheless, it is important to note that all intervention arms in our study exercised significantly more than the control group after the intervention, even without a corresponding increase in self-efficacy. This suggests that improvements in exercise adherence may occur independently of self-efficacy changes. Future research should explore additional support mechanisms, such as coaching approaches grounded in behavioral theories, to further enhance exercise participation. For instance, one study that applied social cognitive theory–based coaching, which focuses on psychological factors such as self-efficacy, found that women in the coaching group had higher exercise adherence (49% versus 31%) compared with the control group, alongside improvements in self-efficacy [69].

The measurement used in our study included perceived social support from friends and family, unfortunately not accounting for potential support the participants might have experienced from their personal trainer. Including data on social support from personal trainers would have offered a more comprehensive understanding of participants' support networks, while also highlighting the trainers' role in promoting exercise adherence. In addition, it could have provided valuable insights into the dynamics of the trainer-participant relationship. However, low social support scores, both before and after the intervention, indicate a lack of sufficient encouragement from the significant others. This finding is important, as social support from family and friends is a key factor that consistently influences exercise adherence [25,26].

Our findings align with the broader literature, highlighting the complex relationship between exercise interventions and psychosocial outcomes among individuals with obesity [70,71]. For instance, Pilates, yoga, tai chi, and qigong have demonstrated potential for improving mental well-being in populations living with obesity [70,71]. However, the evidence regarding their direct effects on broader psychosocial factors remains limited. Further, a recent review showed clear evidence of combined aerobic and resistance training in improving key health indicators, including glycemic control and mental health, among individuals with obesity and type 2 diabetes [72], while our study did not demonstrate significant changes in health-related quality of life across all dimensions. The small improvement in the "change in health" subscale may reflect the cumulative benefit of structured exercise on self-perceived well-being. These results also support that regular exercise may enhance specific quality-of-life dimensions, even without observable changes in other psychosocial variables.

Finally, while this study investigated the effect of hybrid coaching models, targeted exercise regimens, such as high-intensity interval training, are shown to have the potential to improve psychosocial factors, including enhanced self-perceived health [73]. Further, exercise modalities like Pilates and yoga could also complement exercise coaching to improve psychosocial factors, since these approaches offer a less demanding, more inclusive alternative, particularly for individuals facing physical or psychological limitations [70,71,74]. Future research may integrate such modalities within hybrid coaching models to evaluate their combined impact on psychosocial outcomes.

Increasing exercise participation among the population living with obesity could significantly impact public health. Since motivation, barriers, self-efficacy, and social support are key to exercise adherence [25,75], research should explore how various coaching approaches affect these factors. For instance, SDT-based coaching may help personal trainers create a more supportive and motivating environment, improving adherence [30]. Despite the lack of effect on motivation, the intervention's potential for positive impact lies in highlighting the importance of SDT-aligned coaching strategies, which could be key to improving motivation in future interventions targeting populations living with obesity. By integrating behavioral theories into coaching interventions, researchers may better identify strategies to improve motivation, reduce barriers, and strengthen self-efficacy, ultimately promoting sustainable exercise habits and improved health outcomes [76]. While the intervention did not reduce self-reported barriers, it minimized external challenges, highlighting the value of interventions that address personal barriers. Last, although in-person and web-based coaching showed similar effects, the potential cost-effectiveness and accessibility of web-based coaching make hybrid or fully web-based approaches appealing alternatives for supporting exercise adherence among populations living with obesity. This is especially relevant given that logistical and financial barriers often limit consistent participation in in-person coaching [43,44,46]. While our RCT did not demonstrate differences in psychosocial outcomes, it shed light on the feasibility and value of hybrid coaching models to support exercise adherence in obese populations.

Our study is one of the first global pragmatic RCTs of its kind, with a long intervention period and a unique catchment area, including a nationwide intervention spanning both urban and rural regions of Norway. The inclusion of 23 experienced personal trainers, each with at least 3 years of experience, further enhances the robustness and generalizability of our findings in a real-world setting. Another strength is the hybrid approach, combining web-based coaching with in-person sessions. This approach reflects the contemporary trends in exercise supervision and meets the evolving needs of participants in modern society. Our study also contributes to the United Nations' Sustainable Development Goal 5 by focusing on obese women and addressing psychosocial factors through in-person and web-based exercise coaching, thereby supporting efforts to improve health equity and empower women. Finally, we used a range of validated questionnaires to measure the psychosocial outcomes, including motivation (BREQ-2), self-efficacy (Self-Efficacy Survey), social support, and health-related quality of life (SF-36), providing a comprehensive assessment of the psychosocial effects of the intervention.

Limitations

Some study limitations should be considered when interpreting our results. We unfortunately had a notable dropout rate, with only 64% (120/188) of participants completing both the baseline and postintervention questionnaires. However, no significant

XSL•FO
RenderX

differences were found between those who completed the study and those who dropped out in terms of baseline data. Further, the 20-week intervention period may be too short to fully assess the intervention's effects, particularly on psychosocial factors such as self-efficacy, motivation, and health-related quality of life, which often require longer durations to reveal changes or differences. Finally, while this study was conducted in Norway, limiting direct global generalizability, culture and societal similarities between Norway and other Western countries suggests that our findings could apply to similar populations and contexts. Further, the lack of a priori power calculation is another limitation of this study. The sample size was determined based on practical considerations rather than statistical power affecting the robustness and generalizability of our findings, as the study may be underpowered to identify small effects. Last, the Shapiro-Wilk test was used to evaluate whether our data met the assumption of normality. While this test is widely recognized for assessing normality, it is sensitive to sample size and outliers, which may limit its ability to fully characterize data distributions. In our study, as many as 120 participants completed both baseline and postintervention questionnaires. Thus, we believe the results of the Shapiro-Wilk test align with the assumption of normality.

Conclusions

This study indicates that both in-person coaching and 2 combinations of in-person and web-based coaching may lead to a slight improvement in self-perceived health, by higher scores in 1 of the 8 SF-36 subscales. However, these observed improvements are preliminary and may not generalize to broader health or psychosocial domains without further evidence. No significant effects were found on motivation, barriers, self-efficacy, social support, or other health domains. Further research is needed to fully understand how we can increase the ability to maintain regular exercise among women with obesity.

Acknowledgments

We would like to thank Lena Bache-Mathiesen (data scientist and researcher, Norwegian School of Sports Sciences) for conducting the randomization and Håkon Laugsand (ABEL Technologies) for assisting in the recruitment process. The Research Council of Norway and ABEL Technologies funded this study. ABEL Technologies was involved in the planning of the study design and participant recruitment.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

CG wrote the original draft preparation and conducted data analysis. JMK, EMT, HC, and LAAH reviewed and edited the draft. All authors have read and approved the final version of the manuscript and agree with the order of presentation of the authors.

Conflicts of Interest

None declared.

Abstract

Background: Digital interventions can help to overcome barriers to care, including stigma, geographical distance, and a lack of culturally appropriate treatment options. “We Can Do This” is a web-based app that was designed with input from cultural advisors and end users to support Aboriginal and Torres Strait Islander people seeking to stop or reduce their use of methamphetamine and increase psychosocial well-being.

Objective: This study aimed to evaluate the effectiveness of the “We Can Do This” web-based app as a psychosocial treatment for Aboriginal and Torres Strait Islander people who use methamphetamine.

Methods: The web app was evaluated using a randomized waitlist controlled parallel group trial. Participants were Aboriginal and Torres Strait Islander people aged 16 years or older who self-identified as having used methamphetamine at least weekly for the past 3 months. Participants were randomized on a 1:1 ratio to receive either access to the web-based app for 6 weeks or a waitlist control group. Both groups received access to a website with harm minimization information. The primary outcome was days of methamphetamine use in the past 4 weeks assessed at 1, 2, and 3 months post randomization. Secondary outcomes included severity of methamphetamine dependence (Severity of Dependence Scale [SDS]), psychological distress (Kessler 10 [K10]), help-seeking behavior, and days spent out of role due to methamphetamine use.

XSL•FO
RenderX

Results: Participants (N=210) were randomized to receive either access to the web-based app (n=115) or the waitlist control condition (n=95). Follow-up was 63% at 1 month, 57% at 2 months, and 54% at 3 months. There were no significant group differences in days of methamphetamine use in the past 4 weeks at 1 the month (mean difference 0.2 days, 95% CI –1.5 to –2), 2 months (mean difference 0.6 days, 95% CI –1 to 2.4 days) or 3 months (mean difference 1.4 days, 95% CI –0.3 to 3.3 days) follow-up. There were no significant group differences in K10 scores, SDS scores, days out of role, or help-seeking at any of the 3 follow-up timepoints. There was poor adherence to the web-based app, only 20% of participants in the intervention group returned to the web-based app after their initial log-in. Participants cited personal issues and forgetting about the web-based app as the most common reasons for nonadherence.

Conclusions: We found poor engagement with this web-based app. The web-based app had no significant effects on methamphetamine use or psychosocial well-being. Poor adherence and low follow-up hindered our ability to accurately evaluate the effectiveness of the web-based app. Future web-based apps for this population need to consider methods to increase participant engagement.

Introduction

Methamphetamine use is an issue of deep concern in Australia, including in Aboriginal and Torres Strait Islander communities [1-4]. Although rates vary geographically and Aboriginal and Torres Strait Islander people tend to be underrepresented in national population surveys, the available data suggests that nationally, the rate of methamphetamine use is at least two times higher amongst Aboriginal and Torres Strait Islander people compared with the general population (2.9% vs 1.3%) [5,6]. Regular and frequent methamphetamine use is associated with long-term physical, psychological, and social harm [7,8]. Previous research has found that while both Aboriginal and Torres Strait Islander and non-Indigenous people who have recently used methamphetamine experienced harms such as an excess burden of psychological distress, exposure to violence, and economic exclusion [9], Aboriginal and Torres Strait Islander people who have recently used methamphetamine reported significantly higher rates of racial discrimination, excessive grief, perceived social isolation, and complex trauma than their non-Indigenous counterparts [1,9,10]. Key protective factors for Aboriginal and Torres Strait Islander participants included connection to culture and contact with elders [1].

These differences in the social processes leading to use, the contexts in which people use, and the community and cultural strengths that may assist recovery points to a need for culturally specific resources for Aboriginal and Torres Strait Islander people seeking to reduce or stop using methamphetamine [9]. In a context where demand for specialist alcohol and other drug (AOD) treatment across urban, rural, and remote settings in Australia is not met by available services, much of the burden for providing care to people who use methamphetamine falls to primary health care services [11]. The Novel Interventions to Address Methamphetamine in Aboriginal and Torres Strait Islander Communities (NIMAC) project was developed in response to calls from Aboriginal Community Controlled Health Services (ACCHS) and the community at large to find ways to better support ACCHS to reduce the harms associated with methamphetamine use [1,4,9].

Web-based interventions have emerged as a popular, feasible, and cost-effective way to provide treatment for substance use disorders. Evidence suggests that web-based interventions can be effective in the treatment of substance use disorders [12-14]. However, effectiveness can vary according to intervention type, characteristics of both the web-based app and end users, and substances targeted [12-15]. Although research in this space is ongoing, to date, there are limited interventions tailored to the treatment of methamphetamine use [12], and no known interventions targeting methamphetamine use for Aboriginal and Torres Strait Islander communities.

A scoping review of evidence on the uptake of web-based interventions in Indigenous communities internationally, found that such interventions can reduce barriers stemming from geographical distance, access to specialists, or stigma; they can support health practitioners provide better care to clients for a range of health conditions, but they need to be developed in partnership with communities [16]. There is evidence that web-based and digital interventions are acceptable and feasible in Aboriginal and Torres Strait Islander communities, with several such interventions developed for AOD assessment [17,18], psychosocial assessment and care planning [19], and suicide prevention [20]. Given the lack of specialist AOD services and the stigma associated with methamphetamine use, which is known to prevent help-seeking [4], a web-based intervention was considered a possible way to improve access to an evidence-based therapeutic intervention. Furthermore, in a survey conducted within the NIMAC project of 734 Aboriginal and Torres Strait Islander and non-Indigenous people who had used methamphetamine in the previous 12 months, we found

XSL•FO
RenderX

that more than 90% of respondents had a mobile phone, and of these, 80% accessed the internet on their phone, which provided some initial indication that an online intervention may be feasible for this population [9].

The objective of this research was to test the effectiveness of the "We Can Do This" web-based app. The details of the web-based app have been reported elsewhere [21]. In brief, "We Can Do This" comprised 7 modules that were codesigned with clinicians, representatives of Aboriginal Community Controlled Health Services, and people with experience of use. Psychoeducational material, interactive exercises, planning, and goal-setting exercises were drawn from cognitive behavioral therapy (CBT), motivational interviewing, acceptance commitment therapy, and narrative approaches. Content was presented with films based on real narratives developed from qualitative interviews, and cultural content provided by advisors from diverse Aboriginal nations [21].

Our primary hypothesis was that participants who used the web-based app regularly for 6 weeks would have significantly reduced days of methamphetamine use in the last 4 weeks at 1, 2, and 3 months post intervention, compared with waitlisted participants with access to treatment as usual, including information about harm-minimization and where to access support. We also hypothesized that changes in secondary outcomes at 3-month follow-up would include increased help-seeking, decreased psychosocial distress, and fewer days out of role.

Methods

Trial Design

The web app was evaluated in a waitlist randomized controlled trial conducted in partnership with 10 urban and regional ACCHS across 6 Australian states and territories including South Australia (n=2), New South Wales (n=3), Queensland (n=1), Northern Territory (n=1), Western Australia (n=1), and Victoria (n=2). The protocol for this RCT study is already published [21]. The trial protocol was registered with the Australian and New Zealand Clinical Trials Registry (ANZCTRN12619000134123) on April 10, 2019 [21]. Participants were randomly allocated to the intervention or waitlist group with a 1:1 ratio. Random numbers were generated using the statistical software Stata (version 14.0; StataCorp) by a statistician not otherwise involved in the trial.

Participants

Participants were eligible to participate if they were Aboriginal and Torres Strait Islander, aged 16 years or older, and self-identifying that they had been using methamphetamine about weekly for the previous 3 months. Eligibility was confirmed by participant self-report on entry to the web-based app platform. Participants were initially recruited through advertisements in health services and on social media. All participants were invited to provide informed consent through a web-based form before completing any study assessments.

Initially, the web app was designed to facilitate direct referral through the app to weekly support from health practitioners at partner health services. To enable wider recruitment, this function was modified to enable participants to self-refer to a local service regardless of geographical location within Australia. In consultation with the trial management committee, additional changes made posttrial commencement to aid recruitment were (1) providing a voucher for reimbursement for completion of the baseline survey (Aus $25), (2) increasing the value of voucher reimbursement for the first follow-up survey (from Aus $20 to Aus $25), (3) introducing peer recruitment, where peers were offered Aus $20 for every participant referred to the project, (4) reducing the number of questions in the assessments to reduce drop out before reaching randomization, and (5) extending the recruitment period. During this period the average conversion rate was approximately Aus $1=US $0.7.

Procedures

Advertisements directed participants to a web landing page that included information about the project in both written and audio-visual format. After providing consent, all participants completed a survey at baseline before randomization. After participants completed the baseline survey, they were randomized to either the intervention group or a waitlist control group according to a 1:1 ratio. The randomization schedule was developed by a statistician who was not involved with study participants (HW). Random numbers were generated using the statistical software Stata. All participants were followed up at 1, 2, and 3 months post baseline. Assessments were completed through self-reporting online, with an option to have a researcher call to complete the assessment over the phone if this was considered easier. Attempts were made to contact all participants by email, SMS text messages, and phone for follow-up assessments if they failed to respond to follow-up assessments within 2 weeks. After 120 days post baseline, participants were considered lost to follow-up.

Intervention

The intervention group received access to the "We Can Do This" web app for 6 weeks. Participants could access the 7 modules on smartphones, tablets, or computers, and complete them in a self-paced manner. There was no restriction on the order in which participants could complete the modules. To commence the intervention, participants set up an account in the web app. During the 6 weeks of access to the intervention, they received weekly reminders to log in by email, with encouragement to log in for around half an hour per week. If the system identified that a participant had not logged in for 7 days, this triggered a text message with a prompt to log in and a link to the web app [21].

Control Group

Participants allocated to the waitlist group were directed to the study website, with links to harm-minimization information and options for self-referral to AOD counseling. Participants in this group were sent a link with access to the web app immediately following the completion of their final follow-up survey. The waitlist control group then had access to the web app for 6 weeks.

XSL•FO
RenderX

Measures

Primary Outcome

The primary outcome was the number of days the participant used methamphetamine in the past 4 weeks, assessed at baseline and 1, 2, and 3 months post baseline using the Australian Treatment Outcome Profile (ATOP [22]).

Secondary Outcomes

Secondary outcomes were the help-seeking intention, assessed using the General Help-Seeking Questionnaire [23], readiness to change (Readiness to Change Questionnaire [24]), psychological distress (Kessler 10 [25]), severity of dependence on methamphetamine in the past month (Severity of Dependence Scale (SDS) [26]), and other substance use during the past month, including cannabis, alcohol, tobacco, benzodiazepines, heroin, other opioids, cocaine, ecstasy, and other drugs (ATOP [22]), and days out of role during the past month, resulting from methamphetamine use [27].

Other Measures

Usability and acceptability of the web-based app were measured using the Internet Intervention Adherence Questionnaire [28], which includes questions about barriers and facilitators to using the program and optional free-text to report any criticisms or other feedback.

The overall feasibility of the web-based intervention was assessed by observing the uptake and use of the web-based intervention (number of modules accessed). The number of visits to the web-based app overall and per module was monitored using Google Analytics. The Internet Intervention Adherence Questionnaire [28] was included in the second follow-up questionnaire for the intervention group.

Statistical Methods

Based on our previous research, we expected a baseline mean of 16 days of methamphetamine use in the past 4 weeks [29,30]. Our original sample size of 288 participants was intended to detect a reduction from a mean of 16 (SD 14.5) days of use in the past 4 weeks to a mean of 8 use days in the past 4 weeks at each of the follow-up points, with 90% power at $P<.01$, allowing for 30% attrition (ie, 100 per group at follow-up). Our final sample included 210 participants, and we observed a 40% attrition. With this sample, we were able to detect a reduction from 16 days of use in the past 4 weeks to a mean of 6 use days in the past 4 weeks at each of the follow-up points, with 90% power at $P<.01$.

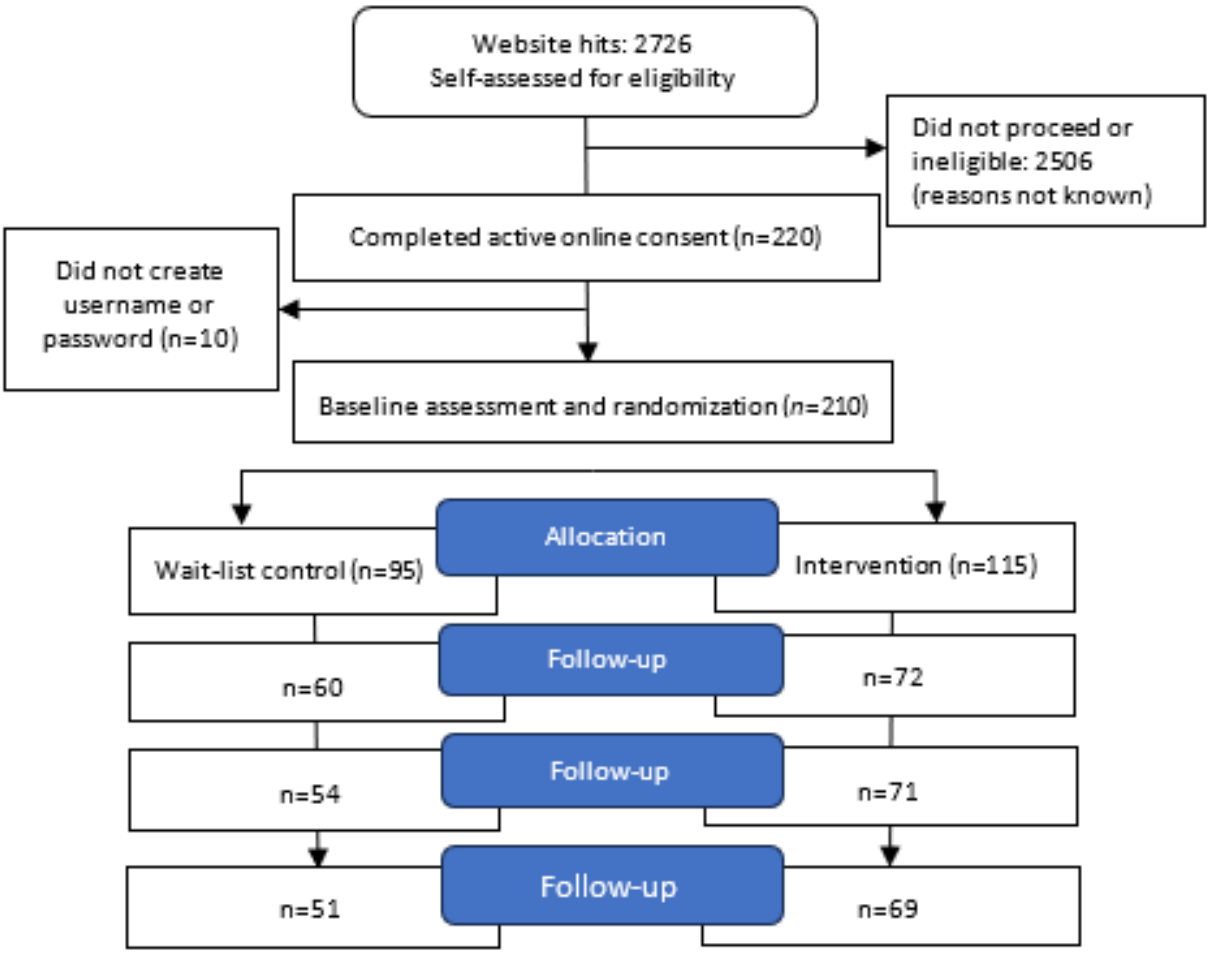
Data Analysis

An intention-to-treat analysis was used to compare the primary and secondary outcomes for the intervention versus the waitlist, 2 and 3 months from baseline. Descriptive statistics of baseline characteristics were provided by the randomization group. Continuous variables were summarized with mean and SD when appropriate, or median and IQR when not normally distributed, and categorical variables were summarized with frequency and percentage.

Multilevel mixed-effects generalized linear model, with either a Gaussian, Poisson, or robust Poisson distribution as appropriate for each specific outcome, were used to estimate change between (1) baseline and 1-month assessment, (2) baseline and 2-month assessment, and (3) 3-month assessment. To compare the changes described above between study arms, the models included a categorical variable for the study arms, a categorical variable for each time point, and an interaction term between arm and time. The use of mixed models has the advantage of allowing the modeling of the correlation between repeats of outcomes recorded within the same participant. A per-protocol analysis was carried out to assess the effect of the intervention for those participants who accessed the app at least once versus those participants who never accessed the app. Sensitivity analyses were also carried out that included baseline outcomes in the models when descriptive analyses showed important between intervention arm differences for baseline scores.

Statistical significance was set at $P<.01$. Statistical analysis was conducted using Stata (version 18) statistical software.

Ethical Considerations



The trial was approved by ethics committees in all relevant jurisdictions: Aboriginal Health Research Ethics Committee of South Australia (04-19-810), Aboriginal Health and Medical Research Council of New South Wales (1484/19), University of Queensland (2020001710), Menzies School of Health Research (2019-3330), Central Australian Human Research Ethics Committee (CA-20-3779), Western Australian Aboriginal Health Ethics Committee (1002), St Vincent's Hospital Melbourne Human Research Ethics Committee (52756: 149/20), and University of Tasmania (23229).

Results

Recruitment continued for a total of 22 months from December 2019 to October 2022 with the final follow-up completed in February 2022. Out of the 210 participants who completed the baseline survey, 95 were randomized into the waitlist control group and 115 into the intervention group. Participant flow and attrition are shown in Figure 1 (Multimedia Appendix 1 shows the CONSORT [Consolidated Standards of Reporting Trials] checklist).

XSL•FO
RenderX

Figure 1. CONSORT flow diagram: Numbers of participants who self-assessed for eligibility, completed online consent and baseline assessment, were randomized to intervention or wait-list control, and retained for follow-up at 1, 2, and 3 months.

Baseline participant characteristics are shown in Table 1. In both groups, close to 90% were Aboriginal, with the remainder either Aboriginal and Torres Strait Islander or Torres Strait Islander. Participants' mean age was 33.9 (SD 8.7) years. They had been using methamphetamine from a median age of 21 (IQR 18-28) years and had used methamphetamine on a median of 20 (IQR 13-25) days in the past 4 weeks. A total of 82 % smoked tobacco (92% of them, daily). Other substance use consisted mainly of cannabis (65%) and alcohol (60%), with cannabis being used more often than alcohol (median 13, IQR 0-28 days for cannabis vs 11, IQR 1-28 days for alcohol). Other drug use was less common (Table 1).

There were more men in the intervention group (64%) compared with the control group (43%), but the 2 groups were broadly equivalent on other sociodemographic variables and drug use (Table 1).

[a]LGBTQI: lesbian, gay, bisexual, transgender, queer/questioning, or intersex.

Outcomes

Days of methamphetamine use reduced significantly in both intervention and control groups (P<.04), but there was no significant difference between the groups at 1, 2, or 3 months post baseline (Figure 2A). As shown in Table 2, there were no significant group differences in the secondary outcomes, including psychological distress (K10), the severity of dependence, help-seeking, days out of role, and other drug use.

XSL•FO
RenderX

Figure 2. A: Mean days and 95% CI of methamphetamine use at baseline (month 0) and at each of the 3 follow-up months—intervention arm versus waitlist arm. B: Mean and 95% CI days of methamphetamine use at baseline (time 0) and at each of the 3 follow-up months for the intervention arm only, for participants who logged in the "We Can Do This" web app at least once after initial sign up versus those who never logged-in the web app after initial sign up.

Usage data acquired through Google Analytics showed a large proportion (80%) of participants logged into the web app once and did not subsequently return. Retrospective analysis of the intervention condition only, comparing those participants who did not log into the web app again after initial sign-up ("never") versus those who logged in at least once more ("at least once"), showed a significant reduction in use amongst those who returned (Figure 2B).

Estimates were derived using multilevel mixed-effects generalized linear models, including random effects for the intercept and for time, with either a Gaussian, Poisson, or robust Poisson distribution as appropriate for each specific outcome. The treatment effect is calculated as the difference between the intervention and waitlist at 1-month assessment, 2-month assessment, and 3-month month assessment. The use of multilevel mixed effect models allows for estimates of treatment effects that are adjusted for between study arms differences at baseline.

XSL•FO
RenderX

Table 2. Mean (95% CI) and rate (95% CI) for each study outcome at baseline, month 1, month 2, and month 3 in each study arm, and corresponding treatment effect (difference of means, relative rate, and 95% CI).

	Baseline	Month 1	Month 2	Month 3

Usability and Adherence

The most common issues participants cited as obstacles to completing the web app (either a "little problem" or a "major problem") were "personal issues stopped me from using the web program" (55%) and "I just forgot to go to the web program" (51%). Problems with the internet or computer were cited by 39%-41% of participants. Issues with navigability and presentation of the web app were less often cited as barriers (20%-29%), although 41% said the program was not useful and 43% said they simply did not want to do it. Practical barriers, like other people using the computer or not having enough time to do the intervention, were cited by 44% and 42% respectively. Items that were most frequently considered major problems for using the web app (>10%) were forgetting to use it, having personal issues, believing it would take too long, not having time, and the computer not working or having problems.

The majority of respondents indicated that several matters were not problems that prevented them from using the web app, including internet connectivity, comprehension of the program, navigation, work issues getting in the way, difficulty reading the screen, or too many words. The frequency of responses to all usability and adherence questions is included in Table S1 in Multimedia Appendix 2.

Discussion

Principal Findings

We found that the web app, "We Can Do This," which targeted Aboriginal and Torres Strait Islander people, was not effective in reducing methamphetamine use. This is consistent with outcomes of a similar but nontargeted internet-based intervention for stimulant use [31,32], which did not produce significant changes in stimulant use. However, it is inconsistent with the broader evidence base for internet-based interventions, which have been found to produce significant, if modest, reductions in substance use [12,33]. These include effective CBT-based online interventions for methamphetamine use [34]. The web app did not produce expected increases in help-seeking intention, motivation to reduce methamphetamine use, and reductions in days out of role, benefits that have been found with nontargeted internet interventions for stimulant use [31,32].

The most likely explanation for the failure to yield expected benefits from "We Can Do This" is poor engagement with this self-directed web-based intervention, with only a small proportion of participants completing the web app modules. This interpretation of the results is supported by our per-protocol analysis, which found evidence of a reduction in methamphetamine use amongst participants who completed at least one module of the intervention. This could suggest that the web app has the potential to be effective for those people who return to it for two or more sessions. However, delivered in its current form, it is unlikely to result in any population shift in methamphetamine use. Keeping people engaged with health-related websites and apps is a universal problem [35,36] and it is also a specific challenge in trials of psychosocial interventions targeting stimulant use [37].

In our case, simply forgetting to use the web app was one of the main reasons cited as an obstacle to engagement. Retention and engagement strategies used in this study included SMS text messages and email reminders. However, more aggressive tactics, such as push notifications, in-app messages, and "gamification" mechanics (using rewards, competition, "unlocking" levels, or time-limited challenges) could be used to increase retention and engagement [15,38]. Contingency management can also be used to increase treatment attendance and engagement with treatment-related activities [39] and may be one option to increase engagement with the web app. Significant work would be required to update the web app to incorporate more of these features for it to be successfully offered as a stand-alone, self-directed intervention available in the community.

Other barriers to not completing the web app were mostly external (eg, personal issues, not finding time, and computer problems) rather than barriers related to the content or layout of the web app. Importantly, personal issues were a major barrier. Further investigation of the type of personal issues that impeded using the web app would be needed to understand the implications of this finding. However, it may reflect the complex and challenging lifestyle associated with having a stimulant use disorder. It may also reflect the mood disturbances commonly experienced by people with a stimulant use disorder, both related to co-occurring mental disorders, but also symptoms of withdrawal from methamphetamine. Further qualitative research and codesign of web apps are likely to be needed to understand and overcome these barriers to adherence.

There are also factors related to the target population that have been associated with poor retention and engagement. At a population level, life stress is generally higher for Aboriginal people in Australia compared with non-Indigenous people [40]; low educational attainment and a lack of income increase the risk of dropping out from alcohol and other drug treatment programs [41], and frequent substance use is associated with poor treatment retention [42,43]. Cognitive factors, although

XSL•FO
RenderX

inconsistently associated with treatment outcomes in other settings [42], may be relevant to a program, such as "We Can Do This," which requires both self-motivation and concentration. In light of this, there may be value in exploring alternative approaches to delivery, for example, clinician-assisted web apps, single brief interventions, or web apps that focus on a broader range of drug use and treatment scenarios. Qualitative research with people who have attempted to engage with the web app will provide a deeper understanding of these issues.

Limitations

The study was subject to several limitations. The major limitation of this study was poor adherence to the internet intervention, which limited our ability to detect a treatment effect in the intention-to-treat analysis. This clearly has implications for any conclusions that can be drawn about the useability of the web app in its current form. Dropout from the assessments may also have biased findings, particularly in the treatment completers analysis. Data on drug use relied on self-report and could not be verified. However, self-reporting in research studies shows high concordance with biological indicators of drug use [44]. The anonymous data collection was deemed necessary to enable participation from people who may otherwise not disclose information about their drug use, but it did limit the ability to confirm the veracity of the data. Although we carefully monitored the use of the web app to identify any instances of unusual access (such as multiple sign-ups from 1 IP address) and contacted several participants by phone to complete assessments (as per protocol), we have no way of being certain that all participants met the eligibility criteria.

Conclusion

We did not demonstrate the effectiveness of this web app in reducing methamphetamine use or increasing psychosocial well-being. Overall, engagement with the web app was poor and hindered our ability to evaluate its effectiveness. Future web apps for this population need to consider methods to increase participant engagement. Understanding the unique challenges and strengths of Aboriginal and Torres Strait Islander participants and communities, and ongoing guidance from communities and ACCHSs will be key to ongoing efforts to identify accessible and effective interventions for methamphetamine use.

Acknowledgments

We thank the Novel Interventions to Address Methamphetamine in Aboriginal and Torres Strait Islander Communities' site coordinators, study advisory group members, research participants, and health service staff, in particular Edward Wilkes, Dennis Gray, Ike Fisher, Harry Miller, Emma Donley, Angela Sloan, Kirsten Button, Peter Fullston, Warren Clements, Paul Briggs, Bree Firebrace, Shani Crumpen, Virginia Lovell, Jack Nagle, Haley Briggs, Daley Hammersley, and Tahlia McDonald; for their creative development. Abstract

Background: HIV self-testing has gained momentum following the approval of self-testing methods and novel technological advancements. Digital HIV self-testing involves completing an oral or blood-based HIV self-test with support from a digital innovation.

Objective: We conducted a systematic review on the existing data analyzing digital HIV self-testing accuracy while updating research on digital HIV self-test acceptability, preference, feasibility, and impact.

Methods: We searched Embase and PubMed for records on HIV self-testing with digital support. Included studies significantly incorporated a form of digital innovation throughout the HIV self-test process and reported quantitative data. For accuracy measures, the search spanned January 1, 2013, to October 15, 2024; for patient-centered and impact outcomes, we updated existing literature (June 16, 2021, to October 15, 2024) reported in a previous systematic review. Studies' quality was assessed using the QUADAS 2 Tool, Newcastle-Ottawa Scale, and Cochrane Risk of Bias Tool 2.

Results: Fifty-five studies (samples ranging 120-21,035, median 1267 participants) were summarized from 19 middle- to high-income countries. Seven studies reported on the accuracy of HIV self-testing with innovations from >5000 participants. Diagnostic performance metrics, including point estimates of specificity, sensitivity, positive predictive value, and negative predictive value were measured (n=3), and ranged from: 96.8% to 99.9%, 92.9% to 100.0%, 76.5% to 99.2%, and 99.2% to 100.0%, respectively. The percentage of invalid test results for oral and blood-based self-tests ranged from 0.2% to 12.7% (n=4). Fifty-one studies reported data on metrics beyond accuracy, including acceptability, preference, feasibility, and impact outcomes from >30,000 participants. Majority (38/51, 74.5%) were observational studies, while 25.5% (13/51) reported data from randomized controlled trials. Acceptability and preference outcomes varied from 64.5% to 99.0% (14/51) and 4.6% to 99.3% (8/51), respectively. Feasibility outcomes included test uptake (30.9% to 98.2%; 28/51), response rate (26.0% to 94.8%; 7/51), and visits to web-based providers (43.0% to 70.7%; n=4). Impact outcomes assessed new infections (0.0% to 25.8%; 31/51), first-time testers (2.0% to 53.0%; 26/51), result return proportions (22.1% to 100.0%; 24/51), linkage to care as both connections to confirmatory testing and counseling (53.0% to 100.0%; 16/51), and referrals for treatment initiation (44.4% to 98.1%; 8/51). The quality of studies varied, though they generally demonstrated low risk of bias.

Conclusions: Digital innovations improved the accuracy of HIV self-test results, and were well-accepted and preferred by participants. Operationally, they were found to be feasible and reported impacting the HIV self-testing process. These findings are in favor of the use of digital HIV self-test innovations as a promising support tool and suggest that digital HIV self-tests' service delivery models hold promise in not only facilitating HIV testing but also impacting operational outcomes that are crucial to reaching Joint United Nations Program on HIV/AIDS targets in middle- to high-income countries.

Introduction

Background

To meet the Joint United Nations Program on HIV and AIDS (UNAIDS) targets, HIV self-testing strategies have been deployed in many countries around the world. HIV self-test methods have risen in popularity since being approved by the Food and Drug Administration (FDA) in 2012, with HIV self-tests now offered as oral or blood-based options, allowing users to receive their results within minutes [1]. Accompanying the rise in HIV self-test usage, digital innovations that support HIV self-testing are becoming widely used in health care, enhancing this method of self-testing. The World Health Organization (WHO) defines digital health innovations as technologies that contribute to improved health outcomes [2]. These technologies can be implemented within any step of the self-testing process including HIV self-testing pre- and posttest counseling, evidence-based knowledge sharing, test ordering, test result interpretation, linkages to care, referrals, and retention in care. Each of these steps plays a major role in the success of HIV self-testing programmatic implementation. The WHO advocates for the adoption and scale-up of digital health innovations to advance global health developments, in support of its One Health Agenda, which includes digital health as the great enabler of the One Health Agenda, which brings light to the integration and unity required to balance the health of humans, animals, and ecosystem [3]. HIV self-test with digital support holds the potential in improving patient-centered and operational outcomes. In the light of recent developments in digital health at the WHO, evidence synthesis was deemed necessary to summarize evidence on digital HIV self-test–based service delivery models [4].

Systematic reviews have sought to summarize global evidence on HIV self-test outcomes, as a result of the increased popularity of self-testing methods. A previous systematic review evaluated studies from January 1, 2010, to June 15, 2021, that focused on patient-reported outcomes including acceptability and preference, and operational feasibility and impact of HIV self-testing methods along with digital innovations [5]. The digital supports examined in this review included web-based interventions (ie, websites, chatbots, and online video counseling), social media and app-based innovations, SMS-based innovations, and digital vending machines. This review found these forms of digital support resulted in reasonably high acceptability (77%-97%), preference (53%-100%), feasibility (93%-95%), and impact (53%-100%) [5]. However, this review neglected to include accuracy metrics, due to insufficient literature at that time.

Despite the expansive integration of digital methods with self-testing during and following the COVID-19 pandemic, there has been limited work focusing on the role of digital support complementing HIV self-testing, particularly regarding the diagnostic performance of these tests. One secondary data analysis of a completed randomized controlled trials quasi–randomized controlled trial (quasi-RCT) has recently evaluated the accuracy metrics of digital HIV self-testing methods and compared them to laboratory HIV reference standards and reported high sensitivity and specificity at 95.5% and 99%, respectively [6]. To inform policy guidance, we need many more studies that analyze the diagnostic performance of digital HIV self-test. A related systematic review evaluating the accuracy of HIV self-testing, notably without digital supports, found that while participants generally performed the self-tests well, errors such as improper kit preparation, misconducting sample collection, and buffer solution spillage were common [7]. The performance accuracy of self-tests also varies tremendously depending on the user, type of test, and test setting, such as whether assistance from health care professionals is available. A systematic review comparing the accuracy of HIV self-tests conducted by the general population to that of diagnostic tests performed by health care practitioners concluded that HIV self-testing innovations were a reliable and accurate method of testing when used by the general population [8]. Although these reviews provide valuable insights into the accuracy of HIV self-testing, no systematic reviews have yet assessed the impact of digital innovations on HIV self-testing accuracy.

Considering the FDA only approved oral-based HIV self-tests in 2012, it is unsurprising that digital innovations in self-testing have rapidly evolved over the past decade, with the COVID-19 pandemic further accelerating advancements in this space, particularly in facilitating accuracy reporting [9]. This updated systematic review aims to address gaps in evidence regarding the effect of digital HIV self-test supports, while providing guidance for policy, practice, and research. These findings are especially relevant in the context of One Health and the global expansion of digital health service delivery models.

Objective

Our objective was to update global evidence on digital HIV self-test, assessing whether digital supports improved patient outcomes, ameliorated the process of conducting and interpreting self-test results, and affected impact outcomes.

We aimed to update evidence on all outcomes with digital innovations for HIV self-test, including patient-reported and operational outcomes such as acceptability, preference, feasibility, and impact.

Methods

Search Strategy

The first search strategy included in this review was conducted as an extension of the earlier systematic review by McGuire et al [5], which reported on the secondary outcomes (acceptability, preference, feasibility, and impact), but excluded accuracy. This review extended the search to include accuracy studies from 2013, reflecting the FDA's approval of oral-based HIV self-testing in 2012 [9]. The second search strategy was developed to expand upon the same secondary outcomes of McGuire et al [5], but from June 2021 onwards, where the original search strategy ended.

We followed the original protocol, registered on PROSPERO, and modified the strategy to incorporate the newly added accuracy outcome.

We followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines and Cochrane guidelines to conduct and report this review.

No study participants or members of the public were involved in the design, conduct, or reporting of this review.

Information Sources

Two reviewers (AB and OV) searched 2 electronic databases (PubMed and Embase), first, for citations pertaining to previously unreported accuracy outcomes for the period of January 1, 2013, to October 15, 2024 (Multimedia Appendix 1); and second, for new citations pertaining to secondary outcomes (acceptability, preference, and feasibility) and impact outcomes for the period of June 16, 2021, to October 15, 2024 (Multimedia Appendix 1). There was an overlap of 3 papers that qualified for both the accuracy and patient-centered outcomes [10-12]. No restrictions were placed on language in either search. We retrieved all full-text studies and conference abstracts, with both authors (AB and OV) independently screening publications.

We also searched abstracts for the following conferences: Annual Canadian Conference on HIV and AIDS Research 2021/2022/2023, Infectious Diseases Society of America IDWeek 2021/2022, the 11th International AIDS Society Conference on HIV Science 2021, and the 24th International AIDS Conference (AIDS 2022).

Eligibility Criteria

We included all studies (observational and interventional [trials and quasi-RCT based experimental] designs) evaluating digital innovations facilitating HIV self-test in any country and those reporting quantitative results.

We included studies only if the digital supports were significantly used in the process of performing HIV self-tests (ie, administration, education, communication, result interpretation, and linkage to care).

We excluded qualitative studies, reviews, protocols, modeling studies, commentaries, narrative studies, case reports, and editorials; studies that did not have HIV as their primary focus did not include HIV self-test or did not use a digital technology; as well as studies not written in English.

Study Selection and Data Abstraction

Titles, abstracts, and full texts were screened independently by 2 reviewers (AB and OV) for eligibility, and the final included data were independently abstracted.

Abstracted data included study design, country, sample size, study population characteristics, digital innovation type, intervention description, and key findings.

A senior reviewer (NPP) was consulted for the resolution of disagreements.

Summary Outcome Measures and Narrative Synthesis of Results

To evaluate the integration of digital technology in HIV self-testing, we focused on a primary outcome (accuracy), and secondary outcomes (acceptability, preference, feasibility, and impact).

Accuracy metrics included sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV), defined in Table 1 [13].

Table 1. Accuracy metrics definitions.

Metric	Definition
Sensitivity	A test's ability to correctly identify those with the disease, the proportion of true positives (numerator) over the proportion of true positives and false negatives (denominator).
Specificity	A test's ability to correctly identify those without the disease, the proportion of true negatives (numerator) over the proportion of true negatives and false positives (denominator).
Positive predictive value	The probability that the disease is present, given the test result is positive, the number of true positives (numerator) over the number of true positives and false positives (denominator).
Negative predictive value	The probability that the disease is absent, given the test result is negative, the number of true negatives (numerator) over the number of true negatives and false negatives (denominator).
Invalid test result	A test result that did not correspond to the expected outcome of control and test lines for either negative or positive results.

Furthermore, secondary outcomes (patient-centered acceptability, feasibility, and preference) and operational impact outcomes were adopted from a previously published systematic review and are defined in Table 2 [5].

XSL•FO
RenderX

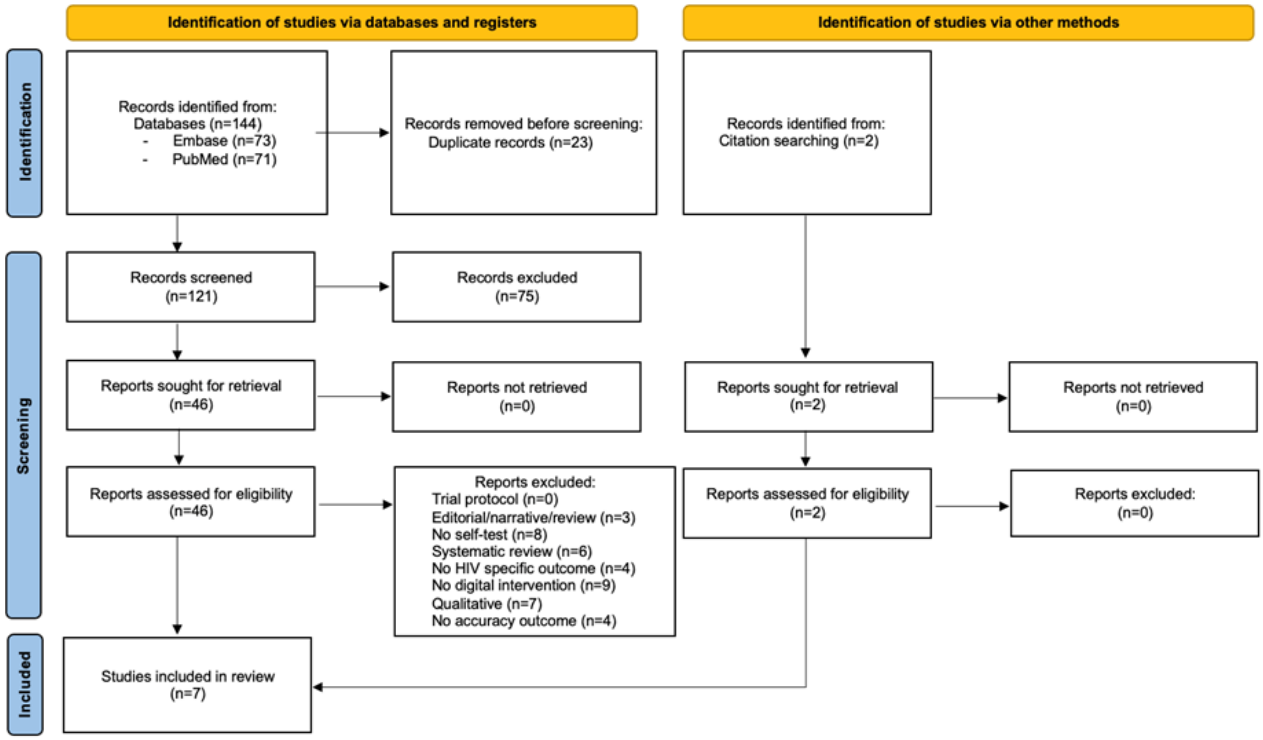
Table 2. Outcome measures and definitions.

Outcome	Definition
Acceptability	The ease of use and willingness of participants to use digital innovations for HIV self-testing, defined as those who agreed to use or try the digital innovation (numerator), over all those who were enrolled in the study (denominator).
Preference	The proportion of study participants who preferred HIV self-tests with digital supports over conventional HIV testing, defined as those who prefer this method of self-testing (numerator) over all those who were enrolled (denominator).
Feasibility	The convenience of using HIV self-test with digital supports, reported with self-test uptake, response rate, and visits to web-based HIV self-testing providers.
Impact	A statistically significant improvement in measured outcomes compared with a comparator group or a net change in outcomes among a particular group that can be attributed to specific intervention–reported metrics include the proportion of first-time testers, detection of new infections, HIV self-test kit return rate, the proportion of participants linked to continued care including counseling or confirmatory testing, and proportion of those referred to treatment.

Quality Assessment

We assessed the quality of diagnostic accuracy studies with the QUADAS-2 (quality of diagnostic accuracy studies) Tool for accuracy outcome papers [14]. We used the Cochrane Risk of Bias Tool 2 (RoB 2) to assess the quality and potential risk of bias of RCTs [15], and the Newcastle-Ottawa Scale (NOS) was used for cohort and cross-sectional studies [16,17].

Results



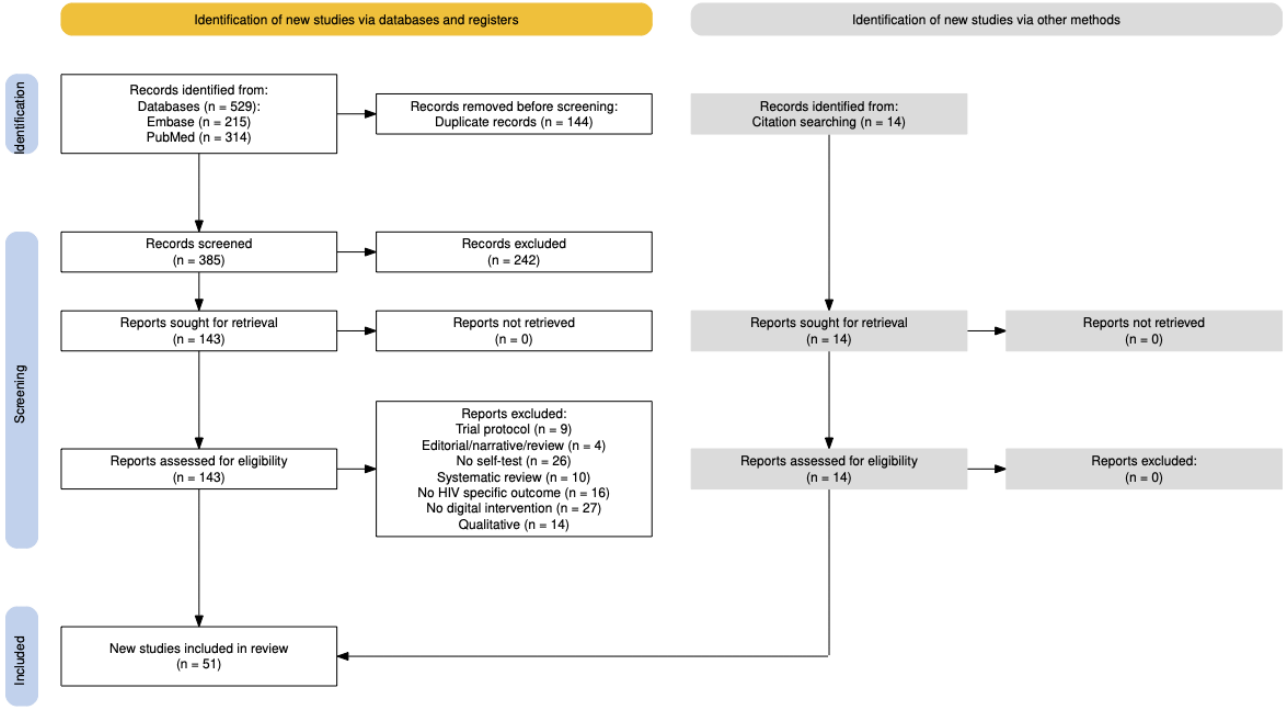
Study Selection

For the first search, 146 studies were retrieved, 139 were excluded, and there was a final set of 7. For the second search, 543 studies were retrieved, 492 were excluded, and there was a final set of 51. Out of 3 of the studies found overall were used for both primary and secondary outcomes, therefore a total set of 55 studies was included in this review. We found significant heterogeneity in the reporting of populations, study designs, HIV self-test interventions, and outcome metrics that precluded a meta-analysis.

Accuracy

For this outcome, 7 studies were included in the final analysis (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram, accuracy outcome.



Secondary Outcomes (Acceptability, Preference, Feasibility, and Impact)

For these outcomes, 51 studies were included (Figure 2).

XSL•FO
RenderX

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram secondary outcomes.

Study Characteristics

Accuracy

Accuracy studies were reported from each the following countries: Canada, Kenya, South Africa, the United Kingdom, the United States, and China (n=2). Out of 4 (57.1%) were cross-sectional, while 2 (28.6%) were cohort, and 1 (14.3%) was a quasi-RCT.

Study sample sizes ranged from 271 to 3259 participants.

Study characteristics are tabulated in, Table S1 in Multimedia Appendix 1.

Most studies used website-based HIVST innovations (5/7, 71.4%), one used app-based digital support (1/7, 14.3%), and another used a multimodal approach to HIV self-test including app-based, SMS-based, social media, and web-based innovations (1/7, 14.3%).

Out of 4 (57.1%) studies were conducted in the general population, and the other 3 (42.8%) recruited key populations (men who have sex with men [MSM], or specifically Black, African American, or Latinx MSM).

Secondary Outcomes

In total, 51 studies reported on secondary outcomes from studies conducted in 18 countries. These included: Canada (19.6%, 10/51), China (19.6%, 10/51), the United States (13.7%, 7/51), South Africa (11.8%, 6/51), India (7.8%, 4/51), and Thailand (3.9%, 2/51). One study (2.0%, 1/51) was reported in each of the following countries: Australia, Brazil, Japan, Kazakhstan, Malaysia, Nigeria, Philippines, Uganda, Ukraine, the United Kingdom, Vietnam, and Zimbabwe.

Sample sizes varied from 120 to 21,035 (median 1269, IQR 3305) participants (Table S2 in Multimedia Appendix 1).

Study design

A majority (74.5%, 38/51) of studies were observational (62.7%, 32/51 cross-sectional; 11.8%, 6/51 cohort) and 25.5% (13/51) of studies were RCTs.

Population

Nearly half of the studies (47.1%, 24/51) focused on MSM populations, while the rest (11.8%, 6/51) specifically focused on Black, African American, or Latinx MSM, and 7.8% (4/51) were conducted in transgender women. Over one-third (43.1%, 22/51) of studies were evaluated in the general population. One study only focused on women, and another only focused on Black, Caribbean, and African-Canadian people.

Interventions

Over half (56.9%, 29/51) evaluated outcomes from web-based innovations, 21.6% (11/51) evaluated mobile app-based innovations, 5.9% (3/51) evaluated social media, digital vending machines, and SMS were evaluated in one study each (2.0%, 1/51), and 11.8% (6/51) of studies evaluated multimodal interventions (web-based, social media, or SMS-based).

Risk of Bias in Studies

QUADAS 2 Tool

Using the QUADAS 2 Tool, we found a low risk of bias for the studies. 71.4% (5/7) missed details on the reference standard test used.

Key findings can be found in Table S3 in Multimedia Appendix 1.

RoB2

Using the RoB 2, we found low risk of bias for the included RCTs. Blinding of participants was reported by 30.8% (4/13) of studies. Although blinding of the participants and assessors

XSL•FO
RenderX

through the trial and analysis was not possible due to the assessed outcomes of digital supports, there were no reports of deviations from the intended interventions that arose in any of the studies. As well, every study had majority or all the data present in the analysis, and attrition bias was minimized. Finally, the outcome was reported in detail, minimizing the possibility of reporting bias.

Further details regarding these key findings can be found in Table S4 in Multimedia Appendix 1.

NOS for Cross-Sectional Studies

Using the NOS, we found that cross-sectional studies were generally fair. 53.1% (17/32) of these studies had an overall fair quality. The possibility of selection bias, confounding, or outcome and exposure misclassification was found in 18.8% (6/32), 25.0% (8/32), and 34.3% (11/32) of these studies, respectively. Many of the cross-sectional studies (90.6%, 29/32) had unjustified sample sizes (no sample size calculation was mentioned).

Further details regarding these key findings can be found in Table S5 in Multimedia Appendix 1.

NOS for Cohort Studies

Using the NOS, we found cohort studies were of average quality. Possibility of selection and confounding bias were low at 33.3% (2/6), respectively. However, 83.3% (5/6) of the cohort studies had a risk of attrition bias.

Further details regarding these key findings can be found in Table S6 in Multimedia Appendix 1.

Primary Outcome: Accuracy

A total of 7 studies evaluated the accuracy of HIV self-test integrated with the use of digital innovations [6,10-12,18-20]. Overall, 42.3% (3/7) reported on blood-based self-tests [12,18,20], 42.3% (3/7) on oral-based self-tests [6,10,19], and one allowed participants to choose between oral or blood-based self-tests but reported no differences in accuracy between the 2 types of tests [11].

A trend was noted on the reporting of invalid test results, since a majority (57.1%, 4/7) of studies reported on the percentage of invalid test results. Invalid tests reported ranged from <0.2% to 12.7%, for both blood- and oral-based self-tests [10-12,18].

One study in which the participants were asked to perform the self-test on site and report their result to the researcher as soon as it was available, reported on diagnostic performance metrics (ie, sensitivity, specificity, PPV, and NPV) of the oral-based Aware HIV self-testing, but notably only as point estimates without CI: Sn 92.9% (13/14), Sp 96.8% (121/125), PPV 76.5% (13/17), and NPV 99.2% (121/122) [19].

A study that was a secondary data analysis of a quasi-RCT found high accuracy metrics when comparing the HIV self-testing result with the reference standard of 2 rapid tests and 1 HIV RNA test [6]. Sensitivity was reported as 95.52% (95% CI 94.48%-96.56%), specificity was 99.93% (95% CI 99.79%-100.00%), PPV was 99.22% (95% CI 98.78%-99.67%), and NPV was 99.57% (95% CI 99.24%-99.90%) [6].

Another notable study that reported on such metrics did so using an AI-based program that was able to read and interpret the result of the participants' self-test [20]. In this study, sensitivity was 100% (44/44), as well as NPV. Specificity was also high at 98.8% (798/808), but the PPV was lower at 81.5% [20].

A fourth study allowed participants to choose between an oral- or blood-based HIV self-testing, but did not include mention of the manufacturers of these tests in the publication. Only 2 of the 4 positive HIV self-tests were confirmed to be positive but neglected to mention if these results were from the oral- or blood-based self-testing options. The participants of this study ordered the self-test and completed it at home, then uploaded their self-test results onto the web-based platform, which could have contributed to the few positive self-tests received. This study also reported the agreement of test interpretation between participants and the research team as 99.1% (95% CI 97.4%-99.8%) [11].

A study from the United Kingdom reported on 24,717 blood-based self-test kits purchased during the study, of which there was only a <0.2% rate of invalid tests and only 3 false positives were reported, which was much lower than they had expected [18].

Further details regarding these key findings can be found in Table S7 in Multimedia Appendix 1.

Secondary Outcomes

Outcome measures beyond accuracy become important when real life implementation is called into question. Due to this, we explored patient-reported acceptability and preference, and operational feasibility and impact outcomes.

Further details regarding these key findings can be found in Table S8 in Multimedia Appendix 1.

Acceptability

Overall, 27.5% (14/51) of the studies reported acceptability measures [21-34].

Ease of Use

A total of 8 studies (57.1%, 8/14) reported acceptability as the ease of use of the digital interventions [22,23,28-30,32-34]. In 1 study, 64.5% of participants found the digital innovation easy or very easy to use [29]. Comparatively, an RCT evaluating an infographic for HIV self-testing found that 73.5% of participants agreed that it was easy to use [30]. Another study reported that only 7.5% (9/120) of participants said the digital support was easy to use, though one participant mentioned: "*It is very easy to use, less stressful very understandable, it is the best and very advanced product one could ever wish for*" [28]. Alternatively, 1 study measured ease of use using a 5-point Likert scale and found a score of 3.8 (SD 1.6) for the ease of uploading results, and a score of 4.2 (SD 0.9) for ease of finding a clinic using the digital innovation [23].

Willingness to Use

Overall, 42.8% (6/14) reported on the willingness of participants to use the self-test with the digital intervention, which was consistently high (72.2%-99.0%) [23-27,31]. A quasi-RCT in the Philippines demonstrated the willingness of participants to

XSL•FO
RenderX

use a community-based HIV self-test distribution model and found that 99.0% (4163/4205) of respondents were interested in getting an HIV self-test [31].

Utility of the Intervention for an Indication

In one study, participants found the digital innovation helpful in reporting of testing results (97.6%), the concept of window period (88.8%), understanding their current risk (85.6%), reducing high-risk behaviors (80.0%), and mitigating fear of HIV testing (72.0%) [22].

Preference

Preference was assessed in 15.7% (8/51) of the studies [11,24,28,35-39].

Preference for the digital innovation versus standard testing methods ranged from 63.0% to 99.3% (3/51) [24,28,37]. An outlier study found that only 5.9% (128/2181) of participants chose to do an HIV self-test with the support of an application on their phone, instead of HIV testing conducted by a health care provider [39].

One study analyzed data from 794 participants on their reasoning for preference of HIV self-testing online versus other methods of testing. These were reportedly: convenience (726/794, 79.0%), not wanting to wait for results (402/794, 44.0%), not wanting to talk about sex with anyone (298/794, 33.0%), not having time to go elsewhere for testing (268/794, 29.0%), and fear of stigma (205/794, 22.0%) [35]. Notably, 21.0% (40/190) of participants who responded to the survey question said they would not test elsewhere at all [35].

One study reported on lower rates of preference; a majority of participants who requested a self-test did not want any form of support (338/434, 77.9%) [11]. However, of those who did want support, digital forms of support including instant messaging, video calls, and chatbots were preferred by 65.8% (102/155) of respondents, compared to in-person support (47.7%, 74/155) [11].

Feasibility

Feasibility was assessed in 60.8% (31/51) of the studies [10-12,21-23,29,31,34,35,40-60].

Uptake

Overall, 90.3% (28/31) of these studies reported uptake of self-tests [10-12,22,31,34,35,40-60], which varied across studies (30.9%-98.2%; 11/31) [10,11,22,31,40-42,44,45,48,49,54]. Out of 9 of the remaining studies measured uptake as the number of HIV self-test kits ordered throughout the study. This included 701 kits ordered by 604 participants, 834 tests ordered by 309 participants, 5840 kits ordered by 5324 participants, 5235 kits ordered by 3627 participants, 5323 kits ordered by 4859 participants, 13,334 kits ordered by 11,332 participants, and 3 studies in which each participant ordered a single test (2610, 7315, and 21,035) [12,46,47,50,52,53,55,57,58]. An Australian study reported that of the 794 participants who ordered an HIV self-testing, 95 of them ordered multiple self-testing kits, between 2 to 7 kits per person [35]. An RCT conducted in the United States investigated the effect that a peer-led online community had on the uptake of the blood-based myLAB Box HIV self-testing [51]. This study found there was an increase of 6.3% in test uptake between the intervention and control groups, with an odd ratio (OR) of 1.43 (95% CI 1.04-1.95, *P*=.03) [51]. Another RCT conducted in China analyzed the effect of monetary incentives and online peer referrals on test uptake of the blood-based SD BIOLINE HIV and syphilis self-test [52]. This study found that the 102 control participants ordered 222 kits, the 103 participants of the monetary intervention group ordered 275 kits, and the 104 participants in the monetary and peer referral intervention group ordered 337, all of which were ordered using a digital intervention [52].

Proportion of Participants Who Responded to the Intervention

About 22.6% (7/31) of studies reported how many of the participating people actually responded to the intervention, with one study reporting a response rate of 26.0% (2467/9505), and the others 61.1%-94.1% (216/345 to 96/102) [11,29,35,47,51,52,54]. The outlying response frequency of 26.0% 2467/9505 referred to responses of an optional online survey asking questions on participants' quality of experience, which was offered once the self-testing process was complete [29]. In RCT, the response proportion was higher among the intervention group (93.4%, 421/450) compared with the control group (92.9%, 418/450) [51]. As well, another RCT found the response rate to be higher among the intervention groups (94.2% and 96.2%) compared with the control group (94.1%) [52].

Visits to the Web-Based Provider

Out of 4 studies reported such, of which three reported as percentages of 43.0% (1475/3431) of participants interacted with the content, 70.7% (531/751) of participants logged onto the app, and 67.9% (19/28) clicked on messages sent on the app [21,23,60]. The remaining paper reported that the study website was viewed about 266,000 times [47].

Impact

Impact was measured in 88.2% (45/51) of the studies [4,10-12,21-25,27,29,31-35,37-50,52,53,55-67].

Detection of New HIV Infections

This was the most prominent metric used in 68.9% (31/45) of the studies [4,10,11,22-24,29,31-33,35,40-50,52,55-59,61,62,64]. A majority of these papers (61.3%, 19/31) reported the proportion of new infections by HIV self-tests result which varied from 0.0% to 25.8%, which were confirmed by laboratory result [10,11,23,24,29,31,32,40,41,44-46,48,49,57-59,61,64]. One study reported that 18 participants returned a positive self-test result [61]. Another study found that of 5048 returned self-test results, 165 were positive [47]. One study noted that 41.1% (130/314) of the participants that tested positive had not received a positive result before [29]. The other 8 papers reported the proportion of new infections as those confirmed by laboratory testing, ranging from 0.0% to 10.1% [4,22,33,35,42,43,52,56]. One study did not specify how many results were returned, but stated that 86 people who conducted the self-test were confirmed via laboratory result at the project sites [50]. Another study found that out of those who sought confirmatory testing, 96.8% (522/539) were confirmed to be HIV positive [55]. A quasi-RCT found the proportion of new

XSL•FO
RenderX

infections to be higher in the intervention group (8.9%), which included unsupervised and supervised self-testing, compared with the control group (6.8%) risk ratio (RR; 1.304, 95% CI 1.023-1.665) [4].

The Proportion of "First-Time Testers"

Reported in 57.8% (26/45) of the studies [11,12,21,24,25,27,31,34,35,37,42,44,45,48,49,52,53,55-57,61-64,66,67]. The proportion of first-time testers for 23 of these studies ranged from 2.0%-53.0% [11,12,21,24,25,27,31,34,35,37,42,44,45,48,52,53,55-57,62,64,66,67]. In addition, one study looked at 1070 returned self-tests and found 43 of them to be positive, all of which were from first-time testers [49]. One study compared the proportion of first-time testers between age groups and found that 53.0% of those who were 18-24 years old were first-time testers, compared with only 20%-30% of those in the higher age groups (OR 3.30, 95% CI 2.88-3.78) [63]. Another study looked at the difference in rate of first-time testers among White participants compared with African, Caribbean, and Black participants and found that the proportion of White first-time testers was 21.0%, compared with 30.0% among African, Caribbean, and Black participants [61].

Result Return Proportion

Defined as the percentage of reported results from participants and was captured in 53.3% (24/45) of the studies, ranging from 22.4%-100.0% [10,12,23,29,31,32,38,39,41,44-46,48,49,52,53,55,56,60-62,64,65,67]. An RCT found that the return rate among the control group (94.0%) was higher than the intervention group that did not receive online peer referral (93.4%), but was lower than the intervention group that did receive online peer-referral (97.3%) [52].

Linkage to Care

Observed in 46.6% (21/45) of studies [4,22,24,29,31,33-35,40,42,43,45-49,53,55,57,62,64]. 76.2% (16/21) of these studies reported this metric as confirmatory HIV testing and linkage to treatment which varied from 53.0%-100.0% [22,24,29,31,33-35,40,42,45,47,53,55,57,62]. Out of 8 studies (38.0%) reported linkage to care as the percent of confirmed HIV-positive participants who were referred to and initiated antiretroviral therapy (ART) and ranged from 44.4%-98.1% [4,43,46,48,49,53,55,64].

A quasi-RCT reported the highest linkage to care, with a greater proportion for the intervention (99.8%) compared to the control (98.5%; RR 1.012, 95% CI 1.005-1.018) [4]. As well, 98.1% of all those who used HIV self-test were either referred to start ART if they were HIV-positive, or for preventive treatment if they were HIV-negative [4].

Referrals to Self-Test

A quasi-RCT also showed that 16.7% of participants in the self-testing group referred someone in their social network, whereas only 3.1% of participants in the conventional testing arm did (RR 5.435, 95% CI 4.024-7.340) [4]. In another RCT, it was reported that 78.0% (479/618) of participants had given a self-test to a social network associate [67].

Discussion

Principal Findings

Accuracy

Invalid tests were not explicitly defined in any of the studies but were assumed to refer to a result that was neither negative nor positive. Invalid results are a product of a defective test, incorrect testing conduct, or result in misinterpretation. Invalids are an important factor to consider for diagnostic performance, as users' trust in the self-testing process may diminish when an invalid result is received. The WHO and other governing bodies lack defined thresholds for acceptable invalid results in screening. We found the highest invalid rate (12.7%) occurred in Canada, using the blood-based bioLytical INSTI self-test, Canada's sole approved HIV self-testing so far [12]. There is a need to define an acceptable threshold of invalid tests at the level of approval.

Sensitivity, specificity, PPV, and NPV are crucial for evaluating the performance of HIV self-testing and determining the reliability of results. Although 7 studies reported high diagnostic performance with HIV self-testing as the low proportion of invalid tests or high sensitivity, specificity, PPV, and NPV, the overall body of literature in this area remains sparse.

One study analyzed the impact of a digital reader in self-result interpretation, compared to the participants' interpretation [20]; however, no studies assessed the improved accuracy of digital intervention-enhanced HIV self-tests compared to those without digital interventions that are widely accessible to the general population. This highlights the need to explore the potential of digital innovations in improving the accuracy of HIV self-test.

Furthermore, it is important to highlight that one of the studies reporting all the ideal accuracy measures evaluated the impact of internet use on HIV self-test uptake and performance, not the direct influence of digital interventions on the self-testing process [19]. This indicates a research gap in understanding the direct impact of digital interventions on the accuracy of HIV self-testing. This study also reported moderate measures of accuracy, suggesting room for improvement of digital supports that are implemented during the testing process.

One of the other studies that reported the ideal accuracy metrics did so comparing interpretation by (1) participants, (2) pharmacy provider, (3) AI tool, and (4) expert panel of 3 HIV self-test readers [20]. The reported accuracy metrics were comparing the AI tool to the expert panel, instead of between the AI tool and participants, which again highlights this gap in existing research [20].

The final study that reported metrics on diagnostic performance did so comparing the HIV self-test result to the reference standard, reporting high accuracy measurements for each outcome [6]. However, there is still a gap in research comparing the results of HIV self-testing with the support of a digital intervention compared to an HIV self-test result on its own. Future research should aim to analyze the accuracy between HIV self-tests alone versus with digital support, to properly

XSL•FO
RenderX

evaluate the direct impact digital innovations have on the self-testing process.

Acceptability

Acceptability of digital interventions for HIV self-test varied across studies, indicating that acceptability is influenced by diverse factors. Persistent willingness to use digital interventions across studies (72.2%-99%) suggests openness and receptiveness to incorporating digital technologies into the self-testing process. To improve the acceptability of digital interventions, future developments should consider comprehensive HIV self-testing integration, including sample collection and result interpretation.

Ease of use varied significantly in definition across the 8 studies that reported this metric, but overall, most study participants found the digital innovations easy to use. It is important to note that the demographics of the participants in these studies may play a role in the reported ease of use. For example, in 1 paper, 122/350 participants were people who had used an online HIV self-testing platform before, which may have increased their report of ease of use [22].

Preference

This systematic review demonstrates generally high rates of preference (63.0%-99.3%) for digital interventions in the context of HIV self-testing, suggesting notable favorability toward digital innovations for HIV self-test.

One study reported lower rates of preference for any form of support during the HIV self-test process, as most participants in that study expressed a preference for not receiving any support [11]. For those seeking support, digital options were preferred over in-person support, underscoring diverse preferences and the need for tailored interventions. The novelty of digital innovations can be overwhelming, particularly among older generations and individuals who are less familiar with technology, which may influence their preferences of digital interventions for HIV self-test. It is crucial to consider the target population and their digital literacy level, and to provide adequate support, education, and user-friendly interfaces to address potential barriers related to technology adoption.

Another study reporting low preference had given participants the choice between HIV self-testing with a mobile app and HIV testing conducted by a health care provider [39]. This study was conducted among youth aged 16-24 years in Zimbabwe and qualitatively asked the participants why they may have chosen standard HIV testing compared with self-testing with the digital app [39]. Common explanations included low general and digital literacy, limited self-efficacy or agency, fear of testing and need for provider support, lack of private digital or physical space, and technical issues [39]. Given the specific geographic region of the age group included in this study, it is possible that these findings may not be replicated if repeated in another area of the world, for example, the United States, where digital literacy is likely to be improved. However, these qualities still need to be addressed in HIV self-testing and provide people with comfort and a sense of autonomy when self-testing, instead of fear and hesitation. As well, the preference rate found in this study cannot be attributed solely to the digital aspect of self-testing, but the self-testing process as a whole. Increasing awareness of HIV self-testing methods could enhance the outcomes of similar studies, as participants with greater familiarity and understanding of the testing approach may feel more confident in selecting the digital self-testing option.

Feasibility

High uptake of self-tests facilitated by digital interventions suggests the broad accessibility and convenience associated with digital HIV self-test.

In one RCT, the overall uptake of HIV self-testing was relatively low, but the inclusion of a digital component increased test uptake by 6% (OR 1.43; 95% CI 1.04-1.95), highlighting the potential of digital interventions to positively influence self-test uptake rates [51].

Another study reported a 25.0% increase in clinical HIV testing through the implementation of a digital solution [43]. This suggests that the widespread application of digital innovations in HIV self-test could contribute significantly to achieving the UNAIDS 2025 targets of increased HIV serostatus knowledge and treatment.

Response rates substantially varied across studies, which may have been influenced by follow-up procedure disparities and the recruitment of vastly diverse populations. Tracking and analyzing response rates are vital to assess the performance of digital interventions and identify effective methods for obtaining feedback via digital means.

Visits to web-based providers varied across the studies, potentially attributed to differences in the methods of exposure to digital innovations. For example, in one study, the intervention involved a campaign about HIV self-test disseminated through social media platforms, which have algorithmic influence on exposure, limiting exposure of certain individuals to the digital intervention [21].

Altogether, the inclusion of digital components has been shown to increase test uptake, and the feasibility of digital interventions are supported by the available evidence. However, response rates and variations in exposure methods should be carefully examined and addressed to optimize the performance and impact of digital interventions in HIV self-testing.

Impact

The use of HIV self-testing methods with digital support has shown potential in reaching the first of the UNAIDS 95-95-95 targets, supported by the proportions of new infections and first-time testers.

The parity between new infections identified via HIV self-test and confirmed HIV cases, 9.8% versus 10.1%, indicates that HIV self-test with digital support is a valuable tool for identifying new cases of HIV. Importantly, a study in South Africa reported an increase in the proportion of new infections among the HIV self-testing arm compared to the conventional testing arm (RR 1.305, 95% CI 1.023-1.665), supporting digital aids in enhancing HIV detection [4].

The proportion of first-time testers supports digital innovations' potential in streamlining HIV self-testing access. Accessibility of digital HIV self-testing methods to the general population is

XSL•FO
RenderX

likely to elevate first-time tester rates, capturing those not engaged via traditional methods, and thus expanding testing coverage.

Digital support facilitated high test result returns across studies, likely attributed to the convenience and accessibility digital reporting affords. The ease of reporting results digitally eliminates the need for physical clinic visits, fostering convenience and potentially encouraging higher rates of result reporting.

While one study observed a lower self-test return rate due to mobile-app user attrition, this could be context specific, as the study was conducted in South Africa in 2018/2019, and thus subject to change due to evolving mobile-app utilization trends and self-testing methods used through the COVID-19 pandemic [23].

Linkage to care is a critical aspect of HIV testing. HIV self-testing without digital support have struggled with adequate linkage to care [68]. Digital innovations significantly aid this process, enabling direct participant connections to care without having to navigate the resources themselves. In one study, there was linkage to post-test counselors, who facilitated staging the disease of those who tested positive and assisted in preventative practices for those who tested negative, yielding a robust linkage proportion (99.7%) among the self-testing arm [4].

The findings of this review support the high linkage to care, as the high proportion of individuals who received a positive self-test result were connected to confirmatory testing, underscoring digital support's role in facilitating real-world follow-up. Furthermore, there was a high proportion of individuals who were confirmed to be HIV-positive and started ART treatment which demonstrates the promising potential of digital interventions in successfully connecting HIV-positive patients to continuative care. These findings highlight the practicality and convenience of digital interventions in the HIV testing and care continuum.

Overall, the use of digital innovations in HIV self-test has resulted in the identification of new infections of HIV, an increased proportion of first-time testers, and a high return rate of test results.

Quality Assessment

The accuracy studies generally had low risk of bias; however, a lot of information was not specified. For 57.1% (4/7) of the studies, invalid test results were used as a proxy for real-world performance and were limited by a lack of reference standards to complete the test performance. The studies did not mention if the participants also received confirmatory laboratory testing, except for 2 [6,19]. The RCTs included in this review had a low risk of bias. There is the confidence that these studies were well conducted and have trustworthy results.

Overall, the cross-sectional studies had low risk of confounding bias, but some or high risk of selection bias and outcome misclassification. The high risk of selection bias was mostly due to lack of justified sample sizes. As for outcome misclassification, the assessment of the outcome was consistently self-reported, considering the nature of self-testing, thus increasing the risk of bias. It is also important to note that many of the conference abstracts neglected to include details pertaining to the quality assessment; therefore, the study may have conducted higher quality of research but was not outlined in the abstract alone.

The cohort studies were of average quality. Out of 2 studies had missing data, and another had only one star and were therefore classified to be of low-level comparability [48,57,58]. Overall, the quality of these studies can be trusted in terms of the selection processes, but there should be some hesitation regarding comparability and outcome biases.

Limitations

The heterogeneity of interventions, outcomes, populations, and settings among the included studies introduced variability and made it challenging to draw definitive conclusions or generalize the findings across various contexts. Heterogeneity in reporting outcomes poses a challenge in synthesizing the evidence. Variation in outcome measures and their assessment methods makes it difficult to pool data and establish a comprehensive understanding of the effectiveness of digital supports. Future studies should adopt standardized outcome measures and reporting guidelines to facilitate meaningful comparisons and meta-analyses.

Limited evidence was available from low-income countries. Many studies included in this review were conducted in the middle- or high-income settings, such as China, the United States, Canada, and South Africa, which may limit the generalizability of the findings to low-income countries. This highlights the need for more research in diverse geographic and socioeconomic contexts to assess the feasibility and effectiveness of digital health interventions across different resource settings.

Several limitations in the review process should also be acknowledged. The search strategy was restricted to 2 databases, which may have resulted in the potential omission of relevant studies published in other databases. Moreover, this review focused on a majority of observational studies, which inherently lack the randomization and control provided by RCTs, potentially influencing the observed effects of digital health interventions.

Implications and Future Research

This review incorporates 14 RCTs (including 6 quasi-experimental trials), 34 cross-sectional, and 7 cohort studies, providing a comprehensive overview of the existing evidence. These studies offer valuable insights into the effectiveness and potential benefits of digital innovation in health care practices in terms of accuracy, acceptability, preference, feasibility, and impact. Moving forward there is a need to enforce reporting of trials in HIV self-testing as per the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) checklist [69], as well as a need to appreciate the use of quasi-randomized designs that provide a greater richness to the breadth of literature by virtue of implementing these solutions in real-life settings. Single-arm interventional studies also provide evidence on why and how an intervention could

XSL•FO
RenderX

be successful in a setting. Bias is an inevitable consequence of all study designs, less so with an RCT, followed by quasi-randomized and single-arm interventional studies, in that order. However, evidence generation with the use of a stronger methodology adds to the evidence base needed to formulate guidelines and to the GRADE (Grading of Recommendation Assessment, Development and Evaluation) approach [70].

In addition, it is important to consider patient preferences in testing processes, as this can have a profound impact on retention rates. Qualitative research underscores digital strategies' flexibility, allowing individuals to tailor their testing experiences to fit their unique needs and circumstances, and patient satisfaction [71]. For instance, digital HIV self-testing strategies have been shown to mitigate barriers such as stigma associated with in-person testing, while providing users with control over the testing process, including the option to involve, or exclude, others during testing [71-73]. However, challenges remain in ensuring that these tools are accessible to all. These findings call for future research to optimize HIV self-testing methods.

While this review highlights the potential of digital innovations to increase accuracy rates, robust studies are required to comprehensively understand the potential benefits and limitations of digital innovations in enhancing the accuracy of HIV self-testing.

HIV self-testing with digital tools is the next step in the armamentarium in our fight against HIV. These tools are best suited when certain conditions are met, including the following:

1. Digital connectivity and tools to avail it are established and are cheap or relatively affordable, depending on the context and the country setting.
2. Populations using these solutions are digitally literate and health literate and are able to navigate care using these solutions.
3. The pathways to clinical care are made navigable and are often facilitated by a corpus of healthcare providers who can offer assistance to those who call, chat, and engage with them.
4. Dashboards and platforms that are set up are often interoperable and can work with country-level network architecture of electronic records and telemedicine that are in place.
5. Linkage services can be set up easily with these solutions and populations identified with infections can be seamlessly integrated within care pathways.
6. Countries have signed on to the treaty on digital health and are aligned with WHO's vision of One Health.
7. Linkage to treatment and retention in care are essential for these tools to be optimally effective, not just screening.
8. A corpus of health care counselors and testers have been trained in the use of digital solutions and through training, have become well-equipped to identify the challenges of navigating care pathways and are ready to help task shift to decrease the pain experience in navigating linkage to care and counseling by testers.

Conclusion

Digital supports enhance HIV self-testing across multiple domains, including improving test accuracy or self-test interpretation and achieving high metrics of acceptability, preference, feasibility, and impact. They have the potential to improve test accuracy by providing clear instructions, result interpretation, and data collection mechanisms, promoting reliable and trustworthy results; however, further evidence is needed in this space.

Digital interventions positively impact acceptability and preference due to their convenience, privacy, and autonomy. Furthermore, they improve the feasibility of HIV self-test, by leveraging technology to provide easy access to testing and result reporting, eliminating the need for physical visits to testing centers or clinics, especially benefitting individuals with time constraints, limited mobility, or those residing in remote areas. Finally, digital supports elevate impact by increasing result returns, attracting first-time testers, identifying new infections, and aiding linkages to care. Leveraging technology's widespread use, digital interventions extend HIV self-test reach, bridging testing coverage gaps, though more research and implementation data are needed in low-income settings and among key marginalized populations affected by HIV. These populations and settings traditionally lack access to connectivity tools, which may impact equity and access to services. Despite challenges, integrating digital tools aligns with health care's evolution, offering the potential to revolutionize HIV testing, ultimately leading to better health outcomes for individuals and communities. These interventions bode well to help us achieve UNAIDS 95-95-95 targets, especially for high-risk HIV populations residing in 191 middle- to high-income countries, who constitute a majority of the world's population.

Acknowledgments

NPP acknowledges the support of the Fonds de recherche du Québec-Santé (Distinguished Research Scholar Award 324154). The agency played no role in the study design, data collection, data analysis, interpretation, or decision to submit for publication. Data Availability

All data generated or analyzed during this study are included in this published article (and Multimedia Appendices 1 and 2).

Authors' Contributions

AB and NPP conducted conceptualization responsible for formulating and evolving the overarching research goal and aims. AB, OV, and NPP managed data curation and software analysis. AB and OV conducted the statistical, mathematical, and formal analysis of the data. NPP secured the funding of financial support for this project. AB conducted the research investigation. NPP created the methodology of the review. AB was responsible for project administration the management and coordination of research. NPP provided the resources required for the execution of this project. NPP generously and successfully provided leadership and support to AB for this supervision project. NPP was responsible for the verification of all processes for this review. AB led the preparation and creation of the review outline and structure.
AB and NPP designed, Writing-original drafted, and reviewed the initial manuscript. AB, OV, NE, TD, CL, and NPP provided critique on subsequent drafts, as well as reviewed and approved the final written manuscript.

Conflicts of Interest

Abstract

Background: British Columbia residents have access to a program called QuitNow that provides behavioral support and information about pharmacotherapy to nicotine and tobacco users. Web- or computer-based smoking cessation programs have been shown to yield an abstinence rate about 1.5 times higher when compared to a control. Although quantitative evidence reveals significant promise for web-based services like QuitNow, there is very little qualitative evidence available. Understanding website utilization and the experiences of end users is key to contextualizing the effectiveness of web-based cessation services and providing directions for enhancing these services.

Objective: This qualitative interview study aims to delve into users' utilization and experiences of QuitNow, which is supplemented by Google Analytics data.

Methods: We interviewed 10 QuitNow users using semistructured interviews to understand what they liked the most and the least about QuitNow. We transcribed these interviews and conducted an inductive thematic analysis using NVivo (QSR International) software to extract common themes about user experiences. We also gathered utilization metrics via Google Analytics (n=13,856 users) to understand which aspects of QuitNow were used the most and which were used the least during the study period.

Results: Thematic analysis yielded four major themes: (1) barriers to information access reduce opportunities to take action, (2) lack of clarity around pharmacological options is discouraging, (3) hearing from others is an important part of the journey, and (4) recognizing own agency throughout the quit process. These themes provided context and support for the Google Analytics data, which showed that end user activity, measured by indicators such as page views and average time spent on each page, was highest on pages about how to quit (10,393 page views), pharmacology information (1999 page views), and the community forum (11,560 page views).

Conclusions: Results of this study point to several important implications for improving the website, as well as directions for enhancing cessation support services in general.

Introduction

Smoking, a leading cause of preventable deaths worldwide, poses a significant challenge for individuals attempting to quit. The prevalence of current cigarette smoking among Canadians aged 15 years and older in 2022 was 10.9%, unchanged since 2020, but decreased from 12% in 2019 [1,2]. Notably, in 2020, British Columbia had the lowest smoking rate among Canadian provinces, at 7.7% [3], and continues to boast the lowest smoking rate of 8.7% among all Canadian provinces in 2022. Similarly, vaping rates are also lowest in British Columbia, with a past 30-day vaping rate of 4.7% in those aged 15 years and older [2]. This achievement can be attributed in part to the British Columbia government's initiatives, such as the British Columbia Smoking Cessation Program, including QuitNow, which supports residents in covering the costs of Nicotine Replacement Therapy (NRT) and smoking cessation prescription drugs and provides those attempting to quit a variety of nicotine products with access to community and expert coaches.

Nearly two-thirds of Canadians who smoke express intentions to quit in the next 6 months and half report that they have tried to quit in the past year [4]. Of Canadians aged 15 years and older who report daily vaping, almost half (42.4%) have made at least one quit attempt in the last 12 months [2]. However, unaided quit attempts have a very low success rate, with fewer than 5% achieving abstinence for 12 months or more [5]. To achieve meaningful reductions in tobacco-related morbidity and mortality, we must increase both the number of individuals who attempt to quit and the success rate of those attempts. Guidelines recommend combining pharmacotherapies with behavioral interventions to enhance the effectiveness of smoking cessation attempts [6,7]. Web-based programs have emerged as a valuable tool in this context. A meta-analysis of 22 randomized controlled trials has demonstrated the clinical efficacy of web-based smoking cessation programs for adults who smoke [8]. This study included 29,549 participants and revealed that web- or computer-based smoking cessation programs yielded an abstinence rate about 1.5 times higher than the control group, and this was observed at both 6 and 12 months of follow-up [8].

Today, 5.18 billion people (two-thirds of the global population) are currently connected to the World Wide Web [9]. From 2000 to 2023, web usage grew more than 1000%, and this number is predicted to continue to grow [10,11]. In recent years, the expansion of web-based systems in Canadian health care has notably enhanced service delivery and patient engagement. For instance, the number of Canadian primary care physicians using electronic medical records has risen from 73% in 2015 to 93% in 2022, facilitating better patient care through improved information sharing between providers, such as lab results and referrals [12]. The COVID-19 pandemic has also led to a rise in the usage of web-based health care, consequently shifting nicotine usage and cessation needs. As the number of global web users grows and the internet becomes increasingly embedded in health care systems, web-based cessation programs are poised to become a more valuable public health strategy [13]. Ensuring the quality and effectiveness of these programs will be crucial in providing accessible support to nicotine and tobacco users worldwide.

QuitNow, a free web-based cessation program provided by the British Columbia Lung Foundation on behalf of the Government of British Columbia, offers information on nicotine and its harmful effects, access to an online community, and one-on-one guidance for individuals seeking to quit or reduce tobacco and e-cigarette use [14]. While previous research has explored the overall impact of online cessation support, there is limited knowledge about the in-depth experiences of end users and how their experiences contextualize specific utilization data [15].

Web-based cessation programs, such as QuitNow, are designed to provide tailored support and resources to individuals seeking to quit smoking or using other nicotine products. The effectiveness of these platforms is heavily dependent on how users interact with the content and features provided. For instance, user engagement metrics, such as page views, time spent on specific sections, and interaction with multimedia elements, offer valuable insights into which aspects of the platform are most effective or need improvement. By analyzing these interactions, developers can make data-driven decisions to enhance the platform's usability, accessibility, and overall impact.

This study aims to address the gap in knowledge by investigating the in-depth experiences of individuals who used QuitNow as a quit aid and examining how these experiences are reflected in utilization data, such as that provided by Google Analytics. By understanding end user experiences better, we can tailor our efforts to support British Columbia residents in reducing nicotine and tobacco use, thereby improving overall health outcomes.

Methods

Participants

Interview data from 10 individuals who had used QuitNow were included in this study. These participants were part of a larger study that aimed to understand the perceptions and experiences of QuitNow among individuals who use a variety of nicotine products. For this study, we examined data only from participants who reported using QuitNow to support their cessation (vs participants who had not used QuitNow) and included participants who had recently quit or were motivated to quit, either smoked, vaped, or both, were aged 16 years or older, lived in British Columbia, and could communicate in English. The recruitment procedures and inclusion and exclusion criteria are described in a previous study [16].

Out of the 10 participants, 8 were interested in quitting smoking or vaping, and 2 had recently quit (one quit smoking, one quit vaping). The mean age of participants was 34.5 (SD 17-55) years; 70% (7/10) were male, 50% (5/10) were Caucasian, 80% (8/10) smoked cigarettes, and 60% (6/10) used e-cigarettes. Most individuals who used traditional cigarettes (7/8, 88%) had been smoking for over 5 years, while 100% (6/6) of individuals who used e-cigarettes had been vaping for less than 5 years. Of all participants, 40% (4/10) only used traditional cigarettes, 30% (3/10) used both traditional and e-cigarettes, and the remaining 30% (3/10) had only used e-cigarettes.

XSL•FO
RenderX

Data Collection

All consenting participants filled out a brief demographic survey encompassing personal characteristics (eg, gender, age) and information about their smoking and vaping history. Participants then engaged in an approximately 60-minute, audio-recorded, semistructured interview via University of British Columbia Zoom. Interviews began with introductions and a reminder about the study's purpose and procedures. After participants answered questions about how they heard about QuitNow and what motivated them to use QuitNow, they were then asked 5 primary questions, including what they liked about QuitNow, what they did not like about QuitNow, suggestions for improving QuitNow, what aspects outside of QuitNow supported their quit journey, and their "ideal world" vision for how QuitNow could help them with quitting in the context of their lives. After interview completion, each participant received a CAD $50 (US $34.97) electronic gift card to thank them for their contribution to the study. Interview recordings were transcribed for analysis.

Data Analysis

We conducted an inductive thematic analysis of 10 interview transcripts following guidelines from Willig et al [17]. The interviews were first transcribed verbatim and uploaded to the qualitative data analysis software program NVivo (QSR International). The analysis process began with two researchers (TS and LS) reading the transcripts while making casual observational notes to engage with and familiarize themselves with the data. After a detailed reading of the transcripts, the researchers began to generate codes and systematically label and synthesize segments of the dataset to reduce and organize it. For example, when participants described barriers of the website for supporting their cessation, the researchers inserted these data under the larger code "barriers to quitting," which then contained specific sublabels for these barriers (eg, "too much text to process;" "can't access the full site without providing personal details"). We did the same with "facilitators to quitting." Data saturation was achieved, whereby we found no new interview data emerged to answer our research question after the sixth interview. Following this, the researchers iteratively developed a coding framework using interview data. One author (TS) then sorted associated tagged data segments according to the developed codes, which were revised or added to as new data were collected. The researchers then examined the codes and their associated data and clustered them to construct themes from a well-rounded understanding of the transcripts. For example, when examining codes around website-based barriers and facilitators to quitting, we recognized overall themes. For example, while participants talked about how too much text limited their ability to really take something away from a certain page and apply it in practice, they also talked about how graphic-based information enabled them to learn and apply ideas to facilitate quitting, something that was lacking. Therefore, these codes were grouped together and formed the theme "Barriers to information access reduce opportunities to take action." These were reviewed and defined to help answer the research question. Author TS then finalized the findings and produced the report, which was reviewed by all other authors for agreement.

Google Analytics Data

To understand empirical information on public usage of the QuitNow website and related trends (eg, which pages on QuitNow were most frequently navigated to, the average duration of time spent per page), Google Analytics data from the period during which participant interviews were conducted (March 3-July 6, 2021) were also gathered. Analytics data included information on overall website usage and user reach, along with detailed web page-level metrics capturing typical user behaviors on the site (eg, number of sessions; length of sessions).

Ethical Considerations

Ethics approval for this study was obtained from the University of British Columbia (Okanagan) Behavioral Research Ethics Board (H21-00145-A006). All participants were required to provide informed consent. Before their interview, participants were provided with an emailed consent form and informed that their participation was voluntary; they then provided written consent via email. Consent to participate and to be audio-recorded was reiterated at the beginning of each interview. In addition, participants were reminded that their participation was entirely voluntary and that they could withdraw from the study at any time. Each participant received a CAD $50 (US $34.97) honorarium to thank them for their contribution to the study. To protect participant identity, participants were given an identification number to anonymize their responses. Personal information such as names and contact details was not included in the dataset and was securely stored separately from the study data. Audio recordings and transcripts were kept in password-protected files, accessible only to the research team. The datasets generated during and analyzed during this study are not publicly available due to the protection of participant identity but deidentified data are available from the senior author (LS) on reasonable request.

Results

Qualitative Themes

Overview

This study resulted in four major themes to capture the experiences of individuals who used QuitNow to support tobacco and nicotine cessation. These themes include: (1) barriers to information access reduce opportunities to take quit action, (2) lack of clarity around pharmacological options is discouraging, (3) hearing from others is an important part of the journey, and (4) recognition of one's own agency in the quit process. Some of these themes contain subthemes, which will be elaborated in the following sections.

Theme 1: Barriers to Information Access Reduce Opportunities to Take Action

Sharing Personal Information to Access Information Is a Barrier

In this study, a number of participants expressed reluctance and discontent with the process of creating an account and sharing personal information, citing various reasons for their reservations. Some of these included discussions on user privacy

XSL•FO
RenderX

and even references to other websites that allow users to be anonymous and thus more genuine. For example, participant 49 (male, an individual who smokes) said:

> *one of the benefits of Reddit is [that it] is anonymous. So people are naturally inclined to be more open.*

Participant 51 (female, an individual who smokes) believes that:

> *[the website] could be a little bit less intrusive with respect to personal information, then that might be helpful (…) I mean, there's so many issues with identity theft and security.*

Participant 17 (male, an individual who vapes) even explicitly stated that:

> *what kept [them] from really using [the website] is the fact that you have to kind of create an account.*

In fact, one participant (P73, male, an individual who dual uses) even wondered:

> *what if somebody is not ready to sign up yet, but they're interested?*

This highlights that web designers should reduce barriers to accessing the website. To address these issues, more than one participant suggested having a "guest function." In describing this feature, participant 73 (male, an individual who dual uses) said:

> *like you don't have to, like log in and have like a name, but you can like be a guest and look at all the other stuff and here are all the options that are available after you make your quit plan.*

Lack of Content Clarity and Usability Is a Barrier

Another barrier to consider is that commonly used formats, such as primarily online-based and text-heavy ones, may not support effective and inclusive engagement for all individuals. Therefore, alternative formats should be considered. These include non–web-based platforms, as well as more accessible online platforms that are user-friendly, incorporate visuals, and use clear and simple language when internet access is not a barrier. Specifically, participant 86 (female, individual who dual uses) states that:

> *a lot of people in [place] don't have internet either so it's like you could tell them about it but they can't access it so maybe a pamphlet would be better.*

To minimize challenges associated with the current online platform, participants recommended reducing the amount of text per page and allocating a tab on the website that would allow immediate access when the cravings hit. To illustrate these ideas, participant 49 (male, an individual who smokes) suggested:

> *point form [and] breaking down to one or two sentences per paragraph.*

Participant 86 (female, individual who dual uses) even brought up how cravings last around 3-5 minutes and the importance of having an easily accessible tab that gives:

> *suggestions about things that you can do […] that might be more productive so that when that craving hits then maybe it's like you have a list of like things to quickly go and do*

Not only can the text be made more comprehensible, but more visual components can be added, as alluded to by some individuals. Participant 49 (male, individual who smokes) said:

> *The information could be supplemented with images or replaced by images" while another participant agrees and describes visiting pages that have a "wall of information and if that can be divided up into more of a visual infographic [then] it would just bring the point across better.*

Theme 2: Lack of Clarity Around Pharmacological Options Is Discouraging

When talking about NRT, participants were pleased that it is provided free of charge through the British Columbia Smoking Cessation Program via Pharmacare. Participant 34 (male, individual who smokes) said:

> *It's a nice feature to have the provincial government sponsoring that.*

However, while they appreciated its availability, they also highlighted the lack of information and clarity about this program on the QuitNow website. Many participants were unaware of the availability of free NRT, how the program functions, and how much NRT they could obtain for free. For example, participant 34 (male, an individual who smokes) said:

> *I mean, I go to the grocery store and look at the patch on the shelf. And it's like, 50, $60, and, you know, for a week, and you're like, yeah, I spend that much on cigarettes or whatever. So it's a no.*

Even when some participants were aware of the program, they still faced difficulties accessing more NRT when needed and expressed frustration due to the lack of clear guidelines on obtaining and using the free NRT.

> *The only frustrating, I think, is like I guess be more information about the nicotine replacement therapy program that's offered for free in B.C. because like I ran out of mine so I couldn't get anymore and so I think like I didn't know that until I went back to get more and they said I was out and like you could only get so much in 3 months. So maybe just some more information about like specifically how to get that because I had to tell a lot of people about it too so like how to get it, how much you can get for free.* [participant 86, female, an individual who dual uses]

Theme 3: Hearing From Others Is an Important Part of the Journey

Hearing From Others Who Smoke

When describing what helped them during their quit journey, participants highlighted the importance of hearing from both current and former smokers who had successfully quit. Participant 34 (male, an individual who smokes) shared:

> *I really liked the inspirational stories about the other people quitting. I think that was really positive.*

XSL•FO
RenderX

> *Especially when you see people have [smoked] for years, and then they've given up and they're happy.*

Similarly, when reflecting on the community forum, Participant 51 (female, an individual who smokes) emphasized the value of going through the process with others:

> *I am really not alone in this journey, right. And also, when people share their experiences, it just helps us connect better. Connect better with the situation, challenges, and success.*

Participant 60 echoed this sentiment, stating:

> *It shows you that it's not just you. A lot of other people are trying to quit, and also using the app and trying hard.*

Communication From Professionals

Participants emphasized the importance of being able to connect with professionals, such as quit coaches, during their quit journey. These experts provided not only practical advice but also emotional support, offering tailored guidance that complemented the information on the QuitNow website. Participant 60 (male, individual who vapes) shared that:

> *what was really…helpful is [that] you can communicate with an agent [..] whenever you need someone to help you, whenever you have questions, whenever you anything, you can just one click.*

Beyond answering technical questions, professional interaction also helped users feel supported in moments of uncertainty or high cravings, reinforcing their motivation to quit. Participants appreciated the immediacy and personalization of the support, which made them feel they were not navigating the process alone. Some suggested that future versions of QuitNow could include more proactive communication, like scheduled check-ins or reminders, to keep users engaged and motivated throughout their quit journey.

Theme 4: Recognizing Own Agency Throughout the Quit Process

While participants provided their insights and experiences with using QuitNow to aid with their cessation, they described how important it was to recognize their own agency in the quit process. When answering the question about what the biggest factor in reducing or quitting was, one participant said:

> *I think it's myself* [participant 51, female, an individual who smokes]

Building on this, participants described how support programs, like online cessation websites, are valuable tools that can support their path toward a smoke-free life, but that the support offered must parallel the smoker's determination to quit. This is exemplified by the following participant statement:

> *But until you want to [quit], I don't know if you can [quit]. I mean, if we change it around and…we were talking about a fitness website, well, the fitness website isn't going to get you fit. It's going to give you a whole bunch of ways to get fit [and] reasons to get fit, lots of help, but it's up to you. I don't see a quit smoking website any different than that…there's no magic button that you're going to click on. And all of a sudden, you're not going to have no desire to smoke* [P39, male, individual who smokes]

Exploring Theme Interrelations

An examination of how the identified themes interrelate reveals a complex and interconnected landscape of user experiences with QuitNow. For instance, "Barriers to information access" (Theme 1) directly influence "Lack of clarity around pharmacological options" (Theme 2). When users face difficulties in accessing or understanding information due to privacy concerns or inadequate dissemination strategies, their ability to fully grasp and use pharmacological aids, such as NRT, is compromised. This lack of clarity can diminish the perceived value of such options, thereby impacting users' motivation to engage with them. In addition, "Recognition of own agency" (Theme 4) underscores the significance of individual determination in the quit process, which can be either supported or undermined by the other themes. For example, overcoming barriers to access (Theme 1) and achieving clarity on pharmacological options (Theme 2) can empower users to take more control over their quit journey, reinforcing their sense of agency. Conversely, insufficient support and unclear information may erode this sense of agency, demonstrating how these themes collectively shape and influence the quit process. By understanding these interconnections, we gain a more nuanced perspective on how different factors interplay to affect user experiences and outcomes in tobacco and nicotine cessation.

Google Analytics Findings

User Characteristics

Over the period of study, QuitNow's web platform was accessed by a total of 13,856 clients across British Columbia. Of these, 1723 were active users of QuitNow digital interventions, a collection of web-delivered services designed to support nicotine cessation goals. By contrast, the provincial Quitline hosted at QuitNow supported a total of 1178 clients over this same period, although it must be noted that we are unable to test for overlap between clientele accessing digital interventions and those contacting the provincial Quitline for support. The QuitNow web platform tended to serve younger clients than the traditional Quitline service, with an average age of 32.8 over the period of study relative to 54.9 among Quitline callers. Both service lines saw a similar distribution of genders, serving approximately 58% female, 40% male, and 2% nonbinary clients.

User Behavior

Of the 66 unique pages that make up the quitnow.ca platform, Tables 1 and 2 identify the 10 most- and the 5 least-trafficked pages during our study period, respectively. Also included are the total unique user counts over the study period for each page, the bounce rate (the percentage of users who only view one page and leave without any interaction, or whose view lasts less than 10 s), average time (how long a user spent browsing a particular page), average session time (how long a user spent on the website), and pages per session (how many pages a user visited during one session).

XSL•FO
RenderX

Beyond basic administrative pages such as the homepage, account creation, and sign-up pages, the most popular features of the QuitNow website tended to be community- and information-driven. The community forum and support pages both feature among the 10 most trafficked, with visitors to the community forum also averaging the most time on site per session. Information-sharing pages also feature heavily in the top-10 list, including "Get started now," "What does smoking cost," and "Medications can help." Less popular pages of the site highlight ways to distract oneself from nicotine cravings; "Get active," "Change your routine," and "Stay busy" are all among the 5 least-trafficked pages on the site.

In Table 1, a list of the top 10 most visited pages on the QuitNow website between March 3 and July 6, 2021, is given, highlights user engagement metrics such as page views, number of unique users, bounce rates, average time spent on each page, average session duration, and pages visited per session. These metrics were analyzed as part of our qualitative study exploring user experiences and engagement with QuitNow. Key observations include high engagement with the homepage and the community forum, which had significant page views and longer average time spent, while pages like "Join" and "Get started now" experienced higher bounce rates, suggesting opportunities for improved user retention. This data provides insights into how users interact with the site and which content resonates most with them.

Table 1. Top 10 pages visited by QuitNow users from March 3 to July 6, 2021.

Page	Topic	Page views	Users	Bounce rate	Average time	Average. session time	Pages per session
Homepage	The introduction page (users logged out)	22,719	9171	33%	00:00:39	00:02:54	1.42
Forum	Community forum for peer and coach support where users can share their experience	11,560	1918	59%	00:04:44	00:02:52	2.07
Quit Plan	Personalized guide for quitting when the users are logged in	10,393	1904	50%	00:02:48	00:05:49	2.84
Join	Web form to join the program	8107	7217	75%	00:01:36	00:01:26	2.04
Sign-in	Page to sign-in into the profile	7655	1326	10%	00:00:19	00:05:57	4.2
Get started now	Explanation of the program, why to create an account and steps	2553	1667	85%	00:01:19	00:00:38	1.36
What does smoking cost?	Interactive calculator to see how much money one spends	2317	1467	63%	00:03:37	00:01:31	1.41
Medications can help	Guide and description of the available medications in the province	1999	1159	75%	00:02:19	00:01:45	1.76
Community and support	Access to the services QuitNow provides to the community	1615	814	59%	00:00:43	00:01:11	2.3
Quitting	More information about stages of the quit process, from thinking about to preparing, to quitting, to staying quit.	1389	799	35%	00:00:33	00:02:38	3.51

In Table 2, the metrics were analyzed as part of our qualitative study exploring user experiences and engagement with QuitNow. These pages cover niche topics such as staying active, scheduling calls with Quit Coaches, supporting loved ones on their quit journey, coping with cravings, and finding distractions. Despite low user numbers, some pages—such as "Get Active" and "Supporting Loved One"—had notably high pages per session and long average session times, indicating deep engagement by the few who visited them. Conversely, other pages like "Stay Busy" and "Change Your Routine" experienced higher bounce rates and shorter time spent, suggesting potential areas for improvement in content or accessibility. This data helps identify underused resources and guides strategies for increasing visibility and user interaction.

XSL•FO
RenderX

Table 2. Least 5 visited pages on the QuitNow website between March 3 and July 6, 2021, focusing on user engagement metrics including number of unique users, bounce rates, average time spent on each page, average session duration, and pages visited per session.

Page	Topic	Users	Bounce rate, %	Average time	Average session time	Pages per session
Get active	The introduction page (users logged out)	107	33	00:01:44	00:05:47	7.33
Schedule a call	Page to schedule a call with one of the Quit Coaches	60	50	00:00:37	00:01:03	3
Supporting loved one	How to support and behave with people who are on their quit journey	52	28	00:00:59	00:07:04	7
Change your routine	Tips to cope with cravings and triggers	65	50	00:00:53	00:03:25	4.25
Stay busy	Advice and recommendations on how to get distracted from cravings	35	50	00:00:30	00:07:52	4.5

Discussion

Principal Findings

This study brings forward the end user experiences and utilization metrics of using a web-based cessation program (QuitNow) among individuals who want to quit smoking or vaping. In light of the shifting trends in nicotine and tobacco product use (eg, rise in use of e-cigarettes), demographic behaviors (eg, high vaping prevalence among youth), the rapid rollout of new digital technologies, and the high use of digital platforms, these findings provide important directions for optimizing such platforms. In particular, the findings bring forward important contextual factors that are unique to today compared with traditional approaches.

As the availability and use of digital platforms continue to rise and as nicotine users, particularly younger demographics (teens and young adults), navigate an increasing number of online platforms, the expectation for engaging and accessible content delivery becomes paramount. As indicated by individuals who use QuitNow, engaging formats not only capture attention more effectively but also contribute to a more relatable and memorable learning experience, which are crucial elements in supporting individuals on their cessation journeys [18]. A lack of information delivered in a variety of accessible, engaging, and visual formats may thus explain why the QuitNow Google Analytics data indicate that end users are not engaging with several pages focused on ways to distract from cravings despite our qualitative findings indicating end users' desire for rapid access to tips for dealing with cravings. Therefore, digital cessation supports must shed their traditional reliance on text-heavy formats and instead, leverage innovative and engaging multimedia elements, such as video testimonials, interactive graphics, podcasts, and opportunities to share on social media. Indeed, existing research highlights that, in the context of nicotine cessation, where motivation and sustained commitment are essential, a visual and interactive presentation of information serves as a powerful catalyst for positive behavioral change [19]. In addition to boosting engagement, interactive modalities may also foster a deeper connection with users by catering to varied learning preferences and thus enhancing accessibility [20]. Therefore, our findings emphasize that the effectiveness of nicotine cessation support websites relies not only on the quality of their content but also on the delivery methods they use.

The qualitative findings also indicate that information on pharmacotherapy options for quitting is desired, and the Google Analytics data indicate that information on pharmacotherapy options ranks among the top 10 pages visited on QuitNow. Pharmacotherapy is vital for individuals seeking to quit smoking and vaping, primarily addressing the physiological aspects of nicotine addiction. Approved pharmacotherapy for smoking cessation includes NRT products and several prescription medications. Research has consistently highlighted the effectiveness of pharmacotherapy, with some research indicating that those who use NRT or prescription medications are up to 2-3 times more likely to quit than those who attempt cessation without pharmacotherapy [21-24]. NRT offers a controlled and regulated supply of nicotine without exposing individuals to the more than 7000 chemicals found in cigarette smoke or vape aerosol [21]. This controlled supply of nicotine helps reduce withdrawal symptoms, such as cravings and irritability, making quitting more manageable and significantly reducing the risk of relapse [25]. The combined use of a long- and short-acting form of NRT (eg, the nicotine patch and the nicotine gum) is considered the most effective method of NRT use [21]. It is particularly effective for those with more severe addictions or those who have not succeeded with single-form NRT [26]. This evidence-based approach, supported by extensive scientific research, underscores the significance of NRT, including combination therapies, as indispensable tools in the cessation process. The prescription medications for cessation include varenicline (brand name Champix) and bupropion (brand name Zyban). Varenicline helps reduce nicotine cravings and reduces the satisfaction one gets from smoking or vaping. Bupropion helps reduce nicotine cravings and withdrawal symptoms. Varenicline is one of the pharmacological tools most likely to help people quit smoking, with 12-16 of every 100 individuals quitting smoking using varenicline compared to 6 of 100 who did not use any medicine. After using bupropion, 9 of 100 people are likely to quit [27].

The British Columbia Smoking Cessation Program has been a commendable initiative aimed at supporting British Columbia residents in their efforts to quit smoking. The program provides free or low-cost access to NRT products, such as gum, patches, and lozenges, for eligible participants, significantly reducing

XSL•FO
RenderX

financial barriers to quitting. In the most recent evaluation of the program, data showed that it had provided coverage for more than 25% of British Columbia residents who smoke. From September 30, 2011, to March 31, 2020, over 354,900 patients received smoking cessation aids (294,700 for nicotine gum, inhaler, lozenge, or patches, and 118,700 for bupropion or varenicline), with the British Columbia Ministry of Health investing approximately CAD $112.2 (US $78.47) million for product coverage. While the program has played a valuable role in aiding smoking cessation, it is essential to acknowledge that there is room for improvement. Currently, the program does not support residents in vaping cessation. In addition, the program does not allow residents to access combination NRT. While current policy allows switching from one product to another during treatment, only one of either NRTs or prescription medication is covered for 12 weeks each calendar year, which may not be enough for residents looking to quit. As well, 12 weeks of treatment is often not sufficient to achieve abstinence and prevent relapse. As a result of this limitation, some residents reported paying out of pocket for the products they used. Of over 4000 residents surveyed for the evaluation, a third of respondents (35%) indicated they had out-of-pocket expenses for other products or activities to help them quit smoking. The average monthly costs associated with these cessation products or activities were CAD $102 (US $71.34) and ranged from CAD $1 to $2000 (US $0.70 to $1398.75) a month. In light of our qualitative findings, the program must adapt to better support residents considering the evolving landscape of nicotine addiction, including the rising prevalence of vaping and emerging research on more effective cessation strategies. Collaboration between the government, community stakeholders, providers, and pharmacies is crucial for enhancing the program's reach and efficacy, ensuring it remains a robust and relevant resource in promoting a smoke-and-vape-free British Columbia. Addressing these needs is critical, as pharmacotherapy is a substantial component of a successful quit trajectory.

Our findings also indicate how incorporating social support on cessation support websites is crucial to providing end users with a sense of community, encouragement, and shared experiences. Existing research mirrors this; peer support has been shown to positively impact cessation outcomes by fostering motivation, accountability, and the exchange of coping strategies [28]. Similar to findings from a previous study on QuitNow, implementing and enhancing features, such as discussion forums, live chat options, or virtual support groups provide end users with the ability to connect, share challenges, and celebrate successes [29]. In addition, integrating social media elements may allow users to easily share their progress, garnering support from friends and family beyond the platform. By fostering a supportive online community, cessation websites like QuitNow can enhance user engagement and ultimately contribute to sustained success with respect to user quit journeys, which is emphasized in our qualitative findings, and further by the Google analytics data indicating that the community forum and support ranked among the top 10 visited pages.

Finally, our findings illuminate the importance of a collaborative and synergistic nature between the quitting individual's personal agency and the resources offered by a cessation platform, like QuitNow. As such, it is crucial for cessation websites to embody a commitment to foster a collaborative relationship with end users in their quit journey versus embodying a commitment to being the "silver bullet"—the perfect solution that removes all responsibility from the person who wants to quit. In this regard, websites must function as allies in this process by providing a structured and informed environment that catalyzes the user's cessation journey (ie, by including personalized tools, expert guidance, and a supportive community). Ultimately, incorporating a collaborative and person-centered lens in website development and delivery can not only acknowledge the significance of personal agency and make users feel more capable but also underscore the role of external support in enhancing the efficacy and sustainability of the quitting process.

Strengths and Limitations

This study is subject to a few limitations. First, our small sample size may have masked existing themes representative of the broader population of QuitNow users. In addition, as we did not explore thematic differences in cessation needs based on gender, ethnicity, or other demographic markers, there may be identity-based nuances in QuitNow user needs that our data did not capture. Participant accounts within qualitative interviews are also subject to recall and social desirability biases, which together with the previous may have influenced which themes were most apparent in the data. Further, our findings are limited by the scope of thematic analytic techniques; coding processes used in the thematic analysis are subjective and open to interpretation and thus are heavily dependent on researcher judgment and participant accounts [30]. Next, our findings are also characterized by limitations based on geographic and temporal contexts. As participants were solely from British Columbia, Canada, participant experiences may not be representative of settings beyond British Columbia. In addition, data were collected during the COVID-19 pandemic (May-August 2021) and since then, changing health and sociocultural contexts and policies may have reshaped experiences and cessation needs of QuitNow and general nicotine users [16]. Finally, the experiences of users were also based on which interface (web vs mobile) they used to access the QuitNow website, which may have influenced their opinions on the site.

Despite these limitations, our study is characterized by unique strengths. First, our use of thematic analysis allowed us to explore both apparent and latent content within user accounts, thus allowing us to capture explicit as well as underlying meanings within the data. In addition, supplementing qualitative themes with web analytics strengthened the analysis by combining subjective insights with quantitative metrics, enhancing the comprehensiveness and credibility of our findings. This dual approach provided a nuanced understanding of user behavior on the QuitNow website and continues to facilitate informed decision-making for targeted content delivery improvements. Finally, collecting rich interview data over months allowed us to capture nuanced, as well as consistent participant viewpoints in the context of an ever-changing pandemic landscape in real time.

XSL•FO
RenderX

Conclusion

In conclusion, our study on QuitNow user experiences and utilization, supplemented by Google Analytics data, reveals important insights. Integrating our qualitative findings with usage patterns provides clear directions for program enhancement: overcoming information barriers, refining pharmacological information presentation, fostering community support, and incorporating creative motivational elements. Future research should investigate user preferences in a larger and more demographically diverse sample to ensure these findings are applicable to the wider population. However, these insights offer practical strategies to optimize QuitNow and, more broadly, advance the effectiveness of web-based cessation services, contributing to improved public health outcomes.

Abstract

Background: Women are particularly vulnerable to depression during pregnancy, which is one of the strongest risk factors for developing postpartum depression (PPD). Addressing antenatal depressive symptoms in these women is crucial for preventing PPD. However, little is known about the effectiveness of internet-based cognitive behavioral therapy (ICBT) in preventing PPD in this high-risk group.

Objective: This study aims to evaluate the short- and long-term effects of ICBT in preventing PPD among women with antenatal depressive symptoms.

Methods: Participants were screened for antenatal depressive symptoms using the Edinburgh Postnatal Depression Scale (EPDS) and randomly allocated (1:1) to either the ICBT group (receiving weekly online modules starting antenatally and continuing into early postpartum) or the control group (observed without treatment). Follow-up assessments were conducted up to 12 months postpartum, and data were analyzed using generalized estimating equations. The primary outcome was the prevalence of depressive symptoms at 6 weeks postpartum. A subgroup analysis based on the severity of antenatal depressive symptoms was also performed. The secondary outcomes included the long-term effects of ICBT on maternal depression, as well as its impact on anxiety, sleep quality, social support, parenting stress, co-parenting relationships, and infant development.

Results: Between August 2020 and September 2021, 300 pregnant individuals were recruited from 5 centers across China. No significant differences were observed in depressive symptoms at 6 weeks postpartum (P=.18) or at any longer-term follow-up

XSL•FO
RenderX

time points (*P*=.18). However, a post hoc subgroup analysis showed that participants with antenatal EPDS scores of 10-12 in the ICBT group had a lower risk of developing depression during the first year postpartum (odds ratio 0.534, 95% CI 0.313-0.912; *P*=.02), but this was not observed for participants with more severe depression. Additionally, this subgroup demonstrated higher levels of co-parenting relationships (*P*=.02).

Conclusions: Among individuals with antenatal depression, ICBT did not prevent the development of PPD. However, ICBT may be a preferable option for those with mild to moderate antenatal depressive symptoms. Future research is needed to explore modifications to ICBT to address more severe depressive symptoms.

KEYWORDS

antenatal depression; postpartum depression; internet-based cognitive behavioral therapy; randomized controlled trial

Introduction

Postpartum depression (PPD), which includes major and minor depressive episodes occurring within 1 year postpartum, is a common maternal complication following childbirth, with clear evidence demonstrating both short- and long-term negative effects on mothers, children, family members, and society [1-3]. It affects approximately 20% of pregnant individuals in low- and middle-income countries [4]. Notably, depression during pregnancy is one of the strongest risk factors for PPD, with approximately one-third of individuals with PPD reporting that their symptoms began antenatally [5]. Furthermore, pregnant individuals have been reported to be particularly vulnerable to depression and anxiety since the COVID-19 pandemic, with an increased likelihood of experiencing thoughts of self-harm [6-8]. This heightened prevalence places a significant burden on the existing health care system and the provision of evidence-based treatment [9]. However, the rates of depression diagnosis and treatment uptake among pregnant individuals are lower than those observed in the general population [10,11]. It is also well-documented that pregnant individuals with depressive symptoms are often reluctant to seek treatment due to individual, community, and health system barriers, particularly in low- and middle-income countries [12,13]. Therefore, addressing antenatal depressive symptoms is critically important for preventing PPD.

Cognitive behavioral therapy (CBT) is a practical and effective treatment for depression in the general population, as it helps individuals change negative thoughts, attitudes, and beliefs while promoting positive emotional and behavioral responses [14]. Evidence suggests that CBT can be initiated during pregnancy to prevent the development of PPD. Compared with traditional face-to-face delivery, internet-based CBT (ICBT) is more accessible and cost-effective, addressing common barriers to help-seeking such as shame, lack of time, transportation challenges, and limited medical resources. In this context, delivering CBT via the internet could be a promising intervention for preventing PPD, particularly after the onset of the COVID-19 pandemic, when social isolation, stigmatization, discrimination, and financial losses were frequently reported.

Although individuals with antenatal depressive symptoms are more likely to develop PPD, most studies evaluating the efficacy of prenatal ICBT for preventing PPD have been designed to recruit general pregnant individuals rather than high-risk groups [15-18]. To date, only 4 single-center randomized controlled trials with relatively small sample sizes have been published on ICBT interventions targeting individuals at high risk of antenatal depression [19-22]. Furthermore, in these studies, participants were screened for depressive symptoms before the third trimester of pregnancy, and the follow-up period was limited to 6 weeks postpartum. However, as pregnancy progresses and the physical burden increases, individuals are more likely to experience frequent urination, joint or pelvic pain, shortness of breath, swelling, constipation, indigestion, and pregnancy-related complications in late pregnancy. The prevalence of depressive symptoms during pregnancy has also been reported to rise over time, increasing from 7.4% in early pregnancy to approximately 12% in mid-to-late pregnancy [23]. Individuals with new-onset depressive symptoms emerging in late pregnancy should receive careful attention. To address these research gaps, we conducted this multicenter trial among individuals with antenatal depressive symptoms in their third trimester to evaluate the effect of ICBT on preventing depression across the first year postpartum.

Methods

Study Design and Setting

We conducted a 2-arm, parallel-group randomized controlled trial across 5 medical centers in 4 different cities in China, adhering to the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Multimedia Appendix 1 [24]). The trial was carried out through obstetric clinics at the International Peace Maternity and Child Health Hospital in Shanghai, along with 4 collaborating medical centers: Shaoxing Maternity and Child Health Care Hospital in Shaoxing, Hunan Maternal and Child Health Care Hospital in Changsha, the Women's Hospital affiliated with Zhejiang University School of Medicine in Hangzhou, and Hangzhou Women's Hospital in Hangzhou.

Ethical Considerations

Ethics approval was obtained from the institutional review board of the International Peace Maternity and Child Health Hospital (approval number GKLW2020-25). Informed consent was

XSL•FO
RenderX

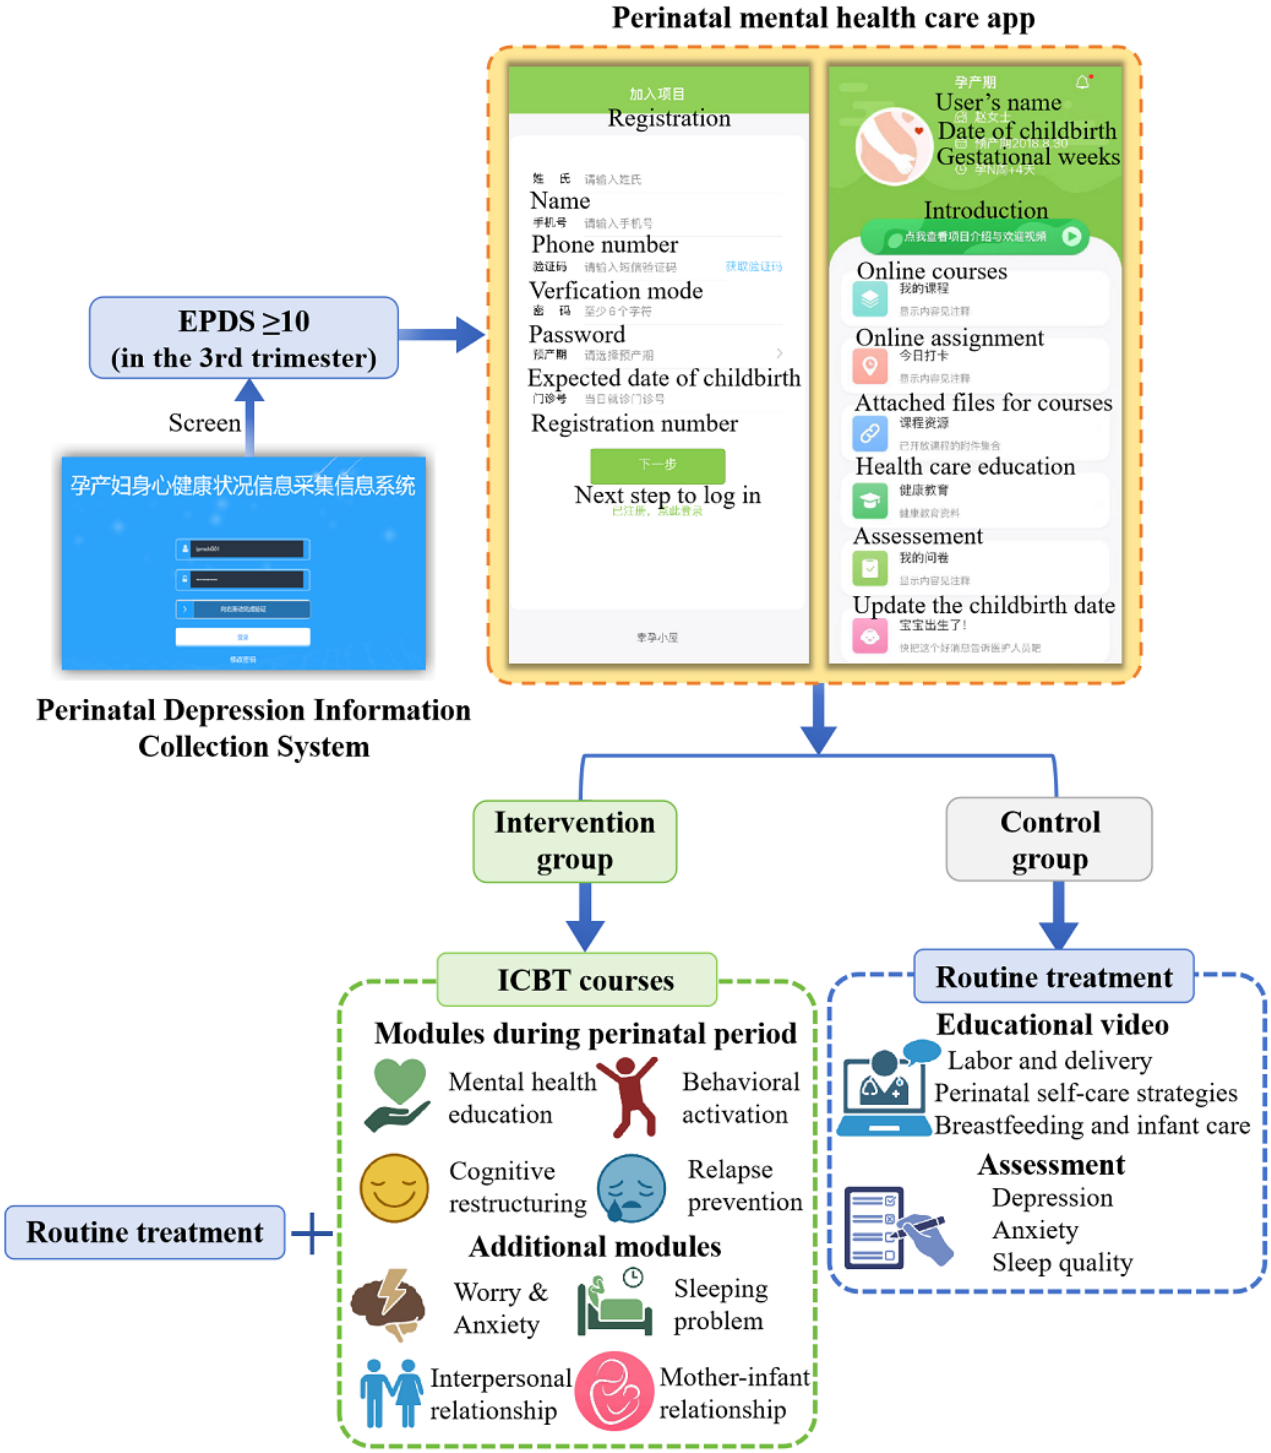
obtained from all participants, and those who completed the trial were financially compensated. To protect participants' privacy, each individual's name was replaced with a computer-generated serial number for identification. The trial was registered with the Chinese Clinical Trial Registry (ChiCTR2000033433), and the detailed protocol has been published [25].

Participant Screening and Recruitment

We screened pregnant individuals for antenatal depressive symptoms using the Edinburgh Postnatal Depression Scale (EPDS) during their third trimester of pregnancy (≥28 and ≤34 gestational weeks) as part of a standardized visit, which all pregnant individuals receive at the 5 participating medical centers. The EPDS is the most widely used screening tool for perinatal depression globally, demonstrating good sensitivity and specificity among Chinese individuals when a cut-off score of ≥10 is applied, as recommended for Asian populations [26]. Additionally, a higher cut-off point of ≥13 on the EPDS, indicating a higher level of depressive symptoms, is recommended in settings with limited resources for further treatment [27,28]. Pregnant individuals were eligible to participate in the trial if they met the following inclusion criteria: having a singleton fetus, being 18 years of age or older, being between ≥28 and ≤37 gestational weeks, being able to read and understand Chinese, having an EPDS score ≥10, and having access to the internet via a smartphone or computer. Individuals were excluded if they had active suicidal ideation, a diagnosis of severe mental illness (eg, schizophrenia), or were currently receiving treatment for depression. Eligible individuals were then contacted and introduced to the study, and those who agreed to participate were asked to complete the informed consent procedures and the baseline questionnaire with the assistance of a research assistant.

Randomization, Blinding, and Enrollment

All eligible individuals were ensured enrollment before 37 gestational weeks by a trained research assistant who was not involved in any other trial activities. Participants were randomly allocated in a 1:1 ratio to either the intervention group or the control group using a computer-generated block randomization procedure provided by the Clinical Research Public Technical Service Platform [29]. The allocation sequence was implemented through a web-based central randomization system, and the block size for randomization was set to 6. Based on the results provided by the computer-generated randomization system, participants were asked to register in the perinatal health care app. They were then assigned to either the intervention or control group by the research assistant. Because of the nature of the intervention, both the research assistant and the therapist providing the ICBT intervention were not blinded to group allocation; however, participants were blinded. To maintain blinding, all eligible individuals were thoroughly informed about the online courses and follow-up assessments, but were not told about the differences in courses provided between the 2 groups.



Treatment

Control Group

Participants in the control group received standard antenatal care, including educational videos and timely depression assessments delivered through the perinatal health care app developed for the trial (Figure 1). The videos provided information on labor and delivery, postpartum self-care, infant care, and breastfeeding. The content of these videos, which is also commonly provided in prenatal courses at medical centers, was not related to depression. Additionally, via the app, participants in the control group were assessed for depressive symptoms using the 9-item Patient Health Questionnaire (PHQ-9) once every 2 weeks before childbirth. It has been reported that the detection rate of prenatal depression measured by the EPDS is relatively higher compared with the PHQ-9 [30], suggesting that the EPDS may have greater sensitivity in screening for depressive symptoms. However, the PHQ-9 has an advantage over the EPDS in distinguishing the severity of depressive symptoms, with scores of ≥5, ≥10, and ≥15 corresponding to mild, moderate, and severe levels of depression, respectively [31]. Individuals with a total PHQ-9 score of ≥15 or a score of ≥2 on the self-harm item were referred to a registered psychiatrist for further assessment.

XSL•FO
RenderX

Figure 1. Flow diagram of participant recruitment and treatment for both groups. ICBT: internet-based cognitive behavioral therapy; EPDS: Edinburgh Postnatal Depression Scale.

Intervention Group

Participants in the intervention group received standard antenatal care as described above, along with online text and video-based modules provided weekly through the perinatal health care app (Figure 1); 3 modules were delivered during pregnancy, and 4 modules were delivered from 2 to 5 weeks postpartum. Participants were required to complete assignments and provide feedback to the therapist via the app after each module was published. If participants had not viewed the weekly modules or submitted feedback, they would receive an automatic reminder message through the app, as well as a personal contact from the therapist. Therapists were graduate-level trainees in psychology, supervised by a registered psychiatrist with experience in treating depression. The training included a 2-day workshop before they began the intervention, and therapists were also provided with a manual outlining the weekly content for ICBT. In addition to regular weekly courses on psychoeducation, cognitive restructuring, problem-solving strategies, behavioral activation, and relapse prevention, 4 additional modules were provided. These modules addressed maternal anxiety and worries, sleep problems, interpersonal

XSL•FO
RenderX

relationship difficulties, and mother-infant relationship development.

Outcomes

Overview

All study participants completed follow-up questionnaires via the app at 6 weeks postpartum, followed by additional questionnaires at 3, 6, 9, and 12 months postpartum.

Primary Outcome

The primary outcome was the prevalence of depressive symptoms at 6 weeks postpartum, measured using the PHQ-9, a 9-item self-report scale with well-documented psychometric properties and a cut-off score of ≥5 indicating possible depression [31].

Secondary Outcomes

To further evaluate the longer-term effect of ICBT treatment on preventing the development of depressive symptoms, the PHQ-9 was readministered at 3, 6, and 12 months postpartum.

Anxiety was assessed using the 7-item Generalized Anxiety Disorder (GAD-7), a scale measuring symptoms over the past 2 weeks. Total scores range from 0 to 21, with a cut-off score >4 suggesting possible anxiety, and higher scores indicating more severe symptoms [32]. The GAD-7 was administered at 6 weeks, and at 3, 6, and 12 months postpartum.

Sleep quality was assessed using the Pittsburgh Sleep Quality Index (PSQI), a 19-item scale with good psychometric properties, measuring sleep quality over the past month [33]. The PSQI evaluates 7 key aspects of sleep, including subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleep medication, and daytime dysfunction. Total scores range from 0 to 21, with higher scores indicating worse sleep quality. A cut-off score >5 is recommended to distinguish between good and poor sleep quality [33]. The PSQI was administered at 3, 6, and 12 months postpartum.

Social support was assessed using the Multidimensional Scale of Perceived Social Support (MSPSS), a 12-item scale that measures the perceived availability and adequacy of emotional and instrumental social support. Total scores range from 12 to 84, with higher scores indicating greater levels of perceived support [34]. The MSPSS was administered at 6 months postpartum.

Parenting stress was assessed using the Parenting Stress Index-Short Form (PSI-SF), a 36-item scale that measures parenting stress. It consists of 3 subscales: Parental Distress, Parent-Child Dysfunctional Interaction, and Difficult Child, with scores ranging from 12 to 60. Total scores are calculated by summing the 3 subscale scores, with scores of ≥90 indicating high levels of parenting stress [35]. The PSI-SF was administered at 9 months postpartum.

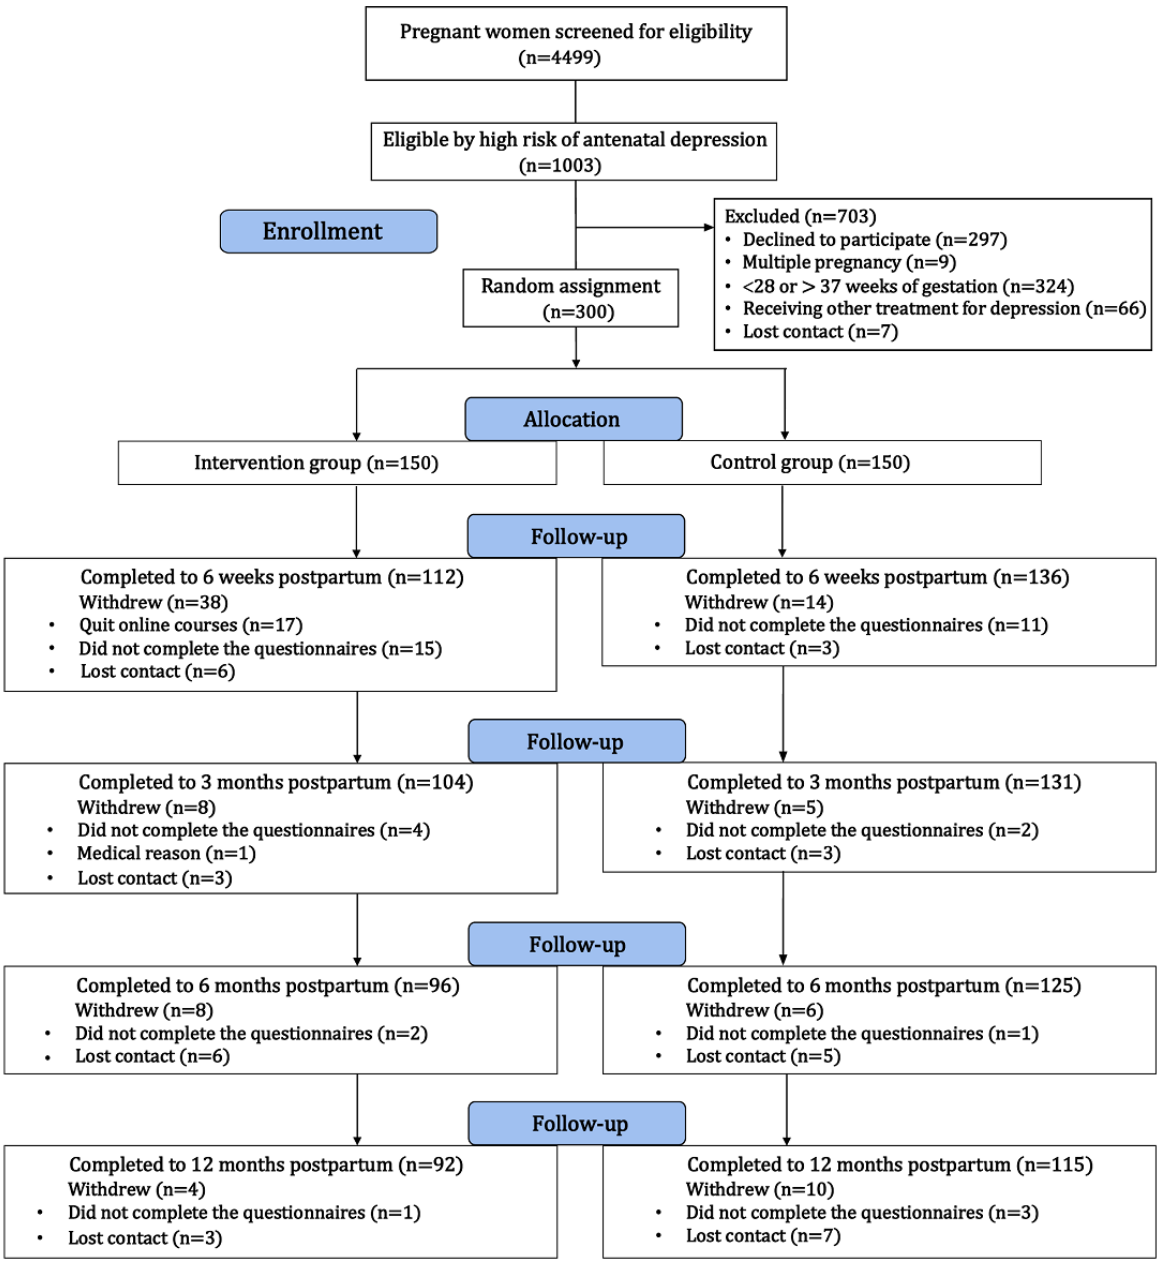
The co-parenting relationship was assessed using the Brief Co-Parenting Relationship Scale (BCRS), a 14-item scale that measures co-parenting dynamics across 7 subscales: co-parenting agreement, co-parenting closeness, exposure to conflict, co-parenting support, co-parenting undermining, endorsement of partner parenting, and division of labor. Lower scores in the subscales of exposure to conflict and co-parenting undermining, and higher scores in the other 5 subscales, indicate a more positive co-parenting relationship [36]. The BCRS was administered at 9 months postpartum.

Infant development was assessed using the Denver Development Screening Test (DDST) II, a developmental assessment tool for infants and children aged 0-6 years. The scale includes items that evaluate gross motor development, fine motor-adaptive development, language development, and personal-social development. Items on the scale that over 90% of children of the same age are expected to pass but are not successfully completed are considered as “developmental delay.” Items that 75%-90% of children of the same age are expected to accomplish but are not completed are scored as a “warning.” Results are categorized as normal (no “developmental delay” or 1 “warning”), abnormal (2 or more “developmental delays”), or suspicious (2 or more “warnings” and 1 “developmental delay”) [37]. The DDST II was administered at 3, 6, and 12 months postpartum.

Sample Size

The sample size for this study was determined based on a previous Chinese trial, which reported lower rates of PPD following face-to-face CBT treatment among individuals with antenatal depressive symptoms (37/167, 22.2% vs 79/167, 47.3%; P=.001) [38]. We calculated a required sample size of at least 178 participants (89 per group, accounting for a 20% loss to follow-up) to detect a 25% reduction in PPD with 90% power and a 2-sided significance level of .05. Considering the potential reduction in efficacy with online CBT compared with face-to-face delivery, we aimed to recruit 300 participants for this study.

Statistical Analysis



Baseline characteristics were summarized using descriptive statistics. Continuous variables with a normal distribution were reported as means and SDs, while those with a skewed distribution were expressed as medians and IQRs. Categorical variables were presented as frequencies with proportions. Primary and secondary outcomes were analyzed according to the intention-to-treat principle. Group differences in continuous variables with a normal distribution were assessed using the Student t test, whereas the Kolmogorov-Smirnov test was applied for variables with a skewed distribution. Group differences in categorical variables at each time point were analyzed using a chi-square test. To evaluate the effect of the ICBT intervention over time, generalized estimating equation modeling with an unstructured correlation structure was used to analyze outcomes measured repeatedly at multiple time points [39]. The generalized estimating equation model was adjusted for covariates selected based on the quasi-likelihood under the independence model criterion. A post hoc subgroup analysis was conducted to further assess the intervention’s effect on preventing PPD among participants with varying severity of depressive symptoms at baseline. All statistical analyses were performed using R software (version 4.0.2; R Foundation), with significance defined as a 2-sided P value less than .05.

RenderX

Results

Between August 2020 and September 2021, 4499 pregnant individuals were screened for depressive symptoms, of whom 1003 were identified with an EPDS score ≥10 (Figure 2 and Multimedia Appendix 1 [24]). Among these, 297 declined to participate, 9 were excluded due to multiple pregnancies, 324 were excluded for not being between 28 and 37 weeks of gestation, 66 were excluded for receiving other treatment for depression, and 7 could not be contacted. Ultimately, 300 individuals met the eligibility criteria and provided informed consent. Of these, 150 were randomized to the intervention group and 150 to the control group.

Figure 2. Flowchart of the study participants.

The baseline characteristics are summarized in Table 1. The median maternal age was 29 (IQR 27-32) years, with the majority of participants being college educated, employed, and primiparous. The median antenatal EPDS score was 12 (IQR 11-15), with 157 of 300 (52.3%) participants reporting mild to moderate depressive symptoms, indicated by an EPDS score ≥10 and <13. Participants in the intervention group had a slightly higher median antenatal EPDS score compared with those in the control group. Among the 248 participants included in the final intention-to-treat analysis, no significant differences were observed between the 2 groups regarding baseline depressive symptom severity, maternal sociodemographic characteristics, or pregnancy complications.

[a]ITT: intention-to-treat.

[b]ICBT: internet-based cognitive behavioral therapy.

[c]EPDS: Edinburgh Postnatal Depression Scale.

Of the 300 participants enrolled, 52 (17.3%) were lost to follow-up at 6 weeks postpartum, 65 (21.7%) at 3 months postpartum, 79 (26.3%) at 6 months postpartum, and 93 (31.0%) at 12 months postpartum. On average, participants in the ICBT group completed 2.5 (SD 1.1) modules during pregnancy and 3.1 (SD 1.5) modules postnatally. Of the 150 in the ICBT group, 129 (86%), 123 (82%), 129 (86%), 118 (79%), 118 (79%), 117 (78%), and 117 (78%), respectively, completed modules 1-7. Notably, 108 (72%) of participants completed all intervention modules delivered via the perinatal health care app.

The primary outcome, depressive symptoms at 6 weeks postpartum, did not differ significantly between the groups (ICBT vs control group: 40/112, 35.7% vs 60/136, 44.1%; *P*=.18; Table 2). Figure 3 illustrates the trajectory of depressive symptoms from 6 weeks postpartum to 1 year, as measured by the PHQ-9. No significant differences in symptom severity were observed between the intervention and control groups at any follow-up time point (*P*=.18; Figure 3, Table 2). Although symptoms worsened over time, this change was not statistically significant (*P*=.07).

Figure 3. Differences in postpartum depressive symptoms between the control and ICBT groups at each time point. EPDS: Edinburgh Postnatal Depression Scale; ICBT: internet-based cognitive behavioral therapy; PHQ-9: 9-item Patient Health Questionnaire.

Interestingly, in a subgroup analysis of participants with a baseline EPDS score ≥10 and <13, those in the intervention group had significantly lower levels of postpartum depressive symptoms (odds ratio 0.534, 95% CI 0.313-0.912; *P*=.02; Table 3). The differences in depressive symptoms were observed at 6 weeks postpartum (ICBT vs control group: 14/57, 25% vs 31/75, 41%; *P*=.04) and at 6 months postpartum (ICBT vs control group: 16/49, 33% vs 36/70, 51%; *P*=.04; Figure 3 and Table S2 in Multimedia Appendix 2). After adjusting for covariates, the subgroup analysis indicated that participants in the intervention group were less likely to develop postpartum depressive symptoms compared with those in the control group (adjusted odds ratio 0.577, 95% CI 0.330-0.965; *P*=.04; Table 3).

[n]Values were adjusted for location and education.

[o]Values were adjusted for location, occupation, intrahepatic cholestasis of pregnancy, and gestational diabetes mellitus.

[p]Values were adjusted for location, occupation, and educational attainment.

No significant differences between groups were found over time for the secondary outcomes of anxiety and sleep quality (Table 2). Additionally, there were no significant group differences related to social support, the co-parenting relationship, parenting satisfaction, or infant development (see Table S1 in Multimedia Appendix 2). However, subgroup analyses of participants with a baseline EPDS score between ≥10 and <13 revealed that those in the intervention group had significantly higher perceptions of co-parenting compared with the control group (ICBT vs control group: mean 7.86, SD 0.52 vs mean 6.35, SD 0.42; *P*=.02; see Table S3 in Multimedia Appendix 2). Although not statistically significant, subgroup analyses also suggested that participants in the intervention group had a higher proportion of infants classified with normal development than those in the control group at 1 year postpartum (ICBT vs control group: 37/45, 82% vs 46/63, 73%; *P*=.08).

Discussion

Principal Findings

This is the largest randomized controlled trial with a multicenter design to evaluate the effect of ICBT in treating depressive symptoms among pregnant participants and preventing the development of PPD. The results suggest that while lower rates of depressive symptoms were observed in the intervention group during the first year postpartum, the findings were not conclusive. However, in a subgroup of pregnant participants with mild to moderate depressive symptoms at baseline, those in the intervention group were significantly less likely to experience depressive symptoms at 6 weeks and 6 months postpartum compared with the control group. Participants in the intervention group were also more likely to report higher levels of co-parenting. These findings suggest that ICBT may be more effective for pregnant participants with mild to moderate depressive symptoms compared with those with more severe symptomatology.

XSL•FO
RenderX

Comparison With Prior Work

Pregnant individuals with depressive symptoms are at high risk of experiencing a continuation of these symptoms into the postpartum period, often with increasing severity. However, few studies have specifically targeted this vulnerable group with the goal of preventing the development of depressive symptoms during the first year postpartum, and the results have been inconsistent. Both Sun et al [21] (N=168) and Forsell et al [20] (N=42) found ICBT to be effective in alleviating maternal depressive symptoms at 6 weeks postpartum among those with antenatal depressive symptoms. Similar positive results were reported in a pilot study (N=25); however, individuals with major antenatal depressive symptoms were excluded from this study [19]. By contrast, Heller et al [22] (N=159) did not observe a statistically significant reduction in postpartum symptomatology following ICBT treatment among pregnant individuals with moderate to severe depressive symptoms. One potential explanation for these inconsistent findings is the timing of depressive symptom identification. Previous studies identified pregnant individuals with depressive symptoms early in the first and second trimesters (<28 gestational weeks). Our trial was the first to initiate ICBT in the third trimester and continue into the early postpartum period, reinforcing antenatal content and addressing transitional stressors immediately after delivery. However, the timing of treatment implementation may have been too late to effectively reduce symptoms and prevent the development of depressive symptoms later in the postpartum period.

Another possible explanation for the overall nonsignificant intervention effect may be an overestimation of the effectiveness of ICBT in improving severe depressive symptoms. Our findings suggest that the ICBT intervention was beneficial for pregnant individuals with mild to moderate symptoms but not for those with more severe symptomatology (baseline EPDS≥13). Similarly, a recent large Japanese trial (N=5017) investigating the effectiveness of ICBT in preventing the onset of major depressive episodes in the third trimester and at 3 months postpartum found no overall beneficial intervention effect [17]. However, the results suggest that ICBT may be beneficial in preventing perinatal depression among pregnant individuals with nonmajor depressive symptoms. Similarly, a German trial involving 406 adults with nonmajor depression found that the use of web-based CBT, compared with enhanced usual care, reduced the incidence of major depressive symptoms over 12 months [40]. These findings align with our trial results and indicate that the effectiveness of ICBT may vary depending on the severity of depressive symptoms. Other trials have demonstrated the benefits of ICBT in preventing major depression and reducing severe depressive symptoms in nonperinatal populations, often after intentionally excluding participants with severe symptomatology due to the perceived need for more intensive treatment or pharmacotherapy [41]. Further research is needed to identify individuals who might benefit most from ICBT.

No significant intervention effects were observed for any secondary outcomes, except for co-parenting support. Co-parenting support plays a crucial role in establishing an effective co-parenting relationship, which is essential for reducing mothers' child-rearing burden and fostering bonding with the infant. Previous studies have also suggested that better co-parenting may lead to a reduction in postpartum depressive symptoms [42]. The effect of ICBT on postpartum anxiety symptoms remains mixed [20-22], while sleep quality improved over time in both groups, likely due to changes in infant sleep and breastfeeding patterns. Although child development was an exploratory outcome in our trial and the study was not powered to detect group differences, we observed a trend suggesting that ICBT may positively influence child development at 1 year postpartum. Previous research has demonstrated that outcomes improve among older children when parents with depression receive intensive treatment interventions [43,44]. However, the mechanisms by which these interventions lead to improvements in child outcomes are complex. Given the evidence showing the adverse effects of PPD on child developmental trajectories [45], interventions may improve child development through various mediators, including enhanced displays of affect, strategies for addressing marital and family conflicts, and improvements in parenting behaviors. These factors may also contribute to alleviating maternal depressive symptoms. Further research evaluating technology-delivered treatments with sufficient power to detect group differences is warranted.

It is important to note that the effect of ICBT on preventing PPD should be interpreted conservatively. PPD differs from other common types of depression, as individuals face unique challenges arising from a combination of physiological and psychological changes during pregnancy, after childbirth, and throughout breastfeeding. The mental health issues resulting from these specific circumstances may exceed the expected effects of traditional ICBT treatment. To address these challenges, we included 4 additional online modules offering self-help materials and strategies for coping with maternal anxiety and worries, sleep problems, interpersonal relationship difficulties, and enhancing the mother-infant relationship. Although these modules were able to address the main concerns of perinatal individuals, they were not directly related to depression. It would have been beneficial to interview the participants to further assess the extent to which ICBT or other mediators in the intervention contributed to alleviating postpartum depressive symptoms.

Our study has several strengths. It is the first to evaluate both the short- and long-term effects of ICBT on reducing depressive symptoms and preventing PPD among pregnant individuals identified through systematic screening at the end of the second trimester. Compared with previous studies aimed at preventing PPD among pregnant individuals with depressive symptoms, our sample is larger and was recruited from multiple sites across China, increasing the generalizability of the findings. While ICBT has been shown to be effective in alleviating depressive and anxiety symptoms among the general adult population during the COVID-19 pandemic [46], only 1 [47] study has focused on maternal depression and evaluated the efficacy of ICBT treatment delivered in a single session. Our study builds on this work and provides evidence that ICBT may be an effective treatment for individuals with mild to moderate

XSL•FO
RenderX

antenatal depressive symptoms, with longer-term benefits observed up to 6 months postpartum.

Limitations

One limitation of this study is that the assessment of depressive and anxiety symptoms relied on self-report rather than a structured diagnostic interview. Although the measures used are internationally recommended and widely adopted, they do not provide a formal diagnosis. A second limitation is that the sample size was based on a previous study showing lower rates of PPD among Chinese pregnant individuals with antenatal depressive symptoms following face-to-face CBT treatment [38]. As a result, our sample size may have been insufficient to examine the secondary and longer-term outcomes. Additionally, in the intervention group, slightly higher baseline EPDS scores were observed, and there was a higher dropout rate, as completing the intervention was more time-consuming for participants. This may have introduced bias into the results. Furthermore, it is difficult to determine whether the COVID-19 pandemic had a more specific and far-reaching impact on the development of PPD, which limits the generalizability of the estimated ICBT intervention effect after the pandemic ended.

Conclusions

Despite these limitations, our results indicate a beneficial effect of ICBT on treating mild to moderate antenatal depressive symptoms and preventing the development of depressive symptoms later in the postpartum period. ICBT may be an affordable alternative for pregnant individuals with mild to moderate depressive symptoms, compared with those with more severe symptomatology (EPDS≥13). Future research is warranted to expand the appropriate application of ICBT for individuals with mild to moderate depressive symptoms and to explore best practices for optimizing engagement and integrating ICBT into care pathways.

Acknowledgments

The study was supported by the National Natural Science Foundation of China (grants 82301719 and 82088102), STI2030-Major Projects-2021ZD0200700, Collaborative Innovation Program of Shanghai Municipal Health Commission (grant 2020CXJQ01), CAMS Innovation Fund for Medical Sciences (grant 2019-12M5-064), Grant for General Program from the Shanghai Mental Health Center (grant 2019-YJ09), Clinical Research Plan of Shanghai Shenkang Hospital Development Center (grant SHDC2020CR1008A), Shanghai Clinical Research Center for Gynecological Diseases (grant 22MC1940200), Shanghai Urogenital System Diseases Research Center (grant 2022ZZ01012), Shanghai Frontiers Science Research Base of Reproduction and Development, and Science and Technology Innovation Fund of Shanghai Jiao Tong University (grant YG2020YQ29). The funders of this study had no role in the study design, data collection, analysis, and manuscript drafting or future publication. We thank Lu-Lu Pan for verifying the data analysis. We thank all participants for their participation in the project. We appreciate the contribution of all researchers, nurses, and clerical workers from cooperative hospitals. The corresponding authors had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Data Availability

Further access to participant-level data sets or statistical codes is available from the corresponding author on reasonable request.

Authors' Contributions

YTW, CCD, and JT designed the study concept. CCD, CZ, JLY, and HLX drafted the manuscript. JT provided professional support for the design of ICBT courses and was responsible for the psychological assessment of patients. CCD, JLY, HLX, DZ, XZ, WTZ, ZYZ, HL, and JYW were responsible for data collection and quality control of each center. CZ was responsible for statistical analysis. YTW, HFH, CLD, and BWJM critically revised the manuscript. All authors provided administrative, technical, and material support and agreed with the final version of the article.

Conflicts of Interest

BWM reports consultancy, travel support and research funding from Merck and consultancy for Organon and Norgine.

Abstract

Background: The key to gestational weight management intervention involves health-related behaviors, including dietary and exercise management. Behavioral theory-based interventions are effective in improving health-related behaviors. However, evidence for mobile health interventions based on specific behavioral theories is insufficient and their effects have not been fully elucidated.

Objective: This study aimed to examine the effects of a gestational mobile health intervention on psychological cognition and behavior for gestational weight management, using an integrated behavioral model as the theoretical framework.

Methods: This study was conducted in a tertiary maternity hospital and conducted as a single-blind randomized controlled trial (RCT) in Changzhou, Jiangsu Province, China. Using the behavioral model, integrated with the protection motivation theory and information–motivation–behavioral skills model (PMT-IMB model), the intervention group received a mobile health intervention using a self-developed app from 14 to 37 gestational weeks, whereas the control group received routine guidance through the application. Psychological cognition and behaviors related to weight management during pregnancy were the main outcomes, which were measured at baseline, and at the second and third trimesters of pregnancy using a self-designed questionnaire. Generalized estimation and regression equations were used to compare the outcome differences between the intervention and control groups.

Results: In total, 302 (302/360, 83.9%) participants underwent all measurements at 3 time points (intervention group: n=150; control group: n=152). Compared with the control group, the intervention group had significantly higher scores for information, perceived vulnerability, response cost, and exercise management in the second trimester, while their scores for perceived vulnerability, response cost, and diet management were significantly higher in the third trimester. The results of repeated measures analysis revealed that, in psychological cognition, the information dimension exhibited both the time effects (T3 β=3.235, 95% CI 2.859-3.611; *P*<.001) and the group effects (β=0.597, 95% CI 0.035-1.158; *P*=.04). Similarly, response costs demonstrated both the time effects (T3 β=0.745, 95% CI 0.199-1.291; *P*=.008) and the group effects (β=1.034, 95% CI 0.367-1.700; *P*=.002). In contrast, perceived vulnerability solely exhibited the group effects (β=0.669, 95% CI 0.050-1.288; *P*=.03). Regarding weight management behaviors, both time (T3 β=6, 95% CI 4.527-7.473; *P*<.001) and group (β=2.685, 95% CI 0.323-5.047; *P*=.03) had statistically significant impacts on the total points. Furthermore, the exercise management dimension also demonstrated both the time effects (T3 β=3.791, 95% CI 2.999-4.584; *P*<.001) and the group effects (β=1.501, 95% CI 0.232-2.771; *P*=.02).

XSL•FO
RenderX

Conclusions: The intervention program was effective in increasing psychological cognitions in terms of information, perceived vulnerability, and response costs, as well as promoting healthy behaviors among Chinese pregnant women. This study provides new evidence supporting the effectiveness of mobile intervention based on behavioral science theory in gestational weight management.

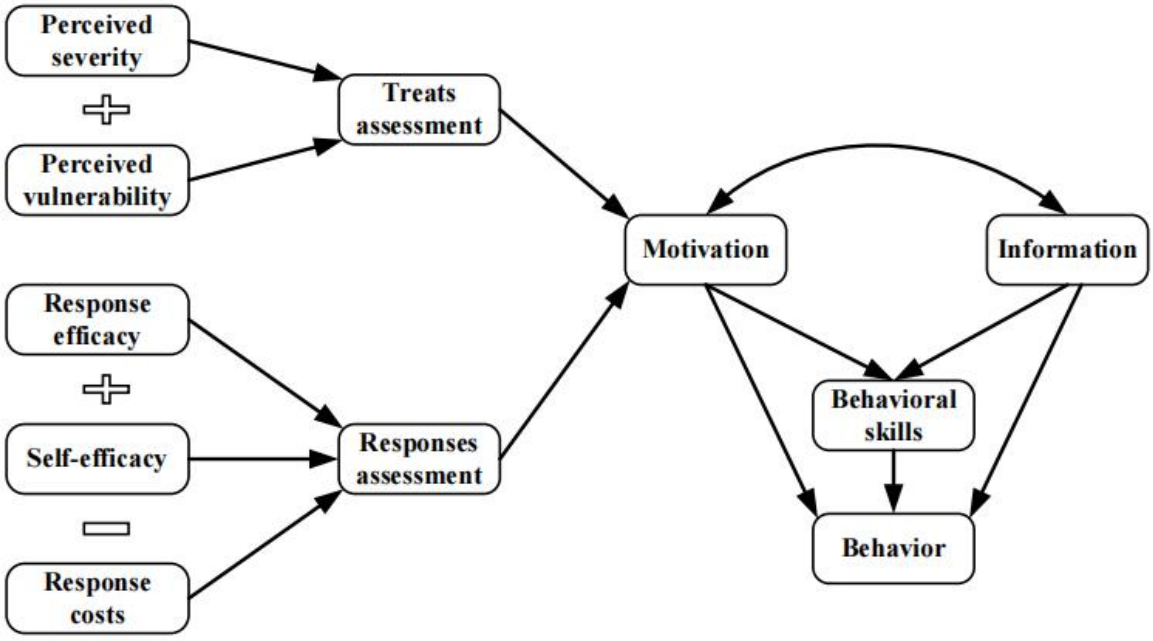
Introduction

Inappropriate gestational weight gain (GWG) remains a public health problem requiring immediate attention [1,2]. The proportion of inadequate weight gain among pregnant women is approximately 20% in the United States, Canada, and Europe, whereas the proportion of excessive weight gain is approximately 50%. Moreover, in Asia, 31% of pregnant women experience inadequate weight gain, whereas 37% experience excessive weight gain [3]. Currently, the appropriate GWG rate in China is less than 50% [4,5]. Appropriate GWG is essential, as both excessive and inadequate weight gain pose adverse risks to maternal and child health [6-9].



Mobile health refers to the use of mobile technologies including mobile phones, personal digital assistants, and even tablet computers to improve patient health [10]. In the current era of rapidly advancing information technology, mobile health is widely used in various medical fields. Despite the identification of various challenges in mobile health during its extensive application, including the lack of regulatory oversight, limited evidence-based literature, and concerns about privacy and security [11], mobile health still has many advantages. It not only overcomes the limitations of time and space but also saves medical and human resources. Notably, mobile health technology has become a popular resource for pregnant women to learn dietary and lifestyle modifications [12]. Mobile health interventions based on gestational diet and physical activity are widely used to promote weight management behavior [13,14], and several reviews have summarized the effectiveness of this emerging internet intervention approach to promote maternal and infant health [10,15,16].

Unhealthy behaviors, such as overeating, physical inactivity, and a sedentary lifestyle during pregnancy, are known to be considerably associated with inappropriate GWG [17]. The key to pregnancy weight management intervention is the promotion of health-related behaviors. Interventions based on health behavioral theory are effective in controlling GWG. For instance, the social cognitive theory [18,19], health belief model [20], and integrated theory of health behavioral change [21], have been used to formulate mobile health interventions aimed at gestational weight management. However, the effects of interventions based on behavioral theory are not universal. For example, the behavioral lifestyle intervention based on social cognitive theory had no impact on gestational weight management in African American individuals with obesity and White individuals [22]. Hence, the effects of these gestational weight management interventions based on behavioral theory have not been fully elucidated; therefore, in the context of mobile interventions targeting GWG, it is also necessary to further explore and validate potentially valuable behavioral theories in combination with practical applications.

In this study, the behavioral model integrated with the protection motivation theory and information–motivation–behavioral skills model (PMT-IBM model) was used to guide the mobile health intervention for gestational weight management. The integrated model involves 8 dimensions: information, behavioral skill, motivation, perceived severity, perceived vulnerability, response efficacy, self-efficacy, and response cost (Figure 1). In this integrated model, the 5 dimensions that explain the generation of motivation in the original protective motivation theory (PMT), namely perceived severity, perceived vulnerability, response efficacy, self-efficacy, and response cost, replace the single motivation dimension in the information-motivation-behavioral skills (IMB) model. These dimensions interact with the information dimension and then either directly influence behavior change or indirectly impact the emergence of behavior through behavioral skill factors [23]. Both PMT and IMB revolve around motivation. Specifically, PMT focuses on the motivation or willingness behind behavior, elucidating the formation of preventive behavioral motivation from a psychological perspective [24]. The IMB model further integrates motivation with information and skills [25]. While gestational weight control is a preventive and beneficial behavior adopted by individuals to safeguard their health [26]. Whether or not individuals have the motivation to engage in behaviors such as maintaining a balanced diet and engaging in moderate exercise during pregnancy reflects their subjective willingness to adopt such protective measures [14]. Therefore, this integrated model is suitable for the development of health education programs for gestational weight control among pregnant women. In a previous independent study, we have already extensively validated the integrated model's fitness and ability to interpret gestational weight management behavior in a cross-sectional survey of 525 pregnant women. The study explains the influencing mechanisms underlying gestational weight management behavior at the individual psychological level [27]. Nevertheless, this initially proven interpretive integrated model has not yet been verified for its effectiveness in guiding interventions in practice.

XSL•FO
RenderX

Figure 1. The behavior model integrated by protection motivation theory and information–motivation– behavioral skills model.

Therefore, this trial aimed to determine whether a mobile health intervention applying the PMT-IBM model as the framework could enhance psychological cognitions and behaviors toward gestational weight management.

Methods

Study Design

This was a single-blind randomized controlled trial (RCT). Eligible participants were randomly assigned by computer to (1) intervention (mobile health based on the integrated model) and (2) control (routine guidance through the mobile application) groups. The study was prospectively registered with the Chinese Clinical Trial Registry (ChiCTR2100043231).

Study Setting and Participants

Between August and December 2021, participants were recruited from Changzhou, one of the central cities in China's Yangtze River Delta region and a developed city in southern Jiangsu Province. The city occupies an area of approximately 4372.15 km^2, with a per capita gross domestic product of more than US $25,000 in 2021. (Changzhou Municipal People's Government, 2022) The study site was a tertiary maternity hospital where approximately 40% of the deliveries in this city are performed (Changzhou Maternal and Child Health Care Hospital, 2021). This study used purposive sampling, where the researchers interning in the obstetrics and gynecology outpatient clinic invited all eligible pregnant women to participate in the study. The inclusion and exclusion criteria are listed in Textbox 1.

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- singleton pregnancy;
- pregnancy confirmed by a pregnancy test (gestational age ≤14 weeks);
- intention to live in the region until delivery;
- ability to complete the questionnaire; and
- agreement to participate and provide written informed consent.

Exclusion criteria

- age <18 years;
- history of neurological, cardiovascular, hepatic, and renal medical complications;
- essential hypertension and diabetes mellitus; and
- other complications, such as deafness and dumbness.

XSL•FO
RenderX

Sample Size

Distinct from the protocol, there has been a change in the outcome indicator used for calculating the sample size in this study. Initially, in the protocol, both GWG and weight management behaviors were primary outcome indicators, and the outcome indicator for sample size calculation was based on data related to GWG in Jiangsu Province. However, due to the pandemic, the final sample size did not meet the requirements for analyzing weight outcomes. Since this study primarily focuses on behavioral changes among pregnant women, the sample size was calculated based on the behavioral indicator (the score on the Gestational Weight Management Behavior Scale). The score, serving as both a behavioral indicator and another primary outcome variable in the protocol, is deemed suitable for sample size calculation in this analysis. The formula for calculating sample size was based on a 2-sample mean comparison: $n1=n2=2[(Z_\alpha+ Z_\beta)s/d]^2$ [28]. The presurvey results were used to obtain the s=11.8 and d=5.25 [27]. Therefore, the estimated sample size was as follows: n1=n2=108. A 20% attrition rate was considered for this study; therefore, the required sample size was increased to 270 participants, including 135 participants in each group.

Randomization and Blinding

In this single-blind RCT, the participants were blinded. The randomization sequence was generated using SPSS software (version 25.0; IBM Corp) by a research assistant who did not participate in the recruitment process. Random numbers were matched to the intervention app. When participants completed the baseline questionnaire, they were assigned a unique registration number. Thereafter, the backend of the app consolidated the participants' information to screen those who met the inclusion criteria. The registration number was then matched against the groups' random sequence, to categorize the participants into intervention or control groups.

Data Collection

Our research team comprehensively studied the operational definitions of each dimension of the PMT-IBM model, as well as designed the questionnaires to strictly comply with the questionnaire design process [27]. Three trained outcome assessors performed face-to-face baseline data collection during the first trimester (T1: gestational age of ≤14 weeks) at the maternity clinic. The follow-up data were collected using a questionnaire link provided on the mobile health app in the second trimester (T2: gestational age of 27-28 weeks) and third trimester (T3: gestational age of ≥37 weeks). During questionnaire completion, the assessors reminded the participants to self-report their actual preceding month circumstances.

Outcome Measures

A detailed baseline evaluation was performed for all participants before initiating the study. The evaluation included the following three parameters: (1) main demographic characteristics: including maternal age, education level, parity, height, and prepregnancy weight. (2) Gestational psychological cognition scales: included 7 dimensions (information, behavioral skills, perceived severity, perceived vulnerability, response efficacy, self-efficacy, and response costs), which were designed by the PMT-IMB model. Each dimension was measured on a 5-point Likert scale (from 1=absolutely disagree to 5=absolutely agree) and included 5 items each, with a total score of 5-25. A higher total score indicated better psychological cognition among pregnant women. The total Cronbach α for the cognition scale of 0.860, ranged from 0.822 to 0.938. (3) Gestational weight management behavioral scales included 4 dimensions encompassing 20 items, each item was rated on a 5-point Likert scale ranging from 1 (never) to 5 (always). Specifically, exercise management dimension (consisting of 9 items, with a score range of 9-45) pertains to diverse exercise management behaviors adopted by pregnant women to maintain optimal GWG, encompassing the duration and type of exercise. The dietary management dimension (including 4 items, with a score range of 4-20) refers to a series of dietary management practices implemented by pregnant women to achieve appropriate GWG. The self-monitoring and regulation dimension (comprising 4 items, with a score range of 4-20) entails pregnant women engaging in weight monitoring, diet tracking, self-regulation, and other related behaviors aimed at maintaining suitable GWG. Then, management objectives (containing 3 items, with a score range of 3-15) involve pregnant women setting their own weight gain, dietary, and exercise goals in accordance with appropriate standards for GWG. Scores were analyzed using the gross for each dimension, with higher scores indicating superior behavioral management in each respective dimension. The total Cronbach α for the behavioral scale of 0.844, ranged from 0.653 to 0.866. The validity test of the scale has been reported in the previous explanatory study [27]. The detailed information for the scales is shown in Multimedia Appendix 1 and the operational definition of gestational weight management behaviors is shown in Multimedia Appendix 2.

Intervention Tool

The mobile health intervention was implemented using a self-developed app, "Pregnancy Assistant." "Pregnancy Assistant" was collaboratively developed by project team members, obstetricians, and computer engineers. The project leader provided the application development framework and relevant requirements, while the obstetricians were responsible for gathering feedback and suggestions from clinical health care professionals regarding the development of a "Pregnancy Assistant." The project members, on the other hand, were tasked with collecting information on pregnancy weight management and understanding the weight management needs of pregnant women.

The application comprises 3 primary user end points: for pregnant women, hospitals, and the integrated system database. The client for pregnant women included modules such as gestational age, a questionnaire, health education, notification, and weight records. Among these, the gestational age, weight records, and questionnaire modules serve as intervention assistance tools. The most crucial intervention involves delivering health education content through the "health education" module, tailored to the dimensions of the model and the specific gestational weeks of the pregnant women, along with corresponding notification reminders. In the notification module, pregnant women can engage in communication and

XSL•FO
RenderX

share their insights and experiences through the created groups. The hospital client could upload health education-related materials. All survey data were downloaded and stored in the database. In the health education module, the content received by the intervention group differs from that of the control group. Specifically, the control group is sent to routine pregnancy health care guidance, whereas the intervention group receives materials that are designed according to the PMT-IMB model (Multimedia Appendix 3).

Control Group

The control group underwent routine prenatal care in accordance with the guidelines for preconception care and prenatal care in China provided by the hospital [29]. This prenatal care encompassed regular prenatal examinations, periodic antenatal information services, and health education and guidance. Notably, the health education component only incorporated information that the country mandates to be imparted to pregnant women. Some of these health education information services would be delivered through the app named Pregnancy Assistant to ensure convenient access to and timely updates of the information.

Intervention Group

In addition to implementing the same routine prenatal care as those provided to the control group, the intervention group implemented specific interventions tailored to the dimensions and corresponding definitions of the behavioral model. These interventions were delivered through a variety of formats, including image texts, videos, expert lectures, and peer communication. According to the research results on the model construction [27], the main contents of the interventions were determined based on the information, motivation, and behavioral skills dimensions. First, we developed various health intervention materials under the 7 psychological cognition dimensions by referring to studies on gestational weight management [29] and gestational guidelines on nutrition [30-32] and exercise [30,33], combined with the recommendations from clinical nutrition experts, obstetricians, and nurses. The intervention materials (ie, image, text, and video) were delivered through the "Pregnancy Assistant" app, (24 items in total, once a week) during the intervention period, which spanned from the 14th to the 37th week of gestation. Throughout this process, researchers also regularly reminded pregnant women via the notification module of the app and WeChat (Tencent) to use the intervention materials to improve compliance. Second, every 2 weeks, a 45-minute expert lecture was held in the application to introduce information regarding the risks and severity of inappropriate GWG, its epidemiological knowledge such as risk factors, susceptible populations, and suitable preventive dietary and exercise methods. Following each expert lecture, a 15-minute question-and-answer session was offered to participants to address existing obstacles against weight management. In addition, to boost confidence and stimulate healthy behavioral changes, experienced participants were encouraged to share their thoughts and experiences via the communication group. The detailed intervention content is shown in Multimedia Appendix 3. The study adheres to the CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) guidelines, and the completed CONSORT-EHEALTH checklist is available in the Multimedia Appendix 4.

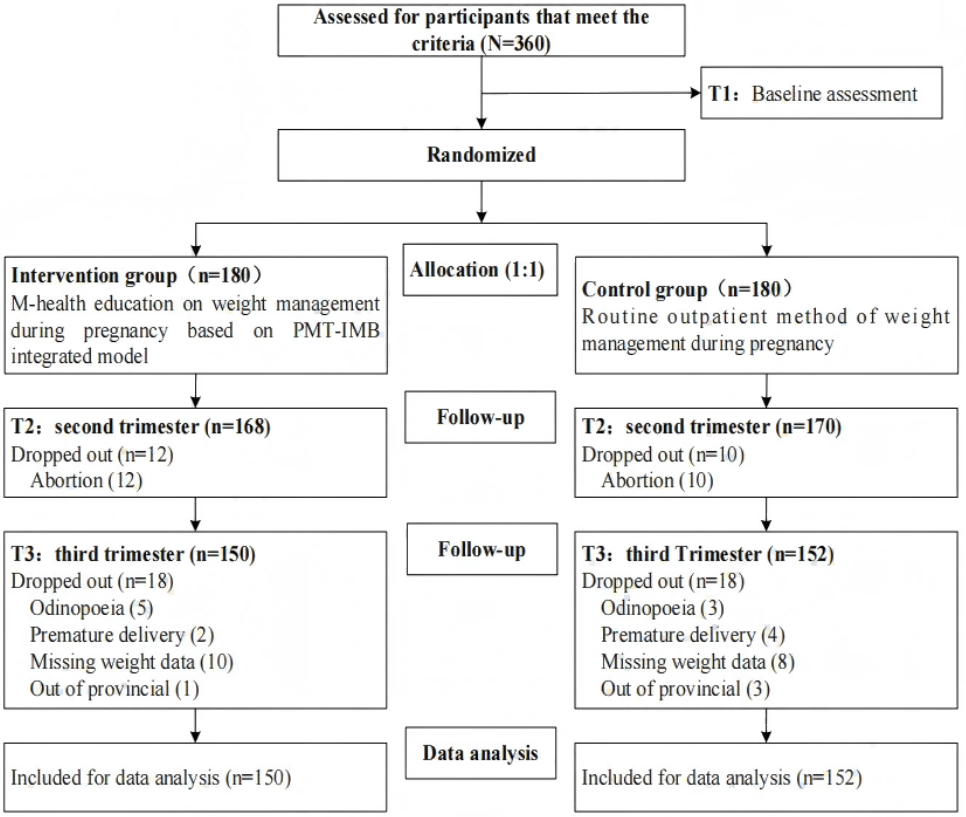
Statistical Analysis

In the descriptive statistical analysis, continuous variables are expressed as mean values and (SDs). Use the Kolmogorov-Smirnov test to verify the normality of these data. For data that met normality, a 2-sample independent *t* test was used to compare the 2 groups, while (ANOVA was used to compare multiple groups. For data that do not meet normality, nonparametric tests were used. Categorical variables, presented as frequencies (%), are compared between groups using the Pearson chi-square test. In a general linear model, the cognition dimensions in the PMT-IMB model and weight management behavioral dimensions were considered as the dependent variables. Intervention or not was considered the primary independent variable (0 for the control group and 1 for the intervention group). Covariates included age, education level, parity, and prepregnancy BMI. Each participant completed the same questionnaire thrice, providing repeatable and dependable measurement data. Therefore, the differential changes in psychological cognitions and behaviors at T2 and T3 with respect to T1 between the 2 groups were assessed using generalized estimating equations. When no statistical interaction between time and group was present, we only included the group's main effect and time terms to demonstrate the intervention's effect. Those who had a miscarriage or premature birth during follow-up were excluded from the final data analysis. Therefore, intention-to-treat analysis was not used in the analysis of this study. All data analyses were performed using IBM SPSS Statistics for Windows (version 25.0), and statistical significance was set at $P<.05$ (2-sided).

Ethical Considerations

This study was approved by the Ethics Committee of Nanjing Medical University (number NMU 2020-63). All participants were comprehensively informed of the voluntary nature of their participation and their right to withdraw from the study at any time. The investigation was performed only after written informed consent had been obtained from the participants. We adhere strictly to confidentiality regarding the obtained information, and we have committed to respecting patients' privacy and confidentiality rights during the data collection process. As a gesture of appreciation for the time spent by the participants completing the questionnaire, US $8.4 was provided to each participant.

Results



Participant Recruitment and Retention

After evaluation, 360 participants satisfied the eligibility criteria at baseline and were randomly assigned to intervention and control groups (n=180 per group). After their inclusion in the study, pregnant women registered themselves on the app using their mobile phones and completed the baseline questionnaire. The T2 follow-up involved 338 participants (intervention group: n=168; control group: n=170; retention rate: 88.9%). By T3,

XSL•FO
RenderX

302 participants with complete follow-up data were included in the final data analysis (intervention group: n=150; control group: n=152). The overall retention rate was 83.9%. Participants who dropped out at each stage of the study are shown in Figure 2. The comparison of demographic and clinical characteristics between dropouts and completers of the intervention revealed no significant differences (*P*>.05 for all comparisons).

Figure 2. Flow chart of the assessment, allocation, reasons for withdrawal, and number of participants included in the data analysis.

Main Demographic Characteristics

The participants' demographic characteristics are presented in Table 1. Among the 302 participants, the mean ages of the intervention and control groups were 29.31 (SD 3.38) and 29.16 (SD 3.49) years, respectively. In both groups, more than half of the participants had at least a college education (59.3%, 89/150 vs 54.6%, 83/152; *P*=.41). Most participants were primipara, and the proportion of participants with an appropriate prepregnancy BMI also exceeded 70%. No statistically significant between-group differences were observed in the main demographic characteristics (*P*>.05).

Intervention Effect on Psychological Cognitions and Weight Management Behaviors

As shown in Table 2, at baseline, only the management objective dimension (adjusted β=0.686, *P*=.04) was significant, whereas all dimensions of psychological cognition and weight management behavior were not significantly different between the 2 groups. Adjusted general linear models demonstrated that participants in the intervention group had noticeably higher scores for information (adjusted β=0.836, *P*=.02), perceived vulnerability (adjusted β=0.894, *P*=.03), response cost (adjusted β=1.101, *P*=.006), and exercise management (adjusted β=2.089, *P*=.01) at T2 than their counterparts in the control group. Furthermore, their scores for perceived vulnerability (adjusted β=1.078, *P*=.01), response cost (adjusted β=1.538, *P*=.001), and dietary management (adjusted β=0.959, *P*=.007) were statistically significantly higher at T3. Although behavioral skills, perceived severity, response efficacy, self-efficacy, self-monitoring and regulation, and management objectives yielded generally better scores in the intervention group than in the control group at T2 and T3, statistical significance was not achieved.

Generalized Estimating Equations for Psychological Cognition and Weight Management Behaviors

Psychological cognition and weight management behaviors were used as dependent variables, while time and group were used as independent variables in the generalized estimating equation analysis (Table 3)**.** Regarding psychological cognitions, a statistically significant group effect on information (β=0.597, 95% CI 0.035-1.158; *P*=.04), perceived vulnerability (β=0.669, 95% CI 0.050-1.288; *P*=.03), and response cost (β=1.034, 95% CI 0.367-1.700; *P*=.002) were observed. Moreover, time had a statistically significant effect on information (T2: β=2.457, 95% CI 2.086-2.832; *P*<.001; T3: β=3.235, 95% CI 2.859-3.611; *P*<.001) and response cost (T2: β=0.702, 95% CI 0.203-1.201; *P*=.01; T3: β=0.745, 95% CI 0.199-1.291; *P*=.01). However, no significant differences were noted in the perceived severity and response efficacy dimensions among the groups and times.

[a]For the group, the control group was the reference; for time, the first trimester (T1) was the reference.

[b]T2: second trimester.

[c]T3: third trimester.

Regarding weight management behaviors, the 2 groups had a statistically significant effect on exercise management (β=1.501, 95% CI 0.232-2.771; *P*=.02). Furthermore, time had a statistically significant effect on exercise management (T2: β=2.262, 95% CI 1.489-3.034; *P*<.001; T3: β=3.791, 95% CI 2.999-4.584; *P*<.001) and dietary management (T2: β=–0.579, 95% CI 0.818-1.824; *P*=.01). Regarding total weight management behavioral scores, the group (β=2.685, 95% CI 0.323-5.047; *P*=.03) and time (T2: β=1.891, 95% CI 0.524-3.258; *P*=.01; T3: β=6.000, 95% CI 4.527-7.473; *P*<.001) effects were all statistically significant.

Discussion

Principal Findings

To the best of our knowledge, this RCT is the first to use mobile health intervention guided by the novel PMT-IBM behavioral theory and test its effectiveness on gestational weight management. Although the mechanism underlying this phenomenon requires further research, statistically significant results suggest that mobile intervention potentially plays positive roles in raising psychological cognitions in weight management including information, perceived vulnerability, and response cost, as well as promoting dietary and exercise management during pregnancy.

Role of Mobile Health App

In this study, the mobile health app “Pregnancy Assistant” played a crucial role in intervening with the weight management of pregnant women. First, the app served as an effective medium for disseminating information. It provided different health education information to both the control and intervention groups. In addition to the routine pregnancy care information available to both groups, the information provided to the intervention group was designed based on behavioral models, making it more targeted and systematic [34]. This difference might have led to varying intervention effects between the 2 groups. The precision of health education information in the intervention group made it easier for pregnant women to clearly understand the weight control goals and methods at different stages of pregnancy, whereas the control group lacked such precision [35]. Second, the app met the social interactive needs of pregnant women. The regular health lectures attended by the intervention group broadened their knowledge base. The question-and-answer sessions following the lectures addressed participants’ concerns, offering personalized guidance that enhanced their confidence and ability in weight management [36]. The peer support groups within the notification module created a supportive social environment. Pregnant women shared experiences and encouraged each other through communication, and this model of coexisting peer pressure and support could improve their enthusiasm and compliance in weight management [37]. Of course, the convenience of the app should not be

XSL•FO
RenderX

overlooked. Pregnant women could access the app anytime, anywhere, via smartphones to obtain necessary information and participate in interactions [38]. This convenience integrated weight management into pregnant women's daily lives, breaking time and space constraints and helping to form long-term, stable health management habits.

Effect on Psychological Cognitions

Based on our findings, promoting healthy behaviors in terms of information, perceived vulnerability, and response cost, via mobile health, are of practical relevance. Mobile health technologies such as apps can be applied to the design of the content of mobile interventions for these important psychological cognition dimensions. The intervention content should focus on increasing awareness regarding GWG and control and perceived vulnerability to adverse outcomes and risks while decreasing perceptions of difficult decision-making and personal insecurities. However, no statistically significant between-group differences were noted in the behavioral skills, perceived severity, self-efficacy, and response efficacy dimensions. This may be because most pregnant women lack awareness and hold misguided beliefs regarding weight gain and management. Moreover, a general lack of awareness regarding the specific risks of being overweight or obese during pregnancy is also an important barrier to appropriate GWG [39]. Meanwhile, most pregnant women lack persistence in long-term dietary management and physical exercise and have limited ability to control weight and achieve exercise compliance based on healthy behaviors in reality [40,41]. Furthermore, some pregnant women insufficiently recognize the seriousness of inappropriate GWG, mistakenly believing that pregnancy is perilous by nature and that the occurrence of complications is random [42]. In addition, due to the free availability of extensive information on the internet, the control group also had extra opportunities to access health information or learn it on their own from other sources, which may have affected the accurate evaluation of the intervention. The effectiveness of interventions informed by the theory may be affected by how successfully the theory is applied to the mobile intervention strategies. Although theories are ideal for explaining and validating behavior, they may not be excellent for guiding mobile interventions because of several complicated variables, including time of exposure and environment (ie, exposure to advertisements promoting fast food and sugary beverages). Therefore, this may result in weak or limited effects on cognitive and behavioral changes [43]. Furthermore, in the process of developing the mobile intervention, attention should be paid to the environment and intensity of intervention; moreover, differences in social, economic, cultural, and other factors should be considered [44].

Effect on Gestational Exercise and Dietary Behaviors

Our findings indicate that the intervention group's exercise management significantly improved at T2. Evidence from a previous meta-analysis also suggests that prenatal exercise may be an effective method to promote appropriate birth weight of newborns and GWG [45]. In this study, exercise behavior was measured only by the gestational weight management behavioral scales, and future studies should include objective measures of physical activity (ie, step number or physical activity measuring tools) at different stages of pregnancy to evaluate the potential of mobile health intervention in improving gestational exercise. At T3, statistically significant improvements were noted in the intervention group's dietary management but not in exercise management. A possible explanation could be that pregnant women may experience obvious weight gain in the T3 compared with that at prepregnancy. The altered body shape potentially results in physical activity restriction, leading pregnant women to prefer weight management through a healthy diet [46]. Therefore, in the T3, physical activity should be emphasized and health education related to suitable exercise should be reinforced. Previous studies have found smartphone applications and other digital interventions to promote a healthy diet among pregnant women with obesity and overweight [47,48]. However, altering the long-term dietary patterns in this intervention study, which focused on psychological cognition, proved difficult, and this might have been influenced by deeply rooted Chinese concepts (ie, "the better the eating during pregnancy, the better the growth of the fetus"). Furthermore, dietary behavioral modification is influenced by external conditions (ie, the convenience of accessing healthy foods), which is beyond the current intervention. Therefore, the ideal dietary intervention should be considered from multiple perspectives, including some external reinforcing factors.

Strengths and Limitations

This study has several strengths. First, compared with previous similar studies [48-50], the population in this study not only included women who were overweight or obese before pregnancy but also included women of all BMI categories. Second, the behavioral intervention integrated mobile intervention with 2 classical behavioral theoretical models so that the mobile intervention framework was multidimensional, providing a multipronged approach to gestational weight management.

However, this study has several limitations that warrant consideration. First, participants were recruited from a single hospital in Jiangsu Province, which may not adequately represent the entire target population globally. Multiregional, multicenter RCT should be conducted in the future. Second, the outcomes were self-reported by participants, thus potentially leading to reporting and recall bias. Third, the nonrandom sampling method could result in some selection bias. Fourth, the mean and SD values of psychological and behavioral scales were similar across the groups; therefore, the significance of the findings needs to be further examined, and the results need to be carefully interpreted.

Conclusions

This study assessed the applicability and effectiveness of a gestational weight mobile health intervention program based on the behavioral model integrated with the PMT-IMB model. This mobile intervention enhanced the psychological cognition among pregnant women in information, perceived vulnerability, and response cost, and improved dietary and exercise management. Further research is necessary to confirm the generalizability, operability, and durability of our findings in the practice of mobile health intervention.

Acknowledgments

We thank all pregnant women for their participation. We give special thanks to the Health Department of Changzhou Maternal and Child Health Hospital for the great assistance and coordination of the data collection. This study was supported by the NSFC (National Natural Science Foundation of China) (No. 72074122) and Philosophy and Social Science Research of Jiangsu Higher Education Institutions of China (2020SJA0306).

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the inclusion of protected personal information but are available from the corresponding author on reasonable request.

Authors' Contributions

HY, MZ, and LW designed the study and critically reviewed, commented on, and revised the manuscript. MZ, HY, and JJG participated in data analysis, performed the final statistical analyses, and prepared the first version of the manuscript. MZ, JJG, LW, and SQZ collected the data. MZ, JJG, and SQZ collected literature materials. DY revised the manuscript. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: Acceptance and commitment therapy provides a psychobehavioral framework feasible for digital and hybrid weight loss interventions. In face-to-face studies, group-based interventions yield more favorable outcomes than individual interventions, but the effect of the intervention form has not been studied in combination with eHealth.

Objective: This study investigated whether a minimal, 3-session group or individual enhancement could provide additional benefits compared to an eHealth-only intervention when assessing weight, body composition, and laboratory metrics in a sample of occupational health patients with obesity.

Methods: This study was a randomized controlled trial with a 12-month intervention, followed by a 12-month follow-up period without additional support (March 2021 to March 2023). Recruited from occupational health care for Finnish municipal employees, 111 working-age adults with a BMI of 30-40 kg/m^2 were randomized to 1 of the 3 treatment arms: eHealth, eHealth+group, or eHealth+individual. All treatment arms received a web-administrated, coach-assisted eHealth program based on acceptance and commitment therapy, and additionally, the eHealth+group and eHealth+individual arms received 3 remotely facilitated group or individual meetings with their designated coach. The participants were assessed for weight, body composition, blood pressure, and laboratory measurements at 0-, 6-, 12-, and 24-month time points. Applying estimated means to decrease bias caused by dropouts, generalized estimating equations were used to study the differences between the 3 groups over time.

Results: There were no between-group differences in primary measurements of weight change or categorical weight change. Secondary outcomes also did not show changes attributable to the intervention arm. Across the entire sample, the total weight loss was 1.5% during the intervention, with 18% (20/111) of the participants attaining a ≥5% weight loss. Sustained at follow-up, waist circumference decreased, and high-density lipoprotein cholesterol increased slightly. The participants completed, on average, 58.6% of the eHealth program.

Conclusions: There were no differences in weight or other somatic health variables between the eHealth arm and intervention combining eHealth with minimal group or individual enhancement. Despite a modest overall weight loss, the intervention shows promise in improving body composition and metabolic health. Moving forward, further research is needed to determine if there is a threshold where face-to-face meetings provide additional benefits in hybrid interventions. Moreover, there is a need to explore for whom and under what conditions eHealth and hybrid models may be most effective.

Introduction

The prevalence of obesity has more than doubled worldwide since the 1970s [1]. Obesity increases the risk for several metabolic, mechanical, and psychiatric conditions, attributing to 8% of deaths worldwide [2,3]. Weight loss is seen to effectively alleviate obesity-related comorbidities, and even a modest 5%-10% weight loss is seen to, for example, lower hypertension and total cholesterol, and prevent the onset of diabetes [4-6].

However, attaining even modest weight loss results is not an easy task because weight is seen to increase by 1-2 kg yearly after weight loss intervention [7]. Research has demonstrated the significant role of psychobehavioral factors in weight management success, leading to the use of psychological components in weight loss interventions [8,9]. Acceptance and commitment therapy (ACT) is a third-wave cognitive behavioral therapy aiming to increase psychological flexibility—defined by Hayes et al [10] as "the ability to contact the present moment more fully as a conscious human being, and to change or persist in behavior when doing so serves valued ends." ACT promotes engagement in health-promoting behavior patterns while enhancing commitment to values-based behaviors [11]. Although ACT primarily targets psychological well-being rather than direct weight loss, it has proven effective in supporting long-term weight management and lifestyle changes [12,13].

In the context of weight loss trials, ACT is usually delivered in a group or workshop format [14-20]. However, in recent years, there has been growing attention to digital interventions for weight loss, offering an accessible, widespread, and cost-effective alternative to traditional face-to-face treatments [21,22]. Indeed, recent systematic reviews have provided compelling evidence supporting the effectiveness of digital interventions (eHealth) in obesity treatment: without distinguishing between different theoretical frameworks, eHealth interventions have demonstrated outcomes on par with traditional face-to-face methods and have consistently outperformed control conditions [23].

Adding personalized human interaction and guidance to eHealth programs has proven to be particularly effective in achieving significant weight loss [24-27]. Furthermore, combining face-to-face meetings with digital interventions, referred to as hybrid interventions, has been shown to further enhance the effectiveness of weight loss [28-30]. ACT-based hybrid interventions are still rare, but studies combining digital ACT interventions with group meetings [31] or telephone support [32,33] have shown promising results. The impact of intervention format (group vs individual) on weight loss has not been studied in combination with eHealth, particularly in the context of ACT. However, in face-to-face trials, group-based interventions have consistently produced more favorable outcomes compared to individual approaches [34,35].

This study aimed to investigate the differences in the ACT-based 12-month eHealth intervention between eHealth, eHealth+group, and eHealth+individual delivered for occupational health patients with a further 12-month follow-up period. Weight and categorical weight change were considered the primary outcomes, and waist circumference, body composition, and laboratory measurements were the secondary outcomes of this study. We hypothesized that enhancing interventions with individual or group meetings alongside the eHealth program would lead to improved weight and health outcomes, particularly favoring the group treatment arm. Additionally, we anticipated significant changes in weight and health parameters across all treatment groups.

Methods

Study Design

This study was a randomized controlled trial with a 12-month intervention and 12-month follow-up period. The participants were allocated to 1 of the 3 treatment arms: eHealth, eHealth+group, or eHealth+individual treatment in a 1:1:1 ratio. All treatment arms received a web-administrated eHealth program, and additionally, the eHealth+group or eHealth+individual arms received 3 remotely facilitated group or individual meetings.

The eHealth program used in this study, Healthy Weight Coaching (HWC), is a 1-year treatment program based on the ACT framework, aiming to increase psychological flexibility and teach skills related to weight management [36]. The program consists of web-administrated weekly exercises integrating ACT with behavioral weight management themes (eating behavior, physical activity, sleep, and stress; Table S1 in Multimedia Appendix 1). The HWC program is readily available in Finnish public health care, and this study was designed to investigate whether minimal enhanced support in a group or individual format could improve attrition and response to the treatment.

The version of the program used in this study adopted a softer, more weight-neutral coaching style than the HWC protocol, with prioritization on value-based actions, mindfulness, and health-promoting changes instead of weight loss itself. The enhanced group and individual meetings in eHealth+group and eHealth+individual arms adhered closely to the ACT framework, incorporated key lifestyle change components of the program, and aimed to deepen the participants' understanding of the program's themes.

The participants were each assigned a personal coach who provided periodic, tailored, one-on-one written feedback and facilitated any additional meetings. All the 3 coaches in this study had master's degrees in nutrition and further education

XSL•FO
RenderX

in psychology. They met biweekly to ensure adherence to this study's protocol. The coaches worked across the 3 treatment arms, being randomly assigned to one-third of each.

Treatment Arms

- eHealth: Participants received the HWC eHealth program, which included a 20-minute kickoff call 3 weeks into the program to ensure they were progressing as expected. They also received written feedback every 2 weeks for the first 3 months and then once every 3 weeks for the remainder of the year, totaling 19 contacts.
- eHealth+group: Participants received the HWC eHealth program (as described in item 1, eHealth) and, in addition, participated in 3 remotely facilitated group meetings using video (each was 2 hours long; due to COVID-19, a transition to remote meetings was necessitated). These group meetings included brief introductions to covered topics (eg, goal setting, stress management, and self-compassion) followed by small group discussions (Table S2 in Multimedia Appendix 1). The group meetings occurred at 1, 6, and 10 months into the 12-month treatment period.
- eHealth+individual: Participants received the HWC eHealth program (as described in item 1, eHealth) and, in addition, participated in 3 remotely facilitated individual meetings using video (each was 45 minutes long). These individual meetings were customized to each participant's current needs, acknowledging successes and seeking solutions to challenging situations. The individual meetings occurred at 1, 6, and 10 months into the 12-month treatment period.

Recruitment

Participants were Helsinki city employees with class 1 and class 2 obesity [37]. Recruitment was conducted by the staff of the occupational health care and through recruitment advertisements on the city employees' communication platforms. Enrollment was carried out by research assistants from February to March 2021. Inclusion criteria required participants to have a BMI between 30 to 40 kg/m^2, the ability to participate in group or individual meetings, access to a computer with internet services, and fluency in the Finnish language. Exclusion criteria included participation in other weight loss programs, pregnancy or lactation within the past 6 months, weight changes exceeding 5 kg within the past 3 months, major medical conditions affecting safety or readiness for weight loss, and the use of weight loss medication.

Power Analysis and Sample Size

The sample size of 23 participants per treatment arm was determined by a statistician (JM) with priori power analysis using a statistical power of 0.80 with 2-sided test and 0.05 α, modeling the mean weight change and SD in previous weight loss studies (mean 3.8, SD 4.6 kg) [38]. With an expected attrition rate of 40%, the target number of participants was set at 38 per treatment arm.

Screening

Following recruitment, participants underwent a health screening on a phone by a medical doctor covering their health status and medications. Those who passed the screening were then referred for laboratory assessments and body composition measurements.

Randomization

In March 2021, participants who provided written consent and completed baseline measurements were randomized into 1 of the 3 treatment arms (see figure in the Results section). Randomization was carried out by a statistician (JM) using stratified random allocation with SPSS (IBM Corp). Participants were stratified by sex (male or female), age groups (20-35, 35-50, and 50-65 years), and BMI categories (≥30 to 35 or ≥35 to 40 kg/m^2).

Outcome Measures

The intervention period lasted for 12 months, from March 2021 to March 2022, after which a 12-month follow-up period was conducted until March 2023 without further support. Participant assessments were conducted at baseline, midintervention (6 months), postintervention (12 months), and follow-up (24 months) at Occupational Health Helsinki. The following measurements were taken:

- Height: Measured to the nearest 0.1 cm using a Gima tape height measure with a scale from 0-200 cm (Gima SpA).
- Weight: Measured after an overnight fast to the nearest 0.1 kg in light clothing, barefoot, on InBody720 or InBody770 (InBody Co Ltd), with repeated measures taken using the same equipment.
- Body composition: Fat mass, muscle mass, and visceral fat were measured with the abovementioned InBody devices.
- Waist circumference: Measured to 0.1 cm using a Hoechstmass nonextensible tape measure (Hoechstmass Balzer GmbH) at the narrowest point between the lower costal border and the umbilicus.
- Blood pressure and heart rate: Systolic and diastolic blood pressure and heart rate were measured 3 times after 10 minutes of rest using an Omron automated blood pressure monitor (Omron Corporation). The mean sum of the last 2 measurements was used in the analysis, and the measurements were repeated if necessary until the difference between the last 2 measurements was <10 mm Hg.
- Blood samples: Blood samples were collected at the laboratory of Occupational Health Helsinki after an overnight fast and analyzed for lipids (total cholesterol, low-density lipoprotein cholesterol, high-density lipoprotein [HDL] cholesterol, and triglycerides), glucose, hemoglobin A1c (HbA1c), alanine transaminase, and high-sensitivity C-reactive protein (hs-CRP).

Of the baseline characteristics (Table 1), metabolic syndrome was calculated from the laboratory and anthropometric measurements following the International Diabetes Foundation's 2006 definition [39]. Smoking was self-reported in a baseline survey. The professional role was determined using Statistics Finland's Classification of Occupations 2010 index [40]. Program usage was obtained from the log file. Medication changes were tracked every 3 months as part of the eHealth program.

[a]*P* values indicate the difference between the 3 treatment arms with the categorical variables analyzed by chi-square test and the continuous variables by ANOVA.

Statistical Analysis

Data analysis was conducted using IBM SPSS Statistics (version 28.0.0.0; IBM Corp). Baseline differences were analyzed by chi-square for the categorical variables and ANOVA for the continuous variables. Differences in mean values between the measurement points and the treatment arms were analyzed using the generalized estimating equations (GEEs) method [41]. The GEE method includes all the available data points and uses estimated means in the analysis, applying the intention-to-treat (ITT) analysis concept to decrease bias caused by dropouts. The article only reports results from the ITT analysis, while completer analyses are available in Multimedia Appendix 1.

Considering GEEs, we first used a model examining the interaction between the measurement points and treatment arms, with post hoc analysis comparing the effects of the eHealth+group and the eHealth+individual arms to the eHealth arm. For further analysis, we used a single-arm model, concentrating on the changes observed across the 4 measurement points in the entire study sample. After the primary analysis, we added baseline weight, sex, age, and applicable medication or medication change (eg, blood pressure medication in systolic and diastolic blood pressure analysis) to the single-arm model to explain the results. The changes in medication are described in Table S3 in Multimedia Appendix 1. Weight, BMI, waist circumference, HbA_{1c}, cholesterol, HDL, low-density lipoprotein, systolic blood pressure, diastolic blood pressure, and pulse rate were normally distributed. Glucose, triglycerides, alanine transaminase, hs-CRP, and muscle percentage had a positively skewed distribution, and thus, gamma distribution with log link function was used in the GEEs analysis. Visceral fat and fat percentage had a negatively skewed distribution, and thus, inverted variables were used in the analysis with gamma distribution and log link function.

Crosstabs with Pearson chi-square was used when analyzing the group level differences of categorical weight variable (participants were divided into 6 categories based on weight loss percentage: <0, 0-2.9, 3-4.9, 5-5.9, 5-9.9, or ≥10), and change in metabolic syndrome prevalence between the measurement points. Categorical weight loss and metabolic syndrome prevalence are reported for the entire baseline sample, with the last observation carried forward. Changes in muscle and fat percentage, as well as metabolic syndrome incidence, are expressed as percentage points (%-point), describing the arithmetic difference between the 2 percentages.

Spearman correlation coefficient was used to analyze correlations between the weight change percentages (nonparametric). Dancey and Reidy's definition was used when determining the strength of the correlation [42].

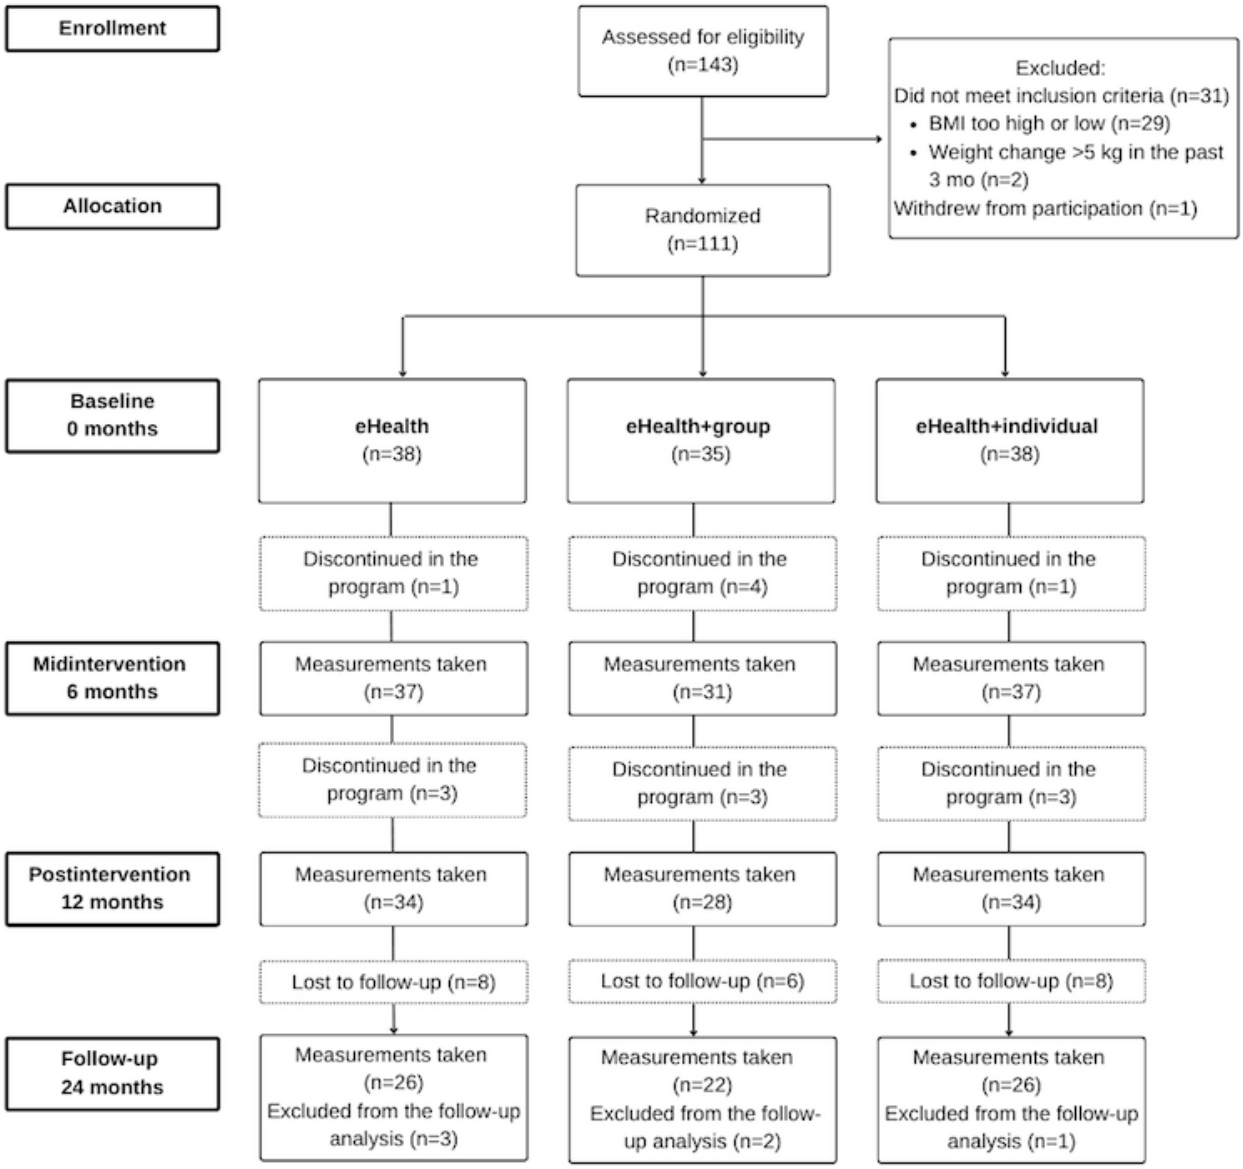
Cohen *d* effect size was calculated using the square root of the average variance of measures. In the analysis comparing the treatment arms, we used an effect size calculator developed by the statistician (JM) that adjusts for baseline differences. For the single-arm analysis, we used the University of Colorado Springs Effect Size Calculator [43].

Figures were drawn with GraphPad Prism (GraphPad Software).

Ethical Considerations

This study's protocol was approved by the Ethics Committee of the Helsinki and Uusimaa Hospital District (April 29, 2020, HUS/922/2020) and conducted per the ethical standards of the Declaration of Helsinki. Informed consent was obtained from all individuals included in this study. To ensure privacy and confidentiality, study data were pseudonymized and securely processed, preventing any association with individual participants. Participants received the intervention and individual health data but received no additional compensation. Neither the participants nor the data assessors were blinded to the treatment arms.

Results



Baseline Characteristics

Of the 143 people assessed for eligibility, 111 were randomized into research groups (Figure 1). Most participants were female (n=92, 83%) and worked as experts (n=46, 41%) or specialized experts (n=34, 31%; Table 1). More than half were either former or current smokers (n=59, 53%). Of the 111 participants, 73

XSL•FO
RenderX

(66%) had metabolic syndrome, 23 (21%) had mental health problems, 21 (19%) had osteoarthritis, 7 (16%) had type 2 diabetes, and 15 (14%) had sleep apnea. The mean age was 50 (SD 8.9) years, and the mean BMI was 34.2 (SD 2.9) kg/m^2. Baseline characteristics did not differ between the groups except for triglycerides (P=.006), which showed statistically significant elevation in the eHealth arm compared to the other two treatment arms.

Figure 1. The flow of participants through the 3 treatment arms (eHealth, eHealth+group, and eHealth+individual) of the randomized controlled trial, with 6 participants' 24-month data excluded from the analysis due to obesity medication use. All available data were included in the overall analysis.

Retention

The retention rate was 95% at the 6-month mark, 86% at the 12-month mark, and 61% at the 24-month mark of the intervention (Figure 1). The participants completed, on average, 58.6% (SD 32.7%) of the eHealth program. There were no differences in retention or progression between the treatment arms.

Intervention Effects

We did not observe any significant between-group differences in changes in the primary outcomes of weight and categorized weight (P=.76 and P=.99, respectively; Table 2, and Tables S4 and S5 in Multimedia Appendix 1). However, we did discover an interaction between the time points and treatment arms for HDL (P=.03) and triglycerides (P=.002).

[a]Degrees of freedom=6 for the between-group analysis and degrees of freedom=3 for the single-group analysis, including all participants.

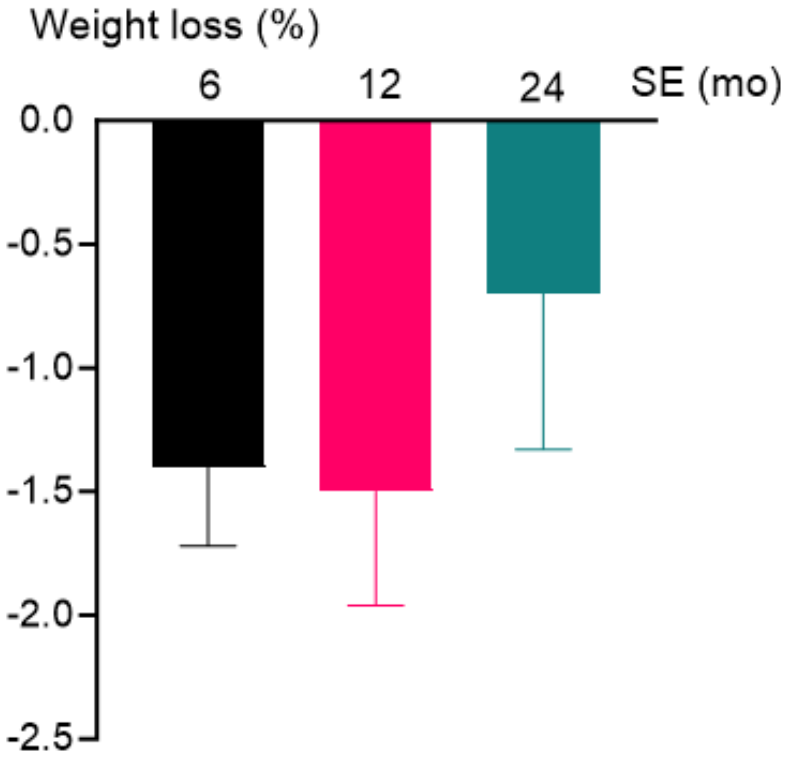
[b]BP: blood pressure.

Considering HDL, further analysis showed a greater increase in the eHealth arm compared to the eHealth+individual arm between 0 and 6 months (*P*=.09, *d*=0.35) and 0-12 months (*P*=.03, *d*=0.28). The interaction between the time points and treatment arms was explained by sex (*P*=.002), cholesterol medication use (*P*<.001), and changes in cholesterol medication (*P*<.001). When participants who were using cholesterol medication at baseline or had changes in their medication were

XSL•FO
RenderX

excluded, the interaction between the treatment arm and time point was insignificant (*P*=.17). This suggests that the difference in HDL between the treatment arms was likely due to variations in medication use.

For triglycerides, the eHealth arm demonstrated a greater decrease than the eHealth+individual arm at all time points relative to baseline (0-6 months *P*=.03, *d*=0.41; 0-12 months *P*<.001, *d*=0.53; 0-24 months *P*=.002, *d*=0.47; Table 2). However, the eHealth arm had higher triglyceride levels at baseline compared to the other groups (Table 1).



To study the overall effect of the intervention, the 3 groups were considered as a single eHealth group and combined for further analysis, as reported below.

Overall Impact

Weight

At the 6- and 12-month mark of the intervention, participants experienced an estimated mean weight loss of 1.3 kg (1.4%, *P*<.001) and 1.4 kg (1.5%, *P*=.002), respectively, compared to baseline (ITT analysis presented in Table 2 and Figure 2, and completer analysis in Table S6 in Multimedia Appendix 1). Overall, weight showed a significant decrease over the 24-month study period (*P*=.003) when analyzed across all time points (0, 6, 12, and 24 months).

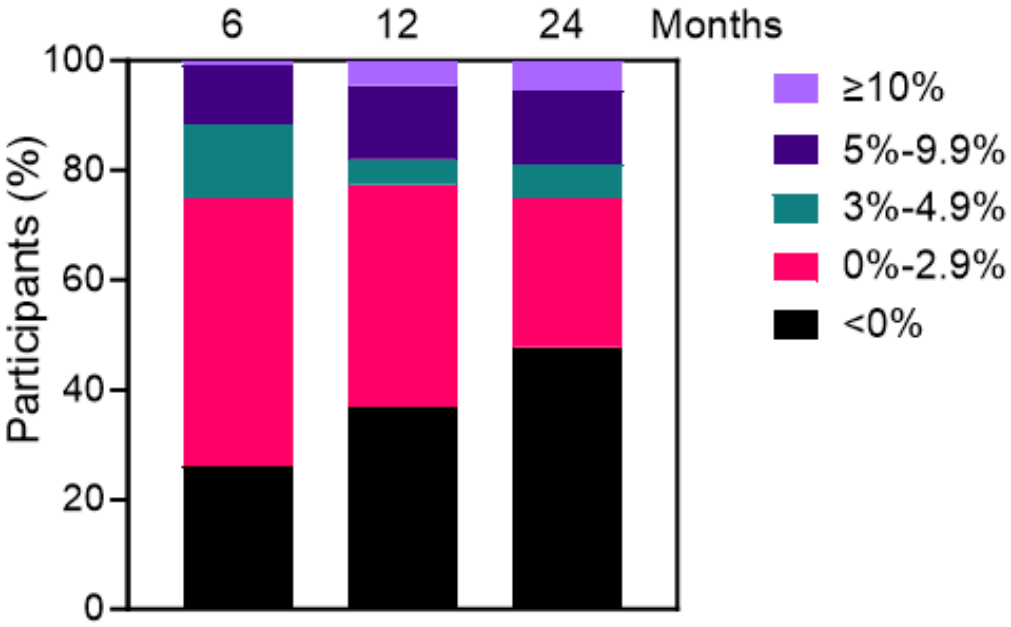


Figure 2. Weight loss (%) and SE midintervention (6 months), postintervention (12 months), and at follow-up (24 months) compared to baseline (0 months) displaying estimated values used by the generalized estimating equations.

Using the entire sample of 111 participants and applying the last observation carried forward principle, categorical analysis at the 6-month time point revealed that 15 (14%) participants had lost 3%-4.9% of their baseline body weight, 12 (11%) participants had lost 5%-9.9%, and 1 (1%) participant had lost ≥10% (Figure 3). At 12 months, 5 (5%) participants had lost 3%-4.9% of their baseline body weight, 15 (14%) participants lost 5.2%-9.9%, and 5 (5%) participants lost ≥10%. Similarly, at the 24-month follow-up, the respective proportions in each category were 7 (6%) participants, 15 (14%) participants, and 6 (5%) participants. Overall, 20 of 111 (18%) participants achieved a clinically relevant weight loss of ≥5% of their initial weight at the 12-month mark, increasing to 21 (19%) participants at the 24-month mark.

XSL•FO
RenderX

Figure 3. Categorized weight loss (%) midintervention (6 months), postintervention (12 months), and at follow-up (24 months; N=111) with last observation carried forward.

The weight changes were correlated between different measurement points. We observed strong correlations between the 0-6–month weight change and 0-12–month weight change (r=0.64, P<.001), and between the 0-12–month weight change and 0-24–month weight change (r=0.66, P<.001). The correlation was moderate between the 0-6–month weight change and 0-24–month weight change (r=0.324, P=.008).

Waist Circumference and Body Composition

The estimated mean decrease in waist circumference was 2.4 cm (SD 0.35 cm; P<.001) and 2.6 cm (SD 0.42 cm; P<.001) at the 6- and 12-month marks of the intervention, respectively (Table 2, Table S6 in Multimedia Appendix 1). At follow-up, the waist circumference continued to decrease, showing a 2.8 cm mean decrease from 0 to 24 months (SD 0.54 cm; P<.001).

The estimated mean decrease in visceral fat was 6.2 cm^2 (SD 3.54 cm^2; P<.001) and 5.8 cm^2 (SD 3.95 cm^2; P=.003) at the 6- and 12-month marks of the intervention, respectively (Table 2, Table S6 in Multimedia Appendix 1). Fat percentage decreased by 0.8% (SD 0.59%, P<.001) and 0.9% (SD 0.64%, P<.001) at the 6- and 12-month marks. Muscle percentage increased by 0.4% (0.11%, P<.001) and 0.5% (SD 0.14%, P<.001) at the 6- and 12-month marks.

The covariate analysis showed a significant interaction for baseline weight with changes in waist circumference, visceral fat, fat percentage, and muscle percentage (Table S7 in Multimedia Appendix 1). Post hoc analysis revealed that participants with lower baseline weight had a greater reduction in waist circumference, visceral fat, fat percentage, and a greater increase in muscle percentage. There was also a significant covariate interaction between age and waist circumference, with older participants having a greater reduction in waist circumference.

Laboratory Measurements and Blood Pressure

The estimated fasting glucose decrease was 0.3 mmol/L at 6 months (P<.001), 0.4 at 12 months (P<.001), and 0.2 (P<.001) at 24 months (Table 2 and Table S6 in Multimedia Appendix 1). There was a significant interaction between diabetes medicine usage and glucose level change, and changes in diabetes medication usage and glucose level change, with greater glucose level reductions observed for participants who had existing medication or who were prescribed new medication to manage blood glucose levels (Table S6 in Multimedia Appendix 1). However, the results of the main analysis remained after excluding these participants (n=9) from the analysis (0-12–month P<.001; 0-24–month P=.002).

There was a statistically significant overall change in HbA_{1c} (P=.01), with the estimated mean value increase of 0.62 mmol/L at 12 months and 0.07 at 24 months. However, these changes were not significant compared to the baseline. Changes in HbA_{1c} levels were significantly associated with changes in diabetes medication (P<.001), with participants who reduced their diabetes medication (n=12) during the intervention showing a greater reduction in HbA_{1c} levels than those who increased or started new medications or who made no changes. However, the main result remained unchanged after excluding the participants with increased or new diabetes medication (n=24).

The HDL increase was 0.1 mmol/L at the 6-month (P=.007), 12-month (P<.001), and 24-month (P<.001) marks of the intervention (Table 2 and Table S6 in Multimedia Appendix 1). The triglycerides decrease was 0.2 mmol at both 6-months (P=.002) and 24-months (P=.004). There was a statistically significant interaction between the changes in cholesterol medicine with HDL (P<.001) and triglycerides (P<.001), but the result of the main analysis remained after excluding these participants (n=2) from the analysis (P<.001 and P=.01, respectively; Table S7 in Multimedia Appendix 1).

XSL•FO
RenderX

The hs-CRP increased by 0.9 mg/L from baseline to 24-month follow-up (P=.004) when outliers with severe elevation of >30 mg/L were excluded (n=4; Table 2 and Table S6 in Multimedia Appendix 1). The result of the pairwise comparison remained significant (P=.01) when lowering the outlier threshold to 10 mg/L (marked elevation). Diastolic blood pressure decrease was 2.4 mm Hg at the 6-month (P<.001) and 2.3 mm Hg at the 12-month (P<.001) marks of the intervention. Covariate analysis flagged a significant interaction between changes in blood pressure medication and diastolic blood pressure (P<.001; Table S7 in Multimedia Appendix 1). Nevertheless, the results persisted (P=.002) even after excluding participants (n=6) who had medication increase or initiation.

Metabolic syndrome prevalence was 66% at baseline (Table 1) and 60% in both 12-month postintervention and 24-month follow-up, indicating a change of -9%. These changes were not statistically significant.

Discussion

Principal Findings

This study examined whether adding minimal individual or group-based face-to-face support to a 12-month coach-assisted eHealth intervention enhances outcomes by strengthening connections with coaches or leveraging peer support. Contrary to our hypothesis, no significant differences in primary outcomes were found between the groups, indicating that 3 live sessions—whether individual or group-based—did not provide additional benefits over the eHealth protocol alone. Interestingly, the eHealth-only group showed greater improvements in HDL cholesterol and triglycerides compared to the individual session group. However, post hoc analyses attributed these differences to cholesterol medication use and higher baseline triglyceride levels rather than the intervention itself. Thus, incorporating infrequent live sessions into the eHealth protocol does not appear to offer additional advantages.

In the entire study population, the intervention resulted in a mean weight loss of 1.5% from baseline to 12-month postintervention and 0.7% from baseline to 24-month follow-up. When considering individual weight change, the results are polarized: the received support promoted weight loss for some participants, while others did not respond. The weight changes were notably correlated between different measurement points, suggesting the individual weight change to be rather consistent.

Throughout the intervention and follow-up, there was a progressive decrease in mean waist circumference, along with improvements in the body composition variables at the 12-month mark.

Additionally, there was a slight enhancement in HDL cholesterol levels at postintervention and follow-up, suggesting positive effects on lipid metabolism. Although we observed a decrease in the fasting glucose levels during the intervention and follow-up, similar results were not observed in HbA_{1c}, a marker measuring the average blood glucose levels over the past few months. This indicates that the observed improvements in glucose levels might not be consistent or lasting enough to affect overall glycemic control.

Unexpectedly, the hs-CRP increased significantly by the 24-month follow-up, suggesting elevated inflammation not attributable to outliers but potentially reflecting mild infections or systemic inflammation [44]. We do not attribute the increase in the hs-CRP to heightened metabolic disturbances, as we noted a slight, though statistically insignificant, improvement in the prevalence of metabolic syndrome.

Comparison With Prior Work

There are several potential explanations for the lack of intergroup differences. It is possible that only 3 sessions in the hybrid conditions do not yield a sufficient difference compared to the coach-assisted eHealth intervention, and by increasing the number of sessions in the hybrid intervention, differences between the groups could be observed. In Teeriniemi et al [29], participants with a BMI over 30 kg/m^2 lost an average of 4.4% of their weight in 12 months when they received a hybrid intervention combining eHealth with 8 group meetings based on cognitive behavioral therapy, compared to just 1.6% weight loss in the eHealth-only arm. Therefore, a more intensively enhanced hybrid approach may be needed to further improve somatic outcomes.

Notably, the intervention took place during the COVID-19 era, leading to all group and individual meetings being conducted remotely. As seen in previous research on therapeutic relationships [45], this shift could have hindered the alliance between the participants and the coach. Particularly, the unplanned move to remote group meetings in the eHealth+group treatment arm may have affected the group's cohesion and perceived peer support [46], thereby impacting effectiveness and attenuating differences between the treatment arms.

Overall, it is likely that differences in weight change between the 3 study arms are attenuated by the lack of power resulting from smaller-than-expected changes in weight, with high variability. The total weight loss is modest compared to the 2019 meta-analysis by Lawlor [12], reporting a mean absolute weight change of 5.5 kg in third-wave cognitive behavior therapies. Furthermore, the weight loss outcomes observed in our study fall short in comparison to the results reported from previous implementations of the HWC eHealth program, which achieved a 4.6% weight loss during the 12-month intervention [47]. Additionally, a "review of reviews" by Kupila et al [23] reported mean differences in weight loss results ranging from –0.12 (95% CI –0.64 to 0.41) kg in eHealth interventions compared with face-to-face care to –4.32 (–5.08 to –3.57) kg in eHealth interventions compared with no care. However, our results align with the 12-month weight loss of –2.08 kg reported by Mueller et al [33] for another ACT-based hybrid intervention (eHealth+phone support) conducted during the COVID-19 pandemic.

Several factors could contribute to the lower weight loss observed in our study. First, our study used a more weight-neutral coaching style than the one in Kupila et al [47], which may have impacted its effectiveness in promoting weight loss compared to the earlier version. It needs to be noted that a newer version of the HWC is already in clinical use. Therefore,

XSL•FO
RenderX

the results of our study do not demonstrate the current effectiveness of the HWC.

Second, our study involved a different population characterized by lower BMI compared to the study of Kupila et al [47]. In their study, the greatest weight loss was observed among individuals with a baseline BMI ≥40 kg/m², a subgroup that was not included in our study. Yet, in Kupila et al [47], the mean weight loss for those with a baseline BMI <40 kg/m² was 3.2%—more than the weight change observed here.

Third, the influence of the COVID-19 pandemic coinciding with the 2021-2022 intervention cannot be overlooked, as research suggests that the pandemic led to disruptions in lifestyle behaviors that could affect weight management. The mean weight gain during the pandemic was higher [48] than average [49], indicating difficulty in weight maintenance. These effects are evident in the Finnish population: between 2017 and 2023, the prevalence of obesity increased 3%-points in men and 4%-points in women [50]. In contrast, the prevalence of obesity had remained unchanged between 2012 and 2017 [51]. In addition, an increase in food consumption and sedentary activity was observed during the pandemic [52]—changes that were potentially intensified in this study population, most of whom worked in expert positions and shifted to remote work during the pandemic.

Lastly, our study involved a different population characterized by significant occupational burden from mentally consuming expert work. This occupational burden may have posed challenges to weight management despite participation in the intervention, especially with the combination of the eHealth program and remote knowledge work. This is per the earlier results showing that early weight loss predicts 1-year weight loss in web-based programs [53] and shows that the early weight loss could even predict long-term weight maintenance.

In the secondary analysis with the overall sample, long-term improvements in waist circumference and lipid metabolism are consistent with findings from previous nondiet studies [54-57]. Additionally, the increase in muscle mass contrasts with previous findings of skeletal muscle mass loss in weight loss studies [58]. These changes are likely attributed to our intervention's focus on guiding participants toward making healthy dietary choices and increasing physical activity without imposing calorie restrictions. However, our findings of no improvement in long-term glucose metabolism contrast with previous studies showing that lifestyle weight loss interventions reduce the risk of elevated fasting glucose levels and HbA_{1c} [59-61], suggesting that a more prominent weight loss may be necessary to achieve sustained improvements in glycemic control.

Strengths and Limitations

This study presents both strengths and limitations. A key strength is the long follow-up period, which allowed for the investigation of the treatment's long-term effects—rare in typical ACT-based interventions. Additionally, the comprehensive array of outcome measures, including body composition and laboratory tests alongside traditional metrics such as weight and waist circumference, offers a holistic understanding of the intervention's effects. This study also ensured accuracy and reliability by conducting all measurements and laboratory tests on-site despite the onset of COVID-19. Additionally, the emergence of new weight loss medications was addressed by screening and excluding participants using weight loss medications, requesting that participants refrain from starting new weight loss medications during the intervention, regularly collecting information on any changes in medication, and excluding from the analysis those who began using them during the follow-up period.

However, some limitations impact especially the interpretation of the overall study effects. First, the participant group was homogeneous—all employed and primarily middle-aged women in expert professions—making generalization to other populations challenging. Second, the lack of blinding and participants' awareness of their treatment arms before randomization could have affected motivation, particularly for those not assigned to their preferred group. Third—affecting interpretation of the overall results—the absence of an inactive control group prevents comparison against a baseline, making it difficult to isolate the treatment effects from external influences or placebo effects and thus establish causality. These limitations, arising from the integration of this study within routine occupational health care services and the need for ethical service provision to willing participants, highlight important considerations for future research aiming to balance real-world applicability with rigorous study design.

Conclusions

Our study found no differences in weight or other somatic health variables between the eHealth arm and intervention combining eHealth with minimal group or individual enhancement. Moving forward, further research is needed to determine if there is a threshold where face-to-face meetings provide additional benefits in hybrid interventions. Moreover, there is a need to explore for whom and under what conditions eHealth and hybrid models may be most effective.

Acknowledgments

We wish to thank all the personnel involved in conducting the trial: coaches Susanne Räsänen, MHS, and Anita Saranpää, PhD; physiotherapists in charge of this study's measurements Minna Mäkelä, BHC, and Mariann Slotte-Jana, BHC; laboratory staff of Occupational Health Helsinki, Jussi Mustonen, MD, and other medical doctors participating in this study; the supportive management of Occupational Health Helsinki Ritva Teerimäki, MD, Eevamaija Tuovinen, MD, and Marko Karvinen, MSc; and Merja Sokka, BHC, and Jaana Ahoranta, BHC, from the Healthy Weight Hub for always being willing to help. Abstract

Background: Cannabis is the most widely used illicit drug, and admissions for cannabis use disorders (CUDs) are increasing globally, posing a significant public health challenge. Despite its negative consequences, a substantial proportion of individuals with problematic use do not seek treatment. In recent years, digital health interventions (DHIs) have emerged as accessible and cost-effective solutions, empowering users to manage their health care. CANreduce is one such eHealth intervention that has demonstrated effectiveness in reducing cannabis use (CU); however, its suboptimal adherence rates underscore the need for strategies to enhance user engagement and motivation.

Objective: This study aims to improve the effectiveness, adherence, and user experience of the Spanish version of CANreduce 2.0 by employing focus groups (FGs) within a user-centered design approach that actively involves both users and professionals.

Methods: Separate FGs were conducted for users and professionals, involving a total of 10 participants. Users were recruited from individuals registered on the CANreduce 2.0 platform and active cannabis users, while professionals comprised addiction specialists familiar with the platform. Each session was held remotely and moderated by 2 interviewers following a semistructured script. Qualitative analysis of the transcripts was performed using MAXQDA software and content analysis methodology to identify key themes related to the acceptability, usability, and utility of CANreduce 2.0.

Results: The qualitative analysis identified 3 main themes, encompassing 15 subcodes. Within the “motivation and awareness” theme, both users (n=6, mean age 31.8 years, SD 4.1 years) and professionals (n=4, mean age 37.25 years, SD 1.71 years) frequently discussed the importance of “motivation” and “problem awareness” as crucial for the success of CANreduce 2.0. In the “guidance and use” theme, the subcode “complement to face-to-face therapy” was the most emphasized. Professionals supported CANreduce 2.0 as a valuable adjunct to in-person therapy, serving as both an educational and monitoring tool, with

XSL•FO
RenderX

no objections raised by either group. Lastly, within the "content and design" theme, "information," "small achievements," and "personalized content" emerged as key areas for improvement, highlighting the need to enhance motivation and adherence through gamification and tailored content.

Conclusions: Personalization, robust motivational strategies, and an engaging, interactive design are essential for the success of DHIs, particularly in addiction treatment. Collaboration among technology developers, health care professionals, and users should be central to the development process, fostering the cocreation of practical and effective solutions that are responsive to the needs of those seeking treatment. This approach ensures that DHIs are not only functional but also widely accepted and impactful. Insights from this study will inform the ongoing refinement of CANreduce 2.0, enhancing its relevance and effectiveness in addressing CU.

Introduction

Cannabis is the most widely used drug worldwide, posing a significant problem due to its negative effects on users' well-being and its broader impact on public health. According to the latest report from the United Nations Office on Drugs and Crime [1], approximately 228 million people consumed cannabis in 2022, with many countries reporting a sustained increase in the prevalence of cannabis use (CU), hospitalizations, and diagnosed psychiatric disorders related to CU.

In Spain, cannabis is the illicit substance with the highest prevalence, particularly among younger individuals. The latest data estimate that 19.1% of individuals under 35 years of age [2] and 21.8% of students aged 14-18 years used cannabis in the past year, with the average age of initiation being 15 years [3]. The National Strategy on Addictions [4] places special emphasis on the normalization of CU among youth and the challenges this poses, given that early onset correlates not only with an increased risk of developing cannabis use disorder (CUD) but also with other mental health conditions. Furthermore, early use is associated with academic and occupational difficulties [1]; involvement in conflicts, fights, or physical aggression [3,5]; and engagement in risky sexual behaviors [3,6].

As a result, the total number of admissions for CU treatment is increasing [2,7], with 93.7% of individuals under 18 years initiating treatment for illicit drug use in Spain doing so for CU [2]. Spain has a well-established, extensive, diversified, and accessible network for addressing drug-related issues. Among the available treatments, motivational interviewing and cognitive behavioral therapies (CBTs) have proven effective in managing substance use disorders (SUDs) as therapeutic and psychoeducational strategies [8-10], both in-person and digitally [11,12].

However, despite the availability and variety of treatments, a significant proportion of problematic cannabis users do not seek help, often due to social stigma, shame, lack of time, or the belief that they can regulate their consumption on their own [13,14]. This issue is particularly pronounced among younger individuals, who not only seek treatment less frequently but also exhibit lower adherence rates [15].

Technological progress in the 21st century is driving the digitalization of everyday life, with screens becoming the primary medium for communication and self-expression among young people [16]. In response to this shift, the development of mobile apps and internet-based interventions for health promotion and treatment has grown steadily over the past 2 decades, offering patients accessible and cost-effective solutions that empower them to take control of their health care journey [17]. In the context of mental health and SUDs, these tools can function as (1) adjuncts to clinical care and (2) strategies for health promotion, enhancing accessibility to treatment.

Multiple meta-analyses have examined the use of digital health interventions (DHIs) for addressing SUDs [18], particularly CUDs [15,19-22]. Evidence from these studies demonstrates a favorable yet modest effect of digital health strategies, with greater efficacy in prevention programs compared with intervention programs. However, both approaches show a lower impact than face-to-face interventions [19], highlighting the need to develop strategies that integrate both modalities [10,21,22].

CANreduce is one of the eHealth tools proven effective in reducing CU. It is a minimally guided, internet-based self-help intervention developed by Schaub et al [23] and has been certified as safe by the European Union, qualifying as a medical device under directives 93/42/EWG and 2007/47/EWG. This interactive online platform consists of 8 modules designed to be completed over 6 weeks, integrating CBT strategies, motivational interviewing, and immediate ecological interventions.

In 2015, the first version of the app proved to be an effective alternative to face-to-face treatment, demonstrating reductions in the frequency and quantity of CU, increased completion of self-help modules, and higher abstention rates, although adherence remained suboptimal [23]. Despite the flexibility DHIs offer, allowing them to be tailored to individual user needs, poor adherence remains a common challenge with this type of tool [17,24]. Adherence is a complex, dynamic process influenced by individual factors such as motivation and self-efficacy, interpersonal elements such as therapeutic alliances and shared decision-making, and therapy-related aspects, including preplanned interventions and medication regimens

XSL•FO
RenderX

[25]. Some of these factors—particularly interpersonal elements—are typically absent from digital interventions such as CANreduce, as they generally do not provide clinician support. Effective strategies to address this issue and improve adherence to digital treatments [26], particularly for CU [20], include incorporating support from a mental health professional or coach [27] and using participation reminders [28].

Following the principles of Adherence-Focused Guidance [29], CANreduce 2.0 was developed and tested in a subsequent clinical trial. This new edition incorporated support from either an "e-Coach" or a team without a specific reference individual, with both interventions proving equally effective in reducing CU frequency and mental health symptoms [30]. In 2022, the app was adapted to Spanish and validated for use within the Spanish population. Data from the corresponding clinical trial are currently being analyzed, and its protocol has been previously published [31]. The adaptation included adding videos featuring Laura, the Spanish e-Coach, along with 6 characters of different ages, genders, and backgrounds, illustrating various situations of cannabis abuse and dependence throughout the modules.

The World Health Organization has emphasized the importance of using a user-centered design in the development of digital tools, noting that most people do not re-engage with an app if it does not initially attract them [32]. Previous research has shown that patients will only use new technologies if they are relevant to their health concerns, visually appealing, easy to use, and effective in facilitating behavior change [17]. Increasing patient involvement in the design of DHIs is essential for creating relevant, usable, and effective solutions and has been linked to greater acceptability and motivation for use [33,34], thereby improving user experience and perceived value [35]. Motivation is a critical component of behavior change, helping predict patient abstinence and reductions in substance use. In the context of SUD and AUD treatment, it is a multidimensional, fluid state that enables individuals to resolve their ambivalence about making difficult changes to avoid substance abuse [25,36]. It has consistently been associated with increased treatment adherence and completion, making it a key construct in the Adherence-Focused model [25]. While motivation is intrinsic to patients, interventions can help them identify their reasons and need for change, as well as facilitate the planning required to achieve it [36].

User-centered design is a multiphase process that involves conducting focus groups (FGs) or interviews with users, modifying designs and content based on qualitative findings, and continuously iterating these steps with additional user and professional input [17,35,37]. Qualitative methods enable an in-depth evaluation by uncovering attitudes, perceptions, and beliefs that influence interaction with the tool, while also assessing user needs and preferences related to interface and usability [38,39].

A co-design approach that actively involves users has a significant impact on health outcomes and provides numerous benefits, including improved adherence [25], fidelity, and reach of digital tools [40]. Additionally, it fosters a broader range of ideas, enhances usability [41,42], and increases user satisfaction, support, and enthusiasm for innovation. It also improves decision-making efficiency and strengthens the patient-clinician relationship [17,35].

This study aims to enhance the effectiveness, adherence, and user experience of the Spanish version of CANreduce 2.0 through a user-centered design approach. As the initial phase of a larger research project, its findings on user perspectives will inform subsequent stages to improve the development of a DHI for CU treatment.

Methods

Recruitment

Discussion groups were conducted separately for users and professionals. For the users' FG, participants were recruited from those who had registered on the CANreduce 2.0 platform within the past 2 years. Following established guidelines [43], the initial FG aimed to include 6-12 participants. Twelve individuals were contacted by phone and invited to participate; however, only 3 attended, necessitating a second FG session. The second group also included 3 participants—active cannabis users attending treatment for the first time—who were instructed to use the CANreduce 2.0 platform before participating in the discussions. These participants were recruited through snowball sampling and contacted by phone to schedule the second online FG. The professional FG comprised 4 mental health and addiction specialists with experience in using digital tools. All professionals were members of the Primary Care Network for Addictions (RIAPAd) and were involved in promoting the CANreduce 2.0 improvement study for future implementation in addiction treatment centers. These participants were invited via email.

In total, 3 FG sessions were conducted: 2 for users (n=6) and 1 for professionals (n=4). Eligibility criteria for both groups included regular use of mobile devices and no diagnosis of a severe mental illness. Users were required to actively use the CANreduce 2.0 platform and report current CU, while professionals needed prior familiarity with the platform. Each FG session was facilitated by 2 interviewers (DFS and JIMP) and conducted remotely via Zoom (Zoom Communications, Inc./Qumu Corporation) to accommodate participants' schedules and geographical constraints. Audio recordings of the sessions were made to facilitate transcription.

Focus Group Interviews

The categories evaluated during the participatory groups were determined through a deductive analysis of usability guidelines focused on user-centered design and a review of scientific literature on digital health apps. Special consideration was given to strategies for motivating change [44,45].

The FGs aimed to elicit expert and participant feedback on both the content and form of the app (interface and materials), as well as the utility of the intervention (assessment of usage and experience). Specific objectives were established: defining the platform's target population, clarifying its specific purposes, updating and enriching available content, optimizing interface design, and promoting user motivation and adherence. Based on these objectives, a series of questions were formulated, with

XSL•FO
RenderX

slight adaptations in each session depending on whether participants were professionals or users. Each FG session lasted approximately 90 minutes.

Semistructured interview scripts were used, allowing for the inclusion of emerging questions relevant to the stated objectives. The questions were designed to align with the study's purpose and objectives, with some formulated to broadly explore each category (eg, "Do you think there are any missing topics or areas?") and others aimed at eliciting specific feedback on particular aspects of the intervention (eg, "Do you think using a mobile app format could improve user adherence to treatment?"). Depending on the depth of information provided in each category, either broad or focused questions were applied. To enhance user motivation within the CANreduce platform, options such as increased reminder frequency and positive reinforcement (eg, congratulatory messages) were explored. These examples served as probes, used only when participants did not provide spontaneous responses, to avoid directing their feedback. Interview guides for the professional and user groups can be found in Multimedia Appendices 1 and 2, respectively, with both having been translated from Spanish to English for publication purposes.

Statistical Analysis

The qualitative analysis of FG transcriptions was conducted using MAXQDA (VERBI GmbH), a software that enabled the systematic coding and analysis of textual data from user transcripts. The software's coding functionality was used to assign text segments to various codes, representing different themes relevant to the research.

This analysis followed the framework of content analysis, a methodological approach that involves identifying and defining categories or codes to capture key topics of interest. This approach enabled researchers to efficiently manage qualitative data, ensuring that the findings were grounded in participants' experiences and perspectives.

Ethics Approval

The study was approved by the Ethics Committee of CEIm-Parc de Salut Mar/IMIM-Hospital del Mar (approval code 2019/8901/I). Before the FGs, informed consent was obtained from all participants. At the start of each session, participants were briefed on key ethical considerations, including confidentiality and voluntary participation, to ensure an ethical and transparent process. Audio recordings were made to facilitate transcription, with no names recorded to maintain confidentiality. Data were fully anonymized throughout the analysis. As compensation, each participant received a €15 (US $15.63) Amazon voucher. No identifying information about participants is included in the manuscript or multimedia appendices.

Results

Demographics

The professional FG included 2 men and 2 women, all with higher education and an average age of 37.25 (SD 1.71) years. Half were psychologists (n=2) and the other half were doctors (n=2). They worked in a detoxification hospitalization unit (n=1), an outpatient addiction center (n=2), and an acute psychiatric hospitalization unit (n=1).

Among users (n=6), the 3 participants who had received online treatment through the platform were Spanish women—2 with technical training and 1 with higher education. The new users (n=3) were all Spanish men with higher education. The mean age of users (n=6) was 31.8 (SD 4.1) years.

Finally, both users and professionals had owned smartphones for more than 10 years, except for 1 professional who had owned a smartphone for 7 years. All participants also possessed at least one other electronic device, such as a laptop or tablet.

Themes

Overview

The codes identified in the qualitative analysis of the transcripts were categorized into 3 main themes: "motivation and awareness," "guidance and use," and "content and design," each containing specific subcodes. For "motivation and awareness," the subcodes included "user age," "motivation," "problem awareness," and "economic awareness." Within "guidance and use," the subcodes comprised "virtual treatment" (further divided into "in favor" and "against"), virtual support from Laura (subdivided into "in favor," "against," and the importance of the "therapist's gender" on the platform), and "complement to in-person therapy" (with "in favor" and "against" subcategories). For the "content and design" theme, the identified subcodes were "app" "notifications," "information," "small achievements and gamification," and the availability of "personalized content."

A comprehensive scheme of all codes can be found in Multimedia Appendix 3. The transcription of participant responses, organized according to the aforementioned codes, is available in Multimedia Appendix 4. Codes, themes, and transcriptions were translated from Spanish into English solely for publication purposes.

To analyze the distribution of codes across FG transcripts, a figure from MAXQDA's Code Matrix Browser was created (Figure 1). Larger symbols in the matrix indicate a higher number of coded segments assigned to a specific code for each group, highlighting key differences and similarities in how users and professionals prioritize different topics.

XSL•FO
RenderX

Figure 1. Code distribution across groups.

In the "motivation and awareness" theme, the subcode "user age" was addressed by all groups, with users from the first FG (registered on CANreduce 2.0 within the past 2 years) discussing it slightly more. "Motivation" was mentioned most prominently by professionals, followed by active cannabis users in the second FG (first-time treatment participants) and the first users' group. Users in the second group prioritized "problem awareness," discussing it more frequently than users in the first group and professionals, while also being the only group to address "economic awareness."

In the "guidance and use" theme, all groups discussed the subcode "virtual treatment," with varying degrees of emphasis. Professionals most frequently highlighted the potential benefits of CANreduce 2.0 as an online treatment for reducing CU but also expressed the greatest concerns about its drawbacks. Active cannabis users in the second FG mentioned some concerns, while users in the first group did not raise objections. The subcode "virtual support from Laura" was addressed equally across all groups, with balanced perspectives on its potential advantages and disadvantages. By contrast, "complement to face-to-face therapy" was primarily explored by professionals, who discussed it extensively and favorably.

In "content and design," users in the first FG referenced subcodes such as "app" and "notifications" the most, emphasizing the importance of usability and engagement tools. However, "information" was the most discussed subcode within this theme across all groups, reflecting its high priority for both users and professionals. Professionals led the discussion on "small achievements and gamification" and devoted the most attention to "personalized information," more so than either user group.

Motivation and Awareness

User Age

Users had mixed opinions on the platform's target population age. Some felt it was better suited for young people due to its online format and emphasis on less invasive treatment methods, which might appeal to those who have not yet recognized the severity of their consumption habits. Others believed it was more appropriate for adults over 30 years, who are more likely to be aware of their behavior and the consequences of CU.

Professionals noted that the content was designed to reflect young people's experiences but pointed out some comments they found "slightly uncomfortable" or "potentially sexist."

Motivation

Users emphasized the importance of self-motivation for the platform's success, noting that without a genuine commitment to reducing or ceasing CU, the provided tools might be ineffective. Some users attributed this to the platform's inherent characteristics, which they perceived as resembling an "online course" or a "control tool."

Professionals emphasized the need for the platform to better align with users' individual goals, noting that it may be less effective in influencing the stage of change, particularly in cases of ambivalence. To address this, they suggested implementing an initial survey or questionnaire to assess the user's profile, allowing for more tailored interventions.

XSL•FO
RenderX

Problem Awareness

Users acknowledged the platform's effectiveness in increasing awareness of cannabis consumption, helping them identify key moments in the change process, track the frequency and quantity of their use, and recognize its impact on daily life. They perceived the activities as tools that enabled them to "name their feelings" and, by "seeing themselves represented," become "more aware of their problem." By articulating their habits, users felt empowered to "reconsider" them and recognize them as problematic. Character testimonies and usage tracking features were seen as facilitators, with the module on managing craving symptoms highlighted as particularly helpful.

Economic Awareness

Users noted the significant motivational role of visualizing the economic impact of their cannabis consumption. They observed that the platform lacks this functionality and suggested incorporating tools to calculate cannabis-related expenditures.

Guidance and Use

Virtual Treatment

Users and professionals identified several benefits of virtual treatment (*in favor*), including greater intimacy and accessibility, particularly for new users or those with moderate cannabis consumption. They noted that the platform enables anonymity, offering a more "private" approach to addressing cannabis abuse. Some professionals viewed virtual treatment as a better first approach, while others emphasized that the platform's modules appeared designed to address both ends of the consumption spectrum—targeting individuals with SUDs as well as those engaging in recreational use—and could serve as a support tool during the maintenance stage.

Some users and professionals raised concerns (*against*) that virtual treatment lacks the warmth and personalization inherent to in-person interactions, which may be essential for users with severe CU. Professionals argued that DHIs "cannot encompass the full scope of work conducted in face-to-face therapy" and warned that users might "become frustrated if they fail to reduce their use," potentially deterring them from seeking in-person help. Specifically, they noted that the platform may not be effective for patients with higher dependency consumption patterns or dual pathology.

Virtual Support From Laura

Some users mentioned that women are often associated with caregiving roles and suggested that having a female therapist (*therapist gender*) as a guide in the app could be more effective "from a marketing point of view."

Many users valued the presence (*in favor*) of a humanized name and persona on the platform, as it enhanced engagement and provided a sense of individualized support. They emphasized the importance of "being able to talk to a person or feeling that someone is answering" and expressed a desire for additional features, such as a forum or chat for real-time dialogue, direct contact with someone, or having "Laura personally check in on their progress" during treatment.

Conversely, some users felt that they "do not need anyone to check on their progress." Additionally, some participants found the online format, including Laura's support, to be overly impersonal, describing text messages (SMS and email) and online assistance as inherently "cold" (*against*).

Complement to In-Person Therapy

Users considered the platform a "starting point for seeking help" and a valuable complement to in-person therapy. They noted that access to cannabis-related information and intake logs could optimize in-person sessions by allowing more time to address "individual and personalized" concerns. To enhance continuity and efficacy in treatment, they emphasized the importance of professionals having access to the information recorded on the platform.

Professionals viewed the platform as a complement rather than a substitute for in-person therapy, recommending its use as an educational and monitoring tool. They highlighted its potential utility for users on therapy waiting lists and its applicability in primary care and various disciplines, such as social work and nursing. The data provided by the platform were seen as beneficial, either by equipping patients with more information to enhance awareness or by serving as a support tool through patient-registered data. However, they noted that the platform currently lacks information on local resources for additional support, which could enhance its effectiveness as a complementary tool.

Content and Design

App

Users emphasized the difficulty in visualizing the app on mobile devices. They expressed a preference for an app with personalized notifications and tracking features to improve interaction and usability. They mentioned the possibility of receiving "feedback" as a desirable feature.

Professionals suggested that adapting the platform into a mobile app could significantly improve adherence and facilitate regular access.

Notifications

Users had varying opinions on the utility of notifications. Some felt that notifications, being common in apps, could serve as reminders to encourage use and improve adherence. Others, however, preferred them to be optional, with one user describing them as feeling "like homework for children." There was no consensus on the preferred frequency of notifications.

Professionals suggested allowing users to customize the frequency and type of notifications to enhance their usefulness and prevent boredom or annoyance. They also noted that notifications could serve as a means to provide valuable information on accessing alternative forms of treatment, further integrating the virtual platform with in-person care.

Information

Users appreciated the information provided but noted that it was occasionally too "dense," leading to boredom. They suggested incorporating more interactive and visual formats, such as videos instead of text, and simplifying language by

XSL•FO
RenderX

reducing technical jargon. While some users found characters illustrating CU experiences helpful, others felt they did not accurately reflect their own situations. Recommendations included adding more information on the negative consequences of CU, stress and anxiety management, improving the visualization of consumption graphs, introducing a search function for quick access to specific information, and incorporating a "panic button" to remind users of their personal goals during moments of craving.

Professionals found the information to be well-written and accessible but agreed with users that it could benefit from being more dynamic and visual. They also emphasized the importance of facilitating navigation to ensure easy access to relevant content, suggesting features such as a search box for specific terms and topics.

Small Achievements and Gamification

Users indicated that incorporating gamification elements could enhance the platform's appeal and motivational impact. They found the forms somewhat boring, with one user noting, "it feels like the platform is an educational course." They also suggested the inclusion of encouraging messages that acknowledge their progress or improvements in their health status.

Professionals suggested implementing progressive goals and rewards to foster user engagement and satisfaction. However, there was no consensus on whether modules should be unlocked sequentially as users progress.

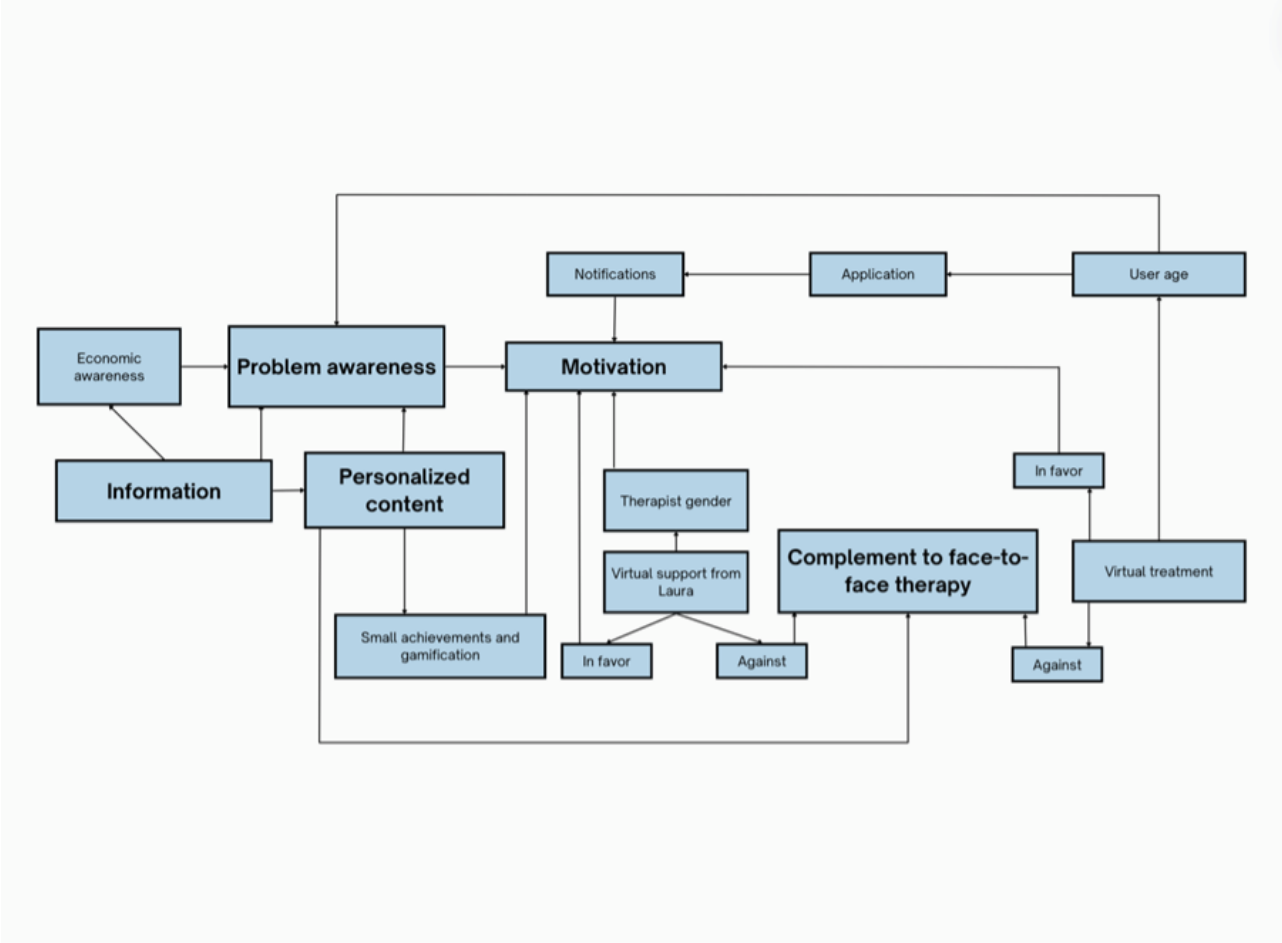
Personalized Content

Users expressed a strong preference for more personalized content tailored to their individual situations and needs, believing this would enhance the platform's relevance and effectiveness. They highlighted the usefulness of sections for recording personal "excuses" and setting individualized goals.

Professionals stressed the importance of customizing content to align with users' stages in the change process and personal goals. They also suggested simplifying content based on users' cognitive or attentional capacities to enhance accessibility and comprehension.

Overview of Research Findings to Define Next Steps

To incorporate users' suggestions into the app, specific recommendations were collected based on each code and its subcodes (Textbox 1). Moving forward, these insights will be integrated into the development process to ensure the resulting DHI remains user-centered.



Textbox 1. Recommendations for enhancing CANreduce 2.0 based on focus group feedback from professionals and users for each subcode.

1. Motivation and awareness
   - User age: personalize according to life stages.
   - Problem awareness: adjust to the level of self-consciousness, including specific information for the precontemplation stage. It could be set with an initial user profile survey.
   - Motivation: include reward systems and more information about the negative consequences of cannabis use.
   - Economic awareness: add functionalities to visualize the economic and social costs of consumption. It could be used as part of the gamification function.
2. Guidance and use
   - Virtual treatment: include a forum or chat to facilitate real-time dialogue.
   - Virtual support from Laura: personalize interaction.
   - Complement to face-to-face therapy: implement its use with patients on waiting lists for therapy and in primary care, particularly with disciplines such as social work and nursing. Allow and promote professionals access to the information registered by their patients.
3. Content and design
   - App: improve usability in smartphones, introduce interactive content (improve form design, introduce a search box).
   - Notifications: implement notifications as reminders and motivational messages, allowing users to choose to receive them or not, the type of notifications, and the frequency.
   - Information: replace part of the text-based content with videos or other visual formats. Include a panic button to be used during cravings, to give quick access to personal reminders of self-goals, pros/cons, or benefits expected.
   - Small achievements and gamification: add motivational messages, incorporate progressive goals, and show the health benefits of the goals achieved.
   - Personalized content: tailor the content to meet users' needs, goals, and capabilities.

To further guide the enhancement of usability and adherence, a relational schema of key themes was developed to illustrate the interconnections and dynamics among the identified codes (Figure 2). This schema visualizes how codes interact and influence each other, highlights emerging patterns, and supports the interpretation of qualitative data. Additionally, it serves as a foundation for generating new hypotheses for future research.

XSL•FO
RenderX

Figure 2. Key themes for increasing usability and adherence in CANreduce 2.0.

The relational schema of codes was developed through a rigorous qualitative analysis of the FG transcripts. The process began with a detailed transcription of all sessions, followed by the coding of meaning units. The resulting codes were then grouped into broad themes representing related concepts. Subsequently, relationships among these codes were analyzed using concept mapping techniques. The final schema was validated by subject matter experts.

Figure 2 visually represents the interrelations among the key themes identified in the analysis—motivation and awareness, guidance and use, and content and design—highlighting core elements that enhance user experience and adherence. Notably, utilizing the "information" provided within the platform and integrating "personalized content" can strengthen "problem awareness," which, in turn, increases user "motivation." Additionally, personalized content is perceived as valuable for using the platform as a "complement to face-to-face therapy," aiming to promote sustained engagement and adherence to the CANreduce 2.0 program and overall treatment for CUD.

Discussion

Principal Findings

This study evaluates the perceptions of users and professionals regarding the utility and potential effectiveness of CANreduce 2.0 in reducing CU, as well as their suggestions for improving its usability and, consequently, adherence to online treatment.

Regarding the main themes evaluated in the FGs, several conclusions can be drawn from the results. First, both users and professionals agreed that CANreduce 2.0 could serve as a valuable complement to in-person therapy. Second, most participants emphasized that the information provided in the modules significantly increased problem awareness and, consequently, sustained motivation to quit or reduce CU. Finally, to enhance adherence to virtual treatment, both users and professionals suggested incorporating notifications, gamification elements, and personalized features to adapt the app to individual users.

Motivation and Awareness

The findings reveal significant discrepancies in perceptions regarding the optimal age for using the platform. Some users viewed the digital format as more suitable for younger individuals, whereas others believed middle-aged adults, who may have greater insight into their consumption habits, could benefit more. While DHIs are generally assumed to be preferred by younger populations, research remains inconclusive [46]. Studies on web-based interventions have shown that recruited participants tend to be older than those typically treated in specialized addiction centers [47], and dropout rates are higher among younger individuals [48]. Given these uncertainties, it is recommended that the intervention be adapted to allow for personalized modules and support features tailored to specific life stages, maturity levels, and self-awareness, ensuring that each age group finds the tool relevant and effective.

XSL•FO
RenderX

Regarding motivation and problem awareness, it is noteworthy that during recruitment for the CANreduce 2.0 study, the Google search advertisement appeared more than 250 times per day, with an average of 19.6 individuals clicking on the app link. Given the rising demand for CU treatment [2,7] and the persistent lack of access for many individuals [15], a freely available tool discoverable through a simple internet search could serve as a highly valuable resource for those seeking help with their consumption but unable or unwilling to engage in traditional interventions. Digital tools offer several advantages, including anonymity, continuous availability, elimination of physical travel, and rapid accessibility [15,27], which were highlighted in the FGs as key benefits of digital health treatments, particularly CANreduce 2.0.

As for motivation, both users and professionals identified it as a crucial factor in achieving changes in consumption patterns. When asked about the potential effectiveness of the intervention in reducing CU, participants closely linked the tool's utility to the user's intrinsic motivation and problem awareness at the time of engagement. Interviewed professionals suggested that CANreduce 2.0 is suitable for individuals in both active consumption and maintenance phases of abstinence, though it may be less effective for those who remain ambivalent. Consequently, they proposed incorporating information specifically tailored for individuals in the precontemplation stage. According to the Stages of Change Model, individuals in this initial stage are not yet considering modifying their consumption habits in the foreseeable future, as they lack full awareness of the associated problems [36]. The first step in addressing an SUD is for the individual to recognize their own problematic behavior and consider making a change. Users acknowledged that the tool effectively assesses their CU, raises awareness of its health consequences, and records instances of excessive consumption, which could positively impact self-efficacy [49]. However, the results also highlighted the need for additional strategies to sustain meaningful and continuous motivation. Proposed features for integration included a reward or incentive system to reinforce progress, expanded information on the negative consequences of CU and withdrawal syndrome, and interactive tools, such as simulations or expense calculators, to help users visualize the economic and social costs of their consumption.

Guidance and Use

There is substantial evidence demonstrating the impact of mental health apps on the general population, including individuals without symptoms. These apps have shown potential as cost-effective, accessible, and low-intensity intervention tools for those unable or unwilling to receive standard treatment [26]. However, adherence to treatment remains a significant challenge in digital mental health and addiction interventions [50]. Evidence suggests that one strategy to improve adherence is the provision of user-centered guidance.

The randomized clinical trial of CANreduce 2.0 conducted in the Swiss population demonstrated the app's efficacy in reducing the frequency of use, severity of dependence, and anxiety symptoms. However, it did not find significant differences between support provided by a personalized figure and that offered by a nonindividualized support team [30].

To thoroughly examine these findings, study participants were asked about their experiences and perceptions regarding the virtual support provided by Laura, the therapist integrated into the treatment process through introductory videos for each module and direct messaging. Opinions were diverse. Supporters of virtual assistance emphasized the importance of "humanizing" the experience, suggesting that a forum or a space for more personalized guidance could be beneficial. They noted that personalized interaction, even in a virtual format, fostered a sense of connection and support. Conversely, some participants expressed disinterest in virtual interaction, preferring to forgo this type of communication. Professionals echoed this concern, criticizing virtual support as impersonal and advocating for in-person accompaniment, which they believed offered a more effective and empathetic form of support.

Despite these perceptions, "Dr. Google" and "ChatGPT" remain among the most frequently used tools for medical and treatment inquiries, with people becoming increasingly familiar with their use [51-53]. Mental health apps are often accessed through internet searches and social media [54], which presents certain risks due to the generally poor quality of online information [55] and the subjective, often biased nature of its evaluation [56,57].

Among the interviewed user groups, there was strong support for using the platform as a virtual treatment. They highlighted its potential as an ecological intervention and recognized its advantages in providing an accessible and flexible treatment option. However, professionals expressed reservations about its effectiveness as a standalone tool, particularly for individuals with severe dependence or dual disorders. Although evidence suggests that individuals with more severe symptoms are more likely to complete such treatments [58], professionals questioned whether the app was adequate for these cases. Nonetheless, both users and professionals acknowledged the platform's value as an adjunct to in-person therapy. With its educational and monitoring features, the information provided could serve as an effective support tool for professionals. This perspective aligns with existing evidence showing that DHIs can enhance treatment effectiveness and support abstinence [59,60]. Integrating the platform with traditional therapy could maximize its strengths in providing ongoing support and monitoring while ensuring comprehensive care for individuals with more complex needs.

Content and Design

The CANreduce 2.0 app implements a program based on motivational interviewing and CBT, designed to increase disorder awareness, confront users with their consumption problem, and encourage commitment to modifying their CU patterns. This combination of methods, along with its modular structure, aligns with evidence suggesting that apps with such designs demonstrate greater effectiveness [30].

The proposal to register CU habits was well received by FG participants, including both users and professionals. This feature was recognized for its utility in patient monitoring and its

XSL•FO
RenderX

potential to promote positive behaviors while reducing negative ones [61]. Additionally, participants suggested incorporating gamification elements and small achievements to enhance motivation and engagement, as these features could provide further incentives for users to stay committed to their treatment and actively engage with the platform's resources.

A limitation of this DHI, as highlighted during FG discussions, is its lack of adaptation to each user's unique case. The customization of digital health apps, particularly in terms of usability, remains an underexplored area compared with commercially driven digital apps [39]. User-centered design extends beyond aesthetics and interface dynamics to encompass adaptation to the demographic characteristics, mental models, and psychological needs of the target population [9]. The flow of app use—spanning user experience and interface design—is a fundamental aspect of digital apps. FG research serves as a key method for evaluating these elements [40], and this study provided insights into the perceptions of both users and professionals. Further exploration of individual user expectations and goals could enhance personalization and improve the care process [62].

Users expressed a preference for a mobile app featuring personalized notifications and interactive content, aligning with research suggesting that such features could enhance engagement and adherence [63]. The importance of tailoring content to individual needs and characteristics was a recurrent theme in discussions.

Regarding the user interface, participants highlighted challenges in accessing the app from mobile devices, as it was initially designed as a web-based platform before being adapted for smartphones. They found the predominantly text-based content burdensome and suggested incorporating videos or other visual formats to improve engagement [15]. Additionally, enhancing the visualization of data graphs was identified as a necessary improvement.

Next Steps

To improve adherence and usability in CANreduce 2.0, feedback from users and professionals (Textbox 1) will be integrated into the DHI. Specifically, motivation and awareness will be enhanced by incorporating a reward system and a visualization tool that highlights the individual economic costs of consumption (expense calculator). Additional content will be included to provide deeper insights into the negative consequences of CU and withdrawal syndrome, along with tailored elements for individuals in the precontemplation stage, as identified through an initial user profiling survey. Motivation and readiness to change are critical mechanisms in mental health therapeutic adherence [25], particularly in the precontemplation stage, where they are most affected. Moreover, motivation is a dynamic process that fluctuates across the different stages of change and varies in intensity over time [25,36]. Thus, integrating specific modules and interventions that address these fluctuations is crucial to maintaining adherence and preventing potential dropouts.

For enhanced guidance and usability, CANreduce 2.0 will incorporate a voluntary forum feature to facilitate peer support and interaction. Additionally, its potential application in addiction treatment centers will be further explored. Consistent with existing evidence [59,60], both users and professionals have recognized CANreduce 2.0 as a valuable complement to face-to-face therapy, particularly for highly motivated individuals. Consequently, future DHI development will prioritize its integration as a therapeutic adjunct, especially for patients on waiting lists and in primary care. Additionally, the feasibility of enabling professionals to access and track patient data will be explored to further enhance clinical support.

Design and content improvements will prioritize usability and accessibility. CANreduce 2.0 will be redesigned as a web application to enhance functionality on smartphones and improve interface interactivity. Planned optimizations include gamification elements, such as the previously mentioned reward system, individual progressive goal tracking, a search tool, optional notifications, and increased visual content to replace text-heavy sections.

Following the implementation of these features, additional FGs will be conducted to gather updated user and professional perspectives, ensuring the continuation of the iterative co-design process. These sessions will also explore areas with limited consensus, such as the optimal user age and necessary adaptations to tailor the intervention for different life stages and levels of self-awareness.

Poor adherence remains a major barrier to implementing DHIs [17,24] and CUD treatments, particularly among younger populations [15]. Motivation, a key construct in the Adherence-Focused model, has been linked to increased treatment completion [25]. As highlighted by FG participants, interventions such as CANreduce 2.0 may heavily depend on user motivation while also supporting individuals in identifying their reasons for change and facilitating planning [36]. For future studies on DHIs, motivation should be carefully considered, as both users and professionals emphasized—consistent with existing literature—that it significantly impacts adherence and, consequently, the intervention's potential success or failure.

Furthermore, the differences observed between groups in Figure 1 emphasize the importance of addressing varying priorities and perspectives when designing therapeutic tools or interventions. Misalignment in certain areas highlights the need to strengthen communication and cocreation processes. Bridging this gap could help ensure that all stakeholders recognize the value of key features and their potential to enhance therapeutic outcomes. Incorporating diverse perspectives throughout the design and development process is crucial for creating interventions that are both effective and widely adopted. A participatory approach—engaging both professionals and users—could align priorities, foster shared ownership of solutions, and enhance long-term impact and sustainability.

Limitations

This study has limitations, including the small group sizes and the fact that some surveyed users were not highly familiar with the app. However, evidence suggests that such unfamiliarity can provide valuable insights into user experience evaluation [64]. While the FG strategy employed in the protocol is effective

XSL•FO
RenderX

for exploring motivations, experiences, and subjective perceptions in-depth, it is inherently limited in its level of evidence, as it lacks statistical representativeness and does not allow for the measurement of phenomena [38].

The use of a co-design model often presents challenges, including the significant time, effort, and financial resources required, as well as the complexity of balancing diverse perspectives, which can complicate decision-making [65-67]. Another common barrier is the generalizability of outputs; as with many co-design studies, our small group sizes may not fully represent the broader user population. Additionally, involving affiliated professionals in the process may influence project direction and introduce potential biases [67]. Despite these challenges, co-design offers substantial benefits, primarily by ensuring that the intervention aligns with end user needs. This approach allows us to directly integrate user perspectives into the design, enhancing relevance, acceptability, and usability [65,68]. Moreover, perceived value or buy-in is widely recognized as a key enabler of co-design, fostering sustained stakeholder engagement and ultimately supporting adoption [67]. The co-design process also generated innovative ideas for improving CANreduce 2.0—such as incorporating notifications and small achievements—making the intervention more applicable to real-life situations and increasing the likelihood of successful integration [66,68].

Conclusions

The findings of this study highlight the complexity of designing effective DHIs for CU. While technology offers unique opportunities to engage users, the results emphasize the need to address the diverse needs of different demographic groups and severity levels to enhance motivation and adherence. Personalization, combined with robust motivational strategies and an interactive design, appears to be critical for the success of such platforms. Furthermore, collaboration among technology developers, health care professionals, and end users is essential to creating digital solutions that are both practical and effective.

Advancing the design of DHIs that effectively address substance use in innovative and engaging ways remains a challenge in medical informatics and mental health. Integrating user perspectives and values into the design process is essential for enhancing the acceptability, usability, and utility of these tools. For CANreduce 2.0, the insights gained from this study will guide the implementation of necessary improvements, refining both the app's content and interactive features.

Acknowledgments

We express our gratitude to all the participants who took part in the focus groups. This study was funded by the Instituto de Salud Carlos III (ISCIII), the European Union NextGenerationEU, and the Mecanismo para la Recuperación y la Resiliencia (MRR; grants RD21/0009/0001, RD21/0009/0004, RD21/0009/0007, RD21/0009/0010, and RD21/0009/0025).

Data Availability

All data generated or analyzed during this study are included in this published article and its multimedia appendices.

Abstract

Background: Decision aids empower patients to understand how treatment options match their preferences. Choice experiments, a method to clarify values used within decision aids, present patients with hypothetical scenarios to reveal their preferences for treatment characteristics. Given the rise in research embedding choice experiments in decision tools and the emergence of novel developments in embedding methodology, a scoping review is warranted.

Objective: This scoping review examines how choice experiments are embedded into decision tools and how these tools are evaluated, to identify best practices.

Methods: This scoping review followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines. Searches were conducted on MEDLINE, PsycInfo, and Web of Science. The methodology, development and evaluation details of decision aids were extracted and summarized using narrative synthesis.

Results: Overall, 33 papers reporting 22 tools were included in the scoping review. These tools were developed for various health conditions, including musculoskeletal (7/22, 32%), oncological (8/22, 36%), and chronic conditions (7/22, 32%). Most decision tools (17/22, 77%) were developed in the United States, with the remaining tools originating in the Netherlands, United Kingdom, Canada, and Australia. The number of publications increased, with 73% (16/22) published since 2015, peaking at 4 publications in 2019. The primary purpose of these tools (20/22, 91%) was to help patients compare or choose treatments. Adaptive conjoint analysis was the most frequently used design type (10/22, 45%), followed by conjoint analysis and discrete choice experiments (DCEs; both 4/22, 18%), modified adaptive conjoint analysis (3/22, 14%), and adaptive best-worst conjoint analysis (1/22, 5%). The number of tasks varied depending on the design (6-12 for DCEs and adaptive conjoint vs 16-20 for conjoint analysis designs). Sawtooth software was commonly used (14/22, 64%) to embed choice tasks. Four proof-of-concept embedding methods were identified: scenario analysis, known preference phenotypes, Bayesian collaborative filtering, and penalized multinomial logit model. After completing the choice tasks patients received tailored information, 73% (16/22) of tools provided attribute importance scores, and 23% (5/22) presented a “best match” treatment ranking. To convey probabilistic attributes, most tools (13/22, 59%) used a combination of approaches, including percentages, natural frequencies, icon arrays, narratives, and videos. The tools were evaluated across diverse study designs (randomized controlled trials, mixed methods, and cohort studies), with sample sizes ranging from 23 to 743 participants. Over 40 different outcomes were included in the evaluations, with the decisional conflict scale being the most frequently used in 6 tools.

Conclusions: This scoping review provides an overview of how choice experiments are embedded into decision tools. It highlights the lack of established best practices for embedding methods, with only 4 proof-of-concept methods identified. Furthermore, the review reveals a lack of consensus on outcome measures, emphasizing the need for standardized outcome selection for future evaluations.

KEYWORDS

decision aid; decision tool; discrete choice experiment; conjoint analysis; value clarification; scoping review; choice experiment; database; study; article; data charting; narrative synthesis

Introduction

Understanding patient values for treatments is particularly important when a demonstrably superior treatment option is not available [1-4]. In these "preference-sensitive decisions" patients need to understand the treatment choices that are available to them, consider their personal values and weigh the trade-offs between treatment benefits and risks to select the optimal treatment that suits them [1-4]. Patient decision aids are used as a supporting tool when patients are faced with a preference-sensitive decision [5,6]. A well-established evidence base of 209 studies shows the effectiveness of decision aids in improving knowledge, reducing decisional conflict, increasing participation in decision-making, and receiving treatment with characteristics that they value [5,7-9]. Notably, digital decision aids also offer distinct advantages over other formats. Digital tools can incorporate interactive elements, allowing patients to personalize their experience by selecting the most relevant information. Moreover, these tools can include algorithms and perform real-time calculations to provide personalized results [7].

An important part of a decision aid, according to the International Patient Decision Aids Standards (IPDAS) collaboration, is an exercise that helps people clarify their values [10]. A value clarification exercise in a decision aid helps patients to identify the relative importance of treatment characteristics (attributes) that are congruent with their values [10] and helps patients to understand how the different treatment options align with their values [7,11].

Increasingly, choice experiments are used as a value clarification method within decision aids [7,11]. The term choice experiment (also called stated preference survey) will be used hereafter as an umbrella term for discrete choice experiments (DCEs) and conjoint analyses. In choice experiments, patients choose their preferred treatment from two or more hypothetical options, each defined by a unique combination of attributes and levels. Subsequent regression analyses of their choices reveal their preferences for the relative importance of treatment characteristics and allow the prediction of treatments that patients would prefer [12].

The field of embedding choice experiments in decision tools has seen an increase in new research since Weernink et al [7] published their review in 2018. Also, new conceptual models on how to integrate choice experiments in decision tools have been published since 2020 [13,14]. To identify best practices and knowledge gaps considering these advancements, a scoping review is warranted. A scoping review is appropriate as it aims to produce a comprehensive map of the research landscape by analysing the volume of research, the methodologies used, and the overall characteristics of the primary studies [15-20]. Unlike systematic reviews, which mainly focus on establishing the effectiveness of decision aids (already addressed by [5]), scoping reviews map the range of approaches used within a field. This broader approach allows the identification of best practices for integrating choice experiments into online decision aids.

The aim of this study is to undertake a scoping review of choice experiments embedded in decision tools to understand the current landscape of best practices. The objectives of this review are to (1) identify key methods used to embed a choice experiment into a decision tool, (2) characterize the design features of choice experiments embedded in decision aids, (3) identify the different study designs and outcomes used to evaluate the tool, and (4) describe how complex information was presented to the participants.

Methods

Overview

This scoping review was conducted following best practices in line with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [21]. A protocol detailing the plan of the methods section was prepared and the PRISMA-ScR checklist was used in this review (Multimedia Appendix 1).

Eligibility Criteria

Studies were selected based on the inclusion and exclusion criteria detailed in Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- A study describes the methods, development, design, presentation and visualization of patient information of a patient decision tool incorporating a choice experiment.
- A study evaluates a patient decision tool embedding a choice experiment or protocols describing the methods of the evaluation and what outcomes were measured to determine the effectiveness of the intervention.

It should also be noted that

- All study designs such as randomized controlled trials, observational studies, cross-sectional studies, and methodological papers, were included. Conference abstracts and existing systematic reviews were excluded.
- All articles meeting the above eligibility criteria were included regardless of the methodological quality as the aim of the scoping review is to gain an overview of the literature on embedding choice experiments in decision tools.
- No restrictions were imposed on the population, for methodological studies population is not relevant and for evaluation studies, the population can include all users that benefit from the decision tool such as patients, carers, or family members.

Exclusion criteria

- Decision aids without a choice experiment task as a value clarification method.
- Decision aids including other preference elicitation methods such as multicriteria decision analysis or time trade-off.
- Non–English-language publications.

Databases

MEDLINE via Ovid, PsycInfo via Ovid, and Web of Science databases were searched in March 2023. These 3 databases provide sufficient breadth of coverage of health-related sources to identify potentially relevant articles. Reference lists of included studies were searched to identify potentially relevant searches. Internet search engines (ie, Google) were used to identify any gray literature such as unpublished guidance documentation (ie, from regulators).

Search Strategy

The search strategy was conducted with the help of an information specialist using an iterative discussion process. The key concepts used in the search strategy are “choice experiment,” “decision aid,” “shared decision making,” “value clarification,” “predicted probability,” and synonyms of these key terms. The search excluded other methods such as “multi-criteria decision,” “analytical hierarchy process,” “time trade-off,” or “standard gamble” since the focus of this review is on choice experiments. The search strategy removed any studies not published in English. A time restriction was also introduced because an existing systematic review conducted a search up until 2016 [7]. Therefore, the current search used a modified version of the Weernink et al [7] search strategy and updated it to find new articles published since 2016. The modified version of the search strategy contained new terms such as “decision tool” and “predicted probability.” The full search strategy is included in Multimedia Appendix 2. The gray literature search used the same keywords mentioned above with Boolean operators. The first 20 potentially relevant records were retrieved for screening.

Screening

All search results were exported to EndNote and any duplicates were removed. All references were screened by one reviewer (NW). However, if the inclusion of a study was unclear, then discussions were held with the wider team to make a final decision (DR and PS). Initially, the references were screened based on title and abstract, followed by a full-text screening of relevant articles based on the inclusion and exclusion criteria. Details about the screening process, including reasons for exclusion were documented in a flow diagram using the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) template.

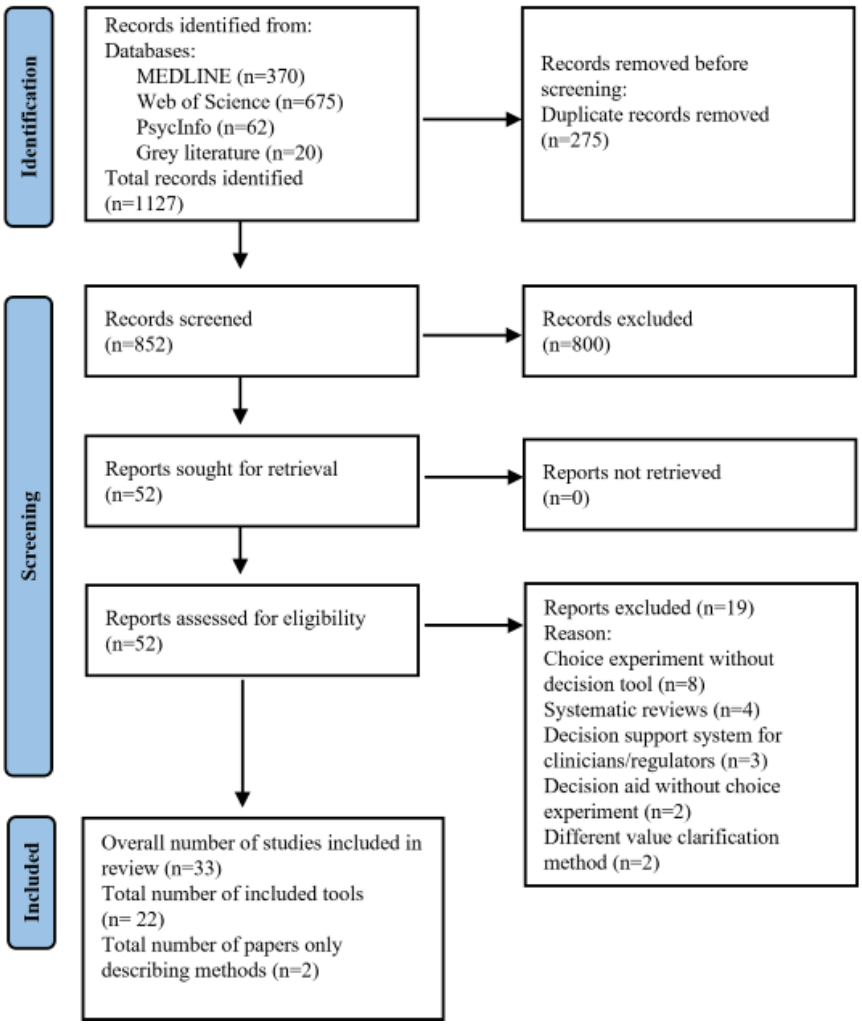
Data Charting

Data charting tables were created in Excel to extract data from included studies. The charting tables were developed iteratively and modified as needed after extracting data from two articles. Data charting was conducted independently by one reviewer (NW). The data items included in the Excel charts were: author, date of publication, name of the tool, country, study aim, disease context, sample size, choice experiment embedding methodology or formula used, number of attributes, number of levels, type of attributes, graphs or visual pictographs used, choice experiment design used, type of choice tasks, number of choice tasks, software program used, description of the patient decision tool (ie, receive feedback on attribute importance or receive a “best match” treatment option that aligns with patients desired attributes, received a report), details about the evaluation, outcomes measured, and mean duration of the task. Since multiple study designs were included, not all the fields were relevant for all studies. For example, for studies that report on methodological aspects, the data charts mainly contained information about the methodology or formula, and the rest of the fields were not applicable.

Collating, Summarizing, and Reporting the Results

Since the aim of the scoping review is to map the literature, the data summarizing used a narrative synthesis of qualitative data with descriptive statistics of quantitative data. Illustrations were used to visualize the results using tables and figures. Where appropriate existing frameworks were used to categorize lists

XSL•FO
RenderX



of qualitative data extracted. The Core Outcome Measures in Effectiveness Trials (COMET) taxonomy [22] was used to systematically classify attributes into core areas and domains. This taxonomy is widely used to classify outcomes of trials [23]. This taxonomy's breadth and granularity, provided by its 5 core areas and 38 outcome domains, made it suitable for classifying the diverse attributes included in this scoping review. Risk of bias assessments were not conducted since the aim of the study was not to test the rigor of the articles, but rather to get an overview of the current literature on embedding choice experiments in decision tools.

Results

Overview

A PRISMA flow diagram detailing the inclusion and exclusion process is presented in Figure 1. A total of 1127 citations were identified. After duplicates were removed, 852 references were screened based on title and abstract. Of the 52 full-text articles that were reviewed, 19 studies that did not meet the inclusion criteria were excluded (Multimedia Appendix 3). Overall, 22 tools were included in the scoping review. The methodology, development and evaluation details of tools were extracted from 33 papers.

Figure 1. Flow diagram of study selection.

Study Characteristics

Table 1 provides a general overview of the types of decision tools that were found in the scoping review. The first decision tool was published in 2007. However, the number of publications has increased since then, with 16 out of the 22 (73%) studies published since 2015 and a peak of 4 publications in 2019. The majority of the decision tools (17/22, 77%) were developed in the United States. In total, 2 out of 22 (9%) tools were conducted in the Netherlands and one each in the United Kingdom, Canada, and Australia. A variety of different terms such as decision-making tool, decision aid, patient preference elicitation instrument, and discussion prioritization tool were used by the investigators to describe the tool they developed. There is no consensus on a clearly defined name for these tools among the included studies.

RenderX

Table 1. General study characteristics[a].

Study	Date	Name of the tool	Country	Purpose of tool	Disease context
Abraham et al [24]	2015	Adaptive conjoint analysis survey	United States	Choice of medical treatments - complex antithrombotic therapy (anticoagulants or antiplatelet drugs)	Cardiovascular disease
Almario et al [25]	2018	Online Patient Decision Aid: IBD and me	United States	Choice between biological treatments for ulcerative colitis	Ulcerative colitis and Crohn's disease
Chhatre et al [26]	2021	Patient preference elicitation instrument: OABCare	United States	Overactive bladder management - relative importance of the key outcomes associated with overactive bladder management (behavioral modification, medications, physical therapy, etc)	Overactive bladder
Cole et al [27]	2022	Electronic health care tool: PRIME	United States	Choice of chemotherapeutic agents for patients with hematologic malignancies - relative importance of outcomes for blood cancer treatments	Hematologic malignancies
de Achaval et al [28]	2012	Adaptive conjoint analysis tool	United States	Choice of different treatment options ("knee replacement surgery" or "pills and physical therapy" versus "unsure") and relative importance of attributes and therapy or total knee arthroplasty	Knee osteoarthritis
Dowsey et al [29]	2016	Decision aid in total knee arthroplasty	Australia	Choice of whether or not to undergo total knee arthroplasty surgery	End-stage knee osteoarthritis
Fraenkel et al [30]	2007	Computer tool	United States	Choice of different treatment options for knee pain	Knee pain, osteoarthritis
Goodsmith et al [31]	2021	Computerized conjoint analysis	United States	Choice of weight management treatment for overweight individuals with schizophrenia	Overweight individuals with schizophrenia
Hawley et al [32]	2016	Interactive, web-based, breast cancer treatment decision tool	United States	Choice of locoregional treatment (mastectomy or lumpectomy with radiation)	Breast cancer
Hazelwood et al [13,33,34]	2020, 2018, and 2016	Decision aid	Canada	Choice between two treatments	Early rheumatoid arthritis
Hess et al [35]	2015	Preference elicitation tool	United States	Choice of medical, surgical treatment or opt-out for abnormal uterine bleeding	Abnormal uterine bleeding
Hutyra et al [36]	2019	FTASD[b] decision tool or Preference-Based Decision Aids	United States	Choice between operative or nonoperative treatment for first-time anterior shoulder dislocation	Anterior shoulder dislocations
Jayadevappa et al [37-39]	2015, 2019a, and 2019b	Patient Preferences for Prostate Cancer Care: PreProCare	United States	Choice between treatment options (ie, active surveillance, surgery, radiation) for early-stage prostate cancer	Prostate cancer
Johnson et al [40]	2016	Patient decision aid	United States	Choice of surgery, radiation therapy or active surveillance for prostate cancer	Newly diagnosed prostate cancer (Men)
Loria-Rebolledo et al [41]	2022	Understanding Persistent Pain Decision Aid Tool: UPP[c] DAT[d]	United Kingdom	Choice of medication for managing persistent pain	Patients living with persistent pain
Pieterse et al [42]	2019	Value Clarification Method - ABEL study	Netherland	Choice of whether or not to undergo short-course preoperative radiotherapy treatment	Newly diagnosed patients with rectal cancer
Pieterse et al [43]	2010	ACA-questionnaire	Netherland	Choice of surgery vs preoperative radiotherapy (PRT) plus surgery for patients with rectal cancer - relative importance of outcomes for rectal cancer	Rectal cancer
Rochon et al [44] and Fraenkel [45]	2014and 2010	Adaptive conjoint analysis decision aid	United States	Choice of different treatment options for knee pain	Knee pain

XSL•FO
RenderX

Study	Date	Name of the tool	Country	Purpose of tool	Disease context
Snaman et al [46-48]	2019, 2021, and 2021	Decision-making tool: MyPref	United States	Choice of chemotherapy treatments	Adolescent and young adults with high-risk cancer
Streufert et al [49]	2017	Shared decision-making tool	United States	Choice of operative and nonoperative treatment for first-time anterior shoulder dislocation	First-time anterior shoulder dislocation
Studfts et al [50] and Byrne et al [51]	2020and 2019	Brief Education and a Conjoint Valuation Survey	United States	Choice of lung cancer screening test	Individuals at high risk of lung cancer
Wittnik et al [52,53]	2018 and 2016	Customized Care - Discussion Prioritization Tool	United States	To help patients disclose their stressors to their primary care provider	Patients with multiple chronic medical conditions in primary care

[a]Two of the 33 studies were excluded from this table because they focused on method development [14,54].

[b]FTASD: first-time anterior shoulder dislocation.

[c]UPP: Understanding Persistent Pain.

[d]DAT: digital decision aid tool.

The tools were developed in various disease contexts, which can be broadly grouped into three categories: musculoskeletal (7/22, 32%), oncological (8/22, 36%), and chronic conditions (7/22, 32%; Table 1). Musculoskeletal conditions include knee pain, early rheumatoid arthritis, anterior shoulder dislocations, and end-stage knee osteoarthritis; oncological conditions include breast cancer, prostate cancer, lung cancer, rectal cancer, hematologic malignancies, and adolescent and young adults with high-risk cancer; and chronic conditions include cardiovascular disease, overweight individuals with schizophrenia, ulcerative colitis, and Crohn disease, patients with multiple chronic medical conditions in primary care, and overactive bladder. The majority of the tools (20/22, 91%) were developed to help patients choose between medical treatments or compare medical treatments with surgery or surveillance. However, 2 out of 22 (9%) tools had different purposes, one study was developed to help patients disclose their stressors (ie, mobility issues and money worries) to their primary care provider and the other to facilitate the decision-making process around the choice of lung cancer screening tests.

Attributes

The various types of attributes that were used to assess patient preferences are listed in Table 2. The COMET taxonomy was used to organize the 91 attributes into meaningful domains and gain insight into the breadth of attributes that were included in the choice tasks. Five core areas and 11 outcome domains were identified when attributes were classified (Table 2). Attributes that were predominantly used in decision tools are: efficacy (20/22, 91%), side effects (15/22, 68%), route of administration (9/22, 41%), cost (7/22, 32%), and limits on daily activities (6/22, 27%). Further details of the attributes are available in Multimedia Appendix 4.

Overall, a range of attributes from 3 to 15 were used in the decision tools (Figure 2). Most tools (8/22, 36%) with a higher number of attributes (8 or above), used a design that allowed them to simplify the choice task and only display a reduced number of attributes (ie, 3 attributes at a time) to the respondents. Further details about the choice of tasks can be found in Multimedia Appendices 4 and 5.

Defining Risk or Efficacy Attributes

The majority of tools (20/22, 91%) incorporated probabilistic attributes to convey uncertainty in treatment efficacy and side effects (Table 3). To enhance comprehension, various approaches were used to express these probabilities, including percentages (9/22, 41%), natural frequencies (9/22, 41%), icon arrays (8/22, 36%), narratives (5/22, 23%), and videos (1/22, 5%). Over half of the tools (13/22, 59%) used a combination of methods, while a minority (4/22, 18%) relied on a single approach. In total 14% (3/22) tools did not clearly describe the method used. The most frequent combination was natural frequencies and icon arrays (7/22, 32%).

XSL•FO
RenderX

Table 3. Methods used to define the risk or efficacy attributes[a].

Study	Percentages (ie, 5% risk of the cancer coming back)	Natural frequencies (ie, 10 out of 100 people will have a heart attack)	Icon arrays (numerical data visualized using simple icons like faces)	Narratives (ie, More than half; side effects - likely; low likelihood)	Videos

Choice Task Design

Five types of designs were used to derive the choice tasks (Table 4). The most frequently used design type was adaptive conjoint analysis (10/22, 45%), followed by conjoint analysis (4/22, 18%), DCEs (4/22, 18%), modified adaptive conjoint analysis (3/22, 14%) and adaptive best-worst conjoint analysis (1/22, 5%). Common characteristics of the choice tasks were the rating of preferred treatments (ie, “strongly prefer left,” to “strongly prefer right”) in 17 out of 22 (77%) tools; and tailoring of choice tasks using various adaptive designs (14/22, 64%). Further details about the different designs can be found in Multimedia Appendix 5.

The number of choice tasks included varied from 6 to 20 (Multimedia Appendix 5). Eight out of 22 tools (36%) did not specify the number of tasks included in the tool. Conjoint analysis typically used a higher range of 16-20 tasks, whereas DCEs and adaptive conjoint analysis designs used a lower range of 6-12 tasks (Multimedia Appendix 5).

XSL•FO
RenderX

Table 4. Types of choice of tasks.

Choice task type	Frequency	Details of the choice task
Adaptive conjoint analysis (adaptive choice-based conjoint, choice-based adaptive conjoint analysis)	10	First, participants were shown an attribute with two different levels and asked to rate how important was the level difference (ie, "strongly prefer left or right"). Second, respondents were shown tailored paired comparisons and asked to rate their preferences (ie "strongly prefer left or right").
Conjoint analysis	4	Paired comparison (or single profile) where respondents rated their preference (ie, strongly prefer treatment option 1/2).
Discrete choice experiment	4	Paired comparisons of treatment profiles where respondents chose one treatment over the other (no rating involved). Efficient designs or balanced overlap designs were generated using Ngene or Sawtooth.
Modified adaptive conjoint analysis	3	First, respondents chose the attribute that is most important to them out of a list of attributes. Second, the respondents rated the importance of each attribute relative to the most important attribute; followed by paired comparisons of treatment profiles which were rated (ie, "strongly prefer left or right").
Adaptive best-worst conjoint analysis	1	Presented three tailored alternative profiles and asked respondents to choose the best and worst of alternatives.

Embedding Choice Tasks in Decision Tools

Table 5 details the choice experiment embedding methods used by the 22 decision tools included in the scoping review. In addition, Table 5 presents a summary of the two methodological papers included [14,54]. Fourteen decision tools used Sawtooth software; one study each used Wisercare [40], Dynamic Computer Interactive Decision Application [13] and Clinvivo software [41]; and 5 tools failed to describe the choice task embedding method.

Sawtooth Software dominated, comprising approximately 64% (14/22) of the decision tools, which allowed real-time data analysis and display of personalized results to respondents. However, details on how the Sawtooth software provided real-time tailored results were limited (n=7). Even when the authors provided information beyond the Sawtooth software name, they only mentioned the name of the regression model used such as hierarchical Bayes (n=3) or least-squares regression analysis (n=4) without providing any specific details regarding the model configuration or the mechanisms enabling real-time personalization (Table 5). Similarly, one study used the Wisercare software, but no further details were provided. The remaining four studies used distinct methods to embed choice tasks in decision tools and these methods are summarized in detail below.

Hazelwood et al [13] used the Dynamic Computer Interactive Decision Application templating tool to develop the decision aid [13]. To provide tailored treatment ranking, DCE data from a previous study [34] was analyzed using a Bayesian model followed by scenario analyses [33]. The decision aid contained 6 DCE tasks. By analyzing the results of the prior DCE, a choice probability was calculated for each of the 64 (2^6) response profiles (ie, AABAAB, ABABAB, BBBAAA…etc) for selecting one of two possible treatments (triple therapy or methotrexate). When a patient completed the 6 choice tasks, the patient was assigned to 1 out of 64 response profiles and the corresponding probability for that response profile of choosing triple therapy or methotrexate was displayed [13].

Gonzalez Sepulveda et al [14] also used data from a prior conjoint analysis [36] to develop a preference diagnostic tool. This paper detailed only the methodology with a simulation study to test the proposed method. First, they analyzed the conjoint analysis data to evaluate the distribution of preferences and identify groups or classes of respondents with similar preferences. The authors refer to these groups as "known preference phenotypes." To identify preference phenotypes, Gonzalez Sepulveda et al [14] suggested using methods such as k-means cluster analysis, latent class analysis, or hierarchical cluster analysis. The second step involved constructing a small number of choice sets that would "maximize discrimination" of respondents belonging to each preference phenotype. To generate choice sets the authors used an evolutionary algorithm. Third, Gonzales Sepulveda et al [14] evaluated the robustness (ie, true positives or true negatives) of the choice sets on correctly predicting preference phenotypes [14]. In the simulation tasks, the investigators constructed three choice tasks, where all respondents saw choice task 1 and based on the answer to the first choice task, respondents either saw choice task 2 or choice task 3. Each new question classified the respondent to the preference phenotype they were likely to belong to. Based on the response patterns to the two questions, the investigators assigned respondents to their likely preference phenotypes [14]. Gonzalez Sepulveda et al [14] argued that a key advantage of their method is the use of a small number of choice tasks to accurately predict the posterior probability of preference phenotype membership.

Table 5. Methods of tool development.

Study	Choice task embedding approach
Abraham et al [24]	Sawtooth software (regression analysis)
Almario et al [25]	Sawtooth software (hierarchical Bayes regression)
Chhatre et al [26]	Sawtooth software (hierarchical Bayesian random effects regression)
Cole et al [27]	Not specified but this tool is a work in progress only protocol published
de Achaval et al [28]	Sawtooth software (no further details provided)
Dowsey et al [29]	Not described
Fraenkel et al [30]	Sawtooth software (least-squares regression analysis)
Gonzalez et al [14]	Developed an algorithm "based on previous information on the distribution of patient preferences in a population" using hierarchical cluster analysis
Goodsmith et al [31]	Not described
Hawley et al [32]	Not described
Hazelwood et al [13,33,34]	Hierarchical Bayes regression from a prior discrete choice experiments (DCEs) is used to find expected choice probabilities of treatments for response patterns. Software used was Dynamic Computer Interactive Decision Application (DCIDA) tool
Hess et al [35]	Sawtooth software (no further details provided)
Hutyra et al [36]	Sawtooth software (no further details provided)
Jayadevappa et al [37-39]	Sawtooth software (no further details provided)
Johnson et al [40]	Wisercare no further details provided)
Loria-Rebolledo et al [41]	Real time estimates using the penalized logit regression coded using Clinvivo software
Pieterse et al [42]	Sawtooth software (Ordinary least squares regression)
Pieterse et al [43]	Sawtooth software (Ordinary least squares regression)
Rochon et al [44] and Fraenkel et al [45]	Sawtooth software (Least squares updating algorithm)
Snaman et al [46-48]	Sawtooth software (no further details provided)
Shaoibi et al [54]	Bayesian collaborative filtering model
Streufert et al [49]	Sawtooth software (no further details provided)
Studfts et al [50] and Byrne et al [51]	Sawtooth software (hierarchical Bayes approach)
Wittnik et al [52,53]	Not described

Shaoibi et al [54] used a Bayesian collaborative filtering model to predict the treatment recommendations. The first step of the proposed method is similar to Gonzales Sepulveda et al [14] as it involves the use of preference phenotypes. A Markov Chain Monte Carlo algorithm was used to identify preference clusters [54]. Then the investigators used data from existing patients to assess posttreatment satisfaction. When a new patient completed the choice task, they were assigned to a preference cluster. Then post treatment satisfaction data that match the cluster were used to make a treatment recommendation.

Loria-Rebolledgo et al [41] used a different approach to the other methods discussed above. This method did not require a 2-stage approach of analyzing data from a previous choice experiment instead, parameters were estimated "live" using a penalized multinomial logit model (pMNL). The Clinvivo software was used to code the decision aid tool. Loria-Rebolledgo et al [41] selected the penalized model because of its flexibility in converging results especially when small sample sizes are used for the estimation. The pMNL is different from a typical multinomial logit model because a bias term is added to the standard likelihood function. This term penalized the model for small sample size bias. Each time a respondent completed the choice task, the pMNL model was run and relative importance scores were calculated.

Presentation of the Decision Tool

After completing the choice task, 64% of tools (14/22) provided respondents with a report, while 8 out of 22 (36%) tools did not provide a clear description of what respondents received. Two types of information were included in this report: (1) attribute importance scores and (2) "best match" treatment options that aligned with patients' desired attributes. Most patients received feedback on attribute importance (16/22, 73%), which was presented to patients using different formats. The majority (14/22, 64%) were displayed as horizontal bar graphs (Figure 3 [42]). There were slight variations in the presentation of horizontal bar graphs: some showed exact percentages, some

XSL•FO
RenderX

showed longer bars to represent increasing importance, and some tools with a long list of attributes only presented the top 5 most important attributes. Diverging from horizontal bar graphs, one tool used a vertical bar graph (Figure 4 [41]). Another study tested multiple different approaches such as a gauge chart (Figure 5 [27]), line graph (Figure 6 [27]) and narrative visualization (Figure 7 [27]). Only 5 out of the 22 (23%) tools provided patients with a "best match" treatment. Two tools used a scale ranging from 0 (worst choice) to 100 (best choice) showing the relative ranking of all the available treatment options (Figure 8 [44]). One tool displayed all available treatments in a choice task format and highlighted the "best match" (Figure 9 [13]); one tool picked the treatment that best fits the respondent and only presented that option in the text and the last tool did not provide sufficient details on how the ranking of treatment options was presented to the patients (Multimedia Appendix 6).

Evaluation of Decision Tools

The decision tools were evaluated in the context of different study designs, including randomized controlled trials (RCTs; n=5), pilot RCTs (n=4), mixed methods studies (n=4), cohort studies (n=4), cross-sectional studies (n=3), qualitative studies (n=1), and nonrandomized studies (n=1). Sample sizes across the studies varied, ranging from 23 participants in mixed methods studies to 743 in RCTs (Multimedia Appendix 7).

Figure 10 shows the breadth of outcomes used to evaluate the decision tools, with over 40 different outcomes included. These outcomes fall into 6 core areas including usability, acceptability, validity, feasibility, informed decision making and patient health outcomes. A variety of instruments were used to assess the usability or user-friendliness of the tools, these include the system usability scale, Dowding's usability principles checklist, single easy questionnaire, poststudy system usability questionnaire, IBM computer system usability questionnaire, and NASA (National Aeronautics and Space Administration) task load index (evaluates mental effort needed to perform tasks). While usability was measured using existing validated instruments, accessibility was mostly measured using items developed by the study teams. The most frequently used acceptability item was whether respondents would discuss the results of the tool with their health care professional, followed by how helpful the tool was to patients in deciding which treatment to choose. The validity of the tool was assessed by examining how well its predictions aligned with patient perspectives. Five tools measured "value concordance," measuring how well the tool's attribute rankings aligned with the patient's own preferences. Two tools measured the similarity between the "best match" treatment generated by the tool and the patient's stated treatment preference. The feasibility of the tool was assessed by recording response rates (n=1) and evaluating the ability of the tool to generate individually tailored reports (n=1).

Informed decision making was assessed using several proxy measures including decisional regret, decisional conflict, self-efficacy, knowledge, patient activation or engagement, and satisfaction. Decisional conflict defined as the "personal uncertainty about which option to choose" was the most commonly used outcome measure (n=6). Decisional regret is defined as "remorse or distress over a decision" and was measured using the 5-item decisional regret scale (n=2) and memorial anxiety scale for prostate cancer regret subscale (n=1). Respondents' self-efficacy or their confidence to make a treatment decision was measured using the decision self-efficacy scale (n=1) and arthritis self-efficacy scale (n=1). Patients' active participation and engagement in care were measured using validated instruments including the preparation for decision making scale (n=2), patient activation measure (n=1), control preferences scale (n=1), and adapted perceived competence scale (n=1). Patient satisfaction was also measured using established instruments such as the six-item satisfaction with decision scale (n=2), patient satisfaction questionnaire (n=1), patient satisfaction scale (n=1), and functional assessment of chronic illness therapy-treatment satisfaction-patient scale (n=1). A variety of patient health outcomes were also collected to measure changes to health outcomes after using the tool, further details are available in Figure 10 and Multimedia Appendix 8.

Discussion

Principal Findings

With the increasing use of choice experiments embedded in decision tools, this scoping review was conducted to map the evidence base in terms of the methods, design, and evaluation of these tools. This review identified 22 decision tools containing a choice experiment for a variety of health conditions including musculoskeletal conditions, oncological conditions, and chronic conditions. The development of these decision tools was led by the United States with the remaining tools originating in the Netherlands, United Kingdom, Canada, and Australia. A notable trend is the increasing use of choice experiments as a value clarification exercise within decision aids, particularly from 2015 onwards. Variations were observed in how the findings from the choice experiment were presented to patients. Most patients received feedback on attribute importance, while only a minority received a "best match" ranking of treatment options. Diverse approaches to presenting probabilities to participants were identified, with a common approach being the use of mixed methods such as percentages, natural frequencies, and icon arrays. A lack of consensus on the terminology used to describe the developed tools was found. Variation was noted in the study designs and outcome measures used to evaluate the tools. The decisional conflict scale was the

XSL•FO
RenderX

most frequently used outcome measure, but no other instrument was widely adopted.

This review also details four relatively new proof-of-concept methods for embedding choice experiments in decision aids, that have been published since 2020. These 4 novel methods include analyzing previous choice experiment data to develop algorithms (scenario analyses) containing expected choice probabilities of treatments according to response patterns [13], classifying respondents into known preference phenotypes [14], using a Bayesian collaborative filtering model [54], or using a penalized multinomial logit model [41]. Developers attempting to embed choice experiments in decision tools are faced with some key challenges: (1) ensuring real-time availability of choice experiment results to patients, (2) tailoring the choice experiment results by incorporating heterogeneity within choice experiment models, and (3) minimizing the number of choice tasks to maintain user engagement alongside the existing information presented in the decision aid. While the new proof-of-concept methods demonstrate potential solutions to these challenges, their validity remains to be conclusively demonstrated. Current evidence is limited to proof-of-concept studies either using small sample sizes or using only simulated data. So, further research is needed to rigorously evaluate these methods and establish their validity.

Comparison With Previous Work

One of the notable findings of this review in comparison to the one conducted in 2018 is that more developers are using choice experiments as a value clarification method in decision tools. In 2018, Weernink et al [7] only identified 8 studies, but since then a further 14 tools have been developed. Despite this increase in research, many of the characteristics of these tools remain unchanged when compared to the results of the previous review [7]. For example, to present the relative importance of attributes it was common to use bar graphs where longer bars reflect relatively more important attributes. Notably, a protocol for a study exploring alternative visual presentations (ie, bar graph, gauge graph, narrative visualization, and line graph) was included in this review [27]. This represents a positive step towards gathering evidence on how to improve the user experience of these tools. Similarly, limited research exists on how to present the "best matched" treatment. Since presenting balanced information is a key criterion of a good decision tool [58], the table format of the choice experiment should lend itself well to presenting this result. Hazelwood et al [13] demonstrated a potential approach using this format. However, further research is needed to evaluate if this presentation method is understood by patients.

This review highlighted the diverse approaches used by studies to present probabilities to participants. It was common to use mixed methods such as percentages, natural frequencies, and icon arrays to describe risk or efficacy attributes in an accessible way to patients. The most common combination was to use natural frequencies and icon arrays to explain probabilities. This finding is congruent with the review conducted by Trevena et al [59] who also found that using visual formats alongside numerical formats helps to improve the understanding of probabilities. However, when combining different methods to display probabilities, caution should be used as there is also evidence to show that when certain methods are combined, such as verbal and numerical formats, probabilities can be overestimated [60]. Presenting probabilities in an unbiased way is challenging, and there is a vast literature exploring how best to do this [59,60]. Bonner et al [60] recommend using consistent numerical formats, such as "x in 100 over 5 years," to display probabilities.

Over 40 different outcome measures were used during the evaluation of decision tools. The decisional conflict scale emerged as the most frequently used outcome measure. Besides the decisional conflict scale, no other instrument was widely adopted to evaluate these decision tools. This variability in outcome measurement highlights the lack of consensus on a core set of outcomes to evaluate these tools. These findings were consistent with previous reviews of decision aids documenting inadequate reporting of details of outcome measures [61], which hinders the development of a robust evidence base of the effectiveness of decision aids.

Limitations

Several limitations should be considered when interpreting the findings of this scoping review. First, the study selection and extraction were performed by a single author. Despite this, the robustness of the selection process was ensured by following the protocol and making selection decisions in conjunction with the wider study team on articles that required a second opinion. Second, the initial search strategy may not have captured all relevant terms used to describe these tools. The included studies used diverse terminology, including "decision-making tool," "decision aid," "patient preference elicitation instrument," and "discussion prioritization tool." This lack of consistent terminology hindered the identification of potentially relevant studies. To address this potential limitation, an updated search was conducted in September 2023, but it did not yield any additional relevant studies. Although an updated search was conducted using additional terms, it remains possible that some tools were missing. Future reviews could benefit from a more iterative approach to search term development. Third, a risk of bias assessment was not conducted in this review. This approach was selected as aligned with the primary objective of the review, which was to provide a comprehensive overview of the existing literature.

Future Directions

The findings of this review point to several areas for future research. Further investigation into the newer proof-of-concept methods identified is warranted, as these methods are still in their infancy more research is needed to validate their effectiveness. Moreover, research on the optimal presentation of choice experiment results to patients is also needed. This includes exploring different visual formats and conveying "best match" treatment information in a clear, unbiased, and understandable way. Furthermore, the development of a core set of outcome measures for evaluating decision tools that incorporate choice experiments would be beneficial. This would facilitate comparisons across studies and help build a more robust evidence base regarding the effectiveness of these tools. Achieving consensus on the terminology used to describe these

XSL•FO
RenderX

tools would aid in indexing and retrieving relevant literature, facilitating future research. In addition, future studies should provide more detail on the model configurations used to enable real-time personalization, beyond just naming the regression model, to improve transparency. Moreover, to maintain their relevance, these decision aids must be adaptable, requiring ongoing updates to incorporate the latest advancements in treatment options. Further research is needed to determine how these tools can be efficiently updated to reflect the rapidly changing medical field. Finally, integrating decision aids effectively within existing electronic systems in hospitals requires further investigation. Implementation of these tools within existing patient portals or linking them with electronic medical records is likely to increase uptake and facilitate more informed and productive discussions with their health care providers. So future research could explore innovative delivery methods to incorporate these tools into routine care.

Conclusion

This scoping review provides a comprehensive overview of the different approaches to embedding choice experiments in decision tools. It highlights key considerations for future studies, including the choice of models used, the presentation of information to patients, and the selection of appropriate outcome measures for evaluating the tools. While several challenges remain, the field is rapidly evolving, and the findings of this review provide a foundation for further research and development in this area. The increasing use of digital technologies, including artificial intelligence, offers possibilities to enhance the interactivity, personalization, accessibility, and integration of decision aids into routine care.

Acknowledgments

We would like to thank Ruth Wong for her valuable input to help conduct the searches for this review. The authors attest that there was no use of artificial intelligence in the generation of text, figures and other information. This research was funded by the National Institute for Health Research (grant NIHR302489).

Data Availability

All data generated during this study are included in this published article and Multimedia Appendices 1-8.

Abstract

Background: In-person nutrition and exercise interventions improve physical function in chronic diseases, yet the acceptability and effectiveness of web-based delivery, especially with different levels of personnel support, require further investigation.

Objective: This study aims to evaluate a web-based nutrition and exercise intervention delivered entirely digitally from recruitment to trial completion.

Methods: A randomized controlled trial was conducted using the Heal-Me version 1 platform across 2 levels of personnel support (Light and Intensive). Eligible adults with a history of cancer, chronic lung disease, or liver or lung transplant; internet access; and prior participation in a rehabilitation program were enrolled in a fully web-based program to minimize barriers to exercise participation. Participants were randomly assigned (1:1:1) to 1 of 3 study groups. The control group received a detailed, self-directed digital nutrition and exercise guide. The Heal-Me Light group received the web-based intervention alongside dietitian and exercise specialist–led group classes. The Heal-Me Intensive group received web-based intervention, group classes, and one-to-one sessions with the dietitians and exercise specialists. All participants received a wearable activity tracker. The primary acceptability outcome was adherence to the intervention based on a priori targets. The primary effectiveness outcome was the change in Lower Extremity Functional Scale (LEFS) score. Secondary outcomes included physical function tests, which were performed and measured by videoconference. Questionnaires were used to assess well-being, quality of life, and food intake. Analyses adhered to the intention-to-treat principle.

Results: Of 216 participants, 202 (93.5%) completed the intervention (mean 61, SD 11 years; female: 130/202, 64.4%; cancer: 126/202, 62.4%). Adherence exceeded a priori targets, with 82% (105/128) attending >75% of the program elements including postintervention tests. Participants rated the program as “quite a bit” or “very” useful, with similar ratings between Heal-Me Light

XSL•FO
RenderX

(56/64, 88%) and Heal-Me Intensive (51/58, 88%) groups (*P*=.69). No significant differences were found for changes in LEFS scores (control: mean 0.8, SD 7.7; Heal-Me: mean 0.3, SD 6.6; *P*=.53). Significant benefits were found in favor of the combined Heal-Me intervention groups versus controls for change in the 2-minute step test, World Health Organization-5 Well-Being Index, Short-Form-36 general, physical health role, energy or fatigue scales, and protein intake. While the change in physical function was similar between the 2 intervention arms, the more intensive one-to-one interaction (Heal-Me Intensive) led to greater improvements in perceived nutrition self-management. No serious adverse events occurred.

Conclusions: The demonstrated satisfaction, adherence, and effectiveness highlight the high acceptability of a web-based, semisupervised nutrition and exercise intervention delivered entirely digitally in individuals with chronic disease. Future studies may benefit from having a baseline physical function inclusion threshold, the use of a more sensitive primary physical function measure, and a higher intensity digital exercise intervention in exercise-experienced participants.

Introduction

Impairments in physical function and physical performance are common in individuals living with serious chronic conditions. Although these impairments increase the risk for morbidity and mortality, they are potentially modifiable with nutrition and exercise rehabilitation [1]. During the COVID-19 pandemic, rehabilitation interventions that were traditionally delivered in person were rapidly transitioned to web-based delivery due to lockdowns and social distancing policies. At the pandemic's onset, limited data were available to guide the feasibility, safety, and effectiveness of delivering digital nutrition and exercise therapy, and standardized protocols for conducting web-based evaluation of physical function were lacking. Internet-connected digital platforms, such as web-based apps, while offering promise for the scalable delivery of multimodal supportive care interventions, have been associated with poor adherence and retention [2]. Moreover, little information was available to guide how much personnel support was needed to optimize app usage in older patient populations living with chronic disease.

In 2019, our research team co-designed a web-based app ("Heal-Me") with people living with chronic debilitating diseases, including cancer, cirrhosis, and lung disease [3]. Version 1 of the app was used in this study and is described in more detail in the protocol paper, which includes illustrations of user interface and app features [4]. The Heal-Me web-based app facilitates semisupervised nutrition and exercise programming tailorable to the unique needs of each patient user. It includes nutrition content—a daily protein tracking system, high protein recipes, and cooking videos; exercise content—customizable follow-along exercise videos and autotracking of videos watched; and a calendar for scheduling and accessing web-based group classes and one-to-one check-ins. To guide behavior change, the capability, opportunity, and motivation behavior (COM-B) model and the theoretical domains framework were used as part of the development of the Heal-Me intervention to provide progress tracking, demonstration videos, and graded tasks [4].

With the availability of Heal-Me, this randomized controlled trial (RCT) was designed in response to COVID-19 to answer questions about the acceptability and effectiveness of a personnel-supported, web-based nutrition and exercise intervention for individuals with chronic disease. To understand the extent of support needed by patient users, there were 2 intervention arms (digital group classes only vs digital group classes with additional one-to-one support). We hypothesized that increased contact with a dietitian and exercise professional would result in greater acceptability as measured by higher adherence to the program and greater effectiveness as evaluated by the change in score on the Lower Extremity Function Scale (LEFS).

Methods

Study Design

Personalized Online Nutrition and Exercise Routines (PIONEER) was a parallel-group, 3-armed RCT conducted using the Heal-Me web-based program across 12 weeks [4]. The study ran from December 2020 to December 2021, during the COVID-19 pandemic, when Albertan public health policies restricted movement and social interactions. Thus, all trial stages, from recruitment through to end-of-study testing, were performed in a completely digital environment, including participant technology training and the collection of data on physical function.

Ethical Considerations

The study was approved by the University of Alberta's Health Research Ethics Board (Pro00103715) and was registered with ClinicalTrials.gov (NCT04666558). Participants provide informed written consent. The privacy and security of the web-based intervention were described previously [4]. There was no monetary compensation provided.

Recruitment

Study advertisement and recruitment were carried out by the digital distribution of recruitment materials by frontline staff

XSL•FO
RenderX

involved in oncology (Alberta Cancer Exercise), pulmonary (Breathe Easy), and posttransplant lung or liver rehabilitation programs (University of Alberta Hospitals) in Edmonton, Alberta. Interested participants were required to contact the research team for further information and eligibility screening. Participants were recruited and enrolled in cohorts that started monthly to facilitate group intervention sessions.

Participants

Inclusion criteria included adults (aged 18 years and older) with an internet-connected device in their home and the ability to read, write, and speak English. Individuals were eligible if they had cancer (completed an initial course of chemotherapy or radiotherapy but could be on maintenance therapy); had undergone a lung or liver transplant; or had chronic lung disease. All had to graduate from an exercise rehabilitation program before the COVID-19 public health restrictions. The requirement of being an exercise graduate reflected concerns over the safety and complexity of participants having to learn exercise in an entirely web-based environment on top of new tasks (eg, wearable device, learning to use the Heal-Me app, nutrition tracking, and participating in home-based digital physical function assessments) all during the time of COVID-19. Individuals were ineligible if they were receiving compassionate care with an anticipated survival of less than 6 months, had unstable disease status, or were unable to provide informed electronic consent.

Randomization and Masking

Allocation tables were generated, validated, and uploaded to the REDCap (Research Electronic Data Capture; Vanderbilt University) information system [5] by an independent statistician. Stratification was based on chronic disease status: cancer, lung, or transplant. Randomization was in a 1:1:1 ratio:

- Control (self-directed, digital nutrition and exercise guide)
- Heal-Me Light (Heal-Me app and digital group sessions led by Heal-Me trainers—trainers defined as a registered dietitian and certified exercise specialists including a physiotherapist)
- Heal-Me Intensive (Heal-Me app, digital group sessions, and one-to-one meetings with trainers)

Allocation was concealed from all study staff. The end-of-trial independent assessor was blinded to the participants' group allocation.

Procedures

Prerandomization Procedures

Web-based activities included advertisement; recruitment; obtaining consent; patient screening; and data collection, including demographics, socioeconomic status, health-related information (eg, medications and comorbidities), and other questionnaires. Outlined in more detail in the protocol [4], the questionnaires included LEFS [6], a validated 20-question survey to assess functional changes in the hip, thigh, knee, leg, ankle, and foot; Physical Activity Readiness Questionnaire [7]; technology proficiency with an internet-connected device (either Computer Proficiency Questionnaire [8] or Mobile Device Proficiency Questionnaire [9]); Unified Theory of Acceptance and Use of Technology [10]; and the Upper Extremity Functional Index-15 [11]. Additional questionnaires were the World Health Organization-5 (WHO-5) Well-Being Index, Generalized Anxiety Disorder-7 [12], De Jong Gierveld Loneliness Scale [13], Short-Form Survey 36-items [14], and self-reported physical activity. The 3-day food records (1 weekend day and 2 weekdays) were completed and emailed to the study coordinator, verified for accuracy by a registered dietitian or dietetic intern, and nutritional intake was analyzed using the FoodProcessor software (version 11.7 .1; ESHA Research). Behavioral beliefs were assessed using the 6-item 0-10 Likert scale for the COM-B [3]. Web-based physical function testing, led by a certified exercise specialist, included the 30-second and 60-second chair sit-to-stands; 1-legged balance; 2-minute step test; shoulder flexion range of motion for left and right sides; and optional tests (if the participants were able and willing), including the chair sit-and-reach and plank test. Height and weight measures were recorded based on patient self-report.

Postrandomization Procedures

Participants were randomly assigned and allocated to 1 of 3 study arms after completing the baseline measures. All participants received a wearable activity tracker (Garmin Ltd) to monitor daily step counts, moderate- to vigorous-intensity physical activity minutes, and digital assistance with setup. The self-directed control group received a 52-page manual containing illustrated exercise routines at 3 levels and nutrition guidance (Alberta Health Services and Canada's Food Guide).

Participants in the Heal-Me Light and Heal-Me Intensive interventions had three web-based sessions as detailed in the protocol [4]: (1) an introduction to and instruction in the use of the Heal-Me app; (2) a dietitian-led nutrition assessment, review of nutrition preferences, and the setting of a protein goal target in the app (1.2-1.5 g/kg/day based on guidelines [15-17]); and (3) a certified exercise specialist–led review of home space for exercise, review of exercise preferences, and setting up of an individualized program in the app. While the focus of nutrition counseling was on protein intake, a condition-specific, guideline-based target for daily caloric intake of 25-30 kcal/kg/day was also presented in the app, and counseling was provided about eating a balanced plate [15-17]. Recognizing the limited data supporting the safety of digital exercise, the certified exercise specialist started all participants at a low-intensity level for exercise. Participants were asked to complete 45-60 minutes of exercise sessions 3 times a week (2 independent sessions and 1 certified exercise specialist–led, web-based group class), track protein intake for 3 days each week, and attend 5 web-based group nutrition classes over the 12-week study. Heal-Me Intensive participants also received one-to-one check-ins with the dietitian (2×, 20-30 minutes) and certified exercise specialist (5×, 20-30 minutes) over the 12-week study period.

After completing the 12-week trial, participants repeated web-based physical function assessments, anthropomorphic measures, questionnaires, and 3-day food records and completed the study satisfaction survey.

Study Objectives

Acceptability

This was comprised of adherence rate and satisfaction. Our primary acceptability outcome was adherence, which was defined as completing more than 75% of the group nutrition and exercise sessions and completing all end-of-study outcomes. Satisfaction was collected from the end of the study program experience and satisfaction questionnaire. Two questions inquired about whether intervention participants felt prepared to continue their nutrition and exercise activities after program completion. Using a 5-item Likert scale (from 1=not at all to 5=very much), participants were asked "Do you feel that the PIONEER nutrition program has prepared you to reach your target protein goal on your own?" and "Do you feel that the PIONEER exercise program has prepared you to reach your exercise goal on your own?" Technology acceptability was evaluated with the Unified Theory of Acceptance and Use of Technology and will be presented in a follow-on publication.

Effectiveness

This was comprised of a battery of objective outcomes including physical function tests and physical activity, and self-reported outcomes including quality of life. Our primary effectiveness outcome was the change in LEFS score from baseline to 12 weeks between the control and combined intervention arms. Secondary objective effectiveness outcomes included the 12-week change in objective physical function comparing the control and intervention groups for the 2-minute step test, chair sit-to-stand (30 and 60 seconds), plank, shoulder range of movement, and 1-legged balance. Step count and moderate- to vigorous-intensity physical activity minutes for weeks 2 to 11 were averaged for each week. Data from weeks 1 and 12 were not considered because postal delivery and setup of the device often extended into the first week, and device return occurred at the end of week 12. Secondary self-reported effectiveness outcomes included Upper Extremity Functional Index-15, mental health, and quality of life (ie, WHO-5 Well-Being Index, Generalized Anxiety Disorder-7, De Jong Gierveld Loneliness Scale, and Short-Form-36). Adverse events were recorded by study staff.

Exploratory Outcomes (Baseline and 12 Weeks)

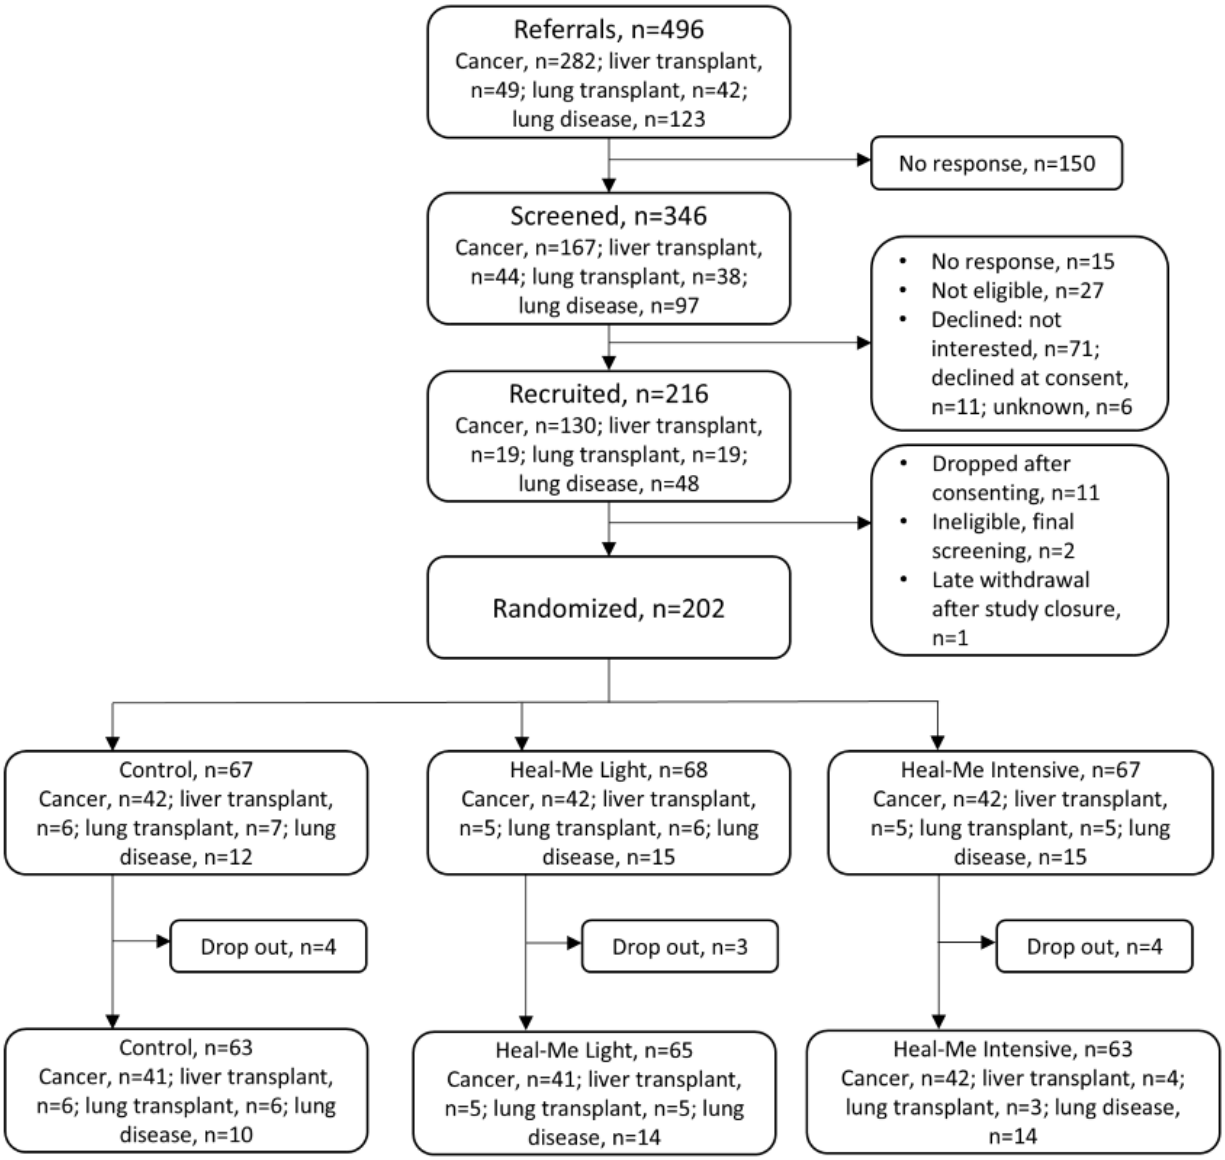
Changes in daily calorie, protein intake, and the proportion of participants reaching target protein intake (>1.2 g/kg/day protein based on ideal body weight using a BMI of 24.9 kg/m^2) were evaluated. The COM-B scale assessed changes in behavioral beliefs, with data planned for presentation in a future publication. For physical activity, the validated Single Item Physical Activity question was used, where participants were asked "In the past week, on how many days have you done a total of 30 minutes or more of physical activity, which was enough to raise your breathing rate?" [18]. Additionally, we explored results comparing the highest and lowest quartiles of baseline function for the 2-minute step test.

Sample Size

The sample size and statistical analysis plans are presented in detail in the protocol [4]. The primary analysis used the ANOVA model to assess the difference in the LEFS scores between the 3 study groups. To preserve type 1 error in 3 between-group comparisons, the α was adjusted by the Bonferroni correction. Thus, with a 2-sided α=.05 (.0167 adjusted for multiple comparisons) and β=.20 (80% power), 60 participants per group (180 in total) were estimated to be required to determine a statistically significant difference for a moderate (0.6) Cohen *d* effect size (minimal clinically important difference of 9 points [19]). To account for a conservative 20% dropout rate, the total sample size was increased to 216 (n=72 per arm).

Statistical Analysis Plan

The intention-to-treat principle was used for all analyses. Descriptive statistics were used to understand the participants' characteristics and outcome variables. The between-groups comparison was analyzed using ANOVA (or its nonparametric alternative) and the Tukey honest significant difference test for pairwise comparisons using a familywise α of .05. The primary analysis, the LEFS score, was then analyzed by linear mixed models with random effects, which were adjusted for the baseline score (T1) as a covariate [20,21]. A 3-group comparison was planned only if the combined 2-group comparison was significant. Exercise adherence rates (proportion completing 80% of exercise sessions over the study) and dietary protein adherence rates (proportion meeting 80% of target intake over the study) were compared between study groups by the chi-square test. The differences in the frequency of adverse events were assessed using the chi-square test. Linear regressions were constructed to determine clinically significant outcomes, adjusted for sex, age, and comorbidity status; group assignment was an independent variable. Missing data resulted in listwise deletion of the cases. Analyses were performed using either SAS (version 9.4 or later; SAS Institute) or SPSS (version 28 or later; IBM Corp).



Results

Participant Characteristics

The 202 participants (Figure 1) were recruited over 10 months, and none were screened out for unstable disease. They had a mean age of 61.0 (SD 11.1) years and 64.4% (130/202) were female. At baseline, 83.2% (168/202) attended postsecondary education, and 44.5% (90/202) earned more than CAD $80,000 (US $ conversion rate for 2023: US $1=CAD $1.3497) per annum (Table 1). The most common chronic condition was cancer (126/202, 62.4%), while the least common was liver transplantation (16/202, 7.9%). The level of comorbidity was high, with a mean Charlson Comorbidity Index of 4.6 (SD 2.0), and the mean BMI was 28.4 (SD 6.2) kg/m^2. The mean technology proficiency measured with the Computer Proficiency Questionnaire and Mobile Device Proficiency Questionnaire was 88.7% (SD 14.9%).

Study Objectives

Acceptability

The completion rate for the study was 94.6% (191/202), and the mean attendance for arms 2 (n=66) and 3 (n=62) combined was 78.6% for the 5 group nutrition classes, 88.5% for the 12 group exercise sessions, and 78.8% for the home exercise videos, with no statistically significant differences (*P*=.84, *P*=.64, and *P*=.67, respectively) between the 2 intervention arms. In response to the statement "Completing the PIONEER program helped me to meet my health and wellness goals," 82.8% (101/122) of participants in Heal-Me Light and 90.2% (110/122) of participants in Heal-Me Intensive answered "quite a bit" to "very much" (2 of the 5 highest categories), with no significant difference between arms (*U*=1920; *z*=0.41; *P*=.69). Although staff services were scored as "excellent" (97/122, 79.5%), participants in Heal-Me Intensive scored staff services statistically significantly higher than participants in Heal-Me Light (*U*=2209; *z*=2.57; *P*=.01). At the end of the study, when participants were asked if PIONEER had prepared them to reach their exercise and protein goals after program completion; for exercise, 81.1% (99/122) responded either "quite a bit" or "very much," and for nutrition, 82.6% (100/121) responded either "quite a bit" or "very much." Those in Heal-Me Light (mean rank 53.6) reported significantly less preparedness to reach their daily protein intake than those in Heal-Me Intensive (mean rank 69.3; *U*=2298; *z*=2.66; *P*=.008). No significant difference between interventional groups was found regarding achieving exercise goals (59.6 vs 63.7; *P*=.495). Overall, participants reported that their program was "quite a bit" or "very" useful (top 2 out of 5 categories) for Heal-Me Light (56/64, 88%) and Heal-Me Intensive (51/58, 88%; *U*=1920; *z*=0.41; *P*=.69). Most participants would recommend the program either "quite a bit" or "very much" (top 2 out of 5 categories) to others living with a chronic disease (Heal-Me Light: 59/64, 92% and Heal-Me Intensive: 57/58, 98.3%; *U*=1843; *z*=–1.00; *P*=.92). More generally, when asked about the perceived burden of doing the web-based physical function assessments, 73.8% (90/122) reported "no burden at all."

Effectiveness

Primary Effectiveness Outcome: LEFS

The baseline LEFS scores for the control and Heal-Me groups were 63.6 (SD 13.9) and 62.9 (SD 14.5), respectively. The difference of –0.53 (95% CI –2.7 to 1.7) was not statistically significant between groups for self-reported physical function, even when analyzed by the disease group (Table 2 and Table S1 in Multimedia Appendix 1).

[a]Adjusted for age, Charlson Comorbidity score, and baseline value.

[b]LEFS: Lower Extremity Functional Scale.

[c]*P*<.001 between-group improvement from T2 to T1.

Secondary Objective Outcomes

A statistically significant, between-group difference was found in favor of the intervention for the 2-minute step test (*P*<.001). Details on the web-based assessed changes in physical function outcomes are presented in Table 2 and Table S1 in Multimedia Appendix 1. The intervention and control groups had similar step counts and moderate- to vigorous-intensity physical activity minutes as measured by the wearable activity tracker (Figures S1 and S2 in Multimedia Appendix 1).

Secondary Self-Reported Outcomes

Changes in the WHO-5 Well-Being Scale (*P*=.02) and the Short-Form-36 general health (*P*=.04) were statistically significantly different between the control and combined intervention arms according to 2-tailed independent *t* tests (Table 3; Table S2 in Multimedia Appendix 1).

Adverse Events

No serious adverse events occurred during the trial. However, 33 minor health or musculoskeletal complaints (eg, muscle pain) were reported among participants in the 3 study groups (control: 10/33, 30.3%; Heal-Me Light: 11/33, 30.3; Heal-Me Intensive: 12/33, 39.4%; *P*=.71). A total of 21 (63.6%) adverse events were reported as "clearly unrelated," 5 (15.1%) as "possibly related," and only 5 (15.1%) as "related" to study participation.

Exploratory Outcomes

A total of 144 (71.2%) participants had a 3-day food record completed at both baseline and the end of study. Analysis of the food records showed that protein and calorie intakes increased in the Heal-Me intervention arms (Heal-Me Light and Intensive) compared to controls (Table S3 in Multimedia Appendix 1). After adjusting for age and comorbidity, the between-group improvements from baseline were presented as mean differences (95% CI) for calories, 246 kcal/kg/d (95% CI 57-436), and protein, 22.8 g/kg/d (95% CI 12.5-33.1). The proportion of participants at goal protein intake (1.2 g/kg/d) at baseline was 53% (23/43) in the control group and 37.6% (38/101) in Heal-Me. By week 12, a total of 53.5% (23/43) of the control group and 81.2% (82/101) of participants in Heal-Me had reached the target protein intake (*P*<.001). Similar proportions of participants in Heal-Me reached the target protein intake (*P*=.53).

In our exploratory analyses of the lowest and highest quartiles of the 2-minute step test, a significant difference was found in favor of Heal-Me Light and Intensive (Figure S3 in Multimedia Appendix 1). For the lowest quartile of participants, the mean difference between the control and intervention groups for the 2-minute step test was 26.3 steps (95% CI 2.24-50.4; *P*=.03) favoring the intervention, as compared to 5.8 steps (95% CI –0.88 to 12.37; *P*=.09) in the highest quartile (Figures S1 and S2 in Multimedia Appendix 1).

Discussion

Principal Findings

To the best of our knowledge, this is the largest, 3-armed, semisupervised nutrition and exercise RCT that has been completed entirely on the web from recruitment to end-of-trial assessments. Acceptability was high across both adherence and satisfaction measures, but the primary effectiveness outcome of self-reported lower extremity function was not significantly different between groups. Statistically significant improvements were found in the Heal-Me intervention for the 2-minute step test, well-being, quality of life, and the proportion of participants reaching target protein intake. Notably, the trial was conducted at a unique time point in our history, against a background of COVID-19 community lockdowns and its associated uncertainties, as well as at the beginning of a now increasing number of studies [22] that are leveraging app-based technologies to support nutrition and exercise interventions.

Acceptability, a primary objective of this study, was met with high rates of adherence and satisfaction. The adherence rate of 82% (105/128) exceeded our a priori level of 75% and is particularly noteworthy given the complexity of the intervention in combination with its fully web-based delivery and evaluation. An in-person prehabilitation intervention of similar complexity (exercise, nutrition, smoking cessation, and psychological support), albeit only 4 weeks in duration, reported that 77% of their 251 participants completed at least 75% of their exercise sessions [23]. In contrast, fully digital prehabilitation interventions have met with lower rates of adherence. In a 4-week digital prehabilitation nutrition and exercise app for colorectal cancer, only 56% (127/227) of participants met the adherence metric of being accessed at least once during the study [24]. In another app-based study of liver transplant candidates (n=31; mean 61, SD 7 years), all received weekly telephone support from a remote physical activity coach during a 12-week physical fitness app intervention [25]. Despite the one-to-one engagement with a trainer, 57% (18/31) of the participants were considered adherent. Consistent with these adherence challenges, a review of supervised and unsupervised mobile health interventions reported an overall adherence of only 56% (55/99), 49% (49/99) for nutrition apps, and 55% (54/99) for physical activity apps [2].

The reasons for the high adherence rates in this study are likely multifaceted. The concept of Heal-Me began with a patient focus group followed by regular interactions with patients and providers, usability or user experience testing, and a pilot study in multiple myeloma, all of which helped shape the app's design, content, and program delivery [3,26]. While there is limited evidence describing the impact of co-design on experimental outcomes, the acceptability and adherence of the Heal-Me app are at least partially attributable to patient and provider involvement across all stages. Moreover, the app included many of the features inventoried in 2 recent systematic reviews for promoting adherence and satisfaction, including ease of use, access to health care information, real-time supervision and monitoring, as well as personalization and automated reminders for calendar events [2,27].

The effectiveness of the intervention was our second objective. The primary outcome of LEFS score was nonsignificant when compared to the control group. Although this may represent a

XSL•FO
RenderX

true lack of effectiveness of multimodal intervention, the lack of significance may also be due to the choice of the LEFS as the primary physical function outcome measure. As a web-based tool, it was selected because of its wide use in populations with musculoskeletal conditions [28] and its association with quality of life, the 6-minute walk test, and clinical outcomes including hospital admissions and falls [4]. As such, during COVID-19, it provided a suitable option over more commonly administered, in-person physical function tests. The normative score of the LEFS is 63 for both male and female individuals aged 60-64 years, with a maximum value of 80 and a minimal clinically important difference of 9 points [28]. In this study, the LEFS score at baseline was already at a mean level of 63 (SD 14.1; n=202), potentially creating a ceiling effect that may have impacted the potential for improvement [23]. Objective measures of physical function are seen as more sensitive indicators of functional abilities [29] and were assessed at baseline and the end of study digitally as secondary outcome measures. A significant between-group difference was found for the 2-minute step test. Of note, unlike the LEFS, this test may have been more sensitive to change as baseline values were more compromised, in the range of the 25th-50th percentile of adults aged 60 to 64 years. In our exploratory analysis of the 2-minute step test, a significant between-group difference was found when comparing results from the lowest and highest quartiles, suggesting primary benefit for those with lower physical functioning, and pointing to future rationale for stratifying inclusion by baseline physical function.

Compared to the control group, the combined intervention group showed statistically significant benefits in some of the quality-of-life measures, which remained when adjusting for age, comorbidity, and baseline values. While the overall sample was comprised of individuals motivated to participate in a nutrition and exercise–supported, web-based program, the average step count, physical activity minutes, and protein intake across groups still fell below the levels recommended by current Canadian public health guidelines [15-17,30].

The study included 2 intervention arms for which we hypothesized that given sufficient statistical power, increased contact with a dietitian and exercise professional would demonstrate greater acceptability and greater effectiveness. The group and one-to-one sessions required a weekly time commitment of approximately 80 minutes in Heal-Me Light and 100 minutes in Heal-Me Intensive in addition to the nutrition tracking and independent exercise. Despite lengthy time commitments, there were similarly high rates of satisfaction and adherence in both groups. This suggests that access to the app and group sessions may have been sufficient to drive acceptability. Unfortunately, the limited differences in the effectiveness outcomes between the intervention and control groups made it impossible to assess the impact of the different levels of personnel support on these measures. While regular interactions with staff and progress monitoring have been previously identified as beneficial facilitators in studies, including those for cardiac telerehabilitation [31] and upper gastrointestinal cancer surgery [32], future studies are encouraged to explore the level of personnel interaction that maximizes participant acceptability and effectiveness.

While adequately powered, the short duration of the study in combination with the heterogeneity across multiple chronic diseases of participants may have contributed to the lack of difference in mean values between the study groups. Furthermore, while biases in self-reporting may have resulted due to social desirability between the participant and staff members, the digital nature of the survey tools was used to minimize bias [33].

This RCT adds to accumulating evidence showing that web-based physical function measures are feasible to conduct. While some data are available to suggest minimal differences between in-person and web-based measures, their validity remains uncertain. In 2023, Heslop et al [34] reviewed 17 studies comparing digital to in-person physical performance test results in older adults. In the 9 studies that assessed digital compared to in-person results, accuracy was reported as “good” (≤5% difference) in 6 studies, “moderate” (5%-10% mean difference) in 2 studies, and “poor” (>10% mean difference) in 1 study. Studies by Guidarelli et al [35] (n=176) and Hoenemeyer et al [36] (n=112) found moderate to strong agreement between remotely evaluated tests with in-person testing. While participants in our study reported little burden with the web-based testing (10% found it “somewhat” or “quite a bit” burdensome), additional certified exercise specialist staff were required to support digital exercise classes for safety. For the web-based physical function tests, two research team members were needed: one to manage the technology (eg, camera view, sound) and lead the test, and the other to score the test.

Limitations

A key limitation of the study was participant selection. Although carried out with sound rationale, we limited enrollment to participants who had graduated from an exercise-based rehabilitation program for their respective chronic diseases. The history of previous exercise participation is associated with self-effectiveness, competence, and adherence to exercise interventions [37,38]. The step count and moderate- to vigorous-intensity physical activity minutes were similar for the intervention and control groups, suggesting a similar degree of physical activity in the control group [39]. Potential contributors that facilitated the control arm exercise were baseline experience with exercise, the provision of an extensive 52-page nutrition and exercise handout, and a wearable activity tracker; the latter are known to increase step count outcomes in adults over the short term [40]. Despite this contamination, improvements were seen in favor of the Heal-Me–supported programming for self-reported health and quality-of-life measures.

Regarding the nutrition component, while significant improvements were seen in target protein intake, verification of the food records was a time-consuming task and frequently involved patient contact for clarification or additional information. Also, challenges were noted with participants submitting their 3-day food records, with only 71.2% with complete records both at baseline and the end of study, suggesting the need to explore additional forms of tracking in future studies [41]. In addition, a completely web-based exercise testing and intervention delivery model was a new experience

XSL•FO
RenderX

for our team. Our digital exercise programs, in retrospect, erred on the side of safety regarding intensity and duration, and for this group of experienced participants, may have been too conservative. Given the multiple secondary outcomes, we acknowledge the potential for type 1 errors. Finally, because of the limited differences seen in outcomes between the intervention and control groups, we were unable to assess the impact of the different levels of personnel support, a factor of interest in future studies.

The Heal-Me PIONEER acceptability and effectiveness trial offers many learnings. As a large trial completed fully digitally during a unique period in our history, it demonstrates the feasibility of rapid recruitment, web-based testing and intervention, and high acceptability and adherence rates among a mixed population with chronic conditions. A comprehensive battery of tests was performed, providing reference points for future studies using the same measures. We also offer considerations for modifications based on our learnings, including stratification for physical function; the selection of a more sensitive objective physical function measure; and the provision of a more tailored, higher-intensity, web-based exercise intervention. In this burgeoning age of digital health, characterized by an increasing reliance on digital assessments and rehabilitative interventions, our findings underscore the feasibility of widespread implementation of nutrition and exercise programming, alongside high participant acceptability and adherence.

Acknowledgments

Funding for this study was provided by a COVID-19 grant from Alberta Innovates Health Solutions. The authors are grateful to all patients who participated in the trial. Study design, all aspects of data management (collection, analysis, and interpretation), and manuscript writing were completed independently of the funding agencies. The co-senior authors (MLM and PT) had full access to the data and were responsible for the manuscript content and the submission decision.

Data Availability

The datasets generated during and/or analyzed during this study are not publicly available due to data sharing policies but are available from the corresponding author on reasonable request.

Authors' Contributions

Conceptualization study funding was acquired by MLM and PT. All authors contributed to data collection. The formal analysis was completed by KPI, PT, MLM, and MY. The original draft was co-written by KPI, MLM, and PT. All authors reviewed the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Digital cognitive training (DCT) has been found to be more effective than traditional paper-and-pencil training in enhancing overall cognitive function. However, a significant barrier to its long-term implementation is that older adults with mild cognitive impairment (MCI) do not continue to use it or even show a dropoff in usage after the initial engagement. Such short-term engagement may limit the potential benefits of DCT, as sustained use is required to achieve more pronounced cognitive improvements. Exploring the reasons for the shift in discontinuous usage behavior is crucial for promoting successful DCT implementation and maximizing its positive effects.

Objective: This study aimed to explore the intrinsic reasons for the transition from initial acceptance to discontinuous usage behavior among older adults with MCI throughout the DCT process, by employing the extended model of IT continuance (ECM-ITC).

Methods: We employed a qualitative research methodology and conducted 38 semistructured interviews before and after the use of DCT (3 times per week over 1 month, with each session lasting 30 minutes) with 19 older adults with MCI (aged 60 years or older) and 4 family members between January and March 2024. Thematic analysis and deductive framework analysis were used to identify the reasons for the discontinuous usage of DCT, with mapping to the ECM-ITC.

Results: Most participants failed to complete the standard dosage of DCT. Data analysis revealed the reasons for the shift to discontinuous usage. Despite their need to improve cognitive function, participants found the cognitive training confusing and discovered that DCT did not align with their preferred method of training upon actual use. The disparity between their vague expectations and reality, combined with the contradiction between the “delayed gratification” of DCT and their desire for “immediate gratification,” made it difficult for them to discern the usefulness of DCT. Participants also viewed DCT as an additional financial burden and tended to avoid training under family pressure. They relied on motivational measures, which further weakened their intention to continue DCT, ultimately leading to the inability to develop continuous usage behavior.

Conclusions: Continuous usage behavior differs from initial acceptance as it evolves dynamically with user experience over time. To encourage older adults with MCI to persistently engage with DCT, it is essential to not only thoroughly consider their genuine preferences and the potential disruptions DCT may bring to their lives but also bridge the gap between expectations and

XSL•FO
RenderX

actual experiences. While ensuring that older adults receive appropriate external incentives and encouragement, it is equally important to foster their intrinsic motivation, thereby gradually cultivating the habit of sustained DCT usage.

digital cognitive training; discontinuous usage behavior; acceptance; mild cognitive impairment; qualitative study

Introduction

Cognitive dysfunction has become a major challenge in global health and social care, with progression to dementia being difficult to reverse [1,2] and imposing substantial disease and economic burdens on individuals, families, and society [3,4]. Mild cognitive impairment (MCI) is a transitional state between healthy cognition and early dementia [5]. Early and effective cognitive training can significantly delay or even reverse cognitive damage, with a reversal rate of up to 26% [6]. This stage is currently the optimal and critical window for cognitive intervention to prevent dementia [7,8].

In recent years, digital cognitive training (DCT), as an emerging training program, has proven more effective in enhancing cognitive functions than traditional paper-and-pencil training [9]. DCT provides personalized training in different cognitive domains based on the performance of older adults, breaking through temporal and spatial constraints. With its convenience, cost-effectiveness, and low operator requirements, DCT is increasingly becoming a preferred alternative [10-12]. In the United States, after the US Food and Drug Administration launched a digital software precertification program in 2017, digital products for cognitive behavioral therapy have been approved [13]. Meanwhile, in China, training software for cognitive dysfunction was approved for the market in 2021 [14], further propelling the development of DCT as a cognitive therapy tool. Millions of older adults have used DCT at home [15], and through digital brain training, they can not only effectively improve cognitive function [16,17] but also reduce the long-term risk of dementia [18].

DCT has shown potential benefits in maintaining cognitive function among older adults and has been applied to prevent and delay cognitive decline in patients with MCI due to its advantages of ease of operation and low cost [19]. Regrettably, significant challenges, such as user attrition, low training completion rates, and weak intentions to continue use, persistently impede its widespread adoption. Over 25% of users reduce participation frequency or drop out of training altogether [20,21], and a striking 52.8% fail to meet the prescribed dosage of cognitive training compliance [22]. After a period of use, compliance and retention rates among some older adults gradually decline [23], with less than 30% of participants completing more than half of the training content [21,24]. Even if older adults with MCI have a positive experience after their initial use of DCT, the intention to continue using it in the future diminishes significantly [25], and they do not continue to use it after the intervention ends [26,27]. More critically, the notable benefit enhancements of DCT largely depend on the long-term continuous use of the training by older adults. Noncompliant behavior not only undermines the potential training effects of DCT [28] but also leads to substantial wastage of medical resources.

Addressing this issue, previous research [29,30] has primarily focused on analyzing the factors that influence older adults' use or nonuse of DCT after an intervention, treating it as an instantaneous, one-off action. Consequently, low DCT utilization rates are often attributed to older adults' anxiety about using technology [29], inadequate computer experience [29,31,32], low self-efficacy regarding digital technology [31,32], and inevitable physical decline [33]. Although some scholars have explored the factors affecting the adoption of DCT from the perspectives of health care providers and family members, the explanations have largely been from a structural societal perspective, clarifying why there is severe noncompliance with DCT in practice, such as nursing staff shortage [34,35], inadequate senior management support and attention [34], caregivers' lack of game technology skills [34,35], and insufficient family supervision [22,36]. These studies have to some extent elucidated the difficulties and barriers encountered in the dissemination of DCT, yet they have overlooked the fact that DCT usage is not a static one-time action but a continuous dynamic process. Moreover, they have not considered the perspectives of older adults with MCI and have not interpreted the behavior of older adults with MCI using DCT throughout the intervention and within their social environment in a phased manner. Within the scope of our literature review, there are currently limited studies on the phases of nonuse and continued use of digital technologies by older adults [26,37]. The troubles and negative impacts of DCT at different stages of use on older adults with MCI, as well as the intrinsic reasons for transitioning from initial acceptance to discontinuous use, have not been adequately explored.

Therefore, from the perspective of this study, continuous and effective usage is key to the successful implementation of DCT programs. We adopted the extended model of IT continuance (ECM-ITC) and conducted qualitative interviews to better understand the reasons behind the shift from acceptance to discontinuous usage among older adults with MCI at different time points before and after using DCT. This model is a representative theoretical framework for exploring individuals' continuance intentions and behaviors [38], providing in-depth insights into the formation processes and motivations of continuous usage behavior in the digital technology domain [39]. Continuance intention, a critical driver of long-term technology use, depends on users' perceived usefulness of the system and their satisfaction with its use, both of which are influenced by the degree of expectation confirmation. Consequently, this research employs the ECM-ITC to conceptualize the usage of DCT by the MCI population as a dynamic and continuous process. The objective is to understand

XSL•FO
RenderX

the reasons contributing to the phenomenon of discontinuous usage over time during the training process and to delve into the perceptions and actual needs of older adults with MCI and their families regarding DCT usage. By starting from their real-life contexts, we explain the reasons for high attrition rates during the continued use phase and provide decision support to enhance the adoption of intervention strategies.

Methods

Study Design

This was a convergent parallel mixed-methods study in which 2 research teams concurrently collected quantitative and qualitative data. The analysis findings from both methods were integrated when interpreting the results to obtain a more comprehensive understanding of the study results [40]. However, this study focuses solely on qualitative data, aiming to deeply explore the underlying reasons that affect the discontinuous use of DCT from the perspectives of older adults with MCI and their families. For the quantitative aspect, we assessed the effectiveness of DCT through an intervention program involving three 30-minute sessions weekly over a 1-month period. The DCT tool used in this study is a cognitive intervention platform based on a gamified design that aims to improve users' cognitive functions by promoting training in various cognitive domains. This tool covers multiple cognitive areas, including memory, attention, logical reasoning, perception, processing, and executive functions. The DCT tool is accessed through WeChat Mini Programs, the most widely used mobile app in China. Its main features include artificial intelligence chat, gamified training (16 training games with 90 levels each; continuously updated), and progress feedback tracking, providing interactive and timely feedback. Additionally, the gamified training is designed with detailed usage instructions and progressive difficulty adjustments to continuously stimulate cognitive improvement. The qualitative component of our study was based on the ECM-ITC, which provided the framework for developing interview outlines and for organizing and analyzing data [38]. This model serves as a representative theoretical framework that explores the processes and motivations behind individuals' continued use of digital technology [39]. This study conducted semistructured qualitative interviews using an interview guide before and after using DCT. This qualitative research complied with the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines [41].

Patient Recruitment

We employed a purposive sampling method to select participants who satisfied the inclusion criteria and could provide rich information. Eligible older adults with MCI and their family members participated in cognitive screening and DCT at a community health service center in Guangzhou, Guangdong Province. The inclusion and exclusion criteria for both the qualitative and quantitative components of the study were identical. The inclusion criteria for patients were as follows: (1) aged 60 years or older; (2) met the diagnostic criteria for MCI (subjective cognitive decline, such as memory loss, reported by the patient or family member; objective evidence of cognitive decline confirmed using the Mini-Mental State Examination [MMSE] screening tool [cognitive impairment cutoff scores set according to different educational levels [42]: illiterate, <20 points; elementary school, <23 points; secondary school or above, <27 points]; further assessment of participants who tested positive on the MMSE and confirmation by professional geriatricians or neurologists based on the 11th revision of the International Classification of Diseases [ICD-11] [43] and Petersen criteria [44]; essentially normal daily living abilities, although complex instrumental activities of daily living might show slight impairment; and did not fulfill the diagnostic criteria for dementia); (3) possessed a smartphone and was able to use WeChat; and (4) provided informed consent (participation was voluntary). The exclusion criteria were as follows: (1) concurrent other neuropsychiatric disorders, such as epilepsy, stroke, and Parkinson disease; (2) severe cardiovascular or cerebrovascular diseases, malignant tumors, or other major physical illnesses; (3) significant sensory-perceptual disturbances that could affect assessment or training; (4) severe visual or auditory impairments hindering communication; and (5) participation in any other cognitive training studies within the past 6 months. The inclusion criteria for family members were as follows: (1) aged 18 years or older, with clear awareness and the ability to read, understand, and express in Chinese normally; (2) had familiarity with the patient's condition, was involved in daily care, and was capable of decision-making; and (3) provided informed consent (participation was voluntary). The exclusion criterion for family members was a history of severe mental illness or physical disease. Health care providers at the community health service center conducted cross-assessments using both paper-based and digital cognitive screening tools. After review by a psychiatrist, 21 older adults met the inclusion criteria. Subsequently, researchers, with the assistance of the community health service center staff, recruited patients with MCI and their family members through on-site face-to-face or telephone interactions. Ultimately, 19 older adults with MCI and 4 family members agreed to participate in DCT. Two older adults declined to participate due to blurred vision or lack of interest.

Data Collection

Data for this study were collected between January and March 2024, encompassing a total of 38 interviews. We conducted semistructured one-on-one interviews with 19 older adults with MCI and 4 family members both before and after the 1-month intervention period. During the interviews, the older adults and their family members were interviewed independently, each in separate rooms. The interview guide used the same version for all participants, with consistent questions. However, the phrasing of the questions was appropriately adjusted according to whether the respondent was an older adult or a family member, ensuring that the questions were more aligned with their context and level of understanding. The average duration of the interviews, both before and after use, was 21 minutes (ranging from 12 to 80 minutes). The interview questions were formulated based on a literature review and the ECM-ITC framework and were further refined following discussions with the research team, as well as consultations with experts in cognitive impairment screening and management, and qualitative research specialists,

XSL•FO
RenderX

culminating in the finalized interview guide (Multimedia Appendix 1).

At their first offline participation in DCT, patients and their family members who met the inclusion criteria were invited to join a WeChat group managed by health care providers, social workers, and researchers for cognitive training. After setting up the DCT at the end of the interview, we assisted the older adults and their families in accessing the Thoven mini-program training games via a WeChat QR code. We guided them on-site on how to open the WeChat mini-program, operate the training games within the mini-program, interpret the game rules, and check their personal training scores. Finally, we reconfirmed that the participants had learned all the training steps and reiterated the prescribed dosage of the training (3 times a week, 30 minutes each session, for a duration of 1 month). Subsequently, during the DCT process, participants received WeChat group messages from staff twice a week. These messages included rankings of the week's training completion status, encouragement to complete DCT, and real-time answers to older adults' questions to help them persist with the training.

During the first interview (after enrollment but before intervention commencement), 14 of the 19 participants underwent face-to-face interviews in community health service center meeting rooms, clinics, or community senior activity centers. The remaining 5 participants, due to scheduling conflicts, opted for telephone interviews at a convenient time after returning home. The preuse interview questions primarily focused on their perceptions of cognitive decline, expectations for improving cognitive health, and willingness to engage in DCT.

After the 1 month of training, all participants were invited for second interviews (postuse interview). Of the 19 participants, 15 engaged in face-to-face interviews in community health service center meeting rooms, clinics, or community senior activity centers. The remaining 4 participants, due to scheduling conflicts, opted for telephone interviews at a convenient time after returning home. The older adults with MCI and their family members shared their experiences with DCT, while researchers assisted in reviewing their preuse expectations and motivations, and discussed the extent to which actual experiences matched initial expectations, the perceived usefulness of DCT, reasons for either persisting with or dropping it halfway through the process without continuing to use it, and their intentions to continue using it in the future.

All interviews were conducted by 2 interviewers (authors SZ and CC), both of whom had received training in qualitative research and had experience conducting qualitative interviews. All interviews were carried out in Chinese and were audio-recorded with the consent of the older adults and their family members prior to the start of the interviews. The recordings were transcribed verbatim within 2 weeks following the interview. During the interview process, researchers also observed and collected nonverbal data, such as the participants' facial expressions, body language, and emotional changes. Before commencing the second interview, researchers reviewed transcription data from the participants' previous time points to aid in recalling their participation expectations and motivations. Data collection ceased when no new information could be extracted from the analysis of the new interview data, which was achieved after 34 interviews, signifying data saturation.

Data Analysis

Data collection and analysis were conducted concurrently. Deductive thematic analysis was employed to analyze the individual interview data [45]. The coding was carried out using NVivo 12.0 software (Lumivero), and manual coding was performed in Microsoft Excel. The entire analysis process was completed under the guidance of NG and JL. The ECM-ITC was used as the coding framework for categorizing subthemes. First, the first (SZ) and second (MW) authors transcribed the original recordings into text and familiarized themselves with the content through repeated readings. Throughout the analysis, initial codes were independently assigned by repeatedly reading the transcripts, listening to the recordings, and incorporating field notes. These codes were then organized and categorized into corresponding subthemes. Subsequently, the research team, together with NG and JL, reviewed and discussed these codes and subthemes. Next, the first author (SZ), under the guidance of NG, who has extensive qualitative research experience, applied a deductive framework analysis method to construct a thematic matrix in Microsoft Excel. This matrix displayed themes, subthemes, and quotations, mapping the subthemes onto the components of the ECM-ITC framework (expectation confirmation, perceived usefulness, and continuance intention). Finally, the first author and all research team members collectively reviewed and discussed the themes and subthemes until a consensus was reached.

Ethical Considerations

This study meets the institutional requirements for human trials and has been approved by the Biomedical Research Ethics Committee of the School of Public Health, Sun Yat-sen University, China (ethics approval number: 2023-129). Subjects have voluntarily signed informed consent forms. Prior to the interviews, participants received both verbal and written explanations about the study, including its objectives, its methods, the approximate duration and frequency of the interviews, and other details. All participants signed written informed consent forms and were given the right to withdraw from the study at any stage. Data from all participants and institutions have been anonymized. Moreover, this research followed the ethical principles of the Declaration of Helsinki.

Rigor

To ensure that the research findings authentically reflect the perspectives of the participants, we scrutinized and assured the rigor of the data based on the criteria established by Lincoln et al [46], which include confirmability, credibility, transferability, and dependability. The purposive sampling method was employed based on the research objectives and questions to select participants, ensuring the complexity and relevance of the subjects under study, thereby yielding a rich diversity of insights. In addition, the credibility of the research was enhanced by multiple rounds of qualitative data collection. Throughout the study, field notes and memos were used, and a thorough

XSL•FO
RenderX

description of the participants and the data collection process was provided to ensure transferability and dependability. Additionally, the study followed a consistent process and employed the ECM-ITC model framework to guide the design of the interview guides, as well as data collection and analysis, thereby enhancing its dependability. Confirmability was established through the systematic handling of recordings and interview transcripts by 2 researchers and the collaborative discussion of data coding among the members of the research team.

Results

Overview

This study conducted a total of 38 interviews with 19 older adults with MCI and 4 of their family members, both before and 1 month after implementing DCT. The sample size was determined based on the principle of informational saturation. Data saturation was achieved after interviewing 17 participants, and we conducted 2 additional interviews to confirm that no new information emerged from the new data. Interviews were carried out either at the participants' homes or on-site. Due to the inability of some participants to attend in person, 9 interviews were conducted via telephone, while 29 were conducted face-to-face on-site. The mean age of the older adults with MCI was 73.3 years (range 60-90 years). Their characteristics are presented in Table 1.

Among the 19 participants, only 32% (6/19) completed the recommended 90 minutes of weekly training, while 68% (13/19) of respondents used DCT occasionally or even discontinued its use. Detailed variations in the participants' training over the 1-month period are illustrated in Figure 1.

In this study, we analyzed the results based on the ECM-ITC (Figure 2) and identified 3 primary themes that revealed the reasons behind the discontinuous usage behavior of DCT among older adults with MCI: (1) discrepancy between vague expectations and actual training experience; (2) unclear perceived usefulness; and (3) suppressed intention to continue usage.

Table 1. Participant characteristics.

Characteristic	Value
Persons living with mild cognitive impairment (n=19)	
Age (years)	
Mean (SD)	73.3 (7.2)
Range	60-90
Sex, n (%)	
Male	6 (32)
Female	13 (68)
Highest level of education, n (%)	
Elementary school	4 (21)
High school	11 (57)
College or trade school	4 (21)
Living arrangement, n (%)	
Staying alone	6 (32)
Staying with spouse only	6 (32)
Staying with family members	6 (32)
Staying with helper	1 (5)
Medical history, n (%)	
Hypertension	7 (37)
Diabetes	7 (37)

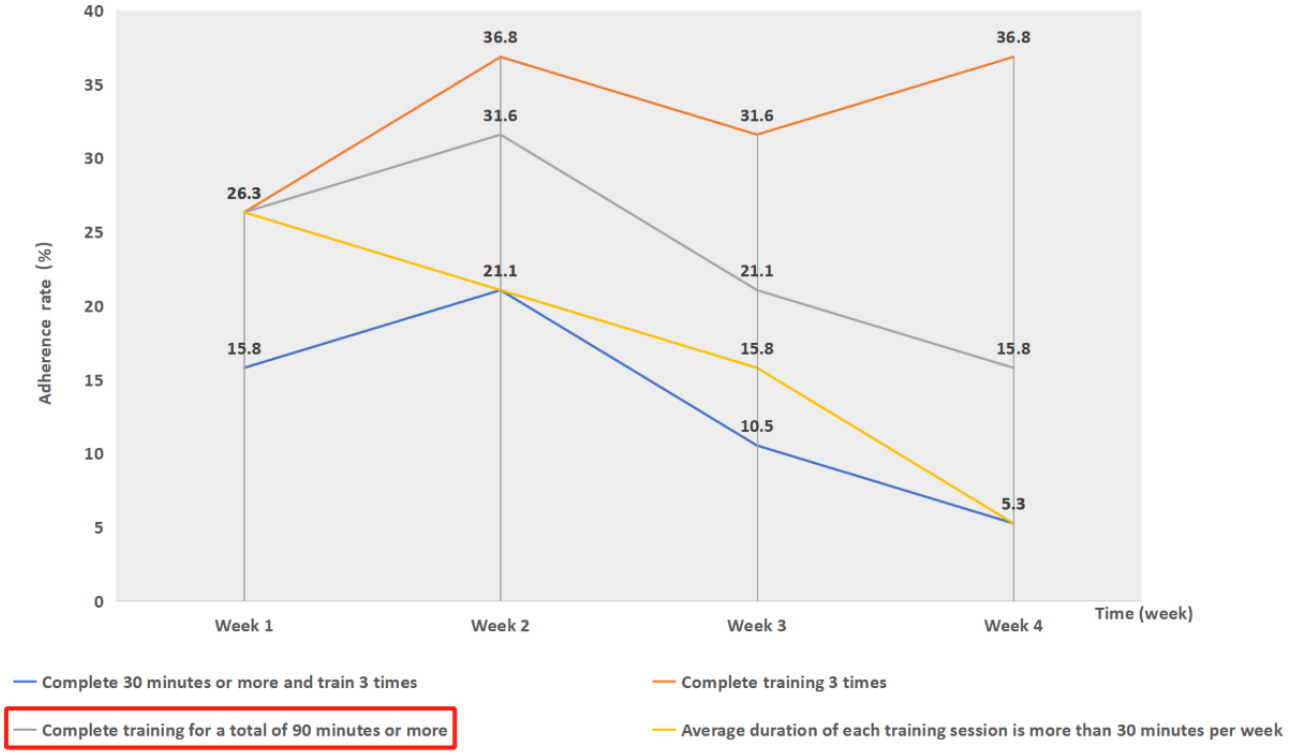

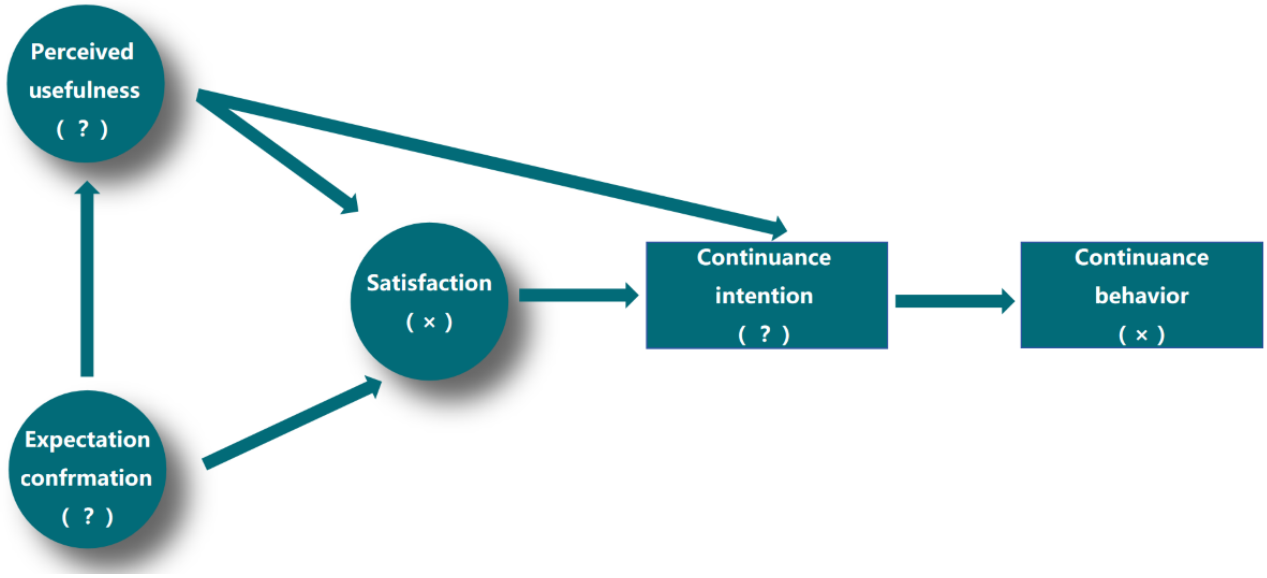

Figure 2. Extended model of IT continuance in digital cognitive training.

Theme 1: Discrepancy Between Vague Expectations and Actual Training Experience

To comprehend the needs of older adults with MCI for DCT, it is crucial to consider the cognitive background and social context in which they live. The majority of participants (14/19, 74%) generally had limited awareness of cognitive impairment diseases and were influenced by misconceptions and prejudices of others regarding cognitive disorders or dementia in their social environment. This led to older adults with MCI needing immense courage to confront discrimination and fear. Cognitive biases and the stigma associated with the disease created confusion in their decision-making process on how to improve memory, causing them to embark on DCT with a sense of bewilderment. However, negative training experiences after use made patients with MCI and their families realize that DCT does not align with their needs. This implies that a greater gap between the ambiguous expectations before using DCT and the actual experience thereafter is associated with a lower level of expectation confirmation. Consequently, over half of the participants (10/19, 53%) expressed reluctance to continue using DCT.

Cognitive Bias and Stigma of Cognitive Impairment

Regarding the issue of memory decline, older adults often held misconceptions. Most respondents (11/19, 58%) regarded

XSL•FO
RenderX

memory deterioration as a normal phenomenon of "aging" rather than a manifestation of disease, thereby failing to fully comprehend the dangers posed by the cognitive impairment:

> *Nowadays, I see that 80% of older adults are forgetful and the brains have degenerated. It's just the way it is when you're old.* [Participant #14, female]

Beyond the barrier of insufficient disease awareness, younger older adults were highly confident in their brain health, firmly believing that the usage of DCT is exclusive to dementia patients and incongruent with their current age stage. A family member of an older adult with MCI who had given up DCT usage expressed that younger older adults are reluctant to acknowledge their aging because they consider themselves as "still young" and not yet at the stage where they need cognitive training.

> *They think it's useless, they're still young, they don't acknowledge that thing (DCT), they feel it's not yet time to engage with it.* [Family member #4, female]

In contrast, older seniors often lacked confidence in using DCT. Due to age-related and physical limitations, they were unable to master the use of smartphones and DCT. Older adults with MCI tended to adopt a go-with-the-flow attitude toward their future lives, which to some extent reflects a negative correlation between advanced age and adherence to DCT. One family member, when talking about cognitive improvement through training, frowned, sighed, and indicated that a sense of meaninglessness in life arises in old age.

> *It's not that I don't want him to do the training, but he (older adults) doesn't care about anything, has completely withdrawn from society, and never trying to get better either, never wanting to change.* [Family member #1, female]

Prejudices against cognitive impairment from those around them made it difficult for older adults to accept cognitive decline and engage with DCT. In the context of this environment, facing cognitive training was particularly challenging. Some participants (2/19, 11%) often chose to hide their condition and remain silent when confronted with cognitive impairment-related diseases.

> *Yes, I have memory decline, but I dare not speak up face to face.* [Participant #16, female]

Disorientation and Perplexity Regarding Cognitive Training: Not Knowing What They Want

When older adults with MCI were informed of their cognitive decline, both patients and their family members often found themselves at a loss. Respondents expressed a need for cognitive improvement when asked about methods they believe could enhance memory. However, they were unclear about which type of cognitive training they desired and were even confused about whether effective treatment methods existed.

> *I want to improve my memory, but I don't know how to do it. Taking medication doesn't seem very convenient either.* [Participant #16, female]
>
> *I don't know (what can improve memory) anymore, maybe participate in activities.* [Participant #18, female]
>
> *Is there a way to improve (memory)? Does such a thing exist? (asked with confusion and urgency)* [Family member #2, female]

Negative Experiences With Training Games: Knowing What They Do Not Want

Negative experiences during the training process can hinder older adults with MCI from actively trying again, reducing their interest and motivation in training games. Some participants (3/19, 16%) pointed out a disconnect between the design of certain training games and the preferences of older adults, stating that the content was "too juvenile" and failed to adequately meet the actual needs of older adults. Others felt frustrated by the training challenges they encountered. After these negative experiences, older adults with MCI and their family members were clear that they did not wish to continue using DCT in the form of training games. In their logic, some traditional training activities (such as playing mahjong, reciting textbooks, etc) could achieve the same effect, leading to a decreased intention to continue using DCT:

> *I didn't play Whac-A-Mole; it's not fun, feels like something for kindergarten kids.* [Participant #13, female]
>
> *I'm really not interested in this game; I've already deleted it. Simpler would be better; this is too complicated.* [Participant #5, female]
>
> *Playing this (game), I want to delete it because it's just testing my memory, I might as well recite a book instead.* [Participant #19, female]
>
> *These little games are no good, Playing this kind of thing isn't as good as playing other things, let him play cards or mahjong tomorrow.* [Family member #3, female]

Theme 2: Unclear Perceived Usefulness

The majority of participants (11/19, 58%) revealed a preference for on-site group training over at-home DCT. Older adults with MCI generally tended to favor what they perceived as substitutable training methods. The perceived usefulness was influenced by the extent of expectation confirmation. A greater discrepancy between preuse expectations and actual postuse experiences was associated with greater skepticism about the usefulness of DCT among older adults with MCI. Although the interviewees acknowledged that persistent long-term training might improve cognitive abilities, the delayed gratification characteristic of DCT did not meet the urgent need for immediate effect among older adults with MCI. This unmet need for instant feedback can influence their attitude toward the usefulness of DCT, which remains uncertain.

Preferences for On-Site Training and Substitutable Methods

Most older adults (9/19, 47%), especially those living alone, disliked loneliness and desired "someone to interact and communicate with" to alleviate loneliness. Therefore, on-site group training aligned better with their daily habits and helped establish an emotional support network.

> *I think it should be offline. I did it with her and felt that we still need to have some of this companionable*

XSL•FO
RenderX

> *atmosphere. She keeps asking me, 'Am I the only one? Are there other people?' It's much better with companions around.* [Family member #4, female]

Out of concern for being socially isolated, many participants (7/19, 37%) mentioned that they cultivated a variety of other interests and hobbies to enrich their lives and maintain social connections.

> *For her, she might be more interested in things like going for a walk by the river, dancing, and practicing Tai Chi. Given a choice, she would choose (other activities). Playing games would definitely be her last choice.* [Family member #4, female]

> *Actually, I have quite a broad range of interests. I like singing, (and) some reading aloud. Sometimes, I also play Idiom Fill in the Blanks on my mobile phone. (As she speaks, she takes out her phone to show photos of herself singing)* [Participant #9, female]

The Conflict Between "Delayed Gratification" of Digital Cognitive Training and "Immediate Gratification" Among Older Adults

The management of cognitive impairment diseases and the improvement of cognitive outcomes rely on sustained long-term training. However, for older adults with MCI undergoing training, immediate positive feedback on memory enhancement was crucial. They believed that achieving "immediate gratification" is key to ensuring adherence to training. One participant expressed a desire for immediate results following training.

> *I wish it would work right after one day of training, the sooner the better.* [Participant #13, female]

However, the greatest challenge of DCT was "delayed gratification," because the effects of the training could not be perceived in time. More than half of the patients (13/19, 68%) found it difficult to continue training when they could not see short-term progress, ultimately choosing to "lie flat" or even "give up."

> *If it's effective, we'll keep doing it; if not, we won't do it (shaking head). A little progress in a week is fine. If there's no effect, spending time on it is a waste.* [Participant #5, female]

> *I know (it requires training over a period of time to be effective), just like the health care products I'm taking now. If trying them out shows some effect, I'll continue buying them; if they haven't effect, then I won't buy them anymore. It's like that.* [Participant #17, female]

Uncertainty About the Usefulness of Training

Older adults with MCI often reduced or withdrew from training before achieving their cognitive enhancement goals, which prevented them from timely experiencing the positive changes that the training could bring and left them with limited knowledge of the importance and potential benefits of DCT. One participant viewed DCT as a tool to provide recreational value and lacked confidence in it as an intervention that could effectively improve cognitive function.

> *I don't know if it's useful or not, I just play with it.* [Participant #17, female]

Interestingly, even those older adults with MCI who had higher compliance with DCT training expressed concerns about whether brain game training can genuinely delay cognitive deterioration, further exacerbating the skepticism among older adults with MCI regarding the usefulness of the training.

> *It should be useful after training, it's bound to be somewhat better.* [Participant #12, male]

> *It (Memory) is all more or less the same, learning a bit more might make the mind a bit more enlightened, but it's hard to say whether it will prevent dementia.* [Participant #18, female]

Theme 3: Suppressed Intention to Continue Usage

The intention of older adults with MCI to continue using DCT was not only influenced by their perceived usefulness but also constrained by various external driving factors. Concerns about the economic risks associated with DCT, lack of support from family members, stringent task requirements from intervention personnel, and the absence of incentives were among the reasons that could trigger their dissatisfaction or even resistance. These external factors negatively impacted the acceptance and user experience of DCT, while participant satisfaction with training was a crucial determinant of their continuance intention. Participant dissatisfaction can weaken their intention to use DCT to delay cognitive decline, even if the training itself is beneficial to cognitive function.

Concerns About the Economic Risks of Game Training

Older adults with MCI generally lacked trust in DCT's QR scanning behavior and training game systems. This low level of trust often stems from negative experiences they have heard from others. Participants expressed concerns that the QR codes might not be a reliable source and that the services and content accessed through scanning could carry the risk of online fraud. One participant, despite being willing to scan QR codes, remained cautious and stated:

> *At that time, when I entered the mini-program, I was also really scared. There are many scams targeting older adults. It would be really bad luck to encounter one, especially now with so much online fraud.* [Participant #14, female]

Additionally, this distrust also led some participants to be highly skeptical about the motives behind data collection by the community health service center staff and those conducting the intervention, worrying about potential breaches of personal information privacy. This made them hesitant to engage in any activities involving QR scanning.

> *You don't know what might happen after scanning QR codes. I'm afraid of being charged or that they might do something to the phone after scanning, so I don't like scanning QR codes.* [Participant #17, female]

XSL•FO
RenderX

Among older adults with MCI, even when explicitly informed that DCT was free to use, respondents still worried about potential hidden fees and additional expenses during the DCT process.

> *That's why I'm afraid to play the games; I'm worried about charges, concerned about deductions from my phone bill.* [Participant #16, female]

Avoidance of Cognitive Training Under the Pressure of Family Relationships

The pressures associated with family relationships also had a negative impact on participation in DCT. When discussing the role of their families in supporting and encouraging them to persist with DCT, participants expressed reluctance to proactively inform their family members about their involvement in DCT. They believed that they would not receive understanding or attention from their family members. Additionally, due to heavy family responsibilities and pressures, compared to the misfortunes of their lives, memory decline was rather not a bad thing for them. As a result, engaging in cognitive function training was merely an optional aspect of their lives. An older adult, who had long been responsible for the entire household's chores, mentioned that her life was consumed by a myriad of family tasks, leaving her with almost no personal rest time, let alone time to use DCT during her leisure.

> *My son doesn't care about me at all. It's better not to provoke him. My daughter-in-law has the same attitude; she's very aggressive in the way she speaks. They (my son and daughter-in-law) don't do any housework; I do everything in the house. We, the unpaid nannies, are all the same. That's just how it is for older adults in China. So, I'm actually happier during the New Year when no one bothers me.* [Participant #13, female]

During the training process, understanding and support from family members could help to inspire older adults with MCI to use DCT with enthusiasm. However, participants reported that children rarely took the initiative to care about the health condition of older adults, and complex family relationships could leave older adults with MCI feeling more depressed and demotivated. Sometimes, they felt ignored and lacked the motivation to improve their health. In such circumstances, avoiding DCT became a way for older adults with MCI to alleviate their psychological burden.

> *My son seldom keeps me company (silent, sighs softly). Even when I was sick and hospitalized, he didn't even say a word of greeting when he returned home.* [Participant #16, female]

> *I got divorced from my spouse, and later, when my child was in college, he got swindled by online gambling. I had to send my child to detention for a month. Sometimes, I just can't control him. He (my son) only cares about money; you'd better give money to him. Under these circumstances, it's impossible to feel happy.* [Participant #12, male]

The Intrinsic Paradox of Incentive Mechanisms

Despite older adults with MCI overcoming financial and privacy concerns and being able to obtain support from family and society, they still participated in training in a task-driven, passive manner. Their willingness to persist with the training was primarily a response to the requirements set by community health service centers and their staff. On the one hand, these older adults maintained positive relationships and interactions with the staff at community health service centers or social work stations, which made them more willing to cooperate in activities.

> *I definitely support you and support your work in completing your studies and careers.* [Participant #9, female]

On the other hand, older adults with MCI did not have an intrinsic interest in learning about DCT. In this context, the encouragement and strict demands of intervention personnel became significant external forces driving them to passively complete the training tasks.

> *If you ask me to do it, I'll get your thing done first thing in the day before doing other things. It's mainly to finish the task, not because there's any interest.* [Participant #18, female]

These older adults viewed the use of DCT mainly as a means to cooperate with staff in completing tasks. Therefore, incentive mechanisms play an important role in prompting them to start or continue using DCT. When asked how to make older adults with MCI more willing to persist with training games over the long term, they expressed a desire for "immediate rewards" during the training process, which could provide a great sense of satisfaction.

> *To complete the training, you need to post a record of completion in the group to get a red packet. It's like the classes we attend (lectures on cardiovascular and cerebrovascular health), after the class, you post your notes in the group chat, and then every day they give you 8.88 yuan in cash immediately.* [Participant #13, female]

Furthermore, incentive measures can effectively attract older adults to participate in training in the short term. With rewards available, they treated participating in DCT as a clocking-in task and were thus more willing to continue using DCT and to remember to train regularly.

> *It's better with rewards. When there are little perks, they feel like they haven't done this task today.* [Participant #18, female]

> *If there's a red packet, they'll remember that time. You just stipulate a time to complete the training and give out the red packet. Some people think about the red packet and then they're ready to play.* [Participant #17, female]

Discussion

Principal Findings

Our findings indicate that the 3 dimensions of expectation confirmation, perceived usefulness, and continuance intention are critical factors facilitating continuous usage behavior. Older adults with MCI and their families were unclear about the desired form of training they truly wanted prior to using DCT. However, after the actual experience, they explicitly expressed a preference not to undergo interventions through training games. This significant discrepancy between expectations and actual training experience, coupled with the unclarity of the perceived usefulness of DCT, resulted in their low satisfaction with DCT. Over time, various extrinsic factors further suppressed their intention to continue using DCT, making it difficult to establish adherence to DCT and ultimately preventing the formation of continuous usage behavior.

This study employed the ECM-ITC as a guiding framework, specifically focusing on the social environment and daily life contexts of older adults with MCI. It qualitatively explored the critical reasons that influence the shift from initial acceptance to discontinuous usage of DCT throughout the process of the training intervention. The adoption of digital technology is a nonlinear progression from initial acceptance to sustained usage at a later stage [37], and this progression is particularly challenging for the specific group of older adults with MCI. They may face greater challenges in accepting and continuously using digital technologies. Within the ECM-ITC, low levels of self-efficacy in using digital tools and insufficient convenience of participation have been identified by numerous studies as moderating factors affecting the long-term adherence of older adults to intervention measures [29,31,47]. Previous research has primarily concentrated on assessing the immediate effects following the conclusion of DCT interventions. Ample evidence suggests that DCT can significantly improve overall cognitive function, enhance quality of life, and alleviate psychological symptoms, such as anxiety, in patients with cognitive impairments [17,23,48]. However, the enhancement of cognitive training effects should not only focus on the instantaneous effects of short-term use but also prioritize the more important long-term sustained effects, which depend on good adherence from participants. Regrettably, older adults with MCI are reluctant to continue using DCT after receiving the intervention. Why is this the case? We found that prior research often regards the acceptance behavior of DCT as a static decision, conflating the initial acceptance with continued usage and only analyzing the reasons for the low usage rates of DCT based on participants' postuse experiences and satisfaction. Consequently, this study conducted multiple interviews at different stages before and after training to place the behavior of older adults with MCI using DCT in a dynamic context, exploring the key barriers that prevent their adherence to DCT usage.

Expectation confirmation, which represents the extent to which preusage expectations match postusage actual experiences [38], is a significant initial factor affecting the continuous usage behavior of older adults with MCI. A higher degree of expectation confirmation is associated with a greater likelihood that users will perceive the technology as useful and feel satisfied with it [49]. However, if the individual's expectations are vague and there is a significant gap between the actual experience and expectations, this internal conflict can weaken the user's intention to continue using the technology [50]. Our study found that older adults often have cognitive misconceptions and biases about cognitive impairment diseases, and the associated stigma leads to insufficient attention to cognitive health, which reduces their acceptance and willingness to continue using DCT. This is consistent with previous research [51,52] showing that most community-dwelling older adults lack a comprehensive and correct understanding of MCI. Furthermore, some demographic factors, such as age and education level, limit the improvement of disease cognition [51], and older adults with lower educational levels are more prone to experiencing digital technology anxiety [53]. During the DCT process, the initial detailed guidance, encouragement, and reminders provided by the staff enhanced the initial confidence of the older adults participating in the training. However, as the difficulty and complexity of the training increased and the content went beyond the scope of the initial guidance, the gap between the frustration of the actual training experience and the expected confidence led to a gradual decline in the older adults' interest in DCT. This further weakened their motivation and sense of participation. In the social environment of older adults with MCI, their logical thinking tends to perceive traditional entertainment activities, such as playing mahjong, as more compatible with their accepted method of exercising the brain than DCT. For older adults with MCI, this preference stems from the simplicity and familiarity of traditional entertainment activities, which do not require them to learn new skills or adapt to new rules. In addition, these activities not only provide brain training but also enhance manual dexterity and emotional connections.

This study also found that older adults with MCI are caught in a paradox between the need for immediate gratification and the delayed gratification characteristic of DCT. The effects of DCT are often gradual and not immediately perceptible. Evidence suggests that the average duration of digital health interventions spans from 4 to 24 weeks [54], and it takes 5 to 7 weeks of cognitive training for older adults with MCI to exhibit improvements in working memory [55], a perspective supported by our study results. After completing DCT, older adults can receive immediate visual and tactile feedback, such as improved training scores, increased accuracy, and enhanced hand-eye coordination, allowing them to perceive progress in game task completion and improvements in operational abilities. However, improvements in cognitive functions like memory and executive function often take a longer period of time to manifest. Older adults with MCI are unable to perceive substantial memory improvements from the game in the short term, leading to a lack of sufficient confidence in the usefulness and effectiveness of DCT [28]. This lack of confidence leads them to prefer on-site training or training methods with social attributes [56]. From the patients' perspective, the current research also highlights the importance of combining cognitive training with physical exercise. Previous studies have noted that compared to gamified cognitive training, motor-cognitive training not only has higher ecological validity but also is more effective in improving

XSL•FO
RenderX

cognitive function performance [57,58]. In the context of the widespread prevalence of intelligent and digital technologies, older adults frequently hear many promises about uncertain future outcomes during their involvement in digital interventions. For them, immediate experiences and immediate gratification have become important requirements and experiences in their daily lives, driving a preference for activities that offer immediate satisfaction rather than digital intervention programs that require long-term commitment to see results. Therefore, combining exercise science with cognitive training that provides immediate gratification aligns better with the primary preferences of older adults.

Finally, the interviewees shared their suppressed intention to continue usage, which is a key factor directly affecting individuals' continuous usage behavior. Previous research has shown that a general lack of trust in digital technology and its sources of promotion [59-61], along with significant life stressors [62], hinder the adoption of digital health care by participants. More importantly, usage intentions driven by genuine self-awareness and autonomous motivation to satisfy intrinsic psychological needs are of higher quality, encouraging participants to develop more positive and sustained health behaviors [63]. However, older adults with MCI often choose to participate passively in training, which makes it difficult for them to achieve genuine cognitive improvement from the training. Our study further found that participants hoped to be motivated to persist in using DCT through incentive mechanisms. In China, older adults are considered a "digitally disadvantaged group," with the internet penetration rate among those over 60 years at just 11.3% [64]. For them, the busy lifestyle habits formed in the past nondigital era have solidified their lifestyles, and any activities beyond their daily routines are seen as an additional burden. Only continuous incentives can stimulate their motivation to engage persistently. This aligns with the principles of the achievement goal theory in the social psychological motivation theory, which suggests that motivations driven by external incentives tend to be performance oriented, with goal completion based on external reward mechanisms. However, fostering a mastery-oriented climate can enhance the sustainability of behaviors [63]. While short-term rewards may encourage older adults to participate in training, if the training is seen as a task rather than an opportunity to improve health, it becomes challenging to cultivate a positive motivation model and sustain participation behavior among older adults, and the effectiveness of such incentives is greatly diminished. Moreover, long-term reliance on material rewards not only increases the burden on operating organizations but also may lead to the inability of older adults to continue using DCT after the withdrawal of rewards.

In summary, the behavior of older adults with MCI in using DCT is not static but evolves dynamically over time with accumulated usage experience. Our research findings highlight that the discrepancy between expectations and reality can undermine the perceived usefulness of technology for patients with MCI, jointly reducing their satisfaction. This negative experience further suppresses their continuance intention, ultimately leading to an inability to sustain long-term usage behavior.

Implications for Future Research and Practice

Future research should thoroughly understand the expectations of older adults with MCI regarding DCT before developing training programs and should provide cognitive training formats that better meet their needs based on their postusage feedback [28,65], thereby narrowing and bridging the expectation gap. At the same time, older adults with cognitive impairment should be encouraged to gradually achieve the set goals during interventions to build confidence in sustained participation. In the training of older adults with MCI, by fully stimulating both the intrinsic and extrinsic motivational forces of these older adults, the intention to persistently engage in training can be enhanced, thus achieving a more sustained and effective cognitive training effect. Integrating qualitative research into the program development phase to dig deeper into the key variables that impede continuous participation can provide guidance for subsequent studies. This approach can help explore how to effectively facilitate the conditions and implementation pathways for sustained use. Existing research has shown that co-design procedures can not only identify barriers to accessing rehabilitation for people with dementia but also guide the development of potential solutions [66]. Future studies should involve multiple stakeholders, including older adults with MCI, their family members, and health care providers, in the co-design process of DCT programs. This will help researchers better capture and understand the actual needs and real-life use scenarios of users, thereby integrating DCT into the daily lives of older adults.

Given that older adults generally lack a correct understanding of cognitive impairment and hold a nihilistic attitude toward the existence of effective training methods, this cognitive bias further affects their proactive acceptance of DCT. Therefore, future intervention plans should enhance the scientific understanding of cognitive impairment and DCT among older adults through knowledge education and training. These efforts can help older adults form reasonable expectations about the content and format of DCT, thereby narrowing the gap between expectations and actual experiences. To effectively improve cognitive function, researchers should consider combining DCT with offline exercise training. This integrated approach represents a critical pathway for developing optimal interventions in the future. Only then can intervention programs adequately meet older adults' preferences and needs for DCT and achieve the successful implementation and sustained application of DCT in community or in-home settings.

Strengths and Limitations

In this qualitative study, we adopted the ECM-ITC for the first time to view DCT usage behavior as a dynamic evolutionary process. This model guided our data collection and analysis, providing a comprehensive explanation for the intrinsic reasons of the behavioral shift from initial acceptance to eventual discontinuous usage of DCT among older adults with MCI across different stages of the preuse and postuse periods. Another advantage of this study is the focus on older adults with MCI, placing their attitudes and behaviors regarding the inability to sustain DCT usage within the context of the entire intervention process and their social living environment.

XSL•FO
RenderX

Additionally, incorporating the perspectives of family members provides holistic, family-centered insights.

The study also has some limitations. First, despite our efforts to recruit participants of different genders, over two-thirds of the participants were female, which may be related to the higher prevalence of MCI in women [67]. In addition, we collated and analyzed data based on a predetermined theoretical framework, which might have overlooked important factors outside the ECM-ITC. Finally, although we encouraged family members to participate in the training of older adults with MCI, the sample size of family members was still relatively small. Additionally, the study was conducted in only 1 community health service center in Guangzhou, which may limit the generalizability of the study's findings. Future research could collect more data at the family level for a comprehensive understanding of this phenomenon.

Conclusions

Currently, there is extremely limited research on the discontinuous usage phase of DCT. By using the ECM-ITC, this study comprehensively gained insights from older adults with MCI and their families, identifying reasons for the transition from accepting DCT to discontinued use of DCT among adults with MCI aged 60 years or older. There are opportunities to better engage older adults in adhering to DCT in the future, but it is important to consider that cognitive training is only one part of their lives and to recognize the complex needs of older adults as well as the challenges they may face when using DCT. Future research should optimize and integrate these reasons into intervention programs, designing personalized interventions that align more closely with the needs of older adults to ensure that DCT can be genuinely integrated into the daily lives of older adults with MCI.

Acknowledgments

The authors would like to thank all the older adults with mild cognitive impairment and their families who provided invaluable insights for this study. The authors are also extremely grateful to the health care professionals and social workers at community health service centers who took time and effort out of their daily work pressures to help organize on-site activities, distribute surveys, and assist in recruiting participants.

Data Availability

For protecting participant rights and preventing the potential identification of participants through the complete interview transcripts, the data generated and analyzed during this study will not be made publicly available. However, upon reasonable request, anonymized format summaries of the interview content analysis and relevant data supporting the research findings can be obtained from the corresponding author.

Authors' Contributions

SZ, MW, and NG played crucial roles in conceptualization, methodology, recruitment, data curation, data analysis, visualization, and manuscript writing. RS was responsible for investigation, funding acquisition, and project management. CC handled investigation, data collection, and analysis. ZZ participated in the review and discussion of the study findings, providing comprehensive feedback and editing. JL and NG contributed equally to the methodology, review, editing, and supervision of the manuscript. All authors reviewed and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Sexual health difficulties affect up to 30% of women, with desire and arousal problems being the most prevalent. While cognitive behavioral therapy and mindfulness-based therapy are effective treatments, access is limited by barriers such as specialist shortages, cost, and embarrassment. Web-based interventions offer a potential solution by providing self-paced, cost-effective treatments. eSense, a digital health program, offers cognitive behavioral therapy and mindfulness-based therapy skills targeted to women with low sexual desire, and previous trials find eSense to be highly feasible and efficacious.

Objective: The goal of the present implementation science study was to use the RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance of Implementation) framework to assess the integration of eSense into several sexual health clinics. We chose the RE-AIM framework because it addresses both dissemination (eg, reach) and implementation of an intervention.

Methods: A total of 14 specialty clinics participated, and we report on the reported experiences of those clinics in implementing eSense. We also examined responses from 12 women on waitlists to receive sex therapy or sexual medicine care.

Results: Per clinic outcomes, all aspects of implementation (reach, effectiveness, adoption, implementation, and maintenance) were in the moderate to high range for clinics, reporting that offering eSense helped them overcome negative feelings associated with their long clinic waitlists. The majority expressed a need for eSense and could see how it overcame the limitations of traditional therapy. Nearly all expressed a wish to continue offering eSense to patients after the implementation study was complete. One caveat was that half of the clinics noted cost as a key issue for future implementation, and one-third noted that the administrative burden of implementing eSense as a standard of care may be challenging. For individual users, the majority expressed an interest in knowing more about eSense and a desire to use eSense, though most of these did not complete the program in its entirety. Users experienced a significant improvement in sex-related distress with no clinically meaningful change in other outcomes and a high level of satisfaction with eSense. Most also reported doing things differently in their sexual lives after participating in eSense.

Conclusions: We found that eSense demonstrates potential as a digital intervention for sexual difficulties for women, particularly concerning its moderate implementation outcomes and also because of its ability to reduce sexual distress. Future studies should address the barriers identified for broader adoption of eSense in clinical settings.

Introduction

Background

Difficulties with sexual function, including problems concerning orgasm, genital pain, desire, and arousal, are common and affect up to 30% of women [1]. Difficulties with desire and arousal are the most common [2] and are often triggered by a combination of biological, psychological, and sociocultural factors [3]. Difficulties with sexual arousal and desire can be distressing and lead to negative physical, emotional, and interpersonal outcomes, such as depressive symptoms and relational conflict [4-7].

Face-to-face cognitive behavioral therapy (CBT) and mindfulness-based therapy (MBT) are considered efficacious gold-standard treatments for desire and arousal difficulties in women [8-12]. CBT is change-based and aims to alter maladaptive thoughts and behaviors that impede healthy sexual response [13-15] and build new beliefs and behaviors that refocus attention to erotic cues and pleasure [16,17]. MBT is acceptance-based and encourages present-focused, nonjudgmental attention to body sensations [18,19]. Instead of changing specific thoughts and behaviors, MBT trains an individual to build interoception (ie, awareness of sensations in the body) and positive sexual awareness [20-22].

Barriers to Accessing Treatment

Despite the prevalence of sexual problems and the existence of these evidence-based psychological approaches, there are system-level barriers to accessing help. These barriers include a lack of specialist providers, long waiting lists, high costs for private services, and discomfort talking about sex with professionals [23,24]. Another factor that might impact the willingness to seek help for sexual problems is the lack of awareness of available and evidence-based treatments [25,26].

One possible solution to these barriers is the use of web-based interventions. Here, we refer to “web-based interventions” as treatments that are fully digital rather than simply using internet technologies such as videoconferencing to support traditional face-to-face methods. These interventions are usually delivered online with varying degrees of synchronous or asynchronous guidance [27]. These interventions use digital technologies for screening, health promotion, prevention, early intervention, treatment, or relapse prevention [28].

Internet-based psychological interventions have been found to be as efficacious as face-to-face treatments in many cases [29]. Some advantages of web-based interventions are that they can be delivered at a self-determined pace and intensity, can maintain privacy or anonymity, and may be more cost-effective, potentially offering a more economically viable option for patients [30-33]. Additionally, because web-based psychological interventions are housed on accessible digital platforms, they are uniquely situated in their potential for scalability and widespread use. Of a systematic review investigating the quality of digital health interventions and among their list of 5 recommendations needed to establish that a digital tool is useful, one of them was that “the value delivered by digital health solutions should consider multiple dimensions such as clinical, organizational, behavioral, and technical” [34]. This includes ensuring that the intervention has benefits beyond just the clinical outcomes and benefits of the “system” in which treatments are delivered. As such, there is a need to evaluate the scalability of such interventions to determine their potential, including some of these multidimensional impacts on clinics that deliver care.

Implementation of Web-Based Psychological Treatments

Implementation science involves expanding health care interventions beyond the controlled environment of evaluation studies into real-world contexts [35]. Due to randomized controlled trials often being criticized for limited generalizability [36], there is a growing need for implementation science to see how well effective treatments work when taken out of the strictly controlled research context and are delivered at scale. An interest in scaling up web-based psychological treatments has significantly increased in recent years [37] and has been well-received by many users of these services. For example, Guinart et al [38] found that 82% of patients who partook in a telepsychiatry appointment in the United States rated the overall experience as good or excellent, and 64% indicated they would consider using remote treatment sessions instead of face-to-face sessions in the future. Despite this growing interest, there has been limited research on the implementation of web-based psychological treatments related to sexual health concerns.

One of the few examples of an implementation science investigation in the domain of sexual health was the testing of a web-based program for sexual dysfunction in a Dutch public health setting. The study aimed to evaluate the implementation of a free, anonymous web-based education and self-training program for adolescents and young adults aged 16-24 years. The researchers were able to recruit over 1000 participants in the study but reported a significant dropout rate of 50%, with a primary contributor to the high attrition being the program’s substantial length [39]. The findings of studies such as this provide valuable insights into the facilitators and barriers to the implementation of digital sexual health interventions that we can integrate into future digital sexual health therapeutics. However, to our knowledge, there are no implementation science studies that have evaluated digital sexual health interventions specifically for adult women experiencing sexual difficulties.

eSense: a Digital Sexual Health Tool

eSense is a web-based platform delivering psychological treatment of sexual health concerns that was originally designed to address sexual interest/arousal disorder [40] in females (though more recently it has been adapted to other populations

XSL•FO
RenderX

of females with sexual concerns). This online intervention was created through a multidisciplinary collaboration among clinicians and researchers with expertise in sexual dysfunction, patient partners, web designers, and graphic illustrators. Individuals experiencing sexual difficulties often experience difficulty in accessing care due to geographic distance from qualified health care providers, cost, lack of health care providers specializing in sexual health, and emotional barriers (eg, anxiety, shame, or embarrassment) [41]; therefore, eSense may overcome these gaps and allow women with sexual interest/arousal disorder to access evidence-based care in the privacy of their homes. eSense is built on a WordPress PHP site (with Elementor plug-in) that is HIPAA (Health Insurance Portability and Accountability Act) compliant and uses a cloud server (Digital Ocean) based in Canada. It offers 2 distinct programs: CBT and MBT. Each program or "arm" consists of 8 modules that provide educational content, detailed instructions for therapeutic activities, fictional case examples to illustrate these activities, homework exercises, and troubleshooting tips. The intervention is delivered through a combination of text, video, images, and audio, all carefully designed to be highly engaging for users. Users have 2 options for completing the program: independently or with individual support from nonexpert "navigators" who offer empathetic listening, encouragement, and technology assistance but do not provide formal therapy [42]. Administrators from the research team create a unique log-in for eSense that is provided to an individual user following informed consent. Each user then has a unique database record associated with their account, and their engagement with eSense is then saved to their personal database for future analytics.

In a series of studies, eSense has been demonstrated to be usable and satisfactory, even without individualized guidance [35]. In a randomized trial evaluating eSense along with navigator support, participants reported significant and clinically meaningful improvements in sexual desire, sexual distress, sexual satisfaction, and overall sexual function compared to a control condition, with no loss in gains at the 6-month follow-up [42]. Taken together, while these studies found eSense to be feasible, satisfying, and efficacious when evaluated in the context of a controlled trial, its real-world implementation outcomes remain unknown, and there is a need to directly study unique factors associated with its implementation [43].

Reach, Effectiveness, Adoption, Implementation, and Maintenance of Implementation Framework

Several implementation science frameworks facilitate the deployment of interventions at scale. Notable among these are the PRECEDE-PROCEED model, the Practical, Robust Implementation and Sustainability Model, the Consolidated Framework for Implementation Research, and the RE-AIM (Reach, Effectiveness, Adoption, Implementation, and Maintenance of Implementation) framework. The RE-AIM framework, in particular, is a widely recognized model in implementation science that covers five intervention-related areas of impact [44]: (1) reach as the proportion of those in need who access the intervention, (2) effectiveness per the impact of interventions on health outcomes, (3) adoption as a decision to proceed with implementing the clinical intervention, (4) implementation as the process of embedding and integration of the intervention in routine practice and its consistency of delivery and costs, and (5) maintenance as the institutionalization of the intervention in routine care [45-47]. This framework is considered more applicable than many other implementation science models, as it addresses both dissemination (eg, reach) and implementation aspects [48]. The RE-AIM framework provides a heuristic tool for bridging interventions' internal validity established in well-controlled conditions and their external validity in real-world conditions [46,49]. It is designed to evaluate the public health impact of health-promoting interventions, and it is widely used in implementation research [44]. Glasgow et al [46,50] emphasize its utility in evaluating interventions that tackle multiple underlying factors and consider entire systems, and as such, may be ideal for evaluating the implementation of sexual health interventions. Of note, the hyphen in RE-AIM is intended to differentiate the individual-level factors (reach and effectiveness) from the organization-level factors (implementation and maintenance) [47]. One systematic review evaluating the RE-AIM framework concluded that all 5 domains should be reported on accurately and transparently to facilitate translation into real-world settings [47].

The overall goal of this study was to conduct an implementation science evaluation using the RE-AIM framework of the enablers and barriers to (1) patients using eSense when disseminated through sexual health clinics and (2) sexual health clinics implementing eSense into their existing structures. Due to the nonlinear, exploratory, and dynamic nature of implementation science research [35], we did not formulate a priori hypotheses. The findings were intended to also plan future implementation science studies with eSense once we implemented the key learnings about enhancing its implementation.

Methods

Research Design

We invited clinics in Canada and the United States to offer eSense to women who could not immediately receive treatment (ie, they were waitlisted at the clinic or they declined treatment at the clinic due to factors such as financial barriers). Using the components of RE-AIM [46], we sought to evaluate the impact of eSense by measuring its reach, effectiveness, adoption, implementation, and maintenance at the level of clinics as well as patients.

Participants (Clinics and Patients)

Using the professional network of the first author, we identified several sexual medicine and sex therapy clinics in Canada and the United States and wrote to the clinic leads to inform them about this study. We used a combination of existing society membership listserves and word of mouth, as well as general internet searches to identify potential clinics that might participate. Those interested scheduled an information call with a research team member who explained this study and determined whether the clinic was eligible to participate and had the interest and capacity to refer women to this study. The eligibility criteria for the clinics were that they offered sexual health services and currently had a waitlist.

XSL•FO
RenderX

A point person at each participating clinic was provided with inclusion criteria for this study's participants (ie, patients seeking care in their clinic). Women of any sexual orientation were eligible if they were aged 19 years or older, fluent in English, had no visual impairments, were computer literate with access to an internet-capable computer, had a history of sexual activity, and met telephone screening criteria for sexual concerns regarding low desire or arousal and associated distress.

Procedure

Recruitment began in May 2022, and patients were referred to this study until December 2023. Each participating clinic invited females (either cis or trans women) who were seeking care in their clinic and were currently on their waitlist to consider participating in this study if they met the inclusion criteria (described above). Clinics collected basic information (ie, the reason for seeking treatment at the clinic, demographics, interest in participating in eSense) from all women who were contacted about participation in this study, regardless of whether those women went on to use eSense or not. This basic information was collected to compare participants versus nonparticipants of eSense. The women who participated were provided with the contact information for a member of the research team directly by the clinic staff person.

After consenting to this study, participants received a short description of each of the 2 arms of eSense (CBT and MBT) and chose one. If they did not have a preference, they were randomly assigned to an arm by this study's coordinator.

Because prior research indicates that individualized support—even support that provides no formal therapy [51,52]—decreases attrition, increases adherence, and improves outcomes [53,54], participants had the option to have individualized support sessions with "navigators." Navigators were undergraduate students who received training to encourage participants to engage in the treatment, and they answered practical questions [55]. Navigators were trained by one of the lead researchers on the eSense team. They were given a set reading list, which provided relevant background literature and provided with a standardized protocol and adherence documents for training. They then completed training sessions on the technical aspects of the role (eg, scheduling meetings) and on this study's protocol and participated in an active listening skills workshop led by the researcher. Following this training, they participated in weekly group meetings and biweekly one-on-one meetings with this study's coordinator. Participants could meet with a navigator as often as they wished (up to a maximum of once per week).

Participants filled out a baseline questionnaire using the online program Qualtrics and subsequently received access to the eSense website to work through one of the arms of the program at their own pace. Those who expressed interest in a navigator received a link to an online calendar that they used to schedule navigator meetings. Participants were sent their posttreatment questionnaire 1 week after their intended treatment end date (16 weeks from the date the participant first logged into eSense). At the end of this study, clinic directors and assisting clinic staff were also sent a questionnaire to access clinic-level implementation outcomes.

Because this study used an implementation approach with descriptive primary outcomes (eg, the proportion of women who were told about eSense and contacted us to express interest in participating and the proportion of women requesting navigator support), no power analyses were performed.

Measures

Using the RE-AIM framework [46], we assessed the following outcomes:

Clinic Level

1. Reach: the extent to which clinics were willing to participate in the implementation of eSense. Assessed by determining the proportion of clinics that were approached, expressed interest, and participated, including the reasons for their decisions.
2. Effectiveness: the extent to which clinics perceived eSense as impactful for their patients or the clinic. Assessed by gathering feedback from clinic staff on the effectiveness of eSense for their practice, including any observed benefits, as well as by determining whether user-level outcomes (eg, who was interested in eSense and who was not, participant satisfaction with treatment, or participant changes in sexual distress, interest, and desire) were meaningful to clinic partners (eg, does this information help them make decisions or achieve their goals).
3. Adoption: the extent to which clinics perceived the ease of adoption of eSense into their clinic. Assessed by determining if clinics had costs to support the maintenance of eSense and asking clinic staff why they chose to participate in this study using open-ended questions at the end of this study.
4. Implementation: the extent to which eSense was feasible to implement into their clinic. Assessed by determining the time that was required from research and clinic staff, resources required (if any), descriptions of adaptations, if any, made during this study (eg, changing the phone script at a specific clinic), reasons for adaptations (eg, to reduce costs or to have more people participate), and suggestions for improvements of the implementation procedure. Assessed by determining if clinics had costs to support the maintenance of eSense and asking clinic staff why they chose to participate in this study using open-ended questions at the end of this study.
5. Maintenance: the extent to which clinics perceived implementing eSense in their clinics as maintainable. Assessed by determining whether the organization would like to keep offering eSense, organizational barriers to offering eSense, reasons for continuance or discontinuance, and whether the clinic was willing and able to pay for potential costs associated with distributing eSense.

Clinic feedback forms also included options to provide free responses to any of the questions that also requested quantitative data.

Participant Measures

1. Reach: the extent to which participants were willing to participate in eSense. Assessed by determining the

XSL•FO
RenderX

characteristics of those who participated in the intervention versus those who did not and why.
2. Effectiveness: the extent to which participants benefited from eSense. Assessed by examining changes from baseline to posttreatment in (1) sexual distress, measured by the Female Sexual Distress Scale-Revised [56] and (2) sexual desire, measured by the Sexual Interest and Desire Inventory [57]. As recommended by RE-AIM [46], we measured change in satisfaction with life [58] and satisfaction with sex life. We also assessed satisfaction with treatment by an adapted version of the Erectile Dysfunction Inventory of Treatment Satisfaction Scale [59] and attrition rates.
3. Adoption: the extent to which participants were willing to start eSense. Assessed by determining hesitations participants had before joining this study and starting eSense and if participants were engaged in any other treatment while using eSense.
4. Implementation: the extent to which participants engaged with eSense. Assessed by determining how participants used the intervention, including the average number of modules completed and reported barriers to engaging with eSense.
5. Maintenance: the extent to which participants perceived the long-term effects of eSense. Assessed by determining whether participants planned to continue practicing eSense homework in the future.

Additionally, we examined the demand for navigator support, preference for MBT versus CBT, changes from baseline to posttreatment in motivation to see a health care provider for their sexual concerns, romantic partner involvement, and whether the participants dropped from the clinic waitlists after eSense participation.

Analysis Plan

For our quantitative effectiveness outcomes, we used a paired samples *t* test with 1 within-subject factor of time (treatment) and 2 measurement points (baseline and posttreatment) and included effect sizes, as measured by Cohen *d*. We analyzed the qualitative data descriptively with a focus on key themes.

Ethical Considerations

This study was approved by the Behavioural Research Ethics Board at the University of British Columbia (certificate #H22-02993), and all participants provided written informed consent. All clinic and individual participant data were deidentified before analyses, and all data were analyzed as a group. Although participants were not compensated for participation, clinic-level administrative staff who assisted with data collection were compensated for their time at the hourly rate paid for by their clinics.

Results

Clinic Results

Reach

Of the 194 clinics contacted, 178 did not respond, and 16 wanted to learn more about this study. Of these, 14 (7.2% of the total contacted) clinics agreed to participate after learning more about the details and requirements of this study.

Most clinics involved in this study provided psychological treatment of sexual difficulties (n=13, 92.9%), with fewer offering physical therapy or pharmacological treatment (n=4, 28.6%). A total of 13 of 14 clinics specialized in the treatment of sexual difficulties. In free-response questions at the end of participation, clinics indicated that the most common reason for referring women to this study was because they presented with low desire, arousal issues, or painful intercourse. Clinics also reported that they most commonly referred younger women and women with financial constraints.

Effectiveness

Per effectiveness, the outcomes collected in this study were meaningful to 71.4% (n=10) of clinics. Clinics reported that this study provided valuable support in decision-making, particularly in determining whether referring clients to similar studies would be beneficial. Additionally, the information collected helped shape organizational decisions such as business plan adjustments, next steps for possibly embedding eSense into their clinic, guiding offerings to clients, and improving the services. Some remarked:

> *Super important information that can help direct our business plan, next steps, guide offerings to clients.*
>
> *Would be interested in all that information. That would be helpful in deciding how to utilize the program.*

Per clinics' motivation to participate in this study, most reported their desire to support research, to provide additional client support for those on the waitlist, and to help explore the use of eSense in clinic operations. Several clinics mentioned that being able to offer eSense to waitlist patients alleviated some of the provider guilt associated with extensive waitlist times.

Adoption

Responses regarding adoption focused largely on budget considerations. Regarding the budget for maintaining eSense, 50% (n=7) of clinics stated that their ability to offer eSense to patients depended on its cost, while 28.6% (n=4) indicated they could not support the maintenance costs. One of the clinics stated:

> *We wouldn't be able to afford supporting a cost for clients without getting some reimbursement from clients. If clients were choosing to enroll, and paying for the program directly, we could absolutely support it. We do not have the funds to sponsor it for our clients.* [Sexual medicine center]

The majority, 78.6% (n=11) of clinics, expressed a need for eSense in their clinic, citing the limitations of traditional therapy sessions and the importance of providing clients with additional support for practicing therapeutic tools. One remarked:

> *Therapy is often the space we are processing emotional content. It is nice to provide options for clients who want to have support practicing tools.*

XSL•FO
RenderX

Implementation

Regarding implementation, feedback from clinics revealed a strong interest in continuing to offer eSense after this study, with 92.9% (n=13) of clinics indicating their willingness to do so. The primary reasons for this interest included the program's ability to complement traditional 1-hour therapy sessions by providing additional tools and resources, thereby offering clients more support options. Clinics also highlighted the perceived value of eSense as a resource for women who lack access to sex therapy, noting its reliability and creation by experts in the field. Some of the clinic responses included:

> *Only so much can be covered in a typical one-hour therapy session. Providing clients with tools and resources is of utmost importance to me and my practice.*
>
> *It's a very valuable resource, and much needed! Plus it is offered by the experts in the field, so it is a reliable source.*
>
> *Another option for women to do in their own time and in the comfort of their own home. Seems like a great option for clients who either can't afford therapy, or who are stuck on a wait list.*

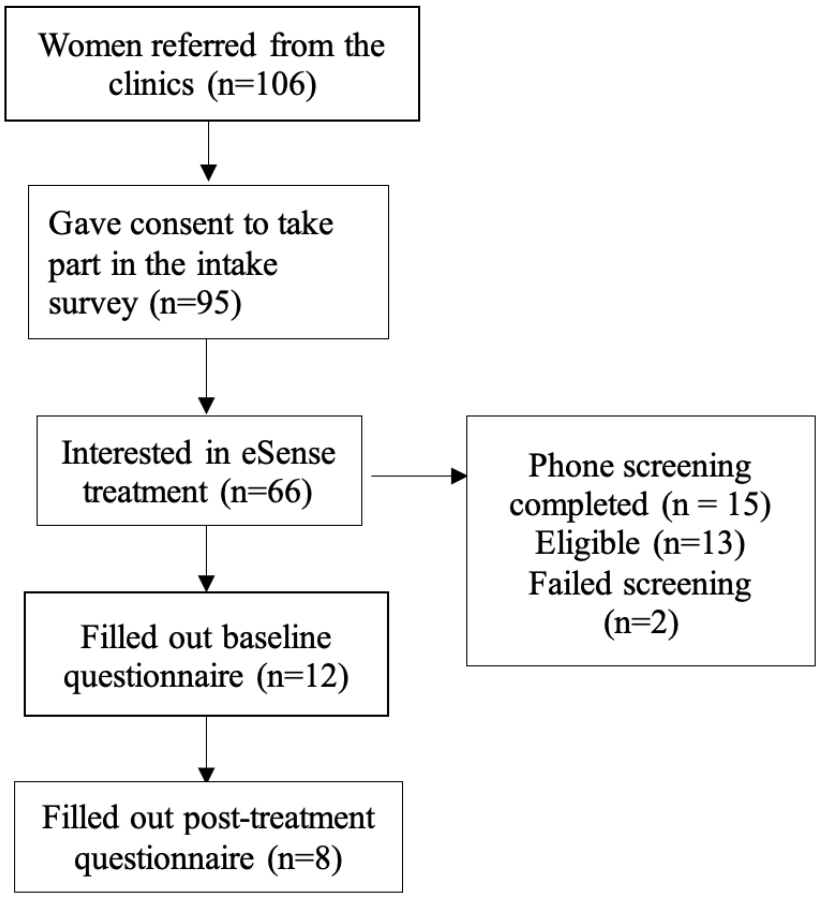
However, 35.7% (n=5) identified barriers to continuing eSense, primarily related to resource intensiveness (eg, additional time required from clinic intake coordinators who would refer women to the program and costs associated with this). Additionally, although clinics were required to have a client waitlist to be eligible for this study, many clinics did not end up having waitlists at their clinics, which reduced their immediate need for eSense. Despite this, they acknowledged that eSense would be valuable when immediate treatment was not possible. There were also challenges in keeping triage and care management staff updated about the program, which would require additional training to keep staff informed about eSense. As 1 clinic remarked:

> *The only barrier is that we've been able to offer timely treatment to potential clients, so clients did not have a need to take part in eSense. However, we realize timely treatment may not always be possible. So it's great to have eSense as an option.*

Maintenance

Regarding maintenance, 92.9% (n=13) of clinics believed that eSense could be successfully integrated into existing clinic operations. Clinics suggested various methods for integration, including using eSense as a support outside of the office settings, assisting with take-home practices and self-paced work, and including eSense as part of a stepped-care model. They also saw the potential for eSense to be an adjunct to ongoing therapy and a resource for current patients, in addition to patients placed on the waitlist. Clinics indicated the possibility of being a referral platform by adding eSense to their resource information lists and websites. In response to asking how eSense could be integrated into the framework of their organization, some of the clinics remarked:

> *It would be part of a stepped-care model that all clients are assessed for.*
>
> *Patients receive a variety of resource information and eSense would be added to this list. Providers can continue to speak about its benefits.*
>
> *I'm not sure yet. But one thing that might be possible is that we could offer a link to eSense on our website in the areas about desire and arousal concerns -- we have a section for each concern with ideas for resources to try on one's own. As long at [sic] the tool is not costly, we could also offer it as we have been for people who choose not to enroll in sex therapy due to cost or other factors.*



Participant Results

Reach

Regarding how well we were able to reach patients, 14 partner clinics referred a total of 106 women to our study, and of those, 95 provided consent to take part in the intake survey and fully or partially filled it in (Figure 1).

XSL•FO
RenderX

Figure 1. Diagram of clinic and participant flow from referral through all stages of participation.

Of the participants who reported why they were seeking treatment at the participating clinic (n=81), nearly half (n=40, 49.4%) indicated that this was for a sexual desire or arousal concern, while the remaining 50.6% (n=41) were seeking help for various other issues such as mood and anxiety, sexual trauma, menopause symptoms, hormone imbalances, and other health concerns.

Among those seeking treatment at the clinic, 39 (55.7% of 80 responses) participants were informed they would be placed on a waitlist for treatment at that clinic. A total of 51 (79.7%) planned to proceed with treatment from their referral clinic, whereas 13 (20.3%) decided to no longer seek treatment from the clinic. The reasons for not seeking treatment included wait times, the transition to primarily online counseling, financial constraints, and insurance coverage issues.

After being told about eSense, 66 (82.5%) women expressed interest in learning more about it, while 14 (17.5%) were not interested in using eSense (Figure 1). Reasons for lack of interest included a perceived irrelevance to their situation, lack of time, preference for in-person interactions, not understanding the treatment, and reporting being already satisfied with their current sex life.

Of the 66 who initially expressed an interest in this study, only 12 went on to participate in this study, and all identified as cisgender (Table 1). Those who decided to participate provided various motivations, such as ongoing issues with arousal difficulties, low desire, and sexual anxiety, which had made participating in sex stressful and guilt-inducing. Other reasons for participating included severe body image issues, histories of eating disorders, and the resulting body shame that inhibited their sexual lives. Others expressed distress over a lack of physical attraction to their primary partners despite emotional connections, leading to relationship stress. A common theme was a marked decrease in libido and a desire to explore new concepts of attraction and improve their sexual lives.

Per reasons for the high rate of attrition, we compared participants to nonparticipants on select demographic variables that were collected among those who declined participation. The 2 groups did not differ in age (P=.91), race (P=.80), relationship status (P=.41), or sexual orientation (P=.054).

Effectiveness

Data for effectiveness are presented in Table 2 and is based on 8 participants who provided full pre and post data. A series of paired samples *t* tests evaluated the effects of eSense on clinical outcomes. Sexual desire (as measured by the Sexual Interest and Desire Inventory) did not significantly differ from pretreatment to posttreatment (*P*=.94), with a negligible effect size (Cohen *d*=0.029), indicating no meaningful change in sexual desire after eSense. The total Female Sexual Distress Scale-Revised score, however, decreased significantly from pretreatment to posttreatment (*P*=.004), with a large effect size (*d*=–1.459), reflecting a substantial reduction in sexual distress. Satisfaction with life did not significantly change from pre- to posttreatment (*P*=.31), with a small effect size (*d*=–0.388). Similarly, satisfaction with sex life also did not significantly change from pre- to posttreatment (*P*=.31), with a small effect size (*d*=–0.388).

XSL•FO
RenderX

Table 2. Pretreatment and posttreatment measures of sexual desire (SIDI[a]), sexual distress (FSDS-R[b]), satisfaction with life (SWLS[c]), and satisfaction with sex life (SWSL[d]). Data presented are means and SDs based on 8 participants who provided full data.

Variable	Pretreatment, mean (SD)	Posttreatment, mean (SD)	Cohen *d*	*P* value
Sexual desire (SIDI)	22.29 (8.98)	22.43 (9.4)	0.029	.94
Sexual distress (FSDS-R)	32 (10.74)	24.88 (10.97)	–1.459	.004
Satisfaction with life (SWLS)	28.63 (5.88)	27.25 (5.01)	–0.388	.31
Satisfaction with sex life (SWSL)	22.9 (4.7)	21.8 (4.01)	–0.388	.31

[a]SIDI: Sexual Interest and Desire Inventory.

[b]FSDS-R: Female Sexual Distress Scale-Revised.

[c]SWLS: Satisfaction With Life Scale.

[d]SWSL: Satisfaction With Sex Life Scale.

Participants' satisfaction with eSense was evaluated in various ways. We measured satisfaction with the experience of having versus not having a treatment navigator. Participants were evenly divided in their initial choice to have the support of a treatment navigator before starting eSense, with 4 choosing to have a navigator and 4 opting not to. Across those who chose to work with a navigator, the total number of navigator sessions was 12. Those who opted for the support of a treatment navigator expressed a range of opinions. Some appreciated having someone to discuss their thoughts and feelings with, which helped them process information and feel validated. Others felt that scheduling meetings and clarity of the navigator's role could have been better. Overall, the mean satisfaction score regarding participants' choice to have a navigator corresponded with "somewhat satisfied." Some felt they would have been more dedicated to the program with a navigator's support but believed they could manage on their own due to their previous therapy experiences. Others preferred not to discuss their concerns with anyone who was not a fully licensed therapist.

Participants provided some feedback on barriers that arose that prevented them from fully engaging with eSense. These included no time due to their job and taking care of children, lack of privacy, avoiding the exercises, and feeling frustrated that a partner was not involved in trying to improve the sexual issues.

The overall mean Erectile Dysfunction Inventory of Treatment Satisfaction Scale score was 73.64 (SD 14.85) of 100, suggesting a high level of satisfaction with eSense.

Adoption

One-third of participants (4 of 12) were initially hesitant to join this study, mainly due to concerns about the time commitment required. The average wait time for participants before they were likely to see a provider was 17 weeks, and many of them agreed to participate in eSense to address their concerns on the recommendation of health care providers or as a proactive step before starting therapy. Most participants were not engaged in any other treatment at the time, although a few mentioned ongoing treatments for other health issues (eg, thyroid medication or pelvic floor physiotherapy).

Implementation

When given the choice of which arm to use, 6 initially requested CBT, and one of these requested a change to mindfulness after starting. Further, 5 participants requested mindfulness from the outset, and 1 participant did not express a preference. Of the 12 who started eSense, 8 completed posttreatment measures, with only 37.5% (3/8) of these completing all 8 modules. The average number of modules completed was 4.3 (of 8). Engagement with homework activities also varied: 25% (n=2) did none, 12.5% (n=1) did a few, 37.5% (n=3) completed about half, and 25% (n=2) engaged with all the homework activities. Barriers to consistent homework engagement were reported by 87.5% (n=7) of participants.

Regarding barriers to engaging with eSense, participants cited various personal and situational challenges. These included changes in job responsibilities, medical issues such as low iron causing fatigue, lack of time and privacy, mental blocks, and frustration from the perception that they were attempting to address a problem primarily viewed as significant by their partner rather than by themselves. Despite these challenges, a majority (87.5%) of participants reported doing things differently in their sexual lives as a result of eSense. These changes included letting go of guilt, practicing mindfulness, improving self-talk, and increasing communication in the bedroom. Some participants also noted changes in the nonsexual aspects of their lives, such as increased mindfulness and attunement to pleasure.

Maintenance

All participants indicated they would continue to use what they learned from eSense in the future, such as the new mindfulness practices, journaling, and the use of "sexual aids" (ie, vibrators, erotica, and fantasy). Participants highlighted the importance of awareness of thought patterns and cognitive biases, with some intending to reflect on these and try behavioral experiments to overcome them. Even those who did not progress far into the material found value in the initial modules and planned to incorporate those learnings into their lives.

Additional Findings

Participants reported increased awareness and a sense of empowerment regarding their sexual health. However, suggestions for improving the program included the addition of more videos, more time between modules, greater clarity on certain instructions, and more flexible options for engaging with a navigator.

Discussion

Principal Findings

This study aimed to evaluate the implementation of eSense, a digital therapeutic intervention including CBT and MBT, for women experiencing sexual difficulties and seeking care from specialty sexual health clinics. Using the RE-AIM framework, we assessed eSense's reach, effectiveness, adoption, implementation, and maintenance across clinic and participant levels. Overall, eSense was associated with a meaningful reduction in sexual distress among participants, with moderate adoption by clinics and high satisfaction from both clinics and participants, despite some limitations in engagement and completion rates.

At the clinic level, a significant challenge was reaching clinics that would be willing to adopt eSense. Although 194 clinics were contacted, only 14 ultimately participated, and many of the nonparticipating clinics indicated that their waitlist was very short and patients seeking treatment were able to be seen quickly by a provider. Many clinics expressed interest in offering eSense as additional support for their waitlisted patients, which alleviated some of the strain associated with long wait times. This finding aligns with prior research suggesting that digital interventions can complement traditional care models and offer value to health care providers in overburdened systems [52].

However, clinics also cited resource limitations, including staff time and financial constraints, as barriers to long-term adoption. This finding is consistent with a systematic review of 221 eHealth intervention studies focused on the barriers and facilitators of successful outcomes [60], which found that an increase in workload and workflow disruption posed significant barriers to implementing eHealth tools [60]. Such barriers are likely particularly important for integrating digital health tools in smaller, less-resourced clinics [54] and, given that most partnering clinics in this study offered psychological services, they may be smaller or less well-funded (or not publicly funded at all) in comparison to larger medical centers.

These findings make it important to explore alternative methods of implementing eSense, including different treatment settings and varying levels of integration. For example, the PTSD Coach App was created to translate gold-standard psychotherapy for posttraumatic stress disorder into a self-guided or clinician-aided online tool similar to eSense. While PTSD Coach is often used by providers in specialty trauma clinics [61], it has also been successfully integrated into generalist primary care clinics, both with and without provider support [62]. One of the benefits of such an approach is that it is possible to achieve broad reach without consistent formal implementation work because the program is viewed as a stand-alone tool rather than a new labor-intensive addition to clinic procedures [63]. Similarly, eSense might achieve maximum reach by being an external resource recommended in general treatment settings rather than via integration into specialty care.

However, existing as a stand-alone tool raises the question of who will or can pay for the service. Indeed, the cost came up during our assessment of adoption, with several clinics noting that they would not be able to cover the additional costs incurred from the use of eSense in the future. During the present trial, eSense was evaluated within a research context, and as such, there were no costs to the clinics that adopted it. However, in the future, when eSense is incorporated and commercial, there may be necessary costs to clinics associated with leasing or purchasing a license. Alternatively, end users could pay for eSense access, with clinics serving only as referral sources. While the specific costs of such activities to clinics or users are unknown at the moment, anecdotal feedback to our team from potential users suggests that those residing in the United States were more likely to expect eSense to be covered by a third-party payer, whereas Canadian potential users were open to paying an individual subscription fee.

Who should bear the cost of interventions such as eSense is fundamentally an issue of equity, and if the cost is shouldered by end users, many of the same inequities present in traditional health care may be replicated, with historically underserved groups having less access and experiencing greater burden. To avoid such negative outcomes, a 2022 summit of the Agency for Healthcare Research and Quality provided a set of recommendations [64] that emphasized the importance of primary care as an avenue of equitable implementation of care, along with the need to actively engage with members of underserved communities, and partner with culturally relevant sectors such as faith organizations and tribal communities. In line with such recommendations, future implementation of eSense should (1) identify ways in which care settings can budget for the additional time and costs associated with integrating it into clinical operations, (2) include active engagement with members of underserved populations (eg, sexual and gender minority individuals), or (3) explore the implementation of eSense in a variety of settings that can allow for equitable access.

At the participant level, eSense was well-received by participants who engaged with it, as evidenced by high satisfaction scores. Of note, of 66 women who initially expressed an interest in this study, only 12 participated and provided pre-post questionnaire data sufficient for analysis. This small sample size impacted the power of our statistical analyses, and as such, the effect sizes obtained should be taken as preliminary. Although 87.5% of participants did not complete all 8 modules, there was a significant reduction in sexual distress and a willingness to continue practicing the skills learned in eSense beyond this study. These findings are consistent with the PLISSIT (Permission, Limited Information, Specific Suggestions, and Intensive Therapy) model [65], which suggests that many individuals with sexual concerns can experience meaningful benefits from early interventions such as normalization and permission-giving elements introduced in eSense's first module. Therefore, the low completion rates may not necessarily reflect dissatisfaction or ineffectiveness but rather that participants received sufficient benefit from earlier parts of the program. The minimally effective dose of eSense to lead to meaningful clinical improvements is unknown and should be the focus of future research.

Although eSense was efficacious in this trial and the original randomized trial [42], this efficacy was not sufficient for

XSL•FO
RenderX

successful implementation. It is well documented that the factors that contribute to a treatment being efficacious in a controlled research study are fundamentally different from programs that are successfully implemented [66]. One reason for the difference is that efficacy trials have strict rules on the setting, conditions, participants, and other factors, whereas implementation trials must be robust across a variety of different settings, conditions, and participants [42]. Another reason is that efficacy trials attempt to control variance by restricting the conditions, whereas implementation trials seek to understand variation across different settings. Given that eSense was highly efficacious but challenges arose with implementation, this suggests that there is a need to understand the moderating factors that contribute to its successful implementation in the future, as these moderating factors will be important if eSense is to be successfully implemented.

Our findings imply that digital interventions such as eSense can be a valuable supplement to traditional therapy, particularly for individuals facing barriers to accessing care, such as long wait times or financial constraints. eSense's ability to reduce sexual distress supports the notion that digital tools may fill critical gaps in the health care system by offering low-cost, accessible solutions, and even without improving key symptoms, the reduction in distress may be particularly meaningful for patients to increase their readiness for future interventions. However, this study also highlights the importance of "fit" when introducing such interventions. Women seeking specialty care at sexual health clinics may differ significantly from the general population, having already invested substantial time and resources into accessing specialized care. These individuals may be less likely to engage fully with digital interventions such as eSense, especially if their expectation is face-to-face therapy.

Despite the promising results of eSense's implementation, this study has several limitations. The primary limitation is the relatively small number of participants, which restricts the generalizability of the findings. Additionally, because we did not formally capture user engagement data (apart from homework completion), we do not know how much participants actually engaged with eSense and what dose of the treatment they were exposed to. There is also a need to implement structured checklists specific to digital health interventions to determine their value [34]. Finally, most participants did not work with a navigator as they completed the eSense modules. Given that the randomized controlled trial showed excellent efficacy when participants were assigned a navigator [42], it is possible that any future implementation of eSense may be more successful if navigator support is included.

Conclusion

This paper addressed a significant gap in the literature on enablers to implement effective sexual health treatments in the clinical setting. This study found that eSense demonstrates potential as a digital intervention for sexual difficulties for women, particularly concerning its moderate implementation outcomes and also because of its ability to reduce sexual distress. However, challenges related to clinic adoption and participant engagement suggest that future iterations may need to consider scalability, clinic resource constraints, and the specific needs of participants seeking specialized care to increase their engagement. In particular, we recommend that costs to clinics be kept minimal, that methods of reducing attrition and enhancing adherence to modules and homework for users be considered, and that flexible options for engaging with navigators might be considered in future implementations of eSense.

Acknowledgments

We wish to thank Kiarah O'Kane, BA, and Raveena Gowda, BA, for their assistance with data collection. Funding for this study was provided by a Michael Smith Health Research BC (British Columbia) Innovation to Commercialization Grant to LAB (principal applicant).

Abstract

Background: Telerehabilitation is promising for improving knee osteoarthritis, but the effect of different telerehabilitation strategies on knee osteoarthritis is unclear.

Objective: This study aimed to examine the effect of a clinic-based strengthening exercise (CbSE) and asynchronous video-based strengthening exercise (AVbSE) on pain, range of motion, muscle strength, quality of life, and physical function among patients with knee osteoarthritis.

Methods: A total of 52 consenting patients participated in this 8-week experimental study; they were assigned to the CbSE or AVbSE group at 2 different study sites. CbSE is a circuit exercise module comprising knee flexion and extension warm-up in sitting, quadriceps isometric setting, quadriceps strengthening exercise, hamstring clenches, wall squat, and a cooldown of knee flexion and extension. The AVbSE is an asynchronous video-based version of the CbSE.
