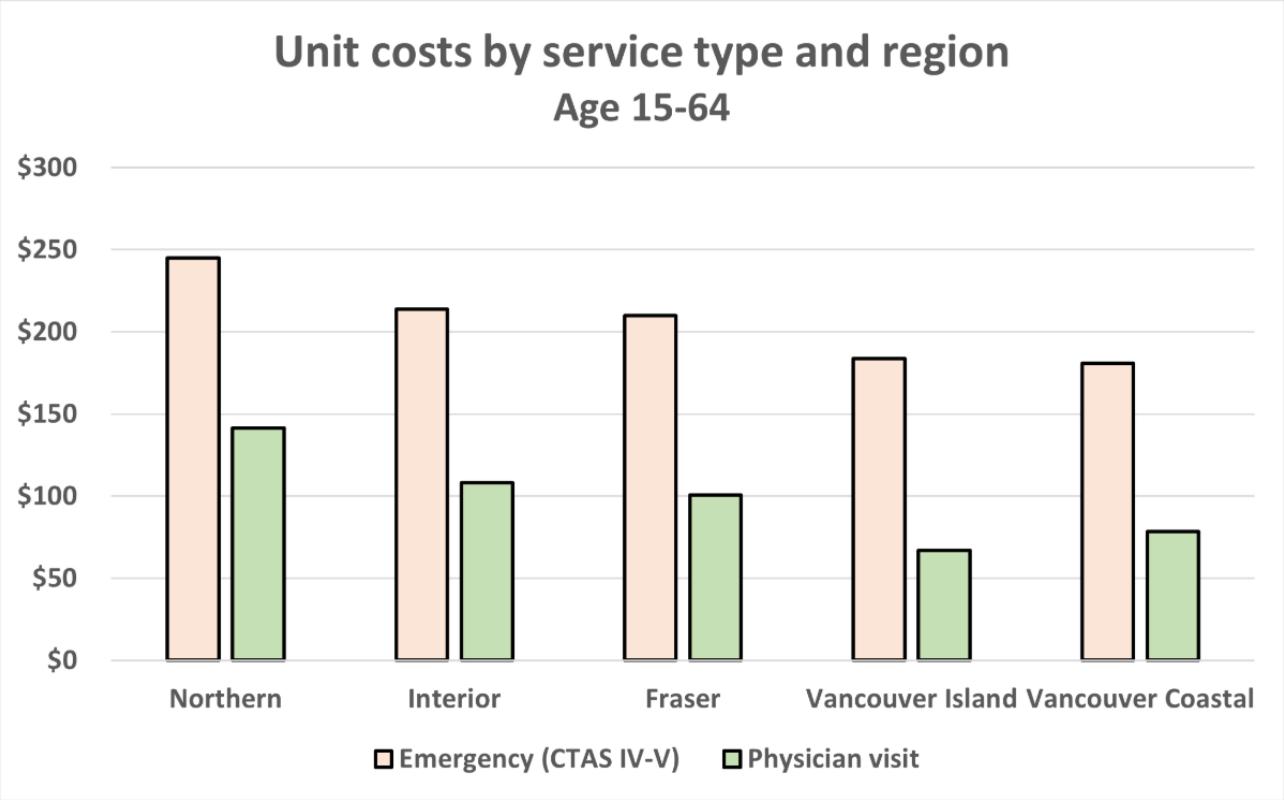
Figure 2. Single visit emergency department (ED) unit costs by region with subunit breakdown. CTAS: Canadian Triage Acuity Scale.



Costs among the 15-64 years age group were driven by lost productivity. This finding relies on the assumption of negligible productivity impacts among the 0-14 and ≥65 years age groups and that the attendance of an informal caregiver is 100% for the 0-14 years group and 50% for the ≥65 years age group. However, when applied to a specific population, it is possible that absolute costs may differ, given that the population may be more heavily weighted toward one or more age groups. We also observe from Figures 3-4 that the geographic trend observed previously continues to hold, with the Northern Health region having the highest costs across all age groups and service types.

Figure 3. Single visit emergency department (ED) unit costs by age group. VIH: Vancouver Island; VCH: Vancouver Coastal.

XSL•FO
RenderX

Figure 4. Single visit unit costs by service type and region. CTAS: Canadian Triage Acuity Scale.

Comparing costs among patients in the age 15-64 group, ED visits at the CTAS IV-V level were higher across all health authorities, ranging from $181 to $245 compared with the estimated $67 to $142 estimated cost for patients to attend primary care appointments.

Unit costs for telehealth visits were found to be $30 for the 15-64 years age group. Given the lack of travel-related costs, telehealth visit unit costs did not vary geographically across the province.

In addition to the aggregation to the health authority level, we calculated unit costs based on a stratification of each CHSA between urban and rural, which are presented in Table 2. This involved aggregating 4 classes of urban CHSAs and 3 classes of rural CHSAs. We then calculated unit costs for physician visits and for ED visits in the CTAS I-III and CTAS IV-V categories. Given the longer travel distances and durations associated with rural locations, we expected to see that rural unit costs are higher than urban for all age groups for both ED and physician service types by a considerable margin.

Table 2. Base per-visit unit costs by urban and rural community health service area (CHSA) classification.

Urban				Rural			
Age group (years)	Physician visit (unit cost), $	Emergency medicine (unit cost), $		Age group (years)	Physician visit (unit cost), $	Emergency medicine (unit cost), $	
		CTAS[a] I-III	CTAS IV-V			CTAS I-III	CTAS IV-V
0-14	52	157	117	0-14	146	250	211
15-64	72	222	162	15-64	196	345	286
≥65	32	92	72	≥65	96	156	136

[a]CTAS: Canadian Triage Acuity Scale.

Greenhouse Gas Emissions

We also determined GHG emissions and costs associated with the travel distance for both the rural and urban CHSAs. We used the same reference vehicle and fuel efficiency (2022 Toyota Corolla, 7.06 L/100 km) and obtained kilograms of CO_2-equivalent emissions per visit, which are shown in Table 3.

XSL•FO
RenderX

Table 3. Base per-visit emissions by urban and rural community health service area (CHSA) classification.

	Distance per visit (km)	CO_2-equivalent emissions per visit (kg)
Rural	91.2	13.92
Urban	18.94	2.89

Sensitivity Analysis

A sensitivity analysis was applied to show how the unit cost outputs change when parameter values are deterministically varied for each of the health services included. The magnitudes of the observed cost variations are similar relative to the base case for each service type and consistently represent a linear 2%-3% change in total unit cost for every $1 change in wage (see Multimedia Appendix 2). Costs in the Northern Health authority had the largest variation and represented the maximum of the range of changes observed. A noteworthy caveat is that although a lower wage value results in lower total costs, this may still represent a larger burden to patients with this income profile. In the case of minimum wage, visit costs are approximately 3.5-4 times the cost of 1 hour of work, whereas in our base case using British Columbia average wage, visit costs are approximately 3-3.5 times the cost of 1 hour of work.

We also varied assumptions about the percentage of appointments attended by a caregiver and found that each 25% change in caregiver attendance resulted in changes of less than $35 in total, except for hospitalizations; the method was sensitive to assumptions about how often a patient has a caregiver attend. The impact changed the estimated patient and family costs by $434-$494, indicating the importance both in the magnitude of this cost overall and also in the significant amount of time that caregivers devote to supporting patients in the hospital. Similar to the analysis of wage changes, costs in Northern Health authority had the largest variation based on a change in caregiver attendance percentage. The observed change in costs for each service type was consistent across all age groups in terms of absolute value. Given that the base case unit costs differ for each service type and age group, the observed change in costs represents a difference in relative change even when the absolute values remain constant. For the 0-14 years age group, a 25% variation in caregiver attendance percentage represents approximately a 17-32% variation in unit costs when compared to the base case. For the 15-64 age group, costs varied by approximately 12.5%-22% compared with the base case. Finally, for the ≥65 years age group, costs varied by 28%-94% compared with the base case. The ≥65 years age group shows significant variation due to 25% caregiver attendance representing a large variation in the absolute value of the unit cost, particularly for hospitalizations, combined with informal caregiving costs being a larger proportion of this age group's total unit cost. Without considering the hospitalization service type, costs varied by approximately 28%-35% for the ≥65 years age group.

Our analysis of the method's travel parameters found that a 10% variation in distance and duration resulted in a change in cost ranging from $2-$8 for patients aged 0-14, $2-$10 for patients aged 15-64 years, and $1-$6 for patients aged ≥65 years. The magnitude of variation remained consistent across all service types. Similar to other parameters included in the sensitivity analysis, the largest variation in costs was observed in the Northern Health authority. While the magnitude of cost variation was consistent for all service types, the relative change in costs did vary due to the difference in the base cost. The observed variation in costs from a 10% change in travel distance and duration represented a change of approximately 0.5%-7.5% compared with the base case. Full sensitivity analysis results for wage, travel, and caregiver parameters are presented in Multimedia Appendix 2.

We also tested the impact of the method used to calculate distance and travel costs within each CHSA by comparing the street distance method with the haversine method. We find that for 167 of 218 (76.6%) CHSAs, the haversine method was within 10 km of the street distance method. The remaining 51 of 218 (23.4%) had a difference greater than 10 km between the two methods; however, for some of the most remote regions, the haversine method underestimated the street distance by up to 137 km.

Simulated Population

We applied our method to our simulated population to determine the total costs of ED, physician visits, and telehealth visits from the patient perspective over 1 year. Demographics and service use for the synthetic population are provided in Multimedia Appendix 1. Total costs are presented in Table 4, organized by service type, acuity, and health authority.

XSL•FO
RenderX

Table 4. Estimated patient-paid costs by service type and acuity for 1 year for a simulated population of 100,000.

Health Authority	Total ED[a] CTAS[b] I-III visit costs ($)	Total ED CTAS IV-V visit costs ($)	Total physician visit costs ($)	Total telehealth visit costs ($)
Fraser	2,292,674	982,692	8,508,221	2,261,474
Interior	1,005,335	431,293	3,987,006	972,891
Northern	424,195	187,685	1,985,431	368,011
Vancouver Coastal	1,350,332	561,400	3,758,996	1,487,933
Vancouver Island	934,499	387,732	3,009,011	1,020,796
Total	6,007,035	2,550,802	21,248,664	6,111,105

[a]ED: emergency department.

[b]CTAS: Canadian Triage Acuity Scale.

We see from this application of the method that substantial costs are likely paid by patients for both ED and physician visits. The simulation showed that ED and physician visits have a cost of just over $30,000,000 over 1 year per 100,000 people. While this total cost is not representative of current absolute costs, it illustrates the type of information that can be obtained by our costing method. Furthermore, we see that while physician visit costs are more than double those of ED visits, ED visits make up just 13.6% (42,573/312,573) of the total visits between the two. This suggests that ED visits are a relatively substantial cost driver despite being smaller in absolute number. In comparison, telehealth visits show considerably less expensive total costs than either ED or physician visits despite a comparable number of total visits to physicians. In addition, GHG emissions were calculated at varying proportions of hybrid care, which assumes both in-person and telehealth visits, the results of which are presented in Table 5.

Table 5. CO_2-equivalent emissions for 1 year for a simulated population of 100,000.

	Estimated number of in-person visits	Total distance (km)	CO_2-equivalent emissions (metric tons)
Physician visits	270,000	3,959,416	586.32
Hybrid care			
25% in-person	67,500	989,854	146.58
50% in-person	135,000	1,979,708	293.16
75% in-person	202,500	2,969,562	439.74
ED[a] visits	42,573	624,311	92.45
60% visits to the ED avoided by telehealth care	25,544	374,586.6	55.47

[a]ED: emergency department.

When applying the method to a population, such as this simulated example, age group definitions can impact total cost output. Labor force participation may vary in complex ways with age or other factors, particularly when youth may start work and when individuals may retire [38,39]. To test the impact of age group definition calculated costs based on age group definitions of 0-19, 20-59, and ≥60 years and compared with the initial results. Total costs for each service type in Table 4 were reduced by 6%-8% with this age group definition.

Discussion

Principal Findings

Our study presents a novel method for estimating the patient-paid portion of costs attributable to receiving medical care with geography as our basis. The core calculation method and the categorization and the types of costs that are included can be applied to any set of parameters, whether they are based on routine data or customized values. Therefore, all parameters are flexible and can be swapped to those relevant to other jurisdictions, allowing the method to be generalizable to many different contexts. Furthermore, when applying the method to populations, labor force participation rates can be applied to change the age group definition or distribution to customized results for the population of interest. Our findings highlight the range and magnitude of cost variations depending on the type of care received, where patients live, and their age. This implies that economic evaluations of telehealth or in-person service from a patient's perspective should consider a range of demographic characteristics of the relevant population to fully capture these costs. Our findings concur with previous research showing that a substantial portion of health care costs are passed off to patients when accessing care, particularly in rural areas [18]. Applying our method to a simulated population estimates that patients in British Columbia may collectively pay up to 30 million dollars per year to access health care services, primarily for medical travel.

XSL•FO
RenderX

Comparison With Previous Work

Our findings add to the literature on patient-paid costs to access health care. These studies, however, are often tied to a specific cohort, using methods to determine travel and other out-of-pocket expenses that consider specific geographic data on patient locations and determine the distance traveled to either the nearest facility or the designated facility appropriate for the relevant treatment. Some methods also use patient location data and then calculate average distances to their facility [8]. Methods used by other researchers to calculate lost productivity—occasionally referred to as opportunity costs—account for total time and multiply by the relevant average wage [9,10,13]. Lost productivity costs using these methods have been estimated at $13.35 (2023 CAD equivalent) for a telehealth visit and $82.35 for an in-person visit [13]. An earlier study estimated the opportunity cost of an in-person visit to be $81.86 [9]. Our method found similar results, with lost productivity costs ranging from $42 to $166 for ED and physician visits. In addition, other studies do not report the per-visit cost directly but estimate cost savings of $124.10 for telehealth care [10]. Depending on the service being analyzed, calculations of patient lost productivity can be done over multiyear time horizons posttreatment and are thus geared toward providing insight on treatment outcomes rather than costs of visits directly. Travel distances, costs, and visit durations contributing to patient cost calculations are also often obtained from patient survey methods [5,7,40]. Survey results have shown that travel-related costs represent a substantial majority of the time spent and the costs that patients pay, with telehealth visits having considerably less cost [5,7,40]. Furthermore, studies of patient travel in Canada show that patients pay an average of $31 of the cost per person for travel to attend primary care appointments [14,41]. By including time costs by lost productivity and informal caregiving, we add the perspective of a comprehensive account of the total costs paid by patients that may be tailored depending on the scope of the economic evaluation. The World Health Organization's methods of quantifying financial hardship currently refer to all costs attributed to out-of-pocket expenses at the time of receiving medical care; however, if there is an opportunity to save patients time during business hours by telehealth care provision, one may argue that accounting for lost productivity would be within the interest of patients, and applicable to providing more patient-centered care.

Strengths and Limitations

Despite a motive for the deliberate embodiment of patient and family costs in evaluation, our method is primarily limited by our stated assumptions and the available evidence about what people pay to access health care. Specifically, our assumptions generalize anticipated differences in wages, labor force participation [38,39], the need for and availability of informal caregiving, fuel, vehicle, and meal costs. In addition, our analysis is limited to an account of the economic and environmental impacts of receiving medical care paid by patients, informal caregivers, and future generations. It does not consider the quality of care, which may result in further avoidable patient costs due to unnecessary services, nor does our method address questions related to the value of care. We rely on local travel maps and assumptions about the day-to-day travel considerations. In doing so, we likely underestimated the impact of seasonal variations, for example, during winter driving conditions or climate-related concerns such as road closures due to flooding or wildfires. The method, in its current form, does not account for constraints on the health care system, such as unanticipated ED closures that will cause patients to travel further. Furthermore, costs that are less easily monetized, such as those attributable to stress and emotional labor involved in emergencies and acute conditions, can create additional costs to patients that are less straightforward to quantify, especially with large distances between many patients and their usual health care centers. Therefore, this may result in the method underestimating the true costs to patients. The inclusion of the sensitivity analysis, while not addressing additional potential costs, is intended to mitigate the impact by showing how costs scale if more weight is given to particular parameters.

Future Directions

This method is applicable to both research and policy contexts for economic evaluations of existing and newly proposed health care services. For example, studies calculating costs for rural health services, especially those with significant travel costs, could be augmented by our method in order to obtain a more comprehensive cost estimate and improve comparability between other studies and evaluations [40,42]. This may be particularly salient in travel reimbursement policies such as Canadian medical transport benefits [43]. Without a comprehensive and accurate calculation of patient costs, the level of burden placed on patients to access care can be unclear and likely underestimate these costs. While it is often indicated that access to care is a greater burden for those living in rural areas, without quantifiable cost information, certain geographic areas and populations may not receive sufficient resources and services. Using the method presented here will allow policymakers to more clearly understand the specific costs of accessing care for all patients in their jurisdiction and thus contribute to a more comprehensive evaluation to inform resource allocation.

Conclusion

In this paper, we present a novel, generalizable method to estimate patient-paid costs and GHG emissions from accessing health care services. Through our geospatial costing method, we are able to show that patients pay substantial costs to access health services. Furthermore, in a simple simulation using historical data, we estimate that patients in British Columbia may be paying millions of dollars to access health care services. By including lost productivity, informal caregiving, and out-of-pocket expenses, the method is able to provide a more comprehensive and accurate calculation of patient-paid costs. Using this method to gain a better understanding of patient-paid costs will allow for more informed evaluations of new and existing services and aid in the comparison between potential alternatives.

Abstract

Background: Effective communication is essential for promoting preventive behaviors during infectious disease outbreaks like COVID-19. While consistent news can better inform the public about these health behaviors, the public may not adopt them.

Objective: This study aims to explore the role of different media platforms in shaping public discourse on preventive measures to infectious diseases such as quarantine and vaccination, and how media exposure influences individuals' intentions to adopt these behaviors in the United States.

Methods: This study uses data from 3 selected top national newspapers in the United States, Twitter discussions, and a US nationwide longitudinal panel survey from February 2020 to April 2021. We used the Intermedia Agenda-Setting Theory and the Protective Action Decision Model to develop the theoretical framework.

Results: We found a 2-way agenda flow between selected national newspapers and the social media platform Twitter, particularly in controversial topics like vaccination ($F_{1,426}$=16.39; P<.001 for newspapers; $F_{1,426}$=44.46; P<.001 for Twitter). Exposure to media coverage increased individuals' perceived benefits of certain behaviors like vaccination but did not necessarily translate into behavioral adoption. For example, while individuals' media exposure increased perceived benefits of mask-wearing (β=.057; P<.001 for household benefits; β=.049; P<.001 for community benefits), it was not consistently linked to higher intentions to wear masks (β=–.026; P=.04).

Conclusions: This study integrates media flow across platforms with US national panel survey data, offering a comprehensive view of communication dynamics during the early stage of an infectious disease outbreak. The findings caution against a one-size-fits-all approach in communicating different preventive behaviors, especially where individual and community benefits may not always align.

Introduction

Background

The shift from traditional to digital media marks a significant change in how the public accesses scientific information, with social media emerging as a central platform [1]. Media coverage may amplify or attenuate risk judgments of its audiences [2], increase risk perception of disease outbreaks [3], and encourage them to take protective actions [4]. Although previous research has explored the relationship between media exposure, risk perception, and protective behaviors during infectious disease outbreaks, the specific impact of distinct media content on the public's adoption of protective behaviors remains unclear. This study aims to bridge this gap by examining how exposure to specific media contents from different sources might alter people's perspectives and willingness to adopt protective measures, building upon but distinct from the broader media agenda-setting literature.

The Role of Different Media in Communicating Preventative Behavior Through the Lens of Intermedia Agenda-Setting Theory

During infectious disease outbreaks, nationwide health messages are warranted for successfully building up healthier collective behavior. It is assumed that such messages, including those to overcome the COVID-19 pandemic, would work if they are clear [5], consistent [6], and come from reliable, nonpolitical sources [7]. These messages typically include descriptions of and recommendations to enact, various protective behaviors for COVID-19. Yet the term "protective behavior" during the pandemic was often used too broadly, covering both simple actions like handwashing and more complex ones like getting vaccinated. It is difficult to effectively address the questions and concerns raised by such varied actions in single messages, or even a single information campaign. This problem is further complicated by other challenges of public health communication, such as engaging diverse communities [8], stigmatization [9], and misinformation, such as antivaccination propaganda [10,11].

Since early 2020, the US Centers for Disease Control and Prevention (CDC) issued guidelines for protective behaviors against COVID-19, such as handwashing and mask-wearing [12]. While some behaviors like mask mandates were communicated top-down from authorities to the public [13], others, like vaccination debates before the widespread availability of COVID-19 vaccines in December 2020, first emerged on social media and then flowed upward (ie, bottom-up) to legacy media [14]. As communication about protective behaviors happens across different media types, it is crucial for scholars to understand the transition of information between traditional media outlets, such as newspapers and television, and social media platforms like Facebook and X (formerly Twitter, during our analysis period).

However, it remains unclear whether these social media discussions are driven by traditional media outlets such as newspapers' coverage or vice versa. Understanding this relationship is crucial because behaviors like mask-wearing and quarantine mandates have different properties that affect their perceived benefits and costs, and may therefore have different origins and dissemination pathways for information about them. Gaining such understanding is key to comprehending how media shapes public health behavior. This leads to our first research focus: investigating the reciprocal influence between legacy newspapers and social media in setting the agenda for COVID-19 protective behaviors. This study specifically looks at the representation of these behaviors, from basic handwashing to complex vaccination debates, in selected national newspapers and on Twitter to discern the pattern and direction of this information flow. The first research question thus aims to dissect this interplay between selected national newspapers, as examples of legacy media, and Twitter, as an example of social media, in setting the agenda for infectious disease protective behaviors, RQ1: in what direction did the agenda for COVID-19 protective behaviors move between the selected top US national newspapers and Twitter?

Intermedia agenda setting serves as a framework for understanding how various news sources influence one another and the consequent breadth of information presented to the public [15]. Originating in political communication, this theory has been applied to health topics to examine the dynamics between traditional and emerging media sources. It highlights the "co-orientation" of narratives within media, influenced by both economic and local social factors [16]. This interaction affects how issues, including health, are framed and perceived, impacting public opinion and decisions. The theory explains how news content transfers between media, illustrating how dominant sources can shape the agendas of others, thereby influencing the entire media landscape [16,17]. For instance, in health communication, significant agenda flows from social media to traditional media have been observed for topics like the Measles, Mumps, and Rubella vaccine-autism debate [18] and climate change [19].

From Communication to Action: How Media Exposure Might Influence People's Protective Behavior

While media agendas on infectious diseases may influence public risk perceptions [20], the evidence of their impact on protective behaviors during pandemics is mixed, particularly in terms of media source and effect. First, there is limited recent evidence on how legacy media use impacts behavioral adaptations. Increased time spent on legacy media can lead to heightened anxiety and stress, which may result in misplaced health-protective behaviors [21]. Official government media use tends to encourage protective actions, while commercial media often results in overprotective behaviors driven by anxiety [22]. Notably, legacy media coverage, including national and local newspapers, television, and radio, has a significant influence on the protective actions of less-educated individuals [23]. Additionally, past research has shown that merely relying on massive media coverage of infectious diseases is not sufficient for promoting protective actions, as other factors like social norms and perceived threats also play crucial roles [24-26].

Second, although social media are key tools for disseminating health messages and can positively influence health-related

XSL•FO
RenderX

behaviors [27-31], their effectiveness in behavior change is not consistent. For instance, increased exposure to media content about Ebola heightened risk perceptions, but a similar increase in exposure to social media content about the Zika virus did not shift risk perceptions among mainland Americans [3,20]. Furthermore, evidence suggests a negative relationship between health-protective behaviors and social media use, where heightened concerns and a lower construal level associated with social media do not encourage preventive actions but instead reinforce negative emotional reactions and mental health problems [32].

In this research, we drew from the Protective Action Decision Model (PADM) for a comprehensive theoretical framework to understand how media agendas of protective behaviors relate to actual individual practices [33]. The PADM framework details how decision-making begins with environmental cues like sight and smell, social cues observed from the behavior of others, and warnings from information sources [33,34]. It specifies prompts for action that are crucial for encouraging engagement in health-related behaviors during infectious disease outbreaks such as H7N9 [35]. The PADM has been applied to the COVID-19 context with a focus on the early stages [36], and in different cultural backgrounds [37,38].

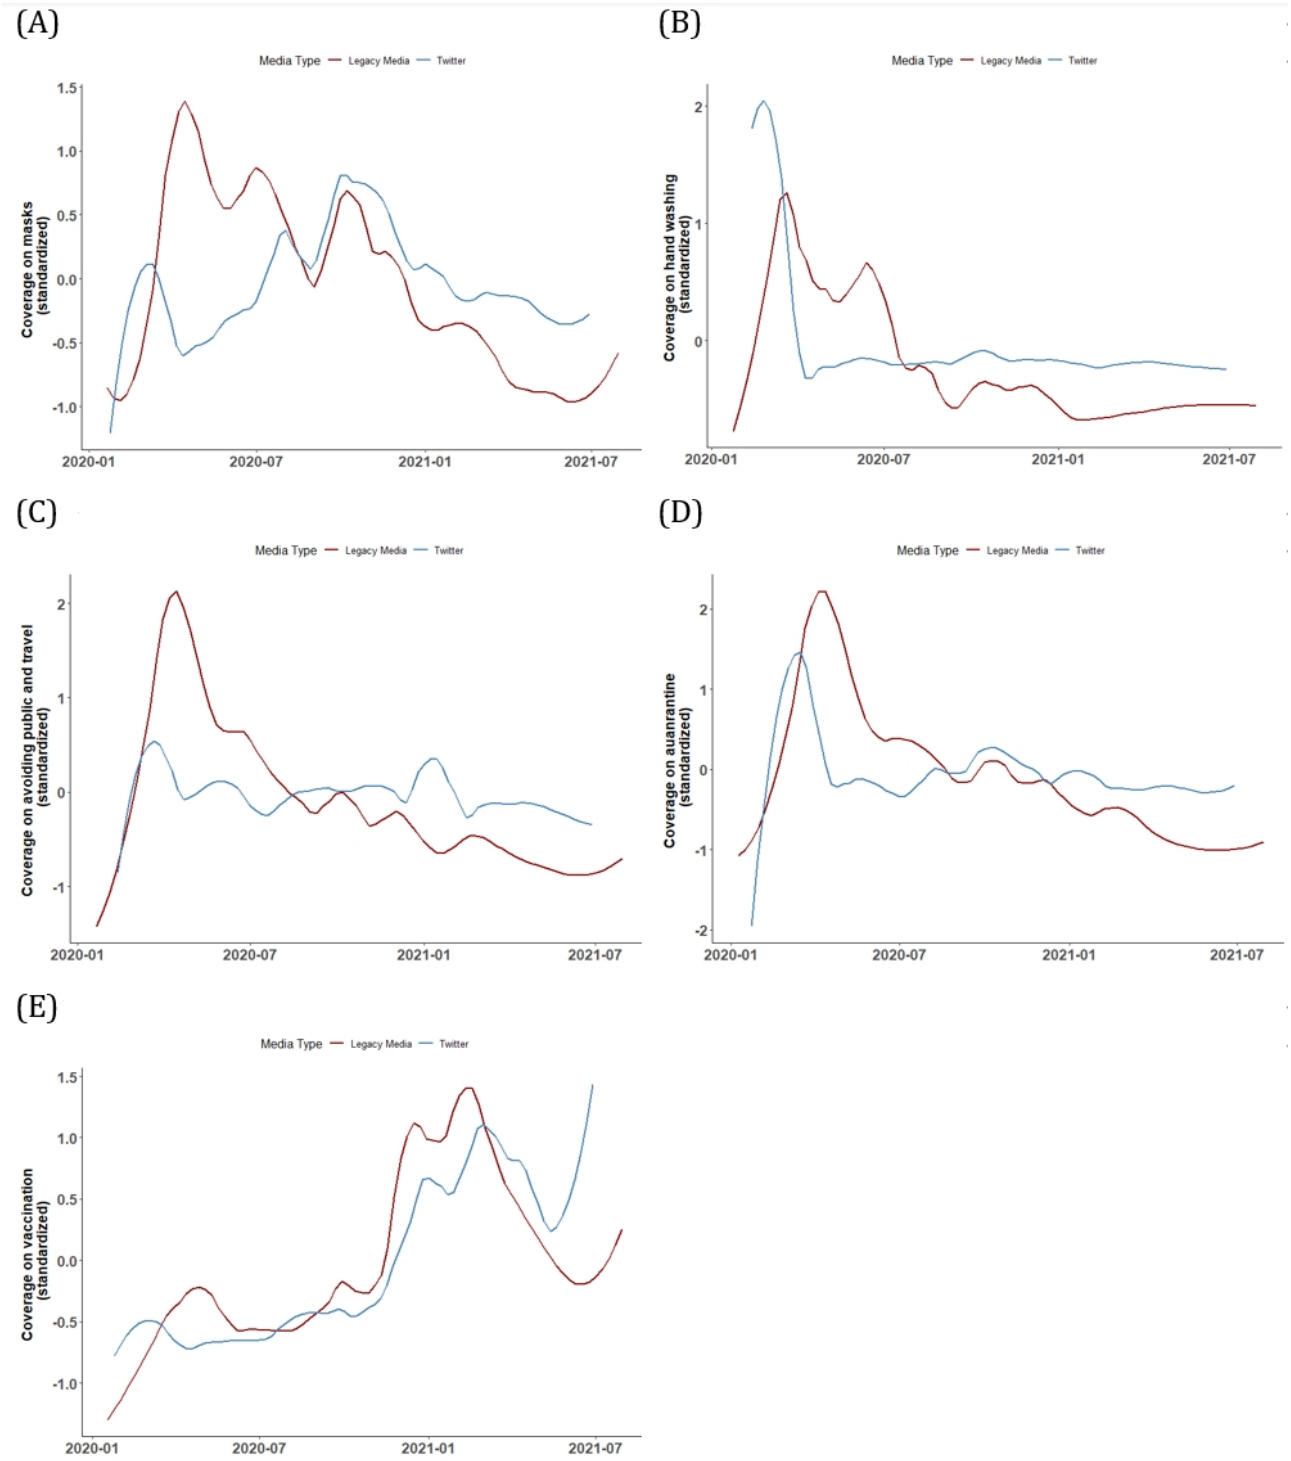
This study collected panel survey data from around 2000 American adults to examine the relationship between media exposure and individuals' behavioral intentions to protect themselves during the COVID-19 pandemic. The dataset spans from early in the US COVID-19 pandemic experience (February 2020) to the period after vaccines became widely available (April 2021). In line with the PADM, which considers intentions as a function of risk perceptions, behavior perceptions, and stakeholder perceptions, this study focuses specifically on behavior perceptions. Since our media content analysis primarily dealt with protective behaviors rather than the overall COVID-19 threat or trust in institutions, we chose to emphasize how respondents perceive the benefits of these behaviors. Based on PADM, we developed our main hypothesis as H1: US individuals' perceived benefit of protective behaviors is positively associated with their media exposure to those behaviors.

We argue that media exposure's impact on behavior is not straightforward but mediated through perceived benefits. According to the original model by Lindell and Perry, before behavior adoption, individuals assess it based on media, evaluating factors such as effectiveness, safety, and relevance. Their perception of these benefits is a crucial factor in deciding whether to adopt certain behaviors, while perceived barriers (such as resource limitations) can hinder the translation of intention into action. During the COVID-19 pandemic, media exposure indirectly influenced health behaviors by promoting protective actions in public spaces through combined perceptions of social initiatives and moderate fear [39], and by positively affecting perceived efficacy and threat awareness [40], leading to improved health-protective behaviors. In other contexts, exposure to health-relevant messages indirectly influences behavioral intentions, such as perceived social norms affecting binge drinking [41] or perceived benefits encouraging regular exercise [42]. This body of evidence, illustrating how media exposure may shape behavior through the lens of perceived benefits, lays the foundation for our second hypothesis H2: the association between media exposure to protective behaviors and the actual practice of these behaviors is mediated by individuals' perceived benefits of these behaviors.

Methods

This section describes our data collection, measurements, and analysis methods for testing our hypotheses.

Data Collection



Example Legacy Media and Social Media Contents

In this study, we used major national newspapers as examples for legacy media, and Twitter as an example for social media. We selected three major US newspapers: the New York Times (NYT), Wall Street Journal (WSJ), and USA Today, due to their high nationwide circulation numbers [43]. This collection of newspapers also represents a range of political ideologies—USA Today is considered centrist, The WSJ leans right of center, and The NYT leans left of center [44]. We collected newspaper coverage of the COVID-19 pandemic via the news data archive Factiva database by searching for the keywords "coronavirus" or "covid-19" between January 2020 and June 2021. Social media data were collected from Twitter using daily searches for the same keywords and within the same time period. While we aimed to focus on US-based conversations, our Twitter dataset may include tweets from English-speaking users outside the United States, as geo-tagging is not always available. In total, we collected 41,235 news articles and 2,398,046 tweets in English mentioning either or both of the keywords "coronavirus" or "covid-19."

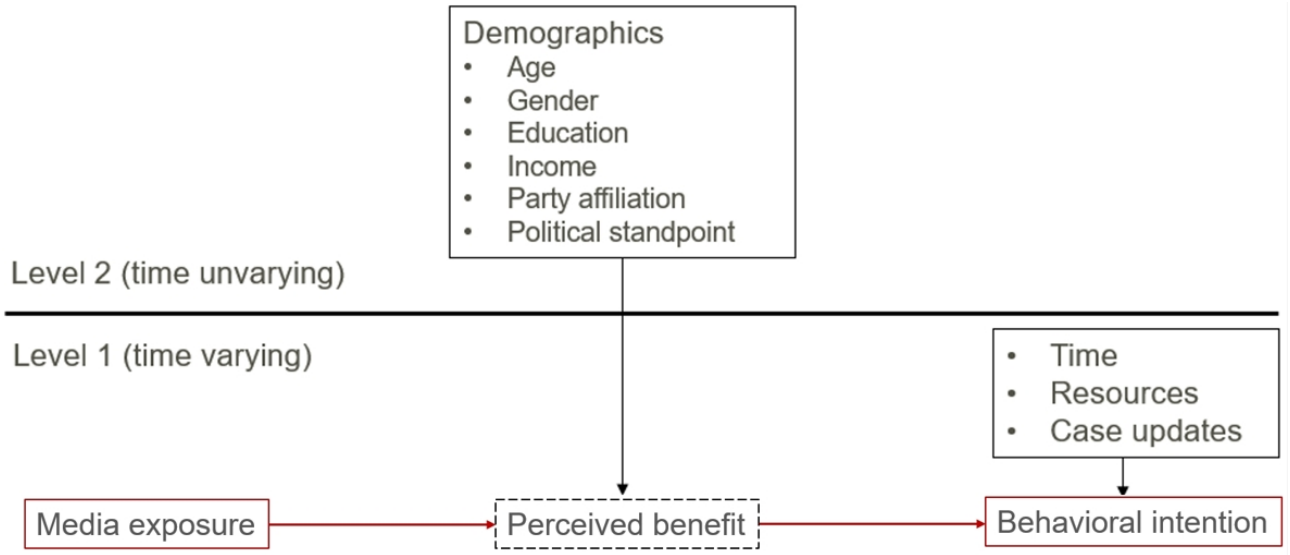
We cleaned the media content data by filtering out those irrelevant to protective behaviors. For initial filtering, we used a regular expression search based on a lexicon that covers all protective behaviors suggested by the CDC, such as handwashing and mask-wearing (Multimedia Appendix 1). However, we recognized that keyword-based filtering alone might miss the broader themes in the media content. Therefore, we used structural topic modeling using the "stim" package in R (R Project for Statistical Computing), with the publication date serving as a covariate [45]. This additional step helped us identify 47 topics in news articles and 20 in tweets (the numbers of topics were decided by the searchK diagnosis function in the R "stm" package). Based on several criteria (Multimedia Appendix 2), we selected models of size 47 topics for newspapers and 20 for Twitter posts as optimal topic models). We then excluded content that was not closely related to health, such as international politics or entertainment (for the human validation process, see Multimedia Appendix 2). In the end, 10,528 news articles and 209,261 tweets met our criteria for health-focused protective behaviors. Figure 1 visually represents how these data trends evolved over time.

XSL•FO
RenderX

Figure 1. Standardized coverage from newspapers and Twitter on protective behaviors (the raw volume of daily Twitter coverage is much greater than that from newspapers. Therefore, we conducted a scaling process [ie, calculating z scores] for each set of coverage to make the figure clearer. We also smooth the trendlines with the spline function for better aesthetic quality) over time including (A) mask-wearing, (B) handwashing, (C) avoiding large public gatherings and traveling, (D) isolation at home (self-quarantine), and (E) getting vaccinated. The red lines represent the volumes of legacy media content (specifically from selected national newspapers), and the blue dashed lines represent the volumes of Twitter content.

Public Opinion Panel Survey

We recruited 2005 American adults from the Prolific digital survey panel for a longitudinal study spanning 1 year and 2 months, consisting of six waves. In this longitudinal design, respondents from each completed wave were invited to the next wave, with the final wave open to all initial respondents. Each wave lasted about 2 weeks, except for the first. Data collection occurred on February 28-29, 2020 (wave 1), April 27-May 6, 2020 (wave 2), August 5-13, 2020 (wave 3), October 12-22, 2020 (wave 4), January 22-February 11, 2021 (wave 5), and March 25-April 13, 2021 (wave 6). However, not all respondents completed every wave or answered all questions, resulting in some variation in response rates across different waves. We had 2002 responses in wave 1, a total of 1613 responses in wave 2, a total of 1197 responses in wave 3, a total of 1026 responses



XSL•FO
RenderX

in wave 4, a total of 866 responses in wave 5, and a total of 1025 responses in wave 6.

Respondents were asked for their intentions about each protective behavior on a 6-point Likert scale from "My household has never considered taking this action" to "My household has taken this action and will continue to take this action as needed." To assess respondents' media exposure to major national newspapers such as the NYT, WSJ, and USA Today, and for the social media platform Twitter, we asked them about the frequency of using these media sources for COVID-19–related information. Some examples of survey questions can be found in Multimedia Appendix 3.

To measure respondents' perceived benefit of protective behaviors, we asked how beneficial they think it is to practice each protective behavior in reducing risks for their household, and separately for vulnerable people in their community. To assess potential barriers to behavioral intentions, we asked respondents if they had sufficient resources to practice protective behaviors like mask-wearing and handwashing. Perceived barriers were coded as "resources" and were included in our analysis as a control on intentions, as shown in Figure 2. We also recorded demographic information, including age and gender, during the first wave.

Figure 2. Multilevel regression model visualization, with independent variables categorized into time-varying (eg, media exposure, perceived benefits, case updates) and time-unvarying factors (eg, demographics), with fixed and random effects to capture perceptual and behavioral changes over time.

Ethical Considerations

Data collection from human participants was approved as exempt by the Decision Research institutional review board chair. After reading an informed consent form at each wave, outlining survey aims, benefits, risks, and other relevant information, consent was indicated by the respondent checking a box for consent. Anyone who checked the "No" box was not allowed to proceed to the survey itself. The prolific panel operator recruited all participants at wave 1, using a compensation scheme that is proprietary (ie, researchers were not informed of its type or amount), and reported all responses to researchers with a unique identifier, so that researchers were unaware of the identity of any respondent. While the survey was not password-protected, it was a closed survey in practice, as only responses from participants with matching unique identifiers were included in this analysis.

Granger Predictive Relationship in Time Series (RQ1)

The Granger causality test is a statistical tool commonly used to infer whether one time series can predict another. It does not establish true causality but rather identifies predictive relationships between variables. This method is often used in intermedia agenda-setting research to examine the lagged predictive influence of one platform's agenda on another [17,46,47].

The Granger causality test requires data to be stationary, as it would otherwise produce unreliable results [48]. Before running this test, we used the augmented Dickey-Fuller stationarity check, which sets a null hypothesis that the data series is nonstationary. Our tests yielded *P*-values less than .05, leading us to reject the null hypothesis for each data series. Therefore, we used Granger tests to explore the predictive relationship between daily newspaper coverage and Twitter activity for each protective behavior. We used daily coverage summary data for both newspapers and Twitter and conducted Granger tests in both directions, that is, from newspaper coverage to Twitter activity and vice versa. This allowed us to examine the predictive influence of each platform's agenda on the other for various protective behaviors.

In this study, statistical analyses were run on R (version 4.1.2), and the time-series analyses in this session were conducted with open-sourced packages "tseries" [49] for the stationarity check and "lmtest" for Granger causality detection [50].

Modeling Respondents' Media Exposure and Protective Behavior (H1)

Comprehensive media coverage of protective behaviors does not indicate everyone gets the same information. To avoid making arbitrary assumptions about individual media exposure, we chose not to solely rely on either "media coverage" or survey-reported "media exposure frequency." Instead, we

XSL•FO
RenderX

calculated a "weekly media exposure" metric for each respondent by multiplying their self-reported frequency of using specific media outlets, like the NYT or Twitter, with the daily proportion of relevant coverage from those outlets. To estimate this weekly media exposure, we used one-week "exposure windows" prior to each survey wave. For each type of protective behavior, such as mask-wearing or handwashing, we calculated the specific daily proportion of coverage related to that behavior in selected top national newspapers and Twitter. Therefore, the media exposure metrics for each respondent are dynamic across different waves of survey and different types of protective behaviors. Details for calculating the media exposure can be found in Multimedia Appendix 4.

According to the PADM, the behavioral response may also be impacted by situational facilitators [33]. For situational facilitators in this study, we referred to the Center for Systems Science and Engineering at Johns Hopkins University for daily confirmed case updates in the United States from January 2020 to June 2021 [51]. More specifically, we chose to present average weekly and monthly trends of their local case updates (ie, the gradient of daily confirmed cases in the same zip code area) before each response date.

We constructed our model with multilevel modeling. As shown in Figure 2, we categorized the independent variables into two sets. The first set includes time-varying variables like respondents' media exposure, perceived benefits, and situational factors, which change with each survey wave. The second set includes time-unvarying variables like demographics, which remain constant throughout the survey. In total, we created five models, each corresponding to one of the five protective behaviors previously mentioned. To test hypothesis H1, we examined the relationship between media exposure and perceived benefits for each protective behavior. For H2, we also looked at how these perceived benefits influence the intention to practice these behaviors. We chose the "lme4" package [52] in R because it can handle our multilevel data, which includes fixed effects like demographics and random effects showing changes in respondents across surveys. This package is effective for modeling individual changes in behavior and perception over time, thus providing a more unbiased view of how behavior changes due to media exposure and perceived benefits. To ensure comparability and interpretability of coefficients, numeric variables were standardized before analysis.

Results

Intermedia Agenda Setting Between Selected National Newspapers and Twitter

Table 1 presents the results of how newspaper coverage of various protective behaviors might predictably influence Twitter discourse. Table 2 shows the reverse results about how Twitter activity might predictably influence newspaper coverage.

Table 1. Granger test results (F statistics) of predictive causality from newspapers to Twitter posts about protective behavior issue agendas.

Lag (in days)	Wash hands, *F* test (df)	Wear masks, *F* test (df)	Self-quarantine, *F* test (df)	Avoid gathering and travel, *F* test (df)	Take vaccination, *F* test (df)
1	3.04 (1, 163)	0.19 (1, 439)	3.62 (1, 434)	1.51 (1, 368)	16.39 (1, 426)[a]
2	0.52 (2, 131)	0.18 (2, 416)	1.19 (2, 410)	0.28 (2, 343)	14.54 (2, 398)[a]
3	0.45 (3, 110)	0.28 (3, 402)	0.63 (3, 398)	0.19 (3, 331)	8.17 (3, 381)[a]

Table 2. Granger test results (F statistics) of predictive causality from Twitter posts to newspapers about protective behavior issue agendas.

Lag (in days)	Wash hands, *F* test (df)	Wear masks, *F* test (df)	Self-quarantine, *F* test (df)	Avoid gathering and travel, *F* test (df)	Take vaccination, *F* test (df)
1	2.75 (1, 163)	0.14 (1, 439)	9.68 (1, 434)[a]	1.57 (1, 368)	44.46 (1, 426)[b]
2	0.99 (2, 131)	0.34 (2, 416)	4.62 (2, 410)[c]	1.54 (2, 343)	19.05 (2, 398)[b]
3	0.57 (3, 110)	0.37 (3, 402)	3.14 (3, 398)[c]	0.42 (3, 331)	11.81 (3, 381)[b]
4	2.14 (4, 92)	0.48 (4, 392)	2.72 (4, 392)[c]	0.41 (4, 321)	9.31 (4, 371)[b]
5	1.45 (5, 77)	0.41 (5, 390)	1.46 (5, 386)	0.70 (5, 312)	7.58 (5, 361)[b]

[a]*P*<.01.

[b]*P*<.001.

[c]*P*<.05.

Our first research question (RQ1) explored the relationship between selected national newspapers and Twitter in shaping agendas around protective behaviors. Contrary to our expectations, the results do not support a clear predictive

XSL•FO
RenderX

relationship in either direction for certain behaviors like handwashing ($F_{1,163}$=3.04; P=.08), mask-wearing ($F_{1,439}$=0.19; P=.66), and avoiding gatherings ($F_{1,368}$=1.51; P=.22). In these cases, no significant patterns were observed, suggesting a lack of agenda influence between newspapers and Twitter.

However, for self-quarantine, Twitter activity was found to predictably influence subsequent newspaper coverage ($F_{1,434}$=9.68; P=.002 at a one-day lag). In the case of the more contentious, high-impact behavior of vaccination, a reciprocal relationship was observed: newspaper coverage appeared to shape Twitter discussions ($F_{1,426}$=16.39; P<.001 at a one-day lag), and Twitter activity, in turn, seemed to influence newspaper coverage ($F_{1,426}$=44.46; P<.001 at a one-day lag).

Predicting Behavioral Response With Media Coverage and Real-World Data

To address the variability in behavioral responses to media coverage of protective behaviors, this section presents a detailed examination of two hypotheses. Our first hypothesis (H1) proposed that individuals' perceived benefit of protective behaviors increases with their media exposure to these behaviors. Additionally, in our second hypothesis (H2) based on PADM, we expected that people's perceived benefit of protective behaviors is positively related to their media exposure. Here, we observed varied patterns from our multilevel regression in the relationship between respondents' media exposure, perceived household benefits, perceived community benefits, and behavioral intention (Bintn; Multimedia Appendix 5).

Access to resources (β=.097; $F_{1,5812}$=64.40; P<.001) and perceived household benefits (β=.294; $F_{1,5812}$=330.55; P<.001) significantly predicted handwashing behavior. Contrarily, perceived community benefits did not significantly influence handwashing (β=–.010; $F_{1,5812}$=0.50; P=.48). Therefore, H1 is only partially supported in the context of handwashing behavior. Besides, the weekly trend of increasing disease cases also positively predicted handwashing (β=.024; $F_{1,5812}$=5.69; P=.02), reflecting behavior change in response to case numbers. However, Twitter exposure had a negative association with both perceived benefits to the household (β=–.058; $F_{1,7589}$=24.70; P<.001) and community (β=–.030; $F_{1,7592}$=5.73; P=.02). Weekly exposure to the selected national newspapers is negatively associated with perceived benefits to the household (β=–.085; $F_{1,7592}$=44.46; P<.001) and to the community (β=–.090; $F_{1,7592}$=45.67; P<.001). These results suggest that increased exposure to Twitter and the newspapers negatively correlates with perceived benefits of handwashing for both the household and community, rejecting H2 in the handwashing scenario.

Regarding mask-wearing behavior, we found that respondents' behavioral intention is significantly predicted by resources (β=.196; $F_{1,5288}$=369.02; P<.001), benefit to the household (β=.164; $F_{1,5064}$=149.13; P<.001), and benefit to the community (β=.101; $F_{1,5465}$=57.09; P<.001), supporting H1. Twitter exposure positively influenced perceived household benefits (β=.057; $F_{1,6403}$=24.70; P<.001) and community benefits (β=.049; $F_{1,6312}$=17.35; P<.001), while news exposure to the three selected newspapers was positively related to household benefits (β=.031; $F_{1,6442}$=6.68; P=.009) but negatively to community benefits (β=–.029; $F_{1,6259}$=5.34; P=.02). These findings were partly in line with H2, which suggests a positive link between media exposure and perceived benefits of mask-wearing behaviors.

For avoiding public gatherings and travel, both perceived benefits for community (β=.044; $F_{1,5698}$=5.13; P=.02) and for household (β=.348; $F_{1,5723}$=280.26; P<.001) significantly predicted respondents' self-reported behavioral intention, supporting H1. Access to resources (β=.157; $F_{1,5688}$=171.46; P<.001) and increasing weekly case trends (β=.035; $F_{1,4468}$=12.78; P<.001) also contributed to this avoidance behavior. Twitter (β=.058; $F_{1,5859}$=28.62; P<.001) and exposure to the three selected national newspapers (β=.031; $F_{1,6458}$=6.70; P=.009) were positively related to perceived benefits for households, while Twitter exposure alone (β=.051; $F_{1,5979}$=20.60; P<.001) enhanced perceived community benefits, partially in line with H2.

Resources (β=.338; $F_{1,5559}$=757.64; P<.001) and perceived household benefits (β=.268; $F_{1,5559}$=246.06; P<.001) were key predictors of quarantine behavior, which aligns with H1. Perceived community benefits (β=.029; $F_{1,5559}$=3.29; P=.07) showed a positive but not significant trend. Exposure to the selected national newspapers negatively impacted perceived benefits for both the household (β=–.081; $F_{1,5617}$=16.16; P<.001) and community (β=–.090; $F_{1,5617}$=12.80; P<.001), which did not support H2 for quarantine behavior.

Resources (β=.176; $F_{1,5808}$=136.69; P<.001) and perceived household benefits (β=.377; $F_{1,5808}$=280.91; P<.001) significantly predicted intentions to vaccinate, suggesting alignment with H1 for household perception. Weekly case trends (β=.026; $F_{1,5808}$=5.40; P=.02) also positively predicted vaccination intentions. Twitter exposure positively affected the perceived benefits for households (β=.073; $F_{1,7590}$=34.03; P<.001) and communities (β=.058; $F_{1,7591}$=18.36; P<.001), indicating support for H2 with respect to social media influence. In contrast, exposure to the selected newspaper sources negatively correlated with household benefits (β=–.026; $F_{1,7590}$=4.24; P=.04) and was not significant for community benefits (β=–.013; $F_{1,7591}$=0.96; P=.33), which presents a mixed outcome for H2 when considering different media sources.

Interestingly, an inspection of the random effects analysis highlights that time-related variance in vaccination behavior (σ^2=0.016) was lower than individual differences (σ^2=0.437). This indicates that differences in vaccination behavior across different time points were relatively small compared to the differences between individuals. The random effects showed substantial variability in baseline vaccination behavior across individuals (σ^2=0.718), suggesting that some individuals were consistently more inclined to vaccinate than others. Additionally, there was a tendency for those with higher initial intentions to experience smaller changes over time (σ^2=0.046, corr.=–0.90), implying that people with strong initial intentions to vaccinate

XSL•FO
RenderX

were less likely to significantly increase or decrease their intentions across the study period.

Discussion

Principal Findings

Our findings advance the literature on health communication in several ways. First, our research contributes to the intermedia agenda-setting theory within the field of health communication that social media platforms, such as Twitter, can set the agenda for some legacy media such as the selected newspaper outlets in our paper, by revealing nuances in patterns across protective behaviors in a pandemic. We noticed no significant agenda flow between the selected newspapers and Twitter in handwashing and mask-wearing, and in avoiding public gatherings. By contrast, there is also a two-way agenda flow—from selected newspapers to Twitter and from Twitter to those newspapers—about vaccination. Contrary to our expectations, the agenda for self-quarantine originated from Twitter and predicted legacy media outlets' content. That is, our results implied that Twitter users' discussion on quarantining causes the coverage of quarantine in these legacy media outlets we chose as examples. One explanation could be the massive mental health concerns reflected on social media platforms early in the pandemic in the United States, considering the widespread policy of quarantine at that time [53-55]. These studies identified Twitter (or other social media) users' mental health concerns at home at an early stage of the pandemic (ie, at or before March 2020). However, it was not until mid-June to July 2020 that there was a boost in these three US top national newspapers' coverage of mental health issues [56].

Second, our research contributes to the PADM by demonstrating that the relationship between media exposure and protective behavior adoption is contingent upon the specific behavior in question. For certain protective behaviors like avoiding public gatherings and travel and taking up vaccination once vaccines become available, increased exposure to the selected top national newspaper content positively influences individuals' perceived benefits and behavioral intentions. This aligns with existing literature on the positive impact of media on health behavior [5]. The controversy about vaccinations—such as the misleading vaccine-autism relationship and vaccination mandate debate—mostly happened on social media platforms such as Twitter [18]. Legacy media outlets, on the other hand, have to shoulder the responsibility for communicating scientific and other authorities' views about appropriate behavior in the pandemic. Therefore, the positive relationship found between exposure to vaccination-related media content and perceived benefit is understandable.

We also see unexpected, but interesting, negative relationships in quarantine and washing hands. People's perception of the benefits of quarantining might decrease or even backfire in the later stages of the pandemic. This could be due to two factors: (1) mental health concerns arising from social isolation, as previously discussed (eg, [53]), and (2) improvements in nationwide pandemic control [57], leading some states to cancel stay-at-home mandates. Whatever the causes, we observed that respondents' self-reported practices of quarantine decreased over time. We advance PADM testing by showing that, while exposure to information sources such as national newspapers and Twitter can indeed affect perceptions about protective behaviors and behavioral intentions as the model posits, we find that this impact varies across both behaviors and media platforms. For some behaviors, such as handwashing and avoiding gatherings, both types of media exposure had the same effect on intentions, whereas for others, such as mask-wearing and vaccination, the media platforms did not contribute equally to the public's behavioral outcomes, with opposite signs for national newspapers and Twitter. There were also differences within a given media type: for instance, while Twitter exposure positively predicts the perceived benefits of mask-wearing and quarantine behaviors, it is negatively associated with the perceived benefits of handwashing in preventing COVID-19. This underscores the need for targeted message strategies that consider platform-specific outcomes to promote public health actions more effectively.

Third, we examined the relationship between media-influenced benefit perception and individuals' behavioral intention. The positive relationship between perceived benefit and behavioral adoption is within our expectations and is consistent with suggestions from multiple health behavior-related theories, such as the Theory of Planned Behavior [58]. We also noticed negative relationships between the perceived benefits of vaccination and handwashing for the community, and behavioral intentions. Currently, we cannot assertively attribute this phenomenon to a definite theory, but it may be related to egoism versus altruism or prosocial intentions. When individual interests conflict with collective interests in considering vaccination, this situation can be seen as a social dilemma and may result in vaccine hesitation. Our results implied that beliefs about the altruistic effects of these two behaviors undermined intentions, while communication findings elsewhere yielded mixed findings. Altruism-centered messages, aiming to increase individuals' perceived benefit of vaccination for the community, showed no significant results in increasing vaccination behavior as well [59]. However, while messages conveying self-protection had no effect on vaccine intentions, altruistic messages emphasizing protecting other individuals, population health, and the economy had substantially stronger effects [60], while individuals are responsive to altruistic messaging about vaccination [61].

Limitations and Future Research

Although we tried to simulate an authentic environment for individuals reading news articles and making decisions, our model cannot replicate the entire decision-making process. The current model suggests that individuals read news articles about protective behaviors, assess their usefulness, consider available resources, check pandemic updates, and then decide whether to adopt these behaviors. However, there are several factors in the PADM missing in this story: for example, it ignores the effects of risk perceptions, or of trust in authorities or the information source, which are also associated with behavioral intentions [36]. There are also limitations in how we calculate the exposure to relevant Twitter content due to the inherent differences in how content is consumed on the platform compared to the national newspaper we selected. In newspaper

XSL•FO
RenderX

outlets like the NYT, the number of studies on a given topic is relatively limited and stable, allowing for a straightforward calculation of exposure based on study frequency and reader habits. Twitter's dynamic, high-volume nature, however, makes a simple multiplication-based metric less meaningful compared to those newspapers.

It is worth noting that the PADM theorists mentioned the factors "should form causal chains" [33], while our statistical test for this model can only convince us of correlation instead of solid causal relationships. The varied patterns in media exposure's relationship with individuals' risk perceptions prompt us to reconsider how we filter media content related to protective behaviors. We focused only on the content discussed, specifically whether keywords were mentioned (first step of dictionary-based filtering) and whether the topic was health-related (second step of topic-based filtering). We did not look into how they discussed these protective behaviors. For example, media coverage about vaccination could vary in tone as the development of effective COVID-19 vaccines evolved from uncertain to clinically proven during our six survey waves [62].

Additionally, this study is US-based, with a US national survey and US national newspapers in analyses, which limits the generalizability of our findings to a global perspective. Although we collected tweets in English and aimed to capture US users' conversations, our dataset may include tweets from English-speaking users outside the United States due to limitations in geo-tagging availability. This introduces a degree of uncertainty in assuming that all social media data reflect US perspectives. Furthermore, there are well-documented differences in public risk perceptions and protective behaviors across countries, influenced by sociocultural factors such as individualistic or prosocial values, trust in authorities, and personal experience with the virus [63]. When applying the US-based findings to other contexts, we cannot ignore the role of cross-cultural variations and how they differently shape people's responses to health risks.

Communication during the COVID-19 pandemic has faced a concern of an "infodemic" with wicked challenges like misinformation, resistance, and fear [64,65]. Exposure to this infodemic might further elicit individuals' worries about uncertainty and information-seeking behavior [66,67]. Therefore, we believe studying the agenda consistency between different media platforms is essential for effective pandemic management. However, scholars have long been concerned that media can have multiple roles in communicating risk-protective behaviors to lay audiences, and different channels (eg, legacy media vs nonlegacy media such as social media) can have different communication effects [4]. The transmission of quarantine agendas from Twitter to the selected top national newspapers, as observed in this study for two of the five behaviors, along with the differing perceived benefits for household versus community protective behaviors, caution practitioners to consider multiple factors that may be salient to audiences when promoting protective behaviors. This study also calls for further steps for building up more profound and solid models in predicting individuals' behavioral intentions in health communication research.

Our findings carry several actionable strategies for health communicators and decision makers to organize and publish media content. First, practitioners can adopt a platform-specific approach. Social media platforms like Twitter and legacy media such as the national newspapers can influence public perceptions in different ways. For Twitter, practitioners should stay aware of trending conversations about key health behaviors (eg, vaccinating) and engage in addressing misinformation or reinforcing protective behaviors, including changes over time (eg, [68]). Such engagement can help in spreading accurate information and serve as a feedback mechanism with metrics such as engagement rates.

Second, although exposure to some legacy media outlets (eg, national newspapers) can raise awareness and perceived benefits of protective behaviors like vaccination, our data show that this awareness does not always translate into self-reported behavior change. For example, high newspaper exposure was associated with lower perceived household and community benefits for quarantine, even though these perceived benefits were a positive indicator of behavioral change. Therefore, practitioners should design campaigns that not only raise awareness but also emphasize actionable steps of specific protective behaviors, such as tailoring clear instructions and feasible solutions to barriers. Public opinion shows there are barriers for individuals to fully follow "safer at home" policies, including emotional strain and practical challenges [69]. By acknowledging these issues, communicators can offer practical solutions and support, enhancing effectiveness, other than merely increasing the behavior's presence in media.

Third, increased media exposure can sometimes have unintended effects by reinforcing negative perceptions, as seen in our findings where both Twitter and newspaper exposure were linked to lower perceived benefits of handwashing. To avoid these unintended consequences, practitioners should pretest messages with diverse audiences to identify potential misinterpretations or negative framing before widespread dissemination. Additionally, focusing on clear, fact-based messaging that emphasizes practical benefits and personal relevance can help reduce skepticism. The overwhelming amount of unclear, ambiguous, and inaccurate information during the early stage of the COVID-19 pandemic contributed to information overload, which heightened health-related anxiety and increased the spread of misinformation [70,71]. Clear communication can help counteract these negative effects by providing trustworthy, straightforward guidance.

Finally, it is important to consider whether the heightened media consumption during the global pandemic translates into healthy communication strategies for more "normal" times, when media use may be more fragmented. Most of our survey respondents (85%) reported in the first wave that they were using their usual media channels for COVID-19 information, with the exceptions primarily COVID-19–specific outlets (eg, US CDC and World Health Organization websites). Furthermore, unpublished analyses of patterns of self-reported media exposure across different media types (eg, the most common was moderate use of national newspapers, digital news, and social media) found that about 10% of people shifted these patterns from one wave to another, again suggesting that there was mainly stability in

XSL•FO
RenderX

media use from before to during the pandemic through April 2021, the last point at which we collected these data. However, media consumption patterns may shift post pandemic, requiring communicators to adjust their strategies.

Conclusions

While news consumption surged during the pandemic [72], postpandemic media engagement has stabilized but remains above prepandemic levels, and audiences are engaging with more new technology [73,74]. Considering this fragmented attention, health communication practitioners should focus on targeting specific platforms, moving away from blanket exposure and toward tailored content that resonates with diverse, targeted audiences [75]. Practitioners should adapt by segmenting audiences and leveraging analytics to track and optimize message delivery across different platforms.

Abstract

Background: Technology-mediated medication adherence interventions have proven useful, yet implementation in clinical practice is low. The European Network to Advance Best Practices and Technology on Medication Adherence (ENABLE) European Cooperation in Science and Technology Action (CA19132) online repository of medication adherence technologies (MATechs) aims to provide an open access, searchable knowledge management platform to facilitate innovation and support medication

XSL•FO
RenderX

adherence management across health systems. To provide a solid foundation for optimal use and collaboration, the repository requires a shared interdisciplinary terminology.

Objective: We consulted stakeholders on their views and level of agreement with the terminology proposed to inform the ENABLE repository structure.

Methods: A real-time web-based Delphi study was conducted with stakeholders from 39 countries active in research, clinical practice, patient representation, policy making, and technology development. Participants rated terms and definitions of MATech and of 21 attribute clusters on product and provider information, medication adherence descriptors, and evaluation and implementation. Relevance, clarity, and completeness criteria were rated on 9-point scales, and free-text comments were provided interactively. Participants could reconsider their ratings based on real-time aggregated feedback and revisit the survey throughout the study period. We quantified agreement and process indicators for the complete sample and per stakeholder group and performed content analysis on comments. Consensus was considered reached for ratings with a disagreement index of <1. Median ratings guided decisions on whether attributes were considered mandatory, optional, or not relevant. We used the results to improve the terminology and repository structure.

Results: Of 250 stakeholders invited, 117 (46.8%) rated the MATech definition, of whom 83 (70.9%) rated all attributes. Consensus was reached for all items. The definition was considered appropriate and clear (median ratings 7.02, IPR 6.10-7.69, and 7.26, IPR 6.73-7.90, respectively). Most attributes were considered relevant, mandatory, and sufficiently clear to remain unchanged except for *ISO certification* (considered optional; median relevance rating 6.34, IPR 5.50-7.24) and *medication adherence phase*, *medication adherence measurement*, and *medication adherence intervention* (candidates for optional changes; median clarity ratings 6.07, IPR 4.86-7.17; 6.37, IPR 4.80-6.67; and 5.67, IPR 4.66-6.61, respectively). Subgroup analyses found several attribute clusters considered moderately clear by some stakeholder groups. Results were consistent across stakeholder groups and time, yet response variation was found within some stakeholder groups for selected clusters, suggesting targets for further discussion. Comments highlighted issues for further debate and provided suggestions informing modifications to improve comprehensiveness, relevance, and clarity.

Conclusions: By reaching agreement on a comprehensive MATech terminology developed following state-of-the-art methodology, this study represents a key step in the ENABLE initiative to develop an information architecture capable of structuring and facilitating the development and implementation of MATech across Europe. The debates and challenges highlighted in stakeholders' comments outline a potential road map for further development of the terminology and the ENABLE repository.

Introduction

Background

Technology-supported interventions for enhancing medication adherence have shown promise [1-3]. Addressing the prevalent low adherence to medication is likely to improve the use of limited resources and population health [4]. However, the sustainable implementation of health technologies in routine practice is lagging, in part due to the lack of accessibility to users in real-life settings [5]. Many repositories have been developed to improve accessibility and, thus, facilitate uptake of digital health [6], including digital apps [7] and medication adherence interventions [8]. Beyond accessibility, despite positive expectations from different stakeholders, digital health uptake is slowed down by misalignment of priorities and lack of a shared understanding of successful implementation, requiring dedicated efforts to increase communication and coordinated action from early development to routine use [9]. For medication adherence technologies (MATechs), additional barriers are the lack of awareness among stakeholders of the high prevalence and negative impact of suboptimal adherence and the lack of coordinated action for large-scale adoption of adherence-enhancing solutions across health systems [10].

The European Network to Advance Best Practices and Technology on Medication Adherence (ENABLE) European Cooperation in Science and Technology Action (CA19132) [11] was a 4-year project (2020-2024) funded by the European Commission bringing together >250 members from 40 countries to (1) raise awareness of medication adherence and related solutions, (2) expand multidisciplinary knowledge on medication adherence at multiple levels, (3) accelerate knowledge translation to clinical settings, and (4) encourage collaboration toward the implementation of MATech across health systems. Within ENABLE, a work package has been dedicated to identifying and showcasing MATech developed or available in participating countries by developing and maintaining a web-based repository where different stakeholders would be able to search for technologies that fit their needs, preferences, and context. The ENABLE repository aims to improve the accessibility of technologies though proactive and continued stakeholder involvement in building a community of practice that would sustain collaborative efforts throughout the process of technology development and implementation.

XSL•FO
RenderX

Managing the knowledge necessary for developing and using appropriate MATech for each health care context is challenging due to the complexity and heterogeneity of the relevant information and of its potential use contexts. This challenge is well known in medical informatics, which has a long history of developing standardized terminologies, classifications, and ontologies for knowledge management in health care [12]. These commonly agreed upon collections of "entities" (objects and phenomena in the world of health care) and their "attributes" (or properties) are used to encode specific types of information and, thus, structure knowledge in ways that allow for automated inference and learning. Such fundaments of information architecture are essential not only for health care delivery but also as a common language for multi-stakeholder communication about health care planning or improvement. Known examples are the World Health Organization (WHO) International Classification of Diseases [13]; International Classification of Functioning, Disability, and Health [14]; and International Classification of Health Interventions [15], as well as the Systematized Nomenclature of Medicine [16]. While well-established terminologies are intended to be comprehensive and evolve with the evolution of health sciences and clinical practice, newer terminologies continue to be proposed focusing on specific knowledge areas and aiming for interoperability with established terms. The recently developed Classification of Digital Health Interventions [17] and the Behaviour Change Intervention Ontology [18] are 2 examples relevant for MATech. The ENABLE work continues these efforts and has already established a definition of MATech and 385 attributes that represent the foundation of the ENABLE repository and MATech-related activities [19] within the broader context of an ENABLE terminology for intervention, technology, and practice established across working groups [20].

Objectives

This paper reports on stakeholders' views on the proposed MATech definition and attributes on which the ENABLE repository is built. We aimed to examine (1) the level of agreement on the relevance, clarity, and completeness of the proposed definition of MATech; (2) the level of agreement on the relevance, clarity, and completeness of the proposed framework of attributes; and (3) the stakeholders' needs and requirements regarding MATech description.

Methods

Study Design and Process

An international interdisciplinary steering committee (SC) was formed by 11 ENABLE members to guide the development of the terminology and repository. The SC prepared the study protocol, proposed relevant attributes for MATech characterization, provided the rationale and methodology for the stakeholder consultation, managed the consultation process, and performed the data analysis and interpretation. The real-time Delphi stakeholder consultation was conducted on the eDelphi platform (Metodix Ltd), which allowed for anonymous data collection and management in line with European regulations on data protection. The real-time Delphi method is appropriate for capturing the views of large groups of experts and encouraging debate to work toward consensus on specific topics. The proposed terminology and the study protocol were improved based on feedback requested from 30 ENABLE members on face validity, user experience, and clarity of the instructions. The description of the ENABLE terminology and its development, the real-time Delphi survey design, and supporting materials are available in the published study protocol [19].

Ethical Considerations

Ethics approval for the ENABLE Action, including this study, was granted by the Málaga Regional Research Ethics Committee (Comite de Etica de la Investigacion Provincial de Malaga) (CEI29.04.2021.MS1) on April 29, 2021, and a data protection assessment was performed by the Data Protection Officer at the University of Basel, which assessed the protocol as compliant with data protection and security standards. Participants were provided with study information and gave informed consent electronically on the study entry page. Anonymity was ensured via the eDelphi platform. No compensation was offered for participation. More details are reported in the published study protocol [19].

Sampling and Sample Size

Purposive sampling was performed to identify at least 195 panelists from 39 countries participating in ENABLE at the time, aiming to represent 5 stakeholder groups in each country: adherence and eHealth research, clinical care, patient representation, policy and decision-making (PDM), and technology development. The sampling aimed to ensure variation in expertise, countries, and other characteristics such as years of expertise and gender. ENABLE Management Committee members in each country were requested to recommend at least 5 panelists among persons in their network whom they considered to have experience in medication adherence in at least one of the stakeholder groups mentioned previously; all recommended persons were invited to take part.

Survey and Supporting Materials

The repository proposed to focus on MATech, defined as "devices, procedures or systems developed based on evidence to support patients to take their medications as agreed with health care providers (i.e., to initiate, implement and persist with the medication regimen)" following established definitions of related terms [21-24]. A framework of attributes was developed to describe MATech, covering 3 domains: *product and provider information* (domain 1), *medication adherence descriptors* (domain 2), and *evaluation and implementation* (domain 3). The survey consisted of several sections. First, information on the aim of the consultation, rules of engagement, and instructions for the survey and informed consent were provided. Second, participants were required to provide information on their sociodemographic characteristics and professional background, including gender, age, country, level of education, field of professional expertise (eg, medicine, pharmacy, nursing, psychology, or data science), stakeholder group (research, practice, PDM, patient representation, or technology development), and years of experience related to the field of medication adherence. Third, participants were asked to rate their level of agreement with and perceived clarity of the

XSL•FO
RenderX

MATech definition and provide comments or revision suggestions as free text. Fourth, they were asked to familiarize themselves with the proposed terminology and provide general feedback on its completeness as free text. Next, attributes were presented to participants to rate their level of agreement with and clarity of each cluster and provide comments and suggestions. To facilitate response, attributes were grouped into 21 thematic clusters following the structure of the attribute framework. The questions addressing relevance and clarity were displayed in a Live2D format, a 2D grid where participants could rate relevance (on the x-axis) and clarity (on the y-axis) simultaneously on 9-point Likert scales, where 1 represented extremely irrelevant/unclear and 9 represented extremely relevant/clear. Participants provided their rating by placing a dot on the grid, which triggered the display in real time of all ratings of previous participants. They were encouraged to reconsider their ratings based on this information and rerate if needed. Participants were also able to view each other's comments and were encouraged to interact in the free-text comment area for each cluster.

Data Collection

Participants' email addresses were entered into the survey management system, which generated automatic email invitations with personalized links. Before starting the survey, every participant provided informed consent electronically. Participants were able to access and answer the survey at any time during the study period between October 25, 2021, and January 15, 2022. To reach the full potential of the real-time approach, participants were encouraged to revisit the survey several times to follow and engage in discussions and revisit their ratings if their opinion changed. Participation was moderated by the study team to encourage interaction and discussions. Summaries of the study progress and active debates and encouragements to participate were provided weekly via email through the platform (Multimedia Appendix 1). The comment areas were monitored for any technical questions, which were answered in the same interactive area accessible to all, and the answers were included in the weekly summaries if appropriate. To monitor and analyze the evolution of survey responses in time, data were downloaded daily from day 7 to the end of the study period (78 days). This was necessary to bypass the platform limitation of overwriting previous data of individual participants if they decided to reconsider their answers. Data collection was stopped when three predetermined criteria were met: (1) a total response rate of ≥30%, (2) ≥10 complete responses in each stakeholder group, and (3) representation of two-thirds of the ENABLE countries. A survey response was considered complete if background questions and at least 75% of the questions on the terminology were answered.

Data Analysis

Quantitative analyses were conducted in R (R Foundation for Statistical Computing) [25], and qualitative analyses were conducted in NVivo Pro (version 12; QSR International) [26]. Descriptive statistics were used for the background characteristics of the sample and to summarize responses on the terminology.

Level of Agreement on Relevance and Clarity

The level of agreement with the definition, completeness, and relevance and clarity of every attribute cluster was quantified using the interpercentile range adjusted for symmetry (IPRAS) analysis technique from the RAND/UCLA Appropriateness Method [27]. The disagreement index (DI) was calculated as a ratio between the interpercentile range (IPR) from the 30th to the 70th percentile and the IPRAS, and DI>1 (ie, IPR>IPRAS) was considered to indicate disagreement [27]. Levels of agreement were determined based on median ratings rounded to the nearest integer, and the DI was used to steer decisions about each cluster (Table 1).

Table 1. Criteria for levels of agreement and decisions about the attribute clusters.

Criterion	Relevance	Clarity
Median 7-9 and DI[a]<1	Attributes are relevant and mandatory.	Attributes are sufficiently clear to remain unchanged.
Median 4-6 or DI>1	Attributes are optional.	Proposed changes to the attributes are optional.
Median 1-3 and DI<1	Attributes are not relevant and candidates for exclusion.	Attributes are not clear and candidates for rephrasing.

[a]DI: disagreement index.

Subgroup Analyses

The descriptive analyses were repeated per stakeholder group to examine variation in opinions among stakeholders applying the criteria described previously and considering each participant in all the groups they identified themselves with. The reliability of the ratings per question within the stakeholder group was determined via intraclass correlation coefficients (ICCs) based on a 2-way random model considering type (average measures) and definition of relationship (consistency), with ICC>0.70 indicating moderate to good reliability [19]. To examine differences per item, 2-level models were performed for each item considering participants nested within stakeholder group. For these models, participants identifying with more than one group were allocated to the group least represented to maximize the equal distribution of participants in the groups.

Analysis of Process Indicators

The coefficient of quartile variation (CQV) was used to describe response stability (ie, the consistency of stakeholders' responses) and was calculated at the end of the study for all participants (CQV_{total}) and within the same stakeholder group (CQV_{sub}), with CQV_{total}<30% and CQV_{sub}<15% indicating a stable (consistent) response [28]. Longitudinal changes in ratings for each question from individual participants, color coded by stakeholder group, and the evolution of median values of ratings for each stakeholder group were explored visually to gain deeper insights into the evolution of responses during the survey period.

RenderX

Qualitative Analysis of Participants' Interactive Feedback

Comments provided in free text were analyzed qualitatively using deductive content analysis based on the structure of the attribute framework [19]. Coding was performed independently by 2 researchers (UNM [pharmacy background and experienced in qualitative analysis] and FH [medicine background and trained new user of qualitative methods]). Both coders had in-depth knowledge of the terminology and had lead roles in managing the consultation process. Discrepancies were discussed and harmonized through an iterative process, initially between the 2 coders and then in discussions with other SC members (AD, JR, TH, and FR). This process generated a revised thematic tree, which was presented in a narrative and table format. Proposed modifications to the terminology were considered if suggested by median ratings or DIs and reflected in participants' free-text comments. The qualitative results guided improvements in the attribute framework (eg, rewording labels and definitions and excluding or adding attributes) and the subsequent development of the ENABLE repository.

Results

Participation Rates and Sample Characteristics

From 250 invited panelists, 174 (69.6%) started the survey, 117 (46.8%) panelists from 29 countries answered the questions on background information and the definition of MATech, and 83 (33.2%) panelists from 27 countries completed the survey (see details in the data analysis report in Multimedia Appendix 2). On average, 3 (SD 2) panelists represented each of the 29 countries, with a minimum of 1 per country (2 countries) and a maximum of 10 per country (1 country). The countries represented in the real-time Delphi study were Albania, Belgium, Bosnia and Herzegovina, Bulgaria, Croatia, Cyprus, Czech Republic, Denmark, Finland, France, Germany, Greece, Hungary, Italy, Latvia, Malta, the Netherlands, Norway, Poland, Portugal, Romania, Serbia, Slovenia, Spain, Sweden, Switzerland, and the United Kingdom. The panel consisted predominantly of women (74/117, 63.2%), participants with PhD-level education (64/117, 54.7%), health care professionals (HCPs; 85/117, 72.6%), and participants with background in research or health care practice (74/117, 63.2% and 62/117, 53%, respectively); 55.6% (65/117) of the participants identified with 1 background, whereas others identified with up to 5 backgrounds (13/117, 11.1%; Table 2).

Level of Agreement on Relevance and Clarity

No disagreements we identified among the 46.8% (117/250) of the participants who contributed to definition and attribute rating. The median level of agreement with the proposed MATech definition was 7.02 (IPR 6.10-7.69), and the median clarity rating was 7.26 (IPR 6.73-7.90). Thus, the definition was considered relevant and sufficiently clear. The median ratings of relevance and clarity for attribute clusters based on 33.2% (83/250) of the participants are presented visually in Figure 1. A total of 95% (20/21) of attribute clusters were considered relevant (Table S1 in Multimedia Appendix 3), whereas 1 attribute (*ISO standard*) received a moderately relevant rating (median 6.34, IPR 5.50-7.24). *Target use scenario* received the highest rating (median 7.66, IPR 6.99-8.01). Thus, most attributes were considered relevant and mandatory for inclusion in the repository except for *ISO standard*, which was considered optional. In total, 86% (18/21) of the attribute clusters were considered clear (Table S2 in Multimedia Appendix 3). A total of 14% (3/21) of the attribute clusters were rated as moderately clear: *medication adherence phase* (median 6.07, IPR 4.86-7.17), *medication adherence measurement* (median 6.37, IPR 4.80-6.67), and *medication adherence intervention* (median 5.67, IPR 4.66-6.61). *Implementation outcomes* received the highest clarity rating (median 7.67, IPR 7.20-8.06). Thus, most attributes were considered sufficiently clear to remain unchanged, whereas for 3 attributes, changes could be considered if appropriate to improve clarity.

XSL•FO
RenderX

Subgroup Analyses

No disagreements were identified at the subgroup level among researchers, HCPs, PDM stakeholders, patient representatives, and technology developers. For the MATech definition, levels of agreement and clarity ratings within the subgroups were above the established thresholds for sufficient relevance and clarity (Table 3). For attribute clusters (Figure S1 in Multimedia Appendix 3), relevance ratings within all subgroups were above the established thresholds for being considered relevant and sufficiently clear except for *ISO certification* (considered optional by all subgroups) and *intervention setting* (considered optional only by technology developers). Clarity ratings within subgroups confirmed the full sample results for *medication adherence phase* and *medication adherence intervention*, which were perceived as moderately clear by all subgroups. *Medication adherence measurement* ratings were above the clarity threshold for subgroups, suggesting that participants identifying with multiple subgroups rated this attribute higher on clarity. Moreover, *target behavior determinants* was considered moderately clear by patient representatives, and *intervention provider* was considered moderately clear by PDM stakeholders, patient representatives, and technology developers.

Across attribute clusters, the ICC value for the median ratings of the 5 subgroups was 0.95 for relevance and 0.97 for clarity, indicating good interrater reliability between subgroups (considered as "raters"). To describe the differences specific to each attribute cluster, 41% (34/83) of the participants, who identified with more than one group, were allocated to the least represented group. This decision resulted in 33% (27/83) of the participants in the research group, 22% (18/83) in the HCP group, 10% (8/83) in the PDM group, 22% (18/83) in the patient representative group, and 14% (12/83) in the technology developer group. For most attribute clusters, the proportion of variance explained by the stakeholder group was either 0 (model almost or near singular) or <0.1, with only 2 items with an ICC of >0.15 (ie, *target health conditions* [relevance; ICC=0.19] and *intervention setting* [relevance; ICC=0.205]). Thus, ≥80% of the variance was within groups, and therefore, the differences across groups did not justify further investigation per item (Multimedia Appendix 4).

Table 3. Descriptive statistics for level of agreement with and clarity of medication adherence technology definition per stakeholder subgroup.

Subgroup and criterion	Median	30th-70th percentile	Interpercentile range	Interpercentile range adjusted for symmetry	Disagreement index
Researchers (n=50)					
Agreement	7.05	6.10-7.77	1.67	5.25	0.32
Clarity	7.48	6.91-8.01	1.10	6.04	0.18

Technology developers (n=24)					
Agreement	6.74	6.01-7.41	1.40	4.92	0.28
Clarity	7.60	7.01-8.01	1.00	6.11	0.16

Process Indicators

For the whole sample, CQV values for the MATech definition were 13.23 for agreement and 12.74 for clarity, indicating consistency (<30%); consistent responses were found for all attribute clusters. Subgroup analyses found CQV values below the established threshold for most subgroups (<15%), with some exceptions. For the MATech definition, response variation was found among HCPs and technology developers. For relevance (Table 4), response variation was found among technology developers regarding *medication adherence intervention* and among researchers, HCPs, PDM stakeholders, and technology developers regarding the *ISO certification.* For clarity (Table 5), response variation was found among one or more stakeholder groups regarding 48% (10/21) of the attribute clusters. Notably, *target health conditions* was below the stability threshold for patient representatives and technology developers; *medication adherence phase* was below the stability threshold for researchers, HCPs, patient representatives, and technology developers; *medication adherence measurement* was below the stability threshold for researchers, PDM stakeholders, and patient representatives; *medication adherence intervention* was below the stability threshold for researchers and patient representatives; *target behavior determinants* was below the stability threshold for technology developers; *intervention setting* was below the stability threshold for researchers, HCPs,

XSL•FO
RenderX

patient representatives, and technology developers; and *ISO certification* was below the stability threshold for researchers and patient representatives. Moreover, *target use scenario*, *medication regimen*, *intervention mode of delivery*, and *behavior change techniques* were below the stability threshold for patient representatives only.

Most participants did not change their ratings throughout the real-time Delphi survey (Multimedia Appendix 4). The visualization of the evolution of median ratings for relevance and clarity for each attribute cluster per stakeholder group (Figure 2) shows a stabilization of the median values in the second half of the real-time Delphi period at levels above the threshold values.

Qualitative Analysis of Participants' Interactive Feedback

Overview

We examined the feedback provided in the interactive comment area of each survey page, pertaining to 6 predefined topics: general feedback on the survey and on the terminology, specific feedback on the MATech definition, and feedback on the 3 attribute domains (*product and provider information*, *medication adherence descriptors*, and *evaluation and implementation*). In addition to identifying suggestions for improving the terminology, we aimed to understand stakeholders' needs and expectations regarding MATech description that would guide further steps in the development of the ENABLE repository and community of practice. Further details and representative quotes are presented in Multimedia Appendix 5.

General Feedback on the Terminology

Several participants noted the complexity and comprehensiveness of the terminology. Some highlighted challenges related to its use for the repository (eg, anticipating how the framework would need to be translated in a data collection tool and expressing concerns on the feasibility of data collection and long-term maintenance of the repository). Some comments pointed to the importance of representing patient perspectives in the terminology (eg, by including patient-related determinants of adherence and technology use such as medication burden, affordability, or inequities of access).

Feedback on the MATech Definition

Many participants commented on the MATech definition, with several aspects generating debate. Referring to the term "technology," some participants considered that MATech should be understood as digital tools, whereas others considered that a broader scope (eg, including also analog tools and services) was appropriate. Different opinions were expressed on whether "medication adherence" stood for taking medicines as *prescribed by* or as *agreed with* an HCP. Debate ensued on the meaning of the term "evidence based," especially concerning the strength of the evidence needed and finding a balance between inclusiveness and evidence standards (ie, between including technologies under development for which limited evidence is available vs limiting the repository to technologies that meet higher thresholds of evidence).

Feedback on Product and Provider Information

In this first domain, 2 general questions were raised. Some participants were concerned about how the product maturity (versioning) would be handled in the repository and how products that comprised a combination of technologies could be described. The implementation of these terms in the repository would need to consider these different scenarios.

Some comments referred to the need to consider the intended use of the product as a first question and adapt the description depending on the response to this question.

XSL•FO
RenderX

Feedback on Medication Adherence Descriptors

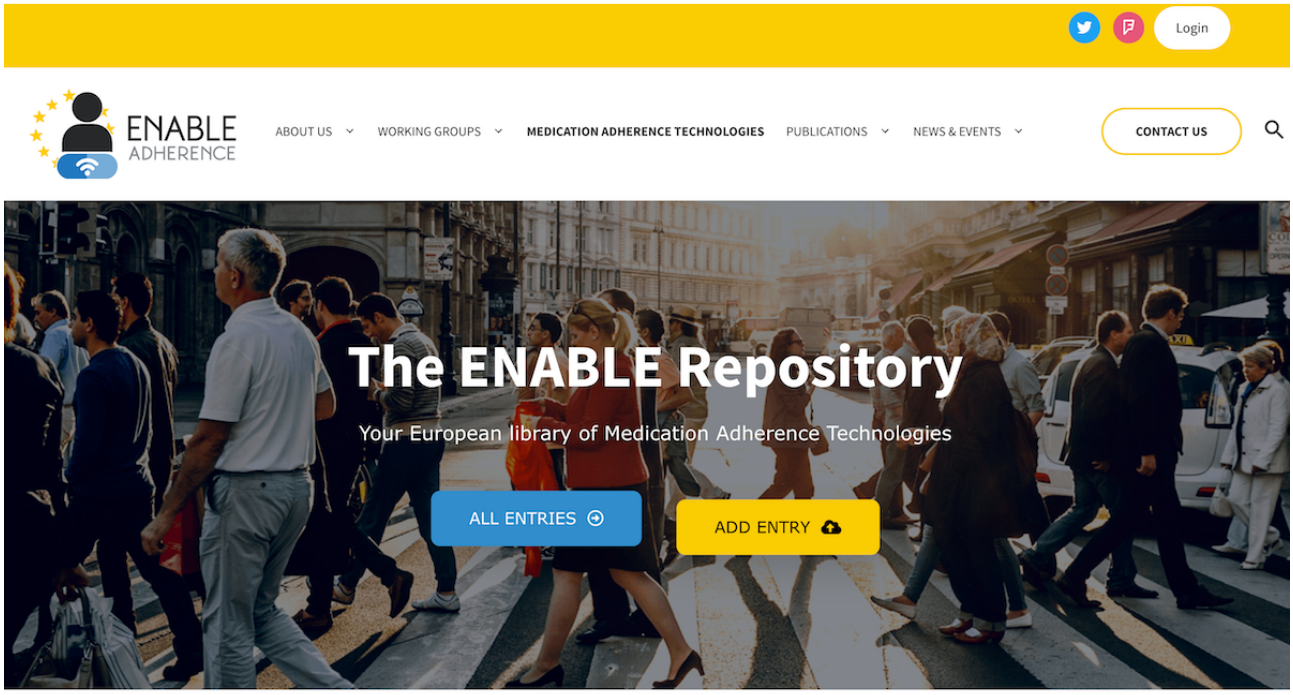
In this second domain, there was debate over the distinction between monitoring and support as 2 elements of adherence management. Some comments recommended to follow the Ascertaining Barriers to Compliance medication adherence taxonomy [21] without adaptations. Others questioned whether an MATech could only monitor the patient without also intervening and affecting their behavior. Inclusion of behavior change techniques following the capability, opportunity, motivation, behavior model was viewed positively by some participants, whereas others questioned whether these models are widely known and simple enough for their use in practice, for example, by HCPs. Suggestions were given on clarifying how certain types of MATech could be described according to the proposed attributes (eg, modes of delivery and provider and setting).

Feedback on Evaluation and Implementation

The third domain was the least commented on. The need for an evidence base, especially scientific evidence, was challenged and considered conditional on the intended use of the technology. Participants expressed that the implementation outcomes and strategies should be more visible in the terminology. Some overlap was noted in the proposed attributes. Several comments referred to the lesser relevance of the ISO certification.

Stakeholders' Needs and Expectations

Some comments highlighted contrasting needs and expectations from participants regarding the MATech description. Some expected more detailed descriptions to provide comprehensive information for different potential users, whereas others preferred more succinct descriptions feasible for MATech providers to enter into the platform. Several comments expressed expectations for continued testing and adaptation of the terminology to evolving technologies. Ensuring accurate information, continuously evaluating MATech, and updating MATech descriptions regularly (eg, every year) were highlighted as important expected features for the repository to provide value to potential users in the context of a rapidly changing field.



Discussion

Principal Findings

The ENABLE European Cooperation in Science and Technology Action offered the opportunity to develop a comprehensive interdisciplinary terminology regarding MATech aligned with existing classifications and ontologies and to consult stakeholders from diverse backgrounds and geographical locations on the terminology's relevance and clarity. We found agreement among stakeholders on the MATech definition and attribute clusters, which indicates an interdisciplinary network ready for collaboration on this conceptual basis. Most terms were considered relevant and clear, and several moderate ratings and related comments suggested further improvements, which informed a new version of the terminology. This initial consensus represents a strong foundation for current efforts to advance the development and use of technologies in medication adherence management across health systems, in which the ENABLE network and collaborating organizations have already made important progress [10,11,20]. This conceptual foundation was an important step in the development of the ENABLE repository (Figure 3 [29]). However, the variation in opinions within stakeholder groups and debates that ensued in the interactive feedback areas over several topics point to the need to continue engaging stakeholders in constructive and inclusive discussions to align conceptual representations and expectations on how they can guide concrete action.

XSL•FO
RenderX

Figure 3. Screenshot of the European Network to Advance Best Practices and Technology on Medication Adherence (ENABLE) repository as available at manuscript submission date.

Interpretation and Comparison to Prior Work

It was agreed that the MATech definition was appropriate and clear; however, several debates ensued regarding "technology," "medication adherence," and "evidence." These debates have practical implications for the ENABLE repository and network. First, the term "health technology," which we adopted from the WHO definition as "the application of organized knowledge and skills in the form of devices, medicines, vaccines, procedures and systems developed to solve a health problem and improve quality of lives" [23], was considered by some participants as too broad for the scope of the repository. At the same time, the attribute framework was criticized for not explicitly including types of technologies considered of high potential, such as bio- and nanotechnologies. Considering this feedback, it was agreed that the scope of the ENABLE repository would focus initially on digital technologies, with the possibility of further extension to other types of technologies in the future. Nevertheless, these different perspectives highlight the challenges inherent in structuring and describing health innovation. The discussion that ensued on the term "medication adherence" as taking medicines "as prescribed" or "as agreed" reflects a long-standing challenge of harmonizing descriptive versus prescriptive definitions of medication adherence. From a descriptive viewpoint, the process of medication taking starts once a prescription has been issued; is operationalized as the comparison between 2 time series (ie, of prescribed and actual dosing); and is distinct from its determinants, including the process of shared decision-making leading to an agreement on the treatment regimen between the patient and their health care team. These distinctions are essential for accurate measurement in research and evaluation [30]. From a prescriptive viewpoint, adhering to a medication regimen would require as a precondition an appropriately prescribed treatment resulting from a process of decision-making that involves mutual agreement on a course of treatment for which responsibility is

XSL•FO
RenderX

shared between the patient and health care team [24]. Thus, integrating treatment agreement into the broader process of medical treatment is essential for a person-centered approach to medication taking. Harmonizing these perspectives requires further consensus work with the involvement of different stakeholders. Third, the role of scientific evidence was debated, with some participants underlining the necessity of including only MATech supported by scientific evidence in the repository and others promoting a more inclusive approach to MATech selection. Following this feedback, we adopted the technology readiness level (TRL) as a framework to guide eligibility, including MATech with at least a small-scale prototype validated in a local environment; however, challenges remained regarding mapping candidate MATech onto the TRL framework [31]. On the basis of these considerations and further work within the ENABLE network on a higher-level ENABLE terminology including medication adherence–enhancing interventions, reimbursement, and best practice, the MATech definition has evolved to "evidence-based health technologies used in the management of medication adherence by different stakeholders" [20]. Therefore, the initial version of the repository includes MATech that (1) are presented as aiming to address medication adherence management (by either obtaining information or offering support), (2) have a digital component as per the DigitalHealthEurope definition [32], and (3) meet at least TRL 4. These criteria are likely to evolve depending on the interest in and uses of the repository by different stakeholder groups.

Most attribute clusters were also considered relevant and clear except for *ISO qualification*, which was considered moderately relevant, and the *medication adherence phase*, *medication adherence measurement*, and *medication adherence intervention* attributes, which were considered moderately clear. The comments received guided improvements; for example, the *ISO qualification* attribute was changed to a broader and more flexible attribute of *certification label*, and the definitions of the medication adherence–related attributes were modified to improve clarity and refer to the Ascertaining Barriers to Compliance taxonomy [21], which informed their selection. The comments on each attribute domain were taken into account by modifying labels and definitions of some terms and restructuring others or in the formulation of the MATech data collection form. While these modifications were considered sufficient for the initial development of the repository, it is necessary to continue improving this terminology and allow it to evolve in synchrony with similar efforts in related fields. In particular, the methodology and evaluation criteria for health technology are evolving rapidly. For example, a recent Delphi study on the assessment of patient-facing eHealth tools reached consensus on 46 criteria classified as "foundational" (eg, technical aspects, clinical utility, and safety) and "contextual" (eg, data protection compliance, safety regulatory compliance, interoperability, and data integration) [33]. While this extensive assessment specific to different use scenarios can be applicable to MATech as well, a briefer description specific to medication adherence would be more appropriate for an initial overview of an MATech at a given moment, which could be followed up with more extensive examination. To facilitate the repository development and its function of boosting research collaborations within the ENABLE network, we subsequently chose to include only a selection of attributes in the MATech description and develop support materials for participating countries to search, contact, and involve MATech developers in describing their products on the ENABLE website. To date, 18 countries have started the MATech search process, and 8 have included at least one MATech in the repository. User feedback will continue to be gathered to inform the iterative development of the terminology and repository.

The subgroup analyses and process indicators showed limited variation in responses between and within groups and a stabilization of responses halfway through the survey. This stability and convergence toward above-threshold ratings for relevance and clarity indicate a strong basis for multi-stakeholder action on this topic. However, there were some attribute clusters that showed moderate clarity only for some stakeholder groups (ie, *target behavior determinants* for patient representatives and *intervention provider* for PDM stakeholders, patient representatives, and technology developers). While these ratings suggest only optional modifications, it is important to interpret these findings as a recommendation to reword and explain professional terminology in all stakeholder-facing materials. Participants recommended repeatedly adapting the technical language to diverse audiences, and this advice has been considered in the development of repository-related materials and needs to guide further developments.

Developing a consensus terminology to structure the description and facilitate the search of available solutions has been used in developing repositories in related areas, such as the taxonomy of self-management interventions on which the Comparing Effectiveness of Self-Management Interventions in 4 High-Priority Chronic Diseases in Europe (COMPAR-EU) platform was built [34]. These frameworks prove useful in systematic searches and descriptions of published research evidence and available digital products, as performed in the COMPAR-EU project [35] and in ENABLE [36]. Other repositories may not rely on an extensive conceptual development and rather adopt a limited number of descriptive terms to serve for initial explorations of the available offer in a specific topic or geographical area. This is the case the Radar Digital Health Uptake [6], the different country-specific repositories cataloged on the European mHealth Hub [7], and Interventienet for medication adherence interventions [8]. As the digital health field will continue to develop, it becomes increasingly relevant to work on the integration and continuity of these platforms. Ontological approaches may provide part of the solution for the technical integration, whereas consensus methodologies such as the Delphi method could be used to reach agreement on policy priorities and their implementation.

Strengths and Limitations

This real-time Delphi study succeeded in engaging a diverse stakeholder panel regarding geographical location, professional experience, and sociodemographic characteristics and in reaching a consensus on a comprehensive terminology to inform research on and adoption of MATech. The real-time web-based format facilitated interactions and flexible participation of

XSL•FO
RenderX

panelists at their chosen time and provided valuable feedback for further improvements. The subgroup and process analyses allowed for a more in-depth understanding of the variation in opinions and, thus, potential avenues for future stakeholder engagement. However, 2 main limitations are important to consider. First, some limitations of the tool did not permit a full analysis of the change in opinions and might have overestimated the level of consensus. For example, once a panelist provided an initial response to a question, they were able to see the responses of others and readjust their response in light of this information, in which case the initial response was overwritten. Nevertheless, survey data were downloaded every day to capture temporal changes. Therefore, while we could not capture changes between initial and reconsidered responses if such changes occurred within the same day, changes occurring in consecutive days were identified. Second, participation rates were <50%, and few participants engaged with the survey multiple times during the survey period. While we attempted to encourage participation via pretesting of materials and weekly summaries emailed to all participants, we could not overcome other likely barriers such as the complexity of the participation task and the novelty of the real-time web-based Delphi format. Thus, our findings likely represent a selected population, and future work on the ENABLE terminology would need to involve a wider audience and apply different methods to communicate and ask for feedback about medication adherence–related terms and their different practical applications.

Future Directions

This initial work opens several avenues for potential development of the ENABLE terminology. An important next step is to develop it into an ontology of MATech research and deployment in health systems in line with methodological recommendations [37]. While our terminology closely followed ontology development principles and steps [19], further work remains to be done, such as testing interrater reliability, specifying relationships between entities, and disseminating and maintaining the future ontology. This work would need to be integrated into the sustainability of the ENABLE repository and community of practice. The ENABLE Action has been encouraging the development of national centers and networks of medication adherence in collaboration with stakeholder organizations [10]. These centers and the pan-European community that has developed during the ENABLE project could adopt and further improve this terminology and conduct translations into different languages following recent examples of other terminologies [38,39]. The repository is intended as a common platform for developing and implementing digital adherence technologies in Europe and needs to be supported by policies that acknowledge medication adherence as a priority for coordinated action, inform of available solutions, and incentivize and support their deployment [40].

Beyond its use to inform the repository, the ENABLE terminology can be applied to assess stakeholder needs and develop training, for example, training HCPs in selecting and using MATech in their practice or MATech developers in assessing user needs and health system requirements for technology adoption. Part of the attribute framework was already used in developing content for an interdisciplinary ENABLE training school in 2023, and other materials are under development. In the long term, the more consistent use of MATech-related terms and definitions has the potential to lead to better standardization of research and implementation efforts, as well as of recording practices in real-life settings, by providing the information architecture to collect real-world data for the development, evaluation, and implementation of MATech in line with current developments to use real-world data for agile regulatory approval [41]. As medication adherence is a transversal topic in health services worldwide, we can envisage the possibility of using future iterations of this taxonomy for standardized operationalization of medication adherence measurement and intervention into digital systems, for example, within the innovative Digital Adaptation Kits recently piloted by the WHO in several clinical areas [42]. Given its built-in interoperability, the ENABLE terminology can also be expanded to encompass terms describing other related medication use processes (eg, medication review and prescribing practices) and other self-management and health behaviors (eg, dietary recommendations, physical exercise, sedentariness, sleep, and alcohol and tobacco use). Continuing its development with an active engagement of patients and other stakeholders would allow for the setting of priorities in line with users' expectations and, thus, maximizing its utility. Challenges remain on aligning stakeholders and maintaining a community of practice that would apply and evolve this taxonomy to serve the effective and efficient development and use of MATech in health systems.

Conclusions

This paper reports reaching an agreement among diverse stakeholders from 27 countries on a comprehensive MATech terminology developed following state-of-the-art methodologies. Therefore, this study represents a key contribution toward the ambitious goal of building an information architecture to facilitate the development and implementation of MATech in health systems. Further improvements to this terminology, together with knowledge mobilization activities such as interdisciplinary networking and training across stakeholder groups, would ensure a shared conceptual and practical foundation for efficient innovation in the field of medication adherence.

Acknowledgments

The authors would like to thank the European Network to Advance Best Practices and Technology on Medication Adherence (ENABLE) members for their feedback on the development of the ENABLE repository and early versions of this work and the ENABLE Core Team for their leadership and coordination of ENABLE activities, which this work is part of. The authors are grateful for the participation of 83 experts in the real-time Delphi study, among whom they are honored to name the following: Pavel Panayotov, Roche Bulgaria; Salvatore Pirri, Sant'Anna School of Advanced Studies, Pisa, Italy; Ema Paulino, National

Abstract

Background: In the digital age, there is an emerging area of research focusing on digital well-being (DWB), yet conceptual frameworks of this novel construct are lacking. The current conceptualization either approaches the concept as the absence of digital ill-being, running the risk of pathologizing individual digital use, or follows the general subjective well-being framework, failing to highlight the complex digital nature at play.

Objective: This preregistered study aimed to address this gap by using a network analysis, which examined the strength of the relationships among affective (digital stress and web-based hedonic well-being), cognitive (online intrinsic needs satisfaction), and social (online social connectedness and state empathy) dimensions of DWB and their associations with some major DWB protective and risk factors (ie, emotional regulation, nomophobia, digital literacy, self-control, problematic internet use, coping styles, and online risk exposure).

Methods: The participants were 578 adults (mean age 38.7, SD 13.14 y; 277/578, 47.9% women) recruited from the United Kingdom and the United States who completed an online survey. Two network models were estimated. The first one assessed the relationships among multiple dimensions of DWB, and the second examined the relationships between DWB dimensions and related protective and risk factors.

Results: The 2 resulting network structures demonstrated high stability, with the correlation stability coefficients being 0.67 for the first and 0.75 for the second regularized Gaussian graphical network models. The first network indicated that all DWB variables were positively related, except for digital stress, which was negatively correlated with the most central node—online intrinsic needs satisfaction. The second network revealed 2 distinct communities: *digital competency* and *digital dependency*. Emotional regulation emerged as the most central node with the highest bridge expected influence, positively associated with emotion-focused coping in the *digital competency* cluster and negatively associated with avoidant coping in the *digital dependency* cluster. In addition, some demographic differences were observed. Women scored higher on nomophobia (χ^2_4=10.7; *P*=.03) and emotion-focused coping (χ^2_4=14.9; *P*=.01), while men scored higher on digital literacy (χ^2_4=15.2; *P*=.01). Compared with their older counterparts, younger individuals scored lower on both emotional regulation (Spearman ρ=0.27; *P*<.001) and digital self-control (Spearman ρ=0.35; *P*<.001) and higher on both digital stress (Spearman ρ=−0.14; *P*<.001) and problematic internet use (Spearman ρ=−0.25; *P*<.001).

Conclusions: The network analysis revealed how different aspects of DWB were interconnected, with the cognitive component being the most influential. Emotional regulation and adaptive coping strategies were pivotal in distinguishing digital competency from dependency.

Introduction

Background

Digital well-being (DWB), which refers to the subjective experience of optimal balance between the benefits and drawbacks obtained from online connectivity, has emerged as a critical area of concern in the current digital era [1]. As of July 2024, global estimates indicate that the number of active internet users has reached 5.45 billion, representing two-thirds of the world's population, with a significant portion also engaging actively on social media platforms [2]. In this context, understanding and promoting DWB has become essential for bolstering individual well-being in an increasingly digitalized society.

Existing studies adopted 2 distinct approaches for conceptualizing this novel construct. The first approach conceptualizes DWB as the absence of problems resulting from internet and technology use, drawing parallels to frameworks of digital addiction (DA) [3-5]. This perspective encompasses various subtypes of problematic digital use, such as internet gaming disorder, smartphone addiction, and social media addiction, which have attracted growing attention from both the professional community and the general public [6-8]. DWB research that follows the DA framework has provided valuable insights into the risks of unhealthy digital behaviors [9-12]. However, equating well-being with the absence of such behaviors fundamentally differs from the broader conception of well-being as a state of "optimal psychological experience and functioning" [13]. An exclusive focus on ill-being can medicalize individuals' relationships with digital devices, thereby overlooking the factors that foster positive and fulfilling digital experiences [1,14,15].

The second approach to conceptualizing DWB is grounded in subjective well-being (SWB) frameworks, emphasizing the hedonic and eudaimonic benefits of digital use [16,17]. This SWB approach to the conceptualization addresses affective well-being (eg, pleasure), satisfaction across various life domains (eg, interpersonal relations and work productivity), and overall satisfaction with contemporary digital life marked by constant internet connectivity and availability [17]. In contrast to the DA framework, the SWB approach highlights the concept of "controlled pleasure" and the use of digital devices to meet individuals' intrinsic needs [18,19]. Despite the advantages of the SWB framework in promoting healthy digital relationships, its reliance on general SWB measures often fails to account for the domain specificity of digital connectivity [18,20].

Toward a Tripartite Framework: Affective, Cognitive, and Social DWB

To address the shortcomings of both the DA and SWB frameworks, Büchi [17] proposed a new DWB framework that emphasizes how distal well-being outcomes (eg, psychological health and SWB) are related to 3 key constructs, namely, digital practices (eg, social media use and online behaviors), proximal harms (eg, digital stress), and benefits (eg, social connectedness and hedonic experience). These connections are further moderated by individual and situational variables [17]. Building on this theoretical understanding, this study expands the SWB framework by conceptualizing DWB as comprising individual dimensions of affective (ie, positive and negative affect), cognitive (ie, intrinsic needs satisfaction), and social (ie, experiences of connectedness and empathy) well-being, with an emphasis on the inherently digital nature of DWB [13,21].

In line with the conceptualization of affective well-being, the affective dimension of DWB reflects both positive and negative emotional experiences. On the negative side, digital stress encompasses the stress arising from the pressure of mobile connectivity, which can lead to expectations for constant availability (ie, availability stress) and feelings of being overwhelmed due to an excess of information on the web (ie, information overload) [22]. These affective stressors have been shown to have negative influences on mental health [22-24]. Conversely, the positive aspect of affective DWB includes the hedonic pleasure derived from engaging in digital activities [1,25].

A key conceptual component of DWB, aligned with the SWB framework, pertains to the cognitive dimension. Cognitive well-being refers to individuals' evaluative judgments of their overall life satisfaction and satisfaction within specific domains [21]. Drawing from the SWB framework, previous DWB research has highlighted the importance of 3 core needs—autonomy, competence, and relatedness—in determining satisfaction with digital use [16]. This study focuses on intrinsic needs for autonomy and competence, which represent eudaimonic benefits derived from digital connectivity [1,16].

The increasingly pervasive role of social media in daily social interactions, a factor that has fundamentally transformed the processes of socialization, highlights the need to examine the social aspect as a distinct dimension of individual DWB. To unpack how individuals perceive and experience their relations with others and society at large through digital activities, this study operationalizes social DWB as comprising online social connectedness and online state empathy [26-30].

Enhancing the DWB Framework: Role of Protective and Risk Factors

To formulate a comprehensive conceptual framework of DWB that addresses the variability inherent in digital connectivity [17], this research incorporates a cluster of DWB-related factors (ie, protective and risk factors).

One body of studies focusing on DWB enhancement highlighted several protective factors, including the ability to regulate one's emotions (ie, emotional regulation), the ability to resolve conflicts between digital use and real-life goals (ie, digital self-control), skillful use of technologies (ie, digital literacy), and adaptive coping strategies such as emotion-focused coping [31-33]. Digital platforms provide users access to emotionally

XSL•FO
RenderX

charged content and facilitate swift emotional exchanges through media emotional affordances such as likes, comments, and reactions [34,35]. Therefore, effective emotional regulation and adaptive emotion-focused coping are essential to prevent negative impacts from these interactions. Studies have indicated that individuals with stronger emotional regulation report better well-being and fewer problematic digital behaviors [36-38]. In addition to emotional affordances, online connectivity poses another threat to people's DWB. Self-control becomes crucial for maintaining responsible internet use and resisting excessive use [4,39-41]. Studies also revealed the important role of digital literacy in a meaningful digital experience, which contributes to individual cognitive well-being by meeting their needs for competence and autonomy through skillful digital use [42,43].

Another body of DWB studies that follows the DA framework has identified several key affective and behavioral risk factors, including emotional attachment to mobile phones (ie, nomophobia), addictive internet use (ie, problematic internet use), maladaptive coping (ie, avoidant coping), and involuntary exposure to unwanted experiences (ie, online risk exposure) [10,44-46]. Meta-analyses revealed the harmful effect of overreliance on phone and internet use on mental health outcomes [47,48]. In addition, online risks, including unwanted explicit content, cyberbullying, sexual solicitation, and leaking of privacy, have been shown to elicit emotional and psychological harm, especially for younger internet users [46,49]. Avoidant coping refers to attempts to ignore or evade stressors rather than addressing them by attending to distractive digital activities. This maladaptive coping can reduce overall resilience and exacerbate feelings of stress, anxiety, and dissatisfaction [50].

In summary, this study examines the relationships among the affective, social, and cognitive dimensions of DWB as well as the associations between its related factors, which are a selected cluster of affective, cognitive, and behavioral protective and risk factors. This study uses a system-based approach [51] to uncover patterns and interactions that contribute to the overall structure of DWB. Using network analysis [52], it aims to reveal how various psychological and contextual factors (ie, related factors) relate to specific DWB components while accounting for the influence of other variables in the network. In doing so, this approach aims to provide a deeper understanding of the construct, illustrating how dimensions of DWB and its related factors collectively shape digital wellness.

Methods

Recruitment

This online study was accessible to participants using any type of digital device with internet access. Recruitment was facilitated through Prolific Academic, a crowdsourcing platform that offers access to large and diverse samples while ensuring high data quality for academic research [53]. Eligible participants included adults aged ≥18 years from the United Kingdom and the United States with a good track record on the survey platform (ie, an approval rate of ≥90% in previous surveys). Participants were informed about the study's objectives, which involved completing a series of survey questions exploring their digital and online habits and activities. The hourly compensation rate of £2.50 (US $2.30) was provided upfront to ensure transparency and encourage voluntary participation. A total of 578 participants were recruited.

Research Design and Procedure

This study used a cross-sectional design to collect data using self-report questionnaires administered through the Qualtrics software. Interested and eligible individuals were directed to a survey via a URL provided on the Prolific recruitment platform. Participants indicated their informed consent by checking a box before starting the survey. The survey included the measures described in the Overview section, which were presented in English and randomized in order. After completing the survey, participants were thanked and compensated.

Measures

Overview

For each variable, the sum scores of the measures were incorporated as nodes in the network. Further details of the measures administered in the study are shown in Table 1.

XSL•FO
RenderX

Table 1. All measured variables included in the network analysis (N=578)[a].

Label	Variable or node	Definition	Sample items
Affective DWB[b]			
ADWB[c]1	Digital stress	The degree to which people felt stressed and pressured due to mobile communication and information overloads	• "I feel stressed by the amount of contact through my mobile phone." • "I am pressured to respond quickly to all calls or texts." • "I am frequently overwhelmed by the amount of information available online."
ADWB2	Web-based hedonic well-being	Hedonic experience from online activities	• "Being online entertains and stimulates my mind."
Cognitive DWB			
CDWB[d]	Intrinsic needs satisfaction	Individual satisfaction with needs for autonomy and competence resulted from the use of social media	• "When I am on social media, I feel free to be who I am." • "When I am on social media, I feel very capable and effective."
Social DWB			
SDWB[e]	Social digital well-being	The ability to understand, feel, and sympathize with others in digital space (online state empathy) and the degree to which people feel connected and related to others on the web (online social connectedness)	• "I knew what the person I was interacting with felt emotionally." • "I felt the same way as the individual I was interacting through digital interactions." • "I feel close to people online." • "I don't feel related to most people on social media." [Reverse coded]
Affective-related factors			
AC[f]1	Emotional regulation	The ability to recognize and exert control over one's own emotional state	• "I have difficulty making sense out of my feelings." [Reverse coded] • "When I am upset, I have difficulty thinking about anything else." [Reverse coded]
AC2	Nomophobia	The fear of being disconnected from the digital space	• "If I did not have my smartphone, I would be uncomfortable because I could not stay up to date with social media and online networks." • "Running out of battery in my smartphone would scare me."
Cognitive-related factors			
CC[g]1	Digital literacy	Individual ability of skillful digital use	• "I know how to open a new tab in my browser." • "I feel comfortable deciding who to follow online (eg, on services like Twitter or Tumblr)."
CC2	Digital self-control	The ability to successfully manage goal conflicts between digital use and real-life activities	• "How often do you give in to a desire to use social media even though your social media use at that particular moment makes you delay other things you want or need to do?" [Reverse coded]
Behavioral-related factors			
BC[h]1	Problematic internet use	Compulsive and excessive use of internet	• "I lose track of time online." • "I feel lost if I can't go online."
BC2	Problem-focused coping	Coping by directly confronting a stressor in an attempt to decrease or eliminate it	• "I've been thinking hard about what steps to take."

XSL•FO
RenderX

Label	Variable or node	Definition	Sample items
BC3	Emotion-focused coping	Coping using skills for processing and dealing with feelings that arise due to stressful situations	• "I've been making fun of the situation."
BC4	Avoidant coping	Coping by not addressing the problem directly but instead disengaging from the situation	• "I've been turning to work or other activities to take my mind off things."
BC5	Online risk exposure	The frequency at which individuals are exposed to unwanted stressful events on the web	• "Someone made rude or mean comments about you or threatened you in some way online." • "You saw online stories, images, or videos that contained excessive violence that made you feel uncomfortable."

[a]This table outlines all the variables tested in the network analysis, detailing their operational definitions and sample items. All the variables were measured using validated psychological scales in an online self-report survey conducted from June 2024 to July 2024.

[b]DWB: digital well-being.

[c]ADWB: affective digital well-being.

[d]CDWB: cognitive digital well-being.

[e]SDWB: social digital well-being.

[f]AC: affective-related factors.

[g]CC: cognitive-related factors.

[h]BC: behavioral-related factors.

Digital Stress

The Entrapment Scale [54] consists of 6 items that assess stress related to mobile communication and 3 items that evaluate information overload. Participants rated each item on a Likert scale ranging from 0 (strongly disagree) to 4 (strongly agree), indicating the extent to which they feel pressured by online communication and information available on the web. The sum score ranges from 0 to 36, with higher scores indicating greater levels of digital stress due to mobile entrapment and information overload.

Web-based Hedonic Well-Being

Web-based hedonic well-being was measured using the Online Hedonic Scale [55], which comprises 3 items that assess pleasant subjective experience with digital activities. Participants rated each item on a Likert scale ranging from 0 (strongly disagree) to 4 (strongly agree), indicating the degree to which they derive pleasure from being on the web. The sum score ranges from 0 to 12, and higher scores indicate greater levels of web-based hedonic well-being.

Intrinsic Needs Satisfaction

The 6-item Autonomy and Competence subscale was adapted from the Intrinsic Need Satisfaction Scale [16], which is a 12-item measure designed to assess individual intrinsic need satisfaction derived from digital use. Participants rated each item on a Likert scale ranging from 0 (strongly disagree) to 4 (strongly agree), reflecting the extent to which they feel their needs for autonomy and competence were fulfilled through social media engagement. The sum score ranges from 0 to 48, with higher scores indicating greater levels of internal need satisfaction.

Online Social Well-Being

The State Empathy Scale [56] is a measure consisting of 9 items that assess an individual's ability to understand, feel, and empathize with others in the digital space. The online social connectedness measures were adapted from the Social Connectedness Scale [28], which also includes 9 items evaluating the extent to which individuals feel connected and related to others on social media. Participants rated each item on a Likert scale ranging from 0 (strongly disagree) to 4 (strongly agree), indicating the extent to which they experience empathy during online interactions. The sum score ranges from 0 to 72, with higher scores indicating greater levels of online social well-being.

Emotional Regulation

The Difficulties in Emotion Regulation Scale [57] consists of 16 items that assess individuals' challenges in recognizing and managing their emotional states. Participants rated each item on a Likert scale ranging from 0 (strongly agree) to 4 (strongly disagree), reflecting the degree to which they experience difficulties in emotional regulation. The item scores are reversely coded, and the sum score ranges from 0 to 64, with higher scores reflecting greater levels of emotional regulation.

Nomophobia

The Nomophobia Scale [58] comprises 20 items that measure the fear of being unable to communicate and access information, losing connectedness, and sacrificing convenience due to disconnection from mobile phone connectivity. Participants rated each item on a Likert scale ranging from 0 (strongly disagree) to 4 (strongly agree), reflecting the extent to which they experience the aforementioned type of fear. The sum score ranges from 0 to 80, with higher scores indicating greater levels of nomophobia.

XSL•FO
RenderX

Digital Literacy

The Digital Literacy Scale [59] consists of 35 items that assess individuals' ability in skillful digital use. Participants rated each item on a Likert scale ranging from 0 (strongly disagree) to 4 (strongly agree), reflecting their level of digital competence. The sum score ranges from 0 to 140, with higher scores reflecting greater levels of digital literacy.

Digital Self-Control

The Social Media Self-Control Failure Scale [60] consists of 3 items that evaluate self-control failures arising from goal conflicts between digital and real-life activities. Participants rated each item on a Likert scale ranging from 0 (strongly agree) to 4 (strongly disagree), reflecting the extent to which they struggle to manage goal conflicts between online engagement and real-life activity. The sum score ranges from 0 to 12, with higher scores indicating greater levels of digital self-control.

Problematic Internet Use

The Problematic Internet Usage Scale [8] consists of 15 items that measure compulsive and excessive internet use. Participants rated each item on a Likert scale ranging from 0 (strongly disagree) to 4 (strongly agree), indicating the extent of their problematic internet use. The sum score ranges from 0 to 60, with higher scores reflecting greater levels of problematic internet use.

Coping Styles

The Brief Coping Orientation to Problems Experienced Inventory [61] consists of 28 items that assess individual preferred coping styles (ie, problem focused, emotion focused, and avoidant). Participants rated each item on a Likert scale ranging from 0 (strongly disagree) to 4 (strongly agree), reflecting the extent to which they adopt a particular coping style. The sum score ranges from 0 to 32 for problem-focused coping, 0 to 48 for emotion-focused coping, and 0 to 32 for avoidant coping. Higher scores indicate greater deployment of the corresponding coping style.

Online Risk Exposure

The Online Risk Exposure Scale [46] consists of 16 items that measure the frequency of involuntary exposure to unwanted stressful events on the web. Participants rated each item on a Likert scale ranging from 0 (never) to 4 (always), indicating the frequency of their risk exposure to unwanted online activities. The sum score ranges from 0 to 64, with higher scores indicating greater frequencies of online risk exposure.

Ethical Considerations

The study was preregistered on the Open Science Framework [62]. Ethics approval for this study was obtained from the Human Research Ethics Committee of the University of Hong Kong before the study began (EA240174). Before participation, individuals were presented with information regarding the study's objectives, their rights to withdraw at any time without consequences, and the requirement for informed consent for research participation. All participants were compensated at a rate of £2.50 (US $2.30) per hour upon completing the study. To protect privacy and confidentiality, all data were anonymized and identified only through a randomly assigned participant ID. Responses were securely stored following data protection guidelines, including encrypting data during both storage and transmission.

Statistical Analysis

All analyses were conducted using R software (version 4.1.3) and RStudio (R Core Team, 2024).

Preliminary Analysis

Shapiro-Wilk normality tests were first used to check normality. Kruskal-Wallis tests were conducted to examine potential differences across gender groups in cases of nonnormally distributed data. If significant differences (ie, $P<.05$) were detected, post hoc pairwise comparisons were performed using the Wilcoxon rank sum test with continuity correction to investigate differences across gender categories. The comparisons were adjusted using the Bonferroni correction method. Spearman rank-order correlation tests were conducted to assess differences based on age distribution.

Network Analysis

The R package *huge* was first used to apply nonparanormal data transformation for skewed data (version 1.3.5; Jiang et al [63]). Following guidelines for network analysis, variables were theoretically selected to avoid conceptual overlap [52,64]. A data-driven method was also applied to confirm this [65]. First, the correlation matrix was checked to ensure that it was positive definite, controlling for linear combinations among the variables. Then, the *goldbricker* function from the R package *networktools* (version 1.5.2; Jones [66]) was used to identify potential redundant variables. No redundancies were found, supporting that the theoretical selection had yielded nonoverlapping variables.

A regularized graphical Gaussian model (GGM) was used to estimate 2 network structures [67,68]. The first network (DWB network) contained the affective, cognitive, and social dimensions of DWB. The second network included DWB factors from the first network and related risk and protective factors selected from previous DWB research. The DWB-related associations were examined in the second network model (DWB-related network).

The network models were constructed using the EBICglasso algorithm in the R package *qgraph* (version 1.9.4; Epskamp et al [69]). This procedure involves using the graphical least absolute shrinkage and selection operator to estimate a GGM through a regularization technique. This method balances model complexity and sample size to select the best-fitting model based on the extended Bayesian information criterion, which includes a penalty term that discourages overfitting. The graphical least absolute shrinkage and selection operator applies L1-regularization, shrinking small edge weights to zero, which results in a simpler network that highlights the most important connections. After constructing a series of networks, the model with the lowest extended Bayesian information criterion is chosen to ensure interpretability and avoid overfitting [70]. Networks were then visualized using the Fruchterman-Reingold algorithm [71]. Thicker edges indicate stronger associations

XSL•FO
RenderX

between nodes, with red edges representing negative and blue edges representing positive associations.

The strength centrality measure for each variable was obtained across the 2 networks. This index reflects the overall strength connectivity of a variable with other variables from the studied system. The node with the highest strength centrality is considered the most central or influential, as it has the most and strongest associations within the network, underscoring its overall importance in the system. In this study, the strength centrality index was used to identify the most influential variable in examining the construct of DWB.

Community Detection for DWB-Related Network

The *spin glass* algorithm was used to detect the community structure of the DWB-related network (Yang et al [72]) using the R package *igraph* (version 7.2.3; Csárdi [73]). The communities represent clusters of nodes, which demonstrate stronger connections with one another compared to nodes from other clusters. In addition to strength centrality measures, the bridge expected influence (BEI) of each node was computed to reflect each node's overall strength of connectivity with other communities detected in the DWB-related network using the R package *networktools* (version 1.5.2 [74]). This BEI index reveals the nodes that act as bridges between the different communities in the network. The node with the highest BEI indicates the crucial role played by the variable in linking the other cluster. In this study, the BEI index allows for the understanding of the mechanisms underlying the relationship between the protective and risk-oriented aspects of digital health.

Network Accuracy and Stability

Nonparametric and case-dropping bootstrapping tests were used to assess the accuracy and stability of the resulting networks using the R package *bootnet* (version 1.6 [75]). The accuracy of edge weights was tested using nonparametric bootstrapping with 1000 iterations. The stability of strength centrality and BEI measures were tested using case-dropping subset bootstrapping with 1000 iterations. In this process, the correlation between the original centrality indices and those derived from smaller subsets was calculated, where up to 75% (434/578) of the participants were dropped. The correlation stability coefficients were then computed, showing the largest proportion of data that can be excluded while still maintaining a correlation ≥0.70 with the original centrality indices, with 95% confidence. A network is considered stable if the correlation stability coefficient is at least 0.25, with a preferred value >0.50 [76].

Results

Preliminary Results

Table 2 summarizes the demographic characteristics of participants of this study.

The descriptive statistics of DWB and its related factors are summarized in Table 3. The Shapiro-Wilk normality results indicated that data for all measurements, except problematic internet use, were nonnormally distributed (Multimedia Appendix 1). Gender was found to be a significant factor in nomophobia (χ^2_4=10.7; *P*=.03), digital literacy (χ^2_4=15.2; *P*=.01), and emotion-focused coping (χ^2_4=14.8; *P*=.01). Specifically, a significant difference was observed, with women (median 48.00, IQR 36.00-60.00) scoring significantly higher than men (median 43.00, IQR 28.35-57.65) on nomophobia (*P*=.02). In addition, women (median 22.00, IQR 19.50-24.50) also scored significantly higher than men (median 21.00, IQR 17.50-24.50) on emotion-focused coping (*P*=.01). Conversely, men (median 113.00, IQR 102.50-123.50) scored significantly higher than women (median 107.00, IQR 96.00-118.00) on digital literacy (*P*=.01).

The Spearman rank-order correlation test results are summarized in Table 4. Statistically significant positive relationships were found between age and intrinsic need satisfaction, emotional regulation, and digital self-control. Conversely, age was found to be negatively related to digital stress, nomophobia, problematic internet use, problem-focused coping, emotion-focused coping, and online risk exposure.

Table 3. Descriptive statistics of digital well-being–related measurements (N=578)[a].

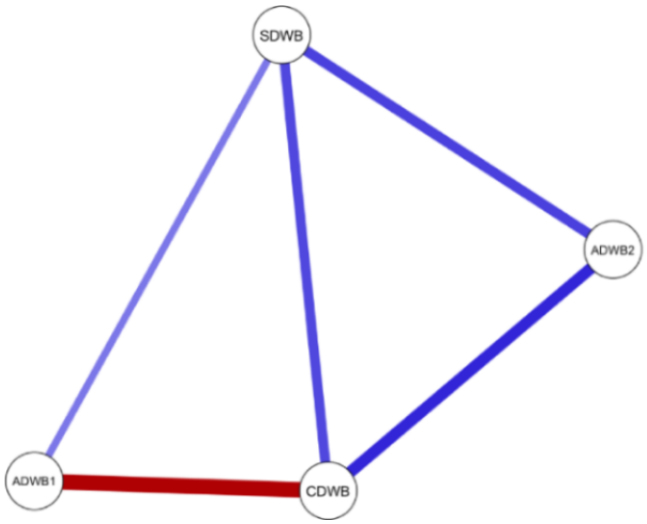
	Scores, mean (SD; range)	Scores, median (IQR)
Digital stress	18.70 (7.07; 1.00-40.00)	18.00 (13.50-22.50)
Web-based hedonic well-being	10.80 (2.43; 0.00-16.00)	11.00 (10.00-12.00)
Intrinsic needs satisfaction	14.90 (4.16; 2.00-24.00)	15.00 (12.00-18.00)
Social digital well-being	35.60 (9.06; 9.00-61.00)	35.00 (29.00-41.00)
Emotional regulation	35.80 (11.80; 4.00-64.00)	36.00 (27.00-45.00)
Nomophobia	43.20 (18.00; 0.00-80.00)	45.00 (31.25-58.75)
Digital literacy	108.00 (17.00; 35.00-138.00)	110.00 (98.50-121.50)
Digital self-control	6.20 (2.76; 0.00-12.00)	6.00 (4.00-8.00)
Problematic internet use	26.80 (8.79; 0.00-49.00)	27.00 (21.00-33.00)
Problem-focused coping	13.70 (8.44; 0.00-43.00)	12.00 (6.00-18.00)
Emotion-focused coping	20.70 (4.52; 4.00-31.00)	21.00 (18.00-24.00)
Avoidant coping	25.90 (5.44; 3.00-42.00)	26.00 (22.63-29.38)
Online risk exposure	13.00 (4.45; 1.00-30.00)	13.00 (10.00-16.00)

[a]This table summarizes the descriptive statistics of all variables assessed in the online self-report survey conducted between June 2024 and July 2024.

Table 4. Spearman rank-order correlation test results of age differences (N=578)[a].

	Spearman rank-order correlation	*P* value
Digital stress	−0.138	<.001
Web-based hedonic well-being	−0.022	.59
Intrinsic needs satisfaction	0.088	.03
Social digital well-being	−0.081	.051
Emotional regulation	0.265	<.001
Nomophobia	−0.200	<.001
Digital literacy	−0.077	.07
Digital self-control	0.350	<.001
Problematic internet use	−0.249	<.001
Problem-focused coping	−0.373	<.001
Emotion-focused coping	0.042	.31
Avoidant coping	−0.204	<.001
Online risk exposure	−0.144	<.001

[a]This table shows the correlational test results between age and measured variables, highlighting age-related patterns in digital behaviors. Data were collected through an online survey conducted between June 2024 and July 2024.



Network Structure of DWB Factors

Network Estimation

Figure 1 presents the regularized GGM network structure of the DWB measures. The well-being components were positively associated with each other, except for digital stress, which was negatively linked to intrinsic needs satisfaction (CDWB) and unrelated to web-based hedonic well-being (ADWB2). The strongest positive association was between CDWB and ADWB2. The second and third strongest positive edges were those between ADWB2 and social digital well-being (SDWB) and between intrinsic needs satisfaction (CDWB) and SDWB.

XSL•FO
RenderX

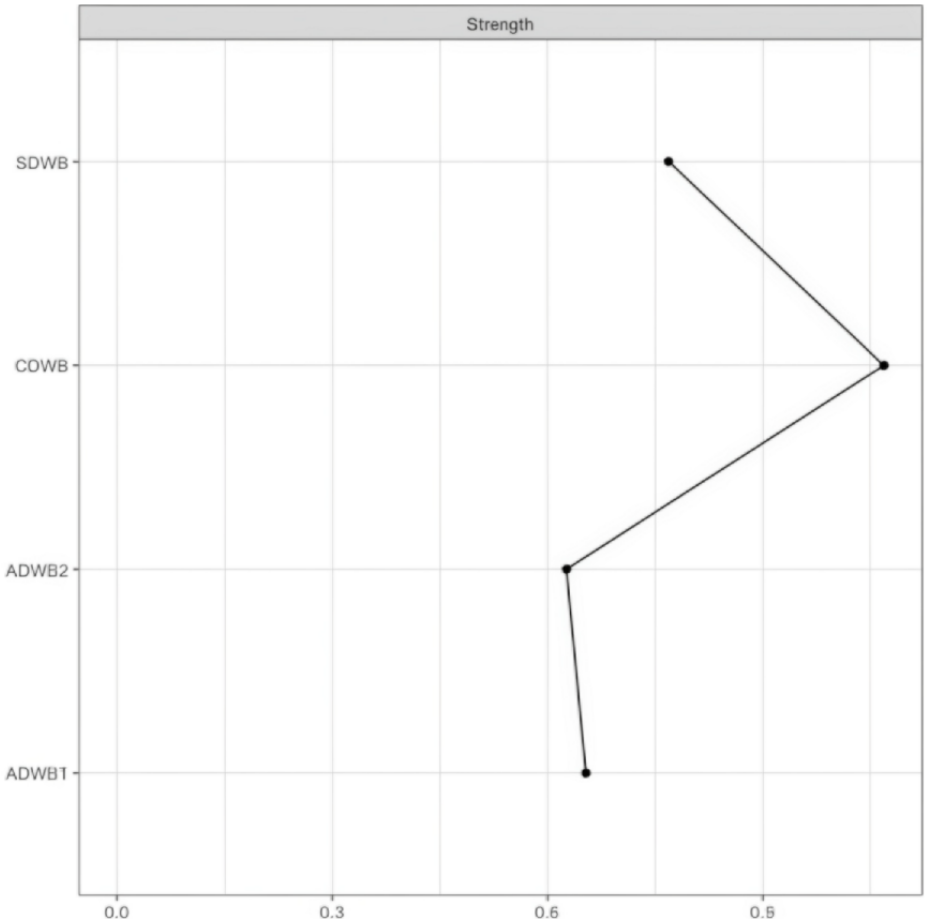


Figure 1. The digital well-being (DWB) network structure (N=578). The figure illustrates the relationships among 4 dimensions of DWB derived from a network analysis performed on survey data collected between June 2024 and July 2024. Blue edges indicate positive associations, while the red edge indicates a negative association between variables. The thickness of each edge reflects the strength of the observed relationships, with thicker edges denoting stronger associations. This DWB network highlights the interconnected nature of the DWB dimensions. ADWB1: digital stress; ADWB2: web-based hedonic well-being; CDWB: intrinsic needs satisfaction; SDWB: social digital well-being.

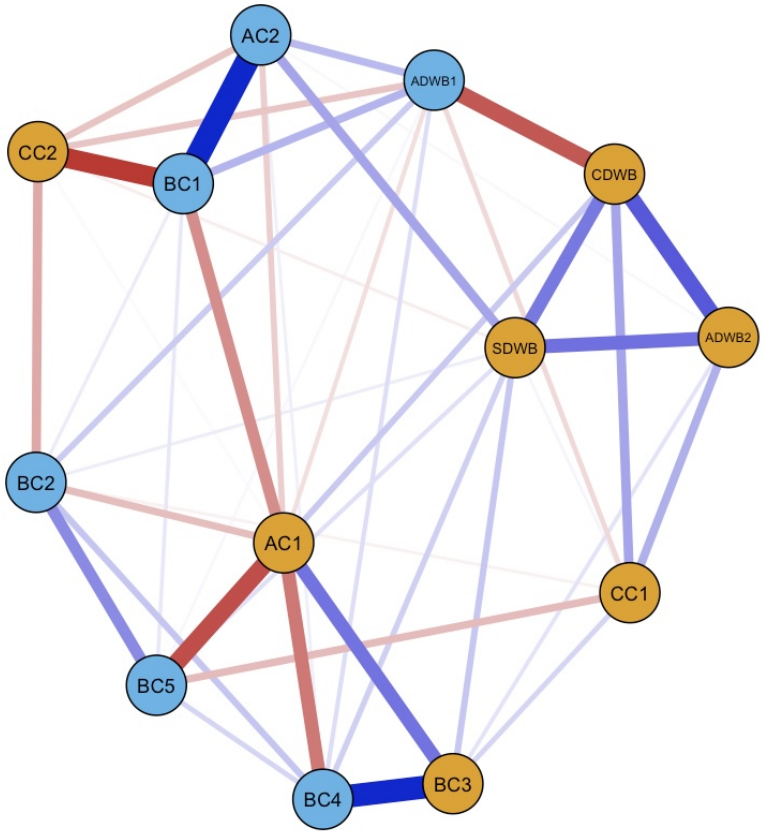
Strength Centrality

To examine the relative importance of each node in the DWB network, Figure 2 presents the strength centrality results. The cognitive component of DWB (ie, intrinsic needs satisfaction) had the highest strength centrality, followed by SDWB, suggesting the important roles played by the cognitive and social dimensions.

Figure 2. The centrality plot of the digital well-being network (N=578). This figure displays the centrality strength of all digital well-being variables derived from a network analysis performed on survey data collected between June 2024 and July 2024, highlighting their relative importance. The x-axis represents the centrality strength values, with higher values indicating more central roles in the network. ADWB1: digital stress; ADWB2: web-based hedonic well-being; CDWB: intrinsic needs satisfaction; SDWB: social digital well-being.

XSL•FO
RenderX

Network Stability



The correlation stability coefficient of strength centrality with the case-dropping subset bootstrapping method was 0.67, indicating that the centrality estimates were stable. Bootstrapping results for the estimated edge weights also provided support for the accuracy of edge weights in the resulting network (Multimedia Appendix 2).

Network Structure of the DWB and Related Factors

Network Estimation

Figure 3 presents the estimated structure of the DWB-related network. The spin glass community analysis detected 2 clusters. Consistent with the DWB network, the DWB factors were split into a *digital competency* (ie, healthy and effective use of technologies) community and a *digital dependency* (ie, harmful reliance on technologies) community. *Digital competency* included all DWB factors except digital stress (ADWB1) and affective and cognitive protective factors, including emotional regulation (AC1), digital literacy (CC1), and digital self-control (CC2). By contrast, negative affective DWB (ie, digital stress) was grouped into *digital dependency* with risk factors, including nomophobia (AC2), problematic internet use (BC1), problem-focused coping (BC2), avoidant coping (BC4), and the measure of participants' past experiences with involuntary online risk exposure (BC5).

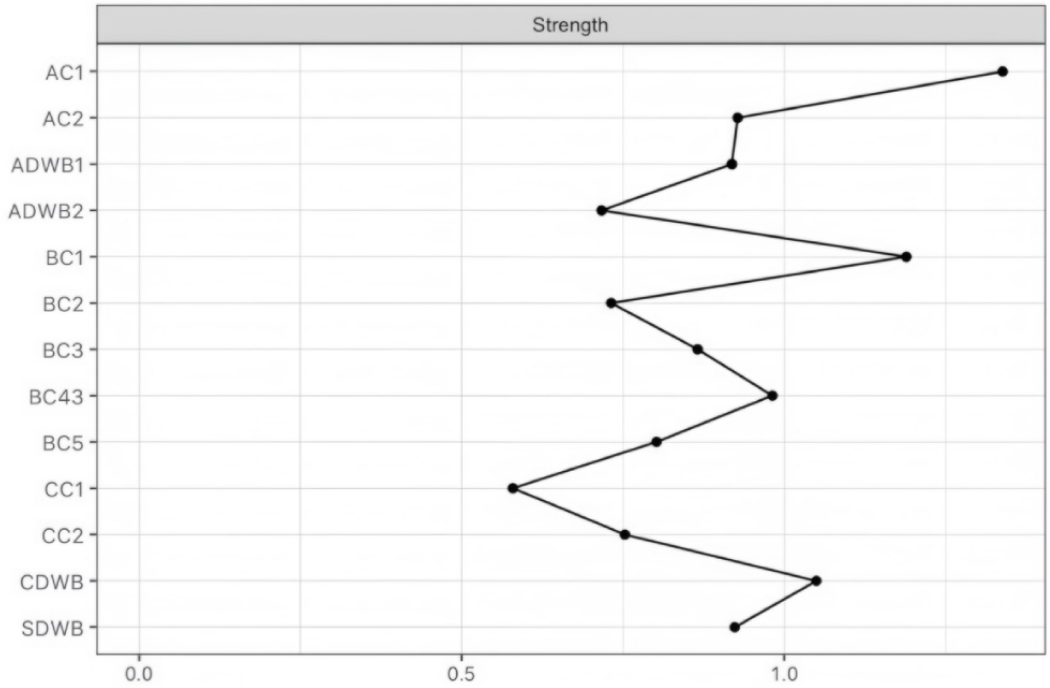
Figure 3. The digital well-being–related network structure (N=578). This figure illustrates the network structure connecting dimensions of digital well-being and associated protective and risk variables derived from a network analysis conducted on survey data collected between June 2024 and July 2024. The nodes represent specific variables, with orange nodes indicating the digital competency cluster and blue nodes representing the digital dependency cluster. Edges between nodes represent associations, with blue edges indicating positive relationships and red edges indicating negative relationships. The edges' thickness corresponds to the associations' strength, with thicker edges denoting stronger connections. AC2: nomophobia; ADWB1: digital stress; BC1: problematic internet use; BC2: problem-focused coping; BC3: emotion-focused coping; BC4: avoidant coping; BC5: web-based risk exposure; CC1: digital literacy; CC2: digital self-control.

Strength Centrality

Figures 4 and 5 present the strength centrality and the BEI measures for all DWB and related protective and risk factors. The nodes with the highest strength centrality indices were AC1, BC1, and CDWB. The most central nodes for each community were then examined. For *digital competency*, the most central factors were AC1 and CDWB. For *digital dependency*, BC1 and BC4 were identified with the highest centrality index.

XSL•FO
RenderX

Figure 4. The strength centrality plot of the digital well-being–related network (N=578). The figure displays the strength centrality indices of each node derived from a network analysis conducted on survey data collected between June 2024 and July 2024. The x-axis represents the relative centrality strength values, with higher values indicating more central roles of the associated variables in the network. AC1: emotional regulation; AC2: nomophobia; ADWB1: digital stress; ADWB2: web-based hedonic well-being; BC1: problematic internet use; BC2: problem-focused coping; BC3: emotion-focused coping; BC4: avoidant coping; BC5: web-based risk exposure; CC1: digital literacy; CC2: digital self-control; CDWB: intrinsic needs satisfaction; SDWB: social digital well-being.



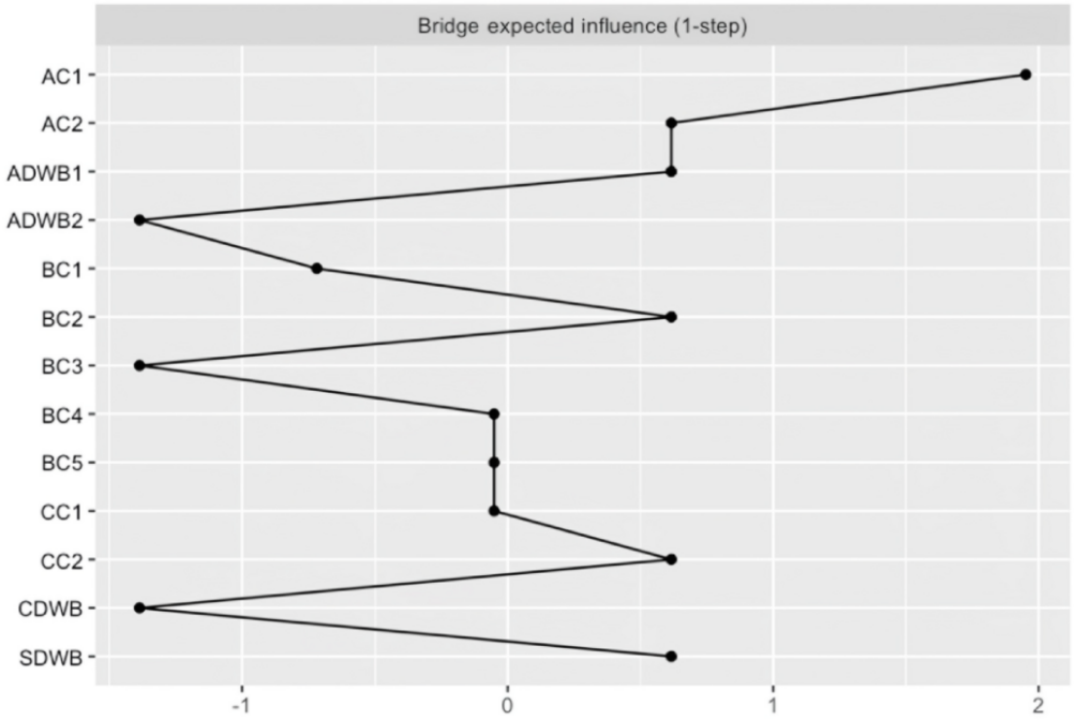


Figure 5. The bridge expected influence of the digital well-being–related network (N=578). The figure illustrates the bridge expected influence (1-step) values for each node in the digital well-being–related network derived from a network analysis conducted on survey data collected between June 2024 and July 2024. The y-axis lists the variables in the network, and the x-axis represents the relative bridge expected influence values. Higher values reflect nodes that act as critical bridging variables, connecting the digital competency and digital dependency clusters. AC1: emotional regulation; AC2: nomophobia; ADWB1: digital stress; ADWB2: web-based hedonic well-being; BC1: problematic internet use; BC2: problem−focused coping; BC3: emotion−focused coping; BC4: avoidant coping; BC5: web-based risk exposure; CC1: digital literacy; CC2: digital self-control; CDWB: intrinsic needs satisfaction; SDWB: social digital well-being.

XSL•FO
RenderX

Intercluster Connections

The importance of each node in connecting the identified communities within the network was examined with the BEI, as illustrated in Figure 5. The node with the highest BEI index was AC1, which played an important role in connecting the *digital dependency* and the *digital competency* cluster. Specifically, greater emotional regulation was positively associated with BC3 in the *digital competency* cluster. By contrast, greater emotional regulation was associated with lower BC5 and less BC4 from the *digital dependency* cluster.

The strongest positive links appeared between AC2 and BC1 in the *digital dependency* cluster and between CDWB and ADWB2 in the *digital competency* cluster. The strongest negative links were between CC2 and BC1, between AC1 and BC5, and between CDWB and ADWB1.

Network Stability

The correlation stability coefficients for strength centrality and BEI were both 0.75, implying a high stability of centrality and BEI indices in the generated DWB-related network. Bootstrapping results for the estimated edge weights also indicated accurate edge weights of the resulting network (Multimedia Appendix 3).

Discussion

This study adopted a system-based framework to yield findings for conceptualizing the construct of DWB [51,64].

Dimensions of DWB

The affective dimension comprises 2 relatively independent components: digital stress and web-based hedonic well-being (Figure 1). This finding contributes to the longstanding debates in affective well-being literature regarding whether positive and negative affect represent bipolar ends of a single construct or operate as independent dimensions [77-79]. Recent evidence supports that interactions between seemingly opposite affective dimensions can be context dependent [79]. In some contexts, people might experience both types of affect simultaneously (eg, during bittersweet experiences), while in other contexts, the presence of one might diminish the other [79].

Building on this line of work, our findings support the independent view of the affective well-being debate that digital stress and hedonic well-being appear relatively independent in digital contexts. The concept of a “stress paradox” on social network sites, where users simultaneously experience enjoyment and stress from factors such as social comparison and information overload, further speaks to our finding [80]. Together, these insights highlight the importance of examining the positive and negative affective dimensions independently, as they may coexist and impact DWB in unique ways.

Indeed, the positive and negative affective DWB showed opposite associations with the most central component of DWB, namely, cognitive DWB. Precisely, online intrinsic needs satisfaction was positively correlated with hedonic well-being and negatively correlated with digital stress. These 2 associations also represented the strongest edges within the DWB network. Such observations align with the self-determination theory, which posits that optimal well-being results from the fulfillment of individual psychological needs for competence, autonomy, and relatedness [81-83]. This study further distinguishes the cognitive needs for competence and autonomy, which directly address the eudaimonic benefits of digital connectivity, from the social needs for relatedness. Consequently, the findings resonate with psychological well-being literature, underscoring that digital eudaimonic experiences (ie, using digital devices to feel competent and autonomous) could play a crucial role in cultivating healthy digital relationships and minimizing potential harm from digital use [83,84].

The social dimension of DWB, encompassing digital empathy and online social connectedness, emerged as the second most central node in the network. It showed positive relations with all the other variables, albeit less strongly with digital stress, which was more closely related to the lack of perceived autonomy and competence. Research has shown that digital platforms not only allow people to extend their social relations but also provide avenues to maintain existing social networks [85,86]. Hence, our findings on the positive associations between the social dimension and the positive affective and cognitive components of DWB emphasize the pivotal role played by online experiences of empathy and connectedness in cultivating a satisfying and pleasurable digital relationship.

These findings have practical implications for intervention designs to leverage digital hedonic and eudaimonic experiences, an area of growing interest with artificial intelligence (AI) advancements. For instance, DWB programs can incorporate AI-driven tools to facilitate online intrinsic needs satisfaction with goal-tracking interfaces and adaptive feedback systems. These features can provide users with a tailored online experience and allow for monitoring of one’s progress, thus satisfying individual needs for competence and autonomy [87]. Moreover, AI-powered interventions could strengthen digital empathy and connectedness by analyzing and responding to online interactions to promote interpersonal understanding, which used to be a key challenge in online interactions due to the lack of nonverbal cues [88]. For example, social platforms could benefit from their large database to train AI to identify opportunities for meaningful engagement, such as recommending empathetic responses or fostering inclusive discussions.

Despite the benefits, caution should also be practiced in designing interventions that incorporate AI-driven tools, as the effectiveness of human-AI collaboration depends heavily on the relative strengths of each contributor [89]. While AI can greatly enhance users’ content creation and analytics strength by automating repetitive tasks, relying on AI for decision-making tasks may undermine human judgment due to the lack of contextual understanding. Therefore, interventions must carefully consider the context in which AI tools are deployed, ensuring that they complement rather than replace human agency. The importance of this balance is further discussed in the following section on digital competency and dependency.

XSL•FO
RenderX

Emotional Regulation in Differentiating Competency From Dependency

To further understand the protective and risk factors associated with positive and negative dimensions of DWB identified in the initial network (Figure 1), the DWB-related network (Figure 3) revealed 2 distinct communities: *digital competency* and *digital dependency*. *Digital competency* refers to the effective integration and responsible use of technologies, such as successful self-control and skillful use, that can enhance one's ability to achieve personal and professional goals while fostering optimal health outcomes [90,91]. By contrast, *digital dependency* represents a reliance on digital technologies that leads to undesirable psychological consequences, such as problematic internet use characterized by excessive or compulsive use of digital media [92,93]. These 2 distinct communities encapsulated the protective and risk-oriented dimensions of DWB, highlighting the dual nature of digital engagement, that is, its potential for both benefits and harm.

The affective aspect played a key role in fostering competency. Specifically, emotional regulation emerged as the most central actor in the network, displaying a positive link with emotion-focused coping from the *digital competency* cluster and a negative link with avoidant coping from the *digital dependency* cluster. This pattern aligns with previous coping literature that revealed a positive connection between successful emotional regulation and emotion approach coping [94]. Emotion-focused coping involves the conscious regulation of emotions to alleviate distress without necessarily resolving the underlying issue [94]. Conversely, avoidant coping, which emerged as the second most central node in the *digital dependency* cluster, involves evasion of both the stressor and the emotional response. It often consists of suppression, distraction, and withdrawal from one's negative emotions, which leads to reduced well-being outcomes [95,96].

In the context of digital connectivity, a common motivation for digital use is to escape from boredom or real-life adversities, which is generally considered negative media consumption [97,98]. However, recent research on media escapism demonstrated that emotion approach coping coupled with cognitive control and self-efficacy can result in positive well-being outcomes [99,100]. Our findings further support this finding by emphasizing the role of emotional regulation in bridging the affective and behavioral coping aspects of DWB, thereby differentiating *digital competency* from *digital dependency*.

Within the *digital competency* cluster, the strongest positive association was between the satisfaction of individual needs for autonomy and competence and hedonic well-being. This finding aligns with the definition of DWB by Vanden Abeele [1] as an experience culminating in "controlled pleasure." The issue of user autonomy has gained increasing significance. Amid the evolution of intricate algorithms, user autonomy is constantly shaped, constrained, and enabled by different dimensions of human-algorithm relations [101]. Consequently, individual decision-making, actions, and consequent well-being outcomes are guided by their knowledge, perception, and critical evaluation of omnipresent algorithmic outputs [101]. A recent study examining user well-being in online retail settings showed that perceived individual autonomy can predict hedonic enjoyment when engaging in both personalized purchase experiences and general browsing [102], supporting the observed link between autonomy need satisfaction and hedonic well-being.

In addition to digital autonomy, digital competence is another key conceptual component of DWB (eg, the European Commission's Digital Competence Framework) [103]. Notably, research conducted during the COVID-19 pandemic revealed digital competence as a significant protective factor for general well-being [104]. Recent studies further advocated the benefits of digital competence across diverse age groups [105-108]. These findings underscore the importance of fulfilling individuals' competence needs in both digital and offline spaces to successfully navigate their daily lives with pervasive technology presence.

The strongest positive association in the *digital dependency* cluster was between nomophobia and problematic internet use, both ascribing to an unhealthy attachment to digital connectivity. This finding aligns with DWB studies that use the DA framework [109,110]. One possible explanation for this positive association could be their shared dependence on mobile devices for connectivity, emotional support, social interaction, and information. Both problematic internet use and nomophobia involve the fear of disconnection and an unhealthy reliance on the internet, creating a cycle of compulsive phone and internet use.

Interestingly, this study revealed a stronger negative link between digital self-control and problematic internet use, while nomophobia displayed a positive, albeit weaker, association with social DWB from the digital competency cluster. The former finding is consistent with most DA literature that identifies self-control failures as the primary predictor for problematic internet use [32,40,111]. By contrast, the observed positive relationship between nomophobia and social well-being points to the need for a critical examination of frequent digital use. Research indicates that nomophobia is often linked to increased smartphone use [39,112]. As tools for social connection, smartphones enable individuals to maintain constant contact with their social networks, both on an interpersonal and societal level. This reliance on smartphones for communication may enhance empathy by fostering emotional exchanges and social feedback loops. Consequently, individuals higher in nomophobia also obtain more opportunities to experience and respond to others' emotional states, thus reinforcing their sense of empathy through online engagement.

However, metacognitive evidence suggests that nomophobia may be related to difficulties in recognizing and expressing emotions and reduced face-to-face empathy [113-115]. Thus, while increased smartphone use may contribute to the observed positive association between nomophobia and social DWB, further studies are needed to understand how experiences of empathy and social connectedness differ in online and offline spaces.

Earlier, we discussed fostering DWB by satisfying users' needs for competence and autonomy using AI-driven tools. However,

XSL•FO
RenderX

there is a risk of AI technologies taking over users' agency, thus leading to dependency. Here, the findings of the DWB-related network highlight the roles of emotional regulation and adaptive coping in distinguishing competency from dependency, thus offering several practical avenues for interventions aimed at reducing excessive use of technologies.

Meta-analytical findings support the effectiveness of digital gaming interventions in fostering adaptive emotional regulation [116,117]. Thus, integrating similar gamified features within digital social platforms could encourage users to identify and regulate their emotions during online interactions. For instance, social media platforms could introduce features such as interactive modules consisting of scenarios (eg, receiving negative feedback on social media), where users are guided through emotional regulation steps to interpret the situation and flexibly cope with the digital stressors presented to them.

In addition to general programs designed to cultivate individuals' emotional regulation skills, tailored interventions can be implemented on digital platforms via emotion-sensitive algorithms to further enhance users' abilities to regulate and cope with potential stressors arising from digital engagement. Excessive screen time or patterns of negative interactions, for example, can be identified to trigger break reminders or suggestions for positive content [118]. Such strategies will not only allow individuals to regulate their emotions but can also give rise to optimal DWB based on our findings.

Gender and Age Differences

In addition to network findings on DWB and its related factors, statistically significant differences were found across age groups, suggesting that younger individuals may be more susceptible to unhealthy online behaviors, including problematic network use, difficulties in maintaining digital self-control, and heightened vulnerability to online risks [44,119]. These findings underscore the need for early onset of DWB interventions. School-based digital literacy programs and interactive workshops can teach students how to navigate digital spaces responsibly, develop appropriate self-control strategies, and critically assess online content. Such interventions should also be tailored to address the developmental needs of adolescents and young adults, equipping them with the tools to balance digital engagement with offline activities and develop healthier long-term digital habits.

Consistent with previous literature on digital literacy, men scored significantly higher than women on digital literacy, implying potential barriers that may prevent women from fully capitalizing on the advantages of digital technologies [120]. Conversely, women scored higher than men on nomophobia, which suggested escalating health concerns faced by women [121]. Interventions to bridge this gap could include gender-focused digital education programs and mentorship initiatives aimed at empowering women in digital spaces, emphasizing skill development in areas such as cybersecurity, data literacy, and content creation. In addition, tailored resources can be created to address the specific challenges women face, such as overreliance on digital connectivity and emotional susceptibility to online interactions.

Limitations and Future Directions

Several limitations should be considered when interpreting the results of this study. One limitation is that the network analysis adopted a cross-sectional design, which presents methodological issues regarding the directionality and temporality of the results. Thus, longitudinal studies with multiple time points are needed to examine temporal changes in the variables included in the networks, as well as how the current networks relate to long-term well-being changes.

Another limitation is that the DWB networks mainly investigated psychological factors at the individual level. Given that DWB is a dynamic construct that emerges from the interplay between users and external digital factors, the influence of external factors should also be investigated [1,17]. For instance, algorithms often prioritize content that maximizes engagement with emotionally charged and polarizing posts, which can inadvertently amplify stress, anxiety, and feelings of inadequacy among users [122]. Similarly, interface nudges, such as the infinite scrolling design of TikTok, can prolong user engagement, making it harder for individuals to disengage and manage their screen time effectively [123]. To capture these dynamics, future efforts should broaden the current conceptualization of DWB by scrutinizing the interactions between psychological and external digital factors, such as unveiling the mechanisms underlying media affordances that serve to fulfill diverse motivational needs among users [35].

In addition to the study design, the sample of this study comprising adults from the United States and the United Kingdom raised issues on the generalizability of findings. The 2023 United Nations' report on information society highlighted a growing gap between digital coverage and technological development between low-income (eg, South Africa) and high-income (eg, North America and Northern Europe) countries [124]. This disparity underscores the importance of contextualizing digital inequality, as it can significantly influence individuals' digital health. For example, residents from countries with limited internet infrastructure may lack access to digital literacy initiatives, which are vital for fostering meaningful online experiences. Besides digital inequality, cultural differences in technology adoption can lead to varying effects of digital use on social well-being outcomes [125,126]. For example, higher self-disclosure has been associated with greater perceived social support and connection in Western cultures, where openness and self-promotion are valued [127]. In contrast, in cultures that prioritize modesty, increased online self-disclosure may lead to discomfort or stress in navigating different digital norms [128]. Therefore, our findings consisting mainly of White participants from Western high-income countries may not fully apply to countries with differing digital landscapes. More large-scale multinational studies on DWB should be conducted to increase the global applicability of our findings.

Conclusions

Despite certain limitations, to the best of our knowledge, this is the first study to empirically conceptualize DWB and its protective and risk factors through a system-based approach. This research found that younger individuals face greater risks

XSL•FO
RenderX

of problematic online behaviors, while gender differences in digital literacy and nomophobia indicate potential obstacles and health risks associated with digital use.

The conceptual network findings on various DWB factors suggest that digital stress and hedonic well-being are independent constructs of the affective dimension of DWB. Consistent with SWB and psychological well-being literature, the most central aspect of optimal DWB concerns fulfilling individuals' psychological needs for competence and autonomy through digital eudaimonic benefits. By contrast, the hedonic experience was closely related to the social dimension of DWB. The network results of DWB and its related factors showed that emotional regulation and adaptive coping are key in distinguishing between digital competency and dependency, emphasizing the role of emotional regulation and cognitive control in fostering positive digital experiences. These insights highlight the importance of promoting autonomous and skilled digital use across demographics to ensure healthier digital engagement.

Abstract

Background: e-Consultations, defined as asynchronous text-based messaging, have transformed how patients interact with their general practitioner (GP). While e-consultations can improve patient access to GP care, concerns about increased workload for GPs are raised.

Objective: This study aimed to address three research questions: (1) For what purpose and with what expectations do patients initiate e-consultations? (2) If e-consultations had not been available, what alternative actions would the patient have taken? and (3) How are the alternative actions associated with patient and e-consultation characteristics?

Methods: A cross-sectional study was conducted through a web-based survey on Helsenorge. Helsenorge is the national citizen portal for digital health services in Norway, including e-consultations with the GP. All users who sent e-consultations through Helsenorge were invited to participate between January and February 2023. The survey addressed questions on users' expectations and experience with e-consultations. The association between patient and e-consultation characteristics and alternative actions to e-consultations were analyzed using multinomial logistic regression.

Results: Overall, 13,011 users answered the survey. The most common reason for initiating an e-consultation was requesting a sick certificate (4940/13,011, 38%). Overall, 68.7% (8802/13,011) of respondents expected an answer within 24 hours, and 17.7% (2310/13,011) anticipated that the GP would ask them to attend a physical examination. If e-consultations had not been available, 45.5% (5917/13,011) of respondents would have booked a GP appointment, and 44.9% (5846/13,011) would have called the front desk. Users who expected a quicker response (odds ratio [OR] 1.64, 95% CI 1.46-1.85) and were less concerned about their health issues (OR 1.29, 95% CI 1.18-1.40) were more likely to call the front desk. Only 2.5% (323/13,011) of respondents would have contacted out-of-hours services. Users with longer travel time to the GP office (OR 6.08, 95% CI 3.46-10.66) and with a new health problem (OR 2.71, 95% CI 2.09-3.51) were more likely to choose this option. In addition, 4.7% (609/13,011) of the users would not have sought help if e-consultations had not been available. Younger patients (OR 2.16, 95% CI 1.38-3.37) and those with a longer travel time to the GP office (OR 2.19, 95% CI 1.27-3.80) or a new health issue (OR 1.74, 95% CI 1.43-2.12) had higher odds for not seeking help.

Conclusions: e-Consultations were often the patients' first choice of access route, and users expected a fast response. e-Consultations were mostly perceived as an alternative to GP appointments or calling the front desk. Patients with lower availability to the GP office had higher odds of using e-consultations as an alternative to out-of-hours service or waiting and not

XSL•FO

seeking GP care. Guidance for patient use should be developed to ensure appropriate and safe use. Further research should assess the effect of e-consultations on health outcomes and efficiency.

Introduction

Background

The increased availability of e-consultations with general practitioners (GPs) has raised questions about how they affect patients' health care service use. An e-consultation consists of asynchronous text-based messaging between the patient and GP [1]. Norwegian authorities state that e-consultations must be used to solve clinical problems [2] and expect that e-consultations will be used as an alternative to physical appointments to relieve GPs from some of the workload pressure [3]. Users perceive e-consultations as more accessible and available than physical GP consultations [4-6]. At the same time, GPs have reported increased workload due to patients seeking help for minor issues [5,7] and a need for follow-ups after e-consultations [8].

e-Consultations in Norwegian General Practice

Remote consultations with the GP can be conducted through e-consultations, video consultations, or telephone consultations. Adoption and use of remote consultations among GPs and patients in Norway experienced significant growth in relation to the COVID-19 pandemic [9]. While e-consultations and telephone consultations were offered by most GPs, video consultations were only used to a limited extent in 2023 [10].

According to Norwegian authorities, e-consultations must provide medical advice, and GPs should generally respond within 5 working days. Patients pay the same out-of-pocket fee for e-consultations as for face-to-face GP appointments [2]. In most situations, e-consultations are initiated by patients. However, there are no official guidelines to assist patients in assessing if their issues can be handled through e-consultations.

Theories and Knowledge About the Use of and Access to e-Consultations

The implementation of e-consultations has changed patients' access to GPs and possibly affected the patients' way of seeking health care [11]. Patients' adoption and use of e-consultations are affected by demographic characteristics [5,12] and health needs [13,14], in addition to perceived availability, accessibility, and capability to use the service [4,15]. Perceived availability and accessibility of e-consultations can, in turn, depend on factors such as self-selected use, information about the service, patient expectations and experience, expected waiting time for a GP appointment, and cost of service [4,5,16,17].

Research shows that patients value e-consultations for their high accessibility and efficiency [18-21]. e-Consultations are primarily used for less severe health concerns [18] and already-known problems [22]. Patients are less willing to use e-consultations for serious issues [20] and think that complex issues should not be addressed in e-consultations [21]. However, a study from Denmark showed that the complexity of the content of e-consultations was high in terms of both the number of questions asked and the disease perspective [23]. An established relationship between GP and patient facilitates good communication around clinical issues and mutual trust in e-consultations [4,24]. If e-consultations are to reduce the workload for GPs, they should be used as an alternative to a face-to-face consultation without the need for a follow-up examination at the GP office [7,25]. However, there is a lack of clear evidence regarding the circumstances under which an e-consultation can effectively replace a face-to-face consultation and the potential impacts of such use [5]. Some studies show that e-consultations are not used as a replacement for face-to-face consultations but rather as an additional service [5,6,26]. Research shows that patients can use e-consultations as an alternative to calling the front desk (ie, patients asking the GP for help to triage their health issues) [3,27,28]. Another study suggests that the high availability of e-consultations can reduce visits to out-of-hours primary care services [29].

It has been argued that e-consultations should not replace other general practice services, instead, they should be viewed as a complementary service that adds flexibility to general care [4,7,18,30,31]. The flexibility and availability of e-consultations can generate new demand for GP care. By lowering patients' threshold for contact, e-consultations may lead to requests that would not have otherwise entered the health care system, thereby increasing the GP workload [25,27]. However, it remains unclear whether this new demand arises from previously unmet needs due to limited access or from patients reaching out more readily for minor issues [20,25].

Study Aim

This study aimed to investigate how users perceived their use of e-consultations. Did they consider it an alternative to other GP services, or was a new demand for GP care created? We defined other GP services as GP appointments, phone calls to the front desk, or out-of-hours services. Information about circumstances for use and how patients perceived the role of e-consultations in the general practice setting is important for future service development.

The research questions (RQs) addressed by this study were as follows: (RQ1) For what purpose and with what expectations do patients initiate e-consultations? (RQ2) If e-consultations had not been available, what alternative actions would the patient have taken? and (RQ3) How are the alternative actions associated with patient and e-consultation characteristics?

XSL•FO
RenderX

Methods

Study Setting

General practices in Norway are organized in a scheme where citizens can choose a specific GP. The average patient list per GP was approximately 1040 patients in 2023 [32]. GPs serve as gatekeepers to specialized health care services and provide welfare services such as sick certifications. They have substantial autonomy in organizing their practices, including the option to offer e-consultations. Most GPs in Norway are responsible for their own GP list but share office locations and support personnel with other GPs. On average, the Norwegian citizen conducted 3 consultations (including e-consultations) with the GP in 2023 [33]. In recent years, the GP scheme has had problems with high work pressure [34]. The national health portal, Helsenorge, hosts several digital health services for citizens and is the main platform for digital GP services, including e-consultations. GPs are also responsible for providing out-of-hours services and taking turns staffing clinics outside regular hours. The out-of-hours service addresses urgent health care needs, such as acute illnesses, injuries, or conditions that cannot wait until regular clinic hours. The Norwegian health care system offers free GP care with minimal out-of-pocket expenses for patients. In January 2023, patients paid the same amount for regular consultations and e-consultations, 160 NOK (US $14.36) or 212 NOK (US $19.03) for consultations with GPs without or with specialization in general practice, respectively. In addition to the out-of-pocket fee from patients, GPs receive extra payment per consultation from the reimbursement system. GPs received the same total amount for both regular consultations and e-consultations, 175 NOK (US $15.71) without specialization or 285 NOK (US $25.59) with specialization [2].

Study Design

We conducted a cross-sectional study through a nationwide web-based survey of e-consultation users. The user survey was developed by the study authors, who have expertise in digital health and primary health care. It was based on academic knowledge and previous research on digital health care use and theories of access to health care [4,12,13,15-17,22]. Textbox 1 shows the survey themes. The survey was in Norwegian. The whole survey, and English translations can be found in Multimedia Appendix 1.

Textbox 1. Overview of survey topics.

Patient's background characteristics

1. Gender
2. Age
3. Education
4. Health care use: both general practitioner (GP) appointments and e-consultations
5. Digital maturity: first-time user or not
6. Proxy user

Availability of GP services

7. Travel time to the GP office
8. Ease of getting through on the phone to the doctor's front desk
9. Ease of getting a GP appointment within a reasonable time

Use of and access to e-consultations

10. Information about the service
11. Used as the first choice for issues in the matter
12. Expected response time
13. Cost of service
14. Satisfaction with the use of e-consultations
15. Alternative action if e-consultations had not been available

Characteristics of the problem handled in the e-consultation

16. Level of concern about the problem
17. Perceived suitability of issue to be handled digitally
18. Reason for sending e-consultation

Experts from Norsk Helsenett, the national service provider of the health portal Helsenorge, revised the survey. The survey was piloted on 5 e-consultation users in different age groups. Norsk Helsenett facilitated the survey invitation on the web page Helsenorge.no. All users who sent an e-consultation to their GP through Helsenorge in 3 weeks from Monday, January 30, 2023, to Sunday, February 2, 2023, received an invitation to the survey. The invitation was presented through a pop-up

XSL•FO
RenderX

on the web page and read "Do you want to participate in research about e-consultations?" The e-consultation service is only accessible through a secure log-in. If a user sent more than one e-consultation during the study period, a pop-up would appear for each e-consultation they sent. The respondents were informed that participation in the survey was voluntary and anonymous. They gave consent by clicking "I agree to be a part of the survey" at the bottom of the page and were then redirected to an external web page containing the survey. The web-based data collection solution used was Questback Essential.

The survey had up to 20 questions (depending on the respondent's answers) distributed over 15 pages. The survey was written in Norwegian, and pilot estimations showed that the survey took about 7 minutes to complete. All questions were mandatory to answer. The questions had multiple choice answers, except for 3 questions about availability and use that were answered through a 5-point Likert scale. Only completed questionnaires were analyzed. It was not possible to calculate the completion rate since no information about uncompleted questionnaires was provided. We used the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist for cross-sectional studies [35] (Multimedia Appendix 2) and the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) [36] when reporting the results (Multimedia Appendix 3).

Data Analysis

The response rate was calculated based on routine data about all patient-initiated e-consultations sent through Helsenorge during the 3-week period.

RQ1 was answered using descriptive statistics, including the frequency and percentages of all respondents. Survey topics 10-18 (except 15) were analyzed (Textbox 1).

RQ2 was answered through survey topic 15 ("If you had not had the opportunity to send an e-consultation, what would you have done?"). The answer options to this question were book a GP appointment, call the front desk, wait or seek information on the internet, or take other actions. These are hereafter called alternative actions. Descriptive statistics were reported, including the frequency and percentages of all respondents.

RQ3 was examined through a multinomial logistic regression. Conducting a regression made it possible to investigate the association between the characteristics of the patients and e-consultations and their alternative action to sending the e-consultation. The dependent variable was the users' assessment of alternative actions to using e-consultation (survey topic 15). The reference group of the analysis was the users choosing "booking a GP appointment." This group was chosen since e-consultations aim to be an alternative to physical GP appointments for their most effective use. We compared it with users who would rather have called the front desk, contacted out-of-hours service, or waited or searched for information on the internet. This gave reasonable indications of use patterns and reasons for sending an e-consultation in different circumstances. The group that answered "other actions" was not included in the analysis. The respondents of this group are presumably heterogeneous, making it difficult to analyze their group characteristics meaningfully. We included all other survey topics as independent variables in the regression, except the time and day for answering the survey (Textbox 1). For simplicity, the survey questions with 5 answer options were merged into 3 options ("strongly agree" and "agree" were merged to "agree," "strongly disagree" and "disagree" were merged to "disagree," "very satisfied" and "satisfied" were merged to "satisfied," and "very dissatisfied" and "dissatisfied" were merged to "dissatisfied").

We examined the dataset for multicollinearity before performing the regression, and no indications of multicollinearity were found. As the goal was to investigate associations rather than build a model, we did not present model fit values. The likelihood-ratio test showed that not all variables were statistically significant; however, we included them all to not bias the results. We presented the odds ratio (OR) and 95% CI. The *P* value for statistical significance was set to .05. All analyses were conducted using SPSS (version 25; IBM Corp).

Ethical Considerations

The study and the data handling procedure were approved by the Data Protection Officer of the University Hospital of North Norway (#03057). According to the Norwegian Act on Medical and Health Research §2 and §4, the study did not require approval from the ethics committee. The study involved human participants. Participants were informed that they gave their consent to participate in the study by answering the survey, and no compensation to participants was given. All data were anonymous.

Results

Respondent Statistics

During the period the survey was available, 163,977 patient-initiated e-consultations were sent in the portal. A total of 13,648 e-consultations were assessed by users in the survey, giving a response rate of 8.32%. After two and a half days, we were informed that the question "If you had not had the opportunity to send an e-consultation, what would you have done?" was mistakenly set up as a multiple-choice question. This was corrected to a single-choice format. Respondents who had provided multiple answers (n=637) were removed, leaving a final sample of 13,011 responses.

Table 1 lists the characteristics of the respondents. A total of 78.1% (10,155/13,011) of the respondents had less than 30 minutes of travel time to get to the GP office. Almost half of the respondents (6095/13,011, 46.8%) agreed that it was usually easy to get through on the phone to the front desk, and 64.3% (8366/13,011) agreed that they usually got a GP appointment within a reasonable time.

Use of e-Consultations: for What Reasons and With What Expectations Were e-Consultations Initiated?

Most respondents (10,351/13,011, 79.7%) used e-consultations as their first choice to contact the GP that day, and 83.9% (10,913/13,011) were satisfied with using it.

The results indicate a lack of information about the service given to users. More than half (7466/13,011, 57.4%) of the users had not received information about the possibility of sending an e-consultation but found out about the service by themselves. As many as 20.5% (2670/13,011) of the respondents did not know whether or not they had to pay to send an e-consultation. Recommendations for GPs' use of e-consultations state that an answer should be given within 5 days. However, more than two-thirds (8802/13,011, 68.7%) of the respondents expected a response to their e-consultations within 24 hours.

Only a minority of the e-consultations (1824/13,011, 14%) dealt with problems the user was very worried about. A total of 17.8% (2310/13,011) thought that the e-consultation would result in the GP asking them to come to the office for a physical examination (Table 2).

Table 3 shows the reasons why a patient sent an e-consultation. Multiple answers were permitted. Most e-consultations contained a request for a sick certification (4940/13,011, 38%) or were about a known problem (4778/13,011, 36.7%). A new health problem was the reason for 23.2% (3015/13,011) of the consultations. Only 8.5% (1110/13,011) of the e-consultations were initiated to ask the GP whether they should book a GP appointment for their problem.

Factors Associated With Using e-Consultation as an Alternative to Other Actions

Overview

Table 5 shows the results from the multinomial regression model. The table presents associations between the characteristics of patients and e-consultations and how the respondent would have handled the medical problem if e-consultations had not been available. The reference category is "Book a GP appointment." Associations with the patient's alternative options (calling the front desk, contacting out-of-hours, and waiting or seeking information) relative to booking a GP appointment are reported with all other variables held constant. Descriptive statistics of all groups are found in Multimedia Appendix 4.

*P<.05, **P<.01, ***P<.001

Calling the Front Desk Relative to Booking a GP Appointment

The patients who expected a response within 12 hours (OR 1.64, 95% CI 1.46-1.85) and 24 hours (OR 1.29, 95% CI 1.14-1.45) had higher odds of calling the front desk compared with those who expected to wait 5 days for an answer.

The respondents who were not worried about the issue handled in the e-consultation had higher odds (OR 1.29, 95% CI 1.18-1.40) of calling the front desk compared with those who were somewhat worried.

The patients who thought the GP would not ask them to come in for a physical examination had higher odds of contacting the front desk (OR 1.37, 95% CI 1.26-1.49) compared with the

XSL•FO
RenderX

group who said they did not know if the GP would recommend a physical examination.

The patients who asked about test results had higher odds (OR 1.31, 95% CI 1.13-1.52) of contacting the front desk in comparison to the ones who did not use e-consultations to ask about test results.

Contacting the Out-of-Hours Service Relative to Booking a GP Appointment

Among the respondents who had more than 30 minutes of travel time to the GP office, the odds of contacting out-of-hours service were much higher (30-60 minutes: OR 1.55, 95% CI 1.17-2.05; 1-2 hours: OR 2.22, 95% CI 1.36-3.61; over 2 hours: OR 6.08, 95% CI 3.46-10.66) compared with those who had less than 30 minutes of travel time.

The odds for contacting out-of-hours services were higher (OR 2.10, 95% CI 1.43-3.08) for those who expected an answer within 12 hours compared with those who expected an answer within 5 days.

For patients who usually get a GP appointment within a reasonable time, the odds of contacting out-of-hours service were lower (OR 0.58, 95% CI 0.43-0.77) compared with patients who answered that they thought GP appointments were neither available nor unavailable.

Among the patients who were very worried about their health issues, the odds of contacting out-of-hours service were higher (OR 2.71, 95% CI 2.07-3.54) compared with those who were only somewhat worried about their health issues.

For patients who had a new problem, the odds of contacting out-of-hours service were higher (OR 2.71, 95% CI 2.09-3.51) compared with those who did not have a new problem.

Waiting or Seeking Information on the Internet Relative to Booking a GP Appointment

Among the patients aged 16-25 years, the odds for waiting or seeking information on the internet were higher (OR 2.16, 95% CI 1.38-3.37) than for users over 70 years old.

Also, among patients with a particularly long travel time to the GP office (more than 2 hours), the odds for waiting or seeking information on the internet were higher (OR 2.19, 95% CI 1.27-3.80) than users with a shorter travel time.

The respondents who expected a short response rate had lower odds (OR 0.77, 95% CI 0.60-0.99 and OR 0.70, 95% CI 0.53-0.92) for choosing the waiting or seeking information on the internet alternative compared with those expecting a response rate of over 48 hours.

Among the respondents who had not received information about the service from health care personnel, the odds of waiting or seeking information on the internet were higher (OR 1.15, 95% CI 1.20-1.78) than the ones who had received information.

If the patients' reason for sending an e-consultation was a new problem, the odds of choosing to wait or seek information on the internet were higher (OR 1.74, 95% CI 1.43-2.12) compared with users who did not ask about a new problem.

Discussion

Principal Findings

This web-based survey gathered experiences from 13,011 users of e-consultation in Norway. Most had short distances to travel to the GP office, but still, 79.6% (10,369/13,011) reported that e-consultations were their first choice for contacting the GP. The 2 most common reasons for sending an e-consultation were obtaining a sick certification or asking a question about an already known health problem. In addition, 1 out of 4 e-consultations concerned a new health issue. However, only 14% (1824/13,011) of the requests addressed issues the patient was worried about. Almost 70% (8801/13,011, 67.7%) of the users expected to receive an answer from their GP within 24 hours, despite the Norwegian recommendation to GPs to provide an answer within 5 working days.

If e-consultations had not been available, 45.5% (5917/13,011) of the patients would have booked a physical GP appointment, and 44.9% (5846/13,011) would have contacted the front desk. Patients who alternatively would have called the front desk were associated with not worrying about their health problems and not thinking a physical examination would be necessary. Few patients (323/13,011, 2.5%) answered that they would alternatively have contacted out-of-hours services. These were associated with longer travel distances to the GP office and low availability of GP appointments. Finally, 4.7% (609/13,011) responded that waiting or seeking information on the internet was their potential alternative for sending an e-consultation. These were associated with younger age, a new health problem they did not worry about, and long travel distances to the GP office.

Strengths and Limitations

Despite a low response rate, which is often the case in web-based surveys, the web-based survey design facilitated an efficient collection of a large sample size. Reminders may have increased the response rate. However, as the survey was made available through a pop-up in the web browser and no e-mail addresses or other identifiers were collected, there was no possibility of sending survey reminders. Since the pop-up with the invitation to the survey appeared for each e-consultation sent, it was potentially possible for a user to answer more than once.

The Norwegian official register data for remote consultations do not distinguish between e-consultations, video consultations, and telephone consultations [9]. No specific data on users of e-consultations on Helsenorge are available. However, Norsk Helsenett have provided us with the total number of e-consultations sent in the portal during the survey period. Because no data are available on the characteristics of e-consultation users, it was not possible to assess the overall representativeness of the survey respondents. We could only rely on the large number of respondents.

The respondents were invited to answer the survey immediately after sending an e-consultation. Therefore, the patients' answers were not biased by the GP's response to the e-consultation. Since data were collected after the COVID-19 pandemic, we

XSL•FO
RenderX

can assume that e-consultations were used for all purposes and not mainly to minimize the spread of infections.

We recognize that different appointment booking systems among general practices could lead to inconsistency in answers about alternative actions for e-consultation. Most general practices have a web-based booking system, but some still arrange appointment bookings by telephone at the front desk. In addition, practices can operate with on-the-day acute appointments only available by booking from the front desk. This could have made it hard for some respondents to choose whether e-consultation was an alternative to calling the front desk or booking a GP appointment. The differences we found between the groups should be interpreted with care.

The regression analysis was based on the simplified assumption that e-consultations were used as an alternative or replacement for other GP services. In real life, a patient may intentionally want to use e-consultations for their request without reflecting if it replaces another service. In this setting, e-consultations have their own valuable and independent role in helping patients manage their health. Despite this simplification of actual use, our analysis provides insights into the circumstances of using e-consultations in different settings. It also provides knowledge of patients' perception of using e-consultations compared with the other GP services.

The study did not measure the outcome of the e-consultation (eg, how many e-consultations required an immediate follow-up at the GP office or how many were perceived as solved in writing). Therefore, we cannot conclude whether the e-consultation service adds extra workload to the GP due to the need for follow-up after e-consultations.

Comparison With Previous Work

Use of e-Consultations

This study confirms previous findings demonstrating that users are satisfied with e-consultations and appreciate their high availability [18,31,37]. The expectation of a rapid response time and that most users found out about the service by themselves, probably while navigating the web-based health portal Helsenorge, aligns with findings from a previous study involving older users of e-consultations in Norway [4]. Our study confirms that e-consultations are mostly used for existing medical problems [22]. However, every fourth e-consultation was about a new problem. This is a high share, taking into account that previous research has shown that e-consultations may be less suitable for newly emerged problems [37]. Using e-consultations for sick certificates has been perceived as more efficient and suitable for known health problems [28,38].

e-Consultation as an Alternative to Physical Consultations

In 45.5% (5917/13,011) of the assessed e-consultations, the respondent answered that a GP appointment would have been the alternative action for help. For both the patient and the GP, a medical issue solved by sending an e-consultation is convenient and efficient. However, the potential efficiency gain decreases if a physical examination or many follow-up e-consultations are required after the e-consultation [4,23,25]. Almost 20% (2310/13,011, 17.7%) of the patients in our study believed that the GP would answer the e-consultation by asking them to come to the office for a physical examination. This indicates a potential follow-up through a face-to-face examination. Research has shown ambiguous findings related to follow-up contact after digital contact [25]. These findings range from 34% of all e-visits in the United States to 66% of all e-consultations in the United Kingdom needing follow-up after initial digital contact [39,40]. Another study indicates that digital contacts do not lead to more or sooner follow-up consultations than in-person service [41]. Our study did not measure how often an issue was solved in an e-consultation or how often a follow-up was required. Thus, it is not possible to draw a definitive conclusion regarding the impact of e-consultations on efficiency in the Norwegian context.

e-Consultations as an Alternative to Calling the Front Desk

Previous research has shown that patients use e-consultations to obtain quick answers to minor issues [4,18,20]. Our study found that 44.9% (5846/13,011) of the users would have contacted the front desk if e-consultations had not been available. These users were associated with health concerns they did not worry about or deem necessary for a physical examination. In addition, the patients who had sent many e-consultations in the last 12 months had higher odds of choosing this alternative. We interpret this as e-consultations that meet a need for communication about minor issues when in-person GP appointments are not necessary. Even for minor issues, these patients had high expectations of a fast response from the GP.

Studies of the eConsult service in England show that issues previously handled by the front desk are directly sent to the GP's inbox after implementing the service [26,28]. The eConsult service differs from the Norwegian e-consultations service, as it is a web-based triage platform meant to be the first point of contact for triaging and often requires a follow-up [42]. In Norway, front desk personnel usually triage incoming phone calls and advise patients by giving in-person advice and clarifying requests. We believe some of the e-consultations to the GP could have been efficiently handled by the front desk personnel, thus reducing the inbox for the GP.

e-Consultations as an Alternative to Out-of-Hours Service

Previous studies have shown that patients seek out-of-hours services when GP offices are closed or are perceived as unavailable [42-44]. The users who answered that out-of-hours services would have been the alternative if e-consultations had not been available were associated with longer travel distances to their GPs. Previous research has shown that the high availability of e-consultations can slightly reduce the demand for out-of-hours services [29]. It raises a concern that users with new and worrisome problems who expect a fast response may turn to e-consultations instead of seeking immediate care. The e-consultation service is unsuitable for urgent care as the response time norm is 5 working days. Ensuring that e-consultations do not become an alternative for urgent care is crucial, as this risks patient safety. The risk of patients using

XSL•FO
RenderX

e-consultations for urgent issues has been highlighted as an unintended consequence of e-consultations in another study from England [28].

e-Consultations as an Alternative for Waiting or Seeking Information on the Internet

Our study found that 4.7% (609/13,011) of the users who initiated e-consultations would alternatively have waited to seek GP care. Earlier research has also described how e-consultations can create an extra demand for GP care [25,45]. The group that alternatively would have waited or sought information on the internet had higher odds of being younger and addressing a new issue they were less worried about. Previous research supports that better access to primary care prompts seeking help for minor complaints [46]. When e-consultations lower the threshold for use and lead to requests that could just as well be handled outside health care services, the GPs' health care resources may be misallocated. It can also add to the GP's workload. On the other hand, our study indicates that users of e-consultations with a long way to the GP office had higher odds of waiting and seeking GP care if e-consultations had not been available. This indicates that e-consultations improve access to GP care for patients who would alternatively not have sought help due to unavailability.

Implications and Future Research

Users of e-consultations are mainly satisfied, probably due to the increased convenience of e-consultations. Our study indicates a potential efficiency gain for patients and GPs as many patients initiate e-consultations in circumstances where they alternatively would have booked a GP appointment. However, we do not know how many e-consultations would need a follow-up, such as a physical appointment or requesting more information in writing. In addition, our findings suggest a slight increase in demand for GP care and a shift in tasks from front desk staff to GPs, which challenges the total efficiency gain for the GP. The pressure on GPs from patients expecting a fast response can also add to the GPs' workload. Our study was not designed to investigate efficiency gains or a potential increase or decrease in GP workload, and this question needs further investigation.

Our findings indicate that some of the initiated e-consultations were probably less suitable for the written modality. Examples include e-consultations in which patients deemed a physical examination necessary or where the issue was new or caused the patient significant concern. Knowing that few users had received information about the service from health care personnel and that several were uncertain about the cost of service shows that more information about the service is necessary. Guidance for patients could help ensure appropriate use. This is important for patient safety, keeping GPs' workload down, and helping GPs prioritize the patients with the most need. Keeping the e-consultation manageable for the GP is important to maintain the offer for the patients. As the service is voluntary for GPs to offer, an overwhelming and unmanageable inbox may drive some GPs to stop providing the service.

Future research is needed to assess the overall efficacy, safety, and impact on GP resource allocation. It should evaluate the added value of e-consultations on health outcomes. A focus should be put on evaluating the added outcome of e-consultation when patients experience increased demand for GP care due to higher availability through e-consultations.

Conclusion

This study demonstrated that e-consultations are primarily used for convenience, as most respondents reported having good access to their GP due to short travel distances to the GP office and relatively accessible GP appointments. Patients' expectations for a fast response to the e-consultation were high. Given that the GP norm is a 5-day response time, the proportion of e-consultations addressing new issues and issues the patient was worried about should raise concerns about patient safety. Nearly all patients would have booked a GP appointment or contacted the front desk had e-consultations not been available. This indicates that e-consultations may serve as an alternative to both these parts of the GP service. The study suggests a small increase in demand for GP care through e-consultations for patients who would not have sought health care if e-consultations had not been available. For patients with low availability to the GP office, some e-consultations seemed to be used as an alternative to out-of-hours service or not seeking help. Patients' concerns about their medical problems influenced how they assessed alternative actions to e-consultations. Those highly concerned had higher odds of alternatively choosing out-of-hours service, while those less concerned were more likely to call the front desk or not seek help. Ensuring appropriate use of e-consultations is crucial for patient safety and managing GP workload. Clear guidance could help patients determine when e-consultations are appropriate. Future research should explore the clinical outcomes and efficiency gains of e-consultations.

Acknowledgments

Abstract

Background: Digitalization is steadily advancing on a global scale, exerting a profound influence on health care systems. To facilitate acceptance of the digital transformation, guiding principles emphasize the need for digital health structures to be person-centered and promote high-quality care. This paper examines the implementation challenges within the German health care system, with a particular focus on how change initiatives engage with existing infrastructures and organizational modes of health care delivery. This approach provides a framework for analyzing how established infrastructure determines new developments while also highlighting the procedural dynamics of change and the integration of innovations within existing information infrastructures. These established infrastructures are referred to as the installed base.

Objective: The aim of the study is to examine the installed base encountered by the digital transformation within the German health care system by investigating information exchange practices among general practitioners (GPs) and their communication with other health care actors.

Methods: A mixed methods study including a quantitative survey and semistructured qualitative interviews was conducted. The study sample consisted of all publicly accessible GP practices (N=1348) situated in the state of Brandenburg, Germany. The survey captured demographic data, communication practices, and perceived barriers to digitalization. The interviews explored experiences with digital applications. Quantitative data were analyzed using R (R Foundation for Statistical Computing), and qualitative data were managed and analyzed in MAXQDA (VERBI Software GmbH) through content analysis.

Results: A total of 250 questionnaires (response rate 18.5%) and 10 interviews with GPs were included in the analysis. GPs primarily use the telephone (n=138, 55.2%, SD 24.64), fax (n=109, 43.9%, SD 25.40), or post (n=50, 20.2%, SD 9.46) to exchange information. Newer digital communication channels such as messenger applications (n=2, 0.8%, SD 0.72) and Communication in the Medical Sector (n=1, 0.5%, SD 0.97) play a minor role. We identified three intertwined clusters displaying diverse barriers to the digitalization of GPs' communication practices: (1) incompatibility issues and technical immaturity, (2) lack of knowledge and technical requirements, and (3) additional technical, financial, and time-related burdens. These barriers were perceived as significant deterrents to the adoption of digital tools, with older GPs more reliant on analog systems and more likely to view digitalization as a source of frustration.

Conclusions: Newly established communication channels in the German health care system compete with the existing information infrastructure, which is deeply integrated into GPs' practice routines and care processes. However, this installed base has been largely overlooked in digital transformation initiatives. While newer channels hold potential, they often malfunction and are

XSL•FO
RenderX

incompatible with long-established, individualized GP workflows. Addressing these issues rather than imposing coercive measures is crucial for increasing adoption. Incorporating health care providers' perspectives and aligning new channels with established routines can prevent frustration and facilitate a smoother digital transformation.

Introduction

Digitalization is steadily increasing worldwide and is also massively impacting health care systems. The hope associated with digital health care systems is that they are able to mitigate the effects of staff shortages, deliver equal care in rural and deprived areas, or provide incentives for people to increase healthy living behaviors [1]. Furthermore, it is assumed that the integration of new technologies in diagnostic procedures contributes to lowering misdiagnosis rates and improving treatment processes, including the reduction of treatment delays [2]. The World Health Organization global strategy on digital health outlines principles for the digital transformation of health care systems, stating that digital health structures will be accepted when they serve quality health care and are person-centered [3]. This approach deliberately includes the health care workforce and calls for consideration of the local context, including its health care system, health needs, and resources. Simultaneously, the strategy emphasizes health data sharing and system interoperability, broadening the objectives of health care systems to encompass data production, thereby illustrating the integral role of technology in achieving these expanded goals.

This becomes particularly relevant when digitalization is considered in relation to information structures. In the context of digitalizing health care systems, the term information infrastructure describes all those "sociotechnical networks consisting of physical facilities and heterogeneous, interconnected subinfrastructures" [4] that are crucial for the exchange of information between the relevant stakeholders in a given health care system. A common way to examine processes of technological disruption in information infrastructures is to study the acceptance and adoption of new systems. Such approaches assume the presence of "old" and "new" systems, with the new either replacing or complementing the old. In this context, challenges in the transformation process are seen in organizational structures, in the users or patients, or in the technologies used [5-7]. Contrasting this perspective, Aanestad et al [8] approach implementation challenges by studying how change initiatives encounter existing infrastructures and modes of organization. Such a perspective, they argue, allows for the investigation of how existing elements shape, mobilize, and represent resources for new developments. Instead of clearly separating "old" and "new" into distinct entities, this approach allows for a focus on the procedural nature of change and the integration of innovations as part of existing information infrastructures. These information infrastructures are deeply embedded in daily work routines across organizations as well as "in social, organizational, and technical fabrics and coevolve with each other" [4,9]. Important work conducted in these routines often is tacit activities that remain hidden in formal work descriptions. Reconfiguring such work routines through technologies can lead to unanticipated and unintended consequences. Given that medical work is supported by technologies that convey information in specific formats, digitalization represents not merely a change in information transmission but actively reshapes the nature of medical practice. This is demonstrated by Vikkelsø [10] in her analysis of electronic records in Danish hospitals, showing that the introduction of digitalization leads to a reconfigured health care system rather than an improved one. She cautions us to understand the complexities and the coemergence of structure and technology rather than viewing change as a binary of good or bad, working or not working, and encourages us to conceptualize innovation in terms of the distribution of work, responsibilities, attention, and risk [10].

According to Aanestad et al [11], the successful development and implementation of information infrastructures require more than just a description of implementation objectives, necessary technological capabilities, and human skills. Instead, it is imperative to maintain a comprehensive awareness of existing organizational, institutional, regulatory, sociotechnical arrangements, established work routines, and the built environment that together form an installed base of information infrastructure in a given setting [11]. Since the existing installed base of infrastructure significantly influences the design possibilities of new infrastructure, failing to consider the existing infrastructure can lead to technical issues in newly implemented systems, poor interoperability with current systems, increased costs, and an overall lack of efficiency [12]. To accelerate the transformation process, the German federal government has enacted significant legislation in recent years to convert the German health care system into a digital one [13-20]. This includes enhancing communication among ambulatory physician offices, hospitals, and patients and resulted in mandation to implement various applications, such as digital health applications (German: *Digitale Gesundheitsanwendungen* [DHAs]) [21], electronic health records (German: *elektronische Patientenakte*) [22], or electronic medication prescriptions (German: *elektronisches Rezept*) [23]. For information exchange in the German ambulatory sector, the telematics infrastructure (TI; German: *Telematikinfrastruktur*) has been developed. The TI is a secure network specifically designed for the exchange of medical data in the German health care system. It serves as a communication platform for various stakeholders in the health care sector, such as physicians, dentists, pharmacies, hospitals, and health insurance companies. It was designed to enable the

XSL•FO
RenderX

secure exchange of medical data, including patient information, electronic prescriptions, emergency data, and electronic patient records. Key technical components of the TI are so-called connectors in all health care facilities, which identify these as authorized participants using digital certificates on chip cards [23]. These connectors have had to be connected to the TI since June 2019. Relevant elements of the TI structure are electronic prescriptions, electronic certificates of incapacity, electronic patient records, but also DHAs, video communication, or the KIM (Communication in the Medical Sector, German: *Kommunikation im Medizinwesen*) module. KIM is an email-based end-to-end encrypted information transmission procedure intended to enable the secure sending and receiving of electronic physician letters and other patient-related documents between different types of providers. The use of KIM to transmit electronic certificates of incapacity for work and electronic physician's letters has been mandatory since 2021 [16]. In the context of this paper, we define the installed base of the information infrastructure as the established communication channels that predate the current digital transformation efforts in the German health care system, which is evident in the implementation of the TI and associated channels. While a limited number of approaches address the installed base within the German context [24], the significance of specific pre-existing modes of information infrastructures for medical work has been regularly underestimated in current transformation processes to more digital information infrastructures [10]. This, in turn, has resulted in somewhat incomplete explanations for the below-average digital development in Germany compared to other European countries [23,25]. For this reason, this paper identifies practices of information exchange between general practitioners (GPs) and other stakeholders in the German health care system, using the state of Brandenburg as an example. Understanding the role and influence of the installed base of information infrastructure, we argue, will aid in anticipating challenges in the ongoing digitalization of health care services.

Methods

Study Design

To reach the study aim of capturing the installed base of information exchange in the health care system from the perspective of GPs, the study was set up as a mixed methods approach using a parallel design both for data collection and analysis (details on this mixed methods study following the Good Reporting of a Mixed Methods Study framework are provided as Multimedia Appendix 1). The quantitative arm of the study consisted of a survey distributed to all GPs residing in the state of Brandenburg in Germany. The qualitative arm consisted of semistructured, qualitative interviews with a subsample of GPs (10 interviews) and with citizens aged 65 years and older (21 interviews). The qualitative interviews were designed to provide an in-depth understanding of information exchange practices as well as the use and challenges of digital applications in ambulatory care settings. In contrast, the survey aimed to capture the current state of these practices, including the stakeholders involved and the methods of information exchange. Data collection for the qualitative study arm was conducted between September 2021 and October 2022, while the quantitative arm took place from March to June 2022. This paper focuses specifically on the perspective of GPs, incorporating data from both the GP survey and interviews.

Ethical Considerations

Ethics approval for this study was obtained from the Brandenburg Medical School ethics committee (E-02-20210531), ensuring adherence to all applicable regulations governing research involving human participants such as the Declaration of Helsinki. Informed consent was obtained from all participants prior to their inclusion in the study, encompassing both quantitative and qualitative data collection and analysis, with secondary analyses explicitly permitted under the primary consent agreements. To safeguard participant confidentiality, pseudonymization was implemented for all data: IDs were assigned to participating GPs during the survey, and pseudonyms were created for each qualitative interview. Identifying information was replaced with pseudonyms in the interview transcripts. The pseudonymization lists and participants' contact information were securely stored in paper form within a locked cabinet at the Institute of Social Medicine and Epidemiology, accessible only to authorized study personnel. All data were securely managed in compliance with institutional policies and General Data Protection Regulation guidelines. Participants were not compensated monetarily, and no identifying details appear in this manuscript or supplementary materials, ensuring both anonymity and ethical integrity throughout the research and publication process.

Data Collection

Quantitative Study Arm

The questionnaire used in this study was developed by the research team in collaboration with GPs from the state of Brandenburg to align with the specific objectives of the study. The survey themes were shaped by a thorough analysis of relevant research gaps identified in the literature. Before implementation, the questionnaire was pilot-tested with 2 GPs to ensure clarity and appropriate understanding of the questions. The finalized instrument comprises 124 items and was designed to assess the communication challenges faced by GPs in their routine practice using a series of targeted queries: (1) frequency of use of specific communication channels for information exchange with specific health care stakeholders, (2) assessment of quality of exchange, and (3) expected barriers to use of digital channels (all 5-point Likert scales). In addition, sociodemographic data on age, sex, number of years of professional experience, type of practice, and population size at the practice location were collected. The questionnaire was offered as a paper-pencil or digital version. All GPs in the state of Brandenburg were invited to participate. The address data of the GPs to be invited were made available via the website of the Brandenburg Association of Statutory Health Insurance Physicians. The total of all GPs in Brandenburg was divided into 2 random subgroups, of which at baseline (T0), one group received the questionnaire by mail as a paper-pencil version including an invitation letter, study information, and consent form, whereas the other group received a mailed invitation letter to participate in a web-based questionnaire including a link and

XSL•FO
RenderX

QR code. After 3 weeks (T1), a reminder in the form of postcards was sent to all GPs who had not yet participated at that time, with each postcard corresponding to an invitation for a web-based questionnaire. After 3 more weeks (T2), a second reminder was sent, with those physicians who received a paper-pencil invitation in the first wave receiving a digital invitation this time and vice versa. The web-based version was hosted on the professional survey platform SoSci Survey (SoSci Survey GmbH) under a commissioned data processing agreement to ensure secure and compliant data collection. The invitation to participate in the questionnaire was sent by post for both the paper-pencil version and the web-based version, with the invitation for the latter containing a QR code that led to the survey provider's website. The invitation and all communication with participants were managed by the study staff at the Institute of Social Medicine and Epidemiology.

Qualitative Study Arm

The semistructured interviews aimed at identifying practices and routines that GPs exhibit in the exchange of information with other health care actors and how these routines affect health care delivery. From this perspective, the communication practices of GPs from the German state of Brandenburg were to be identified, which in turn should shed light on attitudes and concrete behaviors in the communication practices of GPs. In particular, the role of digitalization in medical practices was to be recorded, including the associated potentials and hurdles. An interview guideline, informed by a review of existing literature on communication practices in health care and the role of digitalization in medical practices, was developed and used for conducting the interviews (Multimedia Appendix 2). All qualitative data were collected by the first author (TH). The interviews were audio-recorded and transcribed following the methodology outlined by Kuckartz [26]. GPs were recruited for the qualitative interviews in a variety of ways. On the one hand, eligible individuals from the extended research network of the Institute of Social Medicine and Epidemiology were contacted. These were selected based on convenience sampling logic. Additionally, the General Practitioners Association Brandenburg (German: *Hausärzteverband Brandenburg e.V.*) was involved as gatekeeper, supporting the recruitment by reaching out to members informing about the study and the possibility to give an interview. Finally, interviewed GPs were asked if they knew other potentially relevant GPs who would be interested in being interviewed for the study, using a snowball sampling approach. Identified GP practices received the study information by study personnel, either via email or postal mail. GPs who provided written informed consent were included in the study.

Analysis

Quantitative Study Arm

The frequency distributions of the sociodemographic data were mapped by category using a table, and relevant location parameters (mean, median, and IQR) were reported in text form. Depending on the presence of normally distributed data, 2-tailed *t* tests for independent samples or Mann-Whitney *U* tests were carried out in order to determine whether significant differences exist in the age groups according to sex. Frequency distributions for the variables were visualized using stacked bar charts. The frequency distributions for the variables were visualized with stacked bar charts, whereby categories 1 and 2 as well as 4 and 5 of the Likert scale items were combined. Spearman correlation was used to identify variations in answering behavior by age, practice site, and population size. Eta-squared statistics were calculated to determine the proportion of the variance of the variables that is explained by the grouping by practice type. Point-biserial correlations were used to examine whether participant's sex influenced answering behavior. CIs for the Spearman correlations were calculated using bootstrap replicates (K=1000), and CIs for the point-biserial correlations of the sex variable were calculated using approximations by Fisher Z-transformations. All tests for correlations were solely exploratory. R (version 2022.07.2; R Foundation for Statistical Computing) was used for the statistical analyses. In addition to the standard R functions available in base R, the following packages were used: *readxl* (version 1.4.3), *psych* (version 2.4.1), and *boot* (1.3-28) [27-29].

Qualitative Study Arm

The interview materials and responses to 2 free-text questions from the survey were included in the qualitative analysis, which focused on reasons for poor exchange quality and general experiences with information exchange in general practice. The analysis was conducted using content-structuring qualitative content analysis according to Kuckartz [26]. This method aims to identify content-related aspects within the material, conceptualize the data concerning these aspects, and systematically describe them [30]. Within the framework of the analysis, deductive categories were generated from the semistructured interview guideline. During the analysis, inductive categories using open coding were added. The deductive and inductive categories were then used to categorize the free-text responses of the survey, and additional inductive categories were added to the analysis. The category construction was not theory-based and took place in several steps: first, the deductive categories for the GP interviews were discussed among the authors in terms of precision and meaningfulness. Subsequently, the entire interviews were coded using the deductive categories, and new inductive categories were determined. The newly identified inductive categories were then discussed and finalized before being applied to the interview data. In the final step, the deductive and inductive category system was used to code the free-text responses. Here, additional inductive categories were formed by the coders, then discussed and finalized, and applied to the entire free-text dataset. The analyses took place at the category level, relating the categories developed and their concrete manifestations in the material. The selection of the categories studied in more detail was informed by their importance to the research question and absolute coding frequency. Each step was carried out independently by 2 researchers. Between the individual steps, the categories developed were compared, discussed, and harmonized. All qualitative data were managed using MAXQDA 2022 software (version 22.0.1; VERBI Software GmbH).

Results

Sociodemographic Data

In total, questionnaires were received from 250 of the 1348 GPs contacted, corresponding to a response rate of approximately 18.5%. Of those 250 responses, 81 were collected via the web-based version, and 169 via the paper-based survey, corresponding to 32.4% and 67.6% of the total responses, respectively. Of the participants, 63.6% (n=159) were female, and the 50- to 59-year age group was particularly well represented (n=88, 35.2%). The mean age was 54.03 (SD 9.82; median 56, IQR 46-61) years. On average, the participating physicians had 19.3 (SD 12.16; median 19, IQR 8-30) years of professional work experience. Most practices were located in regions with a population density of 5000 to 20,000 or 20,000 to 100,000 inhabitants. Most participants worked in solo practices (Table 1). Age showed no significant difference between male and female participants. Thus, the distribution of age is comparable for male and female participants in this sample. A total of 10 GPs were included in the interview study, 3 of whom were male and 7 female. The participants' ages ranged from 45 to 67 years. Of the GPs interviewed, 7 practiced in solo practices, 1 in a group practice, 1 in a joint practice, and 1 in a medical care center. The length of the GP interviews ranged from 9 to 93 minutes (mean 44.86, SD 25.1, median 46.73, IQR 28.38-52.13 minutes).

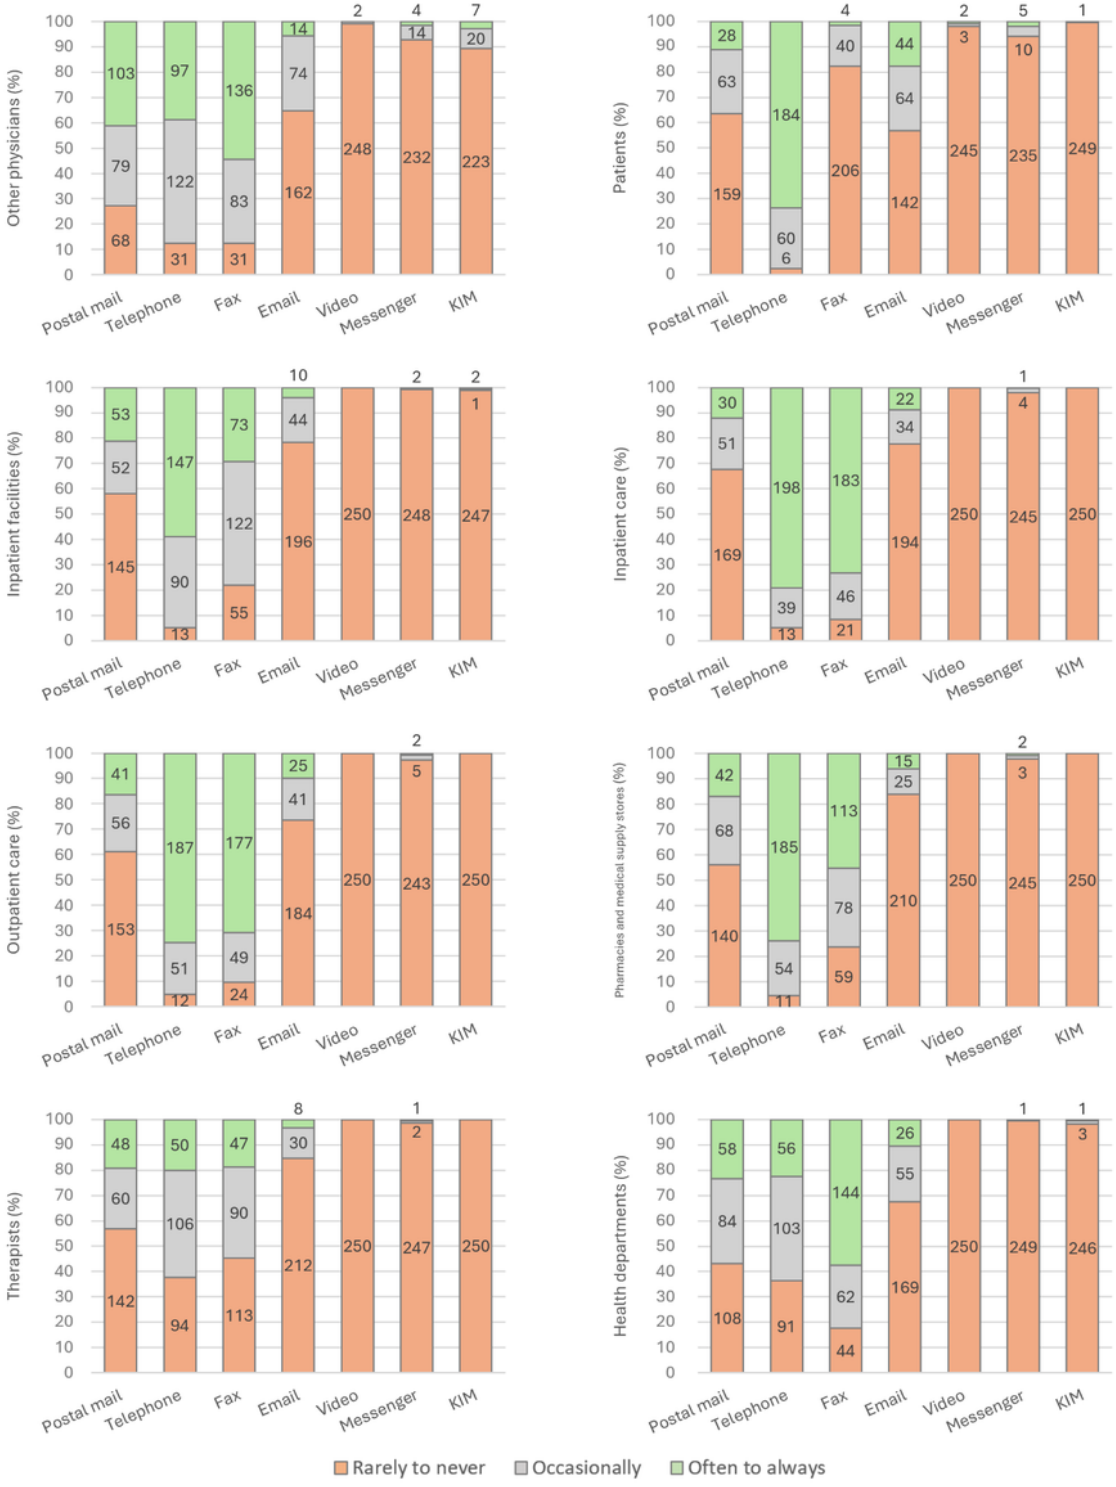
Survey



Frequency of Use of Specific Communication Channels for Information Exchange

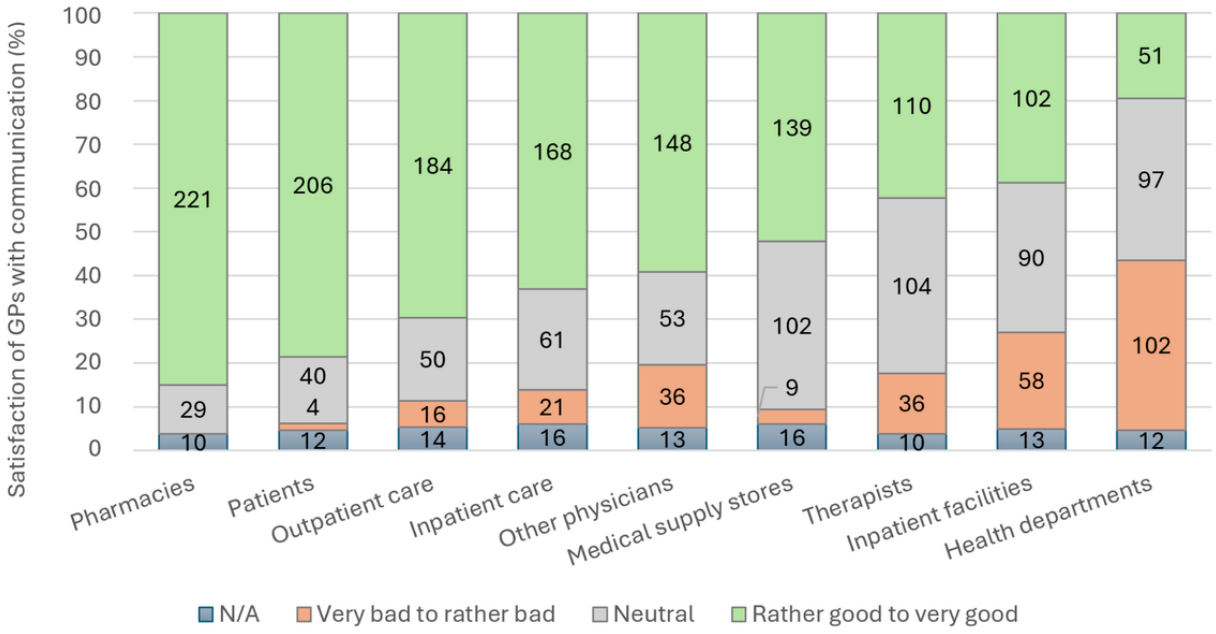
The survey determined how often GPs exchange information with other actors in the health care system via specific channels. It was found that the exchange with all the actors surveyed takes place via channels that have been used for decades, namely, by postal mail, by telephone, and by fax. On average, GPs use the telephone (n=138, 55.2%; SD 24.64), fax (n=109, 43.9%; SD 25.40), and post (n=50, 20.2%; SD 9.46) often to always in order to exchange information with other stakeholder groups.

XSL•FO
RenderX

However, the exact use characteristics of the communication channels differ depending on the communication partner. With other physicians, health departments, care actors, and pharmacies or medical supply stores, faxes in particular are sent frequently. Communication with patients is largely done by telephone and sometimes by electronic or postal mail. Email is the most frequently used of all the more digital applications (n=20, 8.2% among all communication partners; SD 4.65) but is clearly behind the older channels mentioned. Messenger applications (n=2, 0.8%; SD 0.72) and KIM (n=1, 0.5%; SD 0.97), on the other hand, are used very rarely on average (Figure 1).

Figure 1. Frequency of use of selected communication channels for information exchange with various health care system actors from the perspective of general practitioners (n=250) in Brandenburg, Germany (2022). KIM: Communication in the Medical Sector.

Positive correlations between age or professional experience and the frequency of use of numerous different analog channels indicate that older physicians with more professional experience may be more likely to use older communication channels such



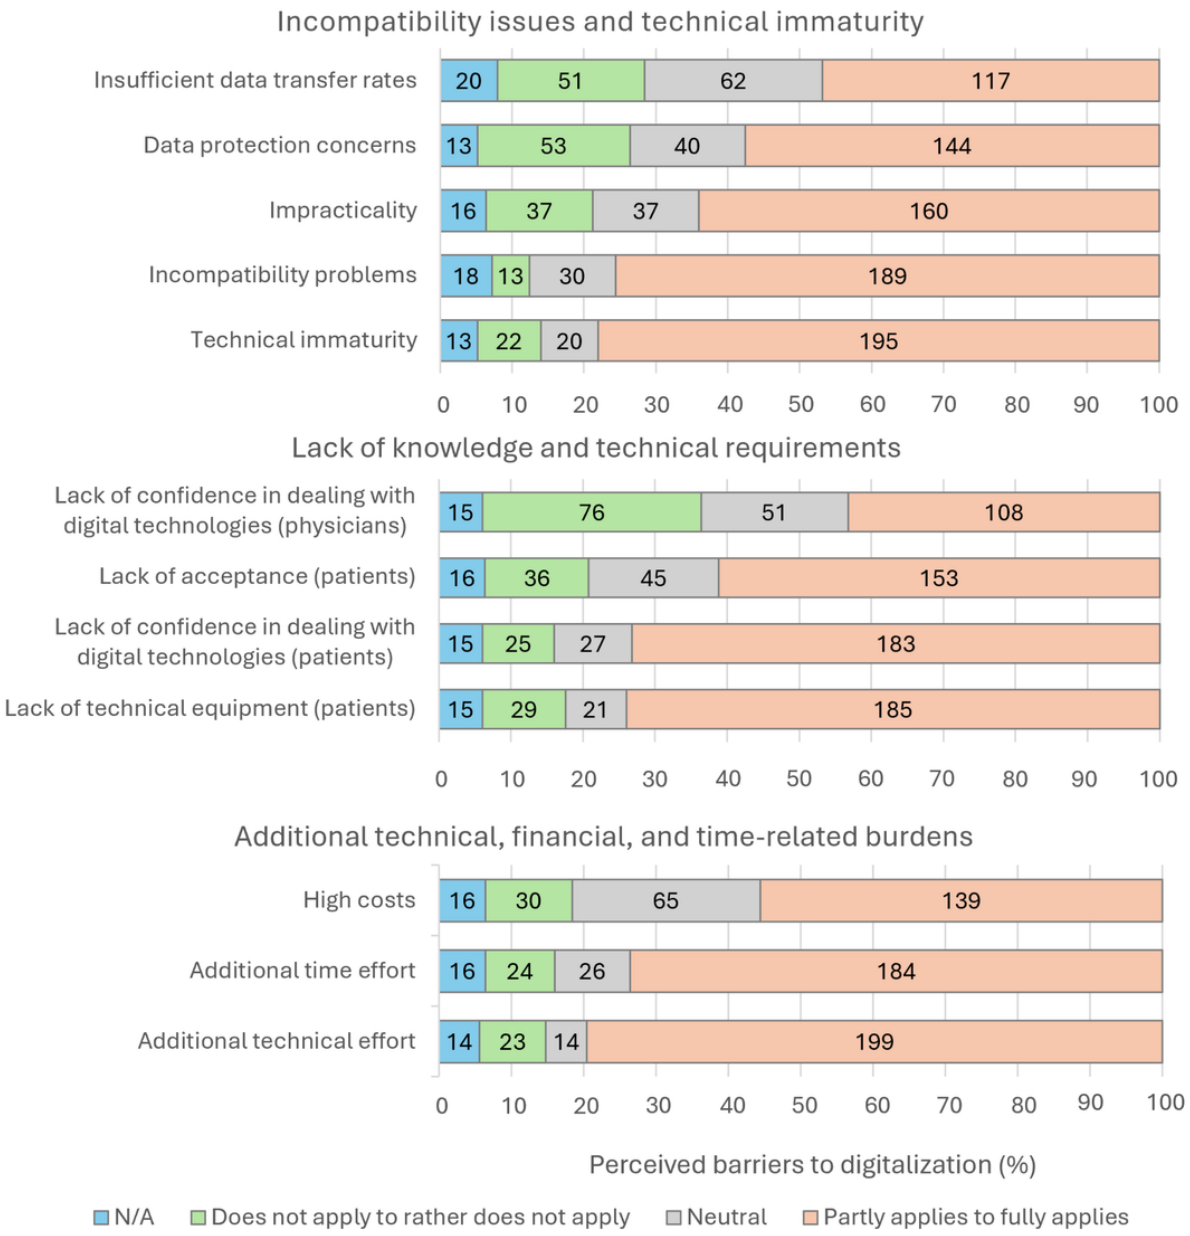
XSL•FO
RenderX

as the telephone and postal mail. Email and fax, on the other hand, show negative correlation coefficients, which indicates that these communication channels are used less with increasing age. However, in all cases, the correlation coefficients are in the low range between –0.3 and 0.3 [31]. In contrast, sex, the size of the population at the practice location, and the type of practice show only minor or no correlation to the use of certain communication channels, which is why an influence on the use of the information channels surveyed is unlikely (Multimedia Appendix 3).

Assessment of Quality of Exchange

Looking at the satisfaction of the physicians surveyed with the exchange of information, it can be seen that GPs are relatively satisfied with the quality of the exchange, especially with pharmacies, patients, and care actors. Health departments, inpatient facilities, and therapists can be seen as exceptions here. Consequently, it might be argued that GPs are generally quite satisfied with the installed base of communication channels (Figure 2).

Figure 2. Satisfaction of general practitioners (n=250) with information exchange across various actors in the health care system in Brandenburg, Germany (2022). N/A: not applicable.



The sociodemographic variables show at best occasional links to satisfaction with the exchange of information with other actors in the German health care system. Age appears to have a certain influence on satisfaction with the exchange of information with certain actors (therapists and medical supply stores). Similarly, an increasing amount of professional years correlates with higher satisfaction with a wide range of actors (patients, health authorities, outpatient care, inpatient care, therapists, and medical supply stores). Thus, increasing age appears to contribute to greater acceptance or satisfaction with the exchange practices. All correlations are weak to moderate. Sex, population size, and practice type show little to no correlation with satisfaction with existing information exchange (Multimedia Appendix 4).

Expected Barriers to the Use of Digital Channels

The survey showed that GPs considered numerous barriers to digitalization to be potentially relevant to their practice (Figure 3). The barriers were assigned to 3 clusters, which are addressed again in the qualitative analysis: cluster 1—"incompatibility issues and technical immaturity" (containing "impracticality," "technical immaturity," "incompatibility problems," "insufficient data transfer rates," and "data protection concerns"), cluster 2—"lack of knowledge and technical requirements" (containing "lack of confidence in dealing with digital technologies [physicians]," "lack of confidence in dealing with digital technologies [patients]," "lack of technical equipment [patients]," and "lack of acceptance [patients]"), and cluster 3—"additional technical, financial, and time-related burdens" (containing "high costs," "additional technical effort," and "additional time effort"). While the additional technical and time expenditure as well as the incompatibilities and technical immaturities are particularly significant, insufficient data transfer rates and GPs' lack of skills in using digital technologies seem less relevant.

XSL•FO
RenderX

Figure 3. Perceived barriers to digitalization among general practitioners (n=250), categorized into 3 clusters: insights from a mixed methods study in Brandenburg, Germany (2022). N/A: not applicable.

Age appears to be relevant in the perception of numerous barriers to digitalization. With the exception of "high costs," "data protection concerns," and "insufficient data transfer rates," all barriers appear to be seen as significantly more problematic with increasing age. In every case, the effect strength is low to moderate. Similar trends can be seen for the participants' years of experience: with the exception of data protection concerns and patients' lack of confidence using digital communication channels, all other barriers show significant correlations of weak to medium strength. Issues of high costs, data protection, and patients' lack of confidence using digital communication channels become more pronounced, as population size increases. In some cases, there are also minor sex-related differences in the perception of digitalization barriers. Female participants are more likely to perceive data protection and insufficient data transfer rates as problematic compared to male participants. Additionally, female participants are more likely to perceive a lack of confidence in dealing with digital technologies on the side of the physician as a barrier. This might indicate a sex difference in how certain challenges or obstacles are viewed, with female participants potentially seeing these barriers as more significant or problematic. However, the effect sizes are again small to medium (Multimedia Appendix 5).

Qualitative Results

Overview

While the survey was able to show to what degree the established base of communication channels is used by GPs and that certain barriers exist in the use of more recent applications, it was not yet possible to understand how these barriers manifest in everyday practice. To do so, the qualitative analyses can offer valuable insights and identify specific needs

XSL•FO
RenderX

regarding digitalization. The results are arranged according to the 3 clusters mentioned earlier, which were developed as part of the categorization of the qualitative data material. They appear to be strongly interrelated.

Cluster 1—Incompatibility Issues and Technical Immaturity

Both the qualitative interviews as well as the free-text analyses revealed that malfunctioning technology is a particularly relevant problem in the digital exchange of information. This includes practice management software and modules of the TI, which sometimes run very slowly. In addition, there are noticeable incompatibilities between numerous existing practice management software options and the TI, resulting in frequent system crashes. This negatively affects the user experience:

> *I have found many colleagues to be fundamentally open to digitalization—but there is a great deal of dissatisfaction with the implementation. The devices and software are often incompatible, it takes more time [to use them], there are system crashes and registrations are complex. Instead of reducing bureaucracy, the introduction of digital structures results in printouts and digital dispatch—which makes twice as much work.*

In particular, the use of KIM, which is intended to enable the secure sending and receiving of electronic physician letters and other patient-related documents between different types of providers, has been prone to numerous errors in the past and is also relatively unintuitive from a physician's perspective and involves too many clicks on the part of the sender. In addition, faulty health insurance card readers regularly cause practice management systems to fail. The various and regularly occurring technical difficulties result in the need to consult external IT support service providers. Participating GPs had varying levels of experience with such providers, but it was frequently noted that services were unsatisfactory, often caused by the associated high costs for GPs as well as poor availability of services due to high levels of capacity use.

Cluster 2—Lack of Knowledge and Technical Requirements

Another barrier associated with digitalization is the lack of knowledge about technical processes, which limits the use of digital applications. This applies to older physicians or those who have little know-how in terms of digitalization:

> *I belong to a generation that never received an introduction to data technology. As a result, all technical applications are all Greek to me. [...] At almost 63 years old, technology is also a huge burden for me, and I don't feel I have the time to cope with the innovations alongside my medical work.*

This also affects patients, especially older ones:

> *Due to the increasing aging of the population, patients are increasingly experiencing cognitive problems, explanations have to be retrieved more frequently, and additional limitations (such as hearing loss) make this even more difficult. The use of digital media overwhelms almost all patients older than 80, many no longer use cell phones, PCs or tablets. In my experience, the intended extensive digitalization does not reach about 25% of my patients, and about 50% of patients with a permanent medication.*

In addition to a lack of technical affinity, affected individuals, especially older patients, lack technical equipment. This includes hardware such as terminal devices (computers, smartphones, and tablets) but also an inadequate internet connection. Especially some rural medical practices only have a poorly developed internet connection at the practice location, which limits the use of the TI:

> *The internet connection is unfortunately inadequate, in some cases only 0.1 Mbit/s when downloading. This is a major hurdle with regard to digitalization, especially when using electronic certificates of incapacity or e-prescriptions.*

Cluster 3—Additional Technical, Financial, and Time-Related Burdens

As a direct consequence of the previously mentioned deficits in digital information exchange, these cause enormous additional time and administrative expenses. The need for frequent error management and software updates ties up physicians' time and limits patient care:

> *We are witnessing terrible changes with the introduction of the telematics infrastructure! It takes an extreme amount of extra time to personally create all the prerequisites for this. You need time for the installation, the constant updates, there is a constant need for remote maintenance for normal working functions of the practice management system. [...] A lot more "clicks" are required for every work step. I don't see any improvement or simplification through the TI, but an extreme time burden with bureaucratic and technical tasks.*

In addition, the various susceptibilities to failure of existing hardware and software result in a technology dependency, which also manifests itself in continuous error management and thus ties up time that could be used for patient care:

> *And it's also a huge nuisance in everyday practice when things don't work. If the system fails, care is actually no longer possible. You can't do anything anymore. You can talk to the patient, but you can't write a prescription. You can't call up a single form. In fact, nothing is possible if the telematics infrastructure is blocked. Because it is also not possible to read the health insurance card.*

The high speed of innovation, expressed in a constant stream of new applications and updates, also makes it necessary for physicians to regularly spend part of their working time keeping up to date with the latest applications and initiating their implementation in their own practices:

> *It takes 3-9 months between being informed about innovations and ordering the components and delivery or installation. After installation, you have to start*

XSL•FO
RenderX

> *reading up again, as you have forgotten the information in the meantime and there were five other innovations in parallel—it never stops and you can't keep up.*

Another significant negative factor is the financial outlay that digitalization entails for GPs. This includes the comparatively high acquisition and setup costs but also the maintenance and update costs, which are correspondingly high if problems occur regularly. In particular, physicians without a deeper understanding of IT and thus problem-solving skills are at risk of having to pay more money for more frequent IT services. This is likely to include older physicians in particular. Furthermore, switching practice management software providers is very costly, since the data must be transferred by external IT companies.

The perceived additional burden of the aspects described here can become problematic for a health care system, especially if it leads to physicians resigning in the face of the hurdles posed by digitalization. In this context, especially older medical practices are at risk, if owners do not feel up to the demands of digitalization. As a result, physicians may give up their professional activities prematurely, which can lead to supply bottlenecks that may not be able to be closed quickly. This is particularly true in very rural regions with a lower physician density:

> *If my daughter hadn't said, with the pandemic and with all this digitalization, "I'm taking over the practice," then it would have been a reason for me to give up the practice. Yes, it would have been a reason for me. I have also had practice nurses who are also my age, that is, those who are about to retire. And I have to tell you, that was really a big challenge for us to handle. And there I would have said, "No, I'm not going to do that to myself now at my age." You know, first and foremost, I'm a doctor and not somebody who's constantly dealing with technology here. Because I can see it. When I come here, there's always some problem. There's always something wrong with all the software and I don't know what all. And I wouldn't have had the nerve to do it anymore. I would have said, "That's enough. I'm not going to do this to myself anymore." So that's where I'm at.*

However, the barriers and especially the high bureaucratic hurdles can also have a deterrent effect on younger generations of physicians:

> *It's just awful that there is such extensive interference with professional self-employment of physicians. I am not surprised if I do not find a successor for my practice. I would never become self-employed again under these circumstances, and I will close my practice at some point, not just at the age of 67—I am used up, exhausted, at the end of my tether.*

Discussion

Principal Findings

This paper examined the role of the installed base in information exchange between GPs and other health care actors in Brandenburg, as an exemplary more rural region in Germany. The analysis revealed several relevant findings. At the time of data collection, the participating GPs very frequently interacted via communication channels that had existed for several decades, such as telephone, fax, or postal mail. The older age of physicians appears to be associated with a greater use of more traditional communication channels within the installed base and to greater skepticism toward digitalization. This is shown in the positive and significant correlations between age or professional experience and the frequency of use of numerous different older channels, indicating that older physicians with more professional experience may be more likely to use older communication channels such as the telephone and postal mail. These older communication channels work well from the perspective of those GPs' who took part in the survey. In contrast, new communication applications developed and introduced in recent years in the context of digitalization have not been used as frequently. Among those applications, the low rate of use of the KIM service is particularly notable since KIM has been mandatory for GPs to use for information transfer while this survey was conducted. The installed base in the form of postal letters, fax, and other channels appears to compete with the newly developed KIM channel, limiting its use. Although the exact use practices varied depending on the communication partner, this general trend applies equally to all of the surveyed actors, namely, other physicians, patients, inpatient facilities, in- and outpatient care actors, therapists, pharmacies, and medical supply stores as well as health departments. As was shown, the participating GPs perceived hurdles in the use of digital communication channels, which are arranged around the 3 clusters "incompatibility issues and technical immaturity," "lack of knowledge and technical requirements," and "additional technical, financial, and time-related burdens." Taken together, the hurdles perceived by GPs could result in digital channels being seen more as an additional burden than an added value, which could limit their use and ultimately jeopardize health care provision.

The results obtained here coincide to a certain extent with those of similar studies. While the user behavior of GPs toward existing information infrastructure for the German context has scarcely been examined from the point of view of the installed base, findings do exist on the barriers to the use of digital exchange channels. In a previous study, Schendzielorz et al [32] found that in a more rural area in Germany, the high cost of applications, technical problems (slow internet connection and nonfunctioning applications), the time required to process digital and analog documents, and a lack of personal contact in particular were obstacles to the use of digital technologies.

According to the "PraxisBarometer" of the German National Association of Statutory Health Insurance Physicians 2021, GPs in Germany have been noted for their rather negative attitudes toward digitalization, with technical hurdles in the use of

XSL•FO
RenderX

associated applications appearing to be particularly significant, as expressed by a lack of user-friendliness, high conversion costs (financial costs, information and training requirements, and time needed), an unfavorable cost-benefit ratio, and concerns about data protection [33]. A lack of knowledge in the use of digital applications as well as a low tolerance for telemedicine and an advanced age are also not conducive to the willingness to use digital applications [34]. It was further shown that physicians rarely receive diagnostic data, doctor's letters, or radiological findings in digital form, and just under a quarter of medical practices do not receive any digital data from other outpatient facilities. In addition, about two-thirds of medical practices did not send any treatment-relevant data in digital form themselves. Further, the frequency of errors in the use of relevant applications has increased over the past few years [33]. These trends have continued across Germany in the years following the data collection for this paper. Despite increasing use rates of corresponding applications, digitalization has not yet become fully established in practices [35,36]. The barriers seem to be similar across applications. With regard to DHAs, for example, it is regularly noted that GPs lack confidence in their ability to introduce patients to DHAs and support their use [37]. In addition, privacy, security, and legal concerns as well as costs related to reimbursement and fees are among the most stated barriers to a more intense use of DHAs [38]. Overall, various barriers to the implementation of digital applications were identified. However, these are by no means unique to Germany but are relevant in many other countries and specialist areas outside of GP care and in relation to various digital tools [39-42].

Ultimately, it can be concluded that the newly established communication channels and applications associated with the TI compete with the installed base of information infrastructure. Some GPs have been using these established channels for decades, with their practice routines and care processes built around them. These systems function adequately for many providers at a procedural level. Moreover, the newer applications experience various malfunctions that exceed the limitations of the older communication channels. If the technical problems of the newer communication channels are sustainably eliminated, the willingness of GPs to rely more on them in their practices would very likely increase. However, if the technical issues persist, health care will be severely impacted, testing the willingness and patience of the physician community. Under these circumstances, the potential of digitalization for health care can only be guessed at. To this end, adjustments must be made above all at the individual, that is, the practice level. This is all the more relevant, as the Digital Act has declared the electronic patient file as an opt-out version for 2025, which will lead to GPs in particular having to deal with the topic and technology more intensively [19].

Strengths and Limitations

This paper is accompanied by some limitations. For example, the survey's response rate of 18.5% (n=250) among Brandenburg GPs may come along with several limitations that warrant consideration. First, the relatively low response rate raises concerns about the representativeness of the sample, which may not adequately reflect the broader population of GPs in the region. This could limit the generalizability of the findings to all Brandenburg GPs. Additionally, nonresponse bias might be present if the GPs who chose to participate differ systematically from those who did not, potentially affecting the validity of the results. It is also possible that those who responded were more likely to have strong opinions or experiences related to the survey topic, which could skew the results. The same logic applies with regard to the interviews. Accordingly, the extent to which the results are applicable to the rest of Germany beyond the federal state of Brandenburg must be carefully considered. However, the participating physicians adequately reflected the German age structure of GPs (German: *Allgemeinmedizin* and *Interne Medizin mit hausärztlicher Tätigkeit*), according to which 7.5% (n=2561) and 8.6% (n=1478) are younger than 40 years of age, 20.7% (n=7127) and 28.5% (n=4893) between 40 and 49 years, 35.3% (n=12,153) and 37% (n=6361) between 50 and 59 years, 20.6% (n=7097) and 15% (n=2584) between 60 and 65 years, and 15.9% (n=5455) and 10.9% (n=1875) older than 65 years. The national average age is 55.3 years [43]. The sex distribution roughly corresponded to the Brandenburg GP group (n=731, 62.9% of Brandenburg GPs are female) [44]. For data protection reasons, the geographical location of the participating practices was not determined. A notable limitation of the parallel mixed methods design was the inability to iteratively refine data collection tools based on preliminary findings from either method. The concurrent collection of quantitative survey data and qualitative interviews precluded adjustments to the survey instrument to incorporate emerging insights from the qualitative interviews or modifications to the interview guide to explore trends identified in the survey responses. This limitation may have constrained the ability to capture more nuanced interconnections between the 2 datasets and to fully investigate unanticipated findings. Finally, while the results presented here show how GPs in Brandenburg communicate with other actors and what kinds of barriers they experience with regard to digitalization, they only show part of the practices in communication. Thus, the perspectives of GPs only provide a limited view of communication. Including the perspectives of GPs' direct communication partners may do justice to the complexity of the German health care system by identifying cross-actor problems and offering more comprehensive solutions. This explicitly includes the concrete needs of patients and citizens with regard to digital communication and their views with regard to the installed base.

Conclusions

In the exchange of information, it appears that a number of conditions must be met in order to guarantee the added value of digitalization compared to those exchange formats associated with the installed base from the physician's point of view. To successfully establish digital communication in the long term, patience and technical support should be granted by the political leadership instead of maintaining formal coercive liability and sanctions. Innovations in information exchange should be integrated in a planned, careful, and step-by-step manner, rather than simply being implemented, to reduce the risk of undesirable effects and potential failures [45,46]. From our data, we see that the sole legislative implementation of an infrastructure

XSL•FO
RenderX

component (like KIM) does not automatically result in its integration as a functional component of the installed base. Quite the opposite, it may even have counterproductive effects on resources. Considering these aspects, irritation, frustration, and even resignation could be limited. This implies that new applications should not be rolled out until their functionality is guaranteed, for example, through completed test phases with the help of pilot practices. Furthermore, the perspectives of the health care providers who use the infrastructure to be replaced should be more integrated into the planning of the adjustments [47], with particular attention to individual practice processes. Primary care in Germany is typically very individualized, with communication practices often based on decades-old routines. Digitalization is forcing such individuals, first, to adapt their established practices and routines and, second, to deal with technologies that might be completely alien to them. The frustration that arises here is reasonable and, if it translates into resignation and abandonment of practice, could potentially lead to problems and bottlenecks in care. This should be prevented. GPs play a crucial role in the digitalization of the German health care system. This is due to several factors, including their involvement in a significant portion of patient-related communication, their role in prescribing DHAs [37], and their responsibility for filling electronic health records with data [22]. Facilitating the associated processes for them seems expedient to the overall objective. In the necessary parallel existence of long-established communication channels like postal mail or fax and newer channels such as KIM, arguments need to be found in favor of the latter that do not run counter to individual practice routines.

As has been shown in this paper, especially physicians of older age and with long-established practices need to be given mediating or organizing instances to overcome the individual hurdles of digitalization. This can be done by younger, more technology-savvy colleagues, specially trained practice personnel who take on the digitalization, or other actors or bodies. In this context, a guidance concept is conceivable, where external personnel provide in-house support in primary care practices or comparable settings. Comprehensive continuing education and training programs appear to be necessary, as well as the visualization of links to existing offers. In addition, central quality criteria for training courses should be established in order to provide interested parties with guidance in selecting suitable programs. Aspects of digitalization should also be integrated into the curriculum of medical students. It seems important to identify the specific technical knowledge physicians need to effectively perform their duties.

Finally, it is relevant to remember that barriers to the use of digital communication channels can have different causes. On the one hand, technologies may not operate appropriately because the technology is prone to failure, because users do not possess relevant knowledge, or for other reasons. On the other hand, however, new applications can disrupt the general work routines of GPs, some of which may have been in place for decades and which can be assumed to have meaning and to meet the individual needs of GPs. At this point, the significance of the installed base of communication channels for health care becomes evident beyond their purely technical-material presence. Understanding how communication channels and technologies interact with practice routines can help align newer applications with the needs and demands of GPs, making them more attractive to them. In this way, health care areas that are characterized by a low provider density and a high average age of the population and medical practitioners can benefit in particular.

Acknowledgments

The study is funded by the Brandenburg Medical School publication fund supported by the Ministry of Science, Research and Cultural Affairs of the State of Brandenburg. The analysis of the data collected in the cause of the underlying project—DigiKO—was financially supported by the Economic Development Agency Brandenburg (Wirtschaftsförderung Brandenburg). The authors would also like to thank Josephin Schliephacke for her organizational support in conducting the study. All authors declared that they had insufficient funding to support open access publication of this manuscript, including from affiliated organizations or institutions, funding agencies, or other organizations. JMIR Publications provided article processing fee (APF) support for the publication of this paper.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to data protection concerns and the written informed consent but are available from the corresponding author on reasonable request.

Authors' Contributions

TH contributed to writing the original draft, data collection and management, qualitative and quantitative data analysis, participant recruitment, methodology, visualization of tables and graphs, as well as reviewing and editing the manuscript. AH contributed to data collection and management, participant recruitment, methodology, and reviewing and editing the manuscript. Abstract

Background: Patient consultations in general practice are undergoing a digital transformation, embracing diverse modalities such as video, text-based, and telephone consultations. The quality of communication in medical consultations is pivotal for successful outcomes, necessitating a comprehensive assessment of the impact of this transformation on doctor-patient communication and interaction.

Objective: This study aims to explore general practitioners' (GPs') perspectives on how the communication between Norwegian contract GPs and patients has been affected by the large-scale implementation of remote consultations following the onset of the COVID-19 pandemic.

Methods: Five focus groups, comprising 18 purposefully recruited GPs from diverse settings and geographical regions in Norway, were carried out in 2022. We applied thematic analysis guided by the framework proposed by Braun and Clarke.

Results: Six themes resulted from the analysis. First, suitability regarding remote communication is context-dependent: knowing the characteristics of the patient as a person and the clinical relationship is more important than the reason for contact or type of health problem—even more so than during ordinary physical consultations. Second, remote consultations favor a demarcated communication style, "keeping things simple—the one-problem approach," which can increase work effectiveness. Third, a downside of such effective minimalism is that the uncritical use of remote consultations may undermine the quality of care. Communication becomes too transactional, limiting the chances of addressing more implicit and complex issues, with the risk of missing vital information. Fourth, remote modalities can help engage hesitant and vulnerable patients. Fifth, GPs make communicative trade-offs in the name of continuity to be able to maintain relationships with patients they see as vulnerable or fugitive. Finally, there are advantages and dilemmas stemming from text-based consultations. Although they offer benefits such as multimedia-enabled patient expression and sharing of digital information, some concerns include the risk of information loss through triage errors, managing informal language, and ending chat-like interactions between patients and doctors.

Conclusions: The implementation of remote consultations has many effects on clinical interaction and communication. Although these modalities can enhance efficiency, there is a discernible risk of compromised retrieval of essential information and unvoiced problems, potentially resulting in unintended consequences. The preservation of continuity of care emerges as a pivotal strategy to mitigate some of these challenges.

Introduction

Background

Strong clinical relationships and effective communication during general practitioner (GP) encounters are considered crucial to the overall quality of primary care [1-5]. This importance extends to remote consultations [6-11], which have seen rapid and widespread adoption in response to the challenges posed by the COVID-19 pandemic [12-15]. This global shift has altered the dynamics of medical consultations [16,17] and had a profound impact on the substance and efficacy of communication between GPs and their patients [8,11,18-24].

Remote communication introduces both novel opportunities and challenges in clinical practice [6-11,25-27]. Remote consultations inherently elevate accessibility, offering efficient, environmentally friendly, and positively received solutions for patients [12]. However, the "gold standard" patient-centered communicative approach was developed before the era of remote communication. In other words, the extensive implementation of digital modalities disrupts established practices in ways that have been hard to anticipate [28-33]. Recent research indicates that remote consultations may compromise communicative and diagnostic quality, posing suboptimal clinical evaluation and the risk of overlooking critical information [24-29]. Furthermore, remote communication might also curtail the handling of social determinants of health [8,12,31].

Seen in isolation, each type of remote communication is associated with documented strengths and weaknesses [24-28]. Telephone consultations are deemed appropriate for noncomplex, relatively simple contacts, including triage [34-37], but are susceptible to limitations, including simplistic dialogue, challenges in conveying emotions and sensitive messages, and unsatisfactory clinical assessment [29,32,38-41]. Video consultations, while comparable with telephone consultations in terms of duration, content, and quality [38-41], still present challenges in establishing a doctor-patient relationship, with patients reporting feelings of rush and difficulties in turn-taking in the conversation [8]. Recent publications nevertheless reveal strengthened alliances between patients and physicians in video consultations, compared with the pandemic context [20,21,38,39]. Video consultations are found to be superior to telephone consultations for more demanding triage involving visual evaluation, certain psychological issues, discussing test results, and addressing changes in medication [20-22,38-41]. Text-based consultations, often recognized for their brevity, can reproduce crucial components of face-to-face consultations, encompassing history-taking, investigation, and final assessment [42-46]. Despite their streamlined nature, text-based consultations may generate additional workload for GPs, stemming from unfiltered access and heightened demands [28,46,47]. Some practitioners have noted a decline in the doctor-patient relationship linked to text-based consultations [44-46]. However, studies have also shown instances of strengthened therapeutic relationships [24,45] and improved accessibility over time, especially for individuals dealing with long-term health conditions, attributable to enhanced availability [30,31,42-46].

Much of the existing research on remote consultations stems from contexts where services were only piloted or during the COVID-19 pandemic when use was forced upon both clinicians and patients [12-15]. Contextual factors evidently play a decisive role [48], and consensus on communicative changes or challenges associated with remote consultations remains elusive [8-11,25,45,49,50].

Consequently, it seems essential to continuously observe the impacts of the digital transition on communication dynamics in remote consultations across different contexts, including contractual GP schemes. How will the digital transformation settle into the "new normal" after the resolution of the pandemic [7-9,18,27]? This study examined remote consultations as an integral part of the daily routines of contract GPs in Norway in a more or less normalized postpandemic situation without societal restrictions. The study's aim was to explore the impact of remote consultations on interaction and communication between GPs and patients in this context.

Study Context

Remote Consultations

This study focuses on 3 types of remote consultations: video, telephone, and text-based consultations. Video and telephone consultations are synchronous interactions occurring between doctors and patients on various devices, including phones, tablets, or personal computers. Text-based consultations occur as asynchronously written dialogues between the patient and the doctor, which are initiated or prearranged with the patient. Norwegian GPs are expected to respond to patient-initiated text-based consultations within 5 working days. Text-based consultations normally take the form of a freely formulated essay-type request potentially supplemented by a predefined questionnaire filled out by the patient.

Remote consultations in Norway peaked at nearly two-thirds of all consultations during the COVID-19 lockdown and have since stabilized at 20%-25% of all GP consultations in 2024 [51]. The prevalence of video consultations remains relatively low [52], while telephone and text consultations have sustained high utilization postpandemic, influenced partly by the reimbursement system [53].

In Norway, 80% of all patients use the national health portal Helsenorge [54] for electronic booking of appointments, electronic prescription renewals, electronic contact with the GP office for nonmedical inquiries, and text consultations for clinical inquiries with the GP. The use of remote consultations is not mandatory for GPs, so each GP can decide whether to offer text, video, or telephone. Patients can typically book physical, video, and telephone consultations on the web.

XSL•FO
RenderX

Technical equipment for video consultations is available through both private and public external providers and is becoming more integrated with patient record systems.

The Norwegian Contract GP Scheme

Norway's health care system is grounded in the principles of universal access, decentralization, and continuity of care [55]. Since 2001, all Norwegian citizens have the option to enroll (or change enrollment) with a GP, a choice exercised by 99% of the population. This scheme is designed to ensure continuity of care, with GPs serving as coordinators of municipal services and gatekeepers to specialized services. Norway's 5391 (per May 2024) contract GPs are each responsible for a defined patient list (typically around 1000 citizens or patients) from 8 AM to 4 PM on weekdays and often participate in evening and night emergency shifts in the municipality or region.

Being a specialist GP is a unique specialty in Norway, similar to, for example, ophthalmology or psychiatry. It entails a 5-year program of specified clinical services in accredited practices or institutions, combined with defined learning objectives such as practical procedures, courses, and guidance. The specialty certification must be reaccredited every 5 years [56].

Contract GPs' income systems vary to some extent. The majority receive a fixed annual contribution per patient to help cover practice expenses. Each consultation is reimbursed by a set fee, with additional reimbursement for specified procedures, for example, electrocardiogram testing, surgical procedures, and conversational therapy. Furthermore, GPs receive out-of-pocket fees from patients, typically around 230 NOK (US $21) per consultation (whether physical, text, telephone, or video), up to an annual maximum per citizen for essential medical expenses (currently 3165 NOK = US $287). Expenses above this are fully covered. The provision of remote consultation services is not mandatory for contract GPs, and a small fraction disables 1 or more of these options.

Alongside the well-developed publicly regulated system (contract GP scheme), a few fully private actors offer regular medical care at the patient's expense, and some private digital care companies offer video or text consultations. Private medical insurance is limited in Norway but is increasing.

Methods

Study Design

We conducted a qualitative focus group study among Norwegian contract GPs. Focus groups are deemed suitable for exploring attitudes, experiences, and areas with limited prior knowledge, and they allow for the exploration of tentative and conflicting views [57-59]. The Standards for Reporting Qualitative Research Reporting Guidelines [60] have been consulted in the reporting process (checklist in Multimedia Appendix 1).

Our research team comprised 2 experienced contract GPs (BLN and BA) with substantial experience with remote consultations, a former GP who is now a full-time professor in behavioral sciences in medicine (LOG), and 2 experienced digital health researchers (PZ and EK) with backgrounds in engineering and economics, respectively. LOG, PZ, and BA hold PhDs, with LOG and PZ serving as professors. LOG and BA are seniors in a general practice research unit, introducing solid academic perspectives on general practice, including the documented relevance of continuity of care, patient-centered communication, and relational trust. BLN has extensive experience as a lecturer in clinical communication for medical students. All senior team members had previous experience with qualitative research.

Recruitment Procedure

We used purposive sampling to include experienced contract GPs with familiarity with remote consultations to participate in the focus groups. We approached participants or educational groups by phone and mail from diverse geographical regions, including both urban and remote municipalities, as well as participants with varying income systems in the contract GP scheme (fixed salary, subsidized positions, or paid per capita).

Participants were recruited in 2 ways: 3 groups comprised GPs from preexisting postgraduate educational groups associated with the formal recertification system for GPs in Norway. Such groups are compulsory and meet regularly to engage in structured activities and discussions of general practice topics. These GPs were professionally acquainted beforehand, something we considered to be a facilitating factor. The remaining 2 groups included experienced, opinionated, and nuanced GPs, individually recruited through the research team's professional network.

All but 1 invited GP agreed to participate. Some of the participants were known to members of the research team beforehand, but there were no personal bonds likely to impact the integrity of the data. The initial plan was to conduct 4 focus groups, but a fifth group was added after preliminary analysis of groups 1-4 to further enhance information power [57].

Following the initial invitation, participants received written information outlining the project's purpose, data handling, and withdrawal procedures (Multimedia Appendix 2). No exclusions or dropouts occurred.

Data Collection

The focus group interviews were conducted a while after pandemic restrictions had been lifted in Norwegian health care, between January 15 and April 20, 2022. Three interviews were conducted physically in local medical center meeting rooms, while 2 were carried out remotely on the platform teams, involving GPs from rural regions and other parts of Norway. Interviews were conducted in Norwegian.

Prior to the recorded interview sessions, participating GPs were reminded that participation was voluntary before they signed informed consent (Multimedia Appendix 2). Participants were instructed to carefully anonymize all patient-related experiences. The participants provided anonymized information about themselves and their practice.

During the interviews, moderators BLN and BA used a semistructured interview guide, collaboratively designed by BLN, BA, and LOG, featuring flexible, open-ended questions (guide in Multimedia Appendix 3). The team's previous publications on remote consultations [4,20] have significantly contributed to a robust database of physician responses, which

XSL•FO
RenderX

in turn informed the thematic focus of the interview guide. The guide was pilot-tested with 2 GPs and 2 nonmedical PhD students involved in qualitative research.

The focus group interviews lasted 95-120 minutes. They were audio-recorded and transcribed verbatim. The process remained open for corrections and additions. One follow-up interview provided in-depth insights into the lack of emotional exchange during remote consultations. Participants were compensated approximately 1000 NOK (US $91), which is about half of the compensation for 2 hours of medical consultant work.

Data Analysis

Reflexive thematic analysis, following the approach proposed by Braun and Clarke [57-59], was used to establish patterns of meaning across the data. Initially, LOG and BLN conducted individual analyses: LOG manually and BLN using NVivo (QSR International [Lumivero]) for digital processing. Along the way, BLN and LOG compared and discussed results, followed by joint meetings with BA. The main analytic strategy was inductively derived from the data, albeit influenced by the researchers' professional situatedness. Some elements of the analysis were deductively guided by theory related to the phenomenon of trust. Subsequently, preliminary themes and candidates for final themes were shared with the entire research team, supported by 2 external project collaborators (see the Acknowledgments section). At this stage, theme development underwent a major revision. This paper focuses on microperspectives (here defined as doctor-patient communication), leaving meso- and macroperspectives (ie, addressing the impact of remote consultations on GP offices and the health care system at large) to a forthcoming publication.

In the final stages of analysis and writing, exchanges among all authors aided in challenging individual biases and presuppositions, enhancing the validity and relevance of our findings.

Ethical Considerations

All participants signed an informed consent to participate. This study was conducted among health care workers, involving no patients or sensitive health care information. According to the Norwegian Act on Medical and Health Research §2 and §4, the study did not require approval from the regional ethics committee. Interview data were safely secured in accordance with national and institutional regulations. In the transcription and publication process, personal and demographic information was anonymized to prevent indirect identification of the GPs. The procedure for handling the data was approved by the Norwegian Center for Research Data NSD/SIKT (reference: 531672).

Results

Participant Characteristics

A total of 18 GPs participated in 5 different focus groups, each consisting of 3-5 members. They all had substantial experience using all forms of remote consultations, but 3 had limited their access to text consultations due to high demand. An overview of participant characteristics can be found in Table 1.

Analysis of the focus group discussions on the communicative aspects of remote consultations unveiled a nuanced landscape marked by both advantages and disadvantages, giving rise to 6 themes, summarized in Figure 1.

Figure 1. Overview of the themes developed from 5 focus group discussions. GP: general practitioner.

Suitability is Context-Dependent

A dominant view in all focus groups was that the applicability of remote consultations to communication between GPs and patients is largely independent of the reason for contact or specific diagnoses. Suitability largely depends on the doctor-patient relationship, the doctor's knowledge of the patient's medical history, and the patient's ability to formulate his or her concerns concisely. In many ways, this theme has an overarching character, connecting and informing the subsequent themes that manifested from our analysis, as shown in Figure 1.

> *When you know the patient well, it is easier to agree on a plan...Background knowledge means a lot for an assessment.* [ID6]

One GP quoted the influential physician Sir William Osler (1848-1919) [61]: "It is much more important to know what sort of a patient has a disease than what sort of a disease a patient has."

The sentiment among GPs resonated with the idea that:

> *Topics in consultations are often interconnected, mutually influencing each other [...]. A troubled marriage can manifest in several ways, and the need for sleeping pills may conceal significant underlying information.* [ID16]

The participants emphasized that both verbal communication and clinical examination and treatment via video were surprisingly feasible, especially when relational trust had been established between the GP and the patient. For example, a GP who had previously prescribed medication to a young patient

XSL•FO
RenderX

with chronic urticaria recounted how it was easy to calm and instruct her over video as she needed to inject the drug:

> *She posed in shorts on her kitchen chair, and she was able to insert this medication subcutaneously without any problem.* [ID5]

Keeping Things Simple—the "One-Problem Approach"

The GPs seemed to agree that remote communication has some fundamental qualities that differ from physical communication. Without any specific preparations or instructions from the GP's side, the modality appeared to narrow things down to what the GPs called a "one-problem approach." This phenomenon could often be perceived as beneficial:

> *The best thing about remote consultations is that they go quickly and smoothly, and you stick to the problem. Concise...it stops everything outside the original theme.* [ID9]

Furthermore, participants described that remote consultations, in general, appeared suitable for (presumably) demarcated problems with negligible risk of missing clinically relevant issues or risk factors. Therefore, they can be performed more quickly. In such instances, GPs experienced that remote consultations represented "good enough" medical work from a here-and-now perspective.

A benefit of keeping things simple relates to worried patients who have a habit of overseeking regular consultations. GPs have noted that even brief remote consultations can "work miracles" (quote from a participating GP) for these patients and reduce the number of time-consuming physical consultations.

Remote communication tends to have a transactional quality that seems to bypass implicit expectations of relational care. Once a distressed patient has waited for a physical consultation and perhaps traveled a long way, expectations can build up, and the GP can sense an obligation to spend more time with the patient as a sign of care and respect. This phenomenon rarely applied to remote consultations:

> *When you take that video, it is a bit more acceptable to...keep simple things simple.* [ID2]

However, the benefits of this approach were balanced by concerns about potential downsides, such as overlooking clinically significant aspects.

Downsides of Effective Minimalism

Consultations characterized by the typical "one-problem approach" apparently entailed diminished cognitive and emotional demands on the GP in a here-and-now perspective, thereby contributing to welcomed work intensity variation during the day. However, the discussions of new potentials did not last long in any of the focus groups before a certain ambivalence and skepticism started to surface. GPs described a risk of being carried away by apparent simplicity, missing clinically significant aspects of their everyday work as they knew it from years of physical consultations. Uncritical use of remote consultations may undermine the quality of care:

> *It can easily take off in a spiral of efficiency—and then it quickly becomes a dangerous disadvantage.* [ID11]

The discussions revealed that the most evident pitfalls of remote consultations represent the flip side of the reported advantages. Participants described how the experienced efficiency could turn into a spiral of unintended minimalism:

> *If the GP makes too much use of remote aids and don't take consultations physically...one can imagine that the doctor fixes things (way) too quickly….* [ID8]

At a more specific level, several GPs were worried that in the flow of efficiency, relevant and essential information associated with the patient's reason for contact remained out of sight and unaddressed:

> *You might miss these things on remote consultations. It can be central to realize that there is something else …something unsaid or unwritten.* [ID17]

GPs shared experiences pertaining to typical communicative qualities of remote consultations. Compared with physical encounters, communication becomes more linear, literal, and business-like. Information residing between the verbal lines seems to go unnoticed or remain unaddressed:

> *It is like an interpreter call…because it has become such an additional filter in between.* [ID14]

Keywords regarding what might easily be lost during remote consultations were context and cues, referring to relational and emotional factors that affect the symptom picture and have relevance for effective resolution:

> *Have you noticed? No one ever cries on video! ….* [ID16]

If contextual insight and emotional cues go unnoticed, the chance of an effective problem solution diminishes. This hampers the GPs' ability to reveal serious illness. It is, therefore, not just about the number of problems that are lost, they elaborated, but more about the range of dimensions lost in communication:

> *I had a patient on video who had difficulty sleeping and wanted sleeping pills...I did not prescribe them. I rather wanted to find out what his life was really like and invited him to have a proper [physical] conversation […] Remote consultations may also generate 4-5 extra consultations for extending sick leave because the patient does not want to talk about his terrible boss on a remote consultation.* [ID16]

GPs recognized a distinct ritual associated with traditional, in-person consultations—a ritual that, for better or worse, imbues the medical encounter with a sense of uniqueness. Traditional health care requires patients to travel, wait, meet the doctor, and possibly undergo physical tests. Remote consultations eliminate these steps, saving time and seamlessly fitting into the patient's daily routine. Participants elaborated that in remote GP appointments, patients often seem less mentally focused. Furthermore, such consultations are often initiated for minor complaints. These are seen as potential

XSL•FO
RenderX

drawbacks. To minimize these drawbacks, some GPs aimed to meet patients physically at an early stage:

> *I like to start with a physical consultation to sense the non-verbal clues and include the big context.* [ID15]

In relation to video consultations, GPs described patients' casual use of mobile cameras, simultaneously multitasking during all kinds of transportation and errands:

> *It is quite common, we have video consultations while the patient is driving, lies in bed or is all over the place.* [ID14]

GPs exhibited ambivalence toward patients' multitasking while in remote consultations, experiencing a spectrum from frustration to recognizing occasional valuable moments. However, they explicitly appreciated their own multitasking opportunities. The pandemic prompted a shift in how GPs use eye contact during video consultations, transitioning from its prioritization to a more flexible approach amidst multitasking demands. This adaptation mirrored the younger generation's informal use of social media, offering GPs a sense of freedom while acknowledging both the advantages and drawbacks.

The traditional face-to-face consultation was seen to strengthen the therapeutic alliance and give the GP a better understanding of the totality of the patient as a person. Overall, it appeared that most GPs remained alert to the potential side effects of "pleasing the patients" too much. Offering all patients who are reluctant to attend a physical consultation a choice of remote consultations as an easy way out might ultimately undermine these patients' abilities to engage in trustful human relations and face the challenges of everyday life in a physical community. Still, none of the focus groups reached a clear consensus as to when or how the physical encounter is clearly to be preferred for therapeutic reasons.

Engaging Hesitant and Vulnerable Patients

In all focus groups, GPs discussed how remote consultations may facilitate the establishment of new relationships. Examples include socially withdrawn patients and young people with high digital competence who have little experience with defining their own problems and seeking formal health care:

> *I have several patients with autism-like diagnoses or personality disorders with relational issues, who prefer to communicate remotely—by text, telephone, or video—rather than sitting in the waiting room for a physical appointment. They communicate better and seem to profit from these new services.* [ID13]

Another communicative gain was referred to by some participants as an "ice-breaking" effect, facilitating the sharing of sensitive information that, for some patients, could be harder to address in a face-to-face consultation:

> *...I do not necessarily think they would have been able to say these things when they were sitting here, right in front of me in a chair. So, sometimes that distance on video can make it easier to bring things up, eventually leading to a physical consultation.* [ID3]

Specific examples of sensitive subjects that might sometimes emerge due to, and not despite, the digital modality involve histories of sexual abuse:

> *It was difficult regarding trust initially…. But then a nice little dialogue started on text-consultation. A few small questions. So, in a way, I understand that she was trying to say something important [about abuse]. And then we go on…finally arriving at what was really the case. And this is a new unique way of working.* [ID14]

Some of the GPs had experienced that remote consultations were used by patients with suicidal thoughts that might not otherwise contact the health care system:

> *I talked to him in the car a good distance from his home and office...When he talked about his suicidal thoughts and how he might end up taking his own life, he liked to sit alone in his car. So, in a way, he set the conditions for being protected…* [ID9]

Communicative Trade-Offs in the Name of Continuity

Although the GPs agreed that communication during remote consultations entailed a risk of losing vital symptoms and unvoiced problems, they shared experiences of how they would sometimes deliberately stretch their limits and agree to perform remote consultations simply to avoid losing young, immature, or otherwise vulnerable, noncommittal patients to competing commercial digital doctors. The GPs thought that such actors might not provide adequate, affordable, and high-quality services for complex patients in the long term because they would lack continuity of care. As one GP said about such patients, with reference to the contract GP scheme:

> *I work hard to "keep them in the system.*" [ID7]

An additional reason why the GPs tried to avoid the involvement of other digital doctors was that such consultations tended to create double work and even more additional work, as the contract GP might typically be contacted anyway and have to sort out the status of a process initiated by an unknown colleague:

> *I would rather help them myself than get help from someone else in the private sector. If that happened, the patients typically say they did not understand anything, so they still come to talk with me.* [ID6]

Ideally, as already mentioned, many of the GPs prefer to see shy and reluctant patients, many of whom have a psychiatric diagnosis, physically with the aim of fostering relational trust and a better working relationship:

> *[I prefer]...making them leave the house, so that they do not just stay at home and isolate themselves. So, it is better to have psychiatric follow-up consultations at the medical center.* [ID18]

However, the GPs consider "good enough" remote medical care by a contract GP to represent an acceptable compromise, if the patient specifically prefers it, to maintain some sort of relationship.

XSL•FO
RenderX

Advantages and Dilemmas of Text-Based Consultations

On the positive side, GPs discussed how text-based consultations have introduced new possibilities. The patient can freely describe his or her reason for contact and include illustrative photographs or videos. In situations with a risk of disease transmission, this can be helpful:

> *We use that quite a lot; text-based consultations for typical wounds, rashes, and similar things. Most recently I had a chicken pox diagnosis last week. It is nice not to have children with chicken pox in the waiting room.* [ID5]

Attachment of photographs or videos was also described as effective in the follow-up of a healing process and rehabilitation. GPs can, on their side, use text-based consultations to attach files with ready-made patient information and other instructive material at any stage of the clinical trajectory. They can also ask patients to fill in various forms digitally, including mental health diagnostic checklists or scales, symptom diaries, or text for declarations required by the Norwegian Welfare System, as well as adding self-written parts in the patient record:

> *That is such a "game changer" for me. It is an incredibly clever new way of doing it, which also makes the patient quite responsible. "Ok, sit down and think about it and write until next time 'or' if you are having a headache, write down all about it from the beginning till now."* [ID13]

The group dynamics then prompted deliberations on more negative aspects, particularly the dilemma regarding the utilization of predefined questionnaires. These questionnaires encompass a series of clinical inquiries presented in a flowchart format intended to streamline the process, reduce dependence on health secretaries for triage, and aid doctors in promptly addressing the patient's reason for contact. The general tone was, however, marked by skepticism and call for precaution:

> *This development [with fixed questions] is happening quickly and quietly without anyone knowing the long-term consequences.* [ID18]

Participating GPs referred to a well-documented communicative routine in physical, effective patient-centered communication, namely, to invite patients to freely formulate their reason for contact before zooming in on further clinical details:

> *Letting the patient express him/herself freely is preferable [...] and prefixed algorithmic questions should be used with the greatest caution. It takes away the information we are so used to handling; listening to what the patient says.* [ID4]

Losing out on the patient's unfiltered, personal account at the beginning of a consultation might lead to time-consuming diversions and a need to revisit the reason for contact at a later stage. In other words, this created more work for the GP.

In text-based consultations, some patients exaggerate to get attention and skip the line:

> *Some patients write dramatically as if it were an emergency, yet there is not...* [ID15]

Another issue of concern related to text-based consultations was that some patients use rough language characterized by profanity and exaggerations, resembling the comment field jargon in social media. GPs worry because the communication is automatically saved in the patient's medical record, with a potential for unforeseen future implications:

> *There is a lot of dialect, slang, profanity, and things that are not suitable for the medical record...They can write anything. There are no restrictions.* [ID12]

Beyond the fear of missing serious disease in a flow of incoming requests, some GPs had noted that informal chat-like text-based consultation sequences back and forth between patient and doctor can be difficult to terminate:

> *It is difficult with text consultations because it turns out to be a running dialogue that goes back and forth all the time, like a tennis match...which I could have ended in a stricter way, but I find it difficult to do it in a gentle way.* [ID11]

Considering all these factors, participants suggested that remote consultations might augment the GP's workload.

Discussion

Principal Findings

This focus group study among Norwegian contract GPs shows that the rapid implementation of remote consultations elicited diverse effects on clinical communication and interaction for better and for worse. The appropriateness of remote communication appears contingent on context; recognizing the patient's characteristics and the clinical relationship takes precedence over the reason for contact or the nature of the health problem. Although entailing a definite potential to enhance efficiency, remote modalities also pose a discernible risk of compromising the retrieval of crucial information and unarticulated problems with clinical relevance. Nonetheless, a somewhat unexpected advantage of remote consultations lies in their potential role as relational "icebreakers," as some patients find it easier to seek help from their GP and broach sensitive topics from a distance than in face-to-face encounters. Text consultations evoke ambivalence among GPs. Although being of beneficial use in relation to clear reasons for contact, their safety hinges on patients' ability to articulate their complaints. Strategic preservation of continuity of care emerges as crucial in mitigating the identified challenges.

Findings in Light of Existing Literature

Context-Dependent Suitability

A central finding in our study is that the observed changes in communication during remote consultations are not primarily associated with specific reasons for contact. Instead, they are more influenced by the quality of the doctor-patient relationship and the GP's evaluation of the patient's individual ability to express health concerns coherently. The context-dependent qualities of remote consultations resonate with the conclusion of health care researcher Greenhalgh et al [62] that dilemmas about establishing remote consultation services cannot be resolved by standard procedures or algorithms but rather by

XSL•FO
RenderX

attending to here-and-now practicalities applied with contextual judgment. Our findings also fit with a recent large in-depth study of patient experiences of remote consultations, stating that it can be influenced by previously unreported patient characteristics and the conditions they consult about [63].

Optimizing Communication Styles and Workflow

Our research indicates that remote communication can enhance workflow and information gathering, streamlining a portion of the tasks encountered in a doctor's daily routine. This aligns with previous research highlighting convenience and time savings offered, especially when physical examination is unnecessary [20-22,63]. Our participating contract GPs reported how, during normal investigations, they could leverage patient-provided information, symptom-scoring forms, and other digitalized documentation more effectively than previously documented [48,52]. However, we also found that remote consultations could potentially increase the overall workload, in accordance with recent research findings [28,33,55]. In total, this paints a nuanced perspective on workflow dynamics and applicability. Ideally, GPs can blend various modalities, leveraging their respective strengths, integrating the straightforward "one-problem approach" with a more comprehensive exploration of the complexity and wider context as needed.

Communicative Threats to Quality of Care

Alongside the aforementioned benefits, we identified concerns about unintended loss of contextual information, which is crucial for gaining a comprehensive understanding of more complex health problems. Disregarding life stressors and sociocultural factors might result in degraded clinical decision-making, imprecise or missed diagnoses, and underestimation of severity, findings that expand on prior research [63-69]. This is consistent with research suggesting that remote communication might lead to heightened clinical uncertainty [28-30]. In summary, these challenges suggest that remote communication not only tends to address fewer issues but may also address each problem with a narrower focus, overlooking certain communicative cues and contextual details. Interestingly, this aligns with patients' perspectives, which highlights the lack of nonverbal communication [26]. Our research also corresponds with a new "masterclass" [23] on communication skills for remote health care, including openings, active listening, and closing nuances, recognizing the differences from face-to-face consultations.

Previous studies have highlighted the constraints of remote consultations in dealing with social determinants of health [12,31,68]. Our results, in particular GPs' reports on "the one-problem approach," indicate that unless the GP actively counteracts the inclination to "narrow down," less urgent but still significant matters on chronic diseases might go unaddressed. This situation calls to mind a noteworthy 1979 paper by GP academic Nigel Stott, who highlighted the distinctive opportunities for including the management of continuing problems and providing some opportunistic preventive health care during routine consultations initiated for other reasons [69]. Our findings suggest an untapped potential for preventive health care on digital platforms. In particular, text consultations give patients more time to formulate nuanced questions, making them well-suited for meeting the needs of patients with complex and chronic conditions over time, in accordance with previous studies [44,45]. Combining informative materials from reputable health libraries with personalized guidance might enhance understanding and patient engagement. However, effective written consultations rely on patients' ability to articulate their concerns [45].

Simultaneously, GPs in our study describe challenges associated with unfiltered, unfocused, and even verbally profane written patient accounts. Patients may invertedly divert their problems away from the most adequate management, delaying the detection of serious conditions and limiting care planning [25-29]. In addition, our contract GPs reported making concessions to "please the customer" when selecting remote modalities as they endeavor to maintain the clinical relationship with vulnerable patients. Overall, our findings underscore the importance of considering precautionary measures to uphold quality in the evolving landscape of remote consultations.

Notably, we found that contract GPs, after having acquired substantial experience with remote consultations, describe themselves as more observant of the multidimensional aspects of communication in traditional physical consultations. They underscore the importance of safeguarding these qualities in the future.

Facilitating Relationships With Reluctant Patients

Up to this point, face-to-face consultations have been considered essential for establishing workable doctor-patient relationships [40,70]. Our study confirms the importance of physical consultations but provides a more nuanced picture. Under certain circumstances, remote consultations can foster new alliances with reluctant patients in need of health care who might otherwise not consult at all. Remote consultations can also function as icebreakers, giving patients an opportunity to open sensitive topics. Examples mentioned included histories of sexual abuse and suicidal thoughts that the patient finds hard to share with the GP in a physical encounter. Furthermore, remote consultations can offer expedited, just-in-time relief to well-known, vulnerable, and unstable patients. In these cases, remote communication seems to consolidate trust over time [71-74]. This also covers text-based consultations, extending the insights from prior literature [32,44]. The findings confirm emerging patient perspectives on text consultations, where attitudes vary widely on their suitability for handling sensitive topics [64].

It has been argued that youth and young adults, groups potentially underusing health services for psychosocial challenges, can benefit from remote consultations, although such consultations have been found to be of shorter duration than physical consultations [68,74]. Our GPs note how consultations with youth often proceed in a somewhat casual manner, with a handheld camera, sometimes on the move, bringing to mind the jargon term "snapping." Similarly, the discourse in text-based consultations with young individuals may "ping-pong" back and forth, resembling a conversational chat. Despite such informality, the GP-patient relationship may derive advantages. We propose that the rise in informality during remote communication, driven by technological advancements

XSL•FO
RenderX

and societal shifts, attracts new user groups to these modalities. Health care professionals adopt this approach to connect with these specific patient groups.

Power, Trust, and Risk

Norwegian philosopher Grimen [71,72] wrote substantially about trust as a fundamentally important phenomenon in clinical relationships, describing a "nexus" of power, trust, and risk. Despite publishing before the era of remote consultations, he underlined that health care is constantly undergoing change and invited others to reflect upon how changes impact the power-trust-risk nexus. We have already discussed how remote consultations might offer new opportunities in relation to certain reluctant and vulnerable patients. At first glance, remote consultations can be seen as empowering patients in general, offering "consumer" freedom. However, if not deliberately chosen as appropriate, the remote mode may undermine the quality of the GP's work and ultimately damage trust. Contrary to some prior research [9,64], our findings imply caution in granting patients unrestricted choice regarding consultation type.

Strength and Limitations

The research team, composed of seasoned contract GPs and digital health researchers, ensured a robust and multifaceted approach to the study. Another key strength was the recruitment and participation of experienced GPs representing diverse demographics, including gender, age groups, and remuneration systems. Their practices spanned urban and rural regions across Norway, contributing to a comprehensive understanding of remote consultations in different settings. This purposive sampling provided a wide range of perspectives. Furthermore, conducting focus groups proved particularly effective for exploring attitudes, experiences, and areas with limited prior knowledge. This methodology facilitated the exploration of tentative and conflicting views, allowing for nuanced reflections, examples, and insights. The use of semistructured interview guides, detailed transcription, and reflexive thematic analysis contributed to the depth and reliability of the findings. We believe that we have sufficient information power to answer our research questions [75].

However, one limitation is that the study did not address potential challenges related to ethnic and cultural diversity among patients and doctors [64]. This omission may be partly due to demographic realities in Norway and the tendency of dedicated regular GPs to avoid repeated digital consultations with patients if they encounter language problems or other contextual barriers, thereby having acquired few significant experiences. We also have sparse data from young GPs; this could have added nuance to our results. The study might also have benefited from the formal inclusion of citizen or patient user perspectives [41].

Potential bias from a few participants' familiarity with the research team may have influenced responses, yet it facilitated more open dialogue. Also, contrary to expectations that remote interviews would reduce data richness, they appeared to yield engaging interactions. The study was not designed to evaluate each consultation modality (ie, video, text-based, and telephone consultations) in depth. It is important to note that the study was conducted during the aftermath of the pandemic, and it is questionable whether enough time had elapsed to establish "the new normal" [12,13]. During the study period, GPs were still receiving full remuneration for telephone consultations, which might have influenced their choices of remote modality. However, since the telephone has long been a contact medium in general practice, participants appeared particularly interested in discussing novel modalities, such as video and text consultations. Finally, the study focused on microperspectives of doctor-patient communication, leaving broader systemic impacts to be addressed in future research.

Conclusions

The implementation of remote consultations introduces a spectrum of effects on clinical interaction and communication. These modalities can enhance efficiency but also pose risks, such as compromised retrieval of essential information and unvoiced problems, potentially leading to unintended consequences. Preserving continuity of care is crucial to mitigate these challenges.

Knowledge of the patient and the context plays a crucial role in determining when remote consultations are appropriate. For some patients, remote communication may even contribute to building trustful alliances and enhancing the doctor-patient relationship. Future research could delve into the possibilities of proactive health care initiatives during remote consultations and examine the broader ramifications they have on physicians, medical practices, and societal dynamics.

Acknowledgments

The authors want to thank professors Chris Salisbury and Helen Atherton for important advice in the analysis and writing process. The paper is part of a PhD project funded by the Research Council of Norway (315404). Norberg also holds a part-time position at the Norwegian Centre for eHealth Research in Tromsø.

Data Availability

The datasets generated and analyzed during this study are not publicly available, but access to the anonymized material can be granted upon reasonable request.

Abstract

Background: The increasing use of social media to share lived and living experiences of substance use presents a unique opportunity to obtain information on side effects, use patterns, and opinions on novel psychoactive substances. However, due to the large volume of data, obtaining useful insights through natural language processing technologies such as large language models is challenging.

Objective: This paper aims to develop a retrieval-augmented generation (RAG) architecture for medical question answering pertaining to clinicians' queries on emerging issues associated with health-related topics, using user-generated medical information on social media.

Methods: We proposed a two-layer RAG framework for query-focused answer generation and evaluated a proof of concept for the framework in the context of query-focused summary generation from social media forums, focusing on emerging drug-related information. Our modular framework generates individual summaries followed by an aggregated summary to answer medical queries from large amounts of user-generated social media data in an efficient manner. We compared the performance of a quantized large language model (Nous-Hermes-2-7B-DPO), deployable in low-resource settings, with GPT-4. For this

XSL•FO
RenderX

proof-of-concept study, we used user-generated data from Reddit to answer clinicians' questions on the use of xylazine and ketamine.

Results: Our framework achieves comparable median scores in terms of relevance, length, hallucination, coverage, and coherence when evaluated using GPT-4 and Nous-Hermes-2-7B-DPO, evaluated for 20 queries with 76 samples. There was no statistically significant difference between GPT-4 and Nous-Hermes-2-7B-DPO for coverage (Mann-Whitney U=733.0; n_1=37; n_2=39; P=.89 two-tailed), coherence (U=670.0; n_1=37; n_2=39; P=.49 two-tailed), relevance (U=662.0; n_1=37; n_2=39; P=.15 two-tailed), length (U=672.0; n_1=37; n_2=39; P=.55 two-tailed), and hallucination (U=859.0; n_1=37; n_2=39; P=.01 two-tailed). A statistically significant difference was noted for the Coleman-Liau Index (U=307.5; n_1=20; n_2=16; P<.001 two-tailed).

Conclusions: Our RAG framework can effectively answer medical questions about targeted topics and can be deployed in resource-constrained settings.

Introduction

Large language models (LLMs) present opportunities for solving complex biomedical natural language processing problems, such as medical question answering (MQA). However, operational challenges (eg, high computational resource requirements) hinder their real-life deployment and use. Another issue with LLM-generated text for MQA is "hallucination": generated text that is plausible-sounding but nonsensical or incorrect [1]. Chain-of-thought prompting [2], self-reflection [1], and retrieval-augmented generation (RAG) are forerunners in mitigating hallucination. RAG also aids in constraining generated texts and improves in-context learning [3]. LLMs in RAG frameworks have been used in the biomedical domain owing to the need for timely, accurate, and transparent responses [4]. As LLMs become increasingly integrated into clinical practice [5], it is important to ensure their operability in low-resource settings [6] while generating accurate and coherent texts.

We present a proof-of-concept study for a two-layer RAG framework for MQA that ingests user-generated medical information from Reddit. We used smaller, quantized, open-source LLMs that can run on personal computers without specialized hardware, allowing our framework to be used in low-resource settings, thus ensuring equitable access to timely medical information.

Methods

Study Design

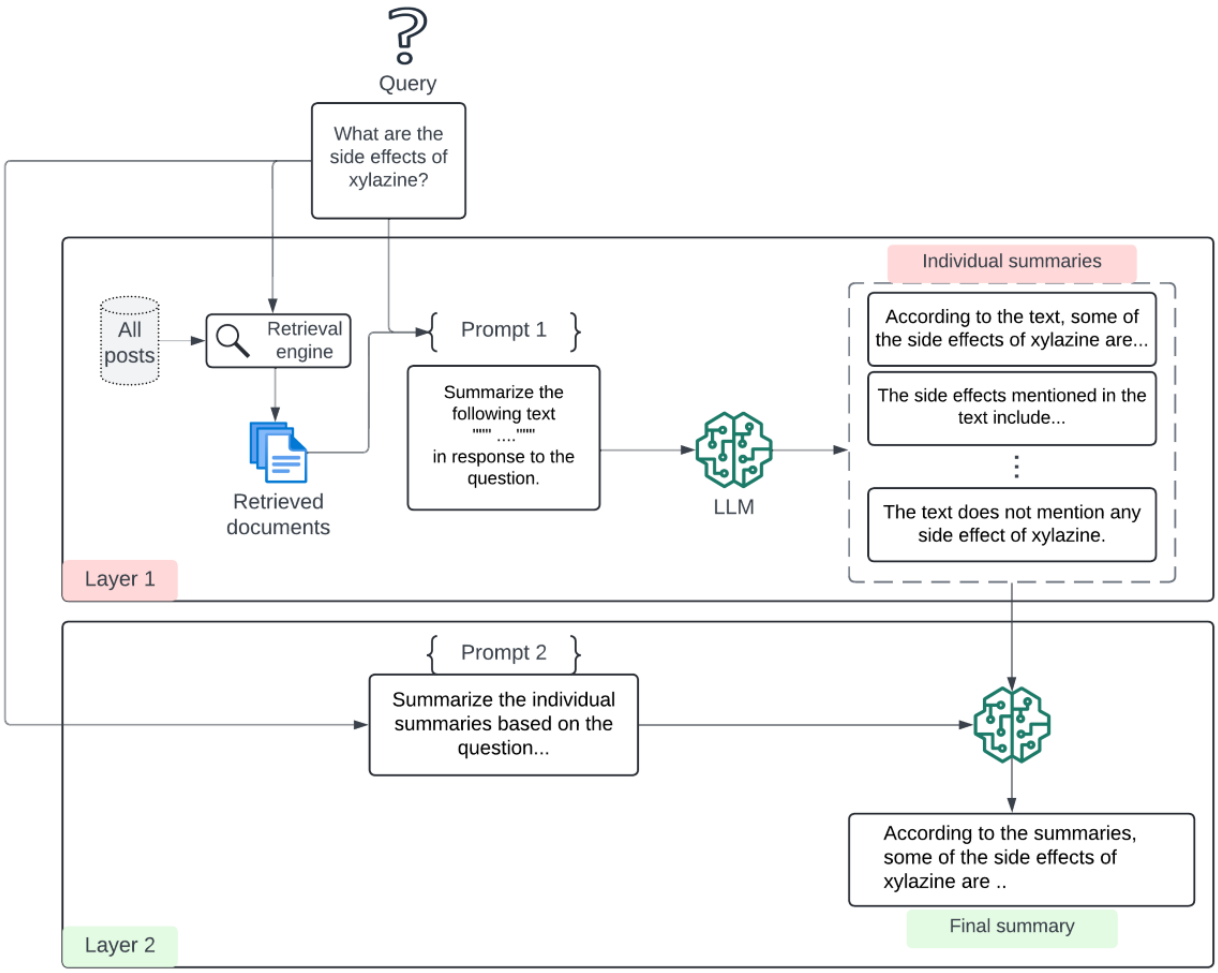
We evaluated our proof-of-concept study in a setting where copious amounts of data are available for a topic but gathering insights and answering questions require substantial manual work—the topic of emerging drugs from Reddit. Reddit has ~52 million daily active users, is commonly used to study emerging medical themes [7], and features numerous discussions on the nonmedical uses of substances. Recently, Reddit data have been leveraged to study novel psychoactive substances since such information is not typically available elsewhere. We chose two substances that have gained attention recently—xylazine (because of its increasing impact and association with the US opioid crisis) and ketamine (because of its recent popularity as a treatment for depression). We collected all available data (~2.5 billion posts) from Reddit until December 31, 2023, and extracted all posts mentioning xylazine (n=177,684) and ketamine (n=7699) for our retrieval engine. Based on clinician-driven interests, we formulated 20 queries (Table 1).

XSL•FO
RenderX

Table 1. Queries used for evaluating the framework.

Query ID	Query
1	What are the side effects of xylazine?
2	What does xylazine do to the skin?
3	How does xylazine impact rehab?
4	What is xylazine withdrawal like?
5	What drugs contain xylazine?
6	What treatments work for xylazine?
7	What drugs are mixed or cut with xylazine?
8	What areas of the United States are impacted by xylazine?
9	How is xylazine different from pure heroin?
10	What is the general sentiment associated with xylazine?
11	Does narcan or naloxone work for xylazine overdose?
12	What are the side effects of ketamine?
13	What is ketamine withdrawal like?
14	What are k cramps like?
15	How do the users describe k hole?
16	Does ketamine work for depression?
17	What drugs are ketamine coused with recreationally?
18	Is ketamine effective for the treatment of suicidal behavior?
19	How can you treat ketamine addiction?
20	Does ketamine use cause cramps?

System Architecture



As depicted in Figure 1, the user submits a query to be parsed by the information retrieval engine, which returns a ranked list of documents. The top n documents are chosen to be sources for answer generation. In the first layer, the LLM is provided with (1) a query, (2) text from the retrieved documents, and (3) a prompt that embeds the text and instructs the LLM to summarize it (Multimedia Appendix 1). Since the prompt context window is finite, feeding the LLM all the retrieved text for answer generation is typically impossible. Even single documents can be too long. Thus, the framework allows for the specification of segment lengths for the retrieved text in each iteration, ensuring the framework is applied to relatively small LLMs with shorter context lengths. The first layer generates short, query-focused summaries (Figure 1). The LLM states if the retrieved text segment does not contain an answer to the question. Examples of this first-layer summarization are provided in Multimedia Appendix 2.

The second layer takes as input the original query and individual short summaries embedded within a second prompt (Multimedia Appendix 1) while ignoring summaries that the LLM states did not contain the answer. Figure 1 depicts an example of the final, synthesized summary.

We used the 8-bit quantized model Nous-Hermes-2-7B-DPO as our LLM, which is tuned on 1,000,000 high-quality instructions [8]. To test the performance of the proposed framework with larger models, we also performed an evaluation using GPT-4 [9].

XSL•FO
RenderX

Figure 1. Overview of the two-layer RAG framework. The first layer generates individual summaries based on retrieved posts relevant to the original query. The second layer generates the final summary based on the individual summaries generated in the first layer. LLM: large language model; RAG: retrieval-augmented generation.

RAG Architecture

Since the retrieval aspect is not our primary focus, we used a simple keyword-based approach using the default search settings provided by our information retrieval package "Whoosh," which uses Okapi BM25F ranking [10]. The top 50 retrieved documents were chosen for generating the first-layer summaries. This number may be adjusted without changes to the architecture. The number of text segments is typically higher when posts do not fit within the context window of the LLM after being embedded within the prompt.

Evaluation

Our evaluation focused on the architecture's summary generation quality, rather than retrieval performance. Commonly used automatic summary evaluation methods, such as Recall-Oriented Understudy for Gisting Evaluation (ROUGE) [11] and bilingual evaluation understudy (BLEU) [12], primarily focus on text overlap between generated and gold-standard summaries. In the absence of gold-standard summaries, subject matter experts manually and qualitatively evaluated the important nuances of generative summaries, which is impossible with ROUGE or BLEU. We used Likert-scale evaluations (Table 2). Each query–individual summary–final summary triplet was evaluated by ≥2 evaluators (at least a master's degree in medicine, public health, informatics, or allied fields). Overall, 21 experts generated 76 evaluations for 20 unique queries.

We also assessed the readability of the final summaries using the Coleman-Liau Readability Index (CLI) [13], which approximates the US grade level required to comprehend text.

We performed nonparametric tests for proportions (Mann-Whitney *U* test) with the null hypothesis (H_0: "The two populations are equal") to determine if the scores assigned to answers generated by GPT-4 and Nous-Hermes-2-7B-DPO vary significantly. All tests were performed using the *SciPy* package [14]. The null hypothesis (H_0) was rejected if $P<.05$ (two-tailed).

XSL•FO
RenderX

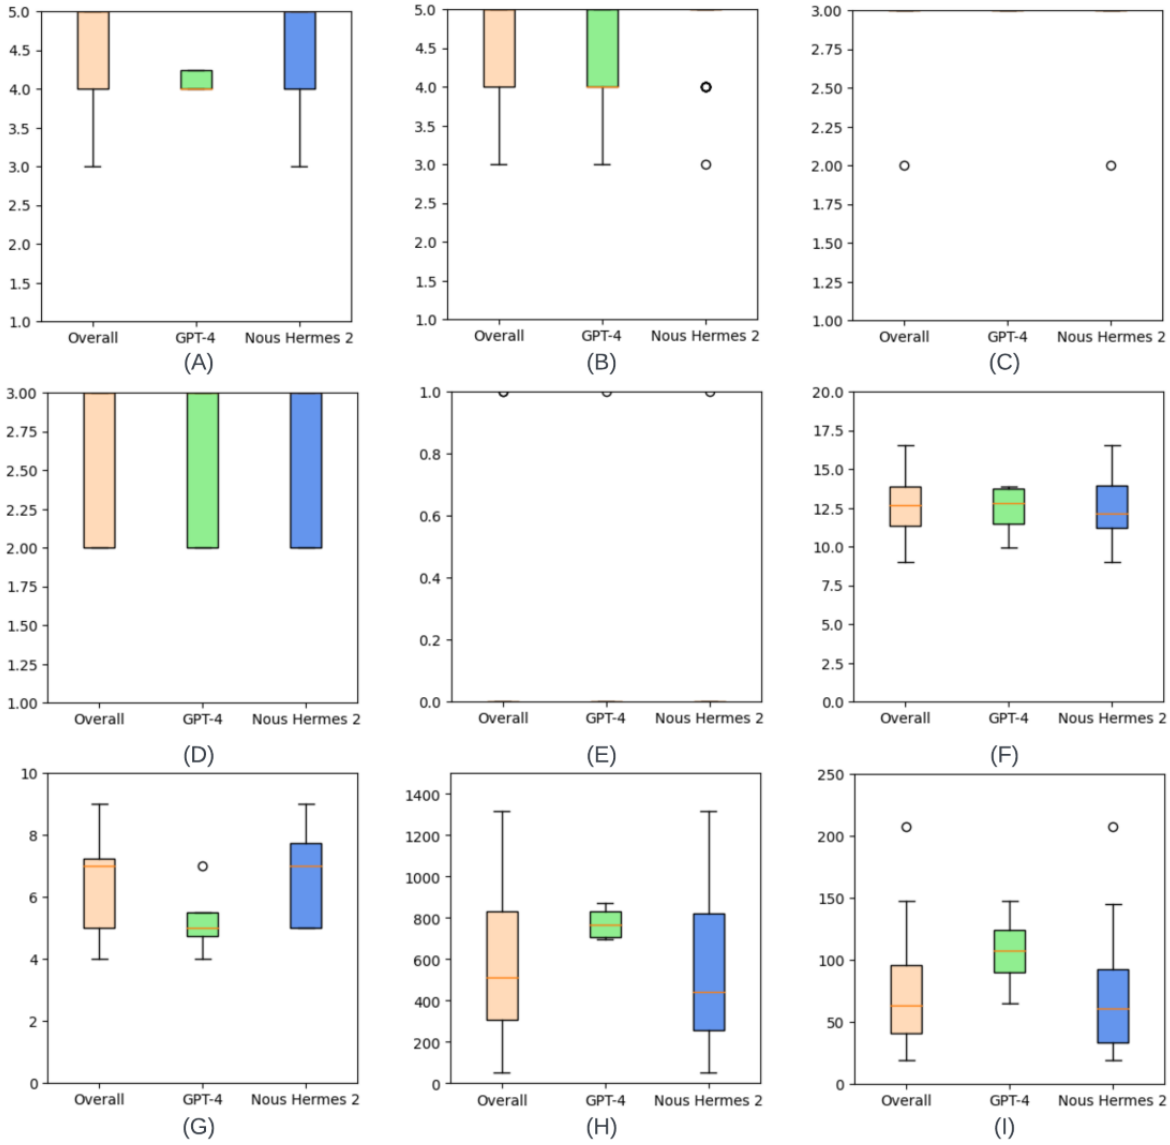
Table 2. Evaluation criteria and scales presented to annotators.

Criteria	Question	Evaluation scale
Coverage	Does the final summary accurately represent the information present in the original text?	• 5: Yes; the final summary covers all the important information present in the original text. • 4: Mostly; the final summary covers most, but not all of the important information. • 3: Somewhat; the final summary covers some of the important information, but also misses some of them. • 2: Not really; the final summary misses most of the important information. • 1: No; the final summary does not cover any of the important information present in the original text.
Coherence	Is the final summary coherent?	• 5: Yes; the final summary is easy to read and understand. • 4: Mostly; the final summary is readable, but not straightforward to understand. • 3: Somewhat; the final summary is readable but confusing. • 2: Not really; the final summary has some grammatical errors or nonsequiturs. • 1: No; the final summary is unintelligible or incomprehensible.
Relevance	Does the final summary answer the original question?	• 3: Yes; the summary answers the original question. • 2: Partially; the summary answers the original question, but not fully. • 1: No; the summary does not answer the original question.
Length	Is the length of the final summary appropriate?	• 3: Yes; the summary is appropriate in length. • 2: Somewhat; the summary could be shorter or longer. • 1: No; the summary is long-winded or too short.
Hallucination	Does the summary contain information not present in the original text?	• 0: No; the summary does not contain information not present in the original text. • 1: Yes; the summary contains information not present in the original text.

Ethical Considerations

This study was deemed to be exempt from review per the Emory University Institutional Review Board's guidelines. The data used in this study are anonymous by default. We ensured that self-disclosed, personally identifiable information is not used by only reporting aggregated data. We removed posts that were deleted by the user.

Results



We conducted extensive expert evaluations of the generated answers for coverage, coherence, relevance, length, and hallucination (Figure 2). Annotators were not made aware of which LLM was used to generate the summaries for fair evaluation. On a 5-point Likert scale, median coverage scores were 5 (IQR 4-5) for both models; the distributions did not differ significantly (U=733.0; n_1=37; n_2=39; P=.89). Median coherence scores were 5 (IQR 5-5 for GPT-4; IQR 4-5 for Nous-Hermes-2-7B-DPO) for both; they did not differ significantly (U=670.0; n_1=37; n_2=39; P=.49).

On a 3-point Likert scale, the median relevance scores were 3 (IQR 3-3) for both; they did not differ significantly (U=662.0; n_1=37; n_2=39; P=.15). Median length scores were 3 (IQR 2-3) for both; they did not differ significantly (U=672.0; n_1=37; n_2=39; P=.55). On a binary Likert scale, median hallucination scores were 0 (IQR 0-0) for both; they did not differ significantly (U=859.0; n_1=37; n_2=39; P=.10). The median CLIs were 16.635 (IQR 13.860-17.675) for GPT-4 and 12.125 (IQR 11.02-13.98) for Nous-Hermes-2-7B-DPO; there was a statistically significant difference (U=307.5; n_1=20; n_2=16; P<.001).

Median token counts for queries posed to GPT-4 and Nous-Hermes-2-7B-DPO were 5 (IQR 5-7) and 7 (IQR 5-8), respectively; there was no significant difference (U=165.0; n_1=20; n_2=16; P=.66). Median lengths of responses generated by GPT-4 and Nous-Hermes-2-7B-DPO were 1118 (IQR 709-2986) and 441 (IQR 231-695) for the combined individual summaries and 141.5 (IQR 115-159) and 61 (IQR 28-87) for the final summaries, respectively. Both were significantly different (U=300.0; n_1=20; n_2=16; P<.001, and U=145.5; n_1=20; n_2=16; P<.001).

XSL•FO

Figure 2. Box plots illustrating the distribution of scores for the evaluation criteria used. (A) Coverage on a 5-point Likert scale. (B) Coherence on a 5-point Likert scale. (C) Relevance on a 3-point Likert scale. (D) Length on a 3-point Likert scale. (E) Hallucination on a binary scale. (F) Values for the Coleman-Liau Index. (G) Token counts for Questions. (H) Token counts for combined individual summaries. (I) Token counts for the final summary.

Discussion

Principal Findings

This study presents a novel two-layer RAG framework for MQA that uses user-generated content from Reddit. Our findings demonstrate that the framework effectively synthesizes accurate and contextually relevant answers even in low-resource settings, aligning with our goal to create an accessible, computationally lightweight tool. Focusing on small, quantized, open-source LLMs ensures equitable access to valuable insights about emerging trends, potential side effects, and general perception of substances, as reflected in Reddit posts.

The modular structure of the framework enables good performance without requiring specialized hardware, which is critical in low-resource environments. This modularity also supports using different retrieval engines or LLMs, providing flexibility to adapt to various use cases. The system's ability to answer nuanced queries (eg "What are k cramps like?"—which would require extensive manual curation) illustrates its potential for real-world applications. The framework's ability to specify temporal ranges in queries allows it to track trends over time, offering opportunities for longitudinal studies and misinformation detection.

Unlike previous work [15], where segments of text are generated chronologically, we performed segmentation at the post level without accounting for chronology. Compared with existing literature, which predominantly relies on large LLMs for MQA [4,16], this study underscores the potential of smaller models for tasks requiring domain-specific, contextually accurate outputs. Prior work often focuses on high-resource settings [17,18] with robust computational infrastructure, leaving gaps

XSL•FO
RenderX

in applicability for low-resource environments. We fill this gap by showing that reliable performance can be achieved with computationally efficient architectures, expanding the reach of artificial intelligence tools to underresourced regions. Although smaller LLMs have been used [19], summarization from large volumes of text with aggregated information has not been addressed before.

Limitations

Despite its promising features, the framework has limitations. It relies on the accuracy and representativeness of the Reddit data it ingests. Reddit posts may include biases, inaccuracies, or misinformation that could influence the system's output. While faithfully summarizing misinformation is valuable for transparency, users need to exercise caution in interpreting the results. Additionally, we evaluated the framework using a small set of queries pertaining to substance use; further validation is necessary to assess performance across diverse medical domains.

Conclusions

This study demonstrates that a modular, lightweight RAG framework can effectively address complex MQA using social media data in low-resource settings. By enabling clinicians to rapidly extract insights about substance use trends and potential side effects from Reddit posts, the framework holds significant potential for improving public health.

Acknowledgments

Research reported in this publication was supported by the National Institute on Drug Abuse of the National Institutes of Health (NIH) under award R01DA057599. The content is solely the responsibility of the authors and does not necessarily represent the official views of the NIH.

Data Availability

All data used in this study were publicly available from Reddit at the time of data collection. The second-level summaries are available in Multimedia Appendix 3. The original posts and social media posts analyzed during this study are available from the corresponding author upon reasonable request and the completion of a data use agreement.

Authors' Contributions

SD and Y Ge led analysis, evaluation, visualization, and original draft preparation. Y Guo, SR, JH, J Powell, DW, SP, and SL contributed to the evaluation and manuscript preparation. SB, MR, RS, YX, SK, RC, NH, DM, RW, JL, A Spadaro, and J Perrone worked on the evaluation. A Sarker conceptualized the study, led model design and implementation, and supervised the project.

Abstract

Background: Artificial intelligence (AI) predictive models in primary health care have the potential to enhance population health by rapidly and accurately identifying individuals who should receive care and health services. However, these models also carry the risk of perpetuating or amplifying existing biases toward diverse groups. We identified a gap in the current understanding of strategies used to assess and mitigate bias in primary health care algorithms related to individuals' personal or protected attributes.

Objective: This study aimed to describe the attempts, strategies, and methods used to mitigate bias in AI models within primary health care, to identify the diverse groups or protected attributes considered, and to evaluate the results of these approaches on both bias reduction and AI model performance.

Methods: We conducted a scoping review following Joanna Briggs Institute (JBI) guidelines, searching Medline (Ovid), CINAHL (EBSCO), PsycINFO (Ovid), and Web of Science databases for studies published between January 1, 2017, and November 15, 2022. Pairs of reviewers independently screened titles and abstracts, applied selection criteria, and performed full-text screening. Discrepancies regarding study inclusion were resolved by consensus. Following reporting standards for AI in health care, we extracted data on study objectives, model features, targeted diverse groups, mitigation strategies used, and results. Using the mixed methods appraisal tool, we appraised the quality of the studies.

Results: After removing 585 duplicates, we screened 1018 titles and abstracts. From the remaining 189 full-text articles, we included 17 studies. The most frequently investigated protected attributes were race (or ethnicity), examined in 12 of the 17 studies, and sex (often identified as gender), typically classified as "male versus female" in 10 of the studies. We categorized bias mitigation approaches into four clusters: (1) modifying existing AI models or datasets, (2) sourcing data from electronic health records, (3) developing tools with a "human-in-the-loop" approach, and (4) identifying ethical principles for informed decision-making. Algorithmic preprocessing methods, such as relabeling and reweighing data, along with natural language processing techniques that extract data from unstructured notes, showed the greatest potential for bias mitigation. Other methods aimed at enhancing model fairness included group recalibration and the application of the equalized odds metric. However, these approaches sometimes exacerbated prediction errors across groups or led to overall model miscalibrations.

XSL•FO
RenderX

Conclusions: The results suggest that biases toward diverse groups are more easily mitigated when data are open-sourced, multiple stakeholders are engaged, and during the algorithm's preprocessing stage. Further empirical studies that include a broader range of groups, such as Indigenous peoples in Canada, are needed to validate and expand upon these findings.

Introduction

Developments in computer science have led to artificial intelligence (AI) models that learn from large datasets and can perform independent analysis [1-4]. Significant progress has been made in these tasks with the development of machine learning (ML). This branch of AI focuses on understanding, generating, and reasoning based on data without explicit human instructions [2,3] Such ML algorithms use datasets known as "training datasets" to capture the patterns required for clustering tasks or predictive modeling [3,4]. These models are now used in multiple contexts and industries to predict the likelihood of an event or to support human decision-making [4]. In health care, AI models applied in radiology can potentially detect and predict the progression of cancerous tumors accurately [5]. Algorithms can also be useful in community-based primary health care (CBPHC) for identifying individuals, such as heart failure or diabetes outpatients, who require specific health care services [6]. As defined by the Canadian Institutes of Health Research, CBPHC encompasses a comprehensive array of services aimed at community well-being, including primary prevention (such as public health), health promotion, disease prevention, diagnosis, treatment, and management of chronic and episodic illnesses, rehabilitation support, and end-of-life care [7].

Despite the potential benefits of AI, such as compensating for workforce shortage and maximizing access to CBPHC [6], algorithm biases toward diverse groups can hinder their application in health care settings. These biases may be perpetuated when protected attributes [1], as identified by the place of residence, race/ethnicity/culture/language, occupation, gender/sex, religion, education, socioeconomic status, and social capital (PROGRESS-Plus) framework [8], are underrepresented or misrepresented in the training data of algorithms [1,9]. Strategies aimed at identifying and mitigating bias, defined as a persistent inclination either in favor or toward something [9], in predictive models are in development and beginning to be empirically applied [10,11]. In computer science, attempts to achieve algorithmic fairness can involve which are (1) preprocessing, (2) in-processing, or even, (3) postprocessing strategies, such as those used in "out-of-the-box" commercial AI models [4]. Academic disciplines beyond computer science, such as medicine, management, and ethics, are also closely involved in addressing issues related to identifying potential bias toward diverse groups in AI models [1,3]. However, there remains a knowledge gap regarding which strategies and methods have been empirically applied to mitigate bias toward diverse groups in CBPHC algorithms [10,12].

To address this gap, we conducted a scoping review aimed at identifying and describing (1) the attempts made to mitigate bias in primary health care AI models, (2) which diverse groups or protected attributes have been considered, and (3) the results regarding bias attenuation and the overall performance of the models.

Methods

Search Strategy

We conducted a scoping review informed by the Joanna Briggs Institute (JBI) [13] and used the Population (or Participant), Concept, and Context Framework [14], as shown in Table 1.

XSL•FO
RenderX

Table 1. Population (or Participant), Concept, and Context framework used for the search strategy.

PCC[a] elements [14]	Definition (per JBI[b] Reviewer's Manual)	PCC elements applied in this review
Population	"Important characteristics of participants, including age and other qualifying criteria" (11.2.4)	Any diverse groups [8] based on their personal or protected attributes [1].
Concept	"The core concept examined by the scoping review should be clearly articulated to guide the scope and breadth of the inquiry. This may include details that pertain to elements that would be detailed in a standard systematic review, such as the "interventions" or "phenomena of interest" (11.2.4)	Strategies, attempts, or methods for assessing and mitigating bias in artificial intelligence.
Context	"May include...cultural factors such as geographic location or specific racial or gender-based interests. In some cases, context may also encompass details about the specific setting."	Community-based primary health care [7].

[a]PCC (Population [or Participant], Concept, and Context) framework [14].

[b]JBI: Joanna Briggs Institute.

Bias Mitigation in Primary Health Care Artificial Intelligence Models

Primary review questions are (1) What attempts have been made to mitigate bias in primary health care AI models? (2) Which diverse groups or protected attributes have been considered? and (3) What are the results regarding bias attenuation and model performance?

In November 2022, we developed a search strategy aligned with the main concepts of our primary review questions with an experienced librarian in 4 relevant databases (MEDLINE [Ovid], CINAHL [EBSCO], PsycInfo [Ovid], and Web of Science). The results of the search strategy in Web of Science were limited to the following 2 indexes: Science Citation Index Expanded and Emerging Sources Citation Index. We used 5 relevant articles to test the sensitivity of our search strategy, focusing on peer-reviewed publications from the past 5 years (between January 1, 2017, and November 15, 2022). The search strategies for each database can be found in Multimedia Appendix 1.

Data Collection

We imported all sources (n=1603) into the web-based collaborative tool Covidence (Veritas Health Innovation) [15], which automatically identified and removed 581 duplicates, with an additional 4 removed manually. The inclusion and exclusion criteria are presented in Table 2. During the title and abstract screening phase, 7 reviewers independently assessed the abstracts based on the selection criteria. We piloted the screening process on 50 sources that all reviewers independently assessed. Reviewers included a source if it met our inclusion criteria, such as featuring an AI predictive model in health, targeting primary health care populations, and presenting a strategy or method for reducing bias. All titles and abstracts were screened independently by at least 2 reviewers, with any discrepancies resolved through consensus involving all reviewers, including at least 1 senior researcher.

Table 2. Inclusion and exclusion criteria.

PCC (Population, Concept, and Context) elements [14]	Inclusion criteria	Exclusion criteria
Population	• Any populations targeted by CBPHC[a] interventions.	• Any populations targeted by hospital or specialized care interventions.
Concept	• All methods or strategies deployed to assess and mitigate bias toward diverse groups or protected attributes in AI models. • All mitigation methods or strategies deployed to promote and increase equity, diversity, and inclusion in CBPHC algorithms.	• Methods or strategies deployed to assess and mitigate bias in the AI model itself (eg, biased prediction of treatment effects), rather than bias related to individuals' characteristics or protected attributes. • Strategies, methods, or interventions that are not related to CBPHC. • CBPHC interventions that do not include any algorithm or AI system.
Context	• Include all CBPHC algorithms (AI) applications that can perpetuate or introduce potential biases toward diverse groups based on their characteristics or protected attributes.	• Algorithms used by primary health care providers for support in administrative tasks and operational aspects, rather than for clinical decisions.
Study design, study type, and time frame	• All empirical studies published in English or French between 2017 and 2022.	• Reviews, opinions, commentaries, editorial content, conference papers, communications, protocols, magazine articles, and so on.

[a]CBPHC: Community-based primary health care.

XSL•FO
RenderX

For the remaining articles assessed for eligibility at the full-text review stage, we searched for and obtained any missing full texts of selected references, then imported them into Covidence. Out of 5 reviewers independently applied the same selection criteria, and all reasons for exclusion were recorded in Covidence. All full texts underwent dual screening. As in the previous stage, any discrepancies regarding the included studies were resolved through consensus among all reviewers, including at least one senior researcher.

Data Extraction

One experienced reviewer performed the extraction of the included studies, and 2 senior researchers validated the data for all of them. We also hand-searched [16] and identified 2 relevant articles [17,18] related to 2 included studies [19,20], which were added to Covidence for extraction. Based on reporting standards for AI in health care [21], we extracted the following information (title of the paper, year of publication, lead author, and country), study objective, discipline and study design, AI model features, study population and setting, AI model architecture and evaluation, bias assessment method, strategy for deployment, diverse groups concerned, bias mitigation results, and the impact on AI model performance and accuracy.

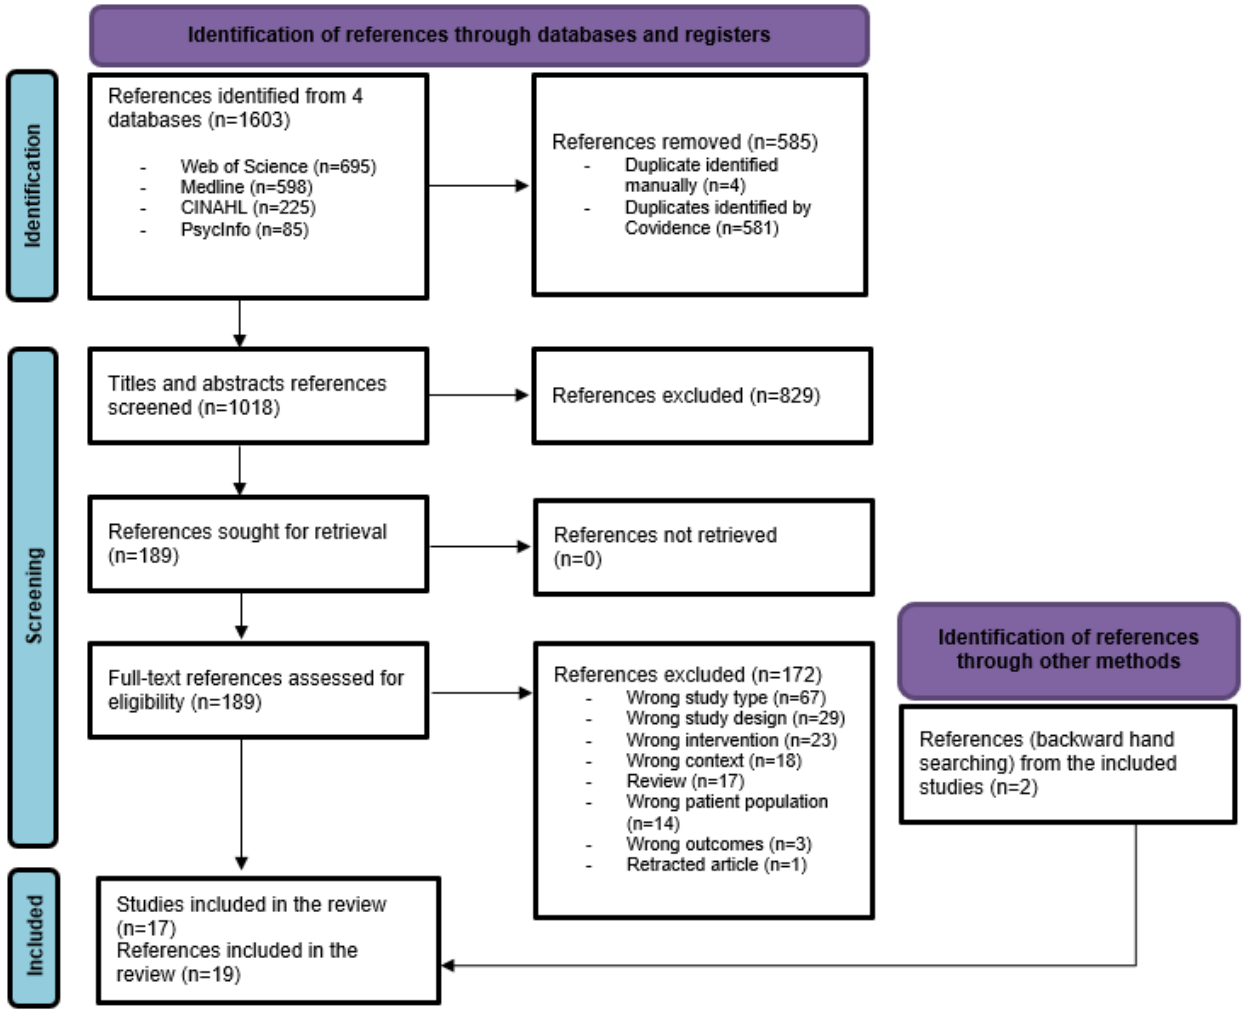
Quality Assessment

One senior reviewer appraised the quality of the included studies by applying the Mixed-Methods Appraisal Tool (MMAT) [22,23] and at least one senior researcher validated each of them.

Data Synthesis

In accordance with the JBI recommendations [24], we synthesized data using structured narrative summaries around our review concepts (eg, model data source, model input, model output, diverse groups, or protected attributes), mitigation strategies deployed, and the results on bias mitigation and overall model performance. We reported our findings based on the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [25].

Ethical Considerations



We obtained approval from the ethics board of the “Comité d’éthique de la recherche sectoriel en Santé des Populations et Première Ligne du Centre Intégré Universitaire de Santé et de Services Sociaux de la Capitale-Nationale” for the Protecting and Engaging Vulnerable Populations in the Development of Predictive Models in Primary Health Care for Inclusive, Diverse and Equitable AI (PREMIA) project (#2023-2726).

Results

Out of a total of 1018 titles and abstracts, along with 189 full-text articles that underwent dual screening, 17 studies [19,20,26-40] met our eligibility criteria. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram is shown in Figure 1 [41].

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) flow diagram.

The relatively high number of exclusions at the full-text review stage (172/189, 91%) can be attributed to our inclusive approach in the previous stage. For example, some reviews (17/189, 9%) and incorrect study types (67/189, 35%), such as editorials, commentaries, or conference papers, were excluded at this stage. Other exclusion reasons (88/189, 47%) included models that lacked AI components, models focusing on health care operational processes (eg, workflow modeling), studies targeting populations receiving specialized care (eg, hospitalized or cancer patients), interventions such as imaging research that were outside the scope of CBPHC, and methods for mitigating bias that were applied to the AI model itself (eg, biased predictions of treatment effects) rather than addressing biases related to diverse groups or personal attributes.

Overview of Included Studies

Of the 17 included studies published between 2019 and 2022, we identified 7 studies in the discipline of data science or informatics, 7 in medical informatics, 1 in medical ethics and informatics, 1 in medical ethics using a Delphi method, and 1 in management care ethics using a user-centered design. Most studies have been conducted in the United States (15/17, 88%), 1 in the United Kingdom, and 1 in Italy. The main characteristics of the included studies can be found in Multimedia Appendix 2.

Quality Assessment of Included Studies

Most studies had a quantitative descriptive study design (14/17, 82%), while 2 used a mixed methods design, and 1 used a qualitative design. All studies showed high quality, receiving scores of 3 or 4 stars (on a possibility of 5). All MMAT scores can be found in Multimedia Appendix 3.

Diverse Groups Considered

The most frequently studied protected attributes were race (or ethnicity), examined in 71% (12/17) of studies, and sex (defined as binary male versus female), considered in 59% (10/17) of studies. None of the studies distinguished between biological sex and socially constructed gender, and 5 of them incorrectly identified sex as gender. Race or ethnicity was most often categorized as White or Black, Black or non-Black or, in one study, as Asian, Black, White, and other.

Other protected attributes considered by the studies included age (7/17, 41%), socioeconomic status or its proxies, such as income, work class, education, health care insurance (5/17, 29%), place of residence (2/17, 12%), marital status (1/17, 6%), and disability status (1/17, 6%).

XSL•FO
RenderX

Categorization of Deployed Bias Mitigation Strategies

We identified considerable heterogeneity across the studies, which used various strategies and methods to assess and mitigate bias in algorithms impacting diverse groups. We categorized these efforts into four groups: (1) addressing bias in existing AI models or datasets, (2) mitigating biases from data sources such as electronic health records (EHRs), (3) developing tools that incorporate a "human-in-the-loop" approach, and (4) identifying ethical principles to guide informed decision-making.

Attempts in Existing AI Models or Datasets

We identified 7 studies that attempted to mitigate biases in existing AI models or datasets [19,20,27,28,35,37,39].

A debiasing attempt was made on an insurance coverage algorithm designed to identify individuals who could benefit from health resources according to their health needs [35]. Risk scores were initially calculated based on projected future costs rather than uncontrolled or unmanaged illnesses, disadvantaging Black patients. By changing the data labeling to focus on future illness rather than future costs, the percentage of Black patients who could benefit from health resources increased significantly [35].

Another cohort study [37] using a Medicaid enrollees' dataset showed that reweighing was more effective at reducing bias in postpartum depression risk scores between White and Black individuals compared with training without the race variable for comparison. Initially, it was found that the White individuals had higher rates of postpartum depression and mental health service use. However, after comparing postpartum depression rates between races based on population surveys, it became clear that the higher rates in White women might be due to disparities in the timely assessment, screening, and detection of symptoms in Black women [37].

A total of three other studies include (1) retraining models with data that incorporated health equity measures resulted in a slight decrease in performance for detecting abnormal electrocardiograms but significantly reduced gender, race and age biases [19]; (2) increasing diversity in the training data of a predictive pulmonary disease model improved its performance [27]; and (3) although a mental health assessment model achieved high accuracy, its performance was statistically higher and more accurate for men than for women [18]. The use of an algorithmic disparate remover, by adjusting the modeling data, significantly reduced this disparity while maintaining high accuracy [20].

Another attempt to assess bias involved replicating models predicting liver disease [39]. Importing an existing dataset reproduced predictive models with high accuracy but revealed a previously unobserved bias, with women experiencing a higher false negative rate.

We identified only 1 in-processing debiasing attempt [28]. Out of 2 algorithmic fairness strategies, group recalibration and equalized odds, were used to recalibrate a predictive model of cardiovascular diseases that was not initially adjusted for attributes such as sex or race. This resulted in an exacerbation of false positive and negative rates differences between groups, as well as overall model miscalibration.

Attempts in Data Sourcing

We identified 5 studies that attempted to mitigate biases in data sourcing [26,31,32,38,40].

Based on published synthetic datasets, such as the analysis of the American Time Use Survey dataset, using fairness metrics revealed potential discrepancies in representativeness between real and synthetic data across age, sex, and race [26].

Out of 4 other studies investigated EHRs datasets [31,32,38,40]. A natural language processing model was developed to extract vital sign features from unstructured notes, comparing risk scores with 2 convenience samples. This method reduced the missingness of vital signs by 31%, thereby mitigating possible discrimination toward diverse groups, such as Black men or Black women [32]. Based on data from a previous study, 2 ML models were trained to compare balanced error rates across different socioeconomic status levels and the incompleteness of EHRs data [31]. Asthmatic children with lower socioeconomic status exhibited larger balanced error rates than those with higher socioeconomic status and had more missing information regarding asthma care, severity, or undiagnosed asthma, despite meeting asthma criteria [31].

Potential bias based on place of residence in EHRs was examined by 2 studies [38,40]. Rebalancing class labels by adding zip-code level information to 19,367 EHRs during the preprocessing step showed no significant deviation in performance, indicating that bias can be mitigated through preprocessing [38]. Meanwhile, a simple 30-day readmission prediction model was developed, categorizing each patient as local (nearby) or not (far) [40]. The performance with and without this variable was assessed, revealing no significant differences. Considering that living locally only affects the observability of the outcome (eg, a patient may be readmitted to a different hospital), differential bias assessment cannot rely solely on observed data [40].

Attempts in Developing Tools With a "Human-in-the-Loop" Approach

We identified 3 studies that attempted to mitigate biases by incorporating a "human-in-the-loop" approach [29,30,36].

These studies led to the development of "human-in-the-loop" tools: (1) a visual tool for auditing and mitigating bias from tabular datasets, which was tested through experiments on 3 datasets with user participation and significantly reduced bias compared with another commercial debiasing toolkit [29]; (2) pragmatic tools developed for better use of risk scores with a Medicare members' dataset, allowing users to identify appropriate risk scores for each subgroup to achieve equality of opportunity [30]; and (3) a tool called "FairLens" capable of identifying and explaining biases, which was tested using a fictitious black box model serving as a decision support system [36]. Empirically validated by injecting biases into this fictitious decision support system, this tool outperformed other standard measures and enabled experts to identify problematic groups

XSL•FO
RenderX

or affected patients, thereby allowing for the detection of potential misclassification [36].

Attempts at Identifying Ethical Principles for Informed Decision-Making

We identified 2 empirical studies that attempted to mitigate biases by identifying ethical principles for informed decision-making [33,34].

To assess the potential missingness of EHR data from phenotyping technology, a Delphi study was conducted to address ethical challenges and reach a consensus on the importance of privacy, transparency, consent, accountability, and fairness [33]. In addition, a user-centered design study was conducted to identify user requirements, mainly intended for health managers and clinicians, to support informed decision-making and confidence in using a hepatitis C severity illness predictive model prototype [34].

Discussion

Principal Findings

The reviewed studies illustrate a multifaceted approach to mitigating bias in primary care AI models. Strategies include retraining, reweighing, relabeling, adding more diversity, and attempting to replicate existing modeling data [19,20,27,35,37,39], as well as algorithmic recalibration applied to an existing prediction model [28]. Other strategies involve the development and application of fairness metrics to ensure equitable distributions in previously published databases [26], and the identification of missingness in EHRs datasets by rebalancing class labels or adding information [31,32,38]. Another group of strategies includes the introduction of visual interactive tools for human-in-the-loop bias auditing [29,30,36]. All these attempts cover a broad spectrum of interventions, ranging from data preprocessing and algorithmic modification to post hoc analysis, demonstrating the complexity and variety of approaches needed to address bias in AI models in primary health care.

The studies collectively address a wide range of protected attributes [1,8], including race or ethnicity [19,26,28-37], sex [19,20,26-31,36,39], age [19,26,27,29-31,36], socioeconomic status (SES) [27,29,31,33,36], and other demographic variables such as place of residence [38,40]. This underlines the recognition of the multifaceted nature of bias, which can intersect across various dimensions of identity and social determinants of health [9,42]. However, we have identified disparities in the number of protected attributes studied. Race (White vs Black) and sex (male vs female) are most frequently investigated, whereas other attributes, such as disability and gender, are underresearched or not studied at all.

Bias mitigation efforts reveal a nuanced landscape where attempts to reduce bias across protected attributes can result in complex trade-offs with model performance. For example, a decrease in overall model performance accompanied by significant reductions in bias was observed following the implementation of constrained optimization [19]. Similarly, improvements in calibration for specific groups came at the cost of increased disparities in false positive and false negative rates between groups [28]. Despite these trade-offs, the efforts have largely been successful in reducing bias, as evidenced by a study that achieved fairer distributions in synthetic data [26], and in another study where human-in-the-loop interventions significantly reduced bias while maintaining utility [29].

These empirical findings reinforce theoretical insights that emphasize the importance of health equity between protected and unprotected attributes [1,8]. To mitigate bias in AI health models, distributive justice options for ML have been proposed: (1) equal patient outcomes; (2) equal performance; and (3) equal allocation of resources [1]. Since these different types of fairness options are often incompatible, optimizing all these parameters seems challenging, as demonstrated by an identified study [28]. Trade-offs are essential, and a participatory process involving key stakeholders, including ethicists, clinicians, and marginalized populations, is strongly encouraged [1]. While striving to create ethically robust AI models, selected studies often reveal tension, as efforts to reduce bias can sometimes lead to a decrease in the model's overall performance. This presents a critical challenge: balancing the imperative of fairness with the need to maintain high accuracy and efficiency in algorithmic outputs.

Comparison With Previous Work

Initiatives focused on the fair use of AI in health care and the assessment of bias risk in AI predictive models have been published in recent years. Notable initiatives include Consolidated Standards of Reporting Trials-Artificial Intelligence (CONSORT-AI) and Standard Protocol Items Recommendations for Interventional Trials-Artificial Intelligence (SPIRIT-AI) [43], which provide guidelines for the ethical presentation of the results of trials conducted with AI in the health care field. To assess the risk of bias in diagnostic and prognostic prediction model studies, the "Prediction Model Risk of Bias Assessment Tool" (PROBAST) [44] can be used. PROBAST consists of a list of signaling questions grouped into 4 categories: participants, predictors, outcomes, and analysis. This tool was used in a systematic scoping review to assess the quality of primary studies reporting applications of AI in CBPHC [45].

However, the objective of our scoping review differs; it is not to identify biases in the AI prediction models themselves, but rather to examine biases toward groups that are underrepresented or misrepresented in these AI models. An identified review has used and adapted PROBAST to assess related protected attributes, but the AI predictive models studied were hospital-based and not relevant to primary care [11]. We also identified a scoping review protocol that focused on bias toward diverse groups in AI systems in primary care; however, unless we are mistaken, the results of this protocol have never been published [10]. Another identified review aimed to assess age-related bias in AI but did not focus on primary health care [46]. Finally, we identified another systematic review investigating health inequities in primary care, but it adopted a system-wide perspective, focusing on aspects such as patient consultation and effects on health systems [47].

XSL•FO
RenderX

To our knowledge, no other published review has the objectives of identifying (1) the bias mitigation strategies or methods in primary health care, (2) the diverse groups that are underrepresented or misrepresented, and (3) the results of bias mitigation and AI model performance.

Strengths and Limitations

The strengths of this review include results that can be translated into recommendations for various stakeholders, such as AI developers, researchers, and decision makers. However, we acknowledge some limitations. First, we limited our search strategy to the last 5 years before November 2022 and focused on 4 databases, which may have excluded some relevant studies. Second, the extraction of studies and quality assessment were conducted only once, although all of them were validated by at least one senior researcher. Third, due to the heterogeneity of the studies, we were unable to combine results through a quantitative synthesis and remained at a narrative level of reporting. Finally, our review primarily identified research from a North American setting, which reduces its transferability to other continents.

Future Directions and Dissemination Plan

This scoping review serves as the initial phase of the iterative project "Protecting and Engaging Vulnerable Populations in the Development of Predictive Models in Primary Health Care for Inclusive, Diverse, and Equitable AI" (PREMIA).

Following the results of this review, we have developed a framework currently validated by a diverse group of experts, including clinicians, public health managers, primary care researchers, data scientists, and patient and citizen partners. This group is concentrating on existing AI predictive models and the bias mitigation strategies identified in our scoping review. Diverse populations, such as older adults, individuals with disabilities, and people from various racial and ethnic backgrounds, are actively involved in this second phase of PREMIA. We plan to prepare and submit a manuscript based on the findings of this Delphi study.

In addition, in recognition of the rapid advancements in this field, we plan to update this literature review in 2027 using a similar search strategy. This iterative approach will allow us to refine our framework and track the progress of bias mitigation in AI models within primary health care. Indigenous peoples in Canada represent a group historically underrepresented in health research, leading to inequities [3]. Since no other study has addressed bias related to Indigenous status, we collaborate with Indigenous representatives to develop methods for mitigating this bias in CBPHC algorithms.

Conclusion

This review identifies strategies and methods for mitigating bias in primary health care algorithms, considers diverse groups based on their personal or protected attributes, and examines the results of bias attenuation and model performance. The findings suggest that biases toward diverse groups can be more effectively mitigated when data are open-sourced, multiple stakeholders are involved, and during the preprocessing stage of algorithm development. More empirical studies are needed, with a focus on including participants who embrace greater diversity, such as nonbinary gender identities or Indigenous peoples in Canada.

Acknowledgments

The Protecting and Engaging Vulnerable Populations in the Development of Predictive Models in Primary Health Care for Inclusive, Diverse, and Equitable AI project is funded by the International Observatory on the Societal Impacts of AI and Digital Technology. The authors would like to thank Karine Gentelet for her contribution to the study's design and for obtaining the funding.

Data Availability

All data generated or analyzed during this study are included in this published article and Multimedia Appendices 1-3.

Authors' Contributions

MS, MPG, CR, VC, PD, JSP, and DD designed the study and obtained the funding. MS, MPG, SO, and FB developed the search strategy. MS, SO, MS, CR, MPG, VC, and FB participated in the screening of sources. MS, SO, and MPG conducted the data extraction. SO, MS, and MPG completed the first draft of the manuscript, and all authors participated in the revision and editing of the manuscript versions. All authors reviewed and approved the final manuscript.

Abstract

Background: The escalating global scarcity of skilled health care professionals is a critical concern, further exacerbated by rising stress levels and clinician burnout rates. Artificial intelligence (AI) has surfaced as a potential resource to alleviate these challenges. Nevertheless, it is not taken for granted that AI will inevitably augment human performance, as ill-designed systems may inadvertently impose new burdens on health care workers, and implementation may be challenging. An in-depth understanding of how AI can effectively enhance rather than impair work conditions is therefore needed.

Objective: This research investigates the efficacy of AI in alleviating stress and enriching work conditions, using intensive care units (ICUs) as a case study. Through a sociotechnical system lens, we delineate how AI systems, tasks, and responsibilities of ICU nurses and physicians can be co-designed to foster motivating, resilient, and health-promoting work.

Methods: We use the sociotechnical system framework COMPASS (Complementary Analysis of Sociotechnical Systems) to assess 5 job characteristics: autonomy, skill diversity, flexibility, problem-solving opportunities, and task variety. The qualitative analysis is underpinned by extensive workplace observation in 6 ICUs (approximately 559 nurses and physicians), structured interviews with work unit leaders (n=12), and a comparative analysis of data science experts' and clinicians' evaluation of the optimal levels of human-AI teaming.

Results: The results indicate that AI holds the potential to positively impact work conditions for ICU nurses and physicians in four key areas. First, autonomy is vital for stress reduction, motivation, and performance improvement. AI systems that ensure transparency, predictability, and human control can reinforce or amplify autonomy. Second, AI can encourage skill diversity and competence development, thus empowering clinicians to broaden their skills, increase the polyvalence of tasks across professional boundaries, and improve interprofessional cooperation. However, careful consideration is required to avoid the deskilling of experienced professionals. Third, AI automation can expand flexibility by relieving clinicians from administrative duties, thereby concentrating their efforts on patient care. Remote monitoring and improved scheduling can help integrate work with other life domains. Fourth, while AI may reduce problem-solving opportunities in certain areas, it can open new pathways, particularly for nurses. Finally, task identity and variety are essential job characteristics for intrinsic motivation and worker engagement but could be compromised depending on how AI tools are designed and implemented.

Conclusions: This study demonstrates AI's capacity to mitigate stress and improve work conditions for ICU nurses and physicians, thereby contributing to resolving health care staffing shortages. AI solutions that are thoughtfully designed in line with the principles for good work design can enhance intrinsic motivation, learning, and worker well-being, thus providing strategic value for hospital management, policy makers, and health care professionals alike.

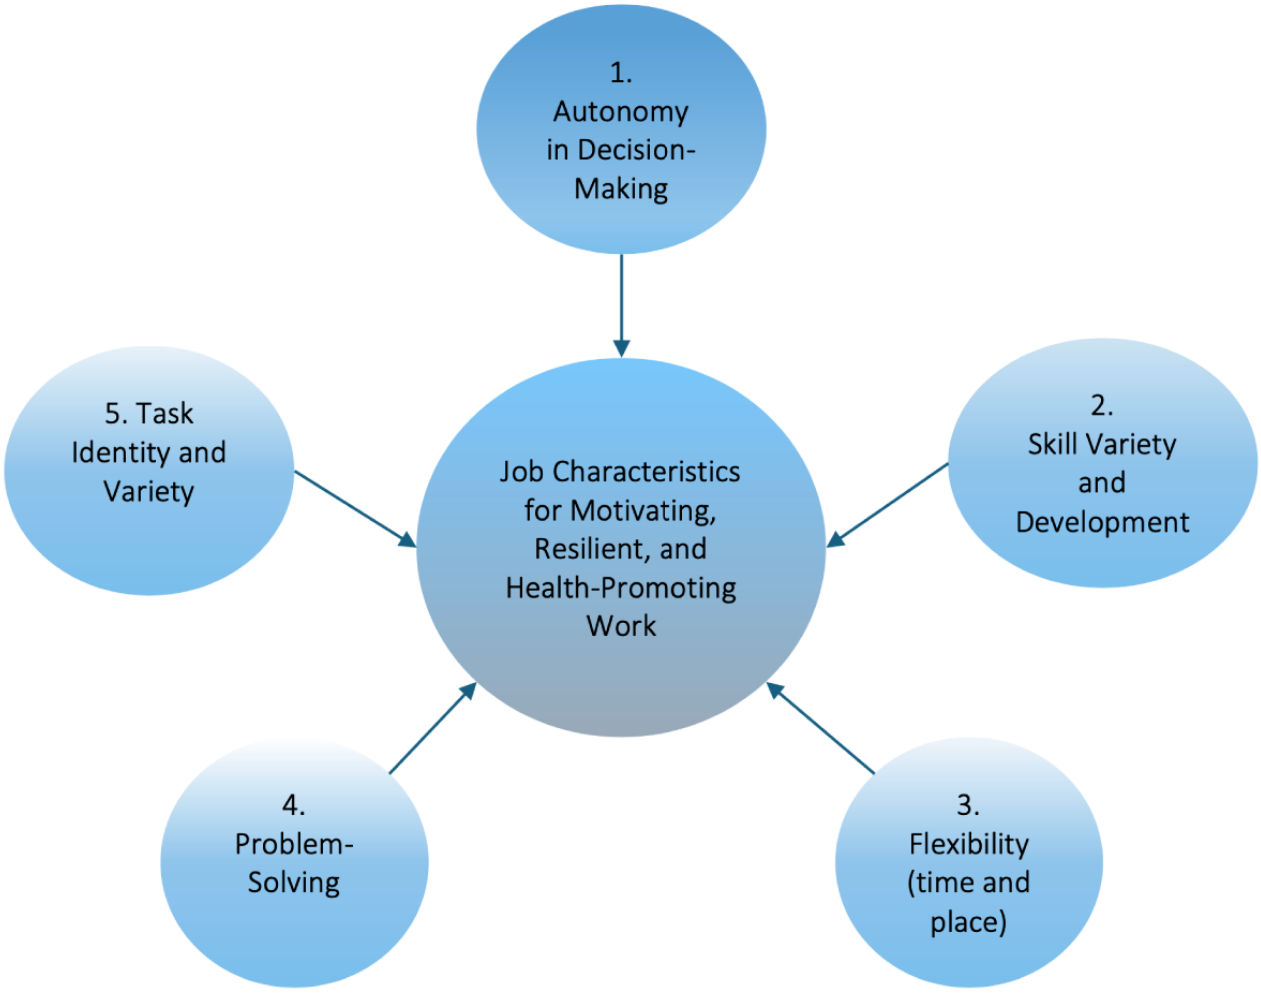
Introduction

According to projections by the World Health Organization, by 2030, the world will witness a global deficit of 18 million health care workers, more than double the current shortfall, with potentially far-reaching implications for patient care and health care delivery [1,2]. This alarming prediction underscores not only a public health crisis but also a wider social and economic dilemma, as the shortage of health care workers significantly impairs the resilience of health systems, undermines public health outcomes, and exacerbates inequities in health care access [3]. This global concern is attributed to demographic changes such as an aging population, an increase in chronic illnesses, and a scarcity of both educational and financial resources [4,5]. Escalating this issue are high rates of absence and turnover, driven by an unprecedented level of physician and nurse burnout due to psychosocial stressors and occupational hazards such as exposure to infectious diseases, shiftwork, or ergonomic challenges, that place health care workers at risk for long-term mental and physical health consequences [6-9]. These conditions are aggravated by the emotional labor and the high-stakes environment of health care settings, resulting in professionals leaving their careers due to overwork, demotivation, or dissatisfaction [10,11].

Artificial intelligence (AI) and machine learning–based applications have emerged as promising tools to address these challenges by potentially improving work conditions and mitigating personnel shortages [12-14]. Yet, the adoption of AI in real-world health care settings has been notably sluggish, a trend associated, in part, with high acquisition costs, increased training needs, and other implementation challenges such as the "black box" nature of AI systems [15,16]. Due to the opacity of current AI systems, health care practitioners often are uncertain about the AI decision-making process, which has implications for trust and AI acceptance [15,17,18]. Moreover, it is a fallacy to presume that AI will automatically enhance human performance and work conditions. As past evidence shows, the introduction of digital technologies intended to improve the work of health care professionals has, at times, introduced new burdens on workers due to systems being ill-designed, with scant regard for the nuances of organizational and worker needs [19-23].



For technology to have the desired positive impact on performance and to engender motivating working conditions for health care staff, a comprehensive sociotechnical system design approach is required—one that incorporates principles of human-centered design along with work design [24,25]. This approach advocates for technology, organizational processes, and human tasks to be jointly designed and implemented to fully harness the benefits of a new technology such as AI [26,27].

While there is abundant research on the human-centered design of AI in health care—with a primary focus on enhancing the user experience and facilitating the interaction between single users and AI [28]—research often overlooks how multiple clinicians use AI collaboratively as an integral part of their work tasks and professional roles. Therein lies a research gap: understanding the use of AI beyond individual interactions to encompass the multiprofessional dynamic collaborations so vital to today's complex health care delivery systems.

We, therefore, examine the design of human tasks and processes within the framework of sociotechnical systems in the introduction of AI within dynamic interprofessional team collaboration in critical care settings. We apply the well-established and empirically validated work system assessment tool COMPASS (Complementary Analysis of Sociotechnical Systems [29-31]), to analyze structured data from workplace observation and interviews and to assess five job characteristics essential for enhancing intrinsic motivation, learning, and resilience among health care workers [32-34]. As depicted in Figure 1, the five job characteristics of human-centered work design are (1) autonomy in decision-making; (2) skill variety and competence development; (3) flexibility in terms of time, place, and type of work; (4) problem-solving opportunities; and (5) task identity and variety.

Figure 1. Five job characteristics for motivating, resilient, and health-promoting work.

Our study of the sociotechnical integration of AI centers around critical care teams, specifically intensive care unit (ICU) nurses and physicians. The ICU context was selected due to the particularly high job demands and increased rates of burnout, which were exacerbated by the extreme work conditions during the SARS-CoV-2 pandemic [35-37]. Because the joint optimization of social and technical aspects of work systems must be considered before a technology is introduced into the workplace [38], we first assess the current work situation in ICUs to then compare it with future work scenarios after AI implementation. This comparison is based on the optimal levels of human-AI teaming for core ICU tasks as identified in a prior study [39] and key job characteristics for motivating, resilient, and health-promoting work. Our findings lead to actionable recommendations for AI design and implementation that alleviate working conditions for critical care nurses and physicians to ultimately improve the quality of patient care.

Methods

Ethical Considerations

Ethics approval was obtained from the ETH Zurich Ethics Commission (EK 2019-N-51 and EK 2019-N-190). Informed consent was obtained from participants before any form of data collection and the option to opt-out was provided. All data were anonymized. Participants did not receive any form of compensation. No patient data or information were collected.

Study Context

The study was carried out in six ICUs that were selected based on unit size (an average of 10 to 14 beds per unit) and patient scope (a capacity of about 800 patients treated per year). Of the 6 ICUs contacted, all agreed to participate in the study. Working shifts lasted 8.5 hours (morning 7 AM to 3:30 PM, afternoon 3 PM to 11:30 PM, and night 11 PM to 7:30 AM).

Sampling Strategy

In line with the COMPASS guidelines (Multimedia Appendix 1), we observed 5 morning shifts in each ICU, resulting in a total of 30 shifts lasting 8.5 hours each. Contingent upon each ICU's number of beds, the team composition varied slightly, with 6 to 8 physicians and 8 to 12 nurses working together for each shift. This resulted in a total of approximately 559 health care professionals observed in this study. All nurses were registered nurses. Nurses in training and nurse practitioners were excluded from the study as they could have distorted the results based on their lower level of expertise and potentially different experience of work demands. Resident physicians oversaw up to 5 patients and attending physicians were ultimately responsible for all patients in the unit. Due to the relatively small number of attending physicians working in each

XSL•FO
RenderX

unit, we combined residents and attending physicians into one professional group, hereafter referred to as physicians. To complement the worker perspectives, we additionally conduct n=12 structured interviews (6 head physicians, 5 nursing staff heads, and one head of nursing education).

Work System Assessment

Assessment Tool

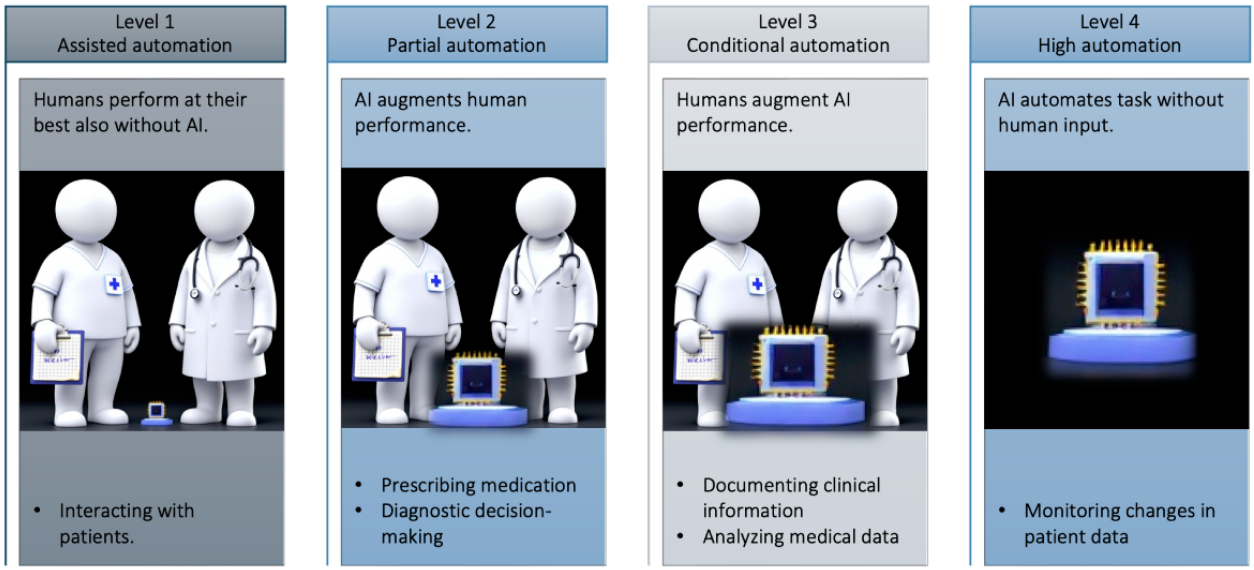
We used the well-established and empirically validated work system assessment tool COMPASS [29-31,40] to assess and compare the current and future work states across the 6 ICUs. COMPASS analyzes structured data from workplace observations and work unit head interviews using normative criteria based on sociotechnical systems theory (Multimedia Appendix 1).

Workplace Observations

The first author (NB)—a work and organizational psychologist with 15 years of experience in work system analysis and qualitative research methodology—applied the structured observational guidelines provided by COMPASS, to observe the work practices of ICU nurses and physicians in-situ (see the full set of observational guidelines and criteria in Multimedia Appendix 1). As a nonparticipant observer, she took detailed notes on a notepad standing in the background about five feet away, and where suitable, asked clarifying questions from health care professionals.

Interviews With Work Unit Heads

In addition to workplace observations, the first author (NB) also conducted 12 structured COMPASS interviews with each of the 6 ICU head physicians, 5 nursing staff heads, and 1 head of nursing education. Interview questions related to the overall work system structure, professional roles and responsibilities, work process variances, and disturbances (see the full list of interview questions in Multimedia Appendix 2). Interviews were conducted in single-person offices, lasted around 60 minutes, and were audio-recorded and transcribed ad verbatim.



Data Analysis

Interview transcripts and notes from observations were methodically analyzed using the COMPASS guidelines [29,30] and a grounded theory approach [41] to ensure qualitative rigor in qualitative research [42]. The software MAXQDA (version 2020; Verbi) was used to facilitate the analytical process [43]. Qualitative results are reported as per the standard published by the Academy of Medicine [44] (see the completed checklist in the Multimedia Appendix 3). To further enhance the trustworthiness of results, the data from observations and interviews were triangulated with additional data gathered from hospital documentation such as descriptions of job profiles and professional competencies, organizational charts, and technology user manuals. A total of 6-member checking workshops [45] were conducted (one in each unit), and 2 work unit heads validated the accuracy and adequacy of the analysis concerning the correctness of medical knowledge, contextual fit of interpretations, and adequate use of terminology [46].

Mixed Methods Study to Identify Optimal Levels of Human-AI Teaming Across ICU Tasks

To assess AI-induced work system changes, we used COMPASS to evaluate each of the 5 job characteristics based on the optimal levels of human-AI teaming for each ICU task. The optimal levels of human-AI teaming for each ICU task were identified in a mixed methods study [39] and summarized in Figure 2 [39].

Figure 2. Summary of results from Bienefeld et al [39], a mixed-method study identifying optimal levels of human-AI teaming in a sample of n=19 data science experts and n=61 nurses and physicians. AI: artificial intelligence.

Results

Overview

In the following, we report the results of our analysis of AI-induced changes to key job characteristics for motivating, resilient, and health-promoting work in the example of ICU nurses and physicians. Table 1 summarizes the 5 job characteristics together with definitions and example quotes from interviews.

Table 1. Five job characteristics, their definition, and example quotes from structured interviews.

Job characteristics	Definition	Example quotes from interviews (n=12 ICU[a] head physicians and nurses)
Autonomy in decision-making	The ability to make work-related decisions based on one's own level of professional expertise rather than decisions by supervisors or SOPs[b]	"Of course, we need to follow lots of standards and guidelines here [in the ICU], but it doesn't feel that way [restrictive] because every patient is different, and I have the possibility to adapt my actions to what a specific patient needs. I always need to anticipate, observe, and decide what's next, not one patient reacts in the same way. That makes it interesting. I see the guidelines as some sort of crash barriers, they are there to protect you. But they cannot be too narrow, you need to improvise sometimes, or else it wouldn't work. Like when things go wrong with technology, you need to solve it quickly on your own because your patient's life depends on it. All this makes our jobs challenging but interesting." [Head nurse, #7]
Skill variety and competence development	Opportunities for using a range of skills, applying one's expertise and further developing competencies based on the qualification demands and the level of qualification	"Sometimes it can be tricky for us [nurses] when we are at the patient's bedside and we clearly see that we need to do something [eg, administer some medication], but technically we can't because it's their [physicians'] responsibility. Rather than having to wait, it would be great if we could check with an AI or something right there in the moment and have the competence to act." [Head of nurse education, #12]
Flexibility regarding time, place, and type of work	Influence over working conditions regarding the type and place of work and temporal flexibility regarding when the work is done	"[The lack of flexibility] in scheduling is what makes it difficult for many of us [nurses]. Especially when you have kids, [working in shifts] is just not compatible. We are quite a good team and organize ourselves via WhatsApp to swap around etc but that's not a great solution. Or if we could at least have lunch in the canteen [away from the ICU], to air out our heads or get some air, that would already help. Sometimes, it feels like you are tethered to your patient's bed all day long." [Head nurse, #8].
Problem-solving opportunities	The degree of cognitive complexity required for problem-solving tasks and the possibility to perform problem-solving tasks	"Doing the mentally challenging detective work [to diagnose a patient] that's what makes this profession [of an ICU physician] so rewarding. When you are able to make a very sick patient well again because you figure out how all the pieces of the puzzle fit together. I think that's an important part [of being a physician] for most of us and I sure wouldn't want to miss it." [Head physician, #1]
Task identity and variety	The ability to perform complete tasks or processes and to perform multiple tasks within the work system	"There is never a dull moment here [in the ICU] for sure. So many different things to do, maybe sometimes too many [laughs]. To me, and I think many of my colleagues is to see when a patient comes to us, very sick and we think he [or she] might not survive. And after several weeks here [in the ICU], he [or she] can go home to his [or her] family. Then we know, we [the team of physicians and nurses] did everything we could to make this happen and that's when I know why I like this job." [Head physician, #3].

[a]ICU: intensive care unit.

[b]SOP: standard operating procedures.

Autonomy in Decision-Making

The generally high levels of autonomy in decision-making and the associated ability to solve problems locally at their source were identified as major strengths in the current work system without AI. When implementing AI in safety-critical systems like the ICU, it is important to maintain high levels of human autonomy to enable agility and resilience in terms of quick reactions to fast-changing patient states, varying patient volumes, technological disturbances, and fluctuating personnel resources. If AI were to drastically increase the levels of AI-based standardization and regulation (eg, to enable robust AI performance), work processes would become more rigid, people's decision-making autonomy would be undermined and the equilibrium between standardization and flexible action by human operators could eventually tip out of balance. In addition, people's sense of autonomy in decision-making is essential for intrinsic motivation and job satisfaction. Physicians generally have high levels of autonomy in performing tasks, though within the typical decision-making hierarchy (eg, attending physicians must sign off decisions suggested by resident physicians). With the proposed level 2 (partial automation) autonomy in decision-making can be maintained for diagnostic decision-making and prescribing medication or treatment tasks but could potentially be threatened for the task of analyzing medical data (level 3). Without AI, nurses' autonomy in decision-making is currently limited with a high dependency on decisions made by physicians for any task that is outside of their decision-making scope (eg, physicians must sign off before medication can be administered). The use of AI could eventually increase autonomy in decision-making for nurses, for example, by using AI to perform additional tasks such as analyzing medical data (level 3) or delivering certain types of treatment (level 2). This increase, however, would require significant changes to nurses' education, their roles, and responsibilities, as will be discussed in more detail below.

XSL•FO
RenderX

Skill Variety and Competence Development

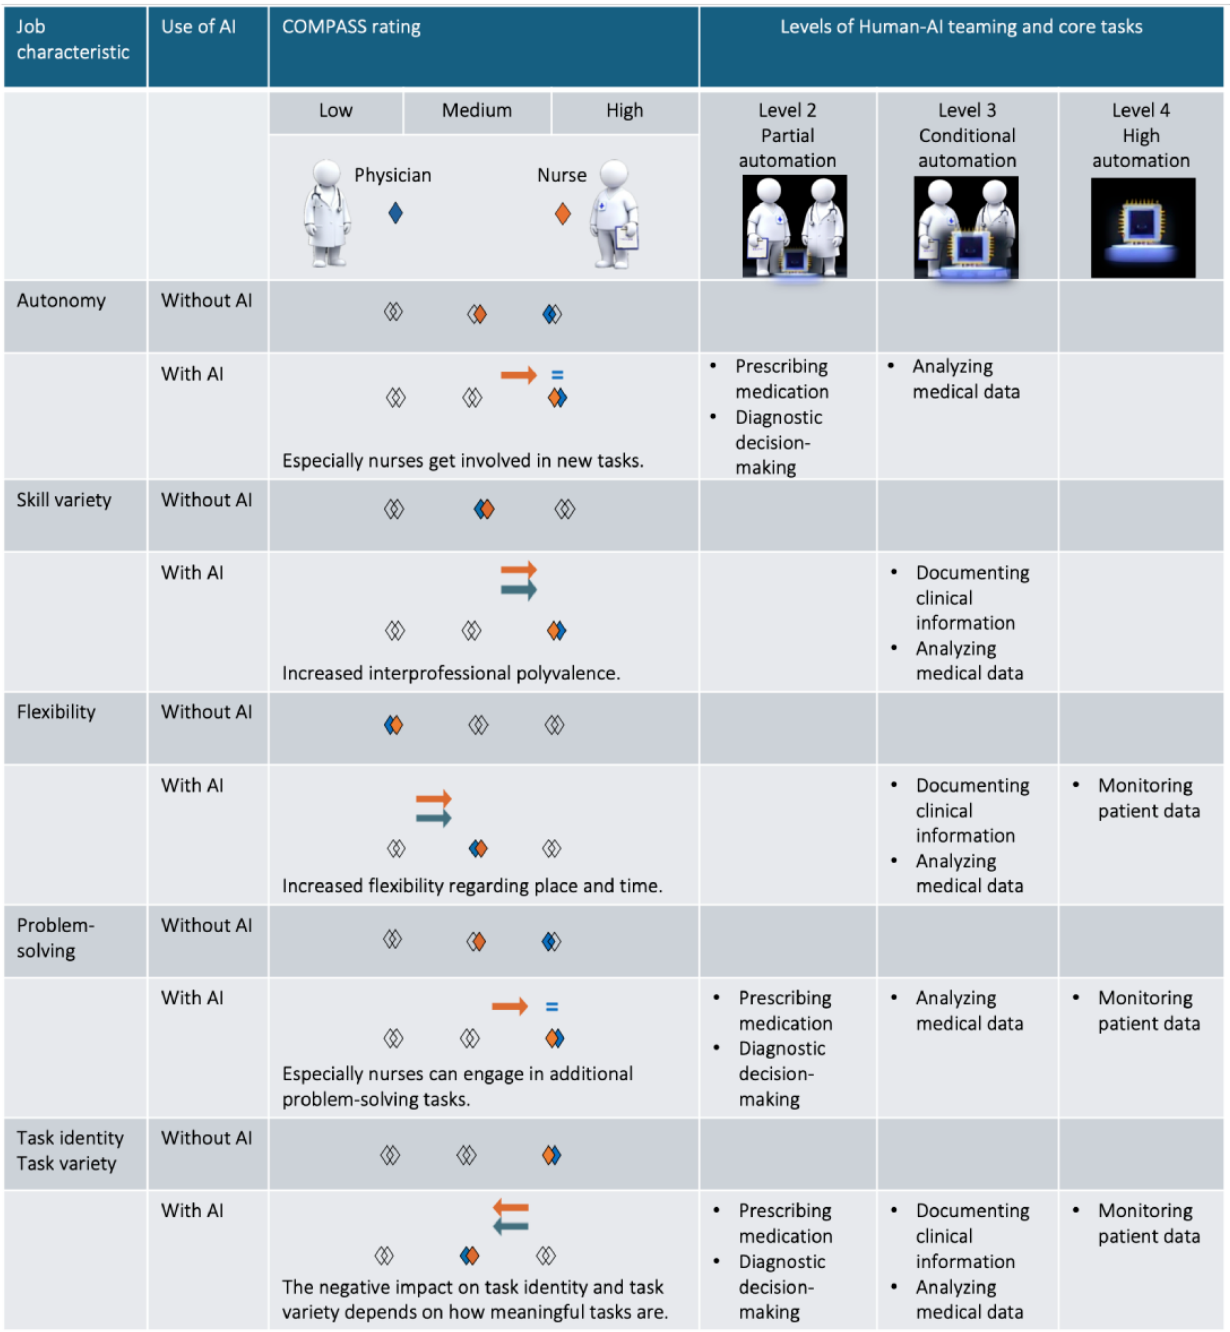
A second consideration for improved work design with AI is the currently low level of cross-skilling between nurses and physicians. This hampers interprofessional collaboration and problem-solving abilities as well as their competence development. Even though without AI, nurses and physicians are regularly applying their unique professional skills and can expand their knowledge through academic or on-the-job learning, these learning opportunities are mostly offered separately within each professional group. With the assistance of increasingly reliable and robust AI, for example, to analyze medical data and document clinical information (level 3), especially nurses could broaden their skill set to increase polyvalence across professional groups. AI augmentation of these tasks would thus potentially enable more cohesive and synergetic interprofessional collaboration practices. At the same time, with AI facilitating administrative tasks, physicians could spend more time interacting with patients, which would further strengthen interpersonal skills.

Flexibility Regarding Time, and Place of Work

The work system analysis revealed that without AI, nurses and physicians have very limited control over the type, time, or place of work. This negatively impacts their sense of personal agency at work. Low flexibility is inevitable due to shift work requiring physical presence 24/7. However, low flexibility is a major barrier to intrinsic motivation and job satisfaction because it restricts people's sense of autonomy and mobility, as well as their ability to integrate work with other life domains [47]. Flexibility could be increased, for instance, if AI would automate the task of monitoring patient data (level 4), enabling nurses to temporarily leave the patient's bedside without missing critical events. Moreover, with highly reliable AI to provide early warnings of upcoming complications, clinical staff could intervene long before patients enter a critical state [48,49]. This would increase their ability to plan and coordinate tasks within and across professional boundaries. In addition, if AI could assist in the documentation of clinical data and the analysis of medical data (level 3), not only would there be significant efficiency gains, but also the flexibility regarding when and where to accomplish these tasks would be increased.

Problem-Solving Opportunities

The analysis of work in the ICU without AI revealed high levels of problem-solving opportunities for physicians and medium levels for nurses. Typical activities performed by physicians such as overseeing, planning, and deciding about patients' diagnoses and treatments, require high levels of cognitive engagement. With AI-based task augmentation in diagnostic decision-making and prescribing medication and treatment (level 2), problem-solving opportunities for physicians are likely to remain high because the ability to validate or refute the suggestions made by an AI requires advanced expert knowledge and problem-solving skills. For nurses, a significant amount of attention and cognitive resources are needed for monitoring patients and interacting with them. With AI automation of monitoring tasks (level 4), nurses would likely require fewer cognitive resources in this area, which would free up cognitive capacity for other problem-solving tasks. For example, experienced nurses who have developed implicit knowledge or intuitive hunches about upcoming patient complications but are uncertain whether to communicate this information across interprofessional hierarchies could use AI to analyze medical data (level 3) in order to validate (or refute) these hunches, which would ultimately improve knowledge sharing and problem-solving in interprofessional care teams.



Task Identity and Variety

The completeness of tasks (eg, doing a work task or process from start to finish), is the basis for task identity; which enables local control of variances and disturbances and allows workers to anticipate and swiftly react to upcoming problems. Without AI, task identity and variety are rated as medium for both nurses and physicians. Physicians concentrate on patient diagnosis, goal setting, and planning behaviors, while nurses focus more on preparation, execution, and controlling behaviors, as well as patient care activities. The suggested levels of AI automation for three core tasks (monitoring medical data, documenting medical information, and analyzing medical data), could lead to a significant decrease in task identity and variety. Furthermore, if nurses and physicians were to take on only supervisory control or trouble-shooting roles when collaborating with AI, their ability to solve problems locally and directly would be heavily diminished. However, whether such changes negatively impact job satisfaction and well-being depends on how important professionals perceive each task as part of their identity. For instance, (partly) automating the labor-intensive and tedious task of documenting medical information might be a welcome relief for physicians, whereas an AI-based analysis of medical data might impair their capacity to anticipate and adequately react to patient complications [50,51].

Figure 3 shows the comparative summary of results, sorted along the 5 job characteristics and optimal levels of human-AI teaming [39]. Level 1 automation is not included because AI developers and clinicians saw the use of AI in direct patient interactions as undesirable due to social and ethical concerns.

XSL•FO
RenderX

Figure 3. Summary of AI-induced changes to key job characteristics, based on a comparative analysis of ICU nurses' and physicians' work with versus without AI combining observational data (approximately 559 ICU nurses and physicians) and data from structured interviews (n=12 ICU head nurses and physicians). Arrows pointing to the right signify an improvement; arrows to the left a deterioration. The equal sign signifies no change. Nurse-specific changes are displayed in orange; physician-specific changes are in blue. The category "Nurses" includes only registered nurses. The category "Physicians" combines resident and attending physicians. AI: artificial intelligence; COMPASS: Complementary Analysis of Sociotechnical Systems; ICU: intensive care unit.

Discussion

Principal Findings

This study has explored how the use of AI can mitigate the increasing rates of stress and dissatisfaction among overworked ICU nurses and physicians, thus improving their work conditions and potentially contributing to reducing the global scarcity of skilled labor in this domain. We applied a sociotechnical system perspective in the analysis of current and future work scenarios to identify how AI impacts key job characteristics for motivating, resilient, and health-promoting work. As discussed in detail below, our findings highlight four areas where AI can enhance work conditions for at least one professional group and one area where the application of AI should be cautiously approached.

First, autonomy in decision-making is a fundamental aspect of work design due to its impact on multiple outcomes such as stress, motivation, learning, and performance. From a stress perspective, autonomy enables individuals to exert control over environmental demands, thereby reducing stress [52]. Moreover,

XSL•FO
RenderX

extensive research suggests that job autonomy contributes to a sense of meaning and purpose in the workplace [53]. This, in turn, leads to lower turnover rates, decreased absenteeism, and increased creativity, proactivity, and, ultimately, performance [54]. Autonomy leads to improved problem-solving because decisions can be made locally, that is, problems are solved directly at the source where they arise [26,55]. A decrease in autonomy in decision-making would not only lead to the loss of these beneficial effects but likely result in limited AI acceptance and adequate use altogether. A recent study demonstrated that when radiologists felt their autonomy in decision-making was reduced by AI (because they could not understand why the system made certain recommendations), they refused to use it or found ways to override the system. Other AI systems that provided higher levels of transparency and allowed radiologists to feel "in charge" had higher acceptance rates and truly augmented their work [56]. Similar results were found in a study on an AI-based system for sepsis prediction [57] and in a study where data scientists and clinicians co-designed an algorithm to predict delayed cerebral ischemia [18]. In line with this literature and work design theory [58], maintaining human autonomy in decision-making is crucial and can be achieved by designing AI systems that provide high levels of transparency, predictability, and controllability [39].

Second, AI can be used to boost skill variety and competence development, two important job characteristics for perceiving work as stimulating, experiencing mastery of one's work, and enabling lifelong learning [59]. Especially nurses would benefit from AI to develop new competencies and gain additional responsibilities. AI-enabled upskilling would not only be an important source of personal growth and motivation for nurses but could create a much-needed interprofessional skill set for managing clinical staff shortages. Furthermore, training nurses and physicians on how to best collaborate with AI—and each other—could help improve interprofessional collaboration overall [60]. On the other hand, failure to consider skill variety and competence development can lead to the deskilling of experienced professionals, that is, the loss of relevant knowledge and skills over time [61]. This would be problematic not only for experienced professionals but especially for younger colleagues who still need to develop a broad set of skills and expertise to be able to evaluate AI-based recommendations and intervene in case of system malfunctions.

Third, providing people with more flexibility regarding time, type, and place of work stimulates personal agency, which is at the core of intrinsic motivation [62]. AI could be used to increase flexibility by (partly) automating the tasks of monitoring patient data and documenting clinical information. By liberating nurses and physicians from such time-consuming monitoring and administrative tasks, they could engage in more meaningful work such as interacting with and more directly caring for their patients. Moving away from the computer and back to the patient's bedside is a wish many health care professionals entertain. Strengthening the uniquely human qualities of empathy, compassion, and interpersonal connection has become increasingly important in a technology-driven world [63]. AI could also increase flexibility regarding the place of work (eg, by predictive analytics and remote patient monitoring [48,64]) and time of work (eg, by designing smart rosters that consider individual needs and preferences). Increased flexibility regarding the time and place of work would ultimately facilitate better work-life integration to accommodate family and other life domains—a known factor associated with high turnover rates in health care professionals [65,66].

Fourth, problem-solving opportunities help create stimulating and meaningful work [67,68]. According to our assessment, problem-solving opportunities are likely to stay high for physicians because they remain in control of tasks such as diagnostic decision-making. For nurses, problem-solving opportunities were associated mainly with monitoring activities. With the automation of monitoring tasks by AI, nurses would have fewer problem-solving needs in this domain, but AI could create new opportunities for problem-solving in other areas. For instance, by developing new skills and using AI to analyze medical data, nurses could engage more deeply in cognitive problem-solving activities, which would deepen their understanding of a patient's medical condition and likely improve interprofessional communication and collaboration. However, given the current hierarchical structure of ICU teams, such changes would require significant adaptations in nurses' educational curricula, roles, and career paths, including new regulations regarding legal accountability and reimbursement strategies [69,70].

Finally, task identity and variety are important factors for intrinsic motivation and worker engagement, and were rated as high in work conditions without AI. To maintain high task identity and variety, it is important to balance different forms of human-AI teaming as suggested by Bienefeld et al [39]. Assigning humans with leftover tasks (ie, tasks that cannot be executed by technology) can otherwise result in decreased motivation and make automated systems brittle and prone to errors [71,72]. Against the common belief that automating complex tasks leaves the easy aspects for humans, automation can make the role of humans more challenging, thus hindering their ability to intervene effectively in the event of system failures. This phenomenon, known as the "out of the loop" performance problem [73], results in human operators becoming progressively less capable of detecting system errors and reacting appropriately when automation malfunctions. This problem has been observed, for example, in the aviation industry, where pilots could no longer foresee or understand the automated actions of the flight management system, prompting inappropriate reactions that led to many tragic accidents [74-76]. Moreover, even as the potential of AI tools in health care increases and more and more tasks can potentially be automated or augmented by AI [77], it is important to allow ICU nurses and physicians to engage in a range of activities to maintain adequate levels of task variety.

Considering today's grand health care challenges such as the high rates of attrition and shortage of skilled labor, we hope that our predictive analysis of how AI will impact the quality of work of nurses and physicians inspires all involved stakeholder groups (eg AI developers, hospital management, and policy makers) to think carefully about whether a given technology really improves the work task or process in question. Our results predict higher worker motivation, satisfaction, and

XSL•FO
RenderX

well-being and fewer AI implementation hurdles if AI tools are developed and implemented in line with the principles for good work and sociotechnical system design [32,58,78]. Future researchers should continue to analyze the short and long-term effects of AI implementation in real-world health care settings, also considering additional factors such as resistance to change, team dynamics, and the role of leadership [79]. Implementation research [80] practices, like technological co-design [18] and stakeholder involvement [81], could be used to facilitate such endeavors.

Limitations and Future Research Directions

As with any study, there are various limitations to consider when interpreting the results. While the COMPASS methodology is a theory-based, empirically validated, and highly structured tool in sociotechnical systems and work design research, we are mindful of the potential biases such as the Hawthorne effect [82] such a tool may introduce. In this study, we have undertaken due diligence to minimize such biases by taking the following measures: (1) observations were conducted as unobtrusively as possible with the observer wearing nurse gowns and standing in the background about five feet away, (2) evenly distributing observations and interviews across the six ICUs to ensure comparability, (3) standardized observer and interview guidelines (Multimedia Appendices 1 and 2), (4) extensive observer training (>15 years of experience using the COMPASS tool), and (5) centering data collection within one experienced qualitative researcher with domain expertise in work and organizational psychology to avoid interrater bias [83]. Furthermore, our findings are likely most applicable to settings with similar boundary conditions regarding workload, tasks, and team dynamics (eg, emergency or acute care teams). Nonetheless, the qualitative nature of our work has allowed us to capture the situated work practices of ICU staff, which we hope provides valuable insights for future research and real-world clinical practice.

Even though we included a relatively large sample of approximately 570 ICU nurses and physicians in this study, we may not have captured the full spectrum of experiences within interprofessional ICU teams.

Future research should examine how additional roles, particularly those with lower levels of experience (eg, nurse students and junior residents), perceive and interact with AI. The use of AI is often seen as particularly beneficial for less experienced professionals [84] but at the same time, is a cause of concern: Less experienced professionals may rely too much on the assistance of AI to perform their work, thus cannot build important skills, and lack the necessary expertise to verify the adequacy of AI outputs. Studies to examine the nuanced effects across different levels of expertise are needed to avoid these dangers and to build AI systems that support all users effectively.

Finally, despite our focus on improving job resources through AI-based technologies, ICU nurses and physicians face multiple job demands such as time pressure, very complex patient cases, and emotionally demanding situations that may continue to exert a toll on them despite AI support. As previously mentioned, a balance between job resources and job demands [33,34] can render these demands tolerable. People-focused strategies such as mentorship or emotional support programs might also help to mitigate the many challenges [85]. In addition, exploring job crafting initiatives [86,87] could enrich our understanding as a complement to the top-down approach used in this study. For instance, job crafting activities, whereby workers themselves initiate changes to their work conditions, have proven highly effective in bypassing potential management or union resistance [58].

Finally, this paper could not delve into broader issues like economic pressures in health care. While worker motivation is multifaceted, fair pay as a fundamental need is, of course, also pivotal [88].

Conclusions

The integration of AI into critical care work presents multifaceted opportunities to enhance job satisfaction and well-being and ease the burden on staff. Specifically, our analysis demonstrates that AI can augment decision-making autonomy, encourage skill diversity and competence development, and increase flexibility—each a critical determinant of job satisfaction, well-being, and professional retention. Moreover, AI's potential to redistribute routine and administrative tasks can allow health care professionals to allocate more time to patient care and collaborative problem-solving, thus amplifying their effectiveness and job fulfillment.

It is imperative to say that AI's contribution extends beyond mere numerical staffing solutions. By strategically leveraging AI's capabilities, health care systems can enhance the quality of work for ICU professionals, fostering environments where job resources are amplified and job demands are diminished. This, in turn, can lead to heightened professional engagement and a corresponding reduction in the attrition rates that exacerbate staffing shortages.

However, it is critical to acknowledge that the deployment of AI must be thoughtfully managed to prevent the deskilling of professionals and to maintain the integrity of task identity and variety, which are essential criteria for continuously safe performance. Thus, while AI holds promise for addressing aspects of the health care staffing crisis, these technologies must be used as part of a broader strategy that includes sociotechnical system design and human-centric principles.

To this end, we conclude that AI—when incorporated in alignment with good work and sociotechnical system design principles—has the potential to significantly alleviate health care staffing shortages by making the work of nurses and physicians more attractive. The study results indicate that by tailoring AI to redistribute work tasks based on the synergistic interplay between human and AI capabilities, intrinsic motivation, resilience, and worker well-being can be elevated, and the retention of professional expertise can be ensured. Future research into the sociotechnical integration of AI in health care should look to include a wider array of team-based settings beyond critical care to encompass a broader spectrum of workers and explore the long-term impacts on the health care workforce and the patients they serve.

Acknowledgments

Our immense gratitude goes to all the clinicians who devoted their time to participate in this study. This work was supported by funding from the Swiss National Science Foundation (grant 407740_187331). The content and conclusions presented in this paper are those of the authors and should neither be construed as the official position or policy of nor should any endorsements be inferred by the Swiss National Science Foundation. We used Grammarly for Microsoft Office (free version) to suggest corrections for grammatical and spelling errors, as well as improve the flow of written sentences [89]. The generative AI tool ChatGPT by OpenAI [90] (free version) was used to suggest the title of this manuscript based on the abstract and in adherence with JMIR author guidelines. The original ChatGPT transcripts are made available as Multimedia Appendix 4.

Data Availability

Datasets generated during or analyzed during this study are available in the ETH Zurich Research Collection repository and accessible by the digital object identifier (DOI; 10.3929/ethz-b-000693893). The DOI issued to datasets in the repository can be included as part of a data citation in publications, allowing the datasets underpinning a publication to be identified and accessed. The full transcripts of the interviews are not publicly available to minimize the risk of participant reidentification. Summaries of the interview contents and related metadata that support these findings are available from the corresponding author upon reasonable request.

Authors' Contributions

NB and GG contributed to the initial study design. EK provided her medical expertise to set up the study and verify findings from the work system analysis. NB conducted all parts of the study and implemented the study protocol. NB and GG contributed to the review and analysis of the results. All authors contributed to the preparation of the manuscript. All authors approved the final version of this manuscript.

Abstract

Background: Speech sound disorders (SSDs) are common communication challenges in children, typically assessed by speech-language pathologists (SLPs) using standardized tools. However, traditional evaluation methods are time-intensive and prone to variability, raising concerns about reliability.

Objective: This study aimed to compare the evaluation outcomes of SLPs and an automatic speech recognition (ASR) model using two standardized SSD assessments in South Korea, evaluating the ASR model's performance.

Methods: A fine-tuned wav2vec 2.0 XLS-R model, pretrained on 436,000 hours of adult voice data spanning 128 languages, was used. The model was further trained on 93.6 minutes of children's voices with articulation errors to improve error detection. Participants included children referred to the Department of Rehabilitation Medicine at a general hospital in Incheon, South Korea, from August 19, 2022, to June 14, 2023. Two standardized assessments—the Assessment of Phonology and Articulation for Children (APAC) and the Urimal Test of Articulation and Phonology (U-TAP)—were used, with ASR transcriptions compared to SLP transcriptions.

Results: This study included 30 children aged 3-7 years who were suspected of having SSDs. The phoneme error rates for the APAC and U-TAP were 8.42% (457/5430) and 8.91% (402/4514), respectively, indicating discrepancies between the ASR model and SLP transcriptions across all phonemes. Consonant error rates were 10.58% (327/3090) and 11.86% (331/2790) for the APAC and U-TAP, respectively. On average, there were 2.60 (SD 1.54) and 3.07 (SD 1.39) discrepancies per child for correctly produced phonemes, and 7.87 (SD 3.66) and 7.57 (SD 4.85) discrepancies per child for incorrectly produced phonemes, based on the APAC and U-TAP, respectively. The correlation between SLPs and the ASR model in terms of the percentage of consonants correct was excellent, with an intraclass correlation coefficient of 0.984 (95% CI 0.953-0.994) and 0.978 (95% CI 0.941-0.990) for the APAC and UTAP, respectively. The *z* scores between SLPs and ASR showed more pronounced differences with the APAC than the U-TAP, with 8 individuals showing discrepancies in the APAC compared to 2 in the U-TAP.

Conclusions: The results demonstrate the potential of the ASR model in assessing children with SSDs. However, its performance varied based on phoneme or word characteristics, highlighting areas for refinement. Future research should include more diverse speech samples, clinical settings, and speech data to strengthen the model's refinement and ensure broader clinical applicability.

KEYWORDS

speech sound disorder; speech recognition software; speech articulation tests; speech-language pathology; child

Introduction

Background

Speech sound disorders (SSDs) are common communication disorders among children, wherein they experience difficulty producing speech sounds or using them correctly when compared to children of the same age [1]. In South Korea, approximately 44.1% of children undergoing speech therapy have SSDs [2], and around 9% of 6-year-old children exhibit articulation problems [3].

SSDs among children are evaluated by prompting spontaneous speech using single-word naming tasks, sentence repetition tasks, and connected speech tasks [4]. In South Korea, standardized assessment tools such as the Assessment of Phonology and Articulation for Children (APAC) and Urimal Test of Articulation and Phonology (U-TAP) have been predominantly used to assess children with SSDs in the clinical setting [5,6]. The percentage of correct consonants (PCC, %) serves as the primary criterion for diagnosing SSDs. Aside from PCC, speech error patterns must also be examined and analyzed throughout the entire transcription to guide the direction of intervention for children.

Nonetheless, traditional evaluation methods face two primary issues. First, these methods are time-consuming [4,7]. In fact, the process by which speech-language pathologists (SLPs) evaluate children with SSDs lasts approximately 2-2.5 hours, due to the need for accurate transcription and analysis of individual speech error patterns [7]. The second issue involves reliability, which has been attributed to slight differences in results depending on the tester, potentially arising from variations in the tester's skill level and the test environment [8,9].

Consensus among the SLPs is influenced by patterns of speech errors, with certain patterns being more readily recognizable than others. Studies have shown that misarticulations involving only one feature change are usually ignored, whereas those with two or more feature changes are readily recognized [9,10]. Moreover, evidence suggests that identifying misarticulations of vowels is more challenging than that of consonants [11], with combinations of both further increasing the difficulty [12]. Regarding consonants, listeners can more consistently detect voicing errors than they would changes in the place of articulation [13]. In particular, Klein et al [14] showed diversity in the ratings of /r/ production among SLPs, due to difficulties in auditory-perceptual discrimination. These studies suggest that SLPs find it more challenging to transcribe incorrectly produced phonemes than those produced correctly. Thus, streamlined and standardized evaluations are essential for achieving accurate and consistent assessments of speech sound errors in children with SSDs.

Prior Studies

Automating the process of transcribing children's speech and analyzing patterns of speech errors could enhance the efficiency and reliability of the evaluation process benefiting both patients and SLPs [8]. Investigations on automatic speech recognition (ASR) for assessing children with SSDs have used various approaches to enhance accuracy and reliability [15-18].

Traditional ASR models using the hidden Markov model (HMM) are divided into three parts: Lexicon, Acoustic, and Language models. Each part is modeled independently from each other. Suanpirintr and Thubthong [16] obtained a phoneme error rate (PER; the number of incorrectly recognized phonemes divided by the total number of phonemes) of 51.5% for dysarthria in Thailand using an HMM. Mazenan et al [17] also used an HMM for Malay SSDs, reporting low PER rates (approximately 3%) on various isolated phonemes; however, their results were limited to Malay alveolar sounds. Lee et al [18] evaluated articulation using an HMM targeting patients with dysarthria in South Korea and confirmed that their PCC results were strongly correlated with those of SLPs; however, no information was provided regarding the agreement between individual phonemes in the actual transcription results. Even though HMM has been used in many studies, developing HMM-based models requires considerable time and expertise, involving detailed data analysis and careful model validation.

Building on the strengths and limitations of HMM-based models, recent advancements have led to more advanced approaches like end-to-end models. These models simplify the process by directly linking inputs to outputs, removing the need for separate steps. As a preliminary investigation to this study, Ahn et al [19] confirmed that the end-to-end model (Wav2Vec2-XLS-R-1B) is suitable for evaluating children with SSDs even with limited training datasets for detecting speech errors. Owing to the pretrained framework of the Wav2Vec2-XLS-R-1B, it effectively learns from a wide variety of waveform contexts [19]. This pretraining allows the model to generalize well from smaller datasets and enables the model to better recognize and more accurately process Korean phonemes. They achieved approximately 90% accuracy in recognizing speech from children with SSDs in 73 Korean words using only about 1.5 hours of training data and without a language model. This suggests that sufficient accuracy can be attained in speech recognition models with low-resource languages to identify speech errors by using an end-to-end model.

Objective

This study aimed to (1) compare the evaluation results of the SLPs and the ASR model using South Korea's standardized SSD evaluation tools, specifically the APAC and U-TAP, and (2) analyze the cases of recognition errors occurring frequently in the ASR model.

Methods

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and was approved by the Institutional Review Board

XSL•FO
RenderX

of the Catholic University of Korea, Incheon St. Mary's Hospital (protocol code OC22OISI0041; received approval on August 19, 2022). All participants provided informed consent and were compensated with KRW 50,000 (approximately US $40) for their participation. Written informed consent was obtained from all parents. For children aged 7 years and older, additional written assent was collected. Research data were securely stored on hospital servers, separate from personally identifiable information except for study identification numbers. Access to and analysis of data were limited exclusively to preapproved researchers. This paper and any supplementary materials contain no identifiable images or personal information regarding participants.

Recruitment

Participants were recruited between August 19, 2022, and June 14, 2023, from children referred for speech and language evaluations in the Department of Rehabilitation Medicine at Incheon St. Mary's Hospital. Eligible participants were native Korean-speaking children younger than 18 years of age who were referred primarily due to concerns with articulation. Exclusion criteria included (1) intellectual disabilities or autism spectrum disorders that impaired effective engagement in the assessment; and (2) motor speech disorders, fluency disorders, a history of cleft palate, or severely reduced speech intelligibility that would hinder accurate transcription. Only children meeting these criteria, and whose parents provided consent, were included in the study.

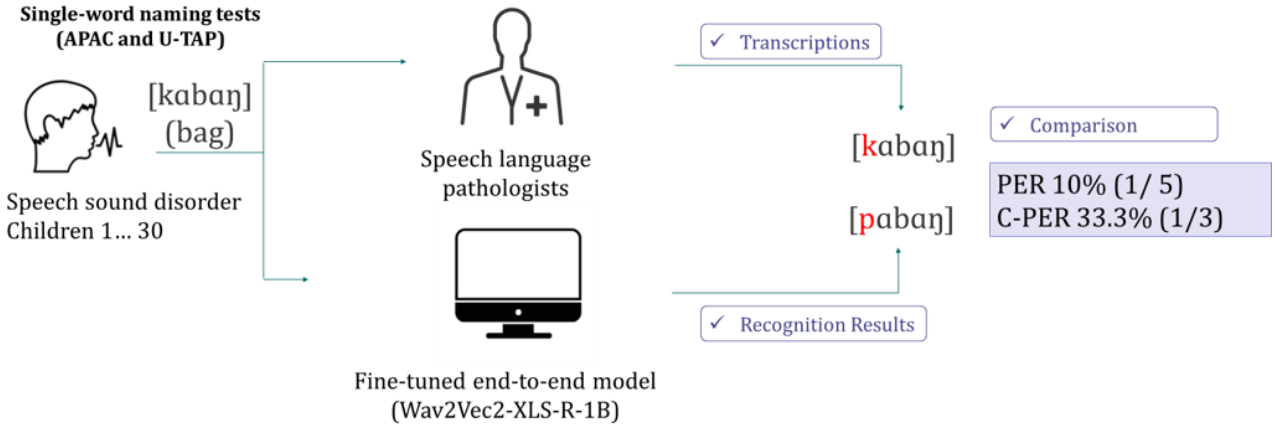
We included 30 children with suspected SSD (20 male and 10 female children; aged 3-7 years). The age and sex distribution of the participants were as follows: aged 3 years (2 male children), aged 4 years (10 male and 5 female children), aged 5 years (4 male and 1 female children), aged 6 years (2 male and 3 female children), and aged 7 years (2 male and 1 female children). The sample size was determined based on the median value observed in previous studies [20]. Additional participant information is provided in Multimedia Appendix 1.

ASR Model

The ASR model used in this study is an end-to-end model (Wav2Vec2-XLS-R-1B) originally provided by Facebook (Meta) as an open-source model [21] and modified by Ahn et al [19] to enhance its ability to detect speech error well in Korean children.

It was originally developed through training with 436,000 hours of data from adult voice databases, encompassing 128 languages. To enhance the model's ability to detect articulation errors, Ahn et al [19] used 93.6 minutes of speech data comprising 73 words from the APAC and U-TAP, and an additional 12 words, yielding a total of 6935 words from 95 children. The additional 12 words were selected during the engine fine-tuning stage to include phonemes and contexts not originally covered in the APAC or U-TAP. Detailed information regarding the word list for the model training can be found in Multimedia Appendix 2 [5,6].

Evaluation of Model Performance



This study used two Korean standardized SSD tests, namely the APAC and U-TAP, which comprised 37 and 30 words, respectively, with 6 words overlapping between the two tests. The examinations and recordings were conducted in the speech therapy room at Incheon St. Mary's Hospital by three experienced SLPs (DHK, JWJ, and DK), all of whom were trained in the assessment and treatment of children with SSDs. Although the facility was not completely soundproof, it was conducted in an environment where external noise was controlled.

During the test, the participants were asked to name pictures, and their responses were recorded using an iPhone X (Apple). In the recording process, a sufficient pause of 500-1000 ms was ensured between each target word. The recordings were saved in WAV format and converted to a 16 kHz sampling rate to verify the recognition results. Each target word was attempted at least twice, allowing for the exclusion of words with quality issues, such as noise or insufficient volume. After recording, files were reviewed, and the most suitable file was selected for analysis.

To ensure transcription accuracy, each word spoken by the participants in Korean was independently transcribed by two SLPs, and any disagreements were resolved by a third party for final decision-making. Transcription agreement between the two SLPs across all phonemes was 95% and 93.80% for the APAC and U-TAP, respectively, based on a 10% random sample of the data. The transcriptions created by the model were then compared to those obtained by the SLPs (Figure 1).

Variables

PER

The PER (%) has been used to determine the difference in the overall phoneme when comparing the transcription results of the SLPs and ASR model. The consonant PER (C-PER, %) was examined separately to analyze consonant errors in the ASR model.

PER and C-PER between the SLPs and the ASR model were conducted across all phonemes, regardless of whether they are target phonemes. This comprehensive approach is crucial given that the accuracy of the entire transcription is essential for assessing the clinical utility of the ASR.

Common ASR Disagreements

This count encompasses discrepancies between the SLPs and the ASR model, including instances where the SLPs flagged correct articulations that were identified as misarticulations by the ASR model, as well as cases where the SLPs identified misarticulations within the set that the ASR model failed to match. This indicator assesses which test words (or phonemes) differed considerably in evaluation between the SLPs and the ASR model during tests.

Target PCC

The PCC (%) is a metric used to assess consonant articulation accuracy. In this study, "target PCC" specifically refers to the percentage of correct consonant sounds produced for the target phonemes, in each word test (ie, the APAC and U-TAP). Additional information about the target phonemes, and the number of production opportunities are provided in Multimedia Appendix 3.

Severity

The *z* scores discussed in this study were based on the target PCC, which is used to evaluate the severity of SSDs. These *z* scores were calculated from the children's assessments conducted by both the ASR model and the SLPs, after which the severity was compared between the two.

Statistical Analysis

All data collected in this study were analyzed using SPSS (version 25.0; IBM Corp) for Windows. Descriptive statistics were used to describe the general characteristics of the evaluation results. The interrater reliability was calculated using the intraclass correlation coefficient (ICC) with a two-way random model, which served as the reliability coefficient for assessing the agreement on target PCC between the SLPs and the ASR model, using the absolute agreement method. Statistical significance was set at .05. The interpretation of the ICC was based on Landis and Koch [22].

Results

PERs

The PER, which indicated that the percentage of phonemes where the transcriptions by the SLPs and the ASR model differed among total phonemes, were 8.42% (457/5430) and 8.91% (402/4514) for the APAC and U-TAP, respectively. Additionally, the C-PER was 10.58% (327/3090) and 11.86% (331/2790) for APAC and U-TAP, respectively. The APAC uses a total of 174 phonemes, whereas the U-TAP consists of a total of 151 phonemes.

Common ASR Disagreements

Disagreements in Correct Articulations

An average of 2.60 (SD 1.54) and 3.07 (SD 1.39) phonemes per child were transcribed as correctly produced by the SLPs but incorrectly produced by the ASR model, totaling 78 and 92 instances among 30 children, in the APAC and U-TAP, respectively. Table 1 presents the percentage of phonemes that were judged by the SLPs as correctly produced but identified as incorrectly produced by the ASR model. Table 2 lists the types of disagreements that occurred three or more times.

Disagreements in Misarticulations

The disagreements for phonemes transcribed as misarticulations by the SLPs averaged 7.87 (SD 3.66) and 7.57 (SD 4.85) occurrences per child, totaling 236 and 227 times among 30 children in the APAC and U-TAP, respectively. Table 3 presents the percentage of sounds that were judged by the SLPs as incorrectly produced but were identified as different by the ASR model. Table 4 lists the types of disagreements that occurred three or more times.

Target PCC

For the APAC, the mean target PCC was 74.76% (SD 15.21%) for SLPs and 76.71% (SD 15.20%) for the ASR model. The ICC for APAC demonstrated excellent reliability, with a value of 0.984 (95% CI 0.953-0.994). Similarly, for the U-TAP, the mean target PCC was 73.88% (SD 16.13%) for SLPs and 76.05% (SD 15.26%) for ASR. The ICC for U-TAP also indicated strong reliability, with a value of 0.978 (95% CI 0.941-0.990). The APAC uses 70 target consonants out of a total of 174 phonemes, whereas the U-TAP is based on 43 target consonants out of a total of 151 phonemes.

Severity

Table 5 displays the *z* scores for the target PCC in each test, as evaluated by the SLPs and ASR. The *z* scores between SLPs and ASR showed more pronounced differences with the APAC than with the U-TAP, with 8 individuals showing discrepancies in the APAC compared to only 2 in the U-TAP. The variations in *z* scores for each child are detailed in Multimedia Appendix 1.

[a]SLP: speech-language pathologist.

[b]ASR: automatic speech recognition model.

[c]APAC: Assessment of Phonology and Articulation for Children.

[d]U-TAP: Urimal Test of Articulation and Phonology.

[e]The APAC and U-TAP provide *z* scores specifically for children aged 2 to 6. Thus, 3 children who were aged 7 were excluded from the analysis of the *z* score comparisons.

Discussion

Overview

This study highlights the effectiveness of the end-to-end model in accurately capturing children's articulations at the phoneme level. The PER between the SLPs and ASR model for the APAC and U-TAP assessments showed close correspondence (approximately 8%), with C-PER exhibiting similar ranges (ie, 10%-11%). Notably, the higher C-PER compared to the overall PER suggests fewer disagreements for vowels. Although the ASR model's results did not perfectly align with the SLPs' transcriptions, it is important to note that studies using standardized tests for SSDs typically report interrater reliability of 0.90 or higher, though it never reaches 100% [5,6,9,23]. Therefore, inherent variability in transcription, even among the SLPs, may have influenced the ASR evaluation process.

The occurrence of ASR disagreements in cases of correct articulation was relatively low, averaging approximately 2-3 instances per child. However, discrepancies in plosive sounds, particularly in the syllable-final word-medial position in the U-TAP, were notably higher compared to the APAC. This difference may stem from children imitating bird sounds when producing 짹짹 [t□* □t□* □] (tweet, onomatopoeia) in the U-TAP, reducing transcription reliability, as seen in common ASR disagreements cases.

In contrast, disagreements between the SLPs and the ASR model for misarticulations were approximately three times higher than for correct articulations. This finding is consistent with Jing and Grigos [9], who noted that the reliability of evaluation diminishes further when assessing misarticulated phonemes rather than correctly articulated ones. Disagreements between the ASR and the SLPs were higher for nasals and plosives but lower for fricatives and affricates in both the APAC and U-TAP, particularly in the syllable-initial word-initial position. This discrepancy may be attributed to the limited dataset, as fricatives and affricates are developmentally acquired later, resulting in a greater opportunity for the model to learn more error data related to these sounds.

The results of this study suggest several implications for the selection of test words when using the ASR. First, test words with long and complex syllable structures, such as 옥수수 [o□s*usu] (corn), 화장실 [hwɑd□aŋ□il] (bathroom), and 눈사람 [nuns*ɑram] (snowman) can hinder ASR systems in recognizing specific phonemes produced by children, particularly when the target phoneme is located in the word-medial position. Furthermore, accurate evaluation of the consonants ㅈ [t□, d□], ㄷ [t, d], and ㄱ [k, g] was challenging when followed by the vowel /i/, as seen in words like 바지 [pɑd□i] (pants) and 귀 [kwi] (ears), with ASR showing confusion between these phonemes. This difficulty is likely attributed to the proximity of their articulatory positions, which leads to similar auditory perceptual characteristics. In other words, assessing the accurate production of the preceding phoneme becomes particularly difficult when followed by the vowel /i/. In addition, the ASR demonstrated low performance in recognizing incorrect articulations of liquid sounds in syllable-final, word-medial positions. For example, it struggled to accurately detect the omission of the /l/ sound, as seen in words like 딸기 [t*ɑlgi] (strawberry) and 빨대 [p*ɑlt*] (straw).

Moreover, certain speech error patterns may not be accurately assessed using the ASR. First, it was difficult to distinguish whether plosive sounds at the end of a word were omitted or correctly produced (eg, 책 [t□ʰ□] (book)). Since syllable-final plosives are unreleased stops in Korean, the ASR may fail to accurately assess the speech of children who omit plosive consonants in the coda. Therefore, visual observation by SLPs should accompany the ASR evaluation to provide a more accurate assessment. Second, children exhibiting deaspiration errors may not be appropriately evaluated by the ASR, as misarticulation of aspirated consonants as tense consonants is difficult to detect (eg, 단추 [tɑnt□ʰu] vs [tɑnt□*u]; buttons). This highlights the limitations of ASR in capturing certain types

XSL•FO
RenderX

of speech errors, underscoring the need for supplementary evaluation methods, such as human auditory judgment, to ensure accurate diagnosis.

In addition, it is essential to compare the PCC and *z* scores derived from the ASR recognition results, as these provide a more comprehensive analysis of its clinical usefulness. The reliability of the ASR model developed by Ahn et al [19], using both the APAC and U-TAP, was deemed excellent, as indicated by the target PCC, which showed a strong correlation with the SLPs' evaluation results. However, this could be inflated with respect to diagnosing SSDs, as it is limited to results for only the targeted phoneme, rather than considering all phonemes in the test word.

When comparing the *z* scores for the target PCC, more pronounced differences were observed when using the APAC than when using the U-TAP (8 vs 2 individuals, respectively). This finding suggests that differences between the ASR model and SLPs may be more pronounced when using the APAC. These differences likely reflect variations in the normative data used for each test, with the inclusion of children with SSD being a key factor. Normative samples should include children with speech or language issues to avoid overidentification, placing normally developing children at the lower end of the distribution [24]. In this regard, the U-TAP included only "normal children," while the APAC incorporated both "general children" and those suspected of having functional articulation and phonological disorders, though the exact number was unspecified. In the U-TAP, most children in this study were classified as severe cases with *z* scores below –2, which may explain the lack of significant change in *z* scores despite slight differences in ASR and SLP evaluations. This finding is also aligned with Yi and Kim [23], who compared *z* scores across different SSD assessment tools [23].

Limitations and Suggestions

The limitations of this study include the use of a fine-tuned end-to-end model based on Korean phonemes, which may not be applicable for assessing speech errors in other languages or distortions not present in Korean.

Additionally, while machine learning relies on human transcriptions, it is essential to acknowledge that SLPs' transcriptions are not always consistent. These discrepancies must be considered in the ASR's training and evaluation, and future research should compare disagreement patterns among SLPs and between SLPs and the ASR.

In particular, this study conducted internal validation, meaning that both the model development and verification processes were carried out within the same setting. In addition, the small sample size makes it challenging to generalize the results. Therefore, external validation using other clinical settings or recording devices and including a larger number of participants is necessary.

For future studies, we suggest that incorporating connected speech tests may enhance the model's applicability in real-world clinical settings. Additionally, integrating automated error pattern analysis programs into the ASR to evaluate and categorize children's speech sound errors could streamline the evaluation process and save time for SLPs.

Conclusions

This study has been the first to assess the efficacy of ASR at the phoneme level in discerning speech errors among children afflicted with SSDs in South Korea. The model exhibited a commendable reliability when compared to transcriptions provided by the SLPs. Thus, our findings clearly confirm the viability and potential of using such a model in the domain of speech-language pathology. Still, given that assessing children with SSDs is difficult solely through auditory perception, ASR cannot fully replace traditional evaluations.

Abstract

Background: Patients undergoing liver transplantation (LT) are at risk of perioperative neurocognitive dysfunction (PND), which significantly affects the patients' prognosis.

Objective: This study used machine learning (ML) algorithms with an aim to extract critical predictors and develop an ML model to predict PND among LT recipients.

Methods: In this retrospective study, data from 958 patients who underwent LT between January 2015 and January 2020 were extracted from the Third Affiliated Hospital of Sun Yat-sen University. Six ML algorithms were used to predict post-LT PND, and model performance was evaluated using area under the receiver operating curve (AUC), accuracy, sensitivity, specificity, and F_1-scores. The best-performing model was additionally validated using a temporal external dataset including 309 LT cases from February 2020 to August 2022, and an independent external dataset extracted from the Medical Information Mart for Intensive Care Ⅳ (MIMIC-Ⅳ) database including 325 patients.

Results: In the development cohort, 201 out of 751 (33.5%) patients were diagnosed with PND. The logistic regression model achieved the highest AUC (0.799) in the internal validation set, with comparable AUC in the temporal external (0.826) and MIMIC-Ⅳ validation sets (0.72). The top 3 features contributing to post-LT PND diagnosis were the preoperative overt hepatic encephalopathy, platelet level, and postoperative sequential organ failure assessment score, as revealed by the Shapley additive explanations method.

Conclusions: A real-time logistic regression model-based online predictor of post-LT PND was developed, providing a highly interoperable tool for use across medical institutions to support early risk stratification and decision making for the LT recipients.

Introduction

Perioperative neurocognitive disorder (PND), encompassing various postsurgical cognitive impairments identified especially in the postoperative period, was first proposed in 2018 [1]. These cognitive changes are consistent with the clinical diagnostic criteria for neurocognitive disorders outlined in the *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders* [Fifth Edition]) [1-3]. In addition to postoperative delirium (POD) [4,5], other components of PND include emergence delirium, delayed neurocognitive recovery, and postoperative neurocognitive dysfunction [2,6]. POD or PND incidence is 2%-3% after general surgery [5,7] and 50%-70% in high-risk patients [8]. In addition, PND not only contributes to increased mortality rates but also extends hospitalization in patients undergoing liver transplantation (LT) [7,9], escalating health care costs and resource use. Preventative strategies and timely interventions for post-LT PND are crucial for enhancing patient outcomes and easing health care burdens [10].

Existing studies identify risk factors for post-LT PND, such as excessive alcohol consumption, Child-Turcotte-Pugh scores, and model for end-stage liver disease (MELD) scores [11,12]. Potential biomarkers for cognitive impairment prediction have also been proposed, including calcium binding protein β and neuron-specific enolase [13], yet their practical application is hindered by complex clinical scenarios and expense.

Machine learning (ML), a branch of artificial intelligence, offers a solution by distilling extensive clinical data into actionable insights, identifying relative risk factors for PND [14,15]. However, there is a dearth of ML-based models predicting post-LT–related complications [16-22] and postoperative delirium during specific surgeries [4,23]. There are currently no appropriate models for predicting PND in LT recipients, with most current clinical prediction models often failing to maintain accuracy when applied to external datasets, resulting in significant limitations to their generalizability.

This study aimed to extract critical predictors and develop an efficient ML algorithm to predict PND in LT recipients using routinely collected clinical data and to validate its performance using the Medical Information Mart for Intensive Care Ⅳ (MIMIC-Ⅳ) database.

Material and Methods

Study Design and Patients

This retrospective, single-center study was conducted at our institution following the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis guidelines. We enrolled 1267 patients who underwent LT between January 2015 and August 2022. Records were extracted using the perioperative specialist database platform (PSDP) and electronic patient record (EPR) systems. The inclusion and exclusion criteria are shown in Textbox 1.

All included recipients were formalized and registered in the China Organ Transplant Response System.

Textbox 1. Inclusion and exclusion criteria for the study.

Inclusion criteria

- Age >18 years.
- Allogeneic liver transplantation.

Exclusion criteria

- Simultaneous liver and kidney transplantation.
- Preoperative overt hepatic encephalopathy.
- Emergency reoperation.
- Persistent postoperative coma and inability to screen for cognitive function.
- Post–liver transplantation cerebral infarction or hemorrhage.
- Incomplete medical records.

Data Collection

The development and temporal validation cohort datasets were created by extracting original records from the Docare System (Medical system), Hospital Information System, and Laboratory Information System, and integrating them into the PSDP platform and EPR systems. To increase ML model accuracy and applicability, we included the following variables: (1) demographic characteristics; (2) liver donor characteristics; (3) preoperative comorbidities, complications, preoperative treatment, and LT etiology; (4) preoperative laboratory test results; (5) intraoperative surgery characteristics and medications; (6) postoperative MELD scores, sequential organ failure assessment (SOFA) scores, and laboratory test results; and (7) complications and prognosis in LT recipients. All of the original data were made anonymous throughout the study.

Definitions of Outcomes

The primary outcome was postoperative PND occurrence from surgery until discharge from the hospital. A summary of perioperative neurocognitive impairments is shown in Table S1 in Multimedia Appendix 1**.** The initial diagnosis criteria was the retrieval of any of the following terms from the medical records: “Delirium”, “Confusion”, “Confusional arousals”,

XSL•FO
RenderX

"Clouding of consciousness", "Soma", "Drowsiness", "Changes in mental status", "Hallucinations", "Disorientation", "Dyscalculia", "Haziness of spirit-mind", "Irritability", "Agitation", "Inattentiveness", "Reactive confusion", "Somatization disorder", "Irritability", and "Somatoform disorders", or equivalent terms in Chinese [4,24,25]. Next, each patient was evaluated based on the *DSM-5* criteria by a designated neurologist without prior access to the patient's records [3,26].

Variable Selection

A comprehensive set of 137 variables was extracted for the initial analysis (Table S2 in Multimedia Appendix 1). Table S3 in Multimedia Appendix 1 provides a concise explanation of the main complications and relevant term definitions. Postoperative SOFA scores were calculated by intensive care unit (ICU) physicians immediately after surgery according to European Society of Intensive Care Medicine criteria [27] and submitted for statistical analysis.

To account for multicollinearity and confounding variables affecting the overall model fitting performance, variables that were statistically significant (P<.05) in the univariate test were subjected to stability selection (Table S4 in Multimedia Appendix 1) [28]. After 100 iterations of least absolute shrinkage and selection operator (LASSO) regression, the top 10 features with the highest selection frequencies were chosen to train the ML models. For each LASSO regression, 90% of the training set samples were randomly selected as subsamples.

Machine Learning Models

The following 6 ML models were developed, and their performances were further evaluated: logistic regression (LR), multilayer perceptron classifier (MLP), extreme gradient boosting with classification trees (XGB), light gradient boosting machine (LGB), support vector machine (SVM), and random forest classifier (RF). All models were constructed using the XGB, LGB, and Scikit-learn packages.

The primary cohort dataset was randomly divided into 80% development and 20% internal validation sets. The bootstrap method was implemented 1000 times on the internal validation set to determine a 95% CI for the discrimination assessment metrics for each model: the area under the receiver operating curve (AUC), accuracy, sensitivity, specificity, and F_1-scores. Considering that ML models have multiple hyperparameters that are essential for model performance, a 5-fold cross-validation grid search method was used to optimize the parameters and AUCs (Table S5 in Multimedia Appendix 1). The Shapley additive explanations (SHAP) method was used to assess predictive feature importance and explain the ML algorithms' predictions [29].

Model Performance Comparison and MIMIC-Ⅳ Dataset

Because the SOFA and MELD scores have been reported as potential predictors of various post-LT complications [16,30], our study also compared the ML model's performance against SOFA and MELD scores.

An external validation set extracted from the MIMIC-Ⅳ (version 2.2) [31] database was used to evaluate the ML model's performance, which was authorized by the review committee of Massachusetts Institute of Technology (agreement 1.5.0). Patients who underwent LT surgery and were diagnosed with PND according to the International Classification of Diseases (9th and 10th revisions) were enrolled. Data extraction and cleaning were performed using PostgreSQL (version 15.3) and Navicate Premium (version 16) with a Structured Query Language (Figure S1 in Multimedia Appendix 1).

Statistical Analysis

Data cleaning used Python (version 3.9.13) packages Pandas (version 1.4.4) and Numpy (version 1.23.5). Data analysis used the Python Scipy package (version 3.7), and SHAP (0.41.0) was used to visualize and analyze feature importance.

Data distribution was evaluated using the Kolmogorov Smirnov test. Normally distributed continuous variables are presented as mean (SD) and were compared by independent sample t tests. Non-normally distributed continuous data are presented as median (IQR) and were compared using the nonparametric equivalent (Mann Whitney test). Categorical variables are expressed as frequencies and percentages and were tested using the chi-square test or Fisher exact test. Long-term survival rates were estimated using the Kaplan Meier method. Group comparisons were conducted using the Gehan-Breslow Wilcoxon test and log-rank tests.

All tests were 2-tailed, with statistical significance set at 0.05. Before ML model training, continuous variables were normalized, dichotomous variables were coded as binary variables, and multicategory variables were coded as uniform numbers.

Variables with missing values exceeding 20% were excluded, and missing values below 20% were imputed with the median (for numeric variables) or mode (for categorical variables). The overall data distribution after imputation exhibited an acceptable level of variability.

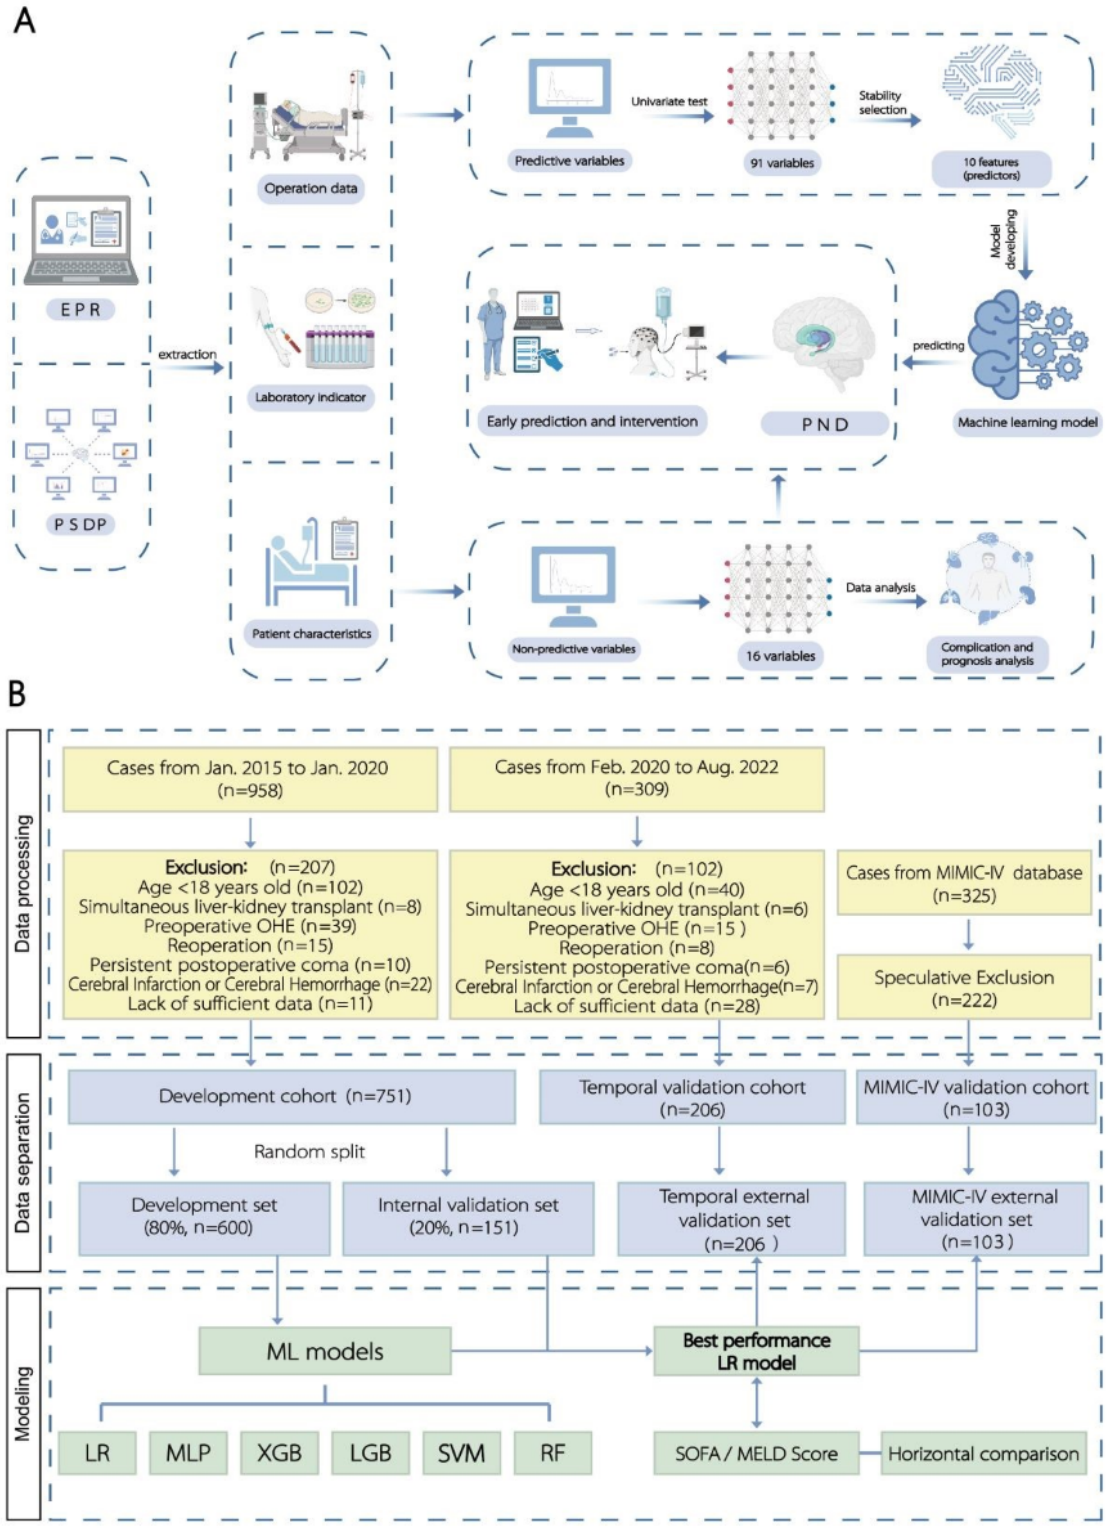
Visualized Online Calculator

An online calculator with a visual interface was developed to facilitate the easy input of clinical variables and to generate clear and meaningful output indicating the absolute risk in percentages.

Ethical Considerations

The study protocol was approved by the Ethics Committee of the Third Affiliated Hospital of Sun Yat-sen University on July 27, 2022 (No. (2019)02-609-04) and was conducted in accordance with the Declaration of Helsinki. The requirement for informed patient consent was waived due to the study's retrospective nature, and all data were anonymized before analysis.

Results



Patient Demographic Characteristics

The flowchart for patient recruitment is shown in Figure 1. Of the 958 patients who underwent LT, 751 patients were enrolled

[a]PND: perioperative neurocognitive dysfunction.

[b]DBD: donation after brain death.

[c]DCD: donation after circulatory death.

[d]DBCD: donation after brain death followed by circulatory death.

Perioperative Characteristics

Among the preoperative characteristics, American Society of Anesthesiologists classification and preoperative comorbidities such as acute respiratory distress syndrome, and laboratory results including hemoglobin, white blood cell (WBC) count, liver function, coagulation function, and serum calcium were significantly different between patients with and without postoperative PND (*P*<.01, Table S6 in Multimedia Appendix 1). Specifically, individuals diagnosed with post-LT PND exhibited a notably elevated prevalence of preoperative cover hepatic encephalopathy (CHE; 45.27% vs 8.77%, *P*<.001) and hypercalcemia (7.57% vs 1.36%, *P*<.001). Furthermore, patients with post-LT PND had higher Child Pugh and MELD scores (*P*<.001), longer preoperative ICU stays, increased continuous blood purification, increased plasma exchange, longer mechanical ventilation, and higher tracheal intubation (all *P*<.001, Table S6 in Multimedia Appendix 1).

Regarding intraoperative characteristics, patients with post-LT PND had longer anesthesia durations; increased sodium bicarbonate levels, red blood cell counts, plasma levels, and levels of cryoprecipitate transfusion; increased estimated blood loss (EBL); and reduced urine output (all *P*<.001, Table S6 in Multimedia Appendix 1). Differences in intraoperative medications between the 2 groups were not significant, except for recombinant activated factor VII (*P*<.001). Interestingly, our results showed no association between day or night surgery and the incidence of PND (*P*=.44, Table S6 in Multimedia Appendix 1).

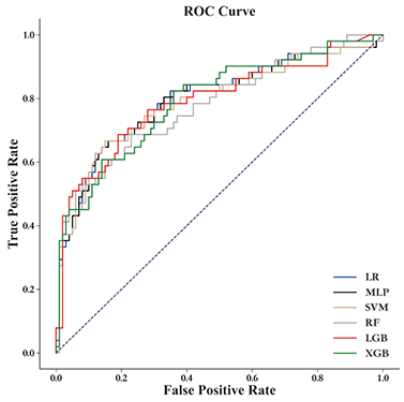
For the postoperative characteristics, patients with post-LT PND showed significantly higher levels of aspartate aminotransferase (AST), total bilirubin, blood urea nitrogen, prothrombin time

XSL•FO
RenderX

(PT), international normalized ratio, hypersensitive C-reactive protein (hsCRP), procalcitonin, and serum calcium, as well as lower levels of hemoglobin, hematocrit, WBC, platelet (PLT), gamma-glutamyltransferase, albumin, and serum osmolality (all $P<.05$, Table S6 in Multimedia Appendix 1).

Feature Selection

The frequency of LASSO algorithm selection for each variable is shown in detail in Figure S2 in Multimedia Appendix 1. The top 10 features chosen as predictors for ML model development were preoperative CHE, PLT, PT, estimated glomerular filtration rate (eGFR), Ca^{2+}, MELD score, intraoperative EBL, postoperative SOFA score, hsCRP, and AST.



Model Performance and Horizontal Comparison

The performance of the 6 ML models is shown in Figure 2. The LR model achieved the highest AUC (0.799, 95% CI 0.709-0.877) with acceptable accuracy (0.722, 95% CI 0.642-0.795), sensitivity (0.714, 95% CI 0.575-0.833), and specificity (0.73, 95% CI 0.639-0.811) compared with the other 5 models.

The SOFA (AUC=0.459, 95% CI 0.365-0.555), preoperative MELD (AUC=0.672, 95% CI 0.581-0.768), and postoperative MELD scores (AUC=0.679, 95% CI 0.587-0.772) had significantly lower AUCs than the LR model in the internal validation set (Figure 3A).

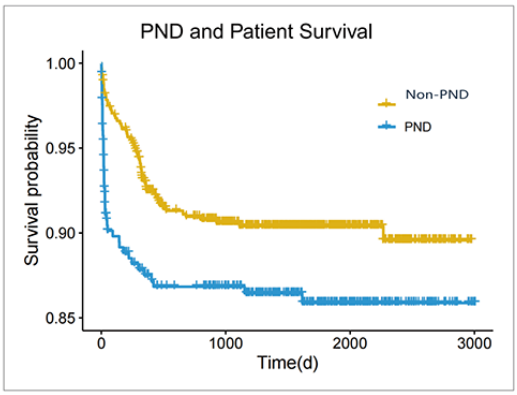
Feature Importance

The SHAP summary plot (Figures 3B and 3C) illustrates the correlation between the feature value magnitudes in the LR model. Both SHAP plots revealed that the presence of CHE, lower preoperative PLT, higher postoperative SOFA score, higher postoperative hsCRP, and higher preoperative PT were associated with a higher SHAP value output in the LR model, indicating a heightened likelihood of post-LT PND and forming the top 5 effective variables.

Three correctly classified examples (eg, patients 48, 80, and 122) are presented in Figure S3 in Multimedia Appendix 1, showing the SHAP decision and force plots.

Temporal External Validation and MIMIC-Ⅳ Dataset Validation

A comparison of the main demographic characteristics and key predictive variables between the development and validation sets is shown in Table S7 in Multimedia Appendix 1, and the incidence rates of post-LT PND in the temporal and MIMIC-Ⅳ external validation were 27.1%, and 20.3%, respectively. The LR model exhibited a comparable performance in the temporal external validation set (AUC=0.826, 95% CI 0.765-0.887) (Figure 3D). Surprisingly, the LR model also provided acceptable predictions for the MIMIC-Ⅳ dataset (Figure 3D, AUC=0.72, 95% CI 0.606-0.829). Figure 3E summarizes the main performance metrics of the LR model.



Effect of Perioperative Neurocognitive Dysfunction on Patients' Outcomes and Prognosis

Compared with patients without post-LT PND, patients with PND were more likely to experience perioperative complications (Table S8 in Multimedia Appendix 1), including higher incidences of sepsis (51.63% vs 21.55%, *P*<.001), pneumonia (75.56% vs 65.46%, *P*<.05), acute kidney injury (69.5% vs 39.75%, *P*<.001), and hemodialysis (51.35% vs 12.81%, *P*<.001). Furthermore, patients with post-LT PND had higher hospitalization costs (CNY 377,801.69 [US $51,566.83], SD 177,855.53 [US $24,275.82] vs CNY 277,018.95 [US $37,810.82], SD 92,779.91 [US $12,663.70]; *P*<.001), prolonged postoperative stays (25 {18} vs 21 {11} days, *P*<.001), longer postoperative ICU stay (113 {114} vs 65 {48.5} hours, *P*<.001), and a markedly higher in-hospital mortality rate (12.44% vs 2.51%, *P*<.001).

Further survival analysis (Figure 4) was conducted to assess patient prognosis. The PND group exhibited significantly lower survival rates at 30 days (87.1% vs 97.84%, *P*<.001), 3 months (83.99% vs 96.46%, *P*<.001), 6 months (82.78% vs 95.38%, *P*<.001), and 12 months (78.85% vs 88.44%, *P*<.001), and overall survival (*P*=.03).

Figure 4. Post–liver transplantation survival associated with perioperative neurocognitive dysfunction. Patients with post–liver transplantation perioperative neurocognitive dysfunction showed a significantly lower survival rate. LT: liver transplantation; PND: perioperative neurocognitive dysfunction.

Clinical Availability of the Logistic Regression Model

Given the accessibility of the 10 predictive features, we constructed a visually oriented online calculator to facilitate clinical decision making. The perioperative information of 2 typical patients was entered into the online calculator: patient 48 had a positive final predicted probability of PND occurrence (probability: 96%), and patient 122 had a negative final predicted probability of PND occurrence (probability: 17%; Figure 5). The online calculator is freely accessible at the hospital website.

XSL•FO
RenderX

Figure 5. Online calculator for the clinical interface of the post–liver transplantation perioperative neurocognitive dysfunction risk prediction logistic regression model. (A) Patient No. 48 post–liver transplantation perioperative neurocognitive dysfunction will occur (probability of perioperative neurocognitive dysfunction: 94%); (B) Patient No. 122 post–liver transplantation perioperative neurocognitive dysfunction will not occur (probability of perioperative neurocognitive dysfunction: 17%).

Discussion

Principal Findings

Our retrospective study assessed 6 different ML algorithms to predict post-LT PND, using 10 readily available clinical parameters. We found that post-LT PND incidence was 33.5%. The 10 predictive features significantly associated with PND included preoperative CHE, PLT, PT, eGFR, Ca^{2+}, MELD score, intraoperative EBL and postoperative SOFA score, hsCRP, and AST. The LR model demonstrated superior performance, with high AUC, accuracy, sensitivity, and specificity, surpassing traditional SOFA and MELD scores in predicting post-LT PND and performed acceptably in the rigorous temporal and MIMIC-Ⅳ external validations.

This study aids clinicians in detecting postoperative cognitive changes in LT recipients. Patients with PND typically faced more perioperative complications, higher hospitalization costs, and prolonged hospital and ICU stays, consistent with previous studies [4,23]. Hepatic encephalopathy has been reported as an independent risk factor for postoperative neurocognitive disorders [32]. To ensure cognitive assessment accuracy, we excluded patients with overt hepatic encephalopathy according to the spectrum of neurocognitive impairment in cirrhosis criteria [33]. CHE emerged as a significant predictor in our model analysis. Both oxidative stress and neuroinflammation have been implicated in POD pathophysiology [10,34]. A recent systematic review also links increased perioperative CRP levels to a high delirium risk [35], supporting our inclusion of hsCRP as a predictor. Calcium ions (Ca^{2+}) are important cell signaling molecules, and previous studies reported a positive correlation between Ca^{2+} concentration and neuronal apoptosis extent in vitro [36], consistent with our results. Furthermore, the model identified PLT as an unconventional indicator of PND, showcasing ML's ability to highlight nontraditional risk factors. This discovery is partly supported by Eyer et al [37] suggesting a relationship between lower PLT and delirium tremens.

Our study used preoperative, intraoperative, and postoperative data (SOFA scores, hsCRP, and AST levels) to develop the LR model. Earlier studies have revealed that multiple postoperative factors were also risk factors for PND [11,12]. The postoperative variables included in this study were predominantly assessed upon initial admission to the ICU. Stability selection analysis revealed a positive correlation between elevated postoperative SOFA scores, hsCRP levels, and AST levels, and an increased likelihood of post-LT PND. This highlights the predictive value of these commonly observed postoperative variables for PND.

Our results suggest that LR outperforms other ML models in predicting post-LT PND, which is not surprising. A recent systematic review showed no performance superiority of other ML models over LR in predicting clinical complications [38]. Wiredu et al [35] also found that compared to ML algorithms, LR had the highest AUC when predicting sex-specific hip fractures. Song et al [4] developed an LR model to predict POD in older adult patients, achieving the highest AUC compared with other models. Given the evident linear relationships among the top 10 features, the LR may be more appropriate for capturing distribution patterns. In contrast to other algorithms, LR performs well on nonoversized and high-dimensional datasets, exhibits computational efficiency, and imposes lower dataset requirements.

As demonstrated by the example of prediction cases (Figure 5), we successfully developed a predictive model for post-LT PND, with its primary advantage in its reliable predictive performance, validated using 2 external datasets. The importance of early detection and prevention of PND in patients undergoing cardiac surgery or transplantation is clearly emphasized in current international guidelines [39]. However, the implementation of preventive measures is often challenged by limited resources [40], especially in cases where the shortage of liver donors persists. On accurate identification by the LR model, patients

XSL•FO
RenderX

at high risk for post-LT POD could be referred to enhanced LT perioperative management strategies, such as individualized pharmacological or nonpharmacological comprehensive multicomponent interventions, according to the 10 commonly accessible predictive parameters filtered by the ML algorithm.

Limitations

However, this study had several limitations. First, it was a single-center retrospective study, meaning the Confusion Assessment Method (CAM) or the associated CAM-ICU and 3D-CAM were inappropriate for our database. Instead, patients with PND were identified from medical records according to the *DSM-5* criteria [3,6,26]. Second, as a real-world study, researchers can only infer precise risk factors based on the data available, and inhomogeneous confounding among the datasets could affect the study conclusions [41]. While our online decision tool has the potential to aid surgeons and anesthesiologists in clinical decision making, the causes and underlying mechanisms of PND remain subjects of intense debate, necessitating further research.

Conclusions

This study successfully develops a real-time and easily accessible parameter requiring LR-based PND prediction algorithm for post-LT settings. The LR model outperformed the other five models owing to its enhanced model performance and interpretability. The optimal use of our freely accessible online predictor would enable timely and convenient risk stratification, enhanced perioperative management strategies, and comprehensive multicomponent interventions.

Acknowledgments

We express our gratitude to Ms Li Jing from the Chinese MCC5 University for her valuable assistance in processing the figures. This study was supported partly by the Special Support Project of Guangdong Province (0720240209), the Natural Science Foundation of Guangdong Province (grant 2022A1515012603), the Joint Funds of the National Natural Science Foundation of China (U22A20276), Science and Technology Planning Project of Guangdong Province-Regional Innovation Capacity and Support System Construction (2023B110006), Provincial-enterprise Joint Funds of Guangdong Basic and Applied Basic Research Foundation (2021B1515230012), Science and Technology Program of Guangzhou, China (202201020429) and the “Five and five” project of the Third Affiliated Hospital of Sun Yat-Sen University (2023WW501).

Data Availability

All data generated or analyzed during this study are included in this published article and Multimedia Appendix 1, and the codes used in this study are all common codes in Python packages mentioned in the “Methods” section of the manuscript.

Authors' Contributions

Authors ZD and CC had full access to all of the data in this study and take responsibility for the integrity of the data and the accuracy of the data analysis. ZD, ZH, and CC contributed to conceptualization and design. ZD, LZ, YZ, YL, and MG handled acquisition, analysis, or interpretation of data. ZD, CC, and WY managed drafting of the manuscript. All authors contributed to critical revision of the manuscript for important intellectual content. ZD, YL, and JY performed statistical analysis. ZH and CC obtained funding. JY and YL managed administrative, technical, or material support.

Abstract

Background: Recent research has revealed the potential value of machine learning (ML) models in improving prognostic prediction for patients with trauma. ML can enhance predictions and identify which factors contribute the most to posttraumatic mortality. However, no studies have explored the risk factors, complications, and risk prediction of preoperative and postoperative traumatic coagulopathy (PPTIC) in patients with trauma.

Objective: This study aims to help clinicians implement timely and appropriate interventions to reduce the incidence of PPTIC and related complications, thereby lowering in-hospital mortality and disability rates for patients with trauma.

Methods: We analyzed data from 13,235 patients with trauma from 4 medical centers, including medical histories, laboratory results, and hospitalization complications. We developed 10 ML models in Python (Python Software Foundation) to predict PPTIC based on preoperative indicators. Data from 10,023 Medical Information Mart for Intensive Care patients were divided into training (70%) and test (30%) sets, with 3212 patients from 3 other centers used for external validation. Model performance was assessed with 5-fold cross-validation, bootstrapping, Brier score, and Shapley additive explanation values.

Results: Univariate logistic regression identified PPTIC risk factors as (1) prolonged activated partial thromboplastin time, prothrombin time, and international normalized ratio; (2) decreased levels of hemoglobin, hematocrit, red blood cells, calcium, and sodium; (3) lower admission diastolic blood pressure; (4) elevated alanine aminotransferase and aspartate aminotransferase levels; (5) admission heart rate; and (6) emergency surgery and perioperative transfusion. Multivariate logistic regression revealed that patients with PPTIC faced significantly higher risks of sepsis (1.75-fold), heart failure (1.5-fold), delirium (3.08-fold), abnormal coagulation (3.57-fold), tracheostomy (2.76-fold), mortality (2.19-fold), and urinary tract infection (1.95-fold), along with longer hospital and intensive care unit stays. Random forest was the most effective ML model for predicting PPTIC, achieving an area under the receiver operating characteristic of 0.91, an area under the precision-recall curve of 0.89, accuracy of 0.84, sensitivity of 0.80, specificity of 0.88, precision of 0.88, F_1-score of 0.84, and Brier score of 0.13 in external validation.

XSL•FO
RenderX

Conclusions: Key PPTIC risk factors include (1) prolonged activated partial thromboplastin time, prothrombin time, and international normalized ratio; (2) low levels of hemoglobin, hematocrit, red blood cells, calcium, and sodium; (3) low diastolic blood pressure; (4) elevated alanine aminotransferase and aspartate aminotransferase levels; (5) admission heart rate; and (6) the need for emergency surgery and transfusion. PPTIC is associated with severe complications and extended hospital stays. Among the ML models, the random forest model was the most effective predictor.

KEYWORDS

traumatic coagulopathy; preoperative; postoperative; machine learning models; random forest; Medical Information Mart for Intensive Care

Introduction

Severe trauma is a significant global public health burden and a leading cause of reduced life expectancy. The Global Burden of Diseases, Injury, and Risk Factors Study 2017 estimates that trauma accounts for 8% of total deaths annually [1]. Traumatic coagulopathy (TIC) is a systemic inflammatory state accompanied by coagulation dysfunction, acidosis, and hypothermia that occurs after traumatic injury [2]. TIC is observed in one-quarter to one-third of patients with trauma [3,4] and is associated with increased rates of massive transfusion and multiple organ failure (MOF), prolonged intensive care unit (ICU) stay and length of stay (LOS), and a 4-fold increase in mortality [3]. Harhangi et al [5] reported that TIC is linked to a 9-fold increase in mortality and a 36-fold increase in the likelihood of adverse outcomes [5]. Early endogenous TIC is associated with increased bleeding, higher red blood cell (RBC) transfusion rates, and a greater risk of secondary complications like multiple organ dysfunction syndrome (MODS) and thromboembolism [6]. Cohen and Christie [7] also reported that patients with TIC have worse prognoses, including higher rates of infection, thromboembolism, acute lung injury, MOF, and mortality. Without proper and timely diagnosis and treatment, posttraumatic bleeding and associated TIC remain potentially preventable causes of MOF [8]. Therefore, the latest European guidelines indicate that the immediate identification and management of TIC can improve outcomes for severely injured patients [9].

In recent years, artificial intelligence (AI) has received significant attention for its potential use in various aspects of human activities, including health care [10]. Sidey-Gibbons and Sidey-Gibbons [11] and Liu and Salinas [12] suggested that machine learning (ML) excels over traditional methods in handling large, unstructured, nonlinear, or incomplete datasets, improving outcome predictions for patients with trauma. With the advent of ML and improved computational analysis methods, recent approaches have aimed to enhance predictions and identify which factors are most important in contributing to posttraumatic mortality [13]. Rashidi et al [14] emphasized the critical importance of rapid diagnosis and intervention for managing hemostatic disorders, which can lead to life-threatening bleeding or clotting. AI or ML models can significantly enhance turnaround times, accuracy, and the timeliness of diagnoses and interventions, potentially improving patient care and outcomes.

Our data show that despite surgical interventions such as hemostasis, vascular reconstruction, fracture reduction, organ repair, blood transfusion, and the correction of electrolyte imbalances in patients who experienced preoperative TIC, 50% of these patients still had TIC postoperatively [15]. These patients were more prone to develop complications during hospitalization, and preoperative and postoperative traumatic coagulopathy (PPTIC) was identified as an independent risk factor for these complications. Therefore, we plan to explore the risk factors for PPTIC in patients with trauma and its relationship with in-hospital complications. We will use admission indicators from patients with trauma to predict the risk of PPTIC, applying 10 different ML models to estimate the probability of PPTIC occurrence and conducting a comprehensive evaluation of each model. This predictive approach can aid clinicians in implementing timely and appropriate interventions to reduce the incidence of PPTIC and related complications, thereby lowering in-hospital mortality and disability rates for these patients.

Methods

Ethical Considerations

Data from 4 medical centers were anonymized and integrated. Ethical approvals were granted by the respective ethics committees: Daping Hospital, Medical Research Ethics (2023) 261; Chongqing Emergency Medical Center, 2023 ethical review (48); the People's Liberation Army Rocket Force Characteristic Medical Center (KY 2023037); and the General Hospital of Southern Theatre Command of People's Liberation Army (NZLLKZ2024021). As this was a retrospective study, patient informed consent was waived by the ethics committees. It was registered with the Chinese Clinical Trial Registry (ChiCTR2300078097) and adhered to the Declaration of Helsinki. This study adheres to 2 key guidelines to ensure rigorous reporting: the TRIPOD-AI (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis—Artificial Intelligence) guidelines for the development and reporting of multivariable ML predictive models in biomedical research (Multimedia Appendix 1) [16] and the STROCSS (Strengthening the Reporting of Cohort Studies in Surgery) criteria, which standardize the reporting of surgical observational studies [17].

XSL•FO
RenderX

Inclusion and Exclusion Criteria

The inclusion and exclusion criteria are as follows:

- Inclusion criteria: Patients who underwent surgical treatment after trauma from January 2017 to February 2023.
- Exclusion criteria: Patients without trauma (snake bites, bee stings, and burns); patients who did not undergo surgery or stopped treatment; patients younger than 18 years of age; patients with hematological diseases; patients with a history of liver cirrhosis; pregnant women; and patients without coagulation-related tests results either preoperatively or postoperatively.

Data Collection

We retrieved patients who underwent trauma or concurrent surgeries using the MIMIC IV (Medical Information Mart for Intensive Care) 2.2 database, with the detailed data extraction process outlined in Multimedia Appendix 2. We then collected the necessary indicators using subject_id and hadm_id, which included the following information: ID number; sex; age; height; weight; type of surgery (elective or emergency); and preoperative comorbidities such as high blood pressure, diabetes, cerebrovascular diseases, chronic obstructive pulmonary disease, chronic bronchitis, asthma, and chronic renal insufficiency. Preoperative indicators included systolic blood pressure, heart rate (HR), saturation of pulse oximetry, and the presence of shock upon admission. The laboratory examination indicators (latest results prior to admission and first results postoperatively) included the following: complete blood count (white blood cell, lymphocyte [%], monocyte [%], neutrophil [%], eosinophil [%], basophil [%], RBC, mean corpuscular hemoglobin concentration, mean corpuscular volume, red cell distribution width, hemoglobin, hematocrit, platelet count [PLT], mean platelet volume, renal function [urea, creatinine, and blood uric acid]), liver function (albumin, alkaline phosphatase, lactate dehydrogenase, gamma-glutamyl transferase, total protein, globulin, direct bilirubin, indirect bilirubin, total bilirubin, alanine aminotransferase [ALT], and aspartate aminotransferase [AST]), electrolytes (sodium, potassium, and calcium), and coagulation function (activated partial thromboplastin time [APTT], prothrombin time [PT], international normalized ratio [INR], and D-dimer). The relevant intraoperative indicators included the need for perioperative blood transfusion. Complications during hospitalization included pulmonary embolism, sepsis, septicemia, heart failure, delirium, pulmonary edema, abnormal coagulation, endotracheal tube intubation, invasive mechanical ventilation, tracheostomy, end-stage renal disease, systemic inflammatory response, acute respiratory distress syndrome, pleural effusion, cardiac arrest, anemia, venous thrombosis, renal failure, acute kidney failure, urinary tract infection, respiratory failure, pneumonia, LOS, in-hospital death, and length of ICU stay. Data from the other 3 medical centers were collected via electronic medical records, consistent with the previously mentioned information. Our definition criteria for TIC were as follows: PLT<100×10^9/L; INR>1.25; PT>14 second; and APTT>36 second [18]. PPTIC was defined as patients who experienced TIC both within 24 hours before surgery (preoperative) and within 24 hours after surgery (postoperative), meeting one or more of the above TIC diagnostic criteria in both timeframes.

Process of ML Modeling

Handling Missing Data

We processed the data using Python (version 3.9; Python Software Foundation), discarding variables with over 40% missing data (Multimedia Appendix 3). For binary and categorical variables, we applied 1-hot encoding. Continuous variables were imputed using k-nearest neighbor (KNN) with k=5, while categorical variables underwent multiple imputations with 5 iterations.

Data Normalization and Feature Selection

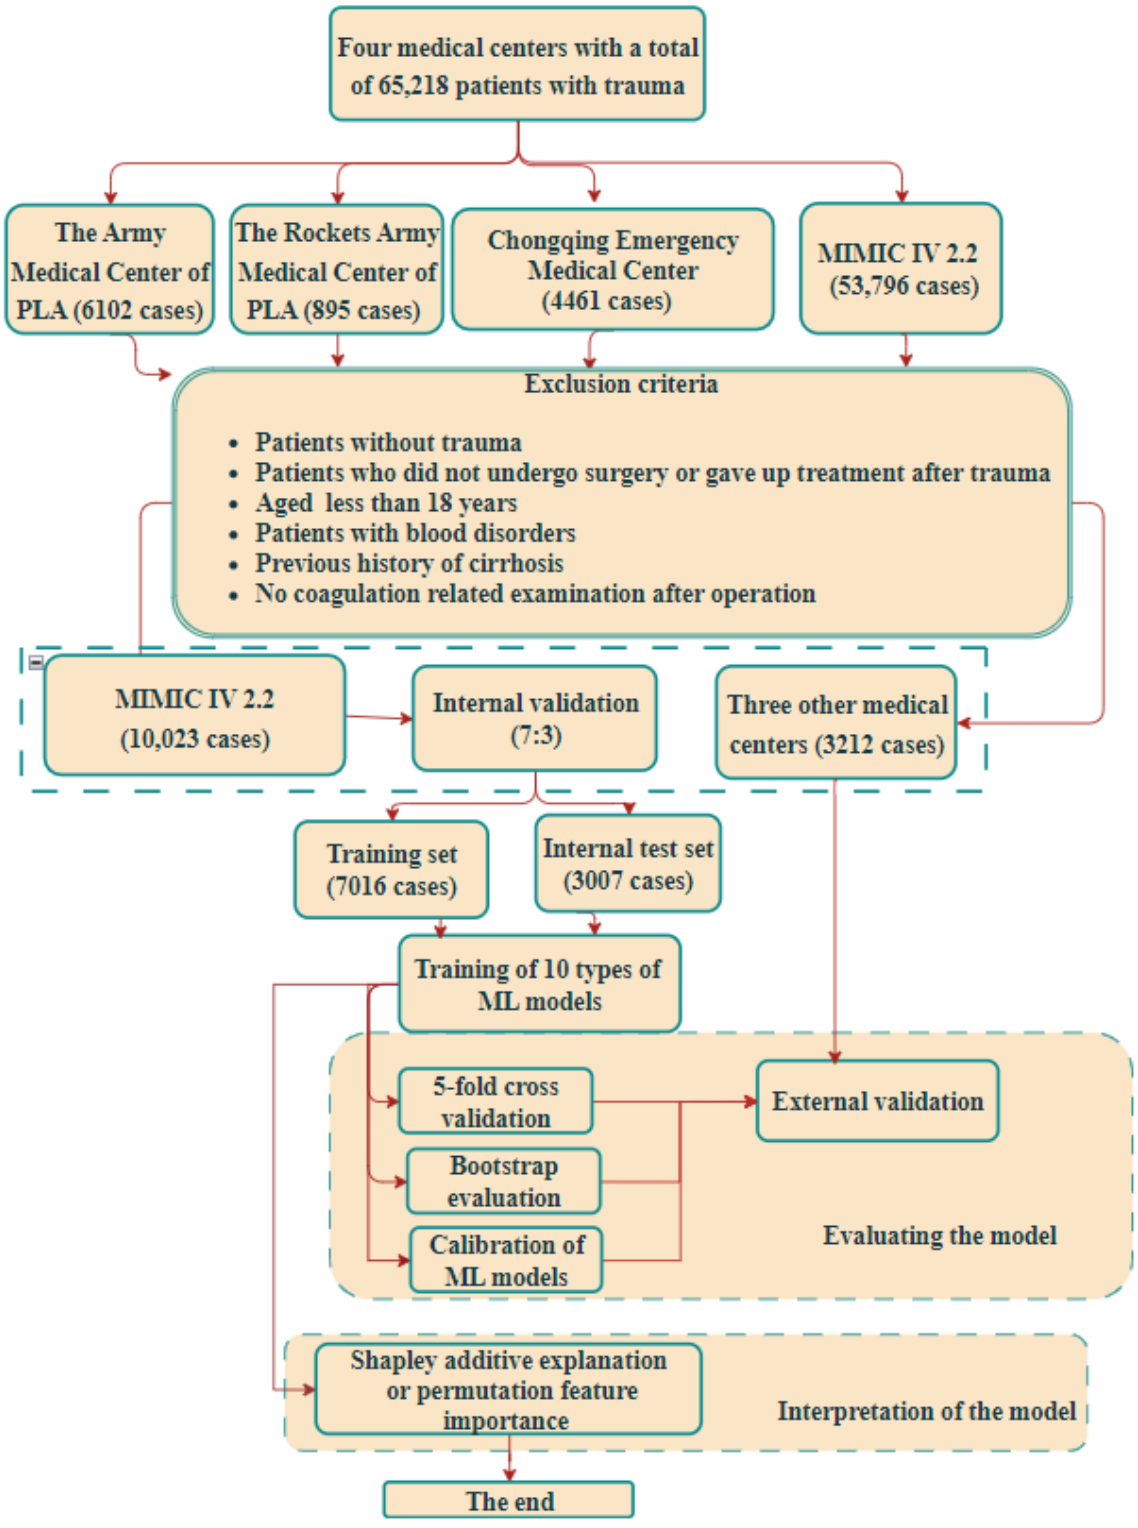
Data Normalization

We created a *StandardScaler* object to standardize the data. Both the training and test data were standardized via the same procedure.

Outlier Handling

We calculated z scores for the training data, considering values above 3 as outliers, and replaced these with the mean using *np.where*.

Feature Selection



We assessed continuous variables with the Pearson correlation coefficient and converted categorical variables to numerical ones via label encoding. Then, the Pearson correlation coefficient was calculated for each feature relative to the target variable, and the top 50 features with the highest correlations were selected. These selected features were then refined using least absolute shrinkage and selection operator regression, resulting in a final set of 25 features.

Dataset Splitting

We modeled data from 10,023 patients with trauma in MIMIC IV, splitting it into a training set of 7631 cases and a test set of 1908 cases (7:3 ratio) using the *train_test_split* function. Additionally, we used data from 3212 patients from 3 other medical centers for external validation (Figure 1).

Figure 1. The data processing. MIMIC: Medical Information Mart for Intensive Care; ML: machine learning; PLA: People's Liberation Army.

Building the ML Models

We used Python 3.9 to build the ML models, using a total of 10 models (Multimedia Appendix 4): logistic regression (LR), random forest (RF), support vector machine (SVM), decision tree (DT), KNN, gradient boosting (GB), neural networks (NN), naive Bayes (NB), AdaBoost, and extreme gradient boosting (XGBoost). We assessed the models' performances via 7 metrics: area under the receiver operating characteristic curve (AUROC), area under the precision-recall curve (AUPRC), accuracy, sensitivity, specificity, precision, and F_1-score. The Python 3.9 packages used for data processing and analysis are shown in Multimedia Appendix 5. Additionally, the full code and data processing steps, along with detailed instructions, have been made publicly available via GitHub [19].

XSL•FO
RenderX

Model Performance and Evaluation

In this study, we used "grid search" for hyperparameter optimization. We conducted 5-fold cross-validation by dividing the dataset into 5 subsets, using each subset once for testing and the remaining four for training. This process, repeated 5 times, helps reduce overfitting, stabilize performance evaluation, and address sample selection bias [20]. We measured accuracy, precision, recall, and F_1-score.

To evaluate the robustness and generalization of 10 ML models, we used bootstrap sampling with 1000 iterations. Each iteration involved retraining the models on a bootstrap sample and calculating accuracy, precision, recall, and F_1-score. We then estimated the distributions and 95% CIs for these metrics, producing 12 key indicators: accuracy mean, accuracy lower or upper 95% CI, precision mean, precision lower or upper 95% CI, recall mean, recall lower or upper 95% CI, F_1-score mean, and F_1-score lower or upper 95% CI.

To assess model calibration, we used the Brier score (BS), which ranges from 0 to 1, with lower scores indicating better accuracy of predicted probabilities. We trained the model, evaluated predictions on the test set, computed the BS, and plotted a calibration curve to visualize the model's performance.

Interpretation of the ML

We use Shapley additive explanation (SHAP) values to assess the significance of variables in the model by evaluating their impact on predictions across all feature subsets and averaging these effects [21]. We used the Python package *SHAP* to visualize and rank the top 15 variables with the highest SHA*P* values related to PPTIC. These variables were integrated into the model, and SHA*P* values ranging from 0 to 1 were used for risk interpretation. We also conducted univariate logistic regression on these top 15 variables.

Statistics

Statistical analysis was performed using SPSS Statistics (version 27.0; IBM Corp). Patients were divided into PPTIC and non-PPTIC groups, with PPTIC as the independent variable and other factors as dependent variables. Categorical data are presented as percentages, and continuous data as mean (SD). Depending on the distribution, continuous variables were assessed via 2-tailed *t* tests or Mann-Whitney *U* tests, and categorical variables via chi-square tests or exact tests. Univariate analysis identified risk factors for persistent trauma-induced coagulopathy, and multivariable logistic regression analyzed complications during hospitalization in the PPTIC group. A *P* value less than .05 was considered statistically significant.

Results

Basic Information of the Patients

We ultimately included 13,237 patients with trauma, among whom 6586 (49.8%) experienced PPTIC. The mean age of our patients was 62.45 (SD 17.85) years. In the PPTIC group, the average age was 63.6 (SD 17.4) years, whereas in the non-PPTIC group, it was 61.3 (SD 18.2) years, with *P*<.001 (Table 1). Among the patients, there were 5590 (42.2%) male individuals and 7646 (57.8%) female individuals, and this difference was significant (*P*<.001). The racial distribution included 3452 (26.1%) Asian individuals, 7402 (55.9%) White individuals, 342 (2.6%) Black individuals, 940 (7.1%) Latino individuals, and 1101(8.3%) individuals of other races.

Results of the ML Models

Training Results of the ML Models

We developed 10 ML risk models for predicting PPTIC. In the training set, all 10 models achieved an AUROC of 0.83 or higher, with RF, DT, and XGBoost reaching AUROC values of 1. In the internal testing set, RF achieved an excellent AUROC of 0.92, whereas the AUROC of SVM was 0.9, that of GB was 0.93, that of NN was 0.9, that of AdaBoost was 0.91, and XGBoost performed well (Figure 2). RF, GB, and XGBoost demonstrated superior performance in both the training and testing sets, with AUROC, accuracy, sensitivity, specificity, precision, and F_1-score all above 0.8 (Multimedia Appendix 6).

XSL•FO
RenderX

Figure 2. The AUROC curves of 10 machine learning models in the (A) training, (B) test, and (C) external validation set for predicting PPTIC in patients with trauma. The ROC curve for predicting PPTIC in patients with trauma is defined by the false positive rate on the x-axis, representing the proportion of negative cases misclassified as positive, and the true positive rate on the y-axis, reflecting the proportion of correctly identified positive cases (sensitivity), with both axes ranging from 0 to 1. The AUROC is a key metric for assessing the model's predictive performance, where a higher AUROC signifies superior discriminatory ability in predicting PPTIC and improved generalizability. AUROC: area under the receiver operating characteristic curve; PPTIC: preoperative and postoperative traumatic coagulopathy; ROC: receiver operating characteristic curve; SVM: support vector machine.

Evaluating the ML Models

Results of the 5-Fold Cross-Validation

The results from the 5-fold cross-validation (Multimedia Appendix 7) showed that our RF, GB, AdaBoost, and XGBoost models consistently performed well across diverse subsets, demonstrating high accuracy and consistency. The SDs of the accuracy, precision, recall, and F_1-scores were minimal, confirming the robustness and reliability of these ML models.

Bootstrap Results

The bootstrap analysis results indicated that RF, DT, GB, AdaBoost, and XGBoost achieved average accuracy, precision, recall, and F_1-score all exceeding 0.91, accompanied by narrow 95% CIs (Table 2). This suggests consistently high accuracy across various sample resampling conditions, underscoring the robustness of these models. Moreover, RF, DT, GB, AdaBoost, and XGBoost demonstrated substantial stability and reliability across their respective performance metrics.

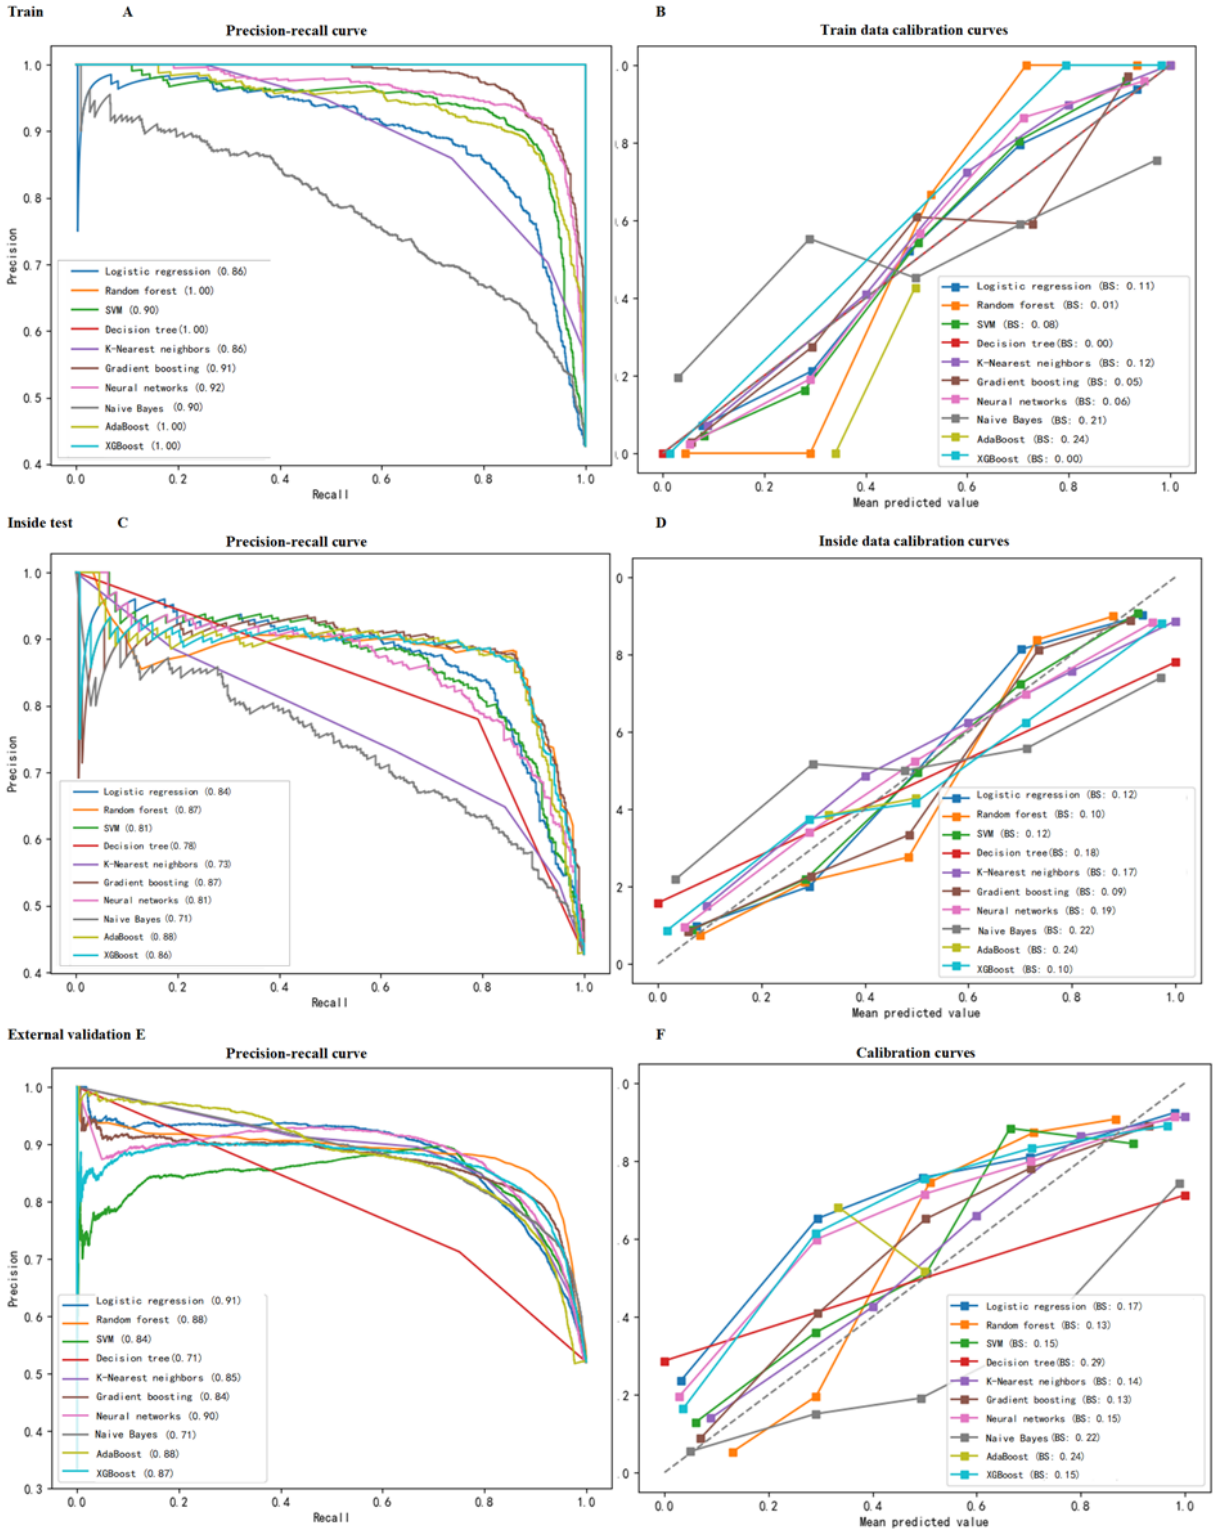
[i]NB: naive Bayes.



[j]XGBoost: extreme gradient boosting.

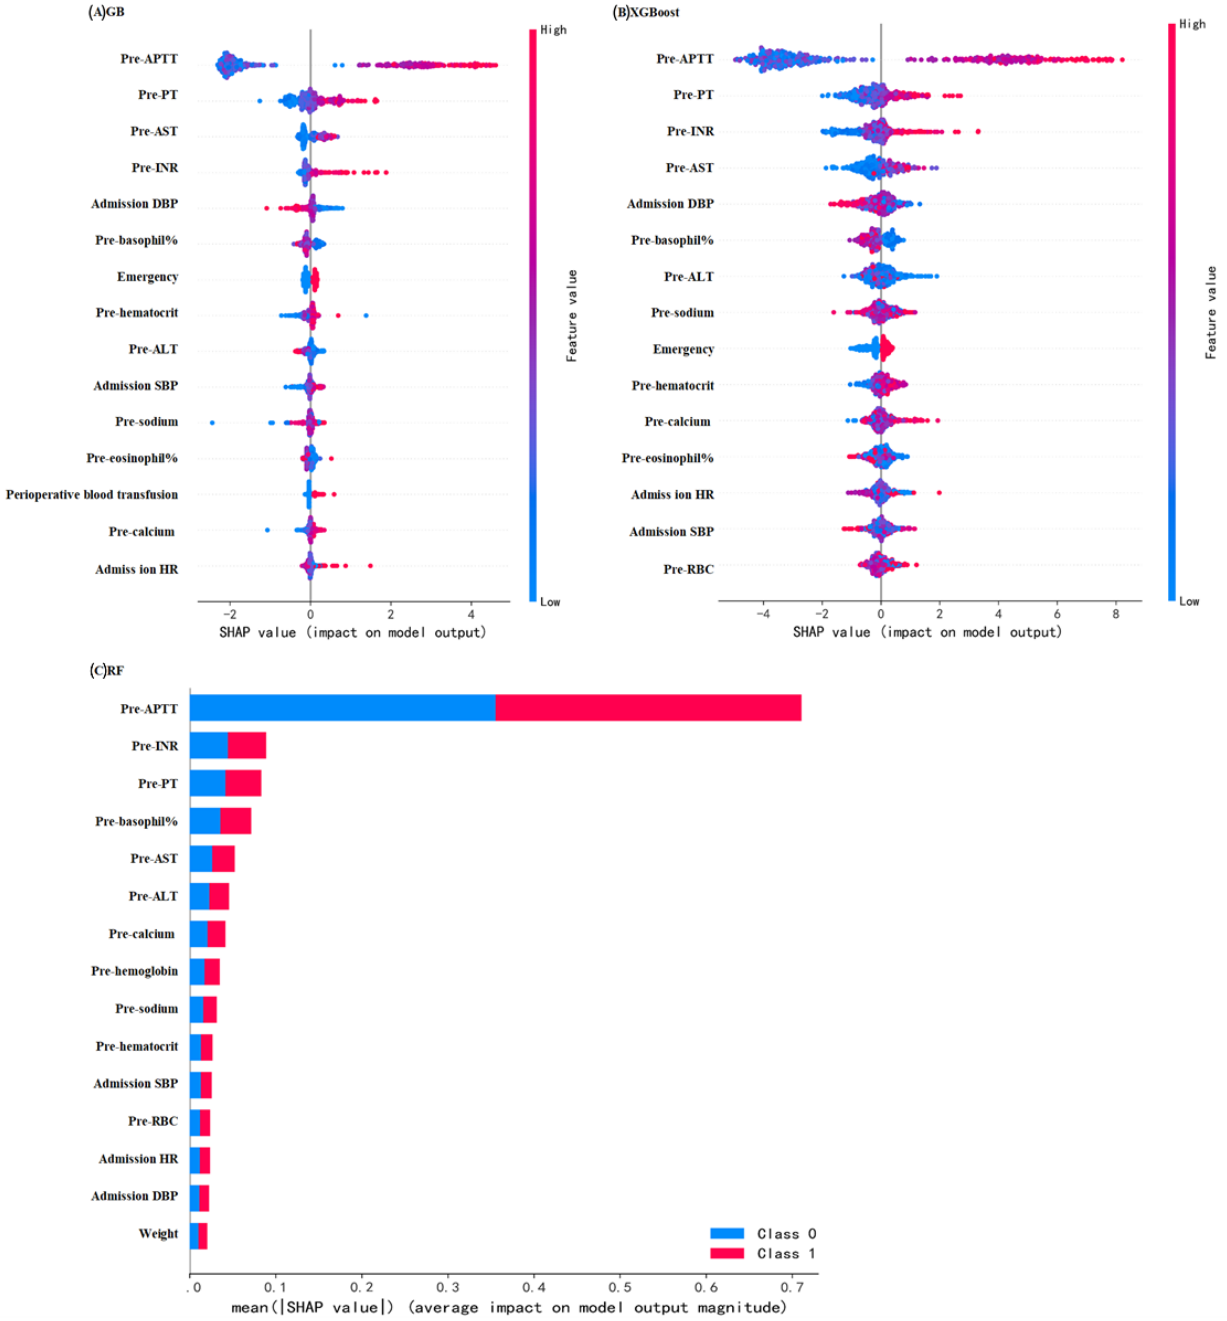
Calibration and Precision-Recall of the ML Models

In the training set, RF, DT, GB, and XGBoost achieved BSs of 0.01, 0.00, 0.05, and 0.00, respectively, with precision-recall values above 0.9, demonstrating robustness. In the internal testing set, RF, GB, and XGBoost had BSs of 0.1, 0.09, and 0.10, and precision-recall values of 0.87, 0.87, and 0.86. During external validation, they recorded BSs of 0.13, 0.13, and 0.15, with precision-recall values around 0.88, 0.84, and 0.87. The BS and precision-recall values of RF, GB, and XGBoost in the external validation set closely mirrored those in the internal testing set (Figure 3), underscoring the consistency and reliability of these models.

XSL•FO
RenderX

Figure 3. The precision-recall curve and train data calibration curve of 10 machine learning models in (A-B) train, (C-D) internal test, and (E-F) external validation sets predicted patients with PPTIC. PPTIC: preoperative and postoperative traumatic coagulopathy; SVM: support vector machine.

Results of the External Validation of the ML Models



In the external validation set, RF, GB, NN, and XGBoost achieved AUROC values of 0.91, 0.89, 0.89, and 0.89, respectively (Figure 2), while other models attained approximately 0.87. RF showed the highest performance with AUROC 0.91 (95% CI 0.90-0.913), AUPRC 0.89 (95% CI 0.88-0.90), accuracy 0.84 (95% CI 0.83-0.85), sensitivity 0.80 (95% CI 0.79-0.81), specificity 0.88 (95% CI 0.87-0.89), precision 0.88 (95% CI 0.87-0.89), and F_1-score 0.84 (95% CI 0.83-0.84). Despite being slightly lower than in the training set, RF's performance remained stable, demonstrating strong generalizability. Thus, RF was identified as the optimal model based on 5-fold cross-validation, bootstrap, calibration, precision-recall, and external validation results.

Interpretation of the ML Models

Analysis of SHAP values highlighted the key features influencing model predictions. For RF, GB, and XGBoost (Figure 4), as well as the other 7 ML models (Multimedia Appendix 8), we observed the top 15 variables ranked by their average impact. In RF, the primary predictors of PPTIC in patients with trauma were preoperative APTT, PT, INR, AST, ALT, calcium, hemoglobin, sodium, hematocrit, admission SBP, RBC, admission HR, and the need for emergency surgery or perioperative blood transfusion (Table 3). Univariate logistic regression identified prolonged APTT, PT, and INR; low levels of hemoglobin, hematocrit, RBC, calcium, and sodium; elevated ALT and AST; and the need for emergency surgery or blood transfusion were significant risk factors for PPTIC.

Figure 4. SHAP values of (A) GB, (B) XGBoost, and (C) RF for predicting the risk of TIC before and after surgery in patients with trauma. We selected the three best-performing ML models (GB, XGBoost, and RF) from a set of 10 to predict PPTIC outcomes and evaluated their SHAP values. The SHAP plot highlights the top 15 features with the most significant impact on model predictions, ranked in descending order of importance from top to bottom. The x-axis represents the SHAP value, while the y-axis lists the corresponding feature names. Red points represent higher feature values, while blue points represent lower feature values. If red points are skewed toward the positive direction (higher SHAP values), it indicates that higher feature values contribute positively to the prediction outcome (increasing the predicted value). Conversely, if blue points are skewed toward the negative direction (lower SHAP values), it suggests that lower feature values contribute negatively to the prediction outcome (decreasing the predicted value). ALT: alanine aminotransferase; APTT: activated partial thromboplastin time; AST: aspartate aminotransferase; DBP: diastolic blood pressure; GB: gradient boosting; HR: heart rate; PPTIC: preoperative and postoperative traumatic coagulopathy; PT: prothrombin time; RBC: red blood cell; RF: random forest; SBP: systolic pressure; SHAP: Shapley additive explanation; TIC: traumatic coagulopathy.

Complications During Hospitalization in Patients With PPTIC

Multivariate logistic regression analysis showed that compared with patients with non-PPTIC, those with PPTIC had significantly higher postoperative risks of the following complications: sepsis (1.75-fold, 95% CI 1.18-2.6; *P*=.006), heart failure (1.5-fold, 95% CI 1.24-1.82; *P*<.001), delirium (3.08-fold, 95% CI 1.62-5.83; *P*=.001), abnormal coagulation (3.57-fold, 95% CI 2.26-5.63; *P*<.001), tracheostomy (2.76-fold, 95% CI 2.02-3.77, *P*=.001), in-hospital mortality (2.19-fold, 95% CI 1.84-2.61; *P*<.001), urinary tract infection (1.95-fold, 95% CI 1.46-2.59; *P*<.001), and longer LOS and ICU stay (Figure 5).

Discussion

ML Models for Predicting PPTIC in Patients With Trauma

Our study found that RF, GB, and XGBoost had AUROC values above 0.89 for predicting PPTIC, with RF performing best at 0.91. RF showed excellent performance across training, testing, and external validation sets. RF is an ML algorithm capable of capturing potential nonlinear relationships between risk factors and outcomes [22]. It operates by creating hundreds or thousands of smaller decision trees and combining their outputs for prediction [23]. This approach helps overcome the tendency of decision trees to overfit [23] while enhancing model generalizability [24]. Therefore, we recommend the use of the RF to predict the occurrence of PPTIC in patients with trauma. The prediction variables were primarily continuous laboratory indicators, eliminating the need for conversion into binary or categorical forms and facilitating practical use. Physicians can directly input these indicators into the RF model to assess the risk of PPTIC in patients with trauma. Recent guidelines highlight the importance of early detection and management of TIC to improve outcomes for severely injured patients [9]. Our study aims to predict PPTIC using preoperative indicators to facilitate early intervention and thereby improve clinical outcomes in such patients.

Most robust PPTIC prediction models in our study are tree-based, such as RF, DT, GB, and XGBoost, a trend also seen in other coagulopathy-related ML models. Perkins et al [25] used BN to predict early TIC, defined as an INR>1.2. Their model, trained on 600 patients with trauma, achieved an AUROC of 0.93 with a BS of 0.06 in the development dataset and an AUROC of 0.95 with a BS of 0.05 in the validation set [25]. In comparison, Our RF model achieved an AUROC of 1 in training, 0.92 in validation, and 0.91 in external validation, with BS values of 0.01, 0.10, and 0.13, respectively. Li et al [26] defined acute traumatic coagulopathy (ATC) as an INR>1.5 and collected data from 818 patients with trauma admitted to the emergency department. They used LR and RF to predict ATC occurrence, with LR achieving an AUROC of 0.858 and RF achieving an AUROC of 0.830 in the internal validation set [27]. Their study used only 2 ML models, with RF and LR achieving moderate predictive performance for ATC. Peltan et al [27] predicted the occurrence of prehospital ATC in 285 severely injured patients, defining coagulopathy as an INR>1.5, with an AUROC value of only 0.73. Previous studies had small sample sizes and moderate predictive power, and were limited to single centers without external validation. In contrast, our multicenter study employed 10 ML models, with 3 demonstrating excellent performance. It included diverse medical centers and populations (White, Asian, Black, and

XSL•FO
RenderX

Latino) and featured external validation, showcasing the models' broad applicability and generalizability.

Preoperative Risk Factors and In-Hospital Complications of PPTIC in Patients With Trauma

The definition of TIC relies primarily on coagulation tests, drawing from extensive literature on the subject. Brohi et al [3] recommended that patients with a PT > 18 s, an INR > 1.5, an APTT>60 s, or a TT>15 s could be diagnosed with the hypocoagulable phenotype of TIC, and this diagnosis was not affected by the use of anticoagulant medications or abnormal blood samples. MacLeod et al [28] predicted early coagulopathy in 20,103 patients with trauma and reported a higher incidence after trauma, which was associated with mortality. They defined early coagulopathy as a PT>14 s, an APTT>35 s, and a PLT<100×10^9/L, highlighting its role as an independent predictor of death despite other risk factors [28]. Currently, the accepted definition of TIC utilizes the INR, with an INR>1.2 being the threshold for detecting TIC [8]. Yuan et al [18] defined TIC for predicting mortality among patients with trauma as a PLT<100×10^9/L, an INR>1.25, a PT>14 seconds, and an APTT>36 seconds [18]. We defined TIC based on coagulation test reference ranges from various centers and literature, using slightly lower standards than Brohi et al [3]. The main reasons for adopting these criteria are as follows: (1) lower diagnostic criteria alert clinicians to take early preventive measures to prevent PPTIC from progressing to disseminated intravascular coagulation; and (2) patients with preexisting TIC have a 50% chance of persisting with TIC postoperatively.

The prolongation of the preoperative APTT, PT, and INR in patients with trauma is understandable as a risk factor for PPTIC. The decreases in hemoglobin, hematocrit, and RBC levels and lower admission DBP are associated mainly with acute anemia due to preoperative bleeding in patients with trauma. Ryan et al [29] noted a close correlation between initial low hematocrit or hemoglobin levels in patients with trauma and hemorrhagic shock. RBC and hematocrit levels are key factors in platelet transport and adhesion to endothelial injury. Platelet adhesion increases 5-fold when hematocrit rises from 10% to 40% [30]. Therefore, the RBC level is closely related to the platelet level. Steele et al [31] reported an independent correlation between hyponatremia at admission and hypocalcemia. Ionic calcium is crucial not only for the formation and stability of fibrin polymerization sites but also for many platelet-related functions [32]. Platelet activation and aggregation are also calcium-dependent [33] and play crucial roles in the pathophysiology of TIC [34]. Elevated ALT and AST levels indicate liver damage, which impacts coagulation factor production and the coagulation process.

Hess et al [35] reported that patients with TIC experience more blood loss, higher transfusion needs, and a greater incidence of MODS compared to those without TIC. Brohi et al [3] highlighted that TIC is associated with a 4-fold increase in mortality, increased rates of massive transfusion and MODS, and prolonged ICU and LOS. Smalls et al [36] reported that patients with TIC due to splenic injury face 2.4 times more complications, with increased mortality (1.3-fold), sepsis (2-fold), acute respiratory distress syndrome (2.6-fold), acute renal failure (1.5-fold), and cardiac arrest (1.5-fold). These findings align with our study, where patients with PPTIC had increased risks of sepsis (1.75-fold), heart failure (1.5-fold), delirium (3.08-fold), abnormal coagulation (3.57-fold), tracheostomy (2.76-fold), mortality (2.19-fold), urinary tract infection (1.95-fold), and longer LOS and ICU stay.

Limitations

This retrospective study focused primarily on predicting PPTIC in patients with trauma via admission laboratory indicators and medical records. In this study, we addressed missing data to varying extents by excluding variables with more than 40% missing values and applying distinct imputation methods for variables with less than 40% missing data (KNN for continuous variables and multiple imputation for categorical variables). While multiple imputation is an effective method to mitigate systematic bias from nonrandom missing data, some data remained missing, which could affect the model's predictive accuracy for specific patient characteristics. Due to missing values exceeding 40% for certain indicators, such as height, admission peripheral capillary oxygen saturation, temperature on admission, pre-lymphocyte, pre-total protein, pre-globulin, pre-direct bilirubin, pre-lactate dehydrogenase, pre-D-dimer, and post-D-dimer (Multimedia Appendix 3), these variables were excluded from model development. As these missing data may impact the predictive performance of the model, future studies could address this by collecting more comprehensive data to improve model robustness. Additionally, large-sample prospective clinical trials are necessary to validate the model's applicability in clinical settings and assess its effectiveness in reducing the incidence of PPTIC.

Conclusions

Our study, using data from 4 medical centers, identified risk factors for PPTIC in patients with trauma. Significant factors included (1) prolonged preoperative APTT, PT, and INR; (2) decreased hemoglobin, hematocrit, RBC, calcium, and sodium levels; (3) lower admission DBP; (4) elevated ALT and AST levels; (5) increased admission HR; and (6) the need for emergency surgery or perioperative transfusion. PPTIC was associated with higher rates of sepsis, heart failure, delirium, abnormal coagulation, tracheostomy, mortality, and extended hospital and ICU stays. Of the 10 ML models evaluated for predicting PPTIC, RF demonstrated the best performance with an AUROC of 0.91, AUPRC of 0.89, accuracy of 0.84, and a BS of 0.13.

Abstract

Background: Sepsis, a critical global health challenge, accounted for approximately 20% of worldwide deaths in 2017. Although the Sequential Organ Failure Assessment (SOFA) score standardizes the diagnosis of organ dysfunction, early sepsis detection remains challenging due to its insidious symptoms. Current diagnostic methods, including clinical assessments and laboratory tests, frequently lack the speed and specificity needed for timely intervention, particularly in vulnerable populations such as older adults, intensive care unit (ICU) patients, and those with compromised immune systems. While bacterial cultures remain vital, their time-consuming nature and susceptibility to false negatives limit their effectiveness. Even promising existing machine learning approaches are restricted by reliance on complex clinical factors that could delay results, underscoring the need for faster, simpler, and more reliable diagnostic strategies.

Objective: This study introduces innovative machine learning models using complete blood count with differential (CBC+DIFF) data—a routine, minimally invasive test that assesses immune response through blood cell measurements, critical for sepsis identification. The primary objective was to implement this model within an artificial intelligence–clinical decision support system (AI-CDSS) to enhance early sepsis detection and management in critical care settings.

Methods: This retrospective study at Tri-Service General Hospital (September to December 2023) analyzed 746 ICU patients with suspected pneumonia-induced sepsis (supported by radiographic evidence and a SOFA score increase of ≥2 points), alongside 746 stable outpatients as controls. Sepsis infection sources were confirmed through positive sputum, blood cultures, or FilmArray results. The dataset incorporated both basic hematological factors and advanced neutrophil characteristics (side scatter light intensity, cytoplasmic complexity, and neutrophil-to-lymphocyte ratio), with data from September to November used for training and data from December used for validation. Machine learning models, including light gradient boosting machine (LGBM), random forest classifier, and gradient boosting classifier, were developed using CBC+DIFF data and were assessed using metrics such as area under the curve, sensitivity, and specificity. The best-performing model was integrated into the AI-CDSS, with its implementation supported through workshops and training sessions.

Results: Pathogen identification in ICU patients found 243 FilmArray-positive, 411 culture-positive, and 92 undetected cases, yielding a final dataset of 654 (43.8%) sepsis cases out of 1492 total cases. The machine learning models demonstrated high

XSL•FO
RenderX

predictive accuracy, with LGBM achieving the highest area under the curve (0.90), followed by the random forest classifier (0.89) and gradient boosting classifier (0.88). The best-performing LGBM model was selected and integrated as the core of our AI-CDSS, which was built on a web interface to facilitate rapid sepsis risk assessment using CBC+DIFF data.

Conclusions: This study demonstrates that by providing streamlined predictions using CBC+DIFF data without requiring extensive clinical parameters, the AI-CDSS can be seamlessly integrated into clinical workflows, enhancing rapid, accurate identification of sepsis and improving patient care and treatment timeliness.

KEYWORDS

sepsis; artificial intelligence; critical care; complete blood count analysis; CBC analysis; artificial intelligence clinical decision support systems; AI-CDSS

Introduction

The World Health Organization classifies sepsis as a critical global health issue, responsible for approximately 20% of all deaths worldwide in 2017, with 48.9 million cases and 11 million fatalities [1,2]. Sepsis, a life-threatening condition triggered by the body's response to infection, leads to severe consequences, such as septic shock, organ failure, and even death if not promptly managed [3]. The mortality rate for sepsis is alarmingly high at 32.2%, and it rises significantly to 38.5% for those who develop septic shock, as reported in a meta-analysis [4]. It predominantly affects high-risk groups such as older adults, intensive care unit (ICU) patients, and those with chronic conditions or compromised immune systems [5]. The prevalence of sepsis, which is intensified by drug-resistant infections, highlights the need for more effective prevention and treatment methods [6] and rapid diagnostic strategies [7], particularly in optimizing their implementation in clinical settings [8]. The key to mitigating the heavy health toll of sepsis lies in its efficient management and, crucially, early detection, which significantly enhances the probability of recovery and diminishes its overall detrimental health impact [1,9].

According to the Surviving Sepsis Campaign, sepsis diagnosis relies on the Sequential Organ Failure Assessment (SOFA) score, which evaluates organ dysfunction resulting from infection by assessing 6 components: respiratory function through the ratio of partial pressure of oxygen in arterial blood to the fraction of inspiratory oxygen concentration, coagulation through the platelet count, liver function with bilirubin levels, cardiovascular status through hypotension or the use of vasopressors, central nervous system function using the Glasgow Coma Scale, and renal function measured through creatinine levels or urine output [3]. An increase of 2 or more points in the SOFA score, combined with suspected infection, indicates sepsis [3,10]. For rapid assessments outside of ICUs, the quick SOFA criteria, altered mental state, respiratory rate of ≥22 breaths per minute, or low blood pressure (systolic blood pressure≤100 mm Hg) are used for prompt evaluation, which is critical for reducing sepsis-related health impacts [3,10]. Alongside identifying and addressing the source of infection or removing suspected infected routes or devices, immediate administration of broad-spectrum antimicrobial agents within 1 hour of detecting sepsis is crucial for effective management [3,10,11]. Rapid intravenous crystalloid resuscitation and ongoing fluid adjustments are essential to maintain circulatory volume and ensure organ perfusion [3,10]. Vasopressors, such as norepinephrine, should be applied if a mean arterial pressure of at least 65 mm Hg cannot be maintained [3,10]. Dynamic monitoring of stroke volume, pulse pressure variations, and respiratory status is essential for effective treatment, enabling precise, real-time adjustments to fluid therapy [3,10].

Traditional diagnostic methods such as clinical assessments, laboratory evaluations, and patient histories, while foundational, often lack the immediacy and specificity required to promptly confirm infections [3,5,12]. The progression from infection to sepsis can be insidious, with initial clinical manifestations that are highly variable and influenced by both host and pathogen factors [10]. This variability can be particularly detrimental, as rapid identification within the first crucial hours is vital; delays in diagnosis or the initiation of antibiotic treatment can lead to rapid deterioration in the patient's condition, significantly worsening the prognosis [10]. While existing machine learning models have sought to reduce these delays by expediting the diagnosis of sepsis, many rely on complex clinical factors that can still delay results or affect accuracy [13-15]. In addition, blood cultures, though critical for identifying pathogens, could take days and are prone to false negatives, further complicating the timely management of sepsis [3,5,12]. This highlights a critical need for simpler, more effective diagnostic approaches that can be swiftly applied and have high reliability.

Addressing these challenges, our research introduces a novel machine learning model centered on complete blood count with differential (CBC+DIFF) data, a routine and minimally invasive test that measures the levels of various blood cell types, including white blood cells, red blood cells, and platelets. This approach was selected for its broad clinical use, rapid analytical time, and ability to evaluate immune response through white blood cell differential analysis (such as neutrophils and lymphocytes), which are crucial for early sepsis detection. This makes it an accessible and cost-effective tool for diagnostics, allowing us to simplify the diagnostic process without sacrificing accuracy. The primary objective of this study was to develop and implement an artificial intelligence–clinical decision support system (AI-CDSS) that uses this model to provide rapid and precise indications of sepsis. This system aims to facilitate earlier intervention and potentially improve patient outcomes across various medical settings, from outpatient departments to emergency departments, with a particular focus on high-stakes environments such as ICUs, where timely decisions are crucial.

Methods

Study Focus and Data Collection

In our retrospective study conducted at the ICU of Tri-Service General Hospital from September to December 2023, we focused on cases suspected of pneumonia-induced sepsis, as approved by the hospital's institutional review board. The study site, a major teaching hospital affiliated with the National Defense Medical Center in Taipei, Taiwan, is a facility with approximately 1800 beds, serving as the primary referral center for 3 branch hospitals in northern Taiwan. This comprehensive medical center provides advanced medical facilities and multidisciplinary care to both civilian and military patients, while its branch hospitals focus on chronic condition management and refer complex acute cases, including sepsis, to the main facility. This centralized health care network structure enabled us to collect data from a diverse patient population across various clinical settings. Our data were exclusively derived from the electronic medical records of patients who were either transferred from the general ward owing to deteriorating conditions or directly admitted from the emergency department owing to severe initial clinical presentations. These records include admission notes, progress notes, laboratory results, and radiographic findings. We included only those patients whose records indicated pneumonia as the suspected cause of sepsis, corroborated by radiographic evidence consistent with pneumonia and an increase in the SOFA score of 2 or more points, indicating significant organ dysfunction. Specifically, we extracted and analyzed data on CBC+DIFF, sputum cultures, blood cultures, and FilmArray analyses. These selected data points formed our core dataset used to analyze the diagnostic and management strategies for pneumonia-induced sepsis in the ICU.

Control Group Selection

In addition to the groups directly involved in the sepsis investigation, the study included a control group of 746 randomly selected outpatients from the same hospital, enrolled during the same period. These patients typically visited the hospital for routine follow-up appointments. On their appointment days, they first stopped at our blood draw station, where standard blood tests were performed. The results of these tests were available to their physicians within 1 hour, ensuring that the most current health data would be reviewed during their visit. Data from these patients were obtained from the hospital's electronic medical records. These records confirmed that none of these individuals required subsequent transfer to the emergency department for acute issues, verifying their stable health condition at the time of their visit. CBC+DIFF data were collected specifically for this group.

Ethical Considerations

Our retrospective study was conducted following strict ethical guidelines approved by the Tri-Service General Hospital's Institutional Review Board (approval C202305073). The study adhered to the principles outlined in the Declaration of Helsinki and relevant local ethical regulations. The study involved analyzing anonymized patient data to ensure privacy and confidentiality and was exempt from the requirement for patient consent under local and international ethical regulations. No compensation was provided to the patients as no direct interaction was involved.

Sepsis Identification and Classification Criteria

Criteria for Confirming Sepsis

We initially considered all ICU patients with suspected sepsis. Confirmation depended on positive sputum or blood cultures, or FilmArray test results [16], in conjunction with clinical symptoms and identified infection sources.

Exclusion Parameters

Cases lacking data or with poor sample quality (including blood samples with volumes less than 10 mL, sputum samples less than 1 mL, or showing contamination indicators such as squamous cell count>10/low power field or mixed bacterial flora), impacting the trustworthiness of culture reports, were excluded.

Determination of Nonseptic Status

Patients with negative results in both culture and FilmArray tests were classified as nonseptic.

Data Processing and Model Formulation

Data Organization

We meticulously organized the patient data using Python's *Pandas* framework (Python Software Foundation) to enhance data handling and analysis efficiency.

Selection of Features

Our approach involved a comprehensive analysis of hematological parameters from the CBC+DIFF data using the Sysmex XN-9100 system, focusing on parameters relevant to sepsis pathology. These included white blood cell count (10^3/μL), red blood cell count (10^6/μL), hemoglobin (g/dL), hematocrit (%), mean corpuscular volume (fL), mean corpuscular hemoglobin (pg), mean corpuscular hemoglobin concentration (g/dL), platelet count (10^3/μL), neutrophil percentage (%), lymphocyte percentage (%), monocyte percentage (%), eosinophil percentage (%), basophil percentage (%), immature granulocyte count (10^3/μL), immature granulocyte percentage (%), neutrophil side scatter light intensity, neutrophil cytoplasmic complexity, and neutrophil-to-lymphocyte ratio. Special attention was paid to neutrophil side scatter light intensity and neutrophil cytoplasmic complexity regarding their insights into neutrophil characteristics. Heat map visualization aided in identifying the most significant features of our predictive model and in discarding less relevant features to optimize the dataset for targeted analysis. In addition, we used Shapley additive explanations (SHAP) values to interpret feature importance and contribution to the model's output. SHAP summary plots generated with the *TreeExplainer* illustrated the impact of individual features on sepsis risk predictions, enhancing our understanding of the model's decision-making process and ensuring interpretability and reliability.

XSL•FO
RenderX

Model Development and Evaluation

Data Segmentation

The dataset was divided, with data from September to November forming the training set and data from December used for validation.

Using Machine Learning Algorithms

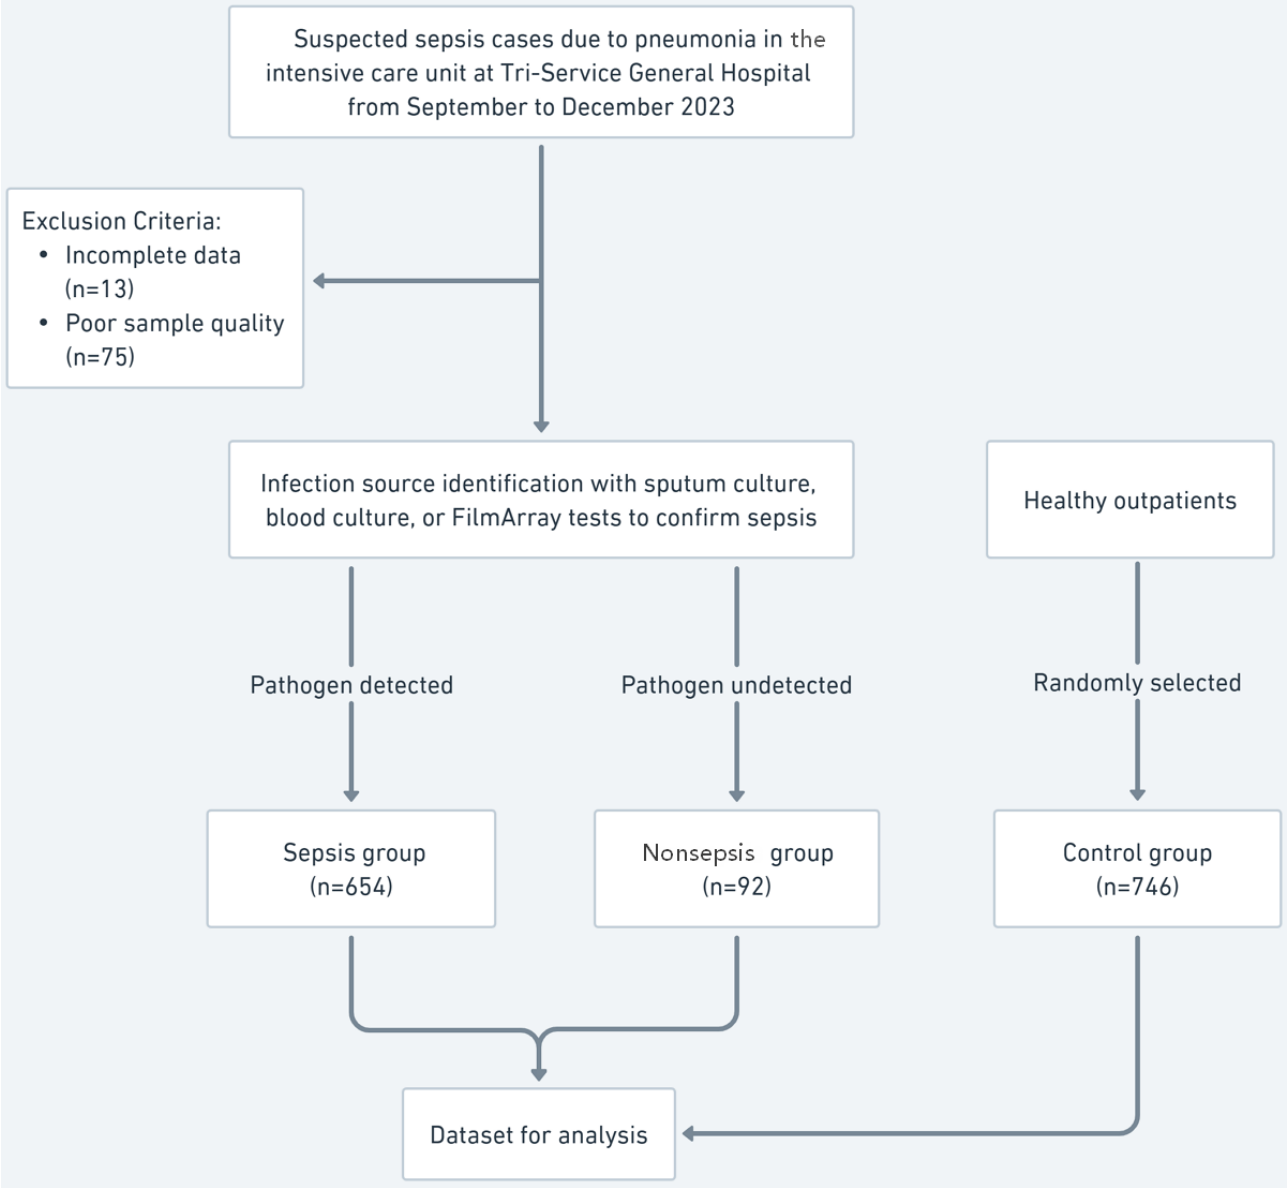
We used a diverse range of machine learning models for the extensive analysis of predictive capabilities. These included logistic regression (LR), linear discriminant analysis, the random forest classifier (RFC), the gradient boosting classifier (GBC), the AdaBoost classifier, extreme gradient boosting (XGBoost), and the light gradient boosting machine (LGBM). Each model was selected to provide a comprehensive perspective on the individual and collective abilities to accurately predict sepsis.

Assessment of Predictive Accuracy

These models were stringently tested using receiver operating characteristic curves, the area under the curve (AUC), sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), and the F_1-score to measure the accuracy of sepsis prediction. We also evaluated the models using the Brier score and Brier skill score (BSS) to assess the accuracy and calibration of probabilistic predictions. The Brier score measures the mean squared difference between predicted probabilities and actual outcomes, with lower scores indicating better accuracy. The BSS compares the model's performance against a baseline model using LR, which provides a more representative benchmark. Values above 0 for the BSS indicate superior performance.

Clinical Utility Evaluation

To select the best-performing model for accurate sepsis prediction, we validated the models using data collected in December and evaluated key performance metrics, including AUC, sensitivity, specificity, PPV, NPV, and F_1-score. The optimal model was saved using Python's *joblib* package for seamless implementation. For clinical deployment, we created a web-based, AI-CDSS interface that allows clinicians to initiate sepsis risk assessment by entering a patient ID. The system retrieves laboratory values, sends them to a Python Flask server for analysis, and then displays the calculated sepsis probability. In addition, health care professionals received comprehensive support through group workshops and online training sessions. Feedback collected through surveys and interviews was used to continuously refine the tool, enhancing its usability and integration into clinical workflows.



Results

Patient Demographics and Analysis

Our study included 746 ICU patients and a control group of 746 randomly selected healthy outpatients, which served as a normative benchmark. Among the ICU patients, 654 were classified in the sepsis group based on confirmed pathogen detection: 243 were identified through FilmArray tests and 411 through culture tests. The remaining 92 patients, initially suspected of sepsis, were reclassified into the nonsepsis group due to the absence of pathogen detection, suggesting alternative etiologies for their symptoms. This classification ultimately yielded a final dataset consisting of 654 (43.8%) sepsis cases out of a total of 1492 cases (Figure 1). We compiled the demographic and clinical characteristics, including the CBC+DIFF parameters, for each group, as detailed in Table 1.

[a]WBC: white blood cell count.

[b]RBC: red blood cell count.

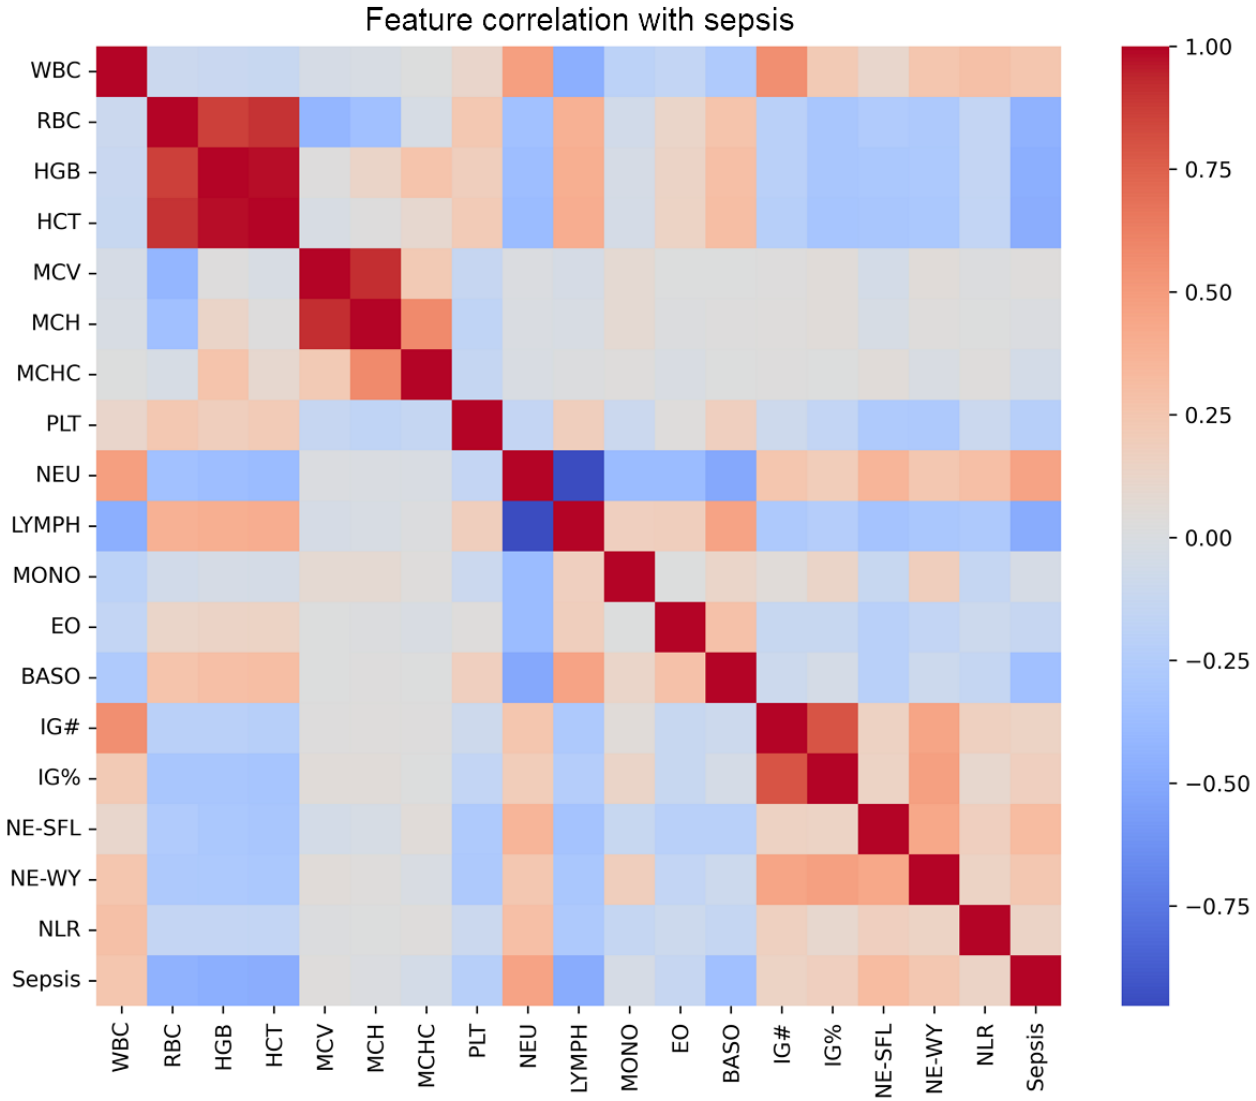
[c]Hb: hemoglobin.

[d]HCT: hematocrit.

[e]MCV: mean corpuscular volume.

[f]MCH: mean corpuscular hemoglobin.

[g]MCHC: mean corpuscular hemoglobin concentration.



In Figure 1, a comprehensive flowchart illustrates the patient selection process used in our study. It outlines the initial screening of ICU patients with suspected pneumonia; the criteria used to confirm sepsis (such as positive results from sputum or blood cultures or FilmArray tests); and how patients were categorized into groups of confirmed sepsis, suspected nonsepsis, and outpatient control. In addition, this flowchart delineates the number of patients at each stage and the reasons for exclusion.

Data Visualization and Feature Analysis

For feature selection, we used heat maps to graphically represent the correlation between various CBC+DIFF parameters and sepsis, as shown in Figure 2. This visualization technique enabled us to eliminate parameters, such as the mean corpuscular hemoglobin concentration, mean corpuscular volume, and monocyte percentage, which had minimal impact on our model's predictions. The SHAP summary plot, as shown in Figure S1 in Multimedia Appendix 1, further revealed that lymphocyte percentage was the most influential feature, with high values decreasing the sepsis risk. Neutrophil percentage and neutrophil-to-lymphocyte ratio strongly correlated with an increased sepsis risk. Features such as mean corpuscular hemoglobin concentration, mean corpuscular volume, and monocyte percentage also show the least impact, aligned with the interpretation from Figure 2. This confirms the critical role of specific blood parameters in sepsis detection and enhances our model's interpretability and clinical relevance.

XSL•FO
RenderX

Figure 2. Correlation heat map of complete blood count with differential (CBC+DIFF) parameters and sepsis. BASO: basophil (%); EO: eosinophil (%); HCT: hematocrit (%); HGB: hemoglobin (g/dL); IG#: immature granulocytes (10^3/μL); IG%: immature granulocytes (%); LYMPH: lymphocyte (%); MCH: mean corpuscular hemoglobin (pg); MCHC: mean corpuscular hemoglobin concentration (g/dL); MCV: mean corpuscular volume (fL); MONO: monocyte (%); NE-SFL: neutrophil side scatter light intensity; NEU: neutrophil (%); NE-WY: neutrophil cytoplasmic complexity; NLR: neutrophil-to-lymphocyte ratio; PLT: platelet count (10^3/μL); RBC: red blood cell count (10^6/μL); WBC: white blood cell count (10^3/μL).

In Figure 2, the heat map depicts the correlations between various CBC+DIFF parameters and the occurrence of sepsis. This effectively shows the relevance of each parameter in predicting sepsis and serves as a crucial tool for identifying and selecting key features for the machine learning model. The color gradients in the heat map correspond to the varying strengths of these correlations.

Machine Learning Model Performance

Our analysis of the machine learning models for detecting sepsis yielded significant results, as detailed in Table 2 and illustrated in Figure 3. The GBC and RFC models exhibited superior predictive performance, with the GBC model achieving a perfect training AUC of 0.99 and a testing AUC of 0.88. The RFC model demonstrated excellent reliability, with a training AUC of 0.94 and a testing AUC of 0.89.

Figure 3. Receiver operating characteristic curves of the evaluated machine learning models.

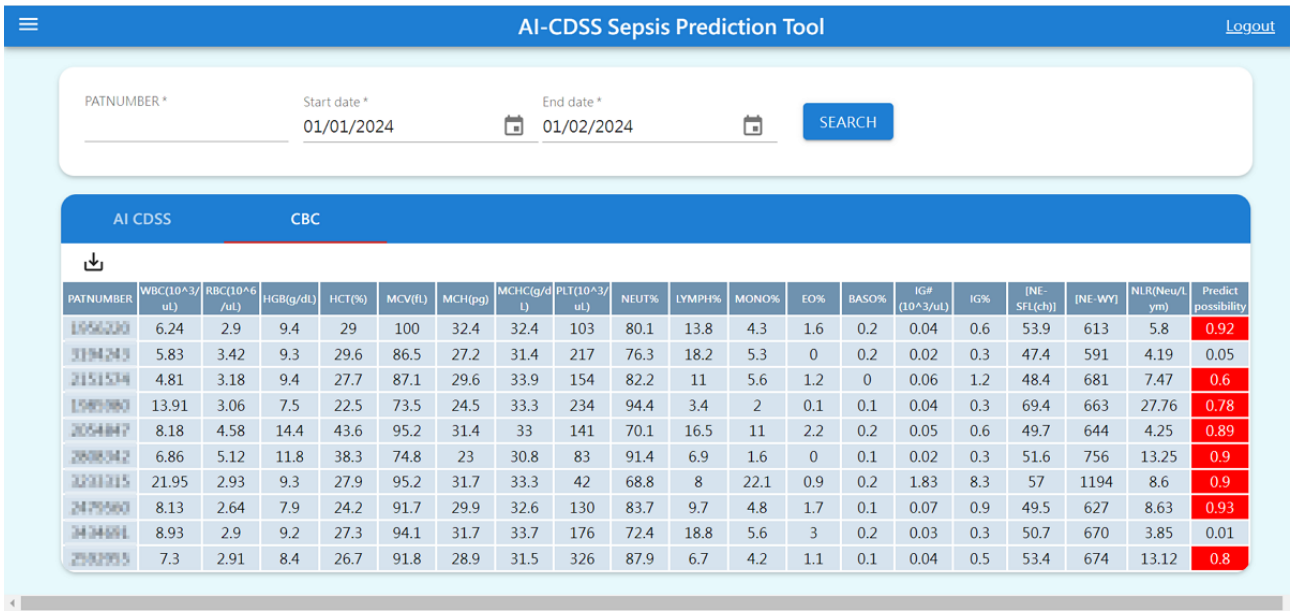
XSL•FO
RenderX

Moreover, the LGBM model surpassed the others in terms of testing accuracy, scoring a testing AUC of 0.90, highlighting its analytical efficiency. The XGBoost model also showed substantial potential for accurately predicting sepsis with an AUC of 0.88.

The GBC model showed a high PPV of 0.75, indicating its effectiveness in correctly identifying septic cases. Furthermore, the RFC and LGBM models also demonstrated strong predictive reliability with PPV of 0.73 and 0.76, respectively, reinforcing their utility for sepsis detection.

Brier score and BSS evaluations reveal that the RFC model achieved the best performance with the lowest Brier Score (0.13) and highest BSS (15.79%), substantially outperforming the baseline LR model with a Brier score of 0.15. The GBC, LGBM, and XGBoost models also showed strong performance, each with a Brier score of 0.13 and BSS values of 12.54%, 10.38%, and 14.33%, respectively. In contrast, the AdaBoost classifier had the highest Brier score (0.22) and a negative BSS (-47.29%), indicating poorer performance. These findings highlight that RFC, GBC, LGBM, and XGBoost models provide both accurate and well-calibrated probabilistic estimates for sepsis, as detailed in Table 2.

In Figure 3, the receiver operating characteristic curves for the various machine learning models are assessed in the study, including the LR, linear discriminant analysis, RFC, GBC, AdaBoost classifier, XGBoost, and the LGBM models. These curves graphically represent the true-positive rate versus the false-positive rate for each model, elucidating their efficacy in differentiating sepsis from nonsepsis cases. The AUC values were also provided to gauge the predictive accuracy of each model.



The receiver operating characteristic curves depicted in Figure 3 provide a direct comparison of the model performances. These curves plot the true-positive rate against the false-positive rate and identify the ensemble models (GBC, RFC, and LGBM) that are particularly effective in differentiating between sepsis and nonsepsis cases, making them valuable tools for ICU diagnostics.

In summary, our findings suggest that the GBC, RFC, and LGBM models, with their high AUC values, balanced performance, and strong PPV scores, are robust tools for early sepsis prediction and can substantially enhance the clinical workflow by enabling timely and accurate sepsis interventions.

Clinical Application of the Predictive Model

Following a comprehensive evaluation, the LGBM model was selected as the backbone of our AI-CDSS owing to its superior performance on key metrics such as the AUC, sensitivity, and specificity. A key advancement in clinical decision-making is the development of a web-based interface for health care professionals. This tool allows for the quick input of CBC data to obtain an immediate assessment of the sepsis risk. A screenshot of this user-friendly functional interface is shown in Figure 4, demonstrating its applicability in real-time clinical settings. This interface marks a significant step forward in applying our machine learning model for swift and reliable sepsis risk evaluation, thereby optimizing the diagnostic process in ICU settings.

Figure 4. Interface demonstration for web-based sepsis risk assessment. A screenshot of the innovative web-based interface developed in this study. This interface was designed to allow health care professionals to load complete blood count data and swiftly assess sepsis risk. AI-CDSS: artificial intelligence–clinical decision support system.

Discussion

Principal Findings

Our research contributes to advancements in rapid sepsis diagnostics through the development and validation of machine learning models that use CBC+DIFF data. The encouraging performance of the LGBM, GBC, and RFC models, as indicated by their AUC values during the testing phases, suggests a potential shift from traditional, more cumbersome diagnostic methods to a swift, data-driven approach using routine blood tests for the early detection of sepsis.

XSL•FO
RenderX

Importance of Early Sepsis Detection and Advanced Diagnostic Technologies

Early detection of sepsis is crucial to prevent progression to severe sepsis and septic shock, improving patient outcomes and reducing mortality. The mortality rate for septic shock (38.5%) is higher than that for sepsis (32.2%) [4], highlighting the need for early intervention and treatment for sepsis. Early intervention can significantly reduce the length of hospitalization; lower health care costs; and most importantly, improve the survival rates of patients [1,9]. Enhanced diagnostic accuracy can be achieved using new parameters that provide information on the morphological and functional characteristics of leukocytes, reflecting their activation and functional activity in response to infections [17]. In our study, we use the Sysmex XN-9100 system, which uses fluorescence flow cytometry along with blood-cell membrane surfactant reagents and fluorescent dyes targeting nucleic acids and proteins. This advanced technology provides detailed insights into the morphological characteristics of neutrophils, lymphocytes, and monocytes, further enhancing our ability to detect and understand sepsis at the cellular level.

Interpreting the Models' Effectiveness

The strong efficacy of LGBM, GBC, and RFC models underscores the potential of regular CBC+DIFF data as a valuable yet underexplored tool for early sepsis detection. The ability of these machine learning models to distinguish between septic and nonseptic states is particularly critical in ICU settings, where prompt diagnosis is of paramount importance [18], as multiple studies endeavor to detect early sepsis using machine learning models [15]. To further understand the contribution of each feature, we used heat map visualizations and SHAP values. The heat map analysis highlighted significant features such as neutrophil percentage, lymphocyte percentage, and neutrophil-to-lymphocyte ratio from the CBC+DIFF data, and SHAP values offered an additional perspective on how each feature influenced the model's predictions, enhancing clinical interpretability. In addition to the AUC, we evaluated the models using other metrics, including accuracy, sensitivity, specificity, PPV, NPV, and the F_1-score. The LGBM model outperformed the RFC and GBC models in these metrics, showcasing its superior overall performance. Furthermore, we assessed the models using the Brier score and BSS. The Brier score for the RFC, GBC, and LGBM models was 0.13, indicating similar accuracy among these models. However, the BSS showed that the RFC model had a slightly higher value of 15.79%, compared to the GBC model's 12.54% and the LGBM model's 10.38%, reflecting better performance relative to the baseline LR model, despite the LGBM model outperforming the RFC model in other metrics. Therefore, the LGBM model was integrated into our AI-CDSS backbone core owing to its overall performance.

Comparison to Previous Work

Our sepsis prediction model based on CBC+DIFF data provides a streamlined and efficient approach compared to existing models that require numerous physiological and clinical parameters from laboratory profiles, electronic health records, vital signs, and monitoring devices [13,14,19]. Unlike these complex models, our approach relies exclusively on readily available hematological data, making it highly accessible across various clinical settings, including non-ICU environments. Despite its simplicity, our model achieves an AUC of 0.90, surpassing the performance of more complex models that report AUCs ranging from 0.83 to 0.87, demonstrating that comprehensive predictive capability can be achieved using basic hematological parameters alone [13,14,19]. The model's simplicity offers significant advantages in terms of speed, cost-efficiency, and ease of implementation, particularly in settings where extensive data collection is challenging. By enabling rapid risk assessment through routine blood work, our model provides relative real-time decision support that facilitates efficient patient management across diverse health care settings, from emergency departments to resource-constrained environments.

Workflow Integration

Currently, our AI-CDSS web system is deployed on our hospital's internal server after validation. Physicians can log in to the system with their account, input the patient's medical record number, and select the relevant CBC+DIFF test values for analysis. The system analyzes the test data and provides an estimated probability of sepsis. This deployment allows for seamless integration into daily clinical workflows, enabling quick and accurate assessments that support timely and informed clinical decisions. Compared to traditional methods, even when physicians use the SOFA score to assess sepsis, they typically have to wait approximately 3 days to confirm a positive bacterial culture from blood or sputum samples. In contrast, our new AI-CDSS system can provide an earlier indication of infection within minutes, allowing physicians to confirm sepsis sooner and intervene earlier, thereby improving patient outcomes.

Clinical Relevance and Implementation

Considering the complex interplay of sepsis-related mortality and underlying diseases [20], the development of more precise diagnostic tools, such as our machine learning models, is essential to improve the early detection and management of sepsis in ICU settings. Our research, centered on the LGBM, GBC, and RFC, aligns with the broader trend of integrating diverse machine learning models in health care [21], reflecting the growing significance of artificial intelligence in enhancing sepsis diagnostics across various hospital settings [15]. Incorporating these models into ICU practices aligns with the emerging trends in health care [7] and could show potential to transform sepsis diagnostics, offering a rapid and precise alternative to traditional diagnostic approaches with only a minimally invasive blood draw required. The models' adoption is expected to enable early therapeutic intervention, thereby enhancing patient outcomes [15]. The creation of a user-friendly, web-based interface for health care professionals exemplifies the practicality of these models, facilitating real-time clinical decision-making and improving patient care.

In resource-limited countries, our study presents a potential innovation for sepsis management using machine learning for CBC+DIFF analysis, providing a rapid, effective alternative to traditional methods, essential where resource constraints cause life-threatening diagnostic delays [22]. Using routine blood tests, health care providers in these regions can rapidly identify sepsis risk, enabling quicker intervention and potentially

XSL•FO
RenderX

reducing the heavy dependence on limited antibiotics [23]. This method could assist in areas with limited access to advanced diagnostic facilities. Our study highlights the potential global impact of artificial intelligence–enhanced blood analysis, offering a promising approach to enhance sepsis diagnosis and improving patient outcomes in under-resourced settings.

Limitations

Although our findings are encouraging, there are some limitations to our study. The retrospective nature of data collection may introduce selection bias, and reliance on a singular data source (CBC+DIFF) could restrict the breadth of the models. In addition, this study was conducted at a single center, although supported by branches that refer to sepsis cases and focused exclusively on pneumonia-induced sepsis, which may limit the generalizability of the findings to other causes of sepsis. Although our results are promising, they are preliminary and require further confirmation through prospective studies in various clinical settings to verify their robustness and applicability.

Future Research

We recommend conducting extensive validation studies to confirm each model's generalizability and performing cost-benefit analyses to evaluate their impact on health care systems. As these models are integrated into clinical practice, it is essential to provide comprehensive training for health care professionals to ensure the optimal utilization of web-based tools. Expanding the model data inputs to encompass more patient-specific factors could further improve the accuracy of sepsis prediction.

Conclusions

In summary, our study contributes to advancements in sepsis diagnostics by exploring the use of machine learning to interpret CBC+DIFF data for enhanced sepsis diagnosis. This innovative approach may represent a significant shift in critical care and has the potential to impact diagnostics in various health care settings, including outpatient and emergency departments. By aiming to enable faster and more precise detection of sepsis, these models could significantly contribute to global health care efforts against sepsis, potentially aiding in improvements in patient care and outcomes. This approach may offer benefits in resource-limited countries, where diagnosing sepsis with only CBC+DIFF data provides a crucial alternative in scenarios where traditional diagnostic means are lacking.

Acknowledgments

Financial support for this research was provided by the Tri-Service General Hospital in Taipei, Taiwan, under grants TSGH_D_114102, TSGH_D_114101, MND-MAB-D-114203, and MND-MAB-D-113168. The sponsors did not participate in the design of the study, the gathering and analysis of data, or the determination to publish this research. Abstract

Background: Neuroimaging segmentation is increasingly important for diagnosing and planning treatments for neurological diseases. Manual segmentation is time-consuming, apart from being prone to human error and variability. Transformers are a promising deep learning approach for automated medical image segmentation.

Objective: This scoping review will synthesize current literature and assess the use of various transformer models for neuroimaging segmentation.

Methods: A systematic search in major databases, including Scopus, IEEE Xplore, PubMed, and ACM Digital Library, was carried out for studies applying transformers to neuroimaging segmentation problems from 2019 through 2023. The inclusion criteria allow only for peer-reviewed journal papers and conference papers focused on transformer-based segmentation of human brain imaging data. Excluded are the studies dealing with nonneuroimaging data or raw brain signals and electroencephalogram data. Data extraction was performed to identify key study details, including image modalities, datasets, neurological conditions, transformer models, and evaluation metrics. Results were synthesized using a narrative approach.

Results: Of the 1246 publications identified, 67 (5.38%) met the inclusion criteria. Half of all included studies were published in 2022, and more than two-thirds used transformers for segmenting brain tumors. The most common imaging modality was magnetic resonance imaging (n=59, 88.06%), while the most frequently used dataset was brain tumor segmentation dataset (n=39, 58.21%). 3D transformer models (n=42, 62.69%) were more prevalent than their 2D counterparts. The most developed were those of hybrid convolutional neural network-transformer architectures (n=57, 85.07%), where the vision transformer is the most frequently used type of transformer (n=37, 55.22%). The most frequent evaluation metric was the Dice score (n=63, 94.03%). Studies generally reported increased segmentation accuracy and the ability to model both local and global features in brain images.

Conclusions: This review represents the recent increase in the adoption of transformers for neuroimaging segmentation, particularly for brain tumor detection. Currently, hybrid convolutional neural network-transformer architectures achieve state-of-the-art performances on benchmark datasets over standalone models. Nevertheless, their applicability remains highly limited by high computational costs and potential overfitting on small datasets. The heavy reliance of the field on the brain tumor segmentation dataset hints at the use of a more diverse set of datasets to validate the performances of models on a variety of neurological diseases. Further research is needed to define the optimal transformer architectures and training methods for clinical applications. Continuing development may make transformers the state-of-the-art for fast, accurate, and reliable brain magnetic resonance imaging segmentation, which could lead to improved clinical tools for diagnosing and evaluating neurological disorders.

Introduction

Neuroimaging refers to the visualization of the structure and function of the brain. It is one of the most important tools in the understanding of different neurological disorders. Generally, neuroimages can be obtained using 3 principal imaging modalities, where each modality shows the complexities of the brain from a different perspective. Of the 3, magnetic resonance imaging (MRI) is still the most frequently used due to high contrasting ability of brain tissues, high spatial resolution, and no risk of radiation exposure [1-3]. For different brain regions to be viewed, multiple MRI sequences are needed, such as T1, T1ce, T2, and fluid-attenuated inversion recovery, as presented in Figure 1 [4]. The second neuroimaging modality is computed tomography (CT), which can produce high-resolution images. On the other hand, it has limited soft tissue characterization, and its radiation risk makes it unsuitable for repetitive use [3,5]. The third neuroimaging modality is positron emission tomography (PET), which integrates nuclear medicine to visualize metabolic activity [2]. PET has high sensitivity, making it effective in detecting metastases, finding abnormalities, and imaging deep structures. However, it has limited resolution, and repeated use causes radiation risk [3,5]. Finding changes in brain tissue through neuroimaging analysis is critical for detecting and monitoring neurological disorders [6] and brain tumors [7]. Segmentation is a useful process in outlining regions of interest in medical images [8], which enables the quantitative assessment of atrophy, growths, and anatomical differences that depict conditions like Alzheimer disease, schizophrenia, and brain tumors among other neurodegenerative diseases [2]. Because of this, segmentation is applied broadly in different medical applications in diagnosis, tissue classification, radiotherapy treatment, and surgical planning [2,9].

Figure 1. Magnetic resonance imaging modalities of brain tumor. FLAIR: fluid-attenuated inversion recovery; T1: T1-weighted imaging; T2: T2-weighted imaging; T1ce: T1-weighted contrast-enhanced imaging.

Segmentation techniques can be classified into 3 categories: manual, semiautomated, and fully automated. Manual segmentation is the standard for segmentation because it is believed to be the most accurate [10]. The technique, however, is laborious, time-consuming, and subjective, since it depends on human judgment, and this may result in variation in the results because of the different interpretations. Due to this, there has been a great deal of research into automated segmentation techniques to replicate the results from manual segmentation but with a higher level of efficiency and consistency [2]. To do this, 2 early paradigms were used: intensity-based approaches, which include thresholding, edge-detection, and region-based [8], and traditional machine learning paradigms, including support vector machine, k-nearest neighbor clustering, and random forest [8,11]. Each of these methods has been applied in 1 or more ways, but their applicability and performance within the task of image segmentation remain limited [11,12]. Since then, deep learning (DL) methods have transformed medical imaging applications and became a strong alternative to classical techniques.

DL is a subclass of machine learning that involves artificial neural networks with multiple layers. These networks are designed to progressively learn hierarchical representations and features of data, which both eliminates the need for manual feature engineering [2] and enables the extraction of complicated patterns from large datasets [13]. Different DL architectures have been used for medical image segmentation, but the most widely used and popular one is convolutional neural networks (CNNs), which have achieved state-of-the-art performances in different medical imaging tasks, including segmentation [12,14]. U-Net [15] is another notable model that was specially designed for biomedical image segmentation and has produced very good results in its field [16-18]. Some other notable models include SegNet [19], ResNet [20], DenseNet [21], 3D-ConvNet [22], and DeepLab [23]. These models have served as a solid foundation for the imaging field and have resulted in a plethora of variants, each developed for specific imaging modalities, anatomical structures, and segmentation tasks. Transformers [24] are a type of neural network architectures that mainly rely on self-attention mechanisms. They were first proposed in 2017 and have since yielded state-of-the-art results in the field of natural language processing [25]. More recently, transformers have also shown success when applied to a wide array of computer vision tasks, one of which is segmentation [26]. Although CNNs have achieved impressive performances in image-related tasks, they may not capture global and long-range dependencies well due to the small kernel size [26,27].

Transformers have recently gained popularity in imaging due to their self-attention mechanism, which can model these long-range dependencies—especially useful in brain segmentation [27]. The great success of transformers has motivated the construction of vision transformers (ViT) [28],

XSL•FO
RenderX

which forego the use of convolutional layers and rely instead on a multihead self-attention mechanism [13,29]. This architecture divides an image into fixed-size patches, linearly embeds them, and processes them through a transformer network, thereby allowing it to model long-range dependencies with reduced inductive bias [27,30]. Recently, ViT architectures specifically designed for medical image segmentation have been explored and resulted in models like TransUnet [31] and Swin-UNet [32] for general-purpose use and models like TransBTS [33] and Swin-UNETR [34] with the backbone for brain tumor segmentation [29,30]. Special study deserves transformer use in neuroimaging, as the structures of the brain are complicated. Neural networks based on transformers can model long-range dependencies and spatial relationships of the brain images [27], which is very important in brain segmentation.

Although transformers have shown very promising results in many medical imaging tasks, their use in neuroimaging segmentation remains an evolving field that had not been systematically reviewed. Existing literature reviews have either examined the use of transformers for general medical image segmentation without focusing specifically on brain segmentation [25,29,30] or have reviewed brain segmentation techniques using various DL methods without emphasizing the role of transformers [2,13]. One more difference that exists between this review and others is the focus on applying transformers to neuroimage segmentation, which is a central task in neurological disorder diagnosis and treatment. For example, compared with more general surveys such as those by Shamshad et al [29] and Xiao et al [26], which address a wide range of tasks or organ systems, our work specifically focuses on the unique challenges and developments within brain image segmentation. Thus, this scoping review will seek to fill the gap by focusing solely on transformer applications in neuroimage segmentation, an area of paramount importance for the diagnosis and treatment of neurological disorders. A scoping review on this topic is appropriate because the application of transformers in this area is relatively new and fast-developing; hence, it allows for comprehensively mapping the current research landscape and identifying knowledge gaps.

The main purpose of this scoping review is to synthesize and critically evaluate the existing literature on the use of different transformer models for neuroimaging segmentation. This review aims at summarizing the types of transformer models applied, their performance, applications in various neurological conditions and imaging modalities, limitations of the current literature, and highlighting the existing gaps in research.

Methods

Study Design

The approach of this scoping review follows the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines (Multimedia Appendix 1) [35]. Our primary research question was “What are the current applications, performance, and limitations of transformer models in neuroimaging segmentation?” The goal was the extraction of key themes within recent literature related to transformer use in neuroimaging segmentation that will guide future research and clinical applications. Only the literature starting from 2019 was considered, since the rapid evolution in the development of transformer models for medical imaging is a key recent development in this field.

We defined transformer models as DL architectures relying on self-attention mechanisms, capable of processing sequential data and capturing long-range dependencies. From the neuroimaging perspective, we considered those studies where these models were applied to different modalities of brain imaging, focusing on MRI due to its prevalence in neurological diagnostics.

Our review process followed a systematic search in 4 major databases: Scopus, IEEE Xplore, PubMed, and ACM Digital Library. We present a comprehensive review of methodologies, results, strengths, and limitations of the included studies to derive useful insights that bridge technical developments with their implications in the clinical domain of neuroimage segmentation.

Search Strategy

Studies were retrieved on May 22, 2023, through searching the following databases: IEEE Xplore, ACM Digital Library, Scopus, and PubMed. The search was limited to 5 years, from 2019 to 2023, to prioritize recent research and consisted of search queries related to transformers such as “transformer,” “deep learning,” and “self-attention”; queries related to neuroimaging such as “brain,” “neuroimaging,” “MRI,” “CT,” and “PET”; and queries related to the medical field such as “health care,” “medical,” “health.”

Study Eligibility Criteria

This review only included papers whose primary purpose was on the use of transformers for the segmentation of neuroimages. Our search included journal papers, conference papers, and dissertations that focused on applying transformer models to imaging scans (eg, MRI and CT) of the human brain. We excluded all studies that (1) used transformers for the segmentation of nonneuroimaging, raw brain signals, or electroencephalogram data; (2) were not in English, review papers, conference abstracts, preprints, protocols, and conference abstracts; (3) focused on neuroimaging tasks other than segmentation (eg, classification and prediction); and (4) were published before 2019.

Study Selection

For this review, we used a 3-step study selection process. First, we used EndNote (Clarivate) to remove duplicate studies returned by our initial search. Next, 3 independent reviewers (MI, AA, and MA) screened the titles and abstracts of the remaining papers to exclude irrelevant studies. We then obtained full texts of the studies that passed the initial screening, and the same 3 reviewers (MI, AA, and MA) examined them against our predefined inclusion criteria. Any disagreements between reviewers during the screening processes were resolved through in-person discussions until a consensus was reached.

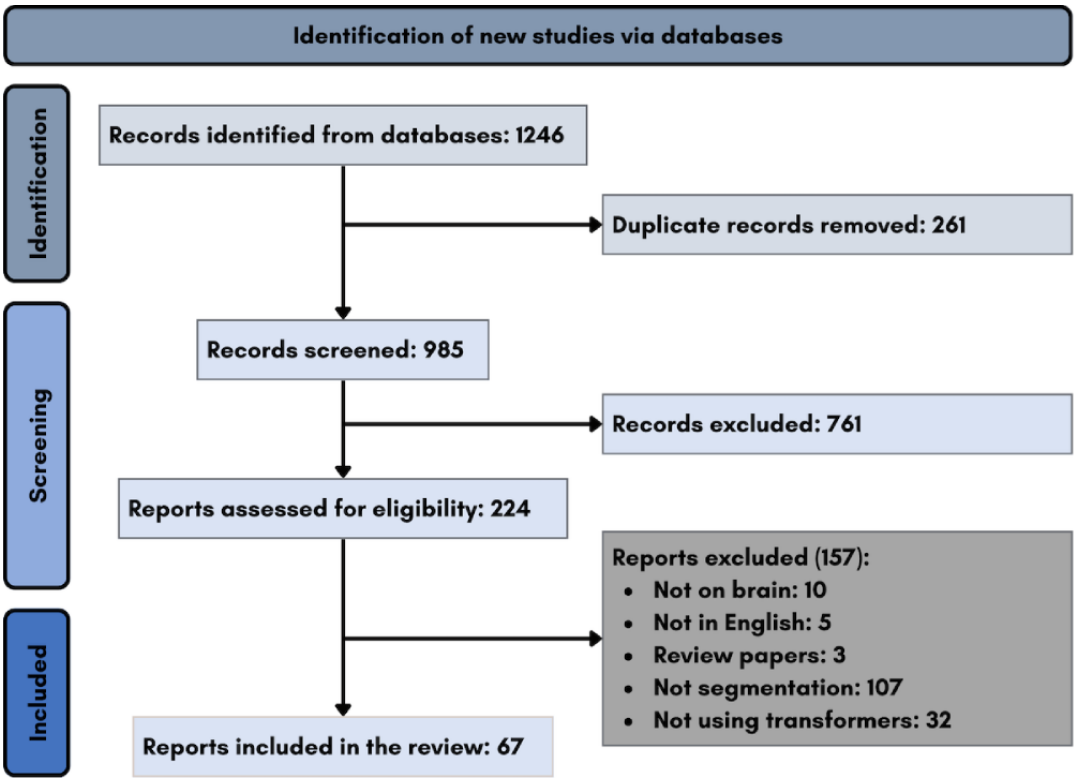
XSL•FO
RenderX

Data Collection

The data extraction for this review is done in Microsoft Excel by 2 independent groups of 2 reviewers (MI and AA and MA and OE) to share the workload for extraction and resolve conflicts between the groups. Disagreements in data extraction were resolved through consensus during face-to-face discussions. Data extractions fall into 3 broad categories: study characteristics, neuroimaging acquisition, and transformer features.

Synthesis of included data was done using a narrative approach. Descriptive texts, tables, and figures describe and show the summary and characteristics of the data. Microsoft Excel was used to manage and synthesize the data. First, we depict the characteristics of each included study concerning publication year, type of publication, and country of origin. Then, we describe the neuroimaging acquisition of these studies by including the imaging modality, dataset, dataset accessibility, and neurological condition. Finally, it explains the transformer architecture of the included studies: the number of parameters, transformer type, hybrid component, and the training and evaluation methodology used along with loss function, optimizer, and metrics.

Ethical Considerations



This scoping review synthesized and analyzed publicly available research studies. No direct human participant research was conducted; therefore, approval from an institutional review board or a research ethics committee was unnecessary. There was no collection, use, or dissemination of personal data from human participants in this study. Data extracted and analyzed in this review had been sourced from published studies, previously subjected to ethical review processes as part of their original publication. The review followed ethics in research practices, in that the representation of the included studies was true to form, and the methodology for the selection of studies and extraction was transparent. No individual participant data were accessed or reported in this review; hence, privacy and confidentiality were ensured. Since this study did not involve direct contact with human participants, issues regarding informed consent and protection of privacy and compensation of participants were therefore not relevant in this study. No images or supplementary material showing identifiable information of any individual were used in this review.

Results

Overview

A total of 1246 publications were retrieved from the initial search of the selected databases. In the first round of screening, 261 duplicates were identified and removed through the use of EndNote X9, leaving 985 publications remaining. In the second round, 761 publications were excluded through the analysis of their titles and abstracts against our predefined inclusion or exclusion criteria. The remaining 224 publications continued to the third round of screening, which included a detailed full-text read-through and resulted in the exclusion of 156 publications. Of the 1246 initial publications, only 68 studies met our criteria and were thereby included in this review. Figure 2 depicts the full screening process in more detail.

Figure 2. PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) flowchart of the study selection process.

Characteristics of the Included Studies

Table 1 depicts the characteristics and metadata of each included study, including the publication year, country, and type. Included studies ranged between 2019 and 2023. Over half of the included studies were published in 2022, followed by 32.84% (n=22) in 2023. Studies included peer-reviewed papers (n=48, 71.64%) and conference papers (n=19, 29.36%). The included studies spanned a total of 13 countries, with China being by far the largest contributor in this domain, representing 68.66% (n=46) of the total studies. Following China, we can find the United States (n=5, 7.46%), the United Kingdom (n=4, 5.97%), and India (n=3, 4.48%), with other countries contributing 1 paper apiece.

Table 1. Characteristics of the studies used in this review, including the year, type, and country of publication.

Features	Studies, n (%)	References
Year of publication		
2023	22 (32.84)	[36-57]

Neuroimaging Acquisition and Neurological Condition

Table 2 depicts the different imaging modalities used, the datasets used, and the different neurological conditions across the included studies. The included studies included a range of 6 different modalities, with MRI being by far the most common with 88% (n=59), followed by CT with 10.45% (n=7), and the remaining modalities with 1 each. Over half of the included studies used only 1 dataset (n=40, 59.70%) for training and evaluation purposes, followed by 23.88% (n=16) using 2 datasets. Of the 44 unique datasets used across the included studies, 70.45% (n=31) are public or open-source datasets, and 29.55% (n=13) are private datasets obtained directly from medical institutions. Regarding the public dataset category, the brain tumor segmentation dataset (BraTS dataset) is by far the most widely used, with 58.21% (n=39) of total studies using its variants (including BraTS 2015, 2017, 2018, 2019, 2020, and 2021), followed by Medical Segmentation Decathlon and low-grade glioma-Kaggle with 5.97% (n=4) each. The main neurological condition of the included studies was the segmentation of brain tumors, with 71.64% (n=48) of studies conducting research specifically in this area.

Transformer-Based Techniques Types, Training Parameters, and Evaluation

The proposed neuroimage segmentation techniques used various artificial intelligence (AI) techniques. In this review, we focused on the deep transformer–based techniques that have gained more attention recently. From the proposed models, we can find transformer-based, CNN with transformer-based, and generative adversarial network with transformer-based techniques. At the same time, the methods based on TransBTS, TransUNet, SeinUNet, and U-Net with transformer are the most used models for neuroimage segmentation. Figure 3 illustrates these models in terms of architecture. Table 3 depicts the characteristics of transformer models used within the included studies. From Table 3, we can find that 58.21% (n=39) of the included studies did not explicitly report the number of parameters of their proposed models. Of the studies that did, however, the majority of the transformer models proposed had between 20 and 40 million parameters (n=10, 14.93%), followed by 1 and 19 million (n=8, 11.94%). A majority of studies implemented a 3D segmentation network (n=42, 62.69%), with 37.31% (n=25) being 2D. An overwhelming 85.07% (n=57) of included studies proposed transformer models that are hybrid, with only 14.93% (n=10) of them being standalone transformer models. ViT was the most used transformer architecture, with 55.22% (n=37) of studies using it as its main component. Another significant transformer model is the Swin transformer, with 20.89% (n=14), followed by TransUnet, with 5.97% (n=4). Of the 57 hybrid transformer models, 55 (96.49%) studies opted for a combination of CNN with their transformer, and of those 55 CNN-transformer models, 56.36% (n=31) were U-Net based, and 9.09% (n=5) were ResNet based. Both generative adversarial network (n=2, 3.51%) and autoencoders (n=2, 3.51%) were also combined with transformers.

[a]ViT: vision transformer.

[b]CNN: convolutional neural network.

[c]GAN: generative adversarial network.

Table 4 depicts the loss function used, the optimizer used, and the different evaluation methods used across each included study. The loss function was not mentioned in 11.94% (n=8) of the included studies. Of the studies that mentioned it, the most popular loss function is a combination of cross-entropy and Dice loss with 40.30% (n=27) of included studies, followed by Dice loss with 19.40% (n=13). Adam is the most used optimizer, with 47.76% (n=32) of included studies using it, followed by AdamW at 14.92% (n=10). However, the optimizer was not mentioned in 22.39% (n=15) of studies. In terms of evaluation, over half of the included studies used at least two evaluation metrics (n=34, 50.75%), followed by 1 metric (n=11, 16.42%). Of these evaluation metrics, the Dice score is by far the most used, with 94.03% (n=63) of all studies using it, followed by HD95, 52.24% (n=35), and sensitivity, 28.36% (n=19).

Strengths and Limitations of Transformer-Based Techniques

Transformers have revolutionized the area of neuroimage segmentation by offering unparalleled capabilities in modeling complex features in medical imaging. It has the ability to model both local and global information, which substantially improves the accuracy of segmentation and therefore becomes very useful in various neurological applications. As shown in Table 5, the common strengths of transformer-based techniques include a high mean Dice score, effective fusion of multimodal MRI, and robust performance across diverse and complex datasets. However, these models also have substantial limitations in terms of high computational and memory costs, sensitivity to small areas of tumors, and possible overfitting on smaller datasets.

XSL•FO
RenderX

Table 5. Strengths and limitations of common transformer-based techniques.

References	Strengths	Limitations
ViT[a]		
[33,36,38, 40,44,46, 47,49-55, 57-60,65, 66,71,73, 75,81-83, 85,87,88, 90,91,93, 95-99]	• Effectively models local and global features in 3D MRIb data. • High mean Dice score. • Demonstrates consistent improvements in segmentation performance. • Effective in emphasizing informative brain regions. • Uses symmetry of brain structures for improved feature learning. • Outperforms state-of-the-art SSLc methods and medical image segmentation models on benchmarks. • Incorporates gradient-based scoring for attentive reconstruction. • Effective multimodal MRI fusion. • Enhanced long-term dependencies within individual modalities. • Complementary contextual information among modalities.	• Computationally intensive. • High computational and memory cost. • Memory constraints when lowering patch resolution. • Complexity in integrating CNNd and transformer features. • Sensitivity to small tumor areas in LGGe. • Overlap in feature dimensions between CNN and transformer branches. • Misclassification of voxels in LGG. • Imbalance in dataset affecting performance. • Need for extensive validation on more diverse datasets.
Swin		
[34,37,42, 43,56,62, 67-69,72, 74,76,77, 89]	• Capable of learning multiscale contextual information, enhancing performance across various tasks. • Combines advantages of ViT and CNNs, balancing both local and global feature learning. • Maintains high-resolution features, crucial for precise segmentation tasks. • Performs efficient tri-level preprocessing, including noise removal improving input quality for better results. • Incorporates advantages of 3D Swin transformer, improving performance in 3D medical image analysis.	• Slight decrease in performance for specific areas like tumor core segmentation in some instances. • ViTs have many parameters and structures, making them complex and resource-intensive. • Potential risk of overfitting on smaller datasets due to high model complexity. • Existing neural network algorithms may often extract redundant features, reducing overall efficiency. • Limited exploration in preprocessing and postprocessing techniques, which might enhance model performance further.
SwinUnet		
[61,78]	• Improves the efficiency of using limited labeled data. • Competitive performance in Dice score, Hausdorff distance, and other segmentation metrics.	• Requires verification of the improvement with diverse and larger datasets. • Lower recall and F1-scores compared to other CNN-based methods.
TransUnet		
[45,70,84, 94]	• High effectiveness in model design. • Combines the strengths of U-Net and transformer models. • Achieves higher Dice scores compared to U-Net and transformer. • Effectively learns global context features in images.	• Some models within the study showed poor performance. • Cross-application limitations in certain scenarios. • High data requirements for effective training. • Limited dataset size affecting generalization.
TransBTS		
[64,92]	• Residual basis blocks reduce feature loss and enhance feature extraction. • Combines CNN and transformer for improved segmentation performance, leveraging both local and global information. • Attention mechanisms enhance the model's ability to focus on relevant features, improving accuracy.	• Increased network depth leads to higher parameter counts, increasing computational requirements. • May struggle with unseen patterns in the testing phase, affecting performance robustness.
Other transformer types		
[39,41,48, 63,79,80, 86,100]	• Effectively capture both local and global context in medical images. • Enhance segmentation accuracy. • Robust across diverse and complex datasets. • Improve semantic information representation. • Combine multiresolution information effectively.	• High computational complexity. • Significant memory use. • Requires substantial hardware resources. • Extensive data preprocessing is needed. • Limited scalability to very large datasets. • Sensitive to variations in input data quality.

[a]ViT: vision transformer.

[b]MRI: magnetic resonance imaging.

[c]SSL: self-supervised learning.

[d]CNN: convolutional neural network.

[e]LGG: low-grade glioma.

Discussion

Principal Findings

The main purpose of this scoping review is to conduct a thorough investigation into the use of different transformer models in the field of neuroimaging, specifically segmentation. From the gathered data, it is clear that the use of transformers in neuroimaging experienced a great boost in research from 2021 to 2022, with over half of the included studies being published in 2022 compared to only 10 studies in 2021. It is also important to note that for the year 2023, only the studies up to May 22 were included; yet, this constitutes a total percentage of the included studies of 32.84% (n=22) and could very well be even higher when the whole year is considered.

From the studies included in this review, it is clear that MRI is by far the most popular image modality for applying transformer models to neuroimaging segmentation. This can be attributed to how common the use of MRI is in the diagnosis of neurological illnesses, especially for brain tumors [27], wherein it is able to provide functional, structural, and metabolic information [27] through the use of its different modalities (T1, T2, T1ce, and fluid-attenuated inversion recovery). MRI is particularly suitable for neuroimaging segmentation purposes because of the high spatial resolution and soft tissue contrast, both being critical for any form of precise segmentation it exhibits, since it is able to show good detailed visualization of structures in the brain and distinction between different tissues of the brain sizes [1,2].

Another reason for the popularity of MRI in the included studies is the availability of brain MRI scans sourced from the widely used BraTS datasets [101]. This yearly and open-source dataset contains a wide variety of different MRI modalities that are manually annotated, making it a very important resource for developing and benchmarking segmentation methods based on different transformer models. This is why it is no surprise that it is by far the most used dataset in the included studies.

When it comes to neurological conditions, a majority of included studies in this review focused on the use of transformers in brain tumor segmentation. This can be attributed to multiple factors, including the availability of MRI scans from the BraTS dataset that are specifically for brain tumor segmentation. Brain tumors are also highly prevalent among all ages and have a high fatality rate [102], making it a prime area for research into new methods of diagnosis and treatment. In addition, brain tumors are fairly complex and irregular in both location and shape [27], which makes manual segmentation a very tedious and time-consuming process that would benefit greatly from increased research into more automated methods for segmentation. The BraTS dataset is also a factor, as it provides a large variety of MRI scans that are specifically for brain tumor segmentation. Transformers are particularly useful for brain tumor segmentation due to their self-attention mechanism, which allows them to account for different variations in tumor characteristics, such as size and shape, during the segmentation process [26].

Most included studies proposed and developed models with 3D segmentation networks, specifically for 3D imaging data. In terms of neuroimaging, 3D scans are more common in part due to the 3D nature of MRI scans. Since MRI is the most common imaging modality used in neuroimaging, it makes sense that it is preferable to develop models for 3D imaging data in order to avoid the loss of information. Even though 3D models are typically more accurate for 3D imaging segmentation, they are computationally expensive [26], which is why some proposed models in the included studies chose to instead extract 2D slices from 3D imaging data. While this technique is suitable, reducing a 3D scan into 2D slices can lead to a degradation of volume and spatial characteristics native to 3D data [103].

CNN-transformer hybrid models were used far more than standalone transformer models in the included studies, specifically in the form of a U-Net and transformer combination. These combinations capitalize on the strengths of both CNN and transformers while minimizing their weaknesses. CNN is particularly useful in extracting local features and spatial information from the provided scans; however, it often struggles to capture long-range dependencies due to its small kernel size [26,27]. On the other hand, transformers are able to model these long-range dependencies due to their self-attention module, making them very useful for neuroimaging segmentation, especially in the case of brain tumors [27]. This is why most included studies opted to use the use of CNN to capture local features and transformers to capture global features to increase the performance of their models in the task of segmentation [102].

Research and Practical Implications

This scoping review provides an overview of the available research regarding the use of transformers in the context of neuroimaging segmentation. These findings underline important implications for future research and applications in this area.

It is a notable finding of this review that many studies apply transformers, specifically to brain tumor segmentation, which might hint at the potential of transformers in assisting diagnosis and treatment planning in this field. As shown here, transformers are well-suited for this task. However, further research is needed to assess the real-world clinical usefulness of transformers for brain tumor segmentation. While brain tumors are an important challenge, the focus on this single application at this level would seem indicative of the current lack of large and good-quality datasets in many other big neurological diseases and conditions, such as Alzheimer and Parkinson disease, and strokes. Making publicly available manually annotated datasets of different neurological conditions would motivate new research and developments on the application of transformers in this field. On top of this, the heavy reliance of studies on the BraTS dataset shows that there is a need to diversify datasets in order to validate different models correctly. Most of the included studies favored hybrid use by combining CNN and transformers, which illustrates the complementary strengths of these architectures for neuroimaging segmentation. Success in hybrid techniques shows that further exploration of novel integrations between transformers, CNNs, and other modules could become a promising direction to achieve better performances on more complex medical image analysis problems. Improved accuracy in neuroimaging segmentation, through the ability of transformer

XSL•FO
RenderX

models to extract local and global features, allows for more accurate identification of neurological conditions such as brain tumors. This will provide earlier diagnosis and treatment. Moreover, automation with these models will save much time of the clinicians in performing manual segmentation so that they can concentrate on the care of patients and other important tasks. Treatment planning may also be improved with transformer models, where the potential for more accurate and consistent segmentation results helps a lot in this respect. Moreover, these models can also potentially be integrated into clinical workflows without much hassle by developing user-friendly interfaces and collaboration between AI researchers and clinicians to ensure these tools are adopted and effectively used in practice.

Strengths and Limitations

This scoping review has numerous key strengths with regard to the analysis of transformer applications in neuroimaging segmentation. First, it gives a broad overview of the fast-evolving field by capturing recent works from 2019 through 2023. Second, it allows focusing on current research so that the review reflects the state-of-the-art in transformer applications for medical imaging. It is a systematic approach, covering 4 major databases; hence, wide and comprehensive coverage of the literature reviewed. The inclusion of journal papers and conference papers facilitates a wide view of both consolidated and emergent research. Third, this review gives elaborate insights into various aspects of transformer use in neuroimaging: imaging modality, dataset, neurological condition, and metric for performance evaluation. This level of analysis provides rich information relevant to both researchers and practitioners within the field. Finally, the review's focus on brain tumor segmentation, while a limitation in some respects, also serves as a strength by providing an in-depth look at transformer applications in a critical area of medical imaging with significant clinical implications.

While this scoping review offers a number of strengths, its limitations need to be acknowledged so as to strike a balance. First, the review was on transformers in neuroimaging segmentation alone, excluding other medical imaging tasks or organs. This narrow focus allows for an in-depth analysis of transformer applications in brain imaging but may not be representative of the full spectrum of use that transformers have seen in medical imaging. This limitation could be reduced by expanding the scope of future reviews to multiple organ systems or imaging tasks, giving a wider look at transformer applications in medical imaging.

Second, the review was focused on studies published in the English language, published from 2019 up to 2023. This narrowing was necessary, as most current works are favored in this novelty area of transformer use in medical imaging. In so doing, this review criterion may have left out important non-English language publications or early applications of transformers. This is likely a limitation in the representation of research trends worldwide. In this respect, future studies can be designed to include more languages, also extending the date range to capture more diverse sets of publications and track the evolution of transformer use in medical imaging over an extended period.

Third, the fact that 58.21% (n=39) of the works included in this review were based on the BraTS dataset introduces a certain bias in the domain toward the segmentation of brain tumors. Though it is a very critical area, it might not be useful to represent transformers completely for other neurological conditions. Future research needs to give more emphasis to developing and publicly releasing manually annotated datasets about more neurological conditions to address this limitation. This will further encourage diverse applications of transformers in neuroimaging and provide a wider understanding of the capability of transformers across different pathologies.

The review demonstrated a high dominance by studies from China, with 46 (68.66%) studies of the total (see Multimedia Appendix 2 for detailed analysis). This aligns with broader publication patterns in AI research where Chinese institutions contribute approximately 40% of global publications. While this distribution reflects documented trends in international research output, future reviews might benefit from more diversified search strategies to ensure comprehensive coverage of global research activities in this field.

Finally, no formal quality or risk-of-bias assessment of the included studies was performed. Although this represents a common approach when it comes to scoping reviews, this limits the degree to which strong conclusions can be drawn about the relative effectiveness of various approaches to transformers. Future systematic reviews or meta-analyses may involve quality assessments to support more robust evidence in terms of the efficacy of transformer models in neuroimaging segmentation.

Future Directions

These findings point to a variety of promising directions for future research on the application of transformers to neuroimaging segmentation. First, future studies should develop novel integrations between transformers, CNNs, and other advanced modules that will further improve performance for complex medical image analysis tasks. This might be achieved by investigating various hybrid models leveraging the strengths of transformers and more traditional DL methods. Second, the extension of transformer applications to more neurological conditions other than brain tumors, which would allow a wider grasp of the potential capability of transformers across different pathologies. More clinical applications are likely to follow from here. Third, the development of new transformer-based methods or their combination with emerging techniques like diffusion models could further improve efficiency and robustness for both 2D and 3D brain segmentation. Fourth, future studies shall be done to bridge the current limitations in dataset diversity. This may be in creating and publishing manually annotated datasets for a wider range of neurological conditions that can enable transformers to apply to neuroimaging in more diversified ways. Finally, the translation of research findings into clinical practice remains a high unmet need. This transition will require extensive validation of transformer models on diverse, real-world datasets and close collaboration between AI researchers and clinicians. Such collaboration could result in the development of more clinically relevant models and user-friendly interfaces, which

XSL•FO
RenderX

would expedite the translation of these advanced technologies into routine clinical practice.

Conclusions

This scoping review has thoroughly investigated the applications of transformers in neuroimaging segmentation and discovered a highly evolving field with great potential. The results of this paper have shown that transformer models, especially combined with CNNs in hybrid architectures, are also very promising for the task of brain MRI segmentation. Some of the big advantages of transformers include the modeling of long-range dependencies in images through self-attention mechanisms while still being able to perform local feature extraction. Such a combination uniquely allows for more accurate and detailed segmentation in highly complex neurological pathologies, like brain tumors.

There is clearly a trend toward 3D transformer models and hybrid CNN-transformer architectures, dominated by ViT as the variant of transformer used most frequently. These approaches also obtain superior performance on benchmark datasets, such as brain tumor segmentation tasks. However, reliance on the BraTS dataset highlights a requirement for more diverse data sources to ensure that performance could be validated across more multiple neurological conditions.

While this is promising, there are still important issues in the field: high computational costs associated with transformer models, overfitting on smaller datasets, and validation in larger clinical settings. Another issue is the geographical concentration of research output that highlights the need for greater diversity in the origins of studies worldwide to improve the generalizability of findings.

The future prospect of transformer models will unlock the potential that neuroimaging segmentation demands. Refining both architectures and training methods and integration into clinical workflows, transformations may provide state-of-the-art for fast, accurate, and reproducible brain-MRI segmentation, hence advancing clinical diagnosis and evaluation techniques for a better outcome in regard to patients with neurological disorders.

Although transformers have shown great improvement in neuroimaging segmentation, much potential is yet to be realized. Future work will need to be focused on present limitations, the extension of applications across a wider range of neurological conditions, and narrowing the gap between research and clinical practice to ensure that transformers are a valuable and impactful technology in medical imaging analysis.

Abstract

Background: The implementation of large language models (LLMs), such as BART (Bidirectional and Auto-Regressive Transformers) and GPT-4, has revolutionized the extraction of insights from unstructured text. These advancements have expanded into health care, allowing analysis of social media for public health insights. However, the detection of drug discontinuation events (DDEs) remains underexplored. Identifying DDEs is crucial for understanding medication adherence and patient outcomes.

Objective: The aim of this study is to provide a flexible framework for investigating various clinical research questions in data-sparse environments. We provide an example of the utility of this framework by identifying DDEs and their root causes in an open-source web-based forum, MedHelp, and by releasing the first open-source DDE datasets to aid further research in this domain.

Methods: We used several LLMs, including GPT-4 Turbo, GPT-4o, DeBERTa (Decoding-Enhanced Bidirectional Encoder Representations from Transformer with Disentangled Attention), and BART, among others, to detect and determine the root causes of DDEs in user comments posted on MedHelp. Our study design included the use of zero-shot classification, which allows these models to make predictions without task-specific training. We split user comments into sentences and applied different classification strategies to assess the performance of these models in identifying DDEs and their root causes.

Results: Among the selected models, GPT-4o performed the best at determining the root causes of DDEs, predicting only 12.9% of root causes incorrectly (hamming loss). Among the open-source models tested, BART demonstrated the best performance in detecting DDEs, achieving an F_1-score of 0.86, a false positive rate of 2.8%, and a false negative rate of 6.5%, all without any fine-tuning. The dataset included 10.7% (107/1000) DDEs, emphasizing the models' robustness in an imbalanced data context.

Conclusions: This study demonstrated the effectiveness of open- and closed-source LLMs, such as GPT-4o and BART, for detecting DDEs and their root causes from publicly accessible data through zero-shot classification. The robust and scalable framework we propose can aid researchers in addressing data-sparse clinical research questions. The launch of open-access DDE datasets has the potential to stimulate further research and novel discoveries in this field.

Introduction

The development of the transformer model [1] has significantly advanced natural language processing (NLP), a key area of artificial intelligence (AI). These models, commonly referred to as large language models (LLMs), often contain billions or trillions of parameters and have greatly improved our ability to extract meaningful insights from unstructured data [2], achieving state-of-the-art results in various NLP tasks since the introduction of bidirectional encoder representations from transformers [3]. LLMs have excelled in tasks, such as translation, answering of questions, summarization, sentiment analysis, language generation, and named entity recognition. They are used in diverse fields, including analyzing corporate filings for investment decisions [4], assessing online reviews [5], and performing sentiment analysis of tweets [6].

Recently, advanced LLMs such as DeBERTa (Decoding-Enhanced Bidirectional Encoder Representations from Transformers with Disentangled Attention) [7] and OpenAI's GPT-4 [8] have demonstrated substantial performance improvements. These enhancements include improvements in model architecture, such as DeBERTa's disentangled attention mechanism and GPT-4's increased model size and training data, which enhance their prediction accuracy and their capacity to handle complex language understanding tasks. These advancements have opened new possibilities for health care applications of NLP, such as analyzing social media and online forums to assess trust and confidence toward vaccine use [9], adverse drug reactions [10,11], and depression [12], among others [13-16]. However, many potential applications of NLP in health care remain underexplored.

One critical issue is early drug discontinuation and nonadherence to prescribed medication, which negatively affects patient outcomes and increases health care costs [17]. The reasons behind early medication discontinuation are not well understood [18,19], and detecting drug discontinuation events (DDEs) from clinical narratives and social media data is underexplored.

Some studies have explored medication discontinuation using data from social media and NLP techniques. Golder et al [20] conducted a mixed methods study analyzing patient-reported reasons for switching or discontinuing statin therapy using social media data from WebMD. Their work focused specifically on statins and relied on manual annotation for classifying DDEs and their root causes. Similarly, van Buchem et al [21] developed and validated the AI patient-reported experience measure (AI-PREM) by analyzing patient experiences using NLP. Their study primarily used sentiment analysis to gauge patient experiences but did not focus on detecting specific events such as DDEs.

Another study by Tsai et al [22] used NLP and network analysis to examine patients withdrawing from life-sustaining treatments using electronic health records from 119 patients in Taiwan. Their approach involved generating document-term matrices and analyzing word frequencies to identify patterns. However, they did not use pretrained LLMs, and their study was limited to a small dataset.

While these studies and others [23-26] contribute valuable insights into patient experiences and reasons for medication discontinuation, they have limitations such as focusing on specific medications, relying on manual annotation, or not leveraging advanced LLMs for broader applicability. To the best of our knowledge, no prior studies have systematically analyzed the root causes of medication discontinuation using state-of-the-art LLMs such as OpenAI's GPT-4o, especially in a zero-shot classification setting applied to large-scale, unstructured patient-generated data from web-based forums.

Historically in many NLP applications, the models needed to be fine-tuned or adjusted for each specific task. However, state-of-the-art LLMs are capable of zero-shot classification, which are especially valuable in settings where data are scarce, as they do not require modifications or fine-tuning on task-specific data. This feature is particularly beneficial in the medical field, where access to data is often limited due to patient confidentiality concerns. Motivated by challenges associated with limited data availability in health care research, the primary aim of this study is to develop a versatile framework for addressing clinical research questions in data-sparse settings by leveraging pretrained LLMs and zero-shot classification of unstructured data from web-based health forums. The specific objectives of this paper are as follows:

1. To present a methodical approach to detecting DDEs posted on web-based health forums
2. To identify the root causes of DDEs posted on web-based health forums
3. To evaluate the effectiveness of different classification strategies and models in identifying DDEs and their root causes
4. To introduce and validate the first open-source DDE detection dataset and the first open-source DDE root cause classification dataset to support ongoing and future research

In addition, our work is novel in 4 additional aspects. First, studies in the extant work mainly used electronic health records (EHRs) as the data source [17]. Due to the poor documentation of drug discontinuation events (DDEs) in EHRs [17], it is crucial to understand the causes of discontinuation from the patient's perspective to improve medication adherence. Traditional EHR data often lack direct patient input, as they are usually filtered through health care providers. Moreover, privacy concerns surrounding patient health data often restrict accessibility to large open-source datasets for health research. Meanwhile, web-based forums such as MedHelp offer unmediated patient perspectives, provide insights not captured in EHRs, and involve a large and diverse population. Identifying the root causes of DDEs from the patient's viewpoint on the basis of a representative sample can enhance our understanding of patient behavior and the challenges they face.

Second, to the best of our knowledge, this is the first work that compares state-of-the-art text-to-text models with the previous generation of models that receive text as an input and respond with text as an output, such as GPT-4o. Many open-source pretrained large language models (LLMs) fine-tuned for zero-shot classification are available through platforms like Hugging Face [27]. These models can predict whether a given

XSL•FO
RenderX

text supports an arbitrary hypothesis without needing additional training for each new task. This means that if a human reader can infer the truth of a hypothesis from the text, the model can make a prediction to do the same [28]. Typically, these models output a probability between 0 and 1, indicating how likely it is that the hypothesis is true based on the given text. To be able to apply these approaches to the problem, we designed a novel framework that leverages these models to identify DDE and the associated root causes.

Third, we demonstrated the effectiveness of LLMs in addressing clinical research questions without extensive training data. This approach overcomes the limitations of previous methods [17] by using transfer learning to tackle data scarcity. Our study shows that LLMs such as bidirectional and auto-regressive transformers (BART) and GPT-4o, with their generalization capabilities, are versatile for new tasks. This novel methodology could revolutionize the way clinical research questions are approached, opening a new paradigm in health informatics research.

Fourth, this paper introduces 2 open-source datasets, the first of their kind: one focused on DDE detection and another on root cause classification of DDEs. By creating and publishing these datasets, we aimed to motivate and facilitate future research efforts toward investigating drug discontinuation. For example, researchers could use these datasets to investigate why patients discontinue specific medications early. By extracting and analyzing comments that describe DDEs, they can identify the root causes and guide future research to address side effects or other factors associated with drug discontinuation.

Overall, this research provides valuable insights into patient behavior and decision-making regarding medication use, highlighting the real-world challenges faced by the patients. These insights can inform health care providers, policy makers, and pharmaceutical companies, helping them to better understand and address barriers to medication adherence.

Methods

Overview

The effectiveness of research outcomes in NLP relies heavily on the methods and materials used. This section outlines the strategies and resources used in this study, focusing on LLMs. In particular, this study introduces an innovative approach by redefining DDE detection as a natural language inference task. This approach enables LLMs to leverage their existing training to deduce relationships between text elements, achieving the desired outcomes without the need for additional training data or model fine-tuning.

We sourced data from MedHelp [29], a publicly accessible web-based health community where users discuss health experiences and share advice. This section details the methodology used for detecting DDEs from comments posted on MedHelp and analyzes the root causes of these DDEs using LLMs.

Data Scraping and Preprocessing

Our dataset was compiled by scraping 759,872 questions and answers from 131 of the 193 communities on MedHelp. Each question or answer has a unique URL, with information corresponding to each being recorded as a separate row in our dataset.

The dataset was then trimmed down by excluding questions and answers that lacked relevant study keywords. These keywords were derived from the International Drug Dictionary dataset [30], reducing our dataset to 183,565 questions and answers.

Data Labeling

Overview

To create the first open-source DDE datasets and to assess the accuracy of LLMs at detecting DDEs and identifying their root causes, we used graduate students to label the data obtained from MedHelp. For DDE detection, 1000 comments were labeled, resulting in 893 (89.3%) non-DDE comments and 107 (10.7%) DDE comments. Of the 89 (8.9%) comments that the labelers did not unanimously agree upon, the majority vote was taken as the “ground truth.” Here, the “ground truth” refers to the correct classification for each comment, based on the consensus of the labelers.

For DDE root cause analysis, 1000 (100%) comments suspected of containing DDEs were categorized based on predefined criteria. Multiple root causes can apply to a single DDE and a single comment can express multiple DDEs, allowing multiple root causes to be assigned to one comment. When the labelers disagreed, they discussed the comments to reach a consensus.

Classifying Comments as DDE or Non-DDE

Labelers were asked to categorize each comment into either of the following categories:

- 0—non-DDE (the comment does not contain a DDE)
- 1—DDE (the comment contains a DDE)

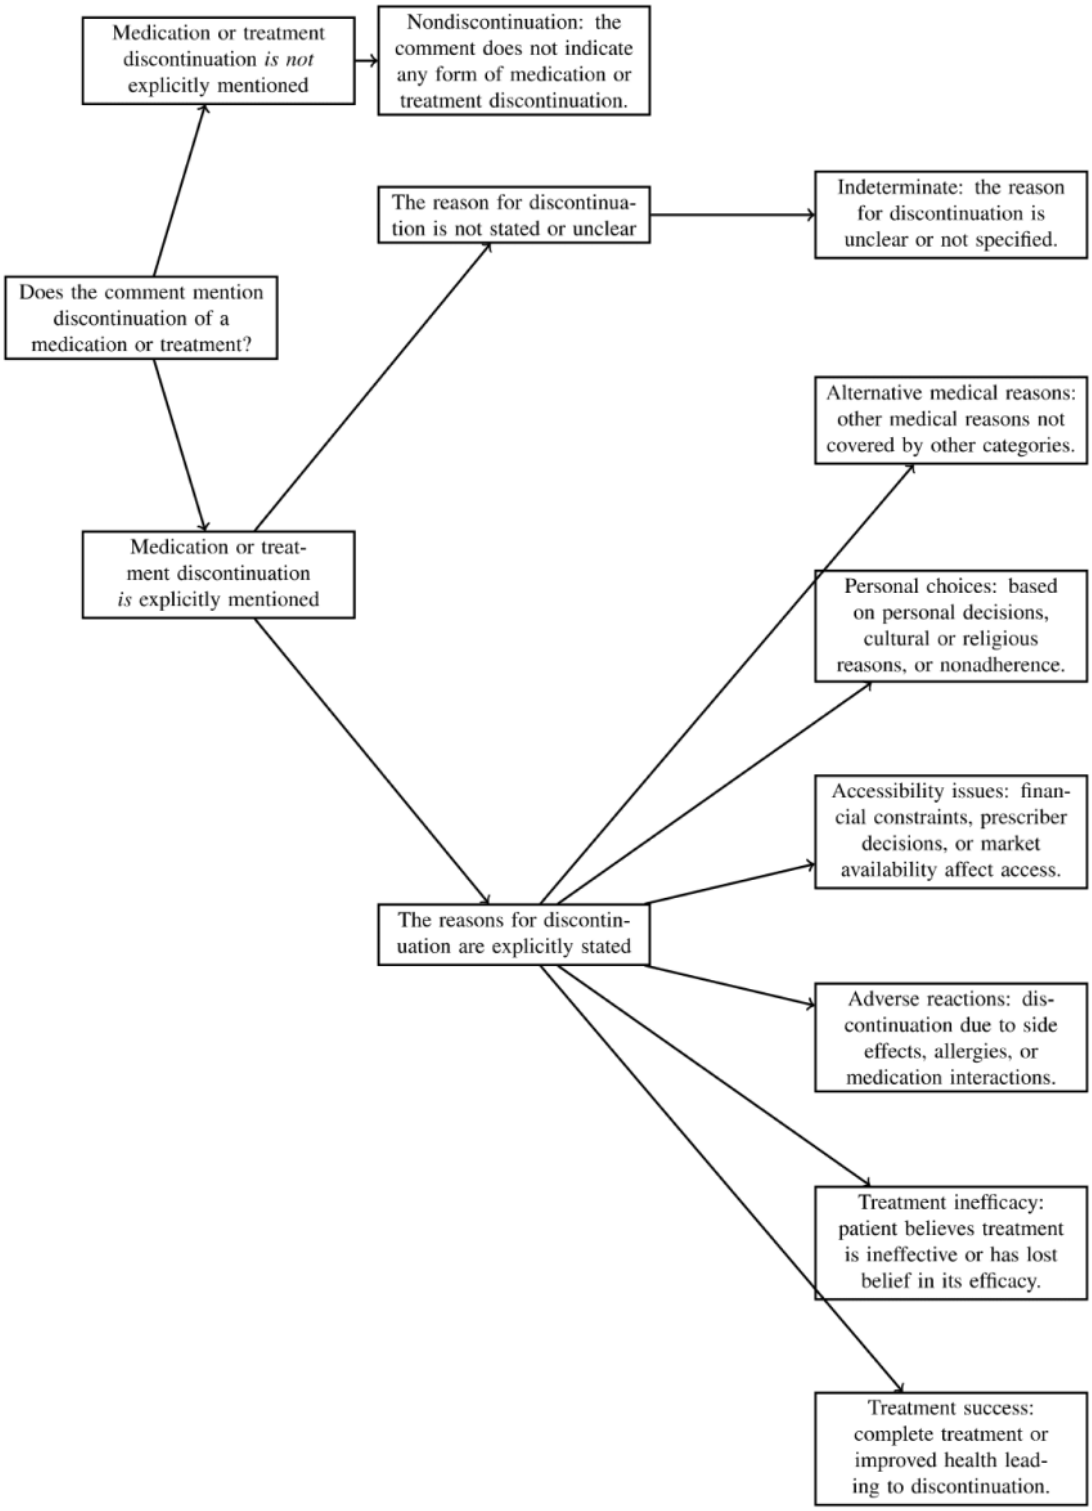
The comments were classified as DDE if a specific person’s discontinuation of a recurring medication or treatment could be inferred from it. Medication changes were considered as DDEs while one-time treatments were not. Apart from this, labelers were asked to indicate their level of confidence in their labels by selecting one of the three confidence levels: (1) very confident (2890/3000, 96.33%); (2) somewhat confident (102/3000, 3.4%); and (3) not confident (8/3000, 0.27%). The percentage in parentheses alongside each confidence level indicates the rate at which the confidence level was selected by the labelers.

Classifying the Root Causes of DDEs

After identifying comments containing DDEs, the next step involved categorizing the root causes of these discontinuations. Labelers were provided with detailed guidelines and definitions for each category to ensure consistency and accuracy (Textbox 1).

Labelers were instructed to apply these categories to each comment identified as containing a DDE. They could assign

XSL•FO
RenderX



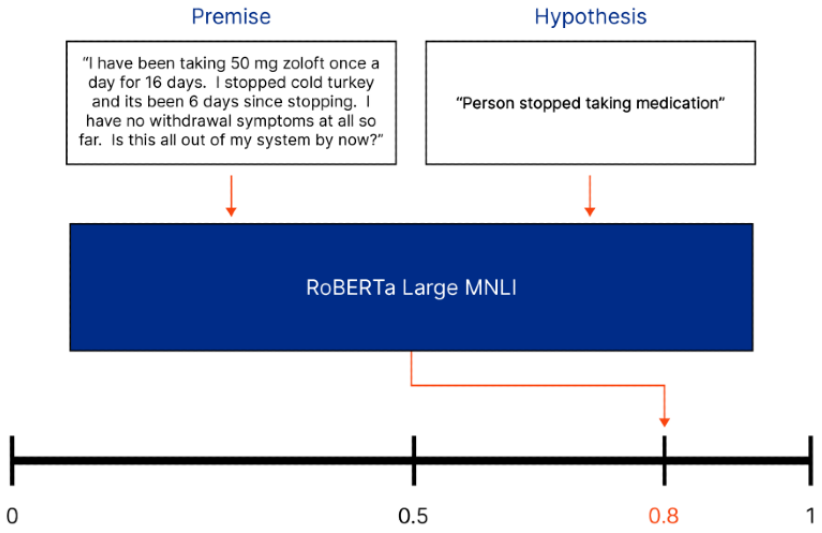
multiple categories to a single comment if it mentioned >1 reason for discontinuation. The comprehensive guidelines, including examples and the decision tree shown in Figure 1, helped labelers accurately and consistently classify the root causes of DDEs. The aim was to capture the complex and multifaceted reasons behind medication discontinuation, providing valuable insights for further analysis.

Textbox 1. Categories for root causes.

- Treatment success: discontinuation due to successful treatment completion or sufficient improvement in health
- Treatment inefficacy: perceived ineffectiveness of the treatment or loss of belief in its efficacy
- Adverse reactions: discontinuation due to adverse side effects, allergic reactions, or negative interactions with other medications
- Accessibility issues: issues related to financial constraints, changes in prescriber decisions, or market availability
- Personal choices: discontinuation based on personal decisions, cultural or religious reasons, or general nonadherence without medical advice
- Alternative medical reasons: other medical reasons not explicitly covered by the other categories
- Indeterminate: unclear or unspecified reasons for discontinuation
- Nondiscontinuation: comments that do not indicate any form of drug discontinuation

XSL•FO
RenderX

Figure 1. Decision tree for labeling the root causes of drug discontinuation events.



Models

In this study, we used the following models from Hugging Face (Hugging Face, Inc)—all of which are LLMs fine-tuned for zero-shot classification—to detect DDEs in comments posted on web-based forums: nli-deberta-base [31]; bart-large-mnli [32]; roberta-large-mnli [33]; distilbert-base-uncased-mnli [34]; nli-distilroberta-base [35].

In addition, we used OpenAI's GPT-3.5 Turbo and GPT-4 models [36]. These LLMs have been trained on a wide range of internet text and can generate humanlike text, making them useful for our research. GPT-3.5 Turbo is smaller and less costly than GPT-4 because of its fewer parameters [37]. As illustrated in Figure 2, these models can be used to analyze a premise from a web-based forum post (eg, a post from MedHelp) alongside a hypothesis (eg, "person stopped taking medication") and output a probability, such as 0.8, for whether the premise entails the hypothesis. This approach allows us to identify potential discontinuation events in a zero-shot manner without requiring additional training data.

XSL•FO
RenderX

Figure 2. Illustration of how large language models fine-tuned to perform natural language inference can be used to perform zero-shot classification. MNLI: Multi-Genre Natural Language Inference; RoBERTa: Robustly Optimized Bidirectional Encoder Representations from Transformers Pretraining Approach.

Data Classification Procedure Used to Detect DDEs

Detecting DDEs can be framed as a binary classification task, where the goal is to determine whether a text sequence contains a DDE or not. For example, the statement "patient stopped Lipitor because of cost" would be classified as containing a DDE. Each model, including GPT-3.5 Turbo and GPT-4, performed zero-shot classification as described in the classification strategies later. For models from the Hugging Face library, comments from MedHelp were treated as premises with the hypothesis being the following: "Person stopped taking medication." Note that the results presented in this paper and the performance of the proposed framework are sensitive to the hypothesis used, and using a different hypothesis could result in different results.

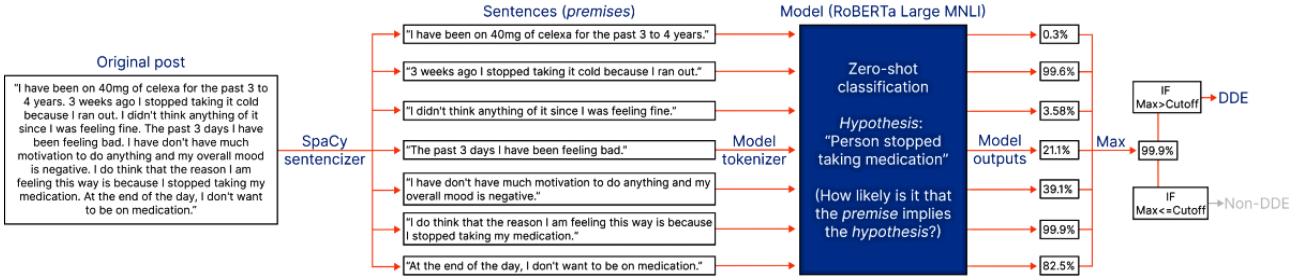
For GPT-3.5 Turbo and GPT-4, the models were prompted to generate a response to a query using the comment as context. The model's output was processed to derive a probability of entailment, which was used for classification. The evaluation setting for the GPT models varied with the classification strategy used and was influenced by the model version. It is important to note that the DDE detection experiments were performed before the release of GPT-4 Turbo and the release of the "set seed" and structured JavaScript Object Notation response features by OpenAI. As a result, carefully structured prompts were needed to obtain parseable responses from the GPT models for the task of DDE detection. These prompts and the complete code used in this work are available on GitHub [38]. The subsequent sections detail the procedures used to classify comments into the 2 categories, with practical examples of these classification strategies shown as figures.

Step 1: Split Each Comment Into Sentences and Tokenize

The models used for DDE detection, including GPT-3.5 Turbo and GPT-4, have a maximum token input length. This means each model can only process text that, when tokenized, is within its maximum token limit. Given that questions and answers on MedHelp can exceed these limits, we split longer comments into smaller chunks for classification. A comment was classified as discussing a DDE if any of its segments were classified as such. To handle the prevalence of typos and missing punctuation, we used the spaCy Python library's Sentencizer method [39] to segment each question and answer into sentences. Despite some inaccuracies due to informal language, typos, or incorrect punctuation, we referred to the output of the Sentencizer as the consecutive "sentences" forming each question or answer from MedHelp.

Step 2: Apply a Classification Strategy

Each comment was processed using 3 distinct classification strategies: classification strategy 1 (CS1, see Figure 3 and Textbox 2), classification strategy 2 (CS2; see Figures 4 and 5 and Textbox 3), and classification strategy 3 (CS3; see Figure 5 and Textbox 4).



In CS1 (Figure 3; Textbox 2), each sentence from the text is treated as a premise and passed into the model individually. The maximum probability (ie, model output) returned for any premise is identified. If this maximum probability is above a user-defined cutoff level, the original post is classified as containing a DDE. In the example shown in Figure 3, the post is classified as containing a DDE because the maximum model output exceeds the user-defined cutoff level (95%).

In CS2 (Figures 4 and 5; Textbox 3), consecutive sentences are concatenated and passed into the model as single premises. The maximum model output for any premise is compared to a user-defined cutoff value. In the example shown in Figure 4, the post is classified as containing a DDE because the maximum probability (99.4%) is higher than the cutoff level (95%).

In Figure 5, an example shows a scenario where the total number of tokens in the original post exceeds the maximum input length that the model can accept. Here, sequential sentences are grouped to ensure no group exceeds the model's maximum token limit (Textbox 4).

XSL•FO
RenderX

Figure 3. An example illustrating classification strategy 1. DDE: drug discontinuation event; Max: maximum; MNLI: Multi-Genre Natural Language Inference; RoBERTa: Robustly Optimized Bidirectional Encoder Representations from Transformers Pretraining Approach.

Textbox 2. CS1—classification strategy 1: individual sentences.

1. Each sentence in a comment was classified individually, generating a "model output" for each sentence ranging from 0 (non-DDE) to 1 (DDE).
2. The "model prediction" was set as the maximum of all the "model outputs" for the sentences.
3. If the "model prediction" exceeded a user-defined cutoff value, the comment was classified as a DDE. Otherwise, it was categorized as a non-DDE.

Figure 4. An example illustrating classification strategy 2 when using a model with a large maximum token input length. DDE: drug discontinuation event; Max: maximum; MNLI: Multi-Genre Natural Language Inference; RoBERTa: Robustly Optimized Bidirectional Encoder Representations from Transformers Pretraining Approach.

Figure 5. An example illustrating classification strategy 2 when using a model with a small maximum token input length. DDE: drug discontinuation event; Max: maximum; MNLI: Multi-Genre Natural Language Inference; RoBERTa: Robustly Optimized Bidirectional Encoder Representations from Transformers Pretraining Approach.

Textbox 3. CS2—classification strategy 2: groups of sentences.

1. Groups of sentences were created by concatenating as many consecutive sentences together as possible while staying within the maximum token input length of the model.
2. Each group of sentences was classified as a single block of text, generating a "model output" for each group of sentences ranging from 0 (non-DDE) to 1 (DDE).
3. The "model prediction" was set as the maximum of all the "model outputs" for the different groups of sentences.
4. If the "model prediction" exceeded a user-defined cutoff value, the comment was classified as a DDE. Otherwise, it was classified as a non-DDE.

Textbox 4. CS3—classification strategy 3: entire text (ChatGPT only).

The entire text is passed into the ChatGPT model at once, and the model is prompted to provide a binary "1" (DDE) or "0" (non-DDE) classification for each comment.

XSL•FO
RenderX

Step 3: Compare the "Model Prediction" to a User-Defined "Cutoff" Value

To derive a binary classification for a comment from the set of model outputs for each sentence (CS1) or block of sentences (CS2), we compared the maximum of all the model outputs to a cutoff value. If the maximum model output for any sentence or block of sentences is greater than the cutoff value, the comment is classified as a DDE. Otherwise, it is classified as a non-DDE. Cutoff values were tested from 0.05 to 0.95 in increments of 0.05. Adjusting the cutoff impacts the trade-off between sensitivity and specificity, reflected in the resulting false positive rate (FPR) and false negative rate (FNR) of each classifier. This approach helps identify an optimal cutoff that balances false positives and false negatives. This structured approach ensures a comprehensive analysis and maximizes the accuracy of DDE detection in unstructured web-based forum data.

Data Classification Procedure Used to Detect the Root Causes of DDEs

Once DDEs were identified, we proceeded to classify the root causes of these discontinuations. The root cause classification was treated as a multilabel classification task, allowing each comment to be associated with multiple reasons for discontinuation.

Applying CS1, CS2, and CS3 to DDE Root Cause Classification

The same classification strategies (ie, CS1, CS2, and CS3) used to detect DDEs were applied to identify the root causes of DDEs.

CS1: Individual Sentences

Each sentence in a DDE-identified comment was classified individually to determine the root causes. Each sentence was analyzed to see if it fit any of the predefined root cause categories in the Classifying the Root Causes of DDEs section.

If any sentence indicated a root cause, it was considered a relevant cause for the entire comment. The final set of root causes for the comment was derived from the union of causes identified in individual sentences.

CS2: Groups of Sentences

Groups of sentences were classified together to determine the root causes. This method ensured that contextual information was preserved, which is crucial for accurately identifying root causes that may span multiple sentences. Each group of sentences was evaluated against the predefined categories of root causes, and the maximum model output for each group determined the presence of specific root causes.

CS3: Entire Comment

The entire text of each DDE-identified comment was passed into the ChatGPT model to classify the root causes. The model was prompted to first summarize the reasons for discontinuation and then was asked to generate a list of applicable root causes from the predefined categories. This approach leveraged the model's ability to understand the context of the entire comment, providing a comprehensive assessment of the root causes.

Comparing Model Predictions to Cutoff Values

For both CS1 and CS2, the maximum model output for each root cause category was compared to a user-defined cutoff value. If the model output exceeded the cutoff, the root cause was assigned to the comment.

The complete set of prompts and hypotheses used for both DDE detection and root cause analysis can be found on our GitHub repository [38]. These details are omitted here for brevity, but they are available on the web and in Multimedia Appendix 1 to ensure transparency and facilitate replication of our methods. Researchers and practitioners can access these resources to better understand the specific inputs used in our classification models and apply similar techniques to their own datasets.

Ethical Considerations

This study involves the analysis of user-generated content on MedHelp, a publicly accessible health forum where individuals share personal medical experiences and seek health advice. Given the sensitive nature of the health information discussed, we are committed to protecting user privacy and ensuring ethical handling of all data. While the content on MedHelp is publicly available, users have not explicitly consented to participate in this research. We acknowledged the need to respect users' implied expectations of privacy, especially given the health-focused context of the discussions. No attempt was made to contact individual users nor were they asked to participate directly in this study. The scraped data have been processed in a way that prevents the association of responses or health conditions with specific users. This study complies with all relevant ethical guidelines for internet-based research, and we did not find it necessary to seek an ethics review board assessment based on the guidelines set by the University of Florida institutional review board.

Results

Overview

This section presents the results of our experiments on detecting DDEs and identifying their root causes. We evaluated the performance of various LLMs, using different classification strategies. The evaluation included precision-recall (PR) curves, receiver operating characteristic (ROC) curves, and detailed performance metrics for each classifier and strategy combination.

DDE Detection Task

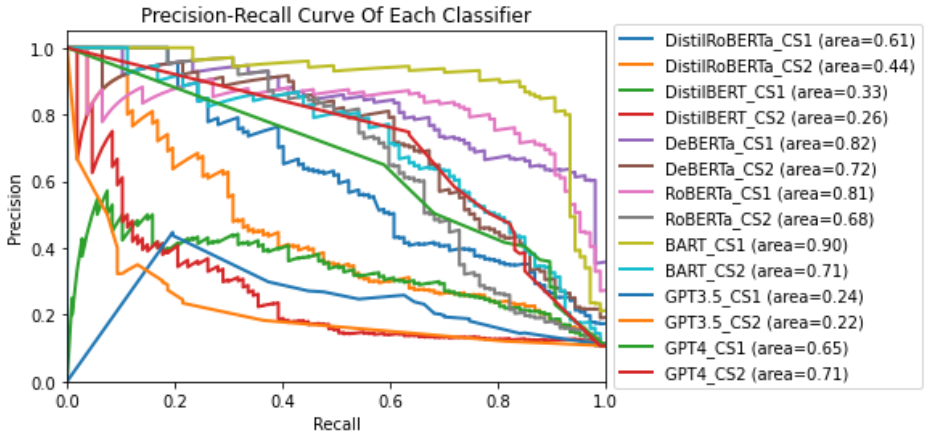
The effectiveness of the classifiers in detecting DDEs was evaluated using PR and ROC curves. Figures 6 and 7 show the PR and ROC curves for each classifier under each classification strategy, respectively. These figures also include the area under the curve (AUC) for each combination of classifier and strategy. Of all the models and classification strategies, bidirectional and auto-regressive transformers (BART) under CS1 achieved the highest ROC AUC of 0.977 and the highest PR AUC of 0.904. On the other hand, GPT-3.5 Turbo under CS2 had the lowest ROC AUC of 0.611 and the lowest PR AUC of 0.215.

Under CS3, GPT-4 achieved an F_1-score of only 0.56, an FPR of 12.9%, an FNR of 18.7%, and an accuracy of 86.5%. GPT-3.5

XSL•FO
RenderX

Turbo performed even more poorly under CS3, achieving an F_1-score of only 0.27, an FPR of 5.6%, an FNR of 76.6%, and an accuracy of 86.8%, illustrating the imbalance in the dataset. In comparison, the best-performing classifier at the task of DDE detection was BART under CS1, achieving an F_1-score of 0.86, an accuracy of 96.8%, an FPR of 2.8%, and an FNR of 6.5%. A summary of these performance metrics can be found in Tables S1-S9 in Multimedia Appendix 1.

Figure 6. The precision-recall curve of each classifier on the task of detecting drug discontinuation events. BART: Bidirectional and Auto-Regressive Transformers; DeBERTa: Decoding-Enhanced Bidirectional Encoder Representations from Transformers with Disentangled Attention; RoBERTa: Robustly Optimized Bidirectional Encoder Representations from Transformers Pretraining Approach.



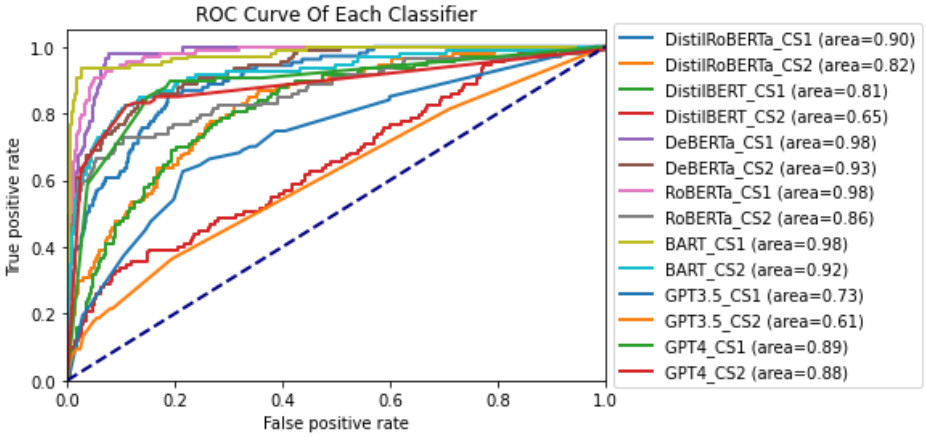


Figure 7. The receiver operating characteristic curve of each classifier on the task of detecting drug discontinuation events. BART: Bidirectional and Auto-Regressive Transformers; DeBERTa: Decoding-Enhanced Bidirectional Encoder Representations from Transformers with Disentangled Attention; RoBERTa: Robustly Optimized Bidirectional Encoder Representations from Transformers Pretraining Approach.

DDE Root Cause Classification Task

To assess the performance of the classifiers in identifying the root causes of DDEs, we used multiple evaluation metrics, including micro-average ROC AUC, macro-average ROC AUC, weighted-average ROC AUC, micro-average PR AUC, macro-average PR AUC, weighted-average. PR AUC, micro-average F_1, macro-average F_1, weighted-average F_1, hamming loss, Jaccard score, and subset accuracy. The results across all DDE root causes are summarized in Tables 1 and 2.

Tables 3 and 4 show the performance of GPT-4 Turbo and GPT-4o at predicting each individual DDE root cause. Overall, GPT-4o performed the best across the board achieving the highest averaged F_1-scores, the lowest hamming loss, and the highest Jaccard score and subset accuracy of all the classifiers. On the other hand, BART and DeBERTa performed very poorly across the board on the task of DDE root cause detection as shown in Tables 1 and 2.

An overview of the frequency of each DDE root cause in our labeled dataset of 1000 comments is provided in Table 5.

The most common DDE root causes in our dataset were *personal choices* with 670 (67%) occurrences and *adverse reactions* with 627 (62.7%) occurrences, and the least common was *treatment success* with 96 (9.6%) occurrences. In addition, only 10% (100/1000) of the comments were labeled as non-DDE by labelers, suggesting the accuracy performance is consistent with the experiments performed regarding DDE detection in a smaller labeled dataset.

Discussion

DDE Detection

Overview

The results from the PR and ROC curves highlight significant differences in the performance of the models at detecting DDEs using the 3 different classification strategies: CS1, CS2, and CS3. These metrics are essential for understanding the trade-offs between sensitivity and specificity in identifying DDEs, which is vital in clinical settings where missing a DDE can have serious implications.

The PR curves (Figure 6) demonstrate the effectiveness of each classifier in handling the imbalanced nature of the dataset. BART under CS1 achieved the highest PR AUC, indicating its superior ability to maintain high precision without sacrificing recall. This performance suggests that BART is particularly adept at identifying DDEs in a dataset where DDEs are relatively rare, representing only 107 (10.7%) of the 1000 comments we labeled. In contrast, GPT-3.5 Turbo under CS2 had the lowest F_1-score of only 0.22, showing significant challenges in balancing precision and recall. These results highlight the limitations of some models when applied with the classification strategies we developed and to our imbalanced data set. However, these results highly depend on the prompts used with the models, and better results may be achieved by using different prompts in conjunction with the proposed classification strategies. Further research into this area is needed to better understand this phenomenon.

Similarly, the ROC curves (Figure 7) illustrate the classifiers' ability to distinguish between DDE and non-DDE cases across various thresholds. The area under the ROC curve provides a measure of the overall discriminative power of the models. BART's high area under the ROC curve under CS1 indicates its robustness in differentiating between the 2 classes, even at different decision thresholds. This robustness is crucial in clinical applications where both high sensitivity and specificity are required to minimize false negatives and false positives.

Classification Strategies

CS1: Individual Sentences

This strategy was particularly effective for both DeBERTa and BART in detecting DDEs, maintaining a higher balance between precision and recall as evidenced by their PR AUC scores. By analyzing sentences individually, this approach mitigates the dilution of relevant information, which is particularly beneficial in contexts where critical information might be embedded within longer text.

CS2: Groups of Sentences

While this strategy provided context by combining multiple sentences, it often resulted in a higher FNR due to the dilution of relevant information with surrounding text. This observation aligns with our hypothesis that feeding multiple sentences to a model simultaneously can lead to relevant DDE mentions being overshadowed by unrelated information. However, an intriguing exception was observed for GPT-4, which performed slightly better under CS2 than CS1 at higher cutoff values. This suggests that GPT-4 might better leverage the entire context of comments to make more informed classifications, indicating its potential to handle more complex and detailed contexts.

CS3: Entire Comment (GPT 3.5 Turbo and GPT-4 Models Only)

Interestingly, the performance of GPT-4 under CS3 was comparable to its performance under CS2 with a cutoff of 0.75, contradicting our initial hypothesis that the GPT models would perform better under the binary classification task considered in CS3. This implies that the architecture and training methodology of GPT-4 may not align with the approach implemented in CS3 or that our prompt design in CS3 was not optimally formulated. Further investigation is needed to understand this phenomenon better.

Key Takeaways

Superior Performance of BART

BART's superior performance, particularly under CS1, highlights its robustness and reliability in detecting DDEs from unstructured patient-generated content. This finding suggests that BART can be effectively used in clinical research to identify relevant data from imbalanced datasets without the need for extensive fine-tuning, which is crucial for real-world applications where data imbalance is common.

Because of BART's exceptional performance in DDE detection, we used BART under the classification strategy and cutoff that it achieved the best performance with to curate the dataset we labeled and used for our DDE root cause analysis. BART achieved the highest F_1-score of 0.86 under CS1 with a cutoff of 0.9.

Class Imbalance

The significant class imbalance, with only 107 out of 1000 (10.7%) comments labeled as DDEs, emphasizes the need for careful evaluation of classifier performance beyond overall accuracy. Metrics such as PR AUC provide a more comprehensive understanding of model performance, ensuring that high accuracy does not mask poor performance in detecting less frequent but critical events.

Real-World Applications

High FPRs and FNRs in DDE detection can lead to missed DDEs or unnecessary interventions, respectively. Therefore, achieving a balance in FPR and FNR, as demonstrated by BART under CS1 with a cutoff of 0.9, is essential for practical applications. This balance ensures that models can effectively support health care providers in making informed decisions based on patient-generated data.

DDE Root Cause Analysis

Our multilabel classification approach enabled the identification of multiple reasons for drug discontinuation within a single comment, offering a comprehensive understanding of patient behavior and decision-making. This robust methodology allowed us to leverage the strengths of LLMs to tackle complex clinical research questions related to DDEs.

XSL•FO
RenderX

Performance Highlights

DeBERTa and BART Struggled at Detecting DDE Root Causes

Both models struggled significantly at identifying the root causes of DDEs, as indicated by their much lower F_1-scores and higher hamming loss in Table 2 in comparison to GPT-4 Turbo and GPT-4o. Another interesting observation was that 10% (100/1000) of the comments in the dataset were non-DDEs, meaning that BART under CS1 with a cutoff of 0.9 inaccurately classified them as DDEs. We noticed that BART tended to label non-DDE comments as DDEs if they contained phrases such as "I am not on any medication." This is an important takeaway as it shows that even the models that performed the best at detecting DDEs still have tendencies to make mistakes in certain scenarios.

GPT-4 Turbo and GPT-4o Performed Exceptionally Well at Detecting DDE Root Causes

These models outperformed DeBERTa and BART across most metrics. GPT-4o, in particular, achieved the highest F_1-scores, lowest hamming loss, and highest Jaccard scores, indicating its superior ability to accurately and reliably classify the root causes of DDEs. The advanced capabilities of GPT-4 Turbo and GPT-4o in processing complex textual inputs holistically contributed to their outstanding performance.

Classification Strategies

CS1 (Individual Sentences) and CS2 (Groups of Sentences)

Although these strategies were effective for both DeBERTa and BART at detecting DDEs, the models struggled at detecting the root causes of DDEs under these strategies, as indicated by their extremely poor performance results shown in Tables 1 and 2.

CS3: Entire Comment (GPT-4 Turbo and GPT-4o Models Only)

GPT-4 Turbo and GPT-4o performed exceptionally well under CS3, likely due to their advanced capabilities in understanding and processing complex textual inputs holistically. This strategy allowed the models to capture the full context of the comments, leading to more accurate and reliable DDE root cause identification.

Key Takeaways

Superior Performance of GPT-4 Turbo and GPT-4o

The outstanding performance of GPT-4 Turbo and GPT-4o models highlights the importance of using advanced language models for complex classification tasks in health care. Their ability to accurately identify the root causes of DDEs can provide valuable insights for health care providers, enabling them to address patient concerns more effectively and improve medication adherence.

Challenges With Indeterminate Class

One notable challenge was the performance of GPT-4 Turbo in detecting DDEs belonging to the *indeterminate* class. For instance, a comment such as "My dad was diagnosed with bipolar disorder and stopped taking his meds after being in a rehabilitation center twice" did not clearly state the reason for discontinuation. Instead of classifying this as *indeterminate*, GPT-4 Turbo attempted to infer specific reasons such as *personal choices* or *adverse reactions*. This tendency to infer explicit conditions from ambiguous statements indicates a potential overfitting issue, where the model predicts more common classes instead of recognizing the ambiguity inherent in the input.

Class Imbalance

The significant class imbalance presented a challenge for all classifiers. Classes with higher frequencies, such as *personal choices* and *adverse reactions*, exhibited better performance. In contrast, less frequent classes such as *indeterminate* showed lower performance, highlighting the need for more balanced training datasets or advanced techniques to handle class imbalance effectively.

Clinical Implications

The superior performance of GPT-4 Turbo and GPT-4o in both DDE detection and root cause analysis underscores their potential application in clinical settings. These models can help health care providers identify common reasons for drug discontinuation, enabling the development of targeted interventions to improve medication adherence and patient outcomes. By leveraging these advanced NLP models, clinicians and researchers can gain deeper insights into patient behavior and decision-making processes, facilitating more effective and personalized health care strategies.

This research emphasizes the importance of capturing the patient's perspective directly from web-based health forums, which offers a richer and more authentic understanding of patient behavior and the real-world challenges they face compared to traditional electronic health record data. By identifying the root causes of DDEs from the patient's standpoint, health care providers, policy makers, and pharmaceutical companies can develop more targeted interventions to enhance medication adherence and patient outcomes.

Future Research Directions

To further enhance the applicability and reliability of these models in real-world settings, future research should focus on the opportunities outlined in the subsequent sections.

Real-World Applications

This research provides a foundation for clinical applications, such as improving patient adherence, by identifying common reasons for drug discontinuation. Health care providers can use these insights to develop targeted interventions and support systems to address the specific challenges faced by patients, ultimately enhancing treatment outcomes. Furthermore, applying these findings in real-world settings, such as clinical decision support systems, where accurate and reliable classification of text can significantly impact patient outcomes and health care processes, represents a substantial opportunity. Developing scalable and cost-effective solutions for deploying these models in practice will be crucial.

XSL•FO
RenderX

Prompt Optimization

Future research should explore various prompt optimization techniques to enhance model performance. This includes experimenting with chain-of-thought prompting, which has been shown to improve the performance of LLMs on complex reasoning tasks. In addition, investigating the impact of prompt specificity and structure on DDE root cause classification performance can provide valuable insights into optimal prompt design. For instance, future research could examine how the performance of GPT-4 Turbo and GPT-4o changes when examples of positive instances for low-frequency classes are included in the prompt. One concern with this approach is the potential for "prompt dependency," where providing specific examples might restrict the model's ability to generalize and accurately classify comments that differ in nature from those presented in the prompt.

Exploring Other State-of-the-Art LLMs

Research should be expanded to include state-of-the-art language models from developers other than OpenAI, such as models from Anthropic, Google, and Cohere. Models such as Claude by Anthropic and Gemini by Google have shown promising results in various NLP tasks and could be valuable for this study. In addition, models from research institutions, such as Command R by Cohere, should also be considered for comprehensive performance comparisons. By comparing the performance of these models on DDE root cause classification, we can identify the best tools for specific multilabel classification tasks and potentially reduce dependency on any single provider. This comparative analysis will help in understanding the strengths and limitations of each model in handling complex health care–related data, ultimately leading to more robust and versatile NLP applications.

Cost Minimization Strategies

Developing strategies to minimize the costs associated with using advanced NLP models is essential. This includes exploring open-source alternatives, such as LLaMA, optimizing model use to reduce application programming interface calls, and implementing efficient data processing pipelines. Research directions toward cost minimization could potentially align with advanced prompting techniques, such as classifying multiple comments with a single prompt and application programming interface call. However, preliminary research suggests that longer prompts lead to degraded performance of LLMs, even when the number of tasks in a single prompt does not increase.

Limitations

In summary, this research provides valuable insights into the ability of LLMs to detect DDEs from textual comments. However, the results should be interpreted with some caution due to the small sample size of DDE-labeled comments and the case imbalance inherent in our dataset. It is also worth mentioning that, as our study was restricted to English language comments from MedHelp, the generalizability of our results to other languages and platforms is not guaranteed. Furthermore, because the models used in this work generate stochastic outputs, the reproducibility of these results may be limited.

Despite these limitations, our study provides a foundation for further exploration into the use of LLMs in health informatics, specifically in identifying DDEs. Future studies should focus on improving the performance of transformer models by investigating other strategies, exploring ensemble methods, refining the classification prompt for the ChatGPT models, or incorporating different forms of data augmentation.

We anticipate that such innovative methods will stimulate and support further research into drug discontinuation, aiding health care researchers in identifying factors associated with the discontinuation of specific medications and treatments. These advancements are crucial in spotlighting new research directions with the potential to ameliorate treatment protocols and mitigate issues associated with medication discontinuation and nonadherence.

The ultimate aim is to enhance the capability of these models in real-world applications where accurate, timely detection of DDEs is of paramount importance. Improved detection can contribute to patient safety, optimize drug therapies, and facilitate better health outcomes.

Conclusions

This study has provided a thorough evaluation of advanced LLMs for detecting DDEs and identifying their root causes using data from MedHelp. The research demonstrates the effectiveness of state-of-the-art LLM models, particularly GPT-4 and GPT-4o, in handling complex multilabel classification tasks without the need for extensive task-specific training.

In conclusion, this research contributes significantly to the field of NLP and health care informatics by showcasing the potential of advanced classifiers to derive actionable insights from patient-generated content. The findings underscore the transformative impact these technologies can have on understanding and improving medication adherence, ultimately leading to better health care outcomes.

Abstract

Background: Digitalization is currently revolutionizing health care worldwide. A promising technology in this context is artificial intelligence (AI). The application of AI can support health care providers in their daily work in various ways. The integration of AI is particularly promising in clinical decision support systems (CDSSs). While the opportunities of this technology are numerous, the problems should not be overlooked.

Objective: This study aimed to identify challenges and barriers in the context of AI-based CDSSs from the perspectives of experts across various disciplines.

Methods: Semistructured expert interviews were conducted with different stakeholders. These included representatives of patients, physicians and caregivers, developers of AI-based CDSSs, researchers (studying AI in health care and social and health law), quality management and quality assurance representatives, a representative of an ethics committee, a representative of a health insurance fund, and medical product consultants. The interviews took place on the web and were recorded, transcribed, and subsequently subjected to a qualitative content analysis based on the method by Kuckartz. The analysis was conducted using MAXQDA software. Initially, the problems were separated into “general,” “development,” and “clinical use.” Finally, a workshop within the project consortium served to systematize the identified problems.

Results: A total of 15 expert interviews were conducted, and 309 expert statements with reference to problems and barriers in the context of AI-based CDSSs were identified. These emerged in 7 problem categories: technology (46/309, 14.9%), data (59/309, 19.1%), user (102/309, 33%), studies (17/309, 5.5%), ethics (20/309, 6.5%), law (33/309, 10.7%), and general (32/309, 10.4%). The problem categories were further divided into problem areas, which in turn comprised the respective problems.

Conclusions: A large number of problems and barriers were identified in the context of AI-based CDSSs. These can be systematized according to the point at which they occur (“general,” “development,” and “clinical use”) or according to the problem category (“technology,” “data,” “user,” “studies,” “ethics,” “law,” and “general”). The problems identified in this work should be further investigated. They can be used as a basis for deriving solutions to optimize development, acceptance, and use of AI-based CDSSs.

Introduction

Background

AI, and in particular machine learning (ML), is becoming more prevalent in health care systems worldwide. This is illustrated, for example, by the number of AI- or ML-enabled medical devices approved in the United States. Here, the annual increase in 2020, 2021, and 2022 was 39%, 15%, and 14%, respectively, and was forecasted to rise to ≥30% in 2023 [1]. In January 2024, the Food and Drug Administration listed 692 medical devices enabling AI and ML [1]. For Europe, no reliable statement can be made about the number of approved AI- or ML-enabled devices as the corresponding European database, the European Database on Medical Devices, does not provide a corresponding filter function [2]. This means that it is not possible to search explicitly for devices with AI or ML component.

AI-enabled devices cover a wide range of medical specialties, such as dermatology, diabetology, gastroenterology, gynecology, heart surgery, cardiology, nephrology, ophthalmology, orthopedics, pathology, psychiatry, and radiation oncology [3]. In the United States, in the first 7 months of 2023, a total of 79% of newly approved devices covered the field of radiology; 9% covered the cardiovascular field; 5% covered the field of neurology; 4% covered the field of gastroenterology or urology; 2% covered the field of anesthesiology; and 1% each covered the ear, nose, and throat as well as ophthalmic fields [1].

Analogous to the large number of medical specialties using AI, there are also many different types of applications. For example, AI can support the detection of infectious disease outbreaks; identify rare and common diseases by combining clinical, genetic, and many other laboratory test results; and support hospital business operations [4].

In addition to the various possibilities to benefit from AI in health care, there are also some concerns and problems with its use. These can be categorized in different ways. While Farhud and Zokaei [5], for example, identified “privacy and data protection,” “informed consent and autonomy,” “social gaps and justice,” and “medical consultation, empathy, and sympathy” as problem areas, Khan et al [6] identified “data collection and algorithm developing,” “ethical,” “social,” and “clinical implementation” as concerns.

An interesting application of AI in the medical context is its use in CDSSs. In general, CDSSs can be classified into knowledge based or non–knowledge based. While the knowledge-based systems follow clear rules (if-then statements), the non–knowledge-based systems use AI, ML, or statistical pattern recognition to make decisions on a data source [7]. Several approaches exist for ML. These include supervised learning, where algorithms benefit from information provided and labeled by humans (eg, by adding the final diagnosis to a set of clinical data), and unsupervised learning, where algorithms search for patterns in the underlying data on their own [8]. There is also reinforcement learning, where algorithms learn by interacting with an environment and receive feedback in the form of rewards to adapt and improve their actions [9]. AI-based CDSSs can be further distinguished based on the number of characteristics (eg, support on demand or unprompted) and in terms of their functions (eg, supporting diagnosis, outcome prediction, treatment planning, prescribing and managing medications, preventative care, chronic disease management, image interpretation, and many others) [10].

Regardless of AI, CDSSs also have several problems in addition to their many benefits. These problems include their content (“elimination or shifting of human roles,” “difficulty in keeping content current,” and “inappropriate content”) and their presentation (“rigidity of the system,” “alert fatigue,” and “potential for errors”) [11].

AI has the ability to evaluate large amounts of data where humans would fail because they cannot perceive the entire context beyond the data [12]. Thus, clinical decision-making can benefit from the use of AI. It can assist with the prognosis, diagnosis, and treatment of diseases; support the clinical workflow; and expand the availability of medical expertise [13]. However, in addition to the benefits, the problems and barriers of AI applications should be critically and responsibly considered rather than ignored [3].

Objectives

The use of AI-based CDSSs affects a large number of different stakeholders, such as physicians, caregivers, patients, and developers, and raises a multitude of different questions (eg, of legal or ethical nature). Therefore, in this research, various stakeholders were interviewed with the aim to identify potential problems and barriers related to AI-based CDSSs.

Methods

Overview

Qualitative research, concretely, semistructured expert interviews, was conducted to identify problems and barriers in the context of AI-based CDSSs. The decision to conduct qualitative research was made with the aim to approach the question exploratively because the use of AI is still not well established in health care systems worldwide. To ensure transparency in all aspects of our qualitative research, we followed the standards by O’Brien et al [14] and subsequently checked the manuscript by applying the 32-item COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [15].

Theoretical Framework

This study is part of a larger research project called KI@work (User-Oriented Requirements for AI-Based Clinical Decision Support Systems) funded by the German Federal Joint Committee. Building on the results of this interview study, a corresponding scoping review, and focus groups with physicians

XSL•FO
RenderX

and carers, a quantitative survey of physicians will be developed to investigate their preferences as well as problems in the context of AI-based CDSSs.

The aim was to collect the perspectives and opinions of experts. The interviews were conducted with stakeholders playing a pivotal role in the context of AI in medicine. On the basis of a previously conducted scoping review in the context of the project, a guideline was created and used to structure the interviews.

During the interviews, we asked about both problems and barriers as well as solutions to overcome them. This paper focuses especially on the problems and barriers identified in the underlying conversations.

Participant Selection

Before contacting potential participants, the project consortium discussed relevant stakeholders. During the discussion, they came to the consensus that, in addition to representatives of patients, service providers, AI developers, and health insurance funds, further experts with knowledge on regulation of AI as well as experts on ethical questions should be included.

Once the relevant stakeholder groups were determined, the University of Duisburg-Essen recruited corresponding experts with the help of the entire consortium. Before conducting the interviews, the stakeholders received an informative letter about the topic of the interviews—problems in the implementation of AI-based CDSSs in patient care—and further information about the procedure, including information about data protection, via email.

A total of 4 contacted stakeholders did not respond to the request. There was no clear refusal to participate in the interviews. After recruitment, during the interviews, none of the experts included dropped out of the study.

Setting and Data Collection

All the interviews were held online either via the videoconferencing platform integrated into Microsoft Teams or Zoom (Zoom Video Communications). Each expert interview was guided by a moderator and accompanied by at least one additional comoderator. All 3 moderators (GDG, PR, and NB) were from the Institute for Health Care Management and Research, University of Duisburg-Essen. While one moderator (NB) is head of the research team, the 2 others are scientific staff within the team. In total, 2 moderators were male (GDG and PR), and one moderator was female (NB). Of the moderators, 2 have a (health) economic background, and the third moderator holds a medical doctor degree in addition (NB). GDG and NB are experienced in conducting qualitative research, especially interviews. PR gained experience in conducting interviews through his previous work in market research. There were no relationships between the researchers and the interviewees. The researchers did not have a clear stance either for or against the use of AI in health care. No further circumstances or events influencing the conversations are known.

Preliminary results of a scoping review conducted within the project (to be published) before the stakeholder interviews served to develop a noninfluencing interview guideline. This guideline followed a uniform structure, including three main topics: (1) general problems with AI-based CDSSs, (2) problems in the development process of AI-based CDSSs, and (3) problems in the clinical use of AI-based CDSSs. Each of the topics started with open questions followed by more specific questions. Each topic included a core set of fixed questions for all stakeholders and was also slightly extended or adapted to the stakeholders to receive stakeholder-specific information (Multimedia Appendix 1).

Data collection took place between the beginning of June 2023 and the middle of August 2023. If the interviews were conducted using Microsoft Teams, they were automatically transcribed using the integrated function. The machine-generated transcripts were revised and pseudonymized by research assistants. If the interviews were conducted using Zoom, the recordings were transcribed by research assistants. In both cases, the transcripts were quality checked by 1 of the 3 moderators. The quality-assured transcripts were sent to the corresponding stakeholders interviewed to allow for requests for changes within 1 week (if no request has been made to extend the deadline). During the study, no adjustments (except for the stakeholder-specific questions in the guideline) were made to the method of data generation as the interviews worked without problems and the guideline proved to be understandable.

Data Analysis

After incorporating the requested changes by 3 stakeholders, the transcripts were loaded into MAXQDA (VERBI Software GmbH), and video recordings were deleted. Subsequently, data analysis started in September 2023 and was completed in October 2023.

As recommended by Kuckartz [16], deductive codes were defined before data analysis and applied subsequently to the transcripts (GDG). Deductive codes were determined according to the structure of the interview and included the 3 topics of the guideline (“general,” “development,” and “clinical use”).

The statements identified were concisely summarized and printed on individual pieces of paper (GDG). In a subsequent workshop (GDG, NB, and PR), the printed statements that were thematically similar were grouped together into clusters (“problem areas”). Whenever a problem or barrier arose that did not fit into an existing cluster, a new cluster was created. The clusters were named appropriately according to the problems and barriers they contained.

Subsequently, thematically similar clusters were organized into higher-level groups (“problem categories”) and named accordingly. Finally, the stakeholder statements and their respective summaries were sorted into a matrix with deductive codes (“general,” “development,” and “clinical use”) on the horizontal axis and inductive codes (“problem categories” and “problem areas”) on the vertical axis.

Ethical Considerations

As the topic of the interviews was not a sensitive subject and sociodemographic or other potentially identifying characteristics of the interviewees were not collected, there was no need for

XSL•FO
RenderX

approval by an ethics review board. This was also confirmed by the Ethics Committee of the Faculty of Medicine of the University of Duisburg-Essen. During the introduction, before the interviews, the participants were informed about the exact procedure and conditions and asked for their consent to participate. Through pseudonymization and deletion of the recordings, reassignment of statements to participants was no longer possible. On request, the experts received an expense allowance of €120 (US $124.27) for their participation. In the end, 4 of the 15 interview partners did so.

Results

Overview

A total of 15 interviews were conducted with 17 experts. In total, 13% (2/15) of the interviews conducted were double interviews with 2 interview partners in each. Experts included all requested stakeholder groups: a patient and a physician representative, developers of AI systems, consultants, experts in the fields of quality assurance and quality management, caregiver representatives, members of research institutions in the fields of AI and health care as well as social and health law, a representative of a health insurance fund, and an expert from an ethics committee. In general, intrinsic motivation and participation were high. An overview of each interview is provided in Table 1.

[a]AI: artificial intelligence.

[b]CDSS: clinical decision support system.

The interviews provided 309 statements on problems and barriers in the context of AI-based CDSSs. A total of 7 problem categories were identified: “technology,” “data,” “user,” “studies,” “ethics,” “law,” and “general.” The categories with their corresponding problem areas are shown in Figure 1.

XSL•FO
RenderX

Figure 1. Identified problem categories and corresponding problem areas. AI: artificial intelligence; CDSS: clinical decision support system.

Even if the aim of qualitative research is more explorative than deterministic, it should be mentioned that some problem categories were more often thematized than others (user: 102/309, 33%; data: 59/309, 19.1%; technology: 46/309, 14.9%; law: 33/309, 10.7%; general: 32/309, 10.4%; ethics: 20/309, 6.5%; studies: 17/309, 5.5%). The problem categories are described in the following sections, and relevant expert statements are reproduced to illustrate the problems. The order of the problem categories does not indicate their relevance. A final list with the systematization of all identified problems can be found in Multimedia Appendix 2.

Technology

Problems described in the "technology" category were directly related to the technology underlying AI-based CDSSs. Named problems concerned 6 areas: "errors and false alarms," "generalizability," "black-box-character," "training," "implicit knowledge," and "reliability."

"Errors and false alarms" were observed in clinical use and in general. While incorrect recommendations resulting from use were seen as a threat to patients, a more general problem in this context was the tension between sensitivity and specificity:

> *[W]ith every AI procedure...there exists an area of conflict. So do I tend to develop the system more towards the direction of being more sensible, so to speak. In other words,...if it triggers, there's a high probability that it's actually correct. But then you lose, then suddenly there might be cases that you don't diagnose....* [Developer of AI-based CDSSs]

In addition to weighing up individualization and generalization during the development process and the system adaptation to local data before use, named problems with "generalizability" were of a more general nature. These problems were observed particularly in relation to regional validity, hospital-specific validity (eg, specialized or smaller hospitals), and population-based validity (eg, genetic). As AI is always developed on a distinct database, experts questioned whether the systems were ubiquitously valid. One expert described that the quality of the results in the real setting is not comparable with the quality of the results based on training and test data:

> *Yes, I see problems with generalizability. We hear from several developers that if they have a data set of a hundred thousand patients, take 50,000 for training and test it with the other 50,000, then they get good results. If they take data outside of this cohort, the results are different.* [Medical product consultant]

Furthermore, the "black-box-character" problem was thematized. In general, more complex AI systems tend to be not comprehensible to humans. As a result, users have a lack of understanding of AI-proposed decisions. This is not only a general problem but also a concrete problem during clinical use, as described by a caregiver representative:

XSL•FO
RenderX

> *[T]raceability is a very important factor for such a system; if I, as a user or collaborator, don't understand it, then the collaboration doesn't work well either.* [Caregiver representative]

During the development process, problems can also occur in the "training" of the AI. This is the case if the training is suboptimal or even poor and biased. This might be due to (1) an insufficiently analyzed database, (2) biased training because of too specific datasets, or (3) the system learning from lowly qualified users. Another problem was observed if the development phase was not completed before actual clinical use (eg, due to the prospect of quick profits). If the development phase is not supervised, so-called drifts can emerge, and the validity of systems might change over time.

Further problems were expressed in the context of "implicit knowledge." As this type of knowledge cannot be represented in words or numbers, experts explained that it cannot be integrated into AI-based CDSSs. Problems in this context concerned mainly clinical use because experts stated the need for this knowledge and warned against neglecting it by using AI. Furthermore, it was assumed that the lack of implicit knowledge might lead to a reductionist patient image:

> *We don't have the context that doctors sometimes have when the patient is right in front of them, and they see him as a human being and ask a few questions. So that's why it's very dangerous, because we end up with a very reductionist image of a patient as far as the AI system is concerned.* [Developer of AI-based CDSSs]

"Reliability" was the last problem area thematized within "technology." A general problem leading to lack of reliability was observed in the functionality of AI, which is based on probabilities and statistics. According to one expert, these would not always lead to the right decisions:

> *[T]he problem with AI is that it is not a physical algorithm, but statistics. That means there will always be things where you can be wrong.* [Medical product consultant]

Furthermore, such systems would neither critically question inputs nor provide absolute reliability. Premature deployment in resource-critical care situations was seen as a particular risk.

Data

"Data" as the underlying input of AI-based CDSSs are essential for the development and use of these systems. During the interviews, numerous problems were described in the context of data. These included "fragmentation," "data quality," "data quantity," "data security," "context of the data," and "data collection."

The first problem in this category is the "fragmentation" of the health care system and, subsequently, the fragmentation of data. Problems concerning "fragmentation" usually have a general background but have a strong impact on the development process. In particular, the German health care system is characterized by a great variety of institutions and actors with different interests, making it very complex. Breaks exist at the boundaries between different sectors (eg, between inpatient and outpatient supply), which means that data are not collected uniformly and, therefore, are often not comparable. In some cases, there was a lack of uniform standards. These problems are also reflected in the development process of AI-based CDSSs. Nonharmonized, nonunified, and unprocessed data, as well as a multitude of different actors, lead to major barriers for the development of these systems. One expert described a lack of standardization as a problem that hinders the comparability of data:

> *Well, first of all, I would say that it heavily relies on the training data, that we have different standards there. And the question is to what extent they can be harmonized or standardized, so that you're not comparing apples with oranges....* [Representative of an ethics committee]

Once the data had been collected, their quality was described to be often insufficient. It was even stated that data do not always represent reality. The insufficient "data quality" is especially a problem during the development process. In this context, the "garbage-in, garbage-out" principle was mentioned. It states that, if the data entered are not good, the results will not be good either:

> *Because that's the garbage-in, garbage-out principle; the worse the data you put in, the worse the result will be.* [Developer of AI-based CDSSs]

A threat in the context of low-quality data was observed in the use of suboptimal data if no other data exist. This might lead to the development of an AI-based CDSS that produces wrong results and is subsequently inappropriate for clinical use.

Experts also saw a problem in "data quantity." While, on the one hand, there was a general lack of data, experts such as a researcher in the field of AI in health care mentioned especially a lack of structured and quality-proved data on the other hand:

> *I think there is a quality problem with the data, that's undisputed....there is a massive problem, but our main problem is the quantity of data that is available at all.* [Researcher—AI in health care]

Furthermore, it was mentioned that some data are not available in digitized form. A special case was observed in rare treatment situations as these would not provide a sufficient data basis. In contrast to the lack of data, one developer mentioned an uncontrolled flood of data.

"Data security" was reported as a further problem. In general, the experts themselves questioned data security and mentioned that patients are particularly afraid of data leaks, too. According to the experts, those leaks and problems with the IT and its cybersecurity could emerge during the clinical use of AI-based CDSSs. A threat was observed in hacker attacks and subsequent manipulation or deletion of training data or algorithms, as well as system failures. The risk of being affected by hacker attacks and the absolute danger that this poses were described as being increased in the context of AI:

> *Data protection is certainly a problem, the more AI you have, the more you are likely to be affected by*

XSL•FO
RenderX

> *external hacker attacks and so on. So, because if I have access to the system, the consequences of a hacker attack will be on another level.* [Representative of a health insurance fund]

A problem in clinical use could emerge if the (medical) "context of the data" changes. Therefore, the quality of the information provided by AI-based CDSSs could change. An example given by an expert of such an altering context was a changing understanding of diseases or a change in diagnoses over time:

> *So, you can't just say that this is a technical problem. You always have to ask again about the current state of science. Is it still valid if I take the data from eight or ten years ago, because sometimes the concept of illness changes, e.g. in the case of psychological experiences, but also in the case of other diagnoses.* [Quality assurance representative]

Finally, it was explained that the "data collection" process might be a problem. Experts stated that only a fraction of treatment data is available in digital form and that the extraction of analog data can be very complex.

User

A major problem category was the "user" of AI-based CDSSs. Related problem areas were "workload," "interprofessionality," "qualification," "automation bias," "decision-making," "loss of knowledge," "alarm fatigue," and "perception of AI."

Lack of time is omnipresent among physicians and caregivers. Therefore, experts warned of additional time expenditure, especially in the context of clinical use. Nevertheless, the lack of time and the additional workload were also a problem during development because caregivers were therefore not able to insert data for training purposes. In the context of clinical use, an additional workload was stated, assumed, considered, or feared by different experts:

> *But in cases where someone has to enter something, you must be careful, what does the doctor have to do, are you taking time away from the patient again?* [Quality assurance representative]

Experts stated that some data cannot be collected automatically and, thus, would lead to a need for additional personnel. Potentially necessary manual corrections of incorrect measurements would be required. Furthermore, a problem related to workload was the attempt to misuse AI-based CDSSs to cut staff costs.

A problem area concerning development was "interprofessionality." Generally, experts stated the need for interdisciplinary development of an AI-based CDSS. Otherwise, they foresaw problems in clinical use or even stated that, without interdisciplinary development, no useful systems would be developed at all. In particular, the lack of involvement of medical and care professionals was expressed by the experts. They mentioned that medical professionals are more likely to notice professional errors during development but also that they tend to underestimate the effort to develop an AI-based CDSS. A further problem with the involvement of physicians is that the development of an AI-based CDSS is usually only a secondary activity for them. The caregiver representatives felt that caregivers are insufficiently involved in the development of such systems, and thereby, important caregiver knowledge would not be incorporated. Development problems are also aggravated by the lack of skilled workers with knowledge of AI.

Once started, development can be difficult because of nonfunctioning cooperation between different professions, the time required for interprofessional communication, different specialist terminology, and conflicts of interest between actors involved:

> *Yes, so I would totally agree. So that's clear in such a—especially in the development phase, there are various stakeholders and various interests that simply come together, and to even get into the discourse, to have a conversation and to unite them, I think that's a very high art.* [Caregiver representative]

The "qualification" of users can also be a problem. It was stated by the experts that, in general, the users are poorly qualified for the use of AI-based CDSSs. They sometimes lack digital experience or further training. A caregiver representative mentioned a low intrinsic motivation of care professionals to deal with the topic of AI-based CDSSs. A lack of experience might also lead to more difficult interpretation and communication in the context of the systems. One expert explained that a lack of training was a problem and that it was not enough to train just 1 employee. Otherwise, it was likely that further problems would result:

> *I think one problem is the training. No matter who uses it, I must train these people. And I believe that's always a source of error, so it's shown to one person. The entire staff that has to use it simply isn't thoroughly trained. Then mistakes can of course happen in the application of this AI.* [Representative of a health insurance fund]

Experts described that users tend to prefer suggestions from (AI-based) CDSSs and ignore contradictory information provided without automation even if it is correct. This was described as blind trust, blind replying, uncritical adoption, or "automation bias." It was assumed that automation bias can lead to inadequate action and potentially jeopardize patient health. The problem was reinforced due to time pressure, stress, and a high shortage of skilled workers. This was especially emphasized by a caregiver representative:

> *So, I definitely see the danger that, especially against the background of such a fast clinical routine, the recommendation is simply adopted without being asked.* [Caregiver representative]

In addition to automation bias, further problems exist within the "medical or caregiving decision-making" process. Thus, AI-based CDSSs can be seen as a decision-making barrier in the case of disagreements. They might endanger the autonomy of users or undermine the medical and nursing expertise. An expert described this new knowledge asymmetry in which the patient is ahead of the physician as follows:

XSL•FO
RenderX

> *And I believe that quite a lot of doctors, and certainly a few nursing experts and nurses, see in it a bit of a curtailment of their field, their expertise, their unique selling point. I mean, when AI-based applications are brought into the public, I, as a person who may even be suffering from a rare disease and knows more through these support systems than my treating doctor, then they have to deal with that too, yes.* [Quality management representative]

A further problem area expressed was "loss of knowledge." In particular, the risk that the regular use of the systems would result in users no longer being able to access their own knowledge, which would then diminish, was described:

> *I see the risk of knowledge loss equally significant in all areas, so we're handing something over to AI in all aspects of life. And we are also losing competencies as a result.* [Caregiver representative]

Furthermore, experts explained that too many (false) alarms might lead to "alert fatigue." This means that system users deliberately ignore alerts or no longer manage to follow them up. It was described that the number of alerts produced across all software systems would be overwhelming and lead to alert fatigue:

> *That's a huge problem, especially false alarms, regardless of artificial intelligence. I mean, all of our or many of our software systems produce alerts. But in such a volume that one can't even follow up on them anymore, and then, of course, we're also talking about alert fatigue.* [Quality management representative]

Finally, the "perception of AI" was described as a problem area emerging from the user side. The problem partly originated in negative communication. The perception described ranged from low or lack of trust to doubts about validity and benefit to a partly irrational fear. A negative perception was observed among patients and health care providers but also among authorities and notified bodies. Health care providers described a fear of being replaced by AI. Excessive expectations of AI and a lack of awareness of the limits of AI systems were also reported. One expert described the perceptions in both directions (positive or negative) as extreme.

In clinical use, it was observed that distrust among users might emerge due to an undermining of medical competence or due to measuring physicians' diagnostic quality. A lack of trust was associated with a lack of added value provided by the systems. During clinical use, the perception of patients toward AI-based CDSS might also be impacted. This could happen through perceived false alerts or misleading medical wording. One expert mentioned that a big problem lies in failing to open up to AI and focusing too narrowly on its problems:

> *And I think, that's one of the biggest problems with AI-based solutions, if I don't approach the whole issue decisively or openly. That means, if I only see all the risks, if I'm somehow maybe even fear the AI-powered, self-evolving robot that might wipe out humanity, so I'm exaggerating it to some extent, but there are still some people out there who have this idea.* [Medical product consultant]

Studies

A further problem category was "studies," which are necessary to examine and demonstrate the evidence in terms of clinical effectiveness, reliability, and real-world applicability of AI-based CDSSs. This included the "study quality"; a "lack of studies"; and problems with "ethics votes," "study funding," and "conception and development."

In general, experts questioned the quality of available studies. They criticized that studies are not conducted with conscientiousness and that results may be manipulated. Furthermore, a risk of low-quality evidence in studies was described. An expert described the varying quality of studies that must be considered:

> *That's just—and I believe that often, work is not done properly enough, because people simply think, "Oh, it's just a study, and it'll be fine." If we look closely...we often find that, well, not all studies are created equally right.* [Representative of a health insurance fund]

In addition to the quality, the "lack of studies" was expressed to be a problem. It was mentioned that there are only few study results from Germany available. In particular, a lack of valid and reliable studies, prospective studies, and studies on the additional benefits of the systems was named:

> *The problem with all these AI algorithms so far is that they are based on retrospective data. And what we need is a prospective—or prospective studies with algorithms, to prove that there is actually a prospective advantage compared to standard treatment.* [Physician representative—intensive care]

"Ethic votes" were described as being an obstacle to study conduct. In detail, according to an expert, this means that ethic votes are usually necessary but might be rejected:

> *[A]nd even if we had data, we would need appropriate ethics approvals for the data, unless it is de-identified, which simply takes a very long time. And I have actually heard from colleagues that such ethics approvals have been rejected because they were supposed to be used for technical AI studies.* [Researcher—AI in health care]

A further problem area in the context of studies was "study funding." The experts called for more funding to be able to conduct studies to prove the evidence of AI-based CDSSs. This was described by a physician representative as giving up medical success due to lack of study funding for fear of AI.

Finally, problems were mentioned in the context of "conception and development." A threat was observed if developers were not independent of influence. Experts questioned the objectivity and knowledge base of algorithms and the transparency and trustworthiness of the development process. The latter was partly described as exploratory instead of purposeful, and the lack of a holistic view of the data was criticized. This was illustrated with the help of a metaphor by an expert:

XSL•FO
RenderX

> *So, if you collect data for the sake of data and then run it through a system, with some machine learning algorithm, and then get something nice out of it, it's just like knowing: Somewhere in a pond there are 20,000 different species of fish. I throw my fishing rod in there, catch a carp and afterwards I end up saying, that's exactly what I wanted. So maybe we should also think about what kind of data do I need for what, so what are my outcomes....* [Caregiver representative]

Ethics

The problem category "ethics" included "general," "dehumanization," and "discrimination." While "general" only consisted of general concerns about ethical problems, the other problem areas were more specified.

During clinical use, "dehumanization" of patients was feared. This was due to the dehumanization of the medical treatment and the risk of deteriorating communication with patients. Experts described that patients might be perceived as data points and their individual stories might not be considered:

> *But the question is, how can you link this in a meaningful way with general practitioners who actually see the patient and their history and not just specific data points?* [Representative of an ethics committee]

The most discussed problem area in the context of ethics was "discrimination." These problems occurred within the "development" category, concerned clinical use, and were partly general. General problems were observed in the reidentification of small population groups and a special paradox:

> *I see it as a bit of a paradox that, on the one hand, you of course want to collect data from as many minorities as possible to make the data more representative and, on the other hand, you have to classify them and that this can lead to new forms of stigmatization.* [Representative of an ethics committee]

An inherent problem of the development of an AI-based CDSS was observed in the dependence on the underlying data. The latter were regularly discriminatory or at least imbalanced between different patient groups. One such discrimination was observed in primarily male-oriented data. Once discrimination exists within the data, the AI developed adopts these patterns and reflects them in clinical use. Thus, a threat was described that the use of AI-based CDSSs might result in discrimination, for example, in terms of social inequalities or racist behavior. That this problem is already subject to research was described by a medical product consultant:

> *Basically, I know that there are a lot of AI research activities to see whether AI behaves in a racist way. So, there are definitely some research projects that point in that direction.* [Medical product consultant]

Law

In terms of law-related problems, experts named the problem areas "approval and certification," "data protection," "liability," "property rights," and "general." The latter encompassed that AI-based CDSSs are currently not sufficiently reflected in medical law.

In the context of "approval and certification," 2 problems were described. First, the certification procedure for AI-based CDSSs was described as overly complex and costly. Among other things, additional work due to different requirements for different authorization regions was named. Especially for start-ups with scarce resources, the framework conditions were described as too cost intensive. Second, experts stated that there are regulatory issues in the context of medical device authorization and uncertainties with and an insufficient number of certifying bodies:

> *The regulator hurdle is the certification as a medical device. There are currently only four notified bodies in the EU for the certification of software as a medical device. And that means we have waiting lists.* [Medical product consultant]

"Data protection" was found to be a general problem but also a problem during clinical use. For clinical use, on the one hand, there were experts that stated that data protection was a real problem. On the other hand, experts stated the problem that data protection was used as a pretext against the use of AI-based CDSSs or to avoid renewal. Real data protection problems in clinical use were observed, for example, in insufficient reading and writing permissions in the digital patient file for caregivers due to data protection.

In general, requirements for data protection and data security were described as cumbersome, and their implementation was seen as problematic. In particular, data that cannot be anonymized and automated data processing were seen as special issues. To some extent, experts described that data protection would hamper the exchange of data even within the same hospital and would lead to poorer data. In the case of withdrawal of consent to use data, identification of specific data among vast amounts of data might be a problem. Finally, it was criticized that data protection was prioritized over health protection:

> *[M]y view is that we have a big problem when it comes to data protection. In my opinion, in Germany or at least in my perception, data protection is more important than health protection.* [Quality management representative]

Furthermore, experts saw problems with "liability." There were concerns that physicians were always liable for decisions even if the errors stemmed from AI-based CDSSs. It was stated that the problem of liability is a difficult question and that, in some cases, responsibility remains unclear or is not regulated at all:

> *Is it actually the user or is it the person who developed the system? Who is actually responsible afterwards if there is some damage because the system did not function properly?* [Researcher—social and health law]

Finally, the issue of "property rights" was raised. Given the multidisciplinary development processes of AI-based CDSSs, it is not always clear who has sovereignty over data and

XSL•FO
RenderX

development results. Therefore, conflicts over ownership of data and patents might arise.

General

The last problem category was "general." It included all problems that could not be matched to another category. It consisted of (nonlegal) framework conditions such as "degree of digitalization," "hospital IT," "definition of AI," or "costs" on the one hand and of more direct problem areas such as "comparability of AI systems," "side effects," or "neglect of caring professions" on the other hand.

Different experts described that there was a lack of digitalization or that the "degree of digitalization" in the health care sector was too low. Furthermore, a lack of integration and, subsequently, a lack of data availability between sectors and institutions was described:

> *If you look at the overall process that a patient goes through, it is ultimately still too analogue and too disruptive and not digitized enough. That's a big problem overall as a basis for AI-based support systems. Because ultimately, you need a relatively large amount of data and also from a specific patient in order to compare it accordingly.* [Physician representative]

A problem area in clinical use was the "hospital IT." It was described as inadequate and lacking in technical equipment, its reliability was questioned, and a lack of IT staff was mentioned. A lack of system compatibility; a lack of interfaces between individual departments; and the unavailability of standardized, structured data within the hospital were more concrete problems. Furthermore, it was described that hospitals are not considered attractive places to work for IT specialists and that their pay would be too low. The unattractiveness of hospitals for IT specialists was, for example, described by a researcher in the field of AI in health care:

> *The costs are exploding of course. The IT sins have of course piled up everywhere and you also know that hospitals are not seen as desirable workplaces for IT specialists.* [Researcher—AI in health care]

Furthermore, problems with "costs" were observed during development in the lack of financial resources for projects, as well as the implementation costs being a barrier for clinical use. A problem that prevents cost savings was observed in AI-based CDSS manufacturers aiming to maximize profits. Within the remuneration system, the lack of specific billing codes for algorithm-based laboratory test results and the absence of separate billing options for AI systems were criticized:

> *Then we certainly have another issue, that the costs for these systems are currently not separately billable. Instead, they are part of the medical service, and you can take the position, well, that's just how it is, because the reimbursement code exists for the image and the diagnosis, and if the doctor buys additional software to save time in diagnosis, then that's an economic effect on his side, which the system doesn't have to worry about.* [Medical product consultant]

A challenge in deciding between different AI-based CDSSs, or whether to adopt such a system at all, could arise from the insufficient "comparability of AI systems." In addition, the lack of reasonable data to make health economic decisions was criticized:

> *I'm not sure whether those who are supposed to use it have sufficient criteria to decide which system to buy and how to compare the different systems with each other. So how do the different systems on the market actually compete with each other in terms of quality?* [Medical product consultant]

A problem expressed by caregiver representatives was a "neglect of caring professions" within the context of AI-based CDSSs. A lack of funding for the development of AI in the care sector, as well as a strong focus on medical applications resulting in a deficit in nursing applications, was described.

Furthermore, the occurrence of "side effects" in the clinical use of AI-based CDSSs was named as a problem requiring evaluation and follow-up to guarantee patient safety.

Finally, experts thematized different "definitions of AI" as a problem:

> *So, if you tell someone in practice that this is artificial intelligence, then there are an incredible number of opinions and ideas about what it could actually be.* [Caregiver representative]

Discussion

Principal Findings

We identified 7 different stakeholder-relevant problem categories ("technology," "data," "user," "studies," "ethics," "law," and "general"). While "technology" included problems that are directly related to the technology of AI-based CDSSs themselves, the other problem categories concerned the environment and the circumstances in which the systems are conceptualized, developed, studied, and used.

While our systematization is fundamentally new, many of the problems identified were in accordance with the literature on CDSSs. For example, Sutton et al [7] described the following problem areas in the context of CDSSs: "fragmented workflows," "alert fatigue and inappropriate alerts," "impact on user skill," "dependence on computer literacy," "system and content maintenance," "operational impact of poor data quality and incorrect content," "lack of transportability and interoperability," and "financial challenges." Similar results were obtained in a review of medication-related CDSSs. Most reported factors influencing the acceptance of such systems were (a lack of) "usefulness," "relevance" of information, "ease of use," and "efficiency" [17].

While these problems were valid for CDSSs in general, our study showed that stakeholders also saw problems that are especially attributable to the integration of AI into these systems (eg, "generalizability," "black-box character," and "perception of AI").

XSL•FO
RenderX

Challenges of AI in health and medicine have been described, for example, by Rajpurkar et al [18]. They found problems similar to those identified in our research. Challenges were identified in "implementation," "accountability," and "fairness." Implementation challenges included model trust and data limitations; accountability challenges stemmed from regulations and responsibilities; and, finally, fairness challenges comprised ethical data use as well as equity and bias.

In the German context in which the study took place, the Ethics Committee of the German Medical Association provides a profound overview on ethical and legal problem areas in the field of AI. Ethical aspects are "trust and trustworthiness," "responsibility," "autonomy," "communication and empathy," "medical expertise," "risk of discrimination," and "data sovereignty and privacy." Legal aspects include "regulation of medical devices," "obligations in the context of examination or treatment methods," "duties of care of physicians," "patient information and consent," "liability," and "data protection and confidentiality" [19].

In addition to individual problems of CDSSs as well as AI, there is some research on factors influencing the acceptance of AI-based CDSSs. Factors described in this context include concern of system failure, overtrusting of the systems, locality of the systems, and an intuitive user interface [20]. Knop et al [21] listed further characteristics and human factors that influence and shape the relationship and collaboration between AI-based CDSSs and humans. Technological characteristics include "training data quality," "performance," "explainability or transparency," and "adapted output or adaptability." Human factors comprise "medical expertise," "technological expertise," "personality," "cognitive biases," and "trust" [21]. While technological characteristics included a part of the problems that we identified and categorized under "technology" and "data," we included human factors under the category "user."

The combination of AI and CDSSs can increase the relevance of individual problems. While traditional CDSSs typically provide transparent and understandable reasoning, the black-box nature of AI-based CDSSs can make it difficult to build trust in these systems. If, for example, the causes of alarms are not clear, this could lead to them being ignored. On the other hand, the need for scrutinizing proposed decisions is even more important in AI-based CDSSs. As the reason for a decision is not comprehensible and relies on statistics, physicians should be even more sensitized to automation bias to uncover wrong decisions.

In the context of AI-based CDSSs, a special focus during development should be placed on the creation of the data basis. As the systems learn from these data, there is a threat that wrong decisions will emerge if the data are inadequate.

A problem that arises specifically with AI-based CDSSs is liability for incorrect decisions. As the systems themselves cannot be held liable, it is conceivable that either the physicians using them or the vendors or health care organizations could be held liable [22]. However, it should be noted that there is no easy way of understanding black-box decisions, and therefore, the responsibility of physicians is not clear.

While the problems identified in our research are in accordance with the literature, it should be emphasized that some stakeholders saw certain topics as problems, whereas others did not. One example is "loss of knowledge." While one caregiver representative mentioned that it would be a problem, another stated that the systems are an upgrade for human decision-making instead of leading to loss of knowledge. Another such example was the problem of executing untested recommendations (automation bias). While most of the stakeholders saw a problem here, one stakeholder emphasized that, if the reliability of the systems was close to 100% in the future, it would no longer be a problem. One interviewee emphasized that, in general, he would rather refer to them as "to-dos" than as problems.

To increase physicians' acceptance of CDSSs, Khairat et al [23] proposed 2 different models. On the one hand, physicians should be included in the design process by examining user needs and expectations as well as the usability of prototypic designs. On the other hand, it is important for physicians to include the CDSS as a component of their decisions while maintaining professional autonomy. These approaches should also be pursued in the context of AI-based CDSSs.

Even if most problems of AI-based CDSSs were already known from CDSSs or AI as individual technologies, our investigation shows that they are still relevant. Our work in particular makes a contribution by compiling and systematizing the problems in the context of AI-based CDSSs. This provides an ideal starting point for further investigation of individual problem categories or manifestations.

Implications

AI-based CDSSs can lead to an improved physician performance and better medical outcomes [24]. Nevertheless, we identified several problems that are in accordance with the literature [7,18,19]. These should be solved as, by addressing errors, the potential of AI to improve the future of medicine can be realized [18].

Even if there are regulations for CDSSs, such as the 21st Century Cures Act in the United States and the Medical Device Regulation in the European Union, not all problems regarding this technology are covered [25]. McKee and Wouters [8] identified five challenges for regulators in the context of AI: (1) the AI application is only one part of a complex clinical system, (2) the training process may incorporate existing values and biases, (3) the performance will change over time using ML, (4) there might be conflicts with data protection legislation, and (5) gathering vast quantities of data might raise issues of privacy.

Given the heterogeneity of the problems in the context of AI-based CDSSs, one cannot assume a definite solution to be available. While many problems emerge from the technology behind AI-based CDSSs, there are other problems emerging from the environment in which the systems should be used. Therefore, existing risks cannot be solved only on the technical level but require interdisciplinary effort. To conceptualize valuable systems, clear communication between IT professionals

XSL•FO
RenderX

(developers) and health care practitioners (users) during development is needed [26].

Even if future systems can reliably derive decisions from databases, the treating physician should not be left out. Some problems, such as lack of implicit knowledge, dehumanization, and most of the ethical problems or the (medical) context of the data, cannot be sufficiently considered by the systems. Therefore, to achieve the best outcome for all actors within the health care system, the goal should be to combine the capabilities and strengths of AI and human intelligence [12,27]. To do so, it is necessary to identify the attitudes of relevant stakeholders toward the technology and its use. Such an approach was adopted by Laï et al [28]. In an interview study with 40 French stakeholders, they found that views on AI were very heterogeneous and that only cooperation between the involved parties would lead to the development of satisfactory AI tools.

As mentioned in the Methods section, this work is part of a research project—KI@work. The results of this interview study together with the results of a scoping review and focus groups with physicians and carers will be used to conceptualize a quantitative survey for intensive care physicians. Thereby, the relevance of individual problems from the point of view of physicians might be determined more precisely.

Limitations

Given the novelty of the technology of AI-based CDSSs, we conducted interviews to explore problems and barriers from the point of view of German stakeholders. Due to the qualitative methodology, we interviewed only representatives of each stakeholder group. Therefore, the results are not necessarily representative and should be interpreted with caution. Thus, the findings of this study should be seen as preliminary evidence to guide further qualitative or quantitative research rather than as definitive conclusions.

There are 2 further limitations of this study that should be mentioned. First, we did not calculate any agreement rate or other measurements regarding coding discrepancies. However, quality assurance was conducted via the internal workshop, which aimed to systematize the identified problems and barriers. Second, as the expert interviews took place in Germany, the interviews were conducted in German. Thus, the statements included in this paper were translated. After a first translation, it was checked within the consortium whether the content of the statements had been changed. Upon reasonable request, the original anonymized citations are available from the authors.

In this study, we aimed to obtain a comprehensive overview of problems and barriers from the point of view of different stakeholders. Nevertheless, we had a slight overrepresentation of care professionals. As the views of patients compared to clinicians differ regarding certain aspects, such as trust [29], further studies should explicitly focus on physicians and patients as key stakeholders of AI-based CDSSs.

As we interviewed German individuals and the German system has specific problems, such as low digitalization in health care [30-32], strict regulation regarding the handling of data [33], and a severe shortage of physicians and caregivers [34], the relevance and transferability of the problems to other health care systems should always be critically scrutinized.

Conclusions

Experts see several problems within the context of AI-based CDSSs. Problems concerned the technology itself as well as the context in which the systems are developed and used. In total, we identified 7 different problem categories, namely, “technology,” “data,” “user,” “studies,” “ethics,” “law,” and “general.” To guarantee a sustainable, safe, and effective integration of AI-based CDSSs, the problems identified in this study should be considered when developing and using these systems. Furthermore, problems that focus on regulation should also be taken into account by policy makers. As this study followed an explorative qualitative design, the results should be further investigated in additional qualitative and quantitative studies.

Acknowledgments

This study is part of a larger research project (User-Oriented Requirements for Artificial Intelligence–Based Clinical Decision Support Systems [KI@work]; project 01VSF22050). The project is funded by the German Federal Joint Committee. The funders had no influence on the study design, the conduct of the study, or the decision to publish or prepare the manuscript. Abstract

Background: Artificial intelligence (AI) has the potential to revolutionize health care by enhancing both clinical outcomes and operational efficiency. However, its clinical adoption has been slower than anticipated, largely due to the absence of comprehensive evaluation frameworks. Existing frameworks remain insufficient and tend to emphasize technical metrics such as accuracy and validation, while overlooking critical real-world factors such as clinical impact, integration, and economic sustainability. This narrow focus prevents AI tools from being effectively implemented, limiting their broader impact and long-term viability in clinical practice.

Objective: This study aimed to create a framework for assessing AI in health care, extending beyond technical metrics to incorporate social and organizational dimensions. The framework was developed by systematically reviewing, analyzing, and synthesizing the evaluation criteria necessary for successful implementation, focusing on the long-term real-world impact of AI in clinical practice.

Methods: A search was performed in July 2024 across the PubMed, Cochrane, Scopus, and IEEE Xplore databases to identify relevant studies published in English between January 2019 and mid-July 2024, yielding 3528 results, among which 44 studies met the inclusion criteria. The systematic review followed PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) guidelines and the Cochrane Handbook for Systematic Reviews. Data were analyzed using NVivo through thematic analysis and narrative synthesis to identify key emergent themes in the studies.

Results: By synthesizing the included studies, we developed a framework that goes beyond the traditional focus on technical metrics or study-level methodologies. It integrates clinical context and real-world implementation factors, offering a more comprehensive approach to evaluating AI tools. With our focus on assessing the long-term real-world impact of AI technologies in health care, we named the framework AI for IMPACTS. The criteria are organized into seven key clusters, each corresponding to a letter in the acronym: (1) I—integration, interoperability, and workflow; (2) M—monitoring, governance, and accountability; (3) P—performance and quality metrics; (4) A—acceptability, trust, and training; (5) C—cost and economic evaluation; (6) T—technological safety and transparency; and (7) S—scalability and impact. These are further broken down into 28 specific subcriteria.

Conclusions: The AI for IMPACTS framework offers a holistic approach to evaluate the long-term real-world impact of AI tools in the heterogeneous and challenging health care context and lays the groundwork for further validation through expert consensus and testing of the framework in real-world health care settings. It is important to emphasize that multidisciplinary

XSL•FO
RenderX

expertise is essential for assessment, yet many assessors lack the necessary training. In addition, traditional evaluation methods struggle to keep pace with AI's rapid development. To ensure successful AI integration, flexible, fast-tracked assessment processes and proper assessor training are needed to maintain rigorous standards while adapting to AI's dynamic evolution.

Introduction

Background

Artificial intelligence (AI) is profoundly transforming health care across a range of applications, enhancing both clinical outcomes and operational efficiency. In medical imaging, AI algorithms improve diagnostic accuracy by analyzing complex imaging data, such as from magnetic resonance imaging and computed tomography scans, for highly precise and rapid clinical diagnostics [1]. Decision support systems powered by AI assist clinicians in making evidence-based decisions by providing real-time data-driven insights and predictive analytics [2]. Large language models are increasingly used for generating detailed medical reports and streamlining triage processes by analyzing and summarizing patient data quickly and accurately [3]. In addition, innovative digital health technologies such as electronic skins use wearable sensor technologies and AI to offer continuous, real-time monitoring of various health indicators, further enhancing personalized care [4]. These advancements have the potential to contribute to a more efficient, accurate, responsive, and holistic health care, reshaping how patient care is delivered and managed.

Despite the growing body of literature on AI in health care, its implementation has lagged behind other industries [5,6]. Previous studies have highlighted substantial barriers to the successful adoption of AI in health care, including issues related to trust; potential risks of harm; accuracy and perceived usefulness; reproducibility; evidentiary standards; and ethical, legal, and societal concerns [7,8]. In addition, uncertainty surrounding postadoption outcomes further complicates the implementation process [7].

A significant barrier identified by health care leaders worldwide is that despite the emergence of various new frameworks for assessing AI in health care, most focus primarily on the quality of study methodologies or technical aspects [9,10]. There remains a lack of a comprehensive, systematic framework that assesses the real-world impact of AI and offers guidance on clinical implementation, monitoring, procurement, and evaluation [9,11]. Most research overlooks the complex, multistep process required for successful AI integration, leaving critical gaps in understanding how to effectively implement and sustain AI tools in clinical practice [9,11]. As a result, the adoption of AI in clinical practice has fallen short of expectations, with only a few algorithms showing sustained clinical impact [12]. This gap is often due to inadequate or incomplete evaluation and the lack of universally recognized standards for AI assessment. The limited understanding of AI's true added value in health care highlights the need for a more comprehensive evaluation framework [13-15]. To ensure confidence in the added clinical value and successful integration of AI into health care workflows, a practical, comprehensive tool is needed so that the translational readiness of AI systems can be evaluated. Current approaches assessing AI in health care often focus on foundational technical metrics such as sensitivity and specificity, which fail to capture the full clinical impact [13,16]. A robust valuation should encompass factors such as patient outcomes, effects on clinical decision-making, workflow efficiency, and the tangible benefits for patients to fully determine AI's true contribution to and impact on health care [10,17,18].

In the context outlined earlier, regulatory approval is an important milestone for demonstrating overall performance, although the scientific evidence supporting AI tools in health care remains limited compared to traditional medical standards [9,19]. In addition, new regulations are being introduced to keep pace with rapidly evolving AI technologies, such as the European Union (EU) AI Act, which aims to ensure the trustworthiness of high-risk AI tools including those used in health care [20]. Despite the potentially positive impact of regulatory frameworks on AI-related developments, a recent study revealed that nearly half of Food and Drug Administration (FDA)–authorized AI devices lacked clinical validation data, raising concerns about their safety and effectiveness [21]. Without robust clinical validation, these technologies could pose significant risks to patient care. Despite efforts to create reporting guidelines for AI in health care, such as Standard Protocol Items Recommendations for Interventional Trials–Artificial Intelligence (SPIRIT-AI) [13], CONSORT-AI (Consolidated Standards of Reporting Trials–Artificial Intelligence) [14], Standards for Reporting of Diagnostic Accuracy Studies–Artificial Intelligence [22], Checklist for Artificial Intelligence in Medical Imaging [23], Prediction Model Risk of Bias Assessment Tool–Artificial Intelligence [24], and others, a unified international consensus on the evaluation of AI-based tools has yet to be established. While these guidelines address key methodological issues and share significant overlap, indicating the importance of certain assessment criteria, the absence of a standardized, universally accepted framework remains a significant challenge [4]. This lack of consensus complicates the consistent evaluation and implementation of AI technologies in clinical practice.

XSL•FO
RenderX

Objectives

The goal of this study was to develop a comprehensive framework for assessing the impact of AI tools in health care. This involved synthesizing and consolidating the various evaluation criteria found in existing literature regarding the quality and impact of AI tools. On the basis of the outcomes of this study, we plan on validating the framework through expert consensus using the Delphi process. However, this validation effort will be addressed in the subsequent phase of the project and is beyond the scope of this foundational paper. This approach aims to create a rigorous, evidence-based structure for AI evaluation, ensuring its relevance and applicability in health care settings.

In doing so, we adopted the perspective of the World Health Organization (WHO) on AI in health care, defining it as "the ability of algorithms and software to analyze complex medical data and support health care providers by improving decision-making, predicting outcomes, and enhancing clinical efficiency" [25]. AI tools in health care span a broad spectrum of applications, such as (1) diagnostic support, (2) prognosis of diseases course, (3) personalized treatment recommendations, (4) patient monitoring, and (5) overall health management, driving innovation across the health care landscape [25].

To address this, a systematic review was conducted to offer a comprehensive and current analysis of the criteria used in existing research to evaluate the quality and impact of AI in health care, from technological, social, and organizational perspectives. The review also explores the potential implications of AI implementation for key stakeholders and offers recommendations on how to effectively assess AI-powered clinical tools under consideration for clinical impact. This study builds upon and extends the findings of a prior research project, which examined the sociotechnical assessment criteria for patient-facing eHealth tools, that is already published [26,27].

We believe the results of this review will provide valuable insights for clinicians, pharmaceutical leaders, insurance professionals, technology providers, and policy makers by presenting an up-to-date, thorough overview of the criteria used to assess AI-powered clinical tools. These insights will help stakeholders make informed decisions about which tools to implement, recommend to patients, invest in, partner with, or provide reimbursement for, based on their assessed quality and potential impact.

Methods

Overview

The methodology for this review was based on established best practices, specifically following the PRISMA (Preferred Reporting Items for Systematic reviews and Meta-Analyses) guidelines [28] and the Cochrane Handbook for Systematic Reviews of Interventions [29]. These frameworks were chosen to ensure a rigorous and methodologically sound approach to the systematic literature review process. All review methods were predetermined and documented in advance, with the protocol being publicly registered in the research registry (reviewregistry1859) to enhance transparency and accountability [30]. The primary research question guiding this systematic review was the following: What technical, social, and organizational criteria should be considered when assessing the quality and impact of AI-powered clinical tools? This question served as the foundation for the analysis and exploration of the criteria relevant to AI's evaluation in clinical settings. The study remained highly consistent with the initial protocol from a methodological standpoint, adhering to the predefined review question; search strategy; databases; inclusion and exclusion criteria; participants, intervention, comparators, and outcomes (PICO) framework elements; data extraction strategy; quality assessment; and data synthesis approach as originally outlined. The only variation from the protocol was in the presentation of the findings: rather than merely listing the results as an inventory of criteria, we organized them into a cohesive framework. This structured approach enhances both the memorability and practical applicability of the results in real-world settings.

Search Strategy

A comprehensive search of the PubMed, Cochrane, Scopus, and IEEE Xplore databases was conducted in July 2024 to identify relevant studies. The review was limited to peer-reviewed papers published in English between January 2019 and mid-July 2024. We focused on this specific time frame and limited the search to the last 5 years to ensure the findings reflect the most recent advancements and challenges, particularly with the emergence of new generative AI technologies. Going back further would have added limited value, as older studies may not capture the rapid technological shifts and evolving complexities that are relevant today. Only fully published research articles were included, while other formats, such as editorials and study protocols, were excluded from the analysis. In accordance with the Cochrane Handbook for Systematic Reviews of Interventions, we chose not to include articles sourced through manual reference list searches, as "positive studies are more likely to be cited," which could introduce bias [29].

This systematic review focused on AI-powered tools designed specifically for clinicians, excluding tools meant solely for patients or medical students as these will most likely not reflect the implementation aspects in real-world health care organizations. The search strategy targeted manuscripts with titles including the terms "AI" or "Artificial Intelligence," reflecting the intervention focus on AI technologies. Outcomes of interest were assessment criteria, captured through titles containing the terms "assessment," "assess," "evaluation," "evaluating," "effectiveness," "efficacy," "quality," "efficiency," "usability," or "usefulness," as well as abstracts mentioning "criteria," "framework," "method," "methodology," "methodologies," "measurement," "toolkit," "tool," "tools," "approach," or "scorecard." No condition-based restrictions were applied, aligning with a broad approach to capture all relevant studies on assessment methodologies for clinician-targeted AI tools.

Textbox 1 illustrates the search string designed using the PICO framework. To ensure the relevance of the retrieved papers, the search was mostly restricted to manuscript titles, focusing on studies that addressed AI assessment criteria comprehensively

XSL•FO
RenderX

rather than those evaluating specific tools or pilot studies. Because comparators were not relevant to this review, they were excluded from the search parameters.

Textbox 1. The search string according to the participants, intervention, comparators, and outcomes framework.

Participants: clinicians

- Focus on artificial intelligence (AI)–powered tools for clinicians, excluding those designed solely for patients or medical students.

Intervention: AI-powered clinician tools

- Focus is on AI-powered clinician tools: the search targeted manuscript titles containing the terms (AI OR "Artificial Intelligence").

Comparator: not applicable

- There were no restrictions on eligible conditions for inclusion.

Outcome: assessment criteria

- The search targeted manuscript titles also containing AND (assessment OR assess OR evaluation OR evaluating OR effectiveness OR efficacy OR quality OR efficiency OR usability OR usefulness). As well as manuscript tiles and abstracts containing AND (criteria OR framework OR method OR methodology OR methodologies OR measurement OR toolkit OR tool OR tools OR approach OR scorecard).

Study Selection

Two researchers (CJ and EL) participated in the screening, eligibility, and inclusion phases of the study. Any discrepancies during these stages were resolved through discussion among them. If consensus could not be reached, a third coauthor was consulted to make the final decision. The team used the open-source Rayyan app (Qatar Computing Research Institute) to streamline collaborative screening efforts [31]. The screening process took place between July and August 2024.

The inclusion and exclusion criteria, outlined in Textbox 2, were developed following the PICO framework. Included studies centered on AI-powered tools in clinical settings, addressing criteria to assess the quality and impact of these tools. Eligible studies were peer-reviewed, published between January 2019 and mid-July 2024, and written in English. Exclusions were made for studies involving only patients or medical students as they were not likely to reflect implementation factors, AI technologies outside clinical settings (eg, patient use chatbots), studies assessing specific tools in isolation, or frameworks solely evaluating AI research methodology or clinical trials rather than the implementation of the tools in real-world settings. Editorials, study protocols, and non-English publications were also excluded.

Following the completion of the screening process and resolution of any conflicting views among the researchers, CJ and EL proceeded to assess the full texts of the selected studies for eligibility. Any remaining disagreements were addressed through consultation with a third coauthor. CJ evaluated the risk of bias using the Critical Appraisal Skills Program (CASP) checklist [32], which assesses key quality criteria in the included studies. These criteria include the following: the presence of a clear statement of the research aims, the appropriateness of the methodology for the research objectives, the suitability of the research design in addressing those aims, the relevance of the recruitment strategy, the adequacy of data collection methods in relation to the research question, the consideration given to the researchers' roles, the evaluation of ethical issues, the rigor of data analysis, the clarity of the study's findings, and whether the researchers discussed the study's contribution to existing knowledge, such as its implications for current practice, policy, or relevant literature. The results of this appraisal are available in Multimedia Appendix 1.

XSL•FO
RenderX

Textbox 2. Inclusion and exclusion criteria according to the participants, intervention, comparators, and outcomes framework.

Inclusion criteria

- Participants: focused on clinicians
- Intervention: focused on artificial intelligence (AI)–powered clinician tools
- Comparators: does not apply
- Outcomes: addresses the different criteria used to assess the quality and impact of AI-powered clinician tools regardless of the condition
- Publication type: peer-reviewed and published papers
- Time frame: studies published between January 2019 and mid-July 2024
- Language: studies published in English

Exclusion criteria

- Participants: focused solely on patients or medical students
- Intervention: technologies used outside of clinical environments, such as chatbots used by patients to obtain health care information
- Comparators: does not apply
- Outcomes: individual assessments of pilot studies singling out specific tools, and assessment frameworks that focus on the reporting and methodological quality of AI research and clinical studies rather than evaluating the AI tool itself
- Publication type: editorials and study protocols
- Time frame: studies published before January 2019 or after mid-July 2024
- Language: studies published in languages other than English

Data Collection and Synthesis

The procedures and outcomes across the included studies were too diverse to support a quantitative analysis. As a result, a narrative synthesis was used following the sociotechnical approach, organized around the social, organizational, and technical criteria used to evaluate the quality and impact of AI-powered tools for clinicians. The authors were influenced by the sociotechnical theory, which emphasizes that the design and performance of innovations can only be fully understood when both social and technical aspects are considered as interdependent components of a larger system [33]. This approach aligns with recommendations from several scholars who advocate for moving beyond purely technology-focused frameworks to incorporate the broader context, including societal and implementation factors [34-36]. To facilitate this process, NVivo (version 1.7.2; Lumivero), a qualitative data analysis software, was used.

Data coding began with a preliminary extraction grid, which was structured around themes derived from previous research and established technology acceptance frameworks. The initial codebook was informed by our prior work on factors influencing eHealth evaluation and adoption [26,27,36-38], with additional codes being incorporated as new themes emerged during the review. Thematic analysis, as outlined by Braun and Clarke [39], was conducted to identify and extract themes based on the social, technical, and organizational assessment criteria relevant to the research question. This analysis followed 7 key phases: familiarizing with the data, generating initial codes, searching for themes, reviewing themes, defining and naming themes, linking themes to explanatory frameworks, and producing the final report.

In line with the approach of Braun and Clarke [40], we opted not to use interrater reliability as it aligns more closely with quantitative methods and standardized interpretation. Thematic analysis in a qualitative context prioritizes depth, subjectivity, and the unique insights each researcher brings to the data. Rather than using numerical reliability measures such as interrater reliability, reliability in this approach is often ensured through collaborative discussions that allow for consensus and a nuanced understanding of the themes. Accordingly, the first author, CJ, conducted the initial analysis and coding and NB reviewed the coding. Any cases of disagreement were discussed and mutually agreed upon in conjunction with a third author. Using the sociotechnical framework as our guide, we developed our initial codebook and grouped the criteria accordingly. This approach ensures a holistic evaluation of each tool, capturing the complex interdependencies between technical capabilities, social contexts, and organizational fit and readiness. By doing so, we moved beyond a narrow technical focus or methodological evaluation at the study level, ensuring that the social and organizational dimensions are fully integrated into the analysis. As a result, this work prioritizes the often-overlooked social and organizational dimensions that are critical for the successful implementation of AI technologies. Unlike frameworks that focus solely on clinical study quality, our analysis and synthesis specifically emphasize social and organizational factors such as user trust, support and training, interoperability, and integration.

However, we intentionally did not apply any hierarchy or prioritization within this foundational framework, as the purpose here is to treat all criteria as equally significant. Prioritization and potential gap identification will occur in the next phase (beyond the scope of this paper), where the Delphi process will engage an expert panel to further refine and prioritize these

XSL•FO

criteria. The coding and analysis process was carried out from August to October 2024.

Results

Study Selection Flow and Characteristics of the Included Studies

Figure 1 presents the PRISMA flow diagram, illustrating the progression of study selection during the systematic review. It details the number of records identified, screened, included, and excluded, along with reasons for exclusion. After applying these criteria, 44 articles were selected for the qualitative synthesis.

Figure 1. Study selection flow diagram based on the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. AI: artificial intelligence.

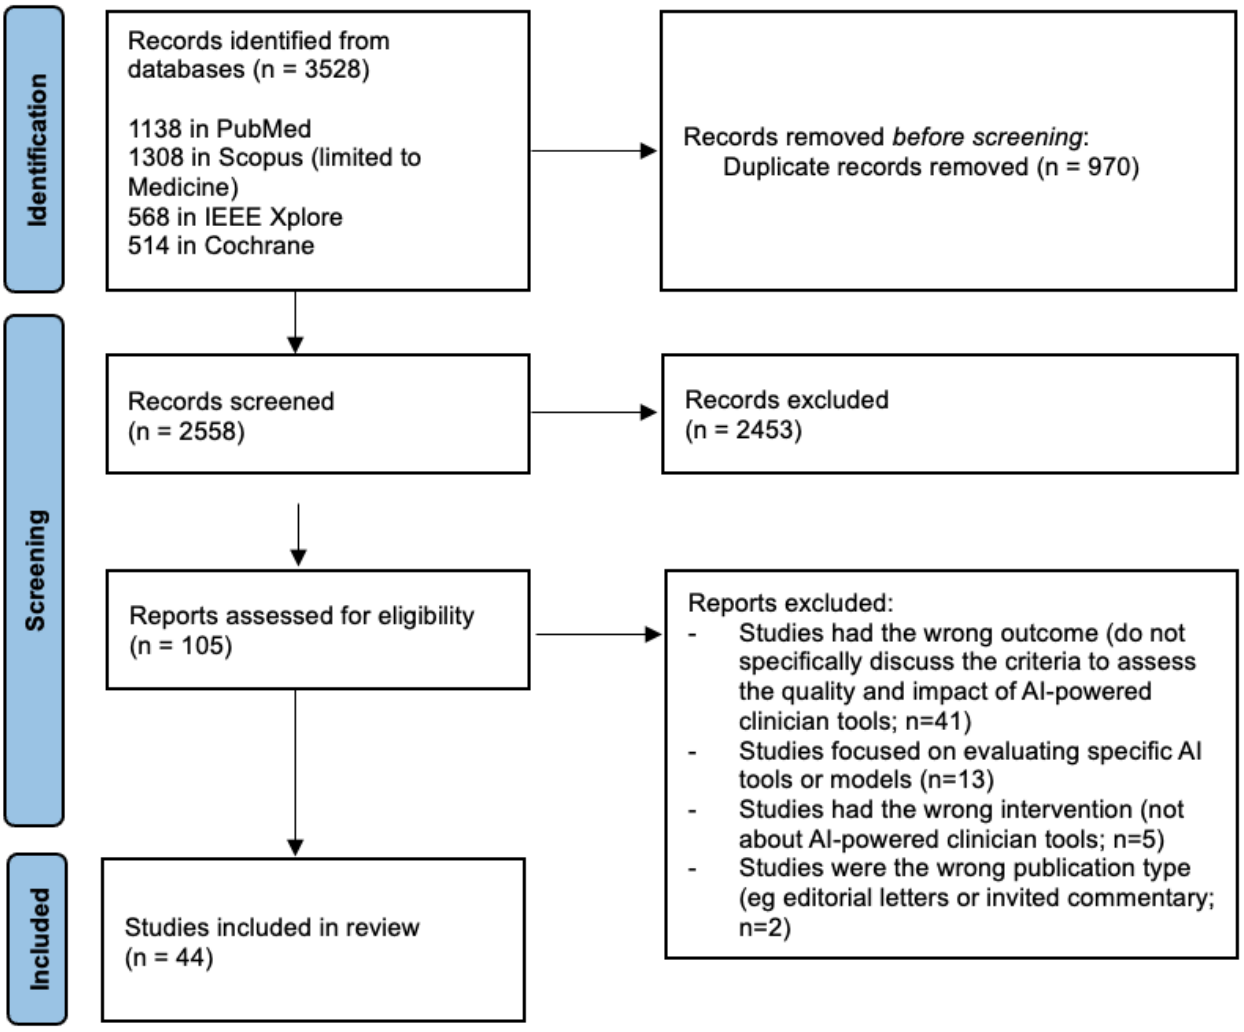

Table 1 outlines the characteristics of these studies, offering insights into their research methodologies, geographic distributions, and clinical focuses. This comprehensive overview highlights the diversity of approaches and topics addressed within the included studies.

Critical Appraisal

We evaluated the quality of the included studies using the CASP checklist [32]. This tool was selected due to the variety of methodologies used in the studies and the narrative approach of our synthesis, which differed from meta-analyses and other quantitative methods. The CASP is widely recognized as the most frequently used tool for appraising the quality of qualitative evidence in health research, with endorsement from the Cochrane Qualitative and Implementation Methods Group [85]. The studies included in our review used a range of methodologies (quantitative, qualitative, mixed methods, and systematic literature reviews), which meant that some questions on the checklist were not applicable to all study types. As per

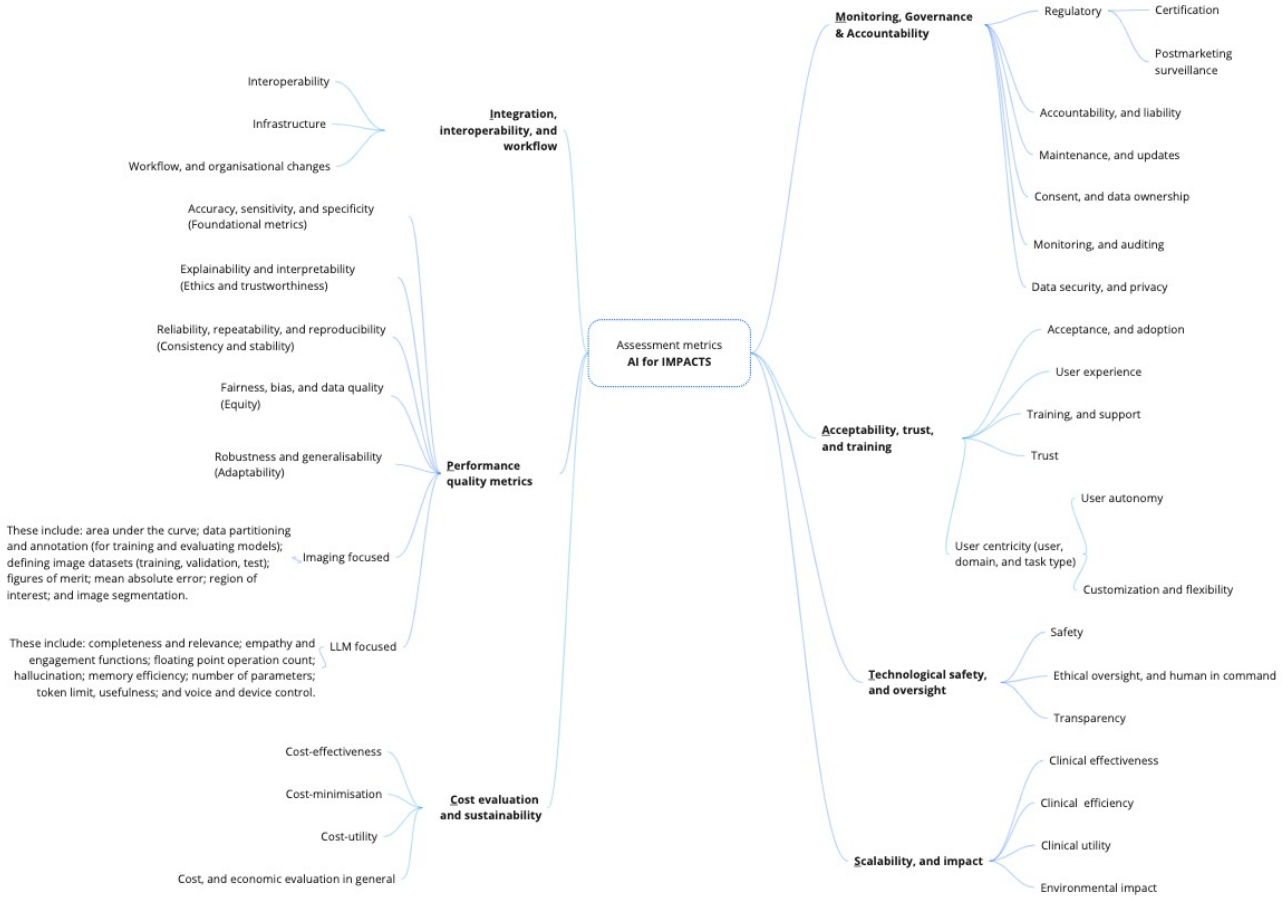
XSL•FO
RenderX

the checklist's recommendations, we did not assign scores to the studies.

Following the critical appraisal of the 44 studies, several issues were identified. While all studies clearly stated their aims, presented well-defined findings, and provided valuable insights for health care stakeholders, 21 (N=44, 48%) studies lacked a dedicated methods section, making it difficult to assess the appropriateness and suitability of their approach. Similarly, the absence of clear methods in these studies hindered the evaluation of the research design and data collection techniques.

In addition, out of 44 studies, 25 (57%) studies did not detail their analysis methods, making it challenging to gauge the rigor and reliability of their approach. Furthermore, 28 (64%) studies lacked validation of their findings, while 8 (18%) offered only partial validation (eg, expert consensus), highlighting the need for empirical validation in real-world clinical applications to ensure the findings' robustness. The comprehensive quality assessment of the included studies can be found in Multimedia Appendix 1.

Studies were not excluded based on the results of the quality assessment, as this was unlikely to significantly impact the definition of the assessment criteria or the development of the aggregated framework. However, the quality assessment offered valuable insight into the overall robustness of the development processes behind the existing frameworks, helping to gauge the strength and reliability of the evidence presented [85]. An in-depth exploration of this topic can be found in the Discussion section, where the challenges associated with current initiatives and frameworks are examined.



Synthesized Assessment Criteria

We synthesized comparable measures from various papers, frameworks, and initiatives, ultimately identifying a set of unique criteria that reflected all relevant assessment methods referenced in the included studies. Notably, several criteria are closely interrelated and could fit into multiple categories; however, they were placed in the most appropriate category based on their significance and impact. For instance, while "user trust" and "model explainability" are inherently linked, because trust often correlates with the level of explainability provided by an AI system, we categorized trust under the cluster "acceptability, trust, and training," which focuses on user-centric aspects, whereas "explainability" was assigned to the cluster evaluating model performance metrics, given its technical focus. In addition, we intentionally included assessment criteria applicable to high-risk tools, enabling us to compile a more comprehensive list. We recognized that not all criteria would apply to lower-risk AI-powered health care tools, such as patient safety assessments, which are more relevant to high-risk tools that pose potential safety concerns. We are guided by National Institute for Health and Care Excellence's Evidence Standards Framework for Digital Health Technologies to assess and understand the risk levels of health care technologies [86].

Figure 2 provides a visual overview of the aggregated criteria, organized into clusters and subclusters, while Table 2 presents these criteria grouped into 7 primary clusters and their respective subcriteria, outlining their occurrences across the included studies, along with their definitions and corresponding references. A detailed exploration of each criteria cluster and its corresponding subcriteria is provided in the Discussion section.

Table 2. Assessment criteria, their definitions, occurrence, and respective references (N=44).

Criteria	Definition	Studies, n (%)	Studies in which the criteria occurred
Integration			
Infrastructure	• The underlying technological, hardware, and software systems required to support the deployment and scalability of the AI[a] tool	15 (34)	[41,44,49,53-55,60,65,68,69,71,75,76,78,84]
Interoperability	• The AI tool's ability to seamlessly exchange and integrate data with different health care platforms and devices	19 (43)	[41,45,51,53-56,59,64,67-69,71,74-78,82]
Workflow and organizational changes	• The degree to which the AI tool impacts existing clinical workflows and health care operations, ensuring minimal disruption while enhancing efficiency, communication, and overall care delivery	22 (50)	[41,45,47,49,51-56,58,64,65,67-69,71,76,78,79,82,84]
Monitoring, governance, and accountability			
Accountability and liability	• The clear attribution of responsibility for errors or outcomes and the establishment of legal and ethical frameworks to address potential issues and ensure proper recourse	13 (30)	[49-51,54,55,63-65,70,75,78,81,84]
Consent and data ownership	• Evaluates the processes for obtaining informed consent from patients regarding the use of their data and ensuring clear policies on data ownership, privacy, and control	5 (11)	[49,54,68,78,81]
Maintenance and updates	• Evaluates the processes for ongoing support, including regular updates and bug fixes, to ensure the AI tool remains effective, secure, and aligned with evolving medical standards and practices	13 (30)	[44,45,49,50,52,53,55,59,65,69,71,76,77]
Monitoring and governance	• Evaluates the systems in place for overseeing the AI's performance, including regular assessments and audits to ensure ethical use and effectiveness	22 (50)	[44,48-56,59,60,64,65,68,69,71,74,76,81,83,84]
Regulatory compliance	• Evaluates adherence to established regulations throughout the AI tool's life cycle, including ongoing monitoring and reporting after deployment to ensure continued safety, efficacy, and adherence to legal requirements	23 (52)	[45,49-55,59,60,63-65,67-69,72,74,76,78,81,83,84]
Security and privacy	• Evaluates the measures implemented to protect sensitive patient data from unauthorized access and breaches while ensuring compliance with privacy regulations	26 (59)	[45,51-56,60,62,64-71,73-75,77,78,80-83]
Performance quality metrics			
Accuracy, sensitivity, and specificity (foundational metrics)	• Accuracy: the proportion of correct predictions (both true positives and true negatives) out of all predictions. It gives an overall measure of performance but may be misleading if the dataset is imbalanced (ie, when one class dominates). • Sensitivity (recall): the ability of the model to correctly identify true positives (ie, people with the condition). In health care, this often refers to how well the model detects cases like diseases. High sensitivity ensures that most cases of the disease are caught, reducing the chance of missing sick patients. • Specificity: the ability to correctly identify true negatives (ie, people without the condition). High specificity means the model avoids false positives, reducing unnecessary interventions for healthy people	26 (59)	[41,43,45-53,57,58,60,62,67,69,70,73,74,76,80-84]

XSL•FO
RenderX

Criteria	Definition	Studies, n (%)	Studies in which the criteria occurred
Explainability and interpretability (ethics and trustworthiness)	• Explainability: refers to the degree to which the model's predictions and decisions can be understood by humans. In health care, explainability is crucial because clinicians need to trust AI recommendations and understand why the AI made a particular decision. • Interpretability: closely related to explainability, it is about how easily a human can comprehend the internal workings of the model. For example, an interpretable model may allow clinicians to track how specific features (like patient age or laboratory results) influenced the AI's prediction	19 (43)	[45,47-49,51,52,55,60,62,67,68,71,73-75,78,80,81,83]
Fairness (equity)	• Fairness: ensures that the AI model does not systematically discriminate against any specific group of people (eg, based on race, gender, or socioeconomic status). Fairness in health care is key to avoid bias in diagnoses or treatments.	32 (73)	[42-47,49,51-56,58,60,62-69,71,73-75,77,78,81,83,84]
Reliability, repeatability, and reproducibility (consistency and stability)	• Reliability: refers to the consistency of the model over time. Can the AI be trusted to perform in the same way under similar conditions in the future? • Repeatability: the ability of the model to provide consistent results when the same input is given multiple times in the same environment. In health care, this ensures that if a patient is reevaluated using the same AI tool, it will give the same outcome. • Reproducibility: refers to how well the model performs when applied to different datasets or by different teams. This is critical in health care, where models trained on one population must still perform well when tested on different populations or data collected in different hospitals.	24 (55)	[42,43,45,48,50-56,58-60,64,67,68,71,74,76,77,81,83,84]
Robustness and generalizability (adaptability)	• Robustness: the model's ability to maintain performance despite slight variations or noise in the input data. In a health care setting, this might mean the model works well even with slightly lower-quality images or laboratory results from different equipment. • Generalizability: the ability of the model to perform well on new, unseen data that may differ from the training data. In health care, it is crucial that an AI model trained in one hospital or region can generalize to others.	23 (52)	[41-46,48,49,52,54-56,58,60,64,67,68,70,71,75,76,83,84]
Imaging-focused	• These may include area under the curve; data partitioning and annotation (for training and evaluating models); defining image datasets (training, validation, and testing); figures of merit; mean absolute error; region of interest and image segmentation	10 (23)	[42,45-48,55,69,76,81,83]
Large language model-focused	• These may include completeness and relevance; empathy and engagement functions; floating point operation count; hallucination; memory efficiency; number of parameters; token limit and usefulness; voice and device control	3 (7)	[57,62,73]
Acceptability, trust, and training			

XSL•FO
RenderX

Criteria	Definition	Studies, n (%)	Studies in which the criteria occurred
Acceptance and adoption	• Evaluates how well the AI tool is embraced by health care professionals and patients, including their willingness to integrate it into routine practice	18 (41)	[47,49,52-54,56,60,63,65,67-69,72,73,75,77,78,82]
Training and support	• Evaluates the effectiveness and availability of resources provided to users for learning and using the AI tool, ensuring they have the necessary guidance and assistance for successful implementation and operation	17 (39)	[45,49,52-55,64,65,67,69,71,76,78,80-82,84]
Trust	• Evaluates the degree to which health care professionals and patients believe in the reliability, accuracy, and ethical considerations of the AI tool, influencing their willingness to use it	11 (25)	[45,47,49,52,60,62,68,73,75,82,84]
Usability	• Evaluates how easily and effectively health care professionals and patients can interact with and use the AI tool, ensuring it enhances rather than hinders the user experience and clinical workflows	18 (41)	[47,49-53,55,56,62,63,68,71,73,75-77,82,84]
User centricity (user, domain, and task type)	• Evaluates how well the AI tool is designed to meet the specific needs, preferences, and contexts of its users, domain-specific requirements, and task types it is intended to support	19 (43)	[42,45,49,52,53,55,56,58,60,62,64,65,71,73,75-77]
Cost and economic evaluation			
Costs and economic evaluation in general	• Evaluates the financial implications of implementing the AI tool, ensuring it provides value without imposing excessive financial burdens on health care systems or patients	18 (41)	[44,49,51,55,59-61,64,67-69,72,73,75,76,79,82,84]
Cost-effectiveness analysis	• Compares the relative costs and outcomes of different interventions. The outcomes are typically measured in natural units like life years saved, cases prevented, or symptom-free days	12 (27)	[41,53,55,59-61,68,71-74,84]
Cost-minimization analysis	• Used when 2 or more interventions or treatments are assumed to produce identical outcomes or equivalent effectiveness. Given that the outcomes are considered the same, the focus is entirely on minimizing costs.	5 (11)	[41,61,72,78,82]
Cost-utility analysis	• Measures outcomes in terms of both quantity (life expectancy) and quality of life. It uses a metric called quality-adjusted life years or disability-adjusted life years to quantify health benefits	3 (7)	[41,61,72]
Technological safety and transparency			
Safety	• Evaluation of an AI tool's ability to avoid causing harm to patients by ensuring that it operates reliably, adheres to clinical standards, and mitigates potential risks	26 (59)	[42,47,49-56,60,62-68,71,73,75,78,80,81,83,84]
Transparency	• Refers to the extent to which an AI tool's processes, decision-making logic, and data sources are made understandable and accessible to stakeholders	27 (61)	[42,44,46,49,50,52-54,56,58-61,63-65,67,68,70,71,73-76,78,80,81]
Ethical oversight, human in command	• Assesses whether the AI tool is designed to support human decision-making, allowing clinicians to maintain control and override AI decisions when necessary, ensuring AI complements rather than replaces human judgment	14 (32)	[41,42,45,49,51,64,65,67,68,70,74,75,78,80]
Scalability and impact			

XSL•FO
RenderX

Criteria	Definition	Studies, n (%)	Studies in which the criteria occurred
Clinical effectiveness	• Assesses how well the AI tool works in real-world practice, including its ability to achieve desired clinical outcomes across diverse populations and settings	26 (59)	[41-44,47-49,51-54,60,63-65,67-69,71-73,75,77,78,83,84]
Clinical efficiency	• Focuses on the optimal use of resources (time, staff, and cost) to deliver care	8 (18)	[47,52,53,55,56,68,76,79]
Clinical utility	• Refers to the practical benefits of a treatment or intervention in improving patient care, such as guiding clinical decision-making or reducing risks	14 (32)	[41-43,47,48,50,52,56,58,60,62,69,77,82]
Environmental impact	• Evaluates how the development, deployment, and operation of AI tools affect environmental sustainability, such as energy consumption and carbon footprint	1 (2)	[75]

[a]AI: artificial intelligence.

With our focus on assessing the long-term real-world impact of AI technologies in health care, we named the framework AI for IMPACTS. The criteria were organized into seven key clusters, each corresponding to a letter in the acronym: (1) I — integration, interoperability, and workflow; (2) M — monitoring, governance, and accountability; (3) P — performance and quality metrics; (4) A — acceptability, trust, and training; (5) C — cost and economic evaluation; (6) T — technological safety and transparency; and (7) S — scalability and impact.

Discussion

Principal Results

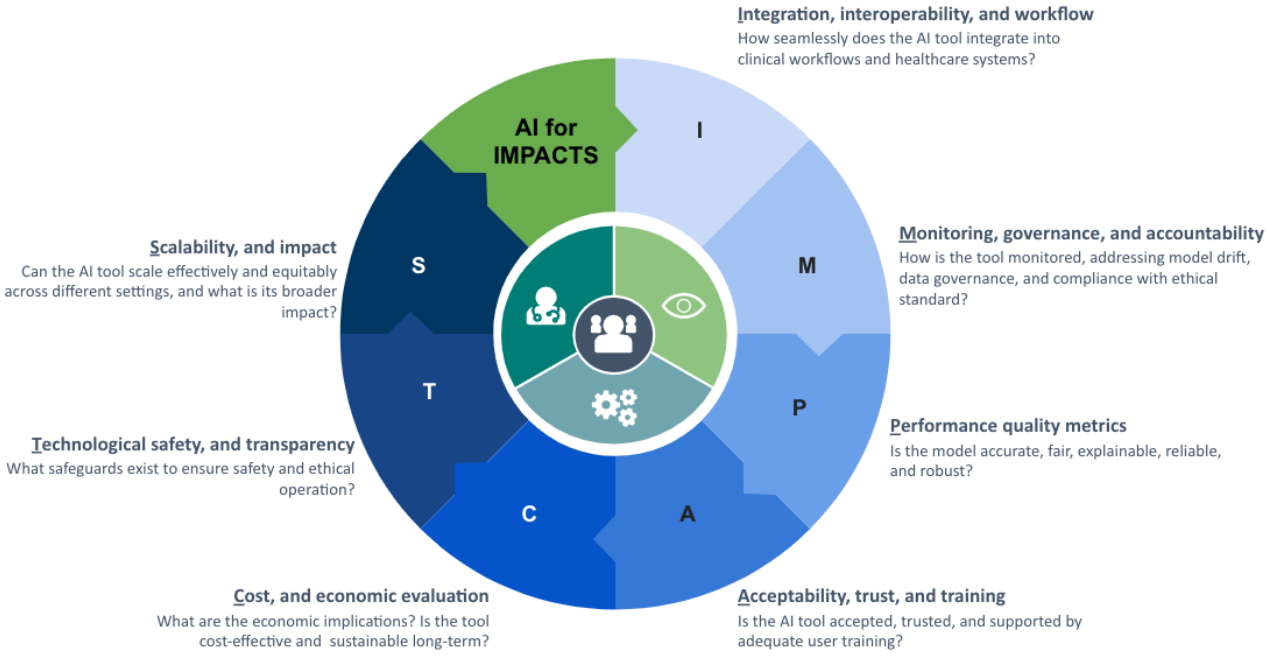
Through our systematic review of the literature, which culminated in the inclusion of 44 relevant papers, we conducted a narrative synthesis guided by the sociotechnical framework. This synthesis identified and categorized the key technical, social, and organizational criteria critical for the practical and effective implementation of AI technologies in health care. The results are organized into 7 main clusters, further divided into 28 specific subcriteria, providing a structured framework to address the multifaceted considerations highlighted in the reviewed literature.

By synthesizing and aggregating the assessment criteria from all included studies, we developed the AI for IMPACTS framework. This framework goes beyond focusing solely on technical metrics or methodological guidance at the study level. It integrates the clinical context and real-world implementation factors to ensure AI tools are evaluated holistically. Most criteria in our proposed framework can be aligned with existing frameworks, but none covers all relevant categories without extensions. For successful AI implementation in health care, it is essential to integrate these tools within the broader organizational context. Frameworks should account for the complexities of the sociotechnical environment, recognizing the interplay between technical, social, and organizational dimensions. Our consolidated framework achieves this by synthesizing and expanding existing frameworks for AI assessment in health care. It uses a sociotechnical approach to consider all contextual factors, their interactions, and the long-term real-world impact of these technologies in clinical practice.

The sociotechnical theory, which emphasizes the dynamic interplay between social, organizational, and technical aspects, provides a holistic approach to evaluating novel technologies [33]. This is critical in health care, where the successful implementation of novel technologies requires a balance of these factors to optimize both technology adoption and clinical outcomes [36]. Each component of the AI for IMPACTS framework reflects this sociotechnical foundation, as described below.

- I: integration, interoperability, and workflow — sociotechnical theory stresses the need for alignment between technology and workflow. This criteria cluster ensures that AI tools integrate seamlessly within existing systems and workflows, minimizing disruptions and supporting health care professionals in their work.
- M: monitoring, governance, and accountability — governance structures are vital for ensuring AI applications adhere to clinical standards and ethical norms. The sociotechnical theory supports the need for oversight that considers not just technical capabilities but also social and organizational responsibilities, promoting accountability in decision-making.
- P: performance and quality metrics — effective AI assessment requires robust performance metrics that span technical and clinical outcomes. By applying sociotechnical principles, this criteria cluster ensures that quality standards are met in ways that resonate with both technical requirements and patient care priorities.
- A: acceptability, trust, and training — for AI to be widely adopted, it must be trusted and understood by users. The sociotechnical theory emphasizes the role of social factors such as trust and user training, which are essential for fostering acceptance among health care providers and patients.
- C: cost and economic evaluation — costs are a key concern in health care. The sociotechnical approach underscores the importance of evaluating not just technical implementation costs but also the economic implications

XSL•FO
RenderX



for patients and health care systems, ensuring that AI tools are financially sustainable and valuable.

- T: technological safety and transparency — safety and transparency are core to AI in health care, as they directly affect user trust and patient safety. The sociotechnical theory highlights that these technical attributes must be coupled with transparent communication and organizational processes that make AI's functioning understandable and dependable.
- S: scalability and impact — sociotechnical principles stress adaptability within complex systems. This criteria cluster considers how AI can be scaled effectively across diverse health care settings, evaluating both technical scalability and the social and organizational impact for expansion.

By leveraging the sociotechnical theory, the AI for IMPACTS framework ensures that each criterion is evaluated in a way that respects the complex interdependencies between technical capabilities, social context, and organizational readiness, providing a balanced and comprehensive approach to AI assessment in health care. We selected the acronym IMPACTS to underscore our emphasis on real-world outcomes over isolated, study-level evaluations. This highlights our commitment to assessing the broader, practical effects in health care settings.

Figure 3 depicts the 7 assessment clusters of the AI for IMPACTS framework. Each cluster contains multiple subcriteria, all of which are summarized in a comprehensive checklist presented in Table 3. The framework provides a systematic approach for evaluating AI's holistic role and potential in health care applications. The following subsections provide a detailed analysis of each criteria cluster and their respective subcriteria, offering a comprehensive breakdown of how each factor contributes to the overall assessment.

Figure 3. AI for IMPACTS: a comprehensive framework for evaluating the long-term real-world impacts of artificial intelligence (AI)–powered clinician tools.

Criteria	Assessment
Integration	
Infrastructure	Does the deployment and scalability of the AI[a] tool require additional technological, hardware, or software infrastructure beyond what is already available in the current clinical setting?
Interoperability	Does the AI tool seamlessly integrate and exchange data with various health care platforms and devices, ensuring interoperability across different systems without requiring significant modifications?
Workflow and organizational changes	Does the AI tool integrate smoothly into existing clinical workflows and health care operations, minimizing disruption while enhancing efficiency, communication, and the overall delivery of care?
Monitoring, governance, and accountability	
Accountability and liability	Is there clear attribution of responsibility for errors or outcomes, supported by well-defined legal and ethical frameworks that ensure accountability and proper recourse in the event of any issues?
Consent and data ownership	Does the AI tool have clear and robust processes for obtaining informed consent from patients, including transparent policies on data ownership, privacy, and control, ensuring patients fully understand how their data will be used?
Maintenance and updates	Does the AI tool have established processes for ongoing support, including regular updates and bug fixes, to ensure it remains effective, secure, and compliant with evolving medical standards and practices?
Monitoring and governance	Does the AI tool have systems in place for ongoing oversight of its performance, including regular assessments and audits to ensure ethical use, effectiveness, and adherence to relevant standards?
Regulatory compliance	Does the AI tool demonstrate adherence to established regulations throughout its entire life cycle, with systems in place for ongoing monitoring and reporting postdeployment to ensure continued safety, efficacy, and compliance with legal requirements?
Security and privacy	Does the AI tool have robust measures in place to protect sensitive patient data from unauthorized access and breaches, while ensuring full compliance with relevant privacy regulations?
Performance quality metrics	
Foundational metrics	These are application-specific metrics to ensure each tool is assessed appropriately based on its function: • Diagnosis and prediction applications: use classification metrics (eg, accuracy, sensitivity, specificity, and area under the curve) for diagnosis tasks and regression metrics (eg, mean absolute error and root mean square error) for predicting continuous outcomes (classification, anomaly detection, and recommendation systems) • Image and pattern analysis: focus on segmentation accuracy and reinforcement learning's long-term performance optimization (eg, Dice coefficient, Jaccard index, and cumulative reward) • Text and language processing applications: evaluate the accuracy and quality of AI-extracted or generated text (eg, completeness and relevance, empathy and engagement, floating-point operation count, and hallucination)
Explainability (ethics and trustworthiness)	Is the AI tool able to clearly show how it reached a specific decision or prediction in a way that clinicians can understand?
Interpretability	Is it easy for clinicians to understand the relationship between the input data and the AI tool's outputs, without needing detailed technical explanations?
Fairness (equity)	Does the AI tool ensure fairness by avoiding systematic discrimination against any specific group, such as race, gender, or socioeconomic status, and promoting equitable outcomes in diagnoses and treatments?
Reliability, repeatability, and reproducibility (consistency and stability)	Does the AI tool demonstrate reliability, repeatability, and reproducibility by consistently delivering the same results over time, under similar conditions, and when applied to different data sets or used by different teams?
Robustness and generalizability (adaptability)	Does the AI tool demonstrate both robustness and generalizability by maintaining strong performance despite variations or noise in input data, and by performing well on new, unseen data from different hospitals or regions compared to its training data?
Acceptability, trust, and training	
Acceptance and adoption	Does the AI tool demonstrate strong acceptance by health care professionals and patients, including their willingness to adopt and integrate it into routine clinical practice?
Training and support	Does the AI tool provide comprehensive and readily available resources for users, ensuring they have the necessary guidance, training, and assistance to successfully implement and operate it in clinical practice?
Trust	Does the AI tool inspire trust among health care professionals and patients in terms of its reliability, accuracy, and ethical considerations, thereby positively influencing their willingness to use it?

XSL•FO
RenderX

Criteria	Assessment
Usability	Does the AI tool offer an intuitive and user-friendly interface that allows health care professionals and patients to interact with it easily and effectively, ensuring it enhances the user experience and integrates smoothly into clinical workflows?
User centricity (user, domain, and task type)	Does the AI tool effectively meet the specific needs, preferences, and contexts of its users, while addressing domain-specific requirements and supporting the relevant tasks for which it is intended?
Cost and economic evaluation	
Costs and economic evaluation	Does the AI tool provide financial value by enhancing care without imposing excessive costs on health care systems or patients, ensuring that its implementation is economically sustainable? This can be measured using one or more of the following methods*:* • Does the AI tool demonstrate cost-effectiveness by offering a favorable balance between its costs and the health outcomes it achieves, such as life years saved, cases prevented, or symptom-free days, when compared to alternative interventions? • Does the AI tool demonstrate cost-utility by providing measurable improvements in both life expectancy and quality of life, quantified through metrics such as quality-adjusted life years or disability-adjusted life years? • Does the AI tool demonstrate cost-minimization by achieving equivalent outcomes or effectiveness compared to alternative interventions, while focusing on minimizing overall costs?
Technological safety and transparency	
Safety	Does the tool reliably adhere to clinical standards, consistently mitigate potential risks, and demonstrate the ability to avoid causing harm to patients through reliable operation and risk management?
Transparency	Does the AI tool provider ensure transparency by making its processes, decision-making logic, and data sources understandable and accessible to all relevant stakeholders?
Ethical oversight, human in command	Does the AI tool incorporate ethical oversight by ensuring that it supports human decision-making, allowing clinicians to maintain control and override AI-generated decisions, when necessary, thereby complementing rather than replacing human judgment?
Scalability and impact	
Clinical effectiveness	Does the AI tool demonstrate clinical effectiveness by consistently achieving the desired clinical outcomes in real-world practice, across diverse patient populations and health care settings?
Clinical efficiency	Does the AI tool demonstrate clinical efficiency by optimizing the use of resources, including time, staff, and costs, to effectively deliver care without compromising quality?
Clinical utility	Does the AI tool demonstrate clinical utility by offering practical benefits that improve patient care, such as guiding clinical decision-making or reducing risks during treatment?
Environmental impact	Does the AI tool minimize its environmental impact by considering sustainability in its development, deployment, and operation, including factors such as energy consumption and carbon footprint?

[a]AI: artificial intelligence.

Integration

This criteria cluster focuses on evaluating how effectively the AI tool integrates into existing clinical workflows and health care systems.

Infrastructure plays a crucial role in the successful implementation of AI tools in health care settings. Adequate computational power, specialized hardware, and robust IT infrastructure are often necessary to support the processing of large datasets and the operational demands of AI technologies [49,71]. This may include advanced components such as graphics processing units, which are not always standard in health care systems [55]. In addition, integrating these tools might require significant investment in new hardware or upgrades [60,69]. For cloud-based AI solutions, attention must be paid to network security and performance [55]. Ensuring infrastructure compatibility is essential for the smooth deployment and optimal functionality of AI in health care [41,54].

Interoperability ensures seamless integration with existing systems, such as electronic health records and imaging software. It allows AI tools to operate within current workflows without disrupting established clinical processes, enhancing data exchange across platforms [41,68]. It also ensures that AI tools adhere to industry standards, facilitating communication between different health care technologies and minimizing issues such as data misinterpretation or workflow inefficiencies [71]. Proper integration can reduce the resource burden on health care facilities and improve the overall usability and effectiveness of AI systems in diverse clinical settings [64].

Understanding the impact on *clinical workflows and organizational structures* is essential. AI tools must be seamlessly integrated into workflows to avoid disrupting clinical processes [49,82]. Evaluating how AI affects the redistribution of tasks among health care professionals and identifying necessary organizational changes are essential [64,67]. Poor integration or failure to align with clinical routines can

XSL•FO
RenderX

negatively impact efficiency, increase cognitive burdens, and require significant resources to adapt systems [45,58].

Monitoring, Governance, and Accountability

This criteria cluster focuses on evaluating how effectively the AI tool is monitored throughout its life cycle, addressing critical aspects such as model drift, data governance, and adherence to ethical standards.

Clarity on *accountability and liability* is essential when assessing AI tools in health care due to the potential risks involved in their implementation [49,81]. AI systems can make errors or offer recommendations that may not be followed by clinicians, raising complex questions about who is responsible when mistakes occur [54,78]. The lack of clear guidelines on whether liability lies with the developer, the health care institution, or the clinician using the tool poses significant legal and ethical concerns [55,84]. Proper assessment frameworks must ensure that accountability is well-defined, including clear roles for all stakeholders involved (eg, clinicians, developers, and institutions) particularly in cases of adverse events or errors [50,64,70].

Data security, privacy, informed consent, and data ownership are vital criteria for assessing AI tools in health care. These tools often require large amounts of sensitive patient data, which must be protected from unauthorized access, breaches, or misuse [75,83]. Ensuring compliance with relevant regulations, such as General Data Protection Regulation or Health Insurance Portability and Accountability Act, is essential to safeguard patient privacy [55,60,71]. In addition, clear processes for obtaining informed consent are critical, ensuring that patients understand how their data will be used [68,81]. Proper data ownership policies must also be in place, ensuring transparency around who controls the data and how it can be accessed or shared [49,78]. These measures are crucial for building trust and ensuring ethical AI deployment in health care settings [54,68].

Regulatory compliance and certification are essential but insufficient assessment criteria for AI tools in health care [21]. Although regulatory bodies like the FDA in the United States and CE marking in the EU set minimum safety and efficacy standards, there are significant gaps between legal certification and real-world clinical validation, workflow integration, and ongoing use [21,45]. For instance, FDA clearance does not always assure users that an AI tool will meet their expectations for effective performance in all clinical settings, leading to skepticism among health care professionals [21,84]. Similarly, in the EU, AI tools with CE marking are often assumed to be clinically validated, but many lack sufficient validation for real-world clinical use, such as in dementia diagnosis via magnetic resonance imaging [45,83]. These gaps highlight the need for stronger regulatory frameworks and postmarket surveillance to ensure AI tools are not only certified but also thoroughly validated and integrated into health care workflows for effective and safe use [21,72,76].

Monitoring and governance mechanisms, including feedback loops, are critical for ensuring the continued safety, effectiveness, performance, and reliability of AI tools in health care [71]. It is essential that the responsibility for monitoring these tools is shared between the developer, regulator, and the health care organization deploying the tool [84]. Developers are responsible for ongoing performance evaluations, including regular updates to address issues such as data drift or algorithmic failure [48,74]. Regulators must ensure compliance with postmarket surveillance requirements and set clear guidelines for monitoring practices [60,84]. Health care organizations must implement local oversight systems, ensuring that the AI tool continues to meet clinical needs without causing disruption or harm [49,64,65,71,83]. By assigning responsibility to all 3 entities, health care systems can ensure comprehensive, multi-layered oversight that addresses technical, clinical, and regulatory concerns [84].

The *maintenance and updating* of AI tools are critical to ensuring their continued effectiveness and safety in health care [71]. Regular updates, including adjustments to algorithms and reference datasets, are essential to avoid performance degradation and ensure accurate results [53,71]. Without proper maintenance, different software versions could introduce biases or inconsistencies, which might affect clinical outcomes [45,76]. Establishing clear protocols for updates, including version control and procedures for managing software changes, ensures that AI tools remain reliable and aligned with current medical standards, safeguarding patient care [50].

Performance Quality Metrics

This criteria cluster focuses on evaluating the performance and quality of the AI tool by assessing key metrics such as foundational performance metrics, fairness, explainability, reliability, and robustness.

Foundational performance metrics play a crucial role in assessing the effectiveness of AI tools. The systematic review revealed that 59% (26/44) of studies primarily focused on accuracy, sensitivity, and specificity as key metrics. However, it is essential to consider application-specific metrics when evaluating AI performance, as different AI tools require tailored measures depending on their intended use. For example, diagnosis and prediction tools encompass applications like classification (eg, disease diagnosis), regression (eg, predicting disease progression), anomaly detection, and recommendation systems. These tools can be assessed through metrics such as accuracy, sensitivity, specificity, and the area under the curve for classification tasks [41,43,69] and mean absolute error and root mean square error for regression tasks [46,81]. Image and pattern analysis covers tasks such as image segmentation and reinforcement learning, using metrics like the Dice coefficient and Jaccard index for segmentation accuracy [87,88], and cumulative reward for evaluating reinforcement learning performance [89]. On the other hand, text and language processing applications, such as natural language processing and large language models, are assessed using metrics like relevance, engagement, empathy, token limits, hallucination rates, memory efficiency, and floating-point operation count [57,62,73]. These metrics ensure the AI tool is properly evaluated based on its intended use and technology type.

Explainability and interpretability are essential for ensuring the ethical and trustworthy use of AI tools in health care. These

XSL•FO
RenderX

criteria allow health care professionals to understand how AI models arrive at their conclusions, fostering trust in their recommendations [47,83]. Explainability helps to demystify the AI's decision-making process, making it transparent and accessible to users [67,68]. This, in turn, improves adoption, as clinicians are more likely to trust and rely on AI tools that are interpretable [49,60]. Ultimately, clear explainability supports ethical deployment, reducing risks associated with "black box" systems [73,78].

Fairness or equity ensures that AI models provide unbiased, consistent performance across diverse demographic groups, including those defined by race, gender, age, or socioeconomic status [62,66,83]. This criterion addresses the risk of bias in training data, including sample size and representativeness, which can lead to unequal treatment or outcomes for underrepresented populations [42,43,71]. By focusing on fairness, AI tools can avoid perpetuating disparities and contribute to more equitable health care delivery for all patients [55,63,71].

Reliability, repeatability, and reproducibility ensure that the AI tool can produce consistent outputs when presented with similar inputs, is repeatable under identical conditions, and is reproducible in diverse environments, including different institutions or patient populations [52,55,56,64]. Maintaining consistency and stability is essential for the tool's trustworthiness and its broader applicability in real-world health care scenarios [54,84].

Robustness and generalizability are essential criteria for assessing the adaptability of AI tools in health care [42,83]. Robustness ensures the tool can maintain high performance even when exposed to slight variations in input data or operational environments [70,83]. Generalizability, on the other hand, evaluates whether the AI tool can effectively perform across different populations, clinical settings, or geographic regions beyond the environment in which it was trained [48,83]. These criteria ensure that AI tools remain reliable and effective when scaled or applied to diverse health care contexts [49,54].

Acceptability, Trust, and Training

This criteria cluster evaluates user-centric aspects of the AI tool, focusing on its acceptance, trustworthiness, and the adequacy of user training and support.

User *acceptance and adoption* are crucial for the successful implementation and translation of AI-powered health tools in real-life settings [56,65,82]. Key challenges include fostering trust and confidence among health care professionals, ensuring ease of use, and integrating these tools seamlessly into clinical workflows [77]. User acceptance depends significantly on the perceived benefits, transparency, and safety of the AI systems [47,49,52]. Moreover, ethical concerns, the potential for bias, and the need for comprehensive testing also impact adoption [67]. Clinicians are more likely to embrace these tools when they complement human expertise and are introduced with adequate training and support, ensuring they enhance patient outcomes without compromising safety [68]. User acceptance and adoption of technology are typically measured through surveys (eg, Technology Acceptance Model and Unified Theory of Acceptance and Use of Technology) assessing factors like perceived usefulness and ease of use, as well as use metrics such as adoption rates, frequency, and retention.

Trust is built through factors such as validation, transparency, safety, privacy, and interpretability of the AI tool [62]. Both health care professionals and patients must trust that the AI tool is reliable, safe, and effective in clinical practice [60,68]. Validating AI performance using local data is essential to build clinician confidence, while demonstrating that the tool adheres to rigorous standards helps address concerns about its real-world application [49,84]. Trust also influences adoption, making it vital for the successful implementation of AI tools in health care [82]. User trust in technology is commonly assessed through surveys and trust scales, such as the Technology Trust Index, which evaluate key dimensions like reliability, competence, transparency, and security. Behavioral metrics, including use patterns and reliance during critical tasks, offer additional insights into how trust manifests in practice.

User centricity emphasizes the need for a clear understanding of the intended users, domain, and specific tasks the AI tool is designed to support [42,58,71]. AI tools must be tailored to meet the unique requirements of their end users, whether clinicians, nurses, or patients, and address the particular medical conditions they aim to diagnose, monitor, or treat [42,56]. Clarity in defining the tool's intended use, the health care domain it serves, and the tasks it performs ensures that it delivers meaningful value in its practical application [64,73].

Usability ensures that the tool is user-friendly and intuitive for both health care professionals and patients [49,53]. An AI tool's ease of use and minimal training requirements are essential for successful adoption [47,53]. Usability also impacts user satisfaction, influencing acceptance and trust in the system [52,77]. Proper design should minimize cognitive load, provide relevant information in context, and allow customization by users [71]. Evaluating usability ensures that AI tools can be effectively deployed in real-world clinical environments, enhancing rather than hindering care delivery [55,56].

Adequate *training* ensures that clinicians and other end users can effectively use AI tools, minimizing user error and maximizing the tool's potential to improve patient outcomes [55,65,71]. Training programs should cover how to interact with the AI interface, interpret its outputs, and understand the tool's limitations [49,54]. Continuous education is also crucial, and end users should not only be trained on interpreting the algorithm's output but also be made aware of the factors that can affect its performance [64]. Moreover, accessible and responsive technical *support* is necessary to address user concerns, provide ongoing assistance, and maintain confidence in the AI tool's reliability and safety over time [52]. Without proper *training and support*, the integration of AI tools into clinical practice may face significant barriers, limiting their overall effectiveness [45,65].

Cost and Economic Evaluation

This criteria cluster evaluates the economic implications of the AI tool to determine its financial viability and long-term sustainability.

XSL•FO
RenderX

Economic evaluation and cost considerations are crucial in assessing AI tools in health care. AI interventions must demonstrate not only clinical value but also health economic impact to ensure their long-term sustainability [76,84]. This includes evaluating both direct costs, such as acquisition, maintenance, and implementation, as well as indirect costs like staff training or workflow disruptions [49,61]. Transparent and comprehensive economic evaluations help health care organizations determine the financial viability of AI tools, guiding decision-making on investments, reimbursement, and long-term sustainability [59,64,67,79]. Incomplete or unclear cost assessments can hinder AI adoption and create financial risks [72,79].

The choice of an economic evaluation method for an AI tool in health care depends on its intended use and desired outcomes. *Cost-effectiveness* analysis is useful when comparing costs with health outcomes like life years saved [41,59,68,71]. *Cost-utility* analysis is ideal when focusing on both life expectancy and quality of life improvements, measured in quality-adjusted life years or disability-adjusted life years [41,61,72]. *Cost-minimization* analysis is appropriate when the AI tool achieves similar outcomes as alternatives but aims to reduce costs [61,72,78]. The method chosen should align with the tool's specific goals and intended health care impact.

Technological Safety and Transparency

This criteria cluster focuses on evaluating the technological safety and transparency of the AI tool by assessing the safeguards in place to ensure safe and ethical operation.

Safety ensures that AI systems operate reliably and securely in clinical environments beyond laboratory settings and clinical trials [73,78]. This includes compliance with safety regulations, minimizing the risks of harmful outcomes, and maintaining high standards for long-term safety and patient protection [53,67,68]. Safety also encompasses the reliability of the AI model after its implementation, ensuring it consistently avoids errors and unintended consequences [47,65,78]. Ongoing monitoring, risk management, and thorough clinical validation are necessary to ensure that AI tools remain safe and effective in diverse health care settings and the long-term safety of constant updates [49,67,68,83].

Transparency is a critical assessment criterion for AI tools in health care, ensuring clarity in data processing, coding standards, and the overall functioning of AI systems [71,78,80]. Transparent models allow health care professionals to understand how decisions are made, promoting trust and enabling accurate assessments of the AI's performance [63,67,68,73]. Clear documentation and disclosure of data processing methods, coding protocols, and the AI's decision-making processes ensures accountability and reproducibility [42,54,64]. A recent review of 692 FDA-approved AI enabled medical devices highlighted major gaps in transparency and safety reporting [90]. Key data such as ethnicity (reported in only 3.6% of approvals), socioeconomic information (absent in 99.1%), and study participants' age (missing in 81.6%) were often underreported [90]. In addition, only 46.1% of devices provided detailed performance results and only 1.9% were linked to scientific publications on safety and efficacy [90]. These findings underscore the urgent need for improved transparency and more comprehensive safety reporting to reduce algorithmic bias and ensure equitable health care outcomes.

Ethical oversight and human in command ensure human control and responsibility in the AI decision-making processes [64,70]. This criterion emphasizes that humans must retain ultimate authority over AI-generated decisions, particularly in critical health care scenarios [68,70]. Human in command ensures that clinicians can review, intervene, or override AI decisions, maintaining ethical standards and safeguarding patient outcomes [42,70]. This oversight protects against overreliance on automated systems and ensures that AI tools support, rather than replace, human judgment in clinical practice [45,68,80].

Scalability and Impact

This criteria cluster focuses on evaluating scalability and impact by determining the AI tool's clinical utility and effectiveness and examining its broader impact.

Clinical effectiveness focuses on the tool's ability to positively impact patient outcomes [68,71,78]. This involves evaluating whether the AI tool contributes to better therapeutic results or patient-reported outcomes [43,71]. The assessment examines how well the AI tool integrates into real-world clinical settings and measures its tangible benefits in terms of patient health and health care quality [49,69]. Clinical effectiveness ensures that AI tools do more than function technically; they must provide meaningful improvements in patient care [47,51].

Clinical utility focuses on how effectively the tool supports clinical tasks and decision-making, including its ability to assist with diagnoses, treatment recommendations, and overall health care delivery [51,82]. Ensuring clinical utility means the AI tool must provide tangible benefits that align with clinical needs and enhance health care practices [43,79]. *Clinical efficiency* focuses on the tool's ability to optimize resource use while maintaining or improving care quality [68]. This includes evaluating how well it improves productivity, reduces time spent on routine tasks, and streamlines workflows for health care professionals [47,53,55].

Environmental impact is an important, yet often overlooked, criterion for assessing AI tools in health care; only 1 out of 44 studies addressed this criterion. The energy consumption and resource use associated with developing, deploying, and maintaining AI systems, such as data centers, computational power, and device infrastructures, can lead to significant environmental harm, including e-waste and greenhouse gas emissions [75]. Implementing eco-responsible practices, such as energy-efficient computing and sustainable data storage, is essential to minimizing the ecologic footprint of AI tools [75].

Practical Implications and Persisting Challenges

The wide array of frameworks and initiatives focused on AI assessment in health care shown in this systematic review highlights the significant lack of standardization in this field, creating additional challenges for stakeholders [43,70,71]. Faced with a growing number of assessment tools, they often struggle to determine which approach is most appropriate or how to

XSL•FO
RenderX

apply it effectively [63]. This diversity in assessment methods can lead to confusion and hinder comparability [43,68,69,79]. Variations in data collection and evaluation methods, ranging from self-reported to objective measures, and from qualitative to quantitative assessments, only add to the complexity, further complicating the establishment of clear, universal guidelines for AI evaluation in health care [62].

Most frameworks included in this analysis were driven by the recognition that many existing methods for assessing AI tools in health care were not specifically tailored to AI-based medical devices or health care applications [62,65,67]. Traditional technology assessments often lack a critical focus on the unique, dynamic challenges and opportunities AI presents [57]. This underscores the need for health care–specific frameworks that account for the evolving nature and complexities of AI systems in clinical environments [60]. Moreover, existing frameworks tend to prioritize technical metrics such as algorithm accuracy, precision, and validation [62,73]. While these factors are undeniably important, this narrow focus often overlooks broader considerations, including clinical relevance, practical application, and long-term impact on patient outcomes [41,56,82]. Consequently, these frameworks can fall short in delivering a holistic evaluation of AI tools, which is essential for ensuring their safe, effective, and seamless integration into real-world health care settings [47,83].

This study builds upon and advances the ongoing discussion on AI assessment in health care, aiming to address the recognized gaps by developing the AI for IMPACTS framework. This proposed framework integrates technical, social, and organizational dimensions, ensuring that the adaptive nature of AI and the complexity of the health care ecosystem are fully considered. By encompassing these critical aspects, the framework provides a more comprehensive and nuanced approach to evaluating AI tools, helping shape the field and offering a robust method for assessing AI's real-world impact in health care settings.

However, numerous challenges still remain. These challenges extend beyond just setting the assessment criteria, to include practical difficulties in implementing, validating, and standardizing these criteria across diverse health care environments. A key challenge in assessing AI tools in health care is the variation across different contexts and settings [64,71]. Most available evidence focuses on high-income countries, limiting the generalizability of findings to diverse health care environments, particularly in low- and middle-income countries [43,49]. Recent studies underscore the importance of collaborative efforts and context-sensitive solutions to effectively address the unique health care challenges faced in these regions [91]. Another challenge is the need for a multidisciplinary team of assessors. Effective evaluation requires collaboration among professionals from various fields, such as medicine, IT, and social sciences to ensure a comprehensive assessment [77,83]. This diversity of expertise is necessary to address the complexities of AI, from technical and ethical considerations to clinical relevance and real-world impact [55,65,84].

It is crucial to emphasize the importance of adequate training in assessment methods [69,74]. Many assessors may lack the specific expertise required to thoroughly evaluate AI-based tools [46]. Proper training in the complexities of AI technology and appropriate evaluation techniques is essential for conducting accurate and meaningful assessments [55]. Without this, the assessment process may be compromised, potentially leading to inaccurate or incomplete evaluations of an AI tool's safety and effectiveness, which could undermine its implementation in health care settings [68]. Furthermore, the rapid pace of AI development, with AI-based medical devices having shorter product life cycles compared to traditional medical devices, underscores the need for more adaptive and fast-tracked health technology assessment processes [49,68]. Conventional health technology assessments are often too time-consuming, taking about a year to complete, which is incompatible with the fast-evolving nature of AI technologies [59]. Balancing the need for robust evidence with the dynamic nature of AI development is essential to ensure timely, informed decision-making and avoid delays in implementation and potential reimbursement [59,68].

Limitations and Future Research

This study enhances the understanding of various criteria for assessing the quality and impact of AI tools in health care, but several limitations must be acknowledged. Relevant studies may have been missed due to language restrictions or limited database searches, and the exclusion of gray literature may have omitted valuable insights. In addition, no follow-up was conducted with the study authors to validate the findings, and manual reference searches were avoided to minimize citation bias. As a result, some relevant frameworks or assessment criteria may not have been captured in this review. Future research could expand to include studies in other languages, offering a more comprehensive understanding of potential interregional or intercultural differences in the assessment of AI tools in health care.

The critical appraisal of the frameworks included in this review highlighted that many papers discussing AI tool assessment in health care lacked rigorous validation, with some omitting the methods section entirely. To address this gap, we propose rigorously validating the AI for IMPACTS framework proposed in this work through a Delphi process. The Delphi method was selected as a means to validate the framework as it is specifically designed to achieve reliable expert consensus, particularly in addressing complex issues [92,93]. This method is widely recognized across various fields of medicine, especially for developing best practice guidance and clinical guidelines, where expert agreement is critical [94,95]. This approach will involve key stakeholders to critically apply, reflect on, and refine the framework, ensuring it is relevant, comprehensive, and user-friendly. The goal is to cocreate practical, accessible tools with industry experts that can support the effective evaluation of AI tools in real-world health care settings.

It is also important to highlight that new frameworks were published after the cutoff date of this systematic review, including the Organizational Perspective Checklist for Artificial Intelligence Adoption [96], Stanford's framework for evaluating

XSL•FO
RenderX

Fair, Useful, and Reliable Artificial Intelligence Models in Health Care Systems [97], and the Transparent Reporting of Ethics for Generative Artificial Intelligence checklist [98]. While an initial review shows that their assessment dimensions align with this work, a deeper integration will be undertaken before the validation study. This will ensure that the foundation for the Delphi process is as comprehensive and up-to-date as possible.

Conclusions

AI has the potential to transform health care by improving clinical outcomes and operational efficiency. However, its adoption has progressed more slowly than anticipated, partly due to the absence of robust and comprehensive evaluation frameworks. Existing frameworks often focus too narrowly on technical metrics, such as accuracy and validation, neglecting real-world factors like clinical impact, workflow integration, and economic viability. Furthermore, the variety of frameworks and initiatives focused on AI assessment in health care, as highlighted in this systematic review, underscores a significant lack of standardization in the field, creating additional challenges for stakeholders and making it difficult to compare and implement AI tools effectively.

This study builds on and advances the ongoing discussion surrounding AI assessment in health care by developing the AI for IMPACTS framework. It aims to address key gaps identified in existing evaluation approaches, offering a comprehensive model that incorporates technical, social, and organizational dimensions. It is organized around 7 key criteria clusters: I—integration, interoperability, and workflow; M—monitoring, governance, and accountability; P—performance and quality metrics; A—acceptability, trust, and training; C—cost and economic evaluation; T—technological safety and transparency; S—scalability and impact.

While the framework provides a more holistic approach, significant challenges persist. The diverse contexts and settings in health care make it difficult to apply a one-size-fits-all framework. Multidisciplinary teams are necessary to evaluate AI tools thoroughly, as expertise from fields such as medicine, IT, and social sciences is required to address the complexities of AI. In addition, many assessors lack the specific training needed to evaluate these tools accurately. The rapid pace of AI development further complicates the assessment process, as conventional evaluation methods are often too slow to keep up with AI's short product life cycles. To ensure successful AI integration in health care, adaptive and fast-tracked assessment processes are essential, allowing for timely decision-making and implementation while maintaining the necessary rigor.

Abstract

Background: The COVID-19 pandemic continues to hold an important place in the collective memory as of 2024. As of March 2024, >676 million cases, 6 million deaths, and 13 billion vaccine doses have been reported. It is crucial to evaluate sociopsychological impacts as well as public health indicators such as these to understand the effects of the COVID-19 pandemic.

Objective: This study aimed to explore the sentiments of residents of major US cities toward restrictions on social activities in 2022 during the transitional phase of the COVID-19 pandemic, from the peak of the pandemic to its gradual decline. By illuminating people's susceptibility to COVID-19, we provide insights into the general sentiment trends during the recovery phase of the pandemic.

Methods: To analyze these trends, we collected posts (N=119,437) on the social media platform Twitter (now X) created by people living in New York City, Los Angeles, and Chicago from December 2021 to December 2022, which were impacted by the COVID-19 pandemic in similar ways. A total of 47,111 unique users authored these posts. In addition, for privacy considerations, any identifiable information, such as author IDs and usernames, was excluded, retaining only the text for analysis. Then, we developed a sentiment estimation model by fine-tuning a large language model on the collected data and used it to analyze how citizens' sentiments evolved throughout the pandemic.

Results: In the evaluation of models, GPT-3.5 Turbo with fine-tuning outperformed GPT-3.5 Turbo without fine-tuning and Robustly Optimized Bidirectional Encoder Representations from Transformers Pretraining Approach (RoBERTa)–large with fine-tuning, demonstrating significant accuracy (0.80), recall (0.79), precision (0.79), and F_1-score (0.79). The findings using GPT-3.5 Turbo with fine-tuning reveal a significant relationship between sentiment levels and actual cases in all 3 cities. Specifically, the correlation coefficient for New York City is 0.89 (95% CI 0.81-0.93), for Los Angeles is 0.39 (95% CI 0.14-0.60), and for Chicago is 0.65 (95% CI 0.47-0.78). Furthermore, feature words analysis showed that COVID-19–related keywords were replaced with non–COVID-19-related keywords in New York City and Los Angeles from January 2022 onward and Chicago from March 2022 onward.

Conclusions: The results show a gradual decline in sentiment and interest in restrictions across all 3 cities as the pandemic approached its conclusion. These results are also ensured by a sentiment estimation model fine-tuned on actual Twitter posts. This study represents the first attempt from a macro perspective to depict sentiment using a classification model created with actual data from the period when COVID-19 was prevalent. This approach can be applied to the spread of other infectious diseases by adjusting search keywords for observational data.

Introduction

Background

The global SARS-CoV-2 outbreak, which began in 2020, remains vivid in the collective memory of humanity as of 2024. It is beyond dispute that it was an unprecedented pandemic in human history. For >3 years since the World Health Organization declared the novel COVID-19 a Public Health Emergency of International Concern on January 30, 2020 [1,2], humanity has grappled with COVID-19 as a major social challenge. As of March 2024, the total number of COVID-19 cases has surpassed 676 million, >6 million people have died, and >13 billion vaccine doses have been administered [3]. To assess the scale and severity of the COVID-19 pandemic, it is crucial to confirm public health indicators such as these. While numerous studies have been undertaken to address the pandemic, from artificial intelligence and medical imaging to printing technology [4], it is also important to conduct sociopsychological observations to understand how citizens have perceived the COVID-19 pandemic.

We assess public sentiment during the pandemic by analyzing social media posts using natural language processing (NLP) techniques, which have significantly advanced since the 2010s. An NLP-based approach can address the limitations of traditional social science research methods, which are often constrained by limited observational data and the potential for indirect bias from nonrespondents [5]. Previous studies that analyzed sentiment during the COVID-19 pandemic can be categorized into 2 main groups. One group focused its investigations on the initial outbreak that occurred in March 2020 [6-10], while the other focused on specific thematic areas, such as vaccination efforts [11-14]. However, no study to date has captured the cyclic fluctuations in social sentiment from macro and long-term perspectives because these studies are based on data collected using keywords related to COVID-19, and these words usually reflect negative feelings. Furthermore, despite variations in the spread of COVID-19 between urban and rural areas [15], many studies have focused on sentiment analysis at the level of language or country, thereby limiting the extraction of insights considering local infection status, which is crucial from a public health perspective.

Our previous study [16] analyzed social media posts about citizens' activities that were constrained by the pandemic, and the degree of sentiment changed depending on the context of the source observational data instead of COVID-19–related texts. In addition, we focused on major American cities such as New York City, Los Angeles, and Chicago, which have similar social conditions. Using this approach, we addressed the problems of previous studies and revealed the general trends of citizens' sentiments from December 2019 to December 2021 during the COVID-19 pandemic.

This study further develops this research and examines the period from December 2021, when the Omicron variants surged, to December 2022, a period when public interest in COVID-19 generally waned. In the United States in 2021, outbreaks caused by the Omicron variant strain continued intermittently, starting with BA.1 at the end of 2021, followed by BA.2 and BA.3 [17], prompting state governments to issue repeated warnings and subsequently rescind them. The World Health Organization's Public Health Emergency of International Concern ended in May 2023 [2], and thus, 2022 can be considered a transition period from the pandemic period to the postpandemic period. We believe it is important to observe citizens' sentiments in the United States during this period. In addition, because previous research involving sentiment classification models relied on lexicon dictionaries or training datasets before 2020 when SARS-CoV-2 emerged, the domain adaption between the lexicon dictionary or training data (source domain) and the observational data (target domain) [18] was not sufficiently considered in NLP. To address this problem, we constructed a sentiment classification model fine-tuned using data extracted under conditions identical to those of the actual observational dataset. Using these methodologies, we propose a definitive approach for estimating social sentiment during the COVID-19 pandemic.

Objectives

Sentiment classification methods based on algorithms can be broadly divided as follows: lexicon-based approaches that infer text sentiment from tokens that have been assigned sentiment scores in advance and machine learning approaches that infer text sentiment from models trained on datasets [19]. There are several studies on lexicon-based sentiment analysis during a crisis. A study in Wuhan, China, tracked the change in public sentiment during the first 12 weeks after the identification of COVID-19 by examining posts on Weibo. The study revealed the pattern of trajectories—from confusion and fear, through disappointment, frustration, depression, and anxiety, and finally to happiness and gratitude—using the Emotion Vocabulary of the Dalian University of Technology [7]. A study in Europe and the United States measured the sentiment toward immigration by examining related tweets in Germany, Italy, Spain, the United Kingdom, and the United States during the early stages of the COVID-19 pandemic. The study estimated the sentiment scores of tweets, using Valence Aware Dictionary and Sentiment Reasoner, and revealed various themes regarding immigration for each country through topic modeling [20].

Some studies on sentiment analysis during crises use machine learning approaches. An analysis in the United States investigated the communication patterns of provaccine and antivaccine users on Twitter (now called X) by visualizing a retweet network related to the measles, mumps, and rubella vaccine during the 2015 California Disneyland measles outbreak. The study classified the users into provaccination, antivaccination, and neutral groups using a support vector machine. The results showed that most of the users were overwhelmingly provaccination, while antivaccine users resided in their own enclosed structural community [21]. A study in the United States also analyzed public perceptions of gig work on Twitter for 2 weeks before and after the COVID-19 emergency declaration. The study trained a machine learning model based on 10 different labels. The results showed that tweets reflected an increased sense of community and concern toward gig workers during the pandemic [22]. An investigation on Instagram demonstrated the changes in hate and misinformation against East Asians that occurred through Meta's content

XSL•FO
RenderX

moderation early in the COVID-19 pandemic. The study used supervised machine learning methods to estimate text emotions associated with human faces in posts with the hashtag #coronavirus [8]. A study on Twitter and Weibo revealed a pattern in which negative sentiment peaked before the 2020 lockdowns in many countries, followed by a gradual recovery in sentiment [9]. A study in China examined the psychological impacts of the COVID-19 epidemic declaration on individuals using Weibo data. Findings revealed an increase in negative emotions, such as anxiety and depression, alongside a decrease in life satisfaction and positive emotions using the pretrained psychological prediction model [10].

The disadvantage of lexicon-based approaches is that they are highly domain oriented [19]. Then, to predict sentiment in a specific domain, such as the discourse space of Twitter during the COVID-19 pandemic, a machine learning–based approach using training data, especially a neural network approach, is reasonable in terms of accuracy. This approach involves Transformer-based models with attention mechanisms [23], which assign weights to tokens based on their relationships, without processing time-series data sequentially, as is done in natural language. Language models such as GPT-1 [24] and Bidirectional Encoder Representations from Transformers (BERT) [25], which leverage the Transformer architecture and have undergone extensive pretraining on large datasets, have become readily available tools for NLP tasks.

A study on Twitter examined how users with different ideological views and follower bases expressed vaccine favorability and specific vaccine-related concerns. Users' perception of the vaccine was classified by a fine-tuned BERT model using training data that were coded by the authors. The results from linear mixed-effects models showed a contrast in vaccines between conservative and liberal users, and users with large numbers of followers tended to be more favorable toward vaccines, while those with an average number of followers were prone to be more concerned about vaccines [11]. A study from January 2021 to January 2022 on Twitter used a change-point detection algorithm to identify significant shifts in public sentiment regarding the pandemic. Validation of these findings was accomplished by cross-referencing with contemporaneous news reports. Furthermore, the estimation used BERT fine-tuned with labeled tweets from Kaggle to gauge public attitudes [26]. A study on Twitter and Reddit investigates public sentiment regarding COVID-19 vaccines from January 2020 to March 2022. Using a fine-tuned DistilRoBERTa model, augmented with back-translation, it reveals that Twitter sentiment was predominantly negative, whereas Reddit sentiment was mostly positive [13]. A study in the United Kingdom used a hybrid model, combining Valence Aware Dictionary and Sentiment Reasoner, TextBlob, and BERT, to analyze public perceptions of COVID-19 contact tracing apps on Twitter and Facebook. Results indicated varying sentiments influenced by debates on centralized versus decentralized data handling in app-based contact tracing [27].

In a language model based on the Transformer architecture, there is a pretraining stage in which initial parameters are set and a fine-tuning stage in which parameters are adapted for a specific target task or domain. Given that language models may not possess adequate pretraining on social discourse after major transformative events such as the COVID-19 pandemic, it is appropriate to fine-tune the model using training data with conditions similar to the observed data. Therefore, the following research question (RQ) initially guided our study: *To what extent can the performance of classification tasks be enhanced through the use of posts on Twitter during the pandemic as training data? (RQ1)*

In addition, since 2020, there have been advancements in large language models (LLMs) such as GPT-3, making them capable of not only understanding but also generating sentences [28]. In this paper, we use GPT-3.5 Turbo [29], which is the latest version that allows fine-tuning, and we ask the following question: *To what extent does GPT-3.5 Turbo enhance the performance of sentiment classification tasks in comparison with conventional Transformer-based models? (RQ2)*

Previous studies have focused mainly on the several months of lockdown starting in April 2020 and the rollout of vaccinations from late 2020 onward, but no study has captured the long-term trend in social sentiment for specific regions during the COVID-19 pandemic period from 2020 to 2023. These tendencies simultaneously indicate the difficulty of analyzing public sentiment during the COVID-19 pandemic from a macro and diachronic perspective. We intend to undertake a long-term and macroscopic observation by targeting text that discusses the social activities of citizens restricted by lockdowns and similar measures implemented in response to the spread of COVID-19, rather than focusing solely on text explicitly containing keywords such as "COVID-19," "virus," and "lockdown," as was the case in the previous studies. According to a study about adaptation to the "new normal," the term "the new normal" first emerged during the 2008 financial crisis and was used again to point out how the COVID-19 pandemic had changed essential aspects of human life [30]. A study compared risk perception in a sample in April 2021 and January 2022, based on the assumption that the "new normal" involved ongoing restrictions starting with widespread vaccine access and the vaccination of populations considered vulnerable. The study found that people tend to overestimate COVID-19 risks, particularly for children and healthy individuals [31]. This study considers this "new normal" period in the time frame from December 2021 to December 2022 and asks the following question: *To what extent will the cyclical sentiment of citizens toward restricted activities in major US cities during the "new normal" period weaken over time following its peak in December 2021? (RQ3)*

Previous studies focused on observations from countries and language areas such as the English-speaking world. However, a geospatial study showed that the spread of COVID-19 in the United States differed between urban and rural areas even within the same state and that infection status was correlated with each county's social vulnerability and community resilience [15]. Moreover, a study that surveyed rural and urban areas during the pandemic showed that rural residents were less sensitive to preventive health behaviors compared with urban residents due to the influence of political ideology or demographic factors [32]. On the basis of these findings, it is imperative to distinguish and analyze urban and rural areas separately,

XSL•FO
RenderX

particularly within the US context. Therefore, in this study, we intentionally focused on major urban centers within the United States to estimate social sentiment and asked the following question: *In comparing citizens' sentiments across major metropolitan areas in the United States, namely, New York City, Los Angeles, and Chicago, between December 2021 and December 2022, what differences or similarities in sentiment were there? (RQ4)*

Methods

Overview

We collected posts on Twitter related to restricted activities during the COVID-19 pandemic in New York City, Los Angeles, and Chicago from October 2021 to December 2022. Posts from October 2021 to November 2021 were used to train the sentiment classification model, while posts from December 2021 to December 2022 were used to estimate sentiment and extract feature words. Then, the correlation coefficient between estimated sentiment and actual infected cases was determined. In addition, the complete code for this study is available on the GitHub repository [33].

Data Collection

In this study, we chose the 3 largest cities in the United States according to the US Census Bureau [34]: New York City, Los Angeles, and Chicago. Specifically, New York County, Los Angeles County, and Cook County were selected as observation targets. In the data collection process, the Full-archive Search Application Programming Interface (API) of Twitter API v2 [35] was used to retrieve messages posted within a 25-mile radius of the latitude and longitude of the city hall for each city. This radius is the upper limit of the Full-archive Search API, ensuring comprehensive coverage of the urban core. Our observation period was from December 2021, when the emergence of the Omicron variant led to record-high number of cases in the United States, to December 2022, when interest in COVID-19 had waned; this builds on the author's previous study [16] that estimated sentiment in the same 3 cities from December 2019 to January 2022. Posts from October 2021 to November 2021 were also used as training data for neural network models.

The search string used for retrieving posts on Twitter uses keywords associated with citizens' activities that were constrained by lockdowns and similar measures implemented in response to the COVID-19 pandemic, as described in the study by Saito and Haruyama [16]. These keywords are shown in Multimedia Appendix 1. The use of these specific keywords enables a coherent overview of the citizens' psychological landscape from a macro perspective. These keywords are categorized by restriction type (ie, stay-at-home order, restrictions on gatherings, and travel restrictions) and are specified as arguments for the Twitter API version 2's Search API, using "OR" conditions. In addition, retweets were excluded from the search, and only English posts were retrieved. The retrieved posts were processed to remove noise, including URLs, mentions, and hashtags, followed by text normalization and deduplication, before being used for training and classification with neural networks.

Observational Data

We obtained posts from December 2021 to December 2022 using the Search API of Twitter API v2. The total number of posts was 119,437, and the total file size was 34.4 MB. Table 1 shows the number of posts by restriction type, and the number of unique users. Moreover, this data collection was conducted during the period from June 15, 2023, to June 22, 2023. For privacy protection, identifying information such as author IDs and usernames was removed, retaining only the text for analysis.

Table 1. Number of posts and unique users collected from Twitter between December 2021 and December 2022.

	New York City	Los Angeles	Chicago
Posts, n (%)			
Stay-at-home order	12,969 (23.97)	9622 (21.98)	5308 (24.64)
Restrictions on gatherings	14,095 (26.05)	13,448 (30.71)	5803 (26.94)
Travel restrictions	27,045 (49.98)	20,715 (47.31)	10,432 (48.42)
Total	54,109 (100.00)	43,785 (100.00)	21,543 (100.00)
Unique users, n	20,575[a]	17,588	8948

[a]For 113 tweets in New York City, unique users could not be identified because the author ID could not be obtained. Therefore, they were excluded from this table.

Neural Network Model

To create a sentiment classifier, we used a Transformer-based neural network model using training data that are searched on the same data source, keywords, geolocation information, and language except for a period as actual observed data.

Training Data

As training data, we used Twitter posts obtained using Search API of Twitter API v2.0 under the same search keywords, geolocation, and language as observed data during the period from October 31, 2021, to November 27, 2021. This period was chosen to prevent any overlap with the observation data. The total number of results obtained was 3149, and the retrieved posts were preprocessed, such as noise removal, text normalization, and deduplication. For these pieces of data, an author and 2 Amazon Mechanical Turk (MTurk) workers labeled them as positive, negative, or neutral based on the instructions shown in Textbox 1, and the final label was determined by a majority vote. Tweets that could not be decided by a majority

XSL•FO
RenderX

vote because each of the 3 people indicated different opinions were labeled as neutral. Concerning the instructions in Textbox 1, positive and negative sentiments were defined based on the available sentiment by [36], and neutral sentiments were defined by the authors according to the characteristics of the Twitter posts obtained. We also selected workers with master's qualifications who have consistently been recognized for their high performance on Amazon MTurk. In addition, only texts were extracted for individual privacy measures, and due to Amazon MTurk's inability to display 4-byte Unicode Transformation Format-8 emojis, we converted them to HTML spans in the task instructions, ensuring that the workers considered emojis when evaluating emotions. After labeling 3149 posts, the unanimous agreement rate among all 3 evaluators was 55.22% (1739/3149), and the 2-out-of-3 agreement rate was 28.74% (905/3149). The remaining 16.04% (505/3149) of posts were marked as neutral because they were of different values.

Labeled posts were shuffled and then filtered to extract 2400 instances for training the neural network model. These were then partitioned into training (1800/2400, 75%) and validation (600/2400, 25%) datasets. The remaining 749 instances were reserved for testing purposes. Table 2 shows the number of divided posts for each sentiment.

Textbox 1. Instructions for 3 evaluators to create training data and the prompt for GPT-3.5 Turbo for classifying sentiment. In the prompt in GPT-3.5 Turbo, this instruction was modified only to return numerical values such as positive to 0, neutral to 1, and negative to 2.

You are requested to perform sentiment classification (positive, negative, or neutral) for each tweet based on the following rules. These tweets have been collected for the purpose of scientific research.

- Positive sentiments: admire, amazing, assure, celebration, charm, eager, enthusiastic, excellent, fancy, fantastic, frolic, graceful, happy, joy, luck, majesty, mercy, nice, patience, perfect, proud, rejoice, relief, respect, satisfactorily, sensational, super, terrific, thank, vivid, wise, wonderful, zest, expectations, etc.
- Negative sentiments: abominable, anger, anxious, bad, catastrophe, cheap, complaint, condescending, deceit, defective, disappointment, embarrass, fake, fear, filthy, fool, guilt, hate, idiot, inflict, lazy, miserable, mourn, nervous, objection, pest, plot, reject, scream, silly, terrible, unfriendly, vile, wicked, etc.
- Neutral sentiments: neither positive nor negative, such as text without sentiment, stating a fact, question, news article, advertisement, solicitation, request, quote, unintelligible text, etc.
- When the sentiment is mixed, such as expressing both joy and sadness, use your judgment and choose the more strongly expressed emotion.

Table 2. Training, validation, and test data for creating the neural network models.

Data types	Positive, n (%)	Neutral, n (%)	Negative, n (%)
Training data (n=1800)	648 (36)	515 (28.61)	637 (35.39)
Validation data (n=600)	225 (37.5)	159 (26.5)	216 (36)
Test data (n=749)	270 (36.05)	214 (28.57)	265 (35.38)

Training of the Neural Network Model

For sentiment classification in this research, we adopted GPT-3.5 Turbo, the latest version of GPT-3 that is trained using huge parameters and can be fine-tuned using real data. GPT-3.5 was trained on data up to September 2021, marking a distinction from GPT-3, which used training data through 2019. This difference suggests a substantial potential contribution to the contextual analysis of the globally prevalent COVID-19 pandemic since 2020. In the development of our model, we used gpt-3.5-turbo-1106 as the base model, subsequently fine-tuning it with the training data described in the Training Data section. The model was created using the following hyperparameters: a learning rate multiplier of 2, a batch size of 3, and a total of 3 epochs. These values were automatically optimized by the fine-tuning API based on the size of the training dataset. Figure 1 presents the learning curve, where the x-axis represents the number of steps and the y-axis represents the loss, which indicates how closely the model's predictions align with the actual outcomes. The validation loss, which reflects the model's performance on unseen data, decreases until approximately step 500 but then fluctuates intermittently up to step 1500, suggesting potential overfitting to the training data. Toward the final step, however, the validation loss decreases to 0.39, indicating that the model stabilizes and improves its generalization performance.

RenderX

Figure 1. The learning curve of fine-tuning GPT-3.5 Turbo.

Ethical Considerations

The study was conducted using publicly posted large volumes of Twitter data collected via the Twitter API, which is permitted only for academic research but does not involve any human subject research. Furthermore, these posts are not produced within a virtual community on Twitter. Data collection, creation of training and test datasets, and analysis were carried out following Twitter's terms and conditions. In addition, all identifying information, such as author IDs, tweet IDs, display names, and usernames, was excluded, with only the tweet content used for the research. This study also ensures adherence to the guidelines outlined in the study by Luo et al [37].

Results

Evaluation of Sentiment Estimation Models

To evaluate the developed classification model, we compared it with the model Robustly Optimized BERT Pretraining Approach (RoBERTa)–large [38], which was fine-tuned using the same training data as the developed model, as well as GPT-3.5 Turbo, which was deliberately not fine-tuned. In addition, the following hyperparameters were used in fine-tuning a RoBERTa-large model: a learning rate of 5e-5, a batch size of 16 for training and 64 for validation, and a total of 3 epochs. In both GPT-3.5 Turbo and GPT-3.5 Turbo with fine-tuning, the same prompt (the role's system parameter of the API) was set based on Textbox 1, with the only change being the modification to return numerical values, such as 0 for positive, 1 for neutral, and 2 for negative. Both models also implemented exception handling to skip the output as a value error if the generated text is not numeric. (There was only 1 value error in this evaluation when using GPT-3.5 Turbo with fine-tuning.)

Table 3 shows the performance evaluation of each model. Accuracy is the proportion of correctly predicted instances out of all the cases in the test data. Recall is the proportion of correctly predicted instances out of all actual instances for each class (positive, neutral, and negative). Precision is the proportion of correctly predicted instances out of all the cases predicted as each class. Although the neutral class recall was low for all models, with precision remaining relatively stable across all models, GPT-3.5 Turbo with fine-tuning still significantly outperformed the other models in the recall. This difference might have a significant impact on the accuracy difference. F_1-score is a metric generally used to evaluate the performance of neural network models, and it provides a balanced assessment by considering both recall and precision. In both models, the F_1-score value for the neutral label was much lower than the values for the other labels, which means that the subtle nuances of the boundaries between negative and neutral and between neutral and positive were not sufficiently trained. However, in both models, the F_1-scores for the positive and negative labels exceeded 0.80, so we assume that there was no fatal effect on the results. Comparing the 2 models, RoBERTa-large and GPT-3.5 Turbo showed small differences in accuracy and average F_1-score, but it can be said that GPT-3.5 Turbo without fine-tuning showed the same performance as RoBERTa-large with fine-tuning.

RQ1 asks to what extent the performance of classification tasks can be enhanced through the use of Twitter's posts during the pandemic as training data. As shown in Table 3, GPT-3.5 Turbo with fine-tuning had a 5% higher accuracy and a 6% higher F_1-score compared with GPT-3.5 Turbo without fine-tuning, which clearly demonstrates the improvement in performance because of fine-tuning. RQ2 asks to what extent GPT-3.5 Turbo enhances the performance of sentiment classification tasks compared with conventional Transformer-based models. GPT-3.5 Turbo with fine-tuning had a 4% higher accuracy and a 7% higher F_1-score compared with RoBERTa-large with fine-tuning, which distinctly demonstrates the performance improvement because of large-scale learning. On the basis of the abovementioned results, this study used GPT-3.5 Turbo with fine-tuning.

Table 4 shows examples of sentiments classified and indexed by GPT-3.5 Turbo with fine-tuning. Each tweet is classified as –1 for positive, 0 for neutral, or 1 for negative. The higher the value of the index, the more pessimistic the sentiment is throughout the week, and the lower the value, the more optimistic the sentiment.

Table 4. Sample of tweets classified by GPT-3.5 Turbo with fine-tuning.

Tweets	Score	Sentiment
“I get you. I feel like masks block my turkey gobbler neck, so, sometimes I don't mind wearing them. That, and they keep my face warm in the winter when I go out. .	–1	Positive
“teaches you how to be an effective, empathetic leader in 0 lessons that you can find at Shot at our Level-0 complex of stages in Sunset Park! . Tô learn more about our stages, please visit .”	0	Neutral
“I have both vaccines and just got the booster (which takes a while to kick in). Unfortunately, there are a lot of people who go out unmasked when they’re sick and are spreading it like crazy,”	1	Negative

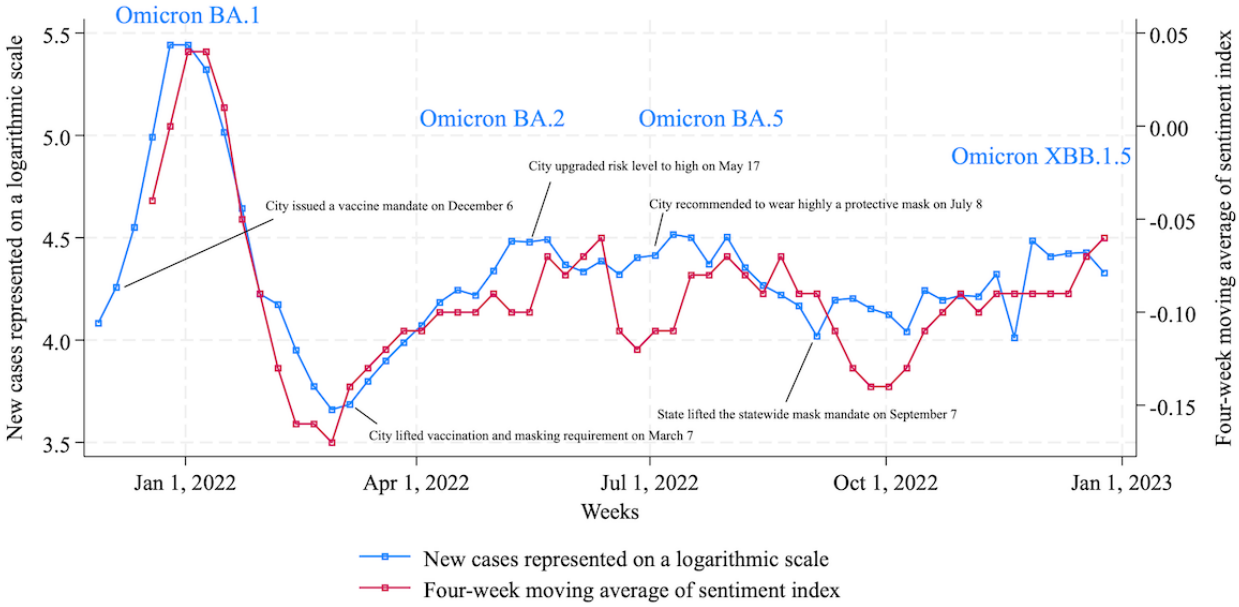
Result of Sentiment Estimation

Overview

To answer RQ3 and RQ4, the sentiment was extracted from posts made between November 28, 2021, and December 31, 2022, in New York City, Los Angeles, and Chicago. Similarly, the number of new cases in New York City, Los Angeles, and Chicago between November 28, 2021, and December 31, 2022, was taken from the New York Times COVID-19 data [39]. The research about the cyclicity of COVID-19 cases reported that in the United States in 2020, the number of new cases was lower on weekends than on weekdays [40]. Therefore, the sentiment was expressed as the weekly arithmetic mean of the sentiment score in each period, which was classified as –1 for positive, 0 for neutral, and 1 for negative. In addition, a 4-week moving average was applied to the sentiment data to smooth out random fluctuations or noise and to account for sentiment trends preceding the number of infected cases [16]. This value is defined as the sentiment index. At the same time, new cases were aggregated weekly to offset the weekend’s effects. The cases were described as a logarithm of 10 to normalize extreme increases due to specific mutant strains. Moreover, these time-series data were plotted on the graph to understand the patterns and trends and to confirm the relevance of each city’s timeline. To quantify the degree and confirm the direction of the linear relationship between the sentiment index and new cases, the correlation coefficient was used to extract the main topics and themes that characterize each period when the number of cases increased or decreased.

New York City

The left axis of Figure 2 shows the number of cases represented by a logarithmic scale in New York County, New York, and the right axis shows the average sentiment over 4 weeks extracted by GPT-3.5 Turbo fine-tuned with training data. In December 2021, citizens in New York were exposed to a surge in Omicron variant [41] cases and subsequently experienced cyclical waves of infections from subvariants such as Omicron BA.2 [42] and Omicron XBB.1.5 [43], which became predominant, particularly in the Northeast, by January 2023. Unlike in 2020, when COVID-19 had a high death rate, measures such as stay-at-home orders, bans on large gatherings, and travel restrictions were not enforced by the state government during this period, although mandates such as vaccinations [44]



XSL•FO
RenderX

for specific workers and indoor mask wearing [45] in clinics were implemented or recommended.

Here, we performed a statistical test on the sentiment waveform. As shown in Table 5, the correlation coefficient between sentiment and cases is 0.89, indicating a strong positive relationship. This suggests that in New York City, the sentiment of posts related to pandemic restrictions was consistently associated with COVID-19 infection status throughout the period. The correlation between the sentiment of posts related to restrictions on gatherings and cases was relatively weaker at 0.40 than for other types. There is a possibility that certain anxiety about commuting to work, going to school, and traveling may have persisted due to the spread of COVID-19, but it can be assumed that citizens exercised less caution when it came to leisure activities such as going to the movies, going on dates, and shopping.

Table 6 shows the feature words extracted using term frequency–inverse document frequency (TF-IDF) for each period according to the infection status. During December 2021, when infections caused by the Omicron strain spiked, themes related to polymerase chain reaction tests and the Omicron strain were dominant, whereas from January 2022 onward, concerns about COVID-19 ceased to be the main topic. Although Table 5 confirms a strong relationship between sentiment and infection status, the number of posts using keywords related to COVID-19 decreased from the beginning of 2022.

Figure 2. New COVID-19 cases and sentiment index extracted by GPT-3.5 Turbo with fine-tuning in New York City. The closer the sentiment index is to 1, the higher the degree of negativity, while the closer it is to −1, the higher the degree of positivity.

June 2022 to July 2022	Rise	"women", "abortion", "highland", "harris", "tamil", "celebrate", "tornado", "session", "send"
July 2022 to August 2022	Fall	"bash", "supplies", "finkl", "saudi", "group", "biden", "bag", "faculty", "lee", "jaz"
August 2022 to October 2022	Rise	"bark", "tickets", "birthday", "dance", "dress", "event", "n", "hc", "downtown", "celebrate"
October 2022 to November 2022	Fall	"halloween", "dailey", "juniors", "sign", "visiting", "encouraged", "hermanos", "fascism", "attend"
November 2022 to December 2022	Rise	"christmas", "thanksgiving", "santa", "winter", "merry", "snow", "tickets", "gift", "storm"

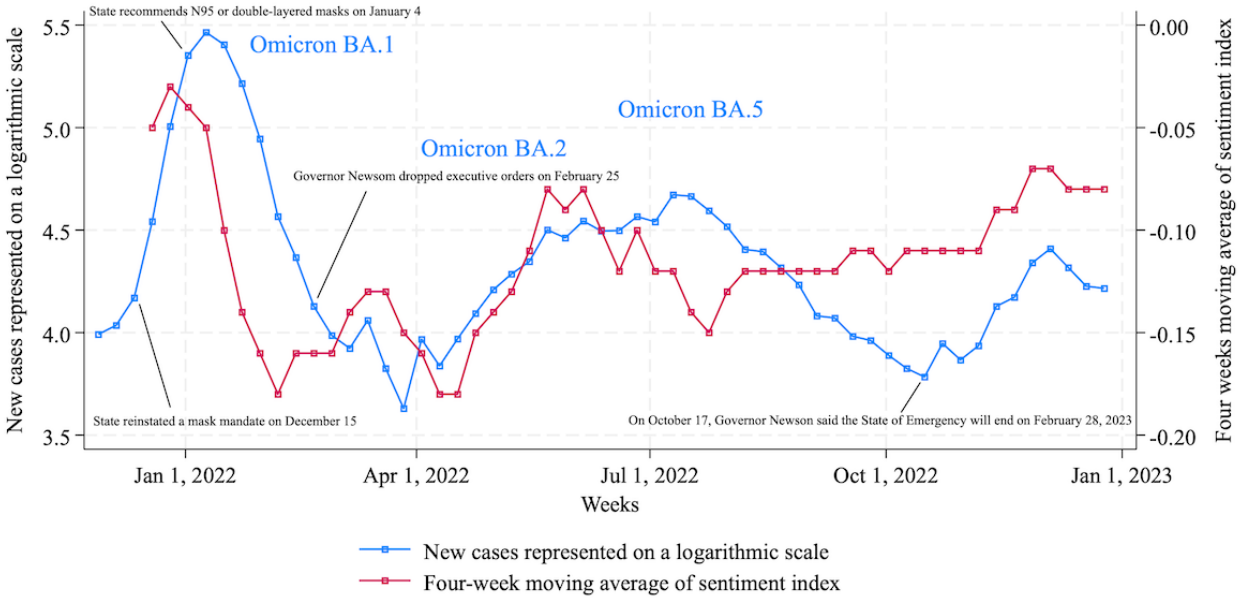
[a]Trend denotes the current infection status of COVID-19. "Rise" signifies the period of infection expansion, and "Fall" indicates the decline or conclusion of the infection period.

[b]Rise signifies the period of infection expansion.

[c]Fall indicates the decline or conclusion of the infection period. Italicized texts in the Feature words column represent words relevant to COVID-19.

Los Angeles

The left axis of Figure 3 shows the number of cases represented by a logarithmic scale in Los Angeles County, California, and the right axis shows the average sentiment over 4 weeks extracted by GPT-3.5 Turbo fine-tuned with training data. Similar to New York City, Los Angeles experienced an increase in Omicron infections in December 2021 [46], followed by subvariant BA.2 infections in spring 2022 [47] and subvariant BA.5 infections in summer 2022 [48]. Unlike in New York City, cases caused by the Omicron subvariant XBB.1.5 were limited in Los Angeles in December 2022 [49]. During this



XSL•FO
RenderX

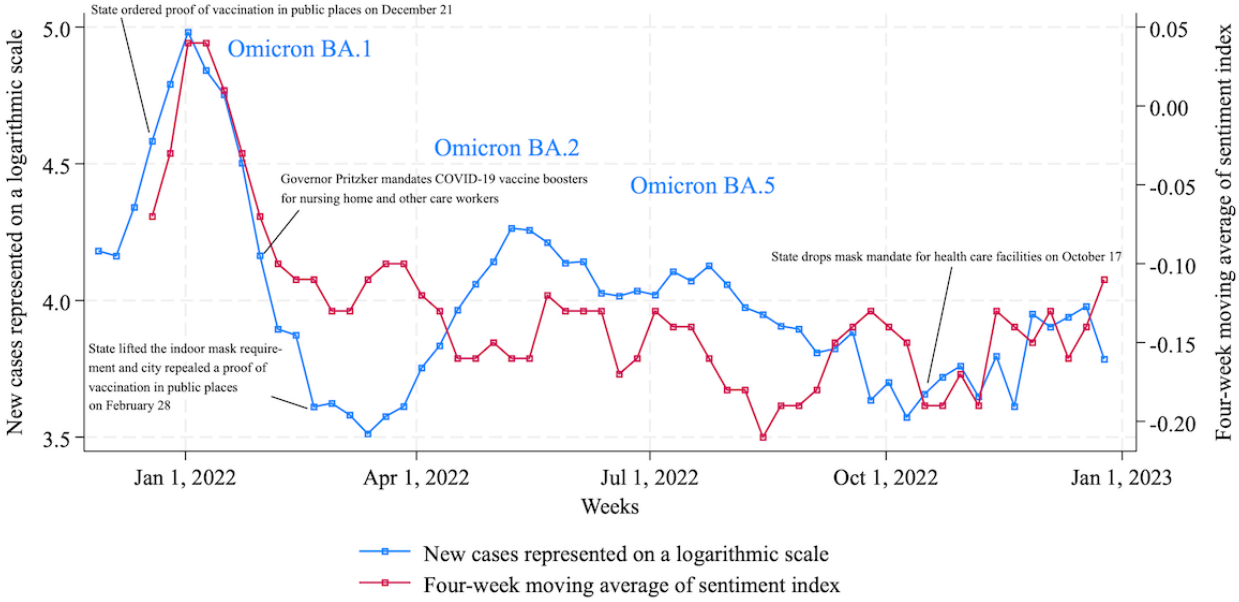
period, as in New York City, the state government did not order any restrictions on public movements, mainly requiring masks in public indoor settings [50] and recommending vaccinations for health care workers [51].

Here, we examine the correlation between sentiment and cases from Table 5. For the total sentiment index and cases pairs, *r* is 0.39, which is lower than that in New York City (*r*=0.89). However, by setting a 2-week lag in cases in the correlation coefficient, it was confirmed that *r* was 0.61 (*P*<.001). From this, it can be confirmed that in Los Angeles, sentiment preceded infection status. Similar to New York City, there was a relatively high correlation (0.52) between posts related to travel restriction and infection status and a low correlation (0.13) between posts related to restrictions on gatherings and infection status. In addition, as shown in Figure 3, it is notable that although the number of cases decreased since fall 2022, sentiment did not move positively as it did in spring 2022.

Table 6 shows the feature words extracted for each period according to infection status. In late December 2021 when infections caused by the Omicron strain rose, words related to Omicron and vaccination became common. However, from January 2, 2022, words related to COVID-19 dropped from the top of the TF-IDF scores, following the same trend observed in New York City. This means that although subvariants such as BA.2 and BA.5 appeared after January 2022, public interest in COVID-19 had waned.

Figure 3. New COVID-19 cases and sentiment index extracted by GPT-3.5 Turbo with fine-tuning in Los Angeles.

Chicago



The left axis of Figure 4 shows the number of cases represented by a logarithmic scale in Cook County, Illinois, and the right axis shows the average sentiment over 4 weeks extracted by GPT-3.5 Turbo fine-tuned with training data. In Chicago as well, after the surge of Omicron infection at the end of 2021 [52], subvariant BA.2 became dominant in spring [53], and BA.5 replaced it in summer [54]. In Illinois, from December 2021 to 2022, vaccination and mask mandates were intermittently issued for specific situations and workers, but as in New York City and Los Angeles, restrictions on movements were also imposed.

As shown in Table 5, the correlation coefficient between cases and sentiment in Chicago was 0.65 throughout the period, which is lower than that in New York City (0.89) and higher than that in Los Angeles (0.39). Regarding the correlation between cases and sentiment, unlike New York City and Los Angeles, there was a relatively higher correlation (0.63) between sentiment related to stay-at-home orders and cases. In Chicago, concerns about going to school or work may have been higher than concerns about social activities and travel.

Table 6 shows the feature words extracted for each period according to infection status. Unlike New York City and Los Angeles, we can see that keywords related to COVID-19 were common until March 2022. In Chicago, the indoor mask mandate was lifted [55], and proof of vaccination in public places was repealed on February 28 [56], but Chicagoans may have had a more sustained interest in wearing masks and getting vaccinated compared with residents in the other 2 cities.

Figure 4. New COVID-19 cases and sentiment index extracted by GPT-3.5 Turbo with fine-tuning in Chicago.

Discussion

Principal Findings

Considering the findings presented in the Results section, here we address RQ3 and RQ4. First, we undertake RQ3: "To what extent will the cyclical sentiment of citizens toward restricted activities in major US cities during the 'new normal' period weaken over time following its peak in December 2021?." Our results indicate a decrease in negative sentiment starting in April 2022, as evidenced by the peak of negative sentiment being below –0.05 in New York City (Figure 2) and below –0.1 in Chicago (Figure 4), despite the emergence of additional variants such as Omicron BA.2 and BA.5. In contrast to New York City and Chicago, sentiment in Los Angeles remained consistently within 75% of the initial peak observed during the week of December 26, 2021, maintaining this level from August 2022 onward (Figure 3). This phenomenon can be attributed to the relatively modest peak value (–0.03) for Los Angeles compared with the peak values of 0.03 in New York City and 0.04 in Chicago during the weeks of January 2 and January 9, 2022. Overall, we confirmed that the tone of the sentiment toward restricted social activities changed from negative to moderate throughout 2022, a trend observed consistently across these 3 US cities. According to the investigation about prolonged pandemic symptoms, significantly lower levels of limiting one's activities were reported among adults aged 18 to 39 years in the United States in June 2022 compared with other age groups [57]. This age group overlapped with the Twitter user group [58], partially supporting the sentiment estimation results.

Second, we address RQ4: "In comparing citizens' sentiments across major metropolitan areas in the United States, namely, New York City, Los Angeles, and Chicago, between December 2021 and December 2022, what differences or similarities in sentiment were there?" In terms of sentiment, the correlation coefficient between New York City and Los Angeles was 0.64, between Los Angeles and Chicago was 0.32, and between Chicago and New York City was 0.60, indicating an overall positive correlation. In feature words extracted by TF-IDF, during the peak of the initial Omicron wave in New York City and Los Angeles, feature words associated with COVID-19 were common; however, they were notably absent in subsequent periods. Meanwhile, in Chicago, feature words related to COVID-19 remained prominent in Twitter's message space until March 2022, indicating sustained interest in COVID-19. From then on, COVID-19–related keywords in each city were replaced by words from political contexts such as "Ukraine" and "abortion," weather-related words such as "hurricane" and "rain," and other words with unknown contexts. The abovementioned results are consistent with the trend of weakening sentiment throughout 2022.

Third, we consider the methodology. A novel aspect of our study is the accuracy of the sentiment estimation model, which was developed using Twitter posts extracted under the same conditions as the observed message group focused on COVID-19 awareness among people in 2021. Previous studies relied on data from before 2020, when COVID-19 emerged in the sentiment classification model. In such cases, a domain shift problem is likely to occur between the registered lexicon or training data and the observed data, which would affect the accuracy of the results. This problem remains an issue to be addressed, from conventional neural networks to LLMs, and technical solutions are being discussed [59,60]. We overcame these issues by training the model explicitly on data from the COVID-19 period.

Comparison With Prior Work

We compare our results with those of previous studies. The novelty of this study is that it showed a positive correlation over time between sentiment and cases during the "new normal" period. In a similar study, a survey in the Greater London area delved into the recovery of sentiment at the city level during the COVID-19 pandemic and found a gradual recovery in sentiment over time after reopening, similar to the findings of

XSL•FO
RenderX

this study [61]. However, this study merely confined the visualization of sentiment estimation results to their association with reopening events and did not reveal a correlation with any variables related to COVID-19. In the prior study, sentiment transitioned positively with a delay after reopening events, whereas in our study, sentiment shifted positively concurrently with the issuance of reopening orders. The difference in these results is thought to stem from whether the observed messages associated with keywords related mainly to COVID-19 or to social activities restricted by the pandemic.

Next, we refer to the previous study conducted by the author [16], which explored sentiment in New York City, Los Angeles, and Chicago from December 2019 to December 2021, using data collected under the same conditions as in this study. The sentiment waveforms correlated with infection status show the same trend, but the crucial difference is the tendency of feature words related to COVID-19 to appear. Both papers show that feature words related to COVID-19 had high TF-IDF values in New York City and Los Angeles from March 2020 to January 2022 and in Chicago from March 2020 to March 2022. In contrast, after the aforementioned period, feature words associated with COVID-19 did not surface among the top rankings in these 3 cities. In the context of COVID-19, it is plausible that Twitter's message space reverted to a state akin to that of February 2020 after the spring of 2022.

Limitations

It is important to acknowledge certain limitations of our study. First, Twitter users in the United States have tended to skew toward the 18- to 39-year age group, which constitutes 62% of the user base [58]. Moreover, there was a notable gender bias, with males accounting for 63% of the total users [62]. It is essential to recognize that these demographics may not perfectly align with the overall population distribution in the United States. Consequently, our study's observed data may exhibit a slight bias toward younger male demographics. Second, in this study, we estimated citizen sentiment by focusing on activities that were restricted during the COVID-19 pandemic, but these may not necessarily be messages posted in the context of the pandemic. As the goal of this study was to capture the societal atmosphere during the "new normal" period, we did not intend to limit our observations to the context of the COVID-19 pandemic. However, it is important to keep this context in mind as a premise.

Conclusions

This study estimated citizens' sentiment in major cities in the United States, spanning the period from the exponential surge in COVID-19 infections to the gradual abatement of the pandemic as it approached its conclusion. This research makes 3 primary contributions. First, it enhances the performance of the sentiment classifier by fine-tuning the LLM using data under the same conditions as the observed target. The efficacy of this improvement was validated through a comparison with previous models using F_1-score metrics. Second, our findings revealed a positive correlation between the estimated sentiment of citizens and actual cases of COVID-19 in New York City, Los Angeles, and Chicago. Although variations exist among these cities, a consistent trend emerged showing a gradual decline in sentiment, which corresponded to a reduction in the number of infections. Third, across these cities in 2022, references to COVID-19 gradually disappeared in the context of restricted social activities as the pandemic neared its end. This phenomenon is evidenced by the disappearance of COVID-19–related words in feature words after the spring of 2022.

The observational data design and sentiment classifier creation method used in this study have potential applications beyond the context of the COVID-19 pandemic. They can be adapted to address various other crises that humanity encounters intermittently, including infectious diseases, natural disasters, terrorism, and warfare. In the future, this field of study is expected to evolve and be applied more broadly to society, supported by stronger collaboration between social science and computer science.

Acknowledgments

The authors received no financial support for this study's research, authorship, and publication.

Authors' Contributions

RS contributed to the study's conception, the development of the neural network model, the execution of experiments, and the writing of the manuscript. ST guided the study's direction and conducted a thorough review of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The latest advancement of artificial intelligence (AI) is generative pretrained transformer large language models (LLMs). They have been trained on massive amounts of text, enabling humanlike and semantical responses to text-based inputs and requests. Foreshadowing numerous possible applications in various fields, the potential of such tools for medical data integration and clinical decision-making is not yet clear.

Objective: In this study, we investigate the potential of LLMs in report-based medical decision-making on the example of acute ischemic stroke (AIS), where clinical and image-based information may indicate an immediate need for mechanical thrombectomy (MT). The purpose was to elucidate the feasibility of integrating radiology report data and other clinical information in the context of therapy decision-making using LLMs.

Methods: A hundred patients with AIS were retrospectively included, for which 50% (50/100) was indicated for MT, whereas the other 50% (50/100) was not. The LLM was provided with the computed tomography report, information on neurological symptoms and onset, and patients' age. The performance of the AI decision-making model was compared with an expert consensus regarding the binary determination of MT indication, for which sensitivity, specificity, and accuracy were calculated.

Results: The AI model had an overall accuracy of 88%, with a specificity of 96% and a sensitivity of 80%. The area under the curve for the report-based MT decision was 0.92.

Conclusions: The LLM achieved promising accuracy in determining the eligibility of patients with AIS for MT based on radiology reports and clinical information. Our results underscore the potential of LLMs for radiological and medical data integration. This investigation should serve as a stimulus for further clinical applications of LLMs, in which this AI should be used as an augmented supporting system for human decision-making.

Introduction

Acute ischemic stroke (AIS) is a major cause of death and disability, requiring effective and efficient therapeutic strategies. To prevent the progression of ischemic damage and improve patient outcomes, timely and accurate diagnosis and treatment are crucial [1-3]. The standard of care and diagnostic workflow for acute AIS involves a combination of clinical information, clinical assessment, imaging, and decision-making tools, such as the National Institutes of Health Stroke Scale (NIHSS) [2,4-6]. Current treatment approaches include the administration of intravenous thrombolytic therapy, as well as mechanical thrombectomy (MT), either as a combined or sole treatment option [5,7,8]. While MT is an invasive procedure aiming for the removal of an occluding thrombus, only patients fulfilling certain requirements are eligible for this specific treatment [9,10]. The indication for MT is established with a combination of clinical assessment, image-based results, and guidelines such as the European Society of Neuroradiology or European Stroke Organization guidelines, taking into account factors such as patient's age, onset time of symptoms, and location and extent of the occlusion [8,10,11].

However, the subjective nature of the clinical assessment and decision-making tools, combined with the growing workload of health care professionals, highlights the need for a supporting, objective, and efficient approach to decision-making [12]. The task of deciding a patient's suitability for MT can be particularly challenging for inexperienced physicians, as it requires a thorough understanding of the latest medical evidence and guidelines, as well as a high degree of clinical judgment [13-15].

Studies have demonstrated the feasibility and potential of using artificial intelligence (AI) in medical decision-making, particularly in the radiology field [16,17]. For example, recent studies show the application of AI in cancer imaging analysis or in detecting acute intracranial hemorrhage on computed tomography (CT) or magnetic resonance imaging scans [18,19]. Similar studies have also shown promising results in the use of AI in the diagnosis of ischemic stroke (IS), with potential improvement of diagnostic accuracy and reduction of variability in the decision-making process. However, these studies all focus on the AI-based processing of visual information [18,20].

As nearly all information can be expressed in human language, recorded in text form in the radiology report, recent advancements in the development of large language models (LLMs) have opened new opportunities for medical information processing [21-24]. One of these autoregressive LLMs is GPT-3 used within the pretrained chatbot application version, named ChatGPT, developed by OpenAI [25]. GPT-3 is a third-generation deep learning model that has been trained on a massive amount of text data on 175 billion parameters, allowing it to generate humanlike logical and semantical responses to text-based questions and input information [26,27]. In an experimental setting, a GPT-3–based LMM model shows a significant improvement in medical question-answering tasks and showed a passing score in a medical licensing examination, due to its ability to provide logical and informational context across most answers [28]. To our knowledge, no large language processing model has been evaluated for immediate clinical decision-making based on radiology report texts. This could carry several benefits, including increasing the objectivity, speed, and standardization of decisions, as well as assisting physicians and medical staff by highlighting or reminding them of potential courses of action based on the latest medical evidence and guidelines.

In the context of AIS diagnosis and treatment, the application of such an LLM to a radiology report with a resulting decision-making component related to treatment using MT represents an exemplary use case. In this way, possible AI-assisted decisions related to MT could be made faster and more standardized based on up-to-date medical evidence and guidelines, which can be checked and correlated to the radiology report. Additionally, the application of an LLM as a monitoring, AI-augmented background system, supporting inexperienced or younger radiologists by highlighting the potential MT indication based on the written report, is conceivable. Thus, this study aims to evaluate the accuracy and efficiency of LLMs in predicting the suitability of patients for MT and to compare its decisions with those made in consensus by experienced health care professionals.

Methods

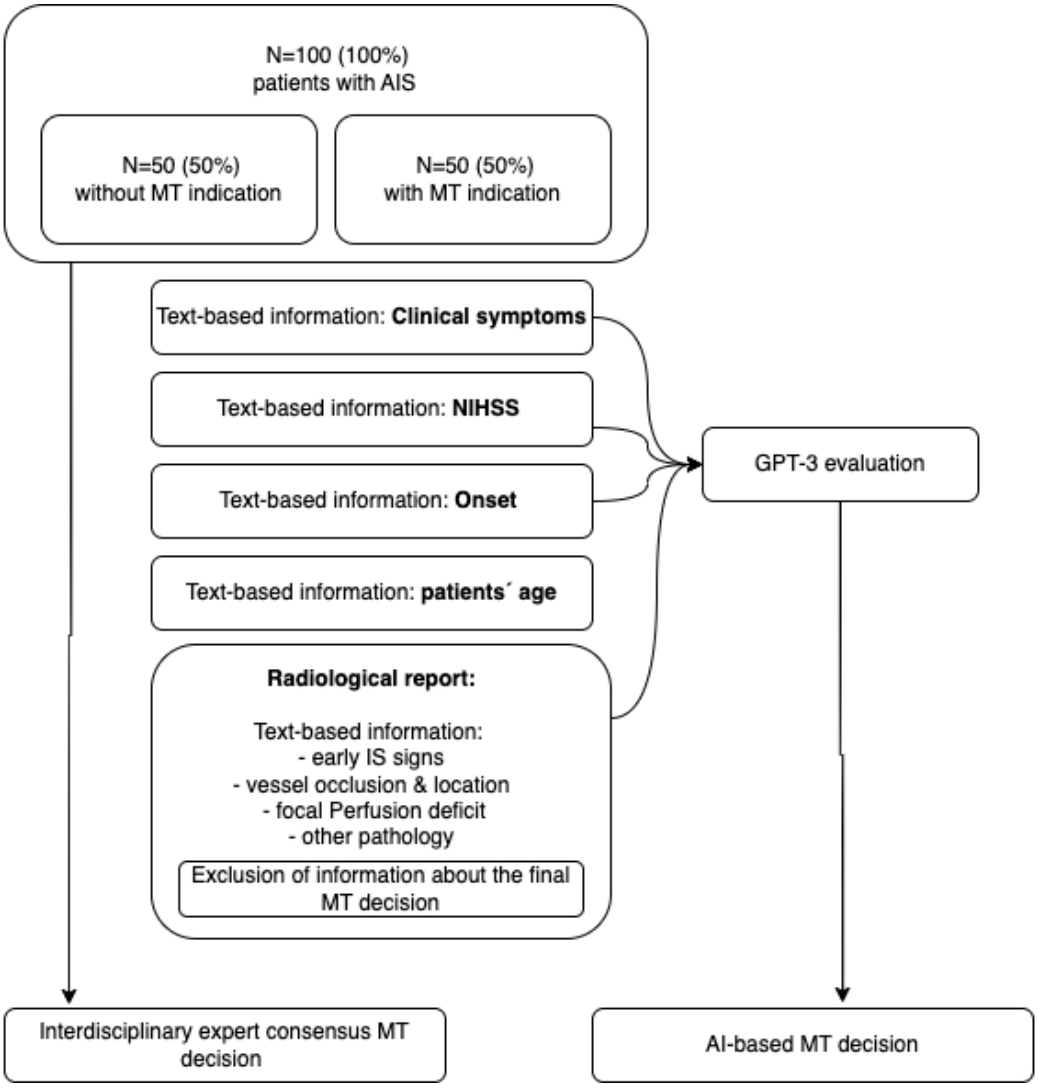
Ethical Considerations

This retrospective study received human subject ethics review approvals (23-1061-retro). Informed consent was waived due to the retrospective design of this investigation including the ability of participants to opt out. Privacy and confidentiality were ensured—beyond the patient's age and sex, no identifiable features about the patient were transmitted to the LLM model; especially, no patient-identifying information was provided to the AI.

Patient Population

The inclusion criteria for this study were (1) clinical symptoms consistent with AIS; (2) evaluable CT scan according to in-house stroke protocol and board-certified radiology report; (3) availability of the NIHSS score; (4) presentation to the hospital within a potential time of treatment options including MT; (5) for group affiliation, the decision to perform MT was evaluated based on an interdisciplinary expert consensus immediately before MT in each case and classified into (a) indication of MT and (b) no indication of MT; and (6) aged 18 years or older.

The exclusion criteria for this study were (1) patients in whom the juristic decision-making authority or written intention potentially influences the decision to undergo MT and (2) significant comorbidities that would limit the ability to undergo MT or the ability to provide informed consent.



Workflow

The Institute for Diagnostic and Interventional Radiology University Hospital Cologne performs about 250 intracranial MT per year. We retrospectively screened the database according to the abovementioned inclusion criteria in the period between January 2020 to December 2022 and randomly selected a total of 100 patients with AIS, whereby 50% (50/100) patients

XSL•FO
RenderX

have an MT indication and 50% (50/100) patients have no MT indication. All patients were eligible for a priori consideration of MT, the NIHSS was assessed before CT imaging, and neurological symptoms were recorded. The onset of neurological symptoms was also recorded based on case history, including unknown time frames. The image information, in the form of the radiology report, was transmitted to the AI, together with additional information on neurological symptoms, symptoms onset, and patients' age, but the final decision regarding MT was not transmitted to the AI (Figure 1). Based on 20% (20/100) of the cases, we performed a test re-evaluation by the LLM.

Figure 1. A hundred patients with AIS were analyzed. The patients were divided into two groups: 50% (50/100) had an indication for MT and the other 50% (50/100) had no MT indication. The image information, in the form of the radiology report, was transmitted to the AI, together with additional information on NIHSS, neurological symptoms, symptoms onset, and patients' age. However, the final decision regarding MT was not transmitted to the AI. The text-based AI was asked whether there was an indication for MT. The AI decision was compared with the decision of the health care professional's. AI: artificial intelligence; AIS: acute ischemic stroke; IS: ischemic stroke; MT: mechanical thrombectomy; NIHSS: National Institutes of Health Stroke Scale.

Neurological Assessment

A comprehensive neurological assessment was performed on all patients by a trained neurologist before the radiological examination. This assessment included the documentation of the NIHSS score including neurological symptoms and their onset, which was then communicated as part of the patient's medical history included in the request for radiologic imaging.

Imaging Protocol

All examinations used 128-254 slice CT scanners. Patients were scanned when supine from head to toe. The protocol included an unenhanced neurocranium CT and arterial phase imaging of cervical and intracranial vessels after injecting 60 mL of contrast media (Accupaque 350 mg/mL) at 4 mL/s, followed by 20 mL saline. Bolus tracking activated a 3-second scan delay after reaching 150 Hounsfield units in the descending thoracic aorta. The settings were pitch 1, 120 kVp, and 512 matrix with the DoseRight 3D-DOM (Philips Healthcare). Images were reconstructed axially with a 0.67-mm slice thickness. In some cases, CT perfusion was carried out with an additional 40 mL contrast agent and 20 mL saline using an 80-kVp, 512-matrix DoseRight 3D-DOM and processed with Philips IntelliSpace software (Philips Healthcare).

XSL•FO
RenderX

Image Analysis

In the study, 12 assistant radiologists (2-4 years' experience in neuroradiological imaging) were primarily responsible for conducting the primary image analysis. The radiologic findings were then secondarily reviewed and evaluated in an interdisciplinary consensus with neuroradiologists and neurologists, who had an average experience of over 5 years in neuroradiological imaging. The final decision regarding MT was reached based on this interdisciplinary consensus.

Radiology Report

The text information in the form of a narrative, text-based radiology report in the German language included various imaging findings related to the presence of an AIS. This information was recorded as a prose text. The radiological findings were transmitted to the LLM together with the patient's age and respective NIHSS score, neurologic symptomatology, and the corresponding time windows (time between onset of symptomatology and time of CT scan). Any information on the final MT decision was not included. No other personal data were transmitted to the LLM during the process. The average word count per report was 186 (SD 14; range 113-278).

LLM-Based Decision-Making

GPT-3 is a commercial-sector, pretrained, state-of-the-art, language-processing AI model developed by OpenAI, which is known for its ability to assess text information and has been seen as a significant advancement in natural language processing technology [27]. It has been trained on a massive amount of text data obtained from the internet and has been fine-tuned for various language tasks such as text completion, translation, and question answering. The used LLM model is specifically designed for conversational AI applications, such as virtual assistants [27].

In this study, GPT-3 in the form of ChatGPT was used for information processing and decision-making tasks. The text-based information received was used to generate a decision response. As described above, the information from the radiology report as well as clinical information and patients' ages were provided to the LLM, and the following request was made to it to provide a decision [29]:

> *Please decide whether mechanical thrombectomy is indicated or not, based on the following data. Please answer yes or no.*

Statistical Analysis

Statistical data analysis was performed using R (version 3.6.2; R Foundation for Statistical Computing) on RStudio (version 1.2.5033.35; R Foundation). Figures were plotted using the *ggplot2* package. Continuous variables were reported as mean and SD. Demographic characteristics were compared using the chi-square test for categorical variables and 2-tailed *t* test for continuous variables. The diagnosis' overall accuracy, specificity, and sensitivity were assessed using contingency tables.

Results

Baseline Characteristics

The demographic data were collected and analyzed for a total of 100 patients with AIS, who were divided into two groups: group 1 (n=50, 50%) received MT treatment, while group 2 (n=50, 50%) did not receive MT treatment. The average age of the participants was 68.34 (SD 6.95) years, with no significant difference between the two groups (*P*=.32). The distribution of sex was 54% (27/50) male in group 1 and 46% (23/50) in group 2 (*P*=.82). There were no significant differences between the two groups according to the demographic data (Table 1).

Table 1. Baseline characteristics of this study's population, presented by treatment group. The table displays the mean age (SD), sex distribution (male and female), and NIHSS[a] score and time from clinical onset to imaging (SD) for two treatment groups. Group 1 received MT[b], while group 2 did not receive MT.

Group	Age (years), mean (SD)	Sex, n (%)		NIHSS score, mean (SD)	Onset to imaging (min)
		Male	Female		
Group 1 (MT; n=50)	67.44 (8.34)	27 (54)	23 (46)	14.28 (2.21)	93 (50[c])
Group 2 (no MT; n=50)	69.23 (5.56)	23 (46)	27 (54)	9.22 (2.71)	129 (113[d])

[a]NIHSS: National Institutes of Health Stroke Scale.

[b]MT: mechanical thrombectomy.

[c]Unknown onset of symptoms in 8 cases.

[d]Unknown onset of symptoms in 14 cases.

Regarding the NIHSS scores, the average score was found to be higher in group 1 (14.28, SD 2.21) than in group 2 (9.22, SD 2.71), suggesting that the patients in group 1 had more severe IS symptoms than those in group 2. The difference between the two groups was statistically significant (*P*=.02; Table 1). In the MT group, the time from the clinical onset of symptoms to CT imaging was on average 93 (SD 50) minutes (unknown onset of symptoms in n=8 cases), while in the no-MT indication group, the time was 129 (SD 113) minutes (unknown onset of symptoms in n=14 cases). There was no significant difference between the two groups (*P*=.051; Table 1).

In both groups, the most common symptoms were paresis and aphasia. In the group with MT indication, 72% (36/50) of patients presented with paresis and 46% (23/50) of patients presented with aphasia. In the group without MT indication, 76% (38/50) of patients presented with paresis and 26% (13/50) of patients presented with aphasia. Anopsia was less frequent,

XSL•FO
RenderX

with only 2% (1/50) of patients in the MT group and 6% (3/50) of patients in the group without MT indication. Loss of consciousness was also less common, with 18% (9/50) of patients in the MT group and 4% (2/50) of patients in the group without MT indication (Table 2).

Table 2. Frequency and percentage of the most common clinical symptoms observed before imaging in two groups.

Group	Paresis, n (%)	Aphasia, n (%)	Anopsia, n (%)	Loss of consciousness, n (%)
Group 1 (MT[a]; n=50)	36 (72)	23 (46)	1 (2)	9 (18)
Group 2 (no MT; n=50)	38 (76)	13 (26)	3 (6)	2 (4)

[a]MT: mechanical thrombectomy.

Performance of AI Decision-Making

The decision-making process of the AI-based model was compared to the interdisciplinary consensus regarding MT. The specificity, sensitivity, and accuracy of the AI-based model were calculated based on the agreement with the expert consensus. The results showed that the AI had a specificity of 0.96, a sensitivity of 0.8, and an accuracy of 0.88 in comparison to the expert consensus (Table 2). The area under the curve for report-based MT decision was calculated to be 0.92, indicating good discrimination between the two treatment options (Table 3). The re-evaluation of 20% (20/50) of the cases showed a 100% (20/20) concordance between the results of the first and second LLM evaluations.

Table 3. Number of true positive, false negative, true negative, and false positive cases for two groups: group 1 (MT[a]) and group 2 (no MT).

Group	True positive, n	False negative, n	True negative, n	False positive, n
Group 1 (MT)	40	10	—[b]	—
Group 2 (no MT)	—	—	48	2

[a]MT: mechanical thrombectomy.

[b]Not applicable.

Discussion

This investigation assesses a new approach applying a text-processing AI model to the decision-making process for MT indication in IS, primarily based on the information from the radiology report. Descriptive information on the radiological findings, along with information on patients' neurological symptoms, symptom onset, and demographic data, were provided to the LLM to evaluate the possibility of MT.

This study compared the AI-based decision-making process with the clinical interdisciplinary consensus for MT. Although the accuracy was good, the specificity of the AI model was lower than the sensitivity, with a specificity of 96% and a sensitivity of 80%. The overall accuracy of the AI-based model was 88%, indicating a good discrimination between the two treatment options, with an area under the curve of 0.92 for the AI report–based MT decision.

One of the strengths of this study is the robust gold truth: the well-defined interdisciplinary performed expert consensus for or against MT. Additionally, all cases were evaluated based on radiographic findings, neurological diagnostic information, as well as demographic data on the patient [10]. The AI model used in this study was not specifically trained for this task of making a clinical decision, being rather a language processing algorithm that considers a large amount of human declarative and conceptual knowledge up until 2021.

However, there are several limitations to this study. First, only text-based information was included in the decision-making process, and descriptive statements can be inaccurate and lack quantitative precision. For example, the adjective "large" can have varying interpretations between individuals, which potentially can lead to misinterpretation of the decision and result in AI decision consequences. Second, as the LLM model only has knowledge up until 2021, newer guidelines and developments in the field are not considered [27]. Third, the basis of a decision made by a model is not deterministically understandable and post hoc traceable, which represents a fundamental "black-box" problem of decisions based on structures of deep neural networks [12]. Moreover, within LLM, there is no possibility to show sources and retrieve information about the source of a decision. Further, and this is a fact that may be attributed to the commercial structure of OpenAI's GPT-3, although the algorithm has been trained on vast amounts of text data, it remains unclear which data have been included or excluded [12,26,27,30]. In particular, the possibility that potentially older outdated information that would not have resulted in an MT indication and has been made available to the algorithm at an unspecified location for training purposes could lead to problems. Another limitation pertains to the fact that the algorithm can only consider general information for the MT decision, without considering individual factors about the individual health care facility or medical personnel. Factors such as (1) availability of material for MT, (2) personnel or time capacities, and (3) personal skills of the interventionist are not part of the MT decision [14]. Experimental settings and individual treatment attempts are not part of a potential LLM-based decision. Another limitation is that only text-based reports from one center in one language were included; further studies should include radiological findings from other centers with diverse linguistic styles and also other languages.

XSL•FO
RenderX

In particular, the described facts that current data and information, as well as the individual skills of the interventionalist, could be considered in the decision-making process may explain the lower sensitivity of the AI-based MT decision in relation to its specificity.

In summary, there are several reasons why AI should not make important medical decisions such as MT decisions on its own. Nonetheless, a decision-making algorithm based on the written radiology report can potentially be used to run in the background and alert to a potential MT indication. A potential application would be in the context of an augmenting system that "monitors" radiology reports of younger or inexperienced physicians in the background and alerts in specific cases so that an experienced colleague can be consulted for the final decision. This integration of augmented text-based AI could be especially useful in night shifts, as it has the potential to shorten the time from diagnosis to MT (door-to-needle time). In summary, this could lead to a sustainable improvement in patient care and apply to other areas beyond interventional neuroradiology.

Future studies should consider incorporating additionally other AI networks, such as deep learning–based image recognition networks, to make decisions based on more quantitative information, rather than just on declarative text information. This could provide more objective information, such as the amount of brain tissue that can be saved, which would help to further refine the decision-making process. In the context of further research, it would be preferable that the algorithm specifies the exact source or guideline on which the decision is based, highlighting the need for stable, finalized, and specifically tuned systems for particular tasks in clinical settings. For clinical use of text-based advanced assist for radiologists, quantitative and qualitative information about the AI training data used should be available. Additionally, future studies should also consider incorporating more recent information and developments in the field, as well as available MT devices and the experience of the treating interventionalist.

In conclusion, this study highlights within a first application the potential of LLMs for integrating text-based radiological information with other clinical data, which may be useful for augmented clinical decision-making. Further research should elucidate the limitations of such systems, particularly regarding the traceability of related training and reference data.

Abstract

Background: Artificial intelligence (AI) shows considerable promise in the areas of lymphoma diagnosis, prognosis, and gene prediction. However, a comprehensive assessment of potential biases and the clinical utility of AI models is still needed.

Objective: Our goal was to evaluate the biases of published studies using AI models for lymphoma histopathology and assess the clinical utility of comprehensive AI models for diagnosis or prognosis.

Methods: This study adhered to the Systematic Review Reporting Standards. A comprehensive literature search was conducted across PubMed, Cochrane Library, and Web of Science from their inception until August 30, 2024. The search criteria included the use of AI for prognosis involving human lymphoma tissue pathology images, diagnosis, gene mutation prediction, etc. The risk of bias was evaluated using the Prediction Model Risk of Bias Assessment Tool (PROBAST). Information for each AI model was systematically tabulated, and summary statistics were reported. The study is registered with PROSPERO (CRD42024537394) and follows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 reporting guidelines.

Results: The search identified 3565 records, with 41 articles ultimately meeting the inclusion criteria. A total of 41 AI models were included in the analysis, comprising 17 diagnostic models, 10 prognostic models, 2 models for detecting ectopic gene expression, and 12 additional models related to diagnosis. All studies exhibited a high or unclear risk of bias, primarily due to limited analysis and incomplete reporting of participant recruitment. Most high-risk models (10/41) predominantly assigned high-risk classifications to participants. Almost all the articles presented an unclear risk of bias in at least one domain, with the most frequent being participant selection (16/41) and statistical analysis (37/41). The primary reasons for this were insufficient analysis of participant recruitment and a lack of interpretability in outcome analyses. In the diagnostic models, the most frequently studied lymphoma subtypes were diffuse large B-cell lymphoma, follicular lymphoma, chronic lymphocytic leukemia, and mantle cell lymphoma, while in the prognostic models, the most common subtypes were diffuse large B-cell lymphoma, follicular lymphoma, chronic lymphocytic leukemia, and Hodgkin lymphoma. In the internal validation results of all models, the area under the receiver operating characteristic curve (AUC) ranged from 0.75 to 0.99 and accuracy ranged from 68.3% to 100%. In models with external validation results, the AUC ranged from 0.93 to 0.99.

Conclusions: From a methodological perspective, all models exhibited biases. The enhancement of the accuracy of AI models and the acceleration of their clinical translation hinge on several critical aspects. These include the comprehensive reporting of data sources, the diversity of datasets, the study design, the transparency and interpretability of AI models, the use of cross-validation and external validation, and adherence to regulatory guidance and standardized processes in the field of medical AI.

KEYWORDS

lymphoma; artificial intelligence; bias; histopathology; tumor; hematological; lymphatic disease; public health; pathologists; pathology; immunohistochemistry; diagnosis; prognosis

Introduction

Lymphoma, a malignancy that originates from the lymphohematopoietic system, is recognized as one of the most prevalent hematological cancers globally. Epidemiological studies indicate that Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL) are prevalent malignant lymphatic disorders that pose significant public health challenges. Data from GLOBOCAN 2020 reveal that the projected global incidence and mortality for HL are 83,087 and 23,376 cases, respectively, while for NHL, these figures stand at 544,352 and 259,793, respectively [1,2]. In China, lymphoma is a considerable public health challenge. Data from the Global Burden of Diseases (GBD), Injuries, and Risk Factors Study for 2019 reveal that the age-standardized incidence rate for HL is 0.57 cases per 100,000 individuals, with an age-standardized mortality rate of 0.15 per 100,000 individuals. For NHL, the age-standardized incidence rate is significantly higher at 4.99 per 100,000 individuals, and the age-standardized mortality rate is 2.32 per 100,000 individuals [3].

Histopathology, which involves examining tissue specimens at the cellular level, is the gold standard for the diagnosis of lymphomas [4]. The conventional diagnostic process typically involves pathologists using hematoxylin-eosin (HE) staining of tissues and immunophenotyping for diagnosis. For the diagnosis of high-grade B-cell lymphomas, fluorescence in situ hybridization (FISH) is also commonly employed in conjunction [5]. However, this method has several drawbacks, including subjectivity, time-consuming procedures, and high costs [6].

Traditionally, pathologists have relied on optical microscopes to analyze pathological tissue sections. However, the advent of digital pathology has seen a shift toward the use of computers for reviewing and analyzing scanned whole slide images (WSIs). This transition is not only driven by the potential for increased efficiency but also opens new avenues for the development of automated diagnostic tools [7]. These tools have the potential to enhance the accuracy, efficiency, objectivity, and consistency of diagnoses, which is crucial in addressing the global shortage of pathologists. They can also increase diagnostic throughput and reduce the reliance on referrals and additional tests [8]. This field of research is burgeoning, and for certain types of malignant tumors, these systems are beginning to demonstrate clinical utility [9]. However, although many research models of artificial intelligence (AI) applied to lymphoma histopathology have been published, it is unclear whether there are methodological biases in these models, and the clinical utility of AI applied to lymphoma histopathology has not been summarized.

In this extensive study, we systematically reviewed the literature exploring the use of AI technologies, including traditional machine learning (ML) and deep learning (DL) methods, to assess digital pathology images for lymphoma diagnosis, prognosis, and other pertinent applications. Our review encompasses research that focuses on individual diagnostic factors, such as histological subtypes, as well as studies that perform computer-assisted tasks like tumor segmentation. We also assessed the clinical utility of these AI methods with consideration of potential biases. The objective of this review is to provide valuable insights and actionable recommendations based on the existing body of literature. Thus, this review aims to provide insights and recommendations based on published literature to improve the clinical utility of future research, including reducing the risk of bias, improving reproducibility, and increasing generalizability.

Methods

Literature Search

A thorough search was conducted across 3 prominent research databases: PubMed, Cochrane, and Web of Science. The search was restricted to peer-reviewed journals and conference proceedings to ensure the quality and credibility of the studies included. The search timeline extended from the inception of each database up to August 30, 2024. We employed MeSH terms for more precise retrieval.

Given the multitude of terms related to AI, our search strategy incorporated keywords such as “artificial intelligence,” “machine learning,” “neural network,” and “network, neural (computer),” along with “lymphoma.” We combined multiple relevant terms for each concept using the OR operator (eg, “artificial intelligence” OR “machine learning”) and then merged “lymphoma” with “artificial intelligence” using the AND operator. This approach ensured that the retrieved studies met both criteria.

Subsequently, we screened the articles based on their relevance to histopathological AI, focusing on the title and abstract. The review protocol was registered on PROSPERO (CRD42024537394) prior to the screening of search results for inclusion. Detailed search strategies and methods are provided in Multimedia Appendix 1.

Literature Selection

A researcher (YF) manually removed duplicate papers with the assistance of the reference management software EndNote 20. Subsequently, another researcher (ZH) independently screened the articles for inclusion in 2 stages: the first based on titles and abstracts, and the second based on the full text. Disagreements were discussed and arbitrated by a third researcher (JL).

The inclusion criteria required the research to evaluate the use of at least one AI approach to make diagnostic or prognostic inferences on human histopathology images from suspected or confirmed cases of lymphoma. Studies were only included if AI methods were applied directly to the digital pathology images

XSL•FO
RenderX

or to features that were automatically extracted from the images. Fundamental tasks, such as segmentation and cell counting, were included as these could be used by pathologists for computer-aided diagnosis. Only conventional light microscopy images were considered, with other imaging modalities, such as fluorescence and hyperspectral imaging, excluded. Publications that did not include primary research, such as review papers, were excluded. Non-English language articles and research where a full version of the manuscript was not accessible were excluded.

In the studies included, models were deemed of interest if they adhered to the same inclusion criteria. When several models were compared against the same outcome, the model of interest was typically the newly proposed one. If this was ambiguous, the model with the best performance during the validation phase was selected. When multiple models from a single study exhibited similar modeling techniques, the one with superior validation performance was included in the assessment. Results from the same model at varying levels of precision (eg, patch level, slice level, and patient level) were not treated as distinct outcomes.

Risk of Bias Assessment

The risk of bias in the models of interest was assessed using the Prediction Model Risk of Bias Assessment Tool (PROBAST) [10]. The tool evaluates the likelihood that the reported results are distorted due to limitations in study design, conduct, and analysis. PROBAST includes 20 guiding questions categorized into 4 domains: Participants, Predictors, Outcomes, and Analysis. These questions are summarized to indicate a high risk or low risk of bias or are marked as unclear when insufficient information is available for a comprehensive assessment and no information is available to suggest a high risk of bias. It is important to note that an unclear risk of bias does not imply a methodological flaw but rather indicates incomplete reporting.

The Participants domain involves the recruitment and selection of participants to ensure the consistency and representativeness of the study population targeting the intended demographic. Relevant details include the recruitment strategy, inclusion criteria, and number of participants enrolled.

The Predictors domain addresses the consistent definition and measurement of predictive variables, which in this context often refers to the generation of digital pathology images. This encompasses methods for the fixation, staining, scanning, and digital processing of tissues prior to modeling.

The Outcomes domain involves the appropriate definition and consistent determination of ground truth labels. This includes the criteria used to ascertain diagnoses or prognoses, the expertise of those determining these labels, and whether the labels are independent of any model outputs.

The Analysis domain encompasses statistical considerations in the evaluation of model performance to ensure valid and not overly optimistic results. It includes various factors, such as the number of participants for each outcome in the test set, the validation methods used (cross-validation, external validation, internal validation, etc), the metrics for assessing performance, and the methods to address the impact of censoring, confounding, and missing data. Some of these factors are interrelated. For example, the risk of bias due to a small dataset is somewhat mitigated by cross-validation, which increases the effective size of the test set and can be used to assess variability, reducing the optimism of the results. Additionally, the risk associated with using a small dataset depends on the type of outcome being predicted; robust analysis for a 5-class classification requires more data than a binary classification. There must also be sufficient data across all relevant patient subgroups; for instance, if multiple subtypes of lymphomas are included, it is not acceptable for 1 subtype to be represented by only a few patients. Due to these interrelated factors, there are no rigid standards for determining the appropriate size of a dataset.

Inconsistencies in methodology often lead to bias risk. For example, inconsistencies in HE staining from different research centers can lead to heterogeneity in the visual characteristics of digital pathology slides, potentially causing spurious correlations through random or systematic differences within or between subgroups in the dataset. Using a large dataset during training may enhance the model's generalizability, but this must be tightly controlled to avoid introducing systematic confounding. Inconsistencies in the determination of outcomes may mean that the results of a study are unreliable due to spurious correlations in the underlying factual labels or invalid due to misjudgment of the labels.

While PROBAST provides a framework for assessing the risk of bias, there is a degree of subjectivity in interpreting the signal questions. Therefore, each model was analyzed by 2 independent researchers (YF and ZH), with at least one computer scientist and one pathologist involved in the bias risk assessment of each model.

The Quality Assessment of Diagnostic Accuracy Studies-AI (QUADAS-AI) tool was used to evaluate the sensitivity of the included studies. QUADAS-AI is the AI-specific extension of QUADAS-2 [11] and QUADAS-C [12], and includes 4 domains for determining the risk of bias (patient selection, reference standard, index test, and flow and timing) and 3 domains for applicability issues (index test, patient selection, and reference standard) (Multimedia Appendix 2).

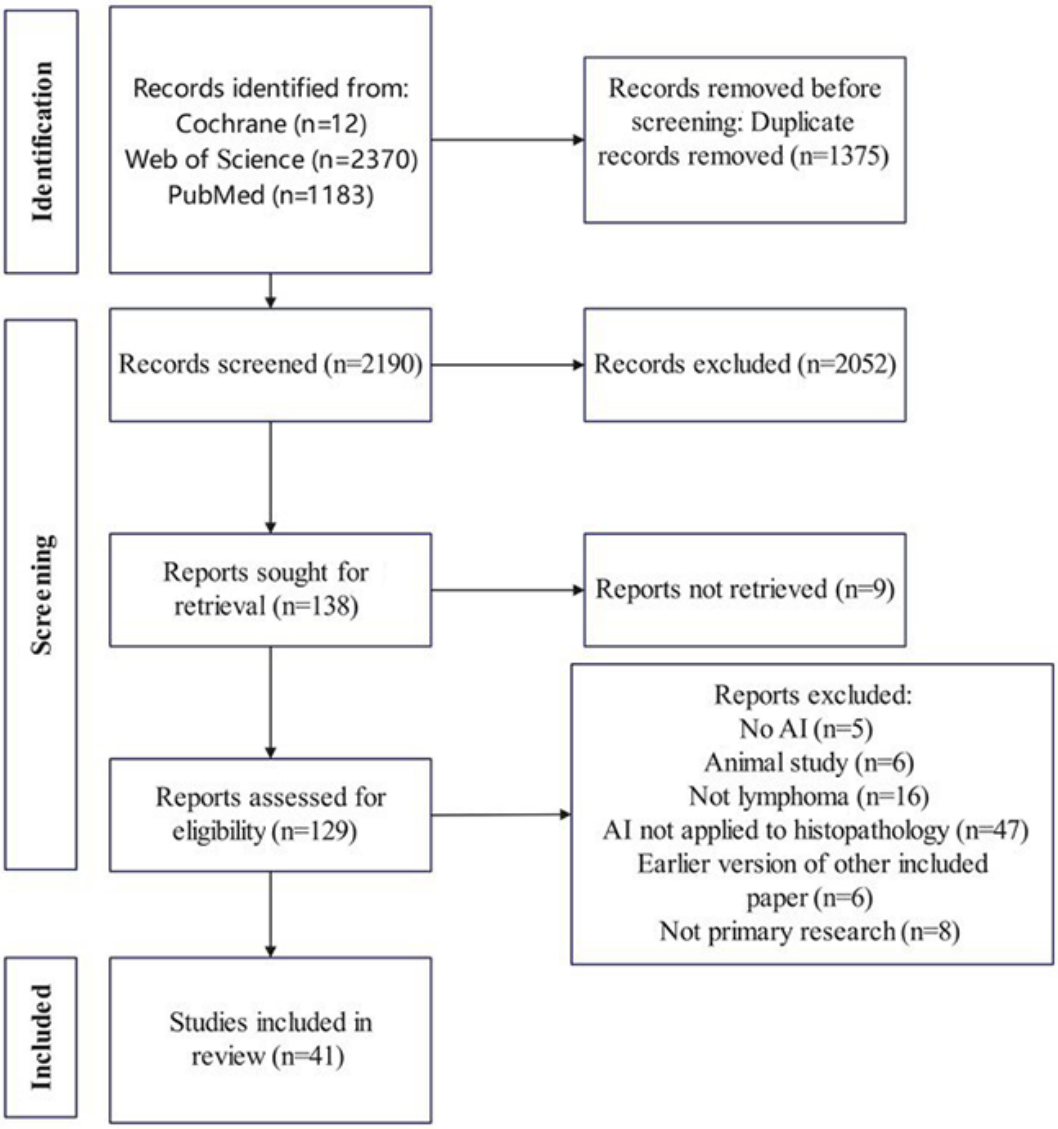
Data Synthesis

Data extraction was independently performed by 2 researchers (YF and MZ), using a form containing 67 fields within the categories Overview, Data, Methods, Results, and Miscellaneous. A summary of this process is provided in Multimedia Appendix 3.

Information was sought from full-text articles, as well as references and supplementary materials where appropriate. Inferences were made only when both researchers were confident that this gave the correct information, with disagreements resolved through discussion. Fields that could not be confidently completed were labeled as being unclear.

All extracted data were summarized in 2 tables, 1 each for study-level and model-level characteristics. Only models of interest were included in these tables. The term model outcome

XSL•FO
RenderX



refers to the model output (whether this was a clinical outcome [diagnosis or prognosis] or a diagnostically relevant outcome that could be used for computer-aided diagnosis, such as tumor segmentation). The data synthesis did not include any meta-analysis due to the diversity of the included methods and model outcomes. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines for reporting systematic reviews were followed, with checklists provided in Multimedia Appendix 3.

Results

Results of Literature Screening

As shown in Figure 1, the initial literature search identified a total of 3565 records, with 1375 being duplicates. After screening titles and abstracts, 2052 records were excluded, leaving 41 studies for inclusion in the review. All studies that met the inclusion criteria were identified through research databases, with no eligible records found in trial registries. Although the search was performed from 1949, all included studies were published since 2010, and more than 80% were published since 2020. The characteristics of these studies are summarized in Table 1. The model construction parameters of the 41 included studies are detailed in Table 2.

Risk of Bias Assessment

The PROBAST assessment findings are detailed in Table 3. Despite some studies encompassing multiple models of interest, each paper highlighted 1 model with superior predictive value for bias risk analysis. Most models exhibited either a high overall bias risk (13/41) or an unclear overall bias risk (28/41), with none of the models presenting a low overall bias risk (0/41). Most high-risk models predominantly allocated their high-risk scores in the Participants domain (10/41). Conversely, most low-risk scores were concentrated in the Predictors (26/41) and Outcomes (26/41) domains. Almost all studies reported an unclear risk of bias in at least one domain, with the Participants (16/41) and Statistical Analysis (37/41) domains being the most frequently affected. Qualitative summaries are presented in Figure 2.

Figure 2. Prediction Model Risk of Bias Assessment Tool (PROBAST) risk of bias.

Data Synthesis Results

Data in the Included Literature

The number of participants across internal datasets varied significantly, with studies recruiting anywhere from 10 to 1005 patients diagnosed with lymphoma. Concurrently, the model development used a broad range of histopathological slides (count: 10-15,353). In most studies, the samples for model development were WSIs involving excised or biopsied tissues (38/41), with other samples using microscopic images (3/41). Most studies used HE-stained tissues (37/41), while others employed various immunohistochemical (IHC) staining methods (4/41). Some studies employed a multimodal analysis method that integrated pathological images with clinical information [25,35,50].

Among the included studies, most (29/41) used single-center data and few (10/41) used multicenter data. A small number of studies had unclear data sources, and the United States was the most common (12/41) source country.

Models in the Included Literature

The studies encompassed a variety of models, with the most prevalent being convolutional neural networks (CNNs), accounting for 30 out of 41 studies. A minority of studies employed support vector machines (SVMs) and random forests (2 studies each). The CNN architectures that were explored included Mobile Net, VGG-16, Hover-Net, U-Net, and ResNet-50. These newer CNNs generally incorporated multiple standardized blocks that featured layers for convolution, normalization, activation, and pooling [23]. One study stood out by leveraging transfer learning and integrating 17 distinct DL models to create a highly accurate platform, achieving a diagnostic accuracy rate of 100% [21]. This approach significantly bolstered the model's ability to generalize. Another innovative study developed a novel architecture by applying a topological optimization method to the conventional VGG-16 model [26]. Some studies opted for a hybrid approach, combining traditional ML techniques with DL. They used CNNs for feature extraction, followed by decision tree–based methods for quantification and classification [24,26]. Notably, 1 study implemented a CNN framework grounded in Multiple Instance Learning (MIL), which autonomously concentrated on image patches from regions of interest within tumors, showcasing an advanced method for image analysis [32].

In the analysis encompassing various models, most studies predominantly used patches (33/41), with a subset operating at

XSL•FO
RenderX

the WSI level (6/41). Two distinct aggregation approaches were implemented: premodeling and postmodeling aggregation. The premodeling method necessitated the creation of slide-level features prior to modeling, whereas the postmodeling approach entailed consolidating patch-level model outputs to formulate slide-level predictions. For models that used patch images as the basis for final modeling, it was essential to segment the original images into individual patches before proceeding with modeling. The patch sizes varied from 40×40 to 2048×2048 pixels, with the most frequently employed dimensions being 224×224 pixels (9/41) and 256×256 pixels (5/41). Subsequently, a variety of feature extraction techniques were applied, encompassing both handcrafted or predefined features (27/41) and features that were automatically learned by the models (12/41).

The handcrafted features encompassed a diverse spectrum of attributes, including texture, color, cellular, and nuclear morphological characteristics. These meticulously crafted features were predominantly employed as inputs for traditional ML algorithms, such as SVM and random forest models.

In contrast, learned features were predominantly extracted through the application of CNNs, which also frequently served as the classifier of choice. Ultimately, the outputs from the patch-level models were synthesized to develop predictive models. This aggregation was achieved through various methods, such as attention-based weighted averaging, concatenation, and more sophisticated embedding techniques. These included Fisher vector encoding and k-means clustering, with the process often culminating in the selection of the maximum value to enhance the predictive accuracy of the models [36,62].

Among the papers that specified magnification levels, the most prevalent were 20× (10/41) and 40× (17/41). A handful of studies employed varying magnifications strategically to pinpoint informative tissue regions and to enhance their modeling accuracy [16,17,40].

A limited number of models integrated histopathological data with other data modalities [25,35,50]. The multimodal approaches observed in the literature included the premodeling integration of unimodal features extracted independently, as well as the amalgamation of unimodal predictions from distinct models [63]. Additionally, transformer-based methods were frequently employed for encoding the intricate relationships between different modalities [64,65]. While attention-based methods have been used in the study of other malignancies for several years [66], their application in lymphoma research is a relatively recent development. Among the studies reviewed, 1 study stood out by using a variant of the transformer architecture to encode the interplay between medical imaging data and clinical records. This study introduced a novel personalized attention mechanism (PersAM) for the classification of lymphoma subtypes, marking a significant advancement in the field [25].

Analysis in the Included Literature

Most studies relied on internal validation (30/41), while external validation using independent lymphoma datasets was seldom conducted (11/41). In terms of internal validation, partial validation was typically executed through a 5-10–fold cross-validation approach. Some papers detailed the hyperparameter selection process using the training dataset, yet only reported evaluations on a test set derived from the same data source [24,33,67]. For external validation, models were trained on WSIs and subsequently validated on either WSIs (10/11) or tissue microarrays (TMAs) (1/11) from separate independent sources. Notably, the model of 1 study was externally validated against data from normal lymph node tissues [14]. In a particular instance, a model that achieved perfect validation accuracy (area under the receiver operating characteristic curve [AUC]=1.0) with internal validation underperformed on external cases, with an AUC ranging from 0.63 to 0.69. This discrepancy may stem from the sensitivity of ML algorithms to preprocessing steps, and neural networks, in accordance with statistical principles, necessitate a representative sample to ensure reliable inductive reasoning [12]. In another study, a comprehensive evaluation was conducted using polynomial, SVM, random forest, and decision tree classifiers to assess the efficacy of the proposed method [30].

Most models were assessed using accuracy or AUC, as well as other metrics, including sensitivity, specificity, hazard ratio, and the C-index. Even when studies reported sensitivity and specificity, CIs were not reported. In the internal validation results of all models, the AUC ranged from 0.75 to 0.99 and accuracy ranged from 68.3% to 100%. In models with external validation results, the AUC ranged from 0.93 to 0.99.

The burgeoning demand for AI methods in health care is undeniable, yet the lack of interpretability remains a significant impediment to their clinical adoption [68,69]. Enhancing the interpretability of AI models is crucial for fostering trust among medical professionals in the future AI systems they will rely upon. In a thorough analysis of the studies included, it was observed that the majority of studies (20/41) undertook efforts to analyze the interpretability of their models, with a notable minority (8/20) delving into visual interpretability analysis of the histopathological images that significantly influenced the model's prognostic assessments. Several studies meticulously characterized the spatial distribution and interrelationships of typical cells, their nuclei, and the microenvironments within the regions of interest [24,32,36,42], thereby showcasing the interpretability of their AI systems. One study presented graphical features that were correlated with clinical prognostic information [38]. A handful of studies opted for traditional ML models, such as decision trees [26], which are inherently more transparent and align closely with human reasoning processes, thus facilitating a more intuitive understanding of the decision-making process.

Clinical Utility

Among the 41 models included, 17 were diagnostic models, 10 were prognostic models, 2 were models to detect gene translocation, and 12 were other prediction- and diagnosis-related information models. The tasks of these models included identification (8/41), classification (24/41), and segmentation (9/41).

XSL•FO
RenderX

In the field of AI-based diagnostic models for lymphoma histopathology, the most common subtypes included diffuse large B-cell lymphoma (DLBCL) (5/41), follicular lymphoma (FL) (8/41), chronic lymphocytic leukemia (CLL) (5/41), and mantle cell lymphoma (MCL) (8/41). Additionally, a small number of studies developed diagnostic models for Burkitt lymphoma, central nervous system lymphoma, high-grade lymphoma, HL, and T-cell lymphoma. A study using CNNs for cell segmentation of WSIs of NHL achieved an average diagnostic accuracy of 100%, 99.73%, and 99.20% for CLL, FL, and MCL, respectively [20]. Researchers have successfully harnessed the power of both DL and traditional ML to develop a diagnostic tool with remarkable accuracy rates ranging from 95% to 100% for identifying MCL, FL, and CLL. This cutting-edge approach involves the precise segmentation of cell nuclei and the meticulous measurement of key morphological features such as area, perimeter, eccentricity, and diameter [30].

In the realm of AI-based prognostic models for lymphoma histopathology, the most common subtypes include DLBCL (3/4), CLL (2/42), HL (2/41), and FL (2/41). Sereda et al [19] used DL-based cell detection on digital slides from patients with nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) to quantitatively assess the histological patterns of lymphocyte-predominant cells. They identified 6 key features of lymphocyte-predominant cell spatial patterns and achieved a high average precision in cell detection (mean 95.24%, SD 0.17%). Furthermore, they found a strong correlation between treatment response and the density and number of lymphocyte-predominant cells (P<.05). Several studies have identified independent prognostic factors for DLBCL and MCL by segmenting cell nuclei and calculating the geometric characteristics of each segmented nucleus [35,36]. Several studies [41-43] addressed the clinical challenge of large cell transformation in indolent B-cell lymphomas, such as FL and CLL. They trained a CNN to predict large cell transformation based on tumor cell morphology, including the small cell proportion, chromatin pattern, presence of distinct nucleoli, and proliferation index. The machine-generated quantifications demonstrated superior reproducibility compared to estimates made by pathologists and showed a stronger correlation with the outcome data. The precise assessment and evaluation of PD-L1 biomarkers are crucial for the targeted immunotherapy triage of cancer patients. Notably, Yan et al [48] developed an AI-based image analysis method that encompasses the detection, segmentation, and classification of PD-L1+ cells for the evaluation of PD-L1 expression in patients with DLBCL. This method has produced highly correlated quantitative results compared to the subjective assessments of pathologists. However, none of the prognostic models included T-cell lymphoma subtypes in the studies.

Regarding AI-based histopathological models for detecting gene translocations in lymphoma, 2 studies focused on DLBCL as the tumor type [39,56]. Their results showed that it is possible to predict MYC translocation based on morphology alone. This would allow simple and fast prescreening, saving about 34% of genetic testing using the current algorithm.

Overall, methodologically, all studies exhibited a high or unclear risk of bias, primarily due to limited analysis and incomplete reporting on participant recruitment. Most high-risk models (10/41) predominantly assigned high-risk classifications to participants. Almost all studies presented an unclear risk of bias in at least one domain, with the most frequent being participant selection (16/41) and statistical analysis (37/41). The primary reasons for this were insufficient analysis of participant recruitment and a lack of interpretability in outcome analyses. In the diagnostic models, the most frequently studied lymphoma subtypes were DLBCL, FL, CLL, and MCL, while in the prognostic models, the most common subtypes were DLBCL, FL, CLL, and HL. None of the prognostic models included T-cell lymphoma subtypes in the studies. In the internal validation results of all models, the AUC ranged from 0.75 to 0.99 and accuracy ranged from 68.3% to 100%. In models with external validation results, the AUC ranged from 0.93 to 0.99.

Sensitivity Analysis

To further evaluate the sensitivity of our conclusions, we conducted a sensitivity analysis by selecting diagnostic models from the literature we included and performing a QUADAS-AI diagnostic evaluation. The results are presented in Multimedia Appendix 4.

Our findings revealed that out of the 17 diagnostic models considered, 15 were rated as high-risk models and 2 were deemed unclear. Most high-risk models were classified as such primarily due to their use of nonpublic datasets (13/17). A minority of studies (2/17) were rated as high risk because they failed to provide a clear description of their data sources. Therefore, we used QUADAS-AI to evaluate the diagnostic models and concluded that all the methodologies included in the diagnostic models were biased.

To further assess the sensitivity of our conclusions, we considered that the distribution of lymphoma subtypes varies by region, which could potentially bias the results. Therefore, we only included studies from the United States, as it was the most common source country (12/41). We found that in the United States, the most common subtypes in AI-based diagnostic models for lymphoma histopathology were DLBCL (5/12), FL (2/12), and MCL (2/12). Regarding AI-based prognostic models for lymphoma histopathology, the most common subtypes were DLBCL (2/12), CLL (3/12), and FL (1/12). In the models for detecting gene translocations in lymphoma histopathology, 1 study focused on DLBCL. These findings are largely consistent with our previous conclusions.

Discussion

Current Status of AI in Lymphoma Assessment

AI has significantly enhanced the precision of lymphoma diagnostics by eliminating the subjectivity often associated with human observation [16,26]. For instance, a study by Achi et al [13] demonstrated the power of CNN in accurately distinguishing between various lymphoma subtypes. Their diagnostic model, designed for 4 distinct lymphoma categories (benign lymph nodes, DLBCL, Burkitt lymphoma, and small lymphocytic lymphoma), achieved an impressive 95% accuracy rate in image prediction. Notably, in a multicenter study [21], the diagnostic accuracy of AI for DLBCL reached 100%.

XSL•FO
RenderX

Moreover, AI provides invaluable insights into the tumor microenvironment, enabling the identification and quantification of image features that surpass simple density assessments. It delves into higher-order relationships and offers a quantitative evaluation of lymphocyte aggregation patterns and the complex interplay between tumor regions. Such capabilities are pivotal for advancing cancer clinical research and the development of new therapeutics [36,70].

However, methodologically, the risk assessments of the included studies in this review were all rated as high or unclear, primarily due to incomplete reporting, absence of detailed patient source information, and inadequate explanation of the predictors used. This highlights the need to expedite the clinical translation of AI in lymphoma diagnosis, ensuring that these advanced tools are rigorously validated and seamlessly integrated into clinical practice.

Frequently omitted details include the precise origin of patient data, the total number of patients involved, the quantity of samples or images used, and the techniques employed for tissue processing and digitization. Most studies reported data from single centers, and this scarcity may stem from AI researchers not dedicating sufficient effort to comprehend these images, whether for training purposes or external validation. Information about the predictors (histopathology images and their features) was generally better reported; however, there remains an absence or inadequacy of the detailing of certain critical aspects. For example, it is often unclear whether the investigators assessed the predictors without knowing the outcomes or whether all histopathology images were processed uniformly, which could have introduced bias. Moreover, some researchers rely on a limited dataset and analyze a single test data split without implementing methods to mitigate overfitting and model optimism, such as cross-validation or external validation. These limitations are prevalent in lymphoma AI research, resulting in weak validation and an elevated risk of bias within the models.

Code sharing is crucial for enhancing the reproducibility of research findings and mitigating the effects of incomplete reporting. However, in the review of 41 papers, only 9 included codes, and the data in the other studies were either incomplete or difficult to access. To foster better reproducibility, code repositories should provide comprehensive documentation. This should include instructions for setting up the environment, an overview of the code's functionality, guidance on how to produce results, and, of course, the code itself [14,17,21,26,38,44,46,48,58].

Several studies are dedicated to enhancing the interpretability of DL tools by employing existing methods. These include post hoc techniques and supervised ML models that interpret the outcomes after DL models have generated predictions [71,72]. In the realm of AI research focused on lymphoma, most current studies offer personalized interpretability for analysis. This includes visual attention heatmaps and traditional ML highlighting the spatial locations of key feature areas and their interrelationships. However, traditional ML, often crafted in partnership with domain experts, can provide greater interpretability as it relies on manually engineered features. Despite this advantage, the process of handcrafting features is inherently challenging and complex. It demands a substantial time commitment from pathologists or oncologists, who are responsible for developing these methods.

In recent years, there has been a notable increase in hybrid approaches that combine DL with handcrafted strategies. These methods might involve using DL algorithms for the preliminary detection of cells or elements, followed by the application of easily interpretable traditional ML techniques for making predictions. By doing so, they harness domain knowledge to ensure the biological interpretability of the approach [73].

Development of the Field

The domain of AI in lymphoma histopathology diagnosis and prognosis is experiencing rapid growth, with a notable surge in scholarly publications since 2019. Most of these studies have leveraged deep neural networks for automated feature extraction and classification. In contrast, a smaller subset of research has employed conventional ML algorithms [24,30,33,40]. Recent investigations have expanded their scope to encompass a wider array of diagnostic outcomes, such as identifying specific lymphoma subtypes [17,21], predicting prognosis [35,36], and detecting genetic translocations [39,56].

Despite advancements regarding the role of AI in lymphoma research, there has not been a noticeable trend toward larger datasets, either in the number of slides analyzed or the number of participants involved. While there is no indication that more recent studies have adopted stricter internal validation methods, there is a positive shift toward increased external validation. Prior to 2019, no studies incorporated external validation on lymphoma data; however, 10 recent publications have done this. Although these validations often involve limited data, their inclusion signifies a step forward in research methodology.

These external validations are essential for the practical application of AI models in clinical settings, as they must be robust enough to handle the visual diversity present in data from various sources. This diversity can fluctuate both between and within different data centers over time. As the field evolves, we expect to see an increase in studies that rigorously validate their models against larger, high-quality, independent datasets. This includes transparent reporting on patient recruitment and selection processes, histopathology slide preparation, and digitization techniques. Such practices will be instrumental in mitigating the biases, limited reproducibility, and restricted generalizability that currently plague much of the research in this domain.

In the realm of oncology, there has been a marked surge in the number of published multimodal research studies since 2019. Notably, this growth includes only a handful of studies focused on multimodal research in lymphoma. Histopathological examination of tissue sections continues to be the cornerstone for cancer diagnosis, yet even seasoned pathologists often seek support from biomarker assays to enhance diagnostic accuracy. Multimodal research, which amalgamates diverse data types, such as genomics, proteomics, transcriptomics, and clinical data, has been pivotal in steering the trajectory of cancer research. This approach not only consolidates information from various sources but also transforms it, offering novel insights

XSL•FO
RenderX

[74,75]. For instance, a multimodal framework can facilitate a dual-modality analysis where a pathological image is processed to yield outputs from another domain, such as genetic sequencing or different imaging formats [63]. Such a model, when adeptly trained, can be leveraged to analyze pathological images from patients without overt medical conditions, extracting valuable indicators pertinent to precision medicine, including genetic sequences. As we anticipate advancements in high-throughput technologies, alongside the fields of transcriptomics, metabolomics, and proteomics, the future holds promise for an increase in the integration of multidimensional omics data with histopathological images in multimodal analyses.

This integration is poised to significantly bolster the clinical utility of AI, enabling more precise and personalized treatment strategies in oncology. By harnessing the power of multimodal research, we can expect a future where AI plays an even more integral role in clinical decision-making, thereby enhancing patient outcomes.

Current Limitations and Future Recommendations

A considerable amount of published research lacks the necessary clinical and pathological details to evaluate potential biases effectively. As a result, it is imperative for AI researchers to meticulously document the origins of their data. This transparency is crucial for understanding the variability within the dataset and for determining whether this diversity has been adequately addressed in the research methodology. Additionally, the modeling and analytical techniques employed must be thoroughly described to ensure the reliability and reproducibility of the findings.

To further improve reproducibility, we recommend that researchers provide code and data whenever possible. Digital pathology studies on lymphoma are currently constrained by the lack of publicly available data. Furthermore, WSIs from different centers can lead to significant heterogeneity in image data due to differences in scanning equipment across various centers. This variability can introduce confounding factors that complicate the task of developing robust AI models and assessing their generalizability. Such limitations can increase the risk of bias and confusion in research findings.

To mitigate these issues, during the image preprocessing stage, it is essential to diligently address and eliminate confounding factors arising from variations in staining, the presence of bubbles, and other artifacts. This meticulous attention to detail will enhance the accuracy and reliability of AI-driven diagnostic and analytical tools.

For AI to be clinically valuable, rigorous validation is paramount, particularly considering the constraints inherent in existing datasets. We recommend that researchers employ comprehensive analytical methods, such as cross-validation and external validation, to substantiate the robustness of their findings and the capacity of their models to extend to new datasets. Moreover, it is essential to report CIs for results, with a focus on the 95% CI, especially when comparing various models. This practice aids in discerning whether observed differences in model performance are genuinely significant or merely a product of random variation. By doing so, researchers can make more informed decisions about the efficacy and reliability of different AI models in clinical settings.

Researchers are recommended to follow regulatory guidance and standardized processes in the field of medical AI, such as reporting guidelines and quality assessment tools, such as QUADAS-AI, which provide a specific framework for assessing the risk of bias and the applicability of studies of diagnostic test accuracy in AI centers.

Moreover, a lack of interpretability is a barrier to the clinical adoption of AI. Therefore, we recommend that researchers strive to demonstrate the interpretability of their models to enhance the understanding and trust of clinical and pathological professionals.

Lymphoma is a diverse type of blood cancer that includes a variety of subtypes. From the literature we have reviewed, the current application of AI in lymphoma histopathology has primarily been focused on the diagnosis and prognosis of B-cell lymphoma. There are relatively fewer AI models for HL or T-cell lymphoma and other rare subtypes. This could be attributed to the higher incidence of B-cell lymphomas compared to other subtypes [1,2]. However, given the high aggressiveness and heterogeneity of T-cell lymphoma and HL [76], we hope that in future model development, more researchers will develop AI models for T-cell lymphoma and HL from a multidimensional clinical perspective.

Conclusion

Methodologically, the diagnostic and prognostic models of AI applied to lymphoma histopathology were evaluated, and the models were found to be biased. The enhancement of the accuracy of AI models and the acceleration of their clinical translation hinge on several critical aspects. These include the comprehensive reporting of data sources, the diversity of datasets, the study design, the transparency and interpretability of AI models, the use of cross-validation and external validation, and adherence to regulatory guidance and standardized processes in the field of medical AI.

Abstract

Background: The rapid evolution of artificial intelligence (AI) presents transformative potential for diagnostic medicine, offering opportunities to enhance diagnostic accuracy, reduce costs, and improve patient outcomes.

Objective: This study aimed to assess the expected future impact of AI on diagnostic medicine by comparing global researchers' expectations using 2 cross-sectional surveys.

Methods: The surveys were conducted in September 2020 and February 2023. Each survey captured a 10-year projection horizon, gathering insights from >3700 researchers with expertise in AI and diagnostic medicine from all over the world. The survey sought to understand the perceived benefits, integration challenges, and evolving attitudes toward AI use in diagnostic settings.

Results: Results indicated a strong expectation among researchers that AI will substantially influence diagnostic medicine within the next decade. Key anticipated benefits include enhanced diagnostic reliability, reduced screening costs, improved patient care, and decreased physician workload, addressing the growing demand for diagnostic services outpacing the supply of medical professionals. Specifically, x-ray diagnosis, heart rhythm interpretation, and skin malignancy detection were identified as the diagnostic tools most likely to be integrated with AI technologies due to their maturity and existing AI applications. The surveys highlighted the growing optimism regarding AI's ability to transform traditional diagnostic pathways and enhance clinical decision-making processes. Furthermore, the study identified barriers to the integration of AI in diagnostic medicine. The primary challenges cited were the difficulties of embedding AI within existing clinical workflows, ethical and regulatory concerns, and data privacy issues. Respondents emphasized uncertainties around legal responsibility and accountability for AI-supported clinical decisions, data protection challenges, and the need for robust regulatory frameworks to ensure safe AI deployment. Ethical concerns, particularly those related to algorithmic transparency and bias, were noted as increasingly critical, reflecting a heightened awareness of the potential risks associated with AI adoption in clinical settings. Differences between the 2 survey waves indicated a growing focus on ethical and regulatory issues, suggesting an evolving recognition of these challenges over time.

XSL•FO
RenderX

Conclusions: Despite these barriers, there was notable consistency in researchers' expectations across the 2 survey periods, indicating a stable and sustained outlook on AI's transformative potential in diagnostic medicine. The findings show the need for interdisciplinary collaboration among clinicians, AI developers, and regulators to address ethical and practical challenges while maximizing AI's benefits. This study offers insights into the projected trajectory of AI in diagnostic medicine, guiding stakeholders, including health care providers, policy makers, and technology developers, on navigating the opportunities and challenges of AI integration.

KEYWORDS

artificial intelligence; AI; diagnostic medicine; survey research; researcher opinion; future

Introduction

Background

Artificial intelligence (AI) is a broad term that covers various technologies such as machine learning, natural language processing, neural networks, and specialized rule-based systems [1,2]. It has emerged as a new paradigm in health care [3-7], with applications in disease risk assessment, treatment outcomes prediction, medical complication prevention or mitigation, clinical research, drug development, and patient care [8]. The AI market in health care is expanding rapidly, with a market size of US $26.69 billion in 2024 and projected to grow to approximately US $613.81 billion by 2034 [9]. In the United States alone, the Food and Drug Administration received <500 submissions between 2016 and 2022 [10].

Specifically, AI is expected to promote major changes in diagnostic medicine [4,11-13]. This branch of medicine focuses on identifying diseases and medical conditions by evaluating symptoms, physical signs, and test results [14,15]. Expected benefits of adopting AI include more reliable diagnoses, reduced screening costs, improved health care access, and reduced physician workload [13,16-18]. AI's ability to analyze large datasets quickly and accurately can also facilitate early detection of diseases [19-21] and support personalized treatment decisions [22], offering opportunities to improve patient outcomes significantly [23]. In addition, AI-driven tools can assist in managing diagnostic workflows by automating routine tasks [23,24], allowing physicians to focus on more complex cases. These benefits are especially desirable as the demand for imaging diagnoses has been rising faster than the supply of physicians for decades [3,11,17].

However, several factors can influence the direction and speed of changes in diagnostic medicine. Among these, one such factor is ethical and regulatory issues, which include difficulties in accessing and sharing databases with patient information [1,19], data validation and auditing [20-22], uncertainties about legal liability for the use of algorithms [23-25], and bias of algorithmic underrepresentation [20,26]. Technical challenges, such as the integration of AI systems into existing health care infrastructure [27] and the need for ongoing training of AI models to adapt to new medical knowledge [28], also pose significant hurdles. In addition, the lack of standardization in AI development and deployment can lead to inconsistent performance across different clinical settings [29,30]. All these factors mean that the future of AI use in diagnostic medicine is still quite uncertain, despite its potential.

Objectives

What, then, is the future of AI use in diagnostic medicine? This study aimed to anticipate future possibilities of AI use in diagnostic medicine, comparing researchers' expectations over time. For this purpose, we conducted 2 global cross-sectional surveys with authors of recent scientific publications on AI and diagnostic medicine, indexed in the Web of Science (WoS) Core Collection database. Some previous studies provided literature reviews to anticipate expected changes in health care using AI [1,3,8,12,18,27,28,31-36]. More specific studies on AI applications in diagnostic medicine focused on specific diagnostic tools, such as medical imaging [29], electrocardiograms [30], or cancer classification [37]. However, none of them comprehensively addressed aspects related to the future use of AI in diagnostic medicine and attempted to follow up on possible changes in the expected future. Our study addresses this gap by surveying the opinions of >3000 researchers worldwide at 2 different moments, in September 2020 and February 2023, with 28 months in between. A similar approach has been adopted in other studies to assess changes in attitudes or perceptions over time [38-41]. The survey participants shared their expectations on aspects related to (1) the probability of occurrence of events pointed out by the scientific literature, (2) the integration between AI and various types of diagnostic instruments, and (3) the main barriers to the use of AI in diagnostic medicine.

This study provides a unique perspective on the expected changes in diagnostic medicine due to the integration of AI and diagnostic medicine. Our findings may help health care providers and policy makers make informed decisions on integrating AI into clinical practice. In addition, our study may interest those investing in research and development and those expected to apply AI technologies in diagnostic medicine.

Methods

Literature Review

A literature review was conducted to explore the challenges and opportunities of AI applications in diagnostic medicine and build the questionnaire. We searched for recent articles, editorials, and reviews on this topic in WoS-indexed journals. The publications were identified using the search strategy provided in Textbox 1.

XSL•FO
RenderX

Textbox 1. The search strategy used to identify publications in Web of Science (WoS)–indexed journals.

TS=("Artificial intelligence" OR "Computational Intelligence" OR "Machine Intelligence" OR "Computer Reasoning" OR AI OR "Computer Vision System*") AND TS=(future* OR foresight* OR forthcoming* OR prospective* OR imminent*) AND TS=(diagnostics OR medicine OR "clinical practice")

AND LANGUAGE: (English) AND DOCUMENT TYPES: (Article OR Editorial Material OR Review)

Indexes: SCI-Expanded; timespan: 2015 to 2020

The search strategy combined thesaurus terms related to AI, medical diagnosis obtained from the Medical Subject Headings (MeSH) of the US National Library of Medicine, as well as free-text words for terms related to the future. In the WoS advanced search mode, we used the tag topic to search for those terms in the titles, abstracts, and keywords of articles, editorial materials, and reviews published between 2015 and May 2020 and indexed in the Science Citation Index (SCI)-Expanded. The SCI-Expanded was used to retrieve documents published in journals of sciences, and the period was set to obtain recent information on applications of AI in diagnostic medicine.

The search was conducted in May 2020 and recovered 536 publication records, imported in plain text format to the data- and text-mining software VantagePoint (version 11.0; Search Technology Inc). After reading their titles and abstracts, we selected 65 publication records for further analysis. These records were then imported into the software Citavi (version 6.1; Swiss Academic Software GmbH), where we read the texts fully and managed the references. Of these 65 publications, we selected 27 (41%) that formed the basis of the literature review and the survey questionnaire [1-3,5,8,11,16-18,20,23,29,33-35,42-52]. As the questionnaire's content could not be changed to allow for comparing the results from both waves, we did not update the literature review.

Survey Design

We followed the Checklist for Reporting Results of Internet E-Surveys [53], and the detailed checklist is provided in Multimedia Appendix 1. The questionnaire considered a horizon of 10 years and was divided into 6 parts. The first part introduced the study's aim, data collection and treatment procedures, anonymity and confidentiality guarantees, voluntary participation conditions, and informed consent. The second part asked about the respondents' knowledge regarding diagnostic medicine. Only those who reported having good or some knowledge qualified for the survey. Those who reported no knowledge were disqualified and excluded from the survey; hence, they were prevented from proceeding further with the main questionnaire. The third part asked about the respondents' expectations of AI's impact on diagnostic medicine in terms of (1) radical changes, (2) future outcomes (eg, reducing physicians' workload), and (3) integration with diagnostic instruments (eg, interpreting brain magnetic resonance imaging). The fourth part asked about the general barriers to using AI in diagnostic medicine. The respondents had to choose 1 of the 4 options as the most important barrier (eg, the difficulty of incorporation into clinical practice). On the basis of their choice, they were directed to a question about specific barriers within that category, where they had to select one as the most important barrier (eg, conflicts between AI and other clinical strategies). The bibliographic references for each question in these parts of the questionnaire are listed in Multimedia Appendix 2.

The fifth and sixth parts were optional and complementary to the questionnaire as they were not part of the survey's core. Thus, the data collected were not considered when calculating the number of fully completed questionnaires. The fifth part was an open-ended question where respondents could provide new information about the use of AI in diagnostic medicine or submit comments on the survey. The last part consisted of 5 demographic questions. As the results of this type of study were not influenced by the respondents' demographics [54-57], these questions were included to provide an overview of respondents' academic degrees, professional occupations, institutional affiliation, professional experience, and the region where they live. The questionnaire consisted of 10 pages.

Respondent Recruitment

Respondent recruitment followed a detailed and systematic process. The first wave (W1) and second wave (W2) respondents were authors of articles or review articles related to AI and diagnostic medicine published in peer-reviewed journals indexed in WoS's SCI-Expanded between January 1, 2015, and September 20, 2020 (W1), and between September 21, 2020, and December 30, 2022 (W2). To identify the participants, we used the query provided in Textbox 2 using the WoS advanced search mode.

Textbox 2. The query used to identify participants using Web of Science advanced search mode.

TS=("Artificial intelligence" OR "Computational Intelligence" OR "Machine Intelligence" OR "Computer Reasoning" OR AI OR "Computer Vision System*") AND TS=(Diagnos* OR Medicine OR Medical OR Ultrasound* OR Ultrasonograph* OR "Ultrasonic Diagnos*" OR Echotomograph* OR Echograph* OR "Radionuclide Imaging" OR "Radioisotope Scanning" OR radiograph* OR Roentgenograph* OR "X-ray")

Refined by DOCUMENT TYPES: (ARTICLE OR REVIEW)

Indexes: SCI-Expanded

The query was designed to capture a broad range of AI applications in diagnostic medicine. The thesaurus terms related to AI and diagnostic medicine were collected in MeSH. The query was set to retrieve recently published peer-reviewed articles and review articles. In W1, conducted in September 2020, we retrieved 15,084 publication records. These records were processed using the VantagePoint software to extract 23,053 authors' emails. The extracted emails were compiled

XSL•FO
RenderX

into a CSV file containing the authors' names, emails, and titles of their respective articles. An in-house Python (Python Software Foundation) script was used to cross-check and link 80.11% (18,469/23,053) of the extracted emails to their respective authors, enabling a more personalized approach to sending the survey invitations.

Similarly, in W2, conducted in December 2022, we retrieved 35,146 publication records, leading to 65,149 author emails. We linked 80.03% (52,138/65,149) of the emails to their respective authors using the same process. This consistent approach ensured the recruitment of a wide-reaching and diverse sample of respondents. The use of personalized invitations, sent directly to authors, aimed to enhance the engagement and response rate. The recruitment process was systematic and designed to ensure the survey's reach across key stakeholders in the AI and diagnostic medicine fields. The procedures used were similar to those of other studies using the same method [39,54,56-60], especially those with 2 survey waves [38]. A summarized and visual representation of this process of recruiting respondents is provided in Multimedia Appendix 3.

In choosing this methodological approach, we aimed to capture the rapidly evolving landscape of AI in diagnostic medicine. The decision to conduct 2 waves of surveys with different cohorts was driven by the need to reflect the dynamic nature of this field. AI technologies and their applications in medicine are advancing at a fast pace, and by expanding the cohort in W2, we sought to provide a broader and more current perspective on these developments. This approach allowed us to present a comprehensive understanding of the trends, challenges, and expectations within the AI and diagnostic medicine community over time.

The inclusion of respondents from engineering and computer science backgrounds was intentional, reflecting the interdisciplinary nature of AI development and its application in diagnostic medicine. The integration of AI into clinical practice is not solely a clinical challenge but also a technological one [34]. Engineers and computer scientists play a crucial role in advancing the algorithms and systems that underpin AI applications in diagnostics. Their insights into technological feasibility, innovation potential, and future directions are invaluable for understanding how these tools might evolve and impact clinical practice. Thus, their contributions are essential to forming a well-rounded perspective on the future of AI use in diagnostic medicine.

Data Collection Procedures

The list of respondents was imported into the web-based survey platform SurveyMonkey (SurveyMonkey Inc), where the questionnaire was designed and the survey was conducted. After uploading the list of respondents, the number of emails was reduced due to bounced emails and opted-out respondents (people who previously chose not to participate in surveys conducted via SurveyMonkey). In W1, the final number was 20,952, whereas in W2, it was 56,480. The personalized email invitations included a direct link to the questionnaire, inviting participants to take part in the survey. The email outlined the purpose of the study, its importance, and instructions for accessing and completing the survey. To encourage participation and improve response rates, reminder emails were sent to nonrespondents every 2 days for a period of 1 week, totaling a maximum of 3 reminders in addition to the invitation to nonrespondents.

In W1, before the formal study, the questionnaire was validated through a pilot study with a random sample of 2000 researchers (2000/20,952, 9.55% of the total emails). In this phase, we evaluated the questionnaire (ie, application routine, consistency, internal logic, completion rate, and response time) and collected feedback from respondents. Of 2000 researchers, 91 (4.55%) who participated in the pilot study did not suggest any changes in the questionnaire. Thus, neither the questionnaire nor the application routine was modified, and the data collected were added to the study results. Following this validation, the full survey was launched to the remaining sample (18,952/20,000, 94.76%), using the same recruitment process for both waves. In W1, the pilot and the formal study were conducted in September 2020. The formal study of W2 was conducted between January and February 2023. To maintain data integrity, each email address was restricted to submitting only 1 response. The SurveyMonkey platform automatically prevented duplicate entries by tracking responses based on individual email addresses. No randomization of questionnaire items was used.

Ethical Considerations

The questionnaire, invitation, and reminder emails informed the respondents about the survey. Before answering the questionnaire, they were informed that the survey was being conducted for research purposes only, personal or sensitive data would not be collected, answers would not be identified in the results, participation would be voluntary, and informed consent would be provided by answering the questionnaire. Thus, all respondents who participated in this survey gave us their informed consent to use the data collected. Given the voluntary participation, anonymity in the results, and absence of sensitive or personal questions, an examination by an ethics committee was not necessary. This study followed the guidelines set forth by Brazilian Resolution 510 of April 7, 2016 (Official Federal Gazette [61]), which provides an exemption from ethics committee registration and evaluation for public opinion research with unidentified participants. In addition, the study data were anonymous, and there was no compensation for the respondents. Again, these procedures followed previous studies that used the same method [39,54,56-60].

Statistical Analysis of the Sample

We used the nonparametric marginal homogeneity test at a 5% significance level to compare the responses obtained in both waves and assess any changes in respondents' expectations over time. This test is typically used to compare nominal data from 2 related samples and determine whether there is a significant difference between their proportions, particularly when the data are not normally distributed [62,63]. It is commonly applied in before-and-after studies [64,65].

In addition to analyzing the differences between W1 and W2 responses, we evaluated the differences between the responses of the 2 knowledge groups (ie, good and some knowledge) for each wave. We used the Mann-Whitney *U* test to identify

XSL•FO
RenderX

whether the level of knowledge interfered with the results. The Mann-Whitney *U* test is a nonparametric statistical test applied when data are not normally distributed [63]. It is commonly used to compare 2 independent groups and determine whether there is a statistically significant difference between them [66]. The test is often applied in cross-sectional research studies [67-69].

Out of the 25 questions presented to the respondents, only 1 (4%) revealed a statistical difference between W1 and W2 by the marginal homogeneity test results. In 2022, the respondents anticipated that AI would be used to interpret heart rhythm and provide improved outcomes in a shorter period than expected in 2020. The results of the tests are reported in Multimedia Appendix 4.

The results of the Mann-Whitney *U* test indicated that there was no statistical difference between most of the responses from the good and some knowledge groups. Only 30% (9/30) of the W1 questions and 10% (3/30) of the W2 questions displayed significant variations between the 2 groups. Hence, we opted to present the aggregated results. The responses categorized by knowledge level are provided in Multimedia Appendix 4.

Results

Table 1 presents an overview of the survey details, including response rates, completed questionnaires, confidence level, margin of error, and the demographics of respondents in W1 and W2. The respondents had a high level of education, with >80% (1039/1245) having a doctoral degree, and the most common occupation was professor or researcher (W1: 901/1039, 72.1% and W2: 1395/2097, 66.5%). Most respondents worked at universities or research organizations (W1: 1007/1251, 80.3% and W2: 1607/2095, 76.7%) and had a varied range of experience, with approximately 30% (383/1249) having 10 to 20 years and 25% (345/1249) to almost 30% (664/2097) having >20 years of experience in both waves. The most common regions of residence were Europe (W1: 458/1251, 36.6% and W2: 849/2099, 40.5%), Asia (W1: 367/1251, 29.3% and W2: 640/2099, 30.5%), and North America (W1: 258/1251, 20.6% and W2: 350/2099, 16.7%).

In addition to the demographic questions, we mapped the publication profile of both participants and nonparticipants of the survey through the metadata of their article records collected in WoS. The results are provided in Multimedia Appendix 5, and it shows that the survey participants and nonparticipants are similar concerning the research areas whose publications have been indexed.

We first asked the respondents about their general expectations of AI's potential to change diagnostic medicine radically in the future. Most respondents (W1: 965/1410, 68.5% and W2: 1555/2324, 66.9%) anticipated that this would happen within 10 years, while a smaller proportion (W1: 420/1410, 29.7% and W2: 706/2324, 30.1%) expected this to take longer. A minor percentage (W1: 25/1410, 1.8% and W2: 63/2324, 2.7%) believed that such a radical change was unlikely.

The respondents' expectations of 7 future events resulting from using AI in diagnostic medicine are depicted in Figure 1. Reduction of patients' hospitalization time (<50% in both waves) and improvement in treatment compliance (>50% in both waves) received the lowest percentages of likely before 10 years in both waves. Most respondents expected a lower screening cost (W1: 942/1360, 69.3% and W2: 1514/2243, 67.6%) and a higher diagnosis reliability (W1: 926/1362, 68% and W2: 1479/2244, 66%) within 10 years. The latter was also the most agreed-upon event, with only approximately 3% (37/1362) of respondents considering its occurrence unlikely. Improvements in treatment compliance and reduction in patients' hospitalization received the highest percentages of unlikely in both waves.

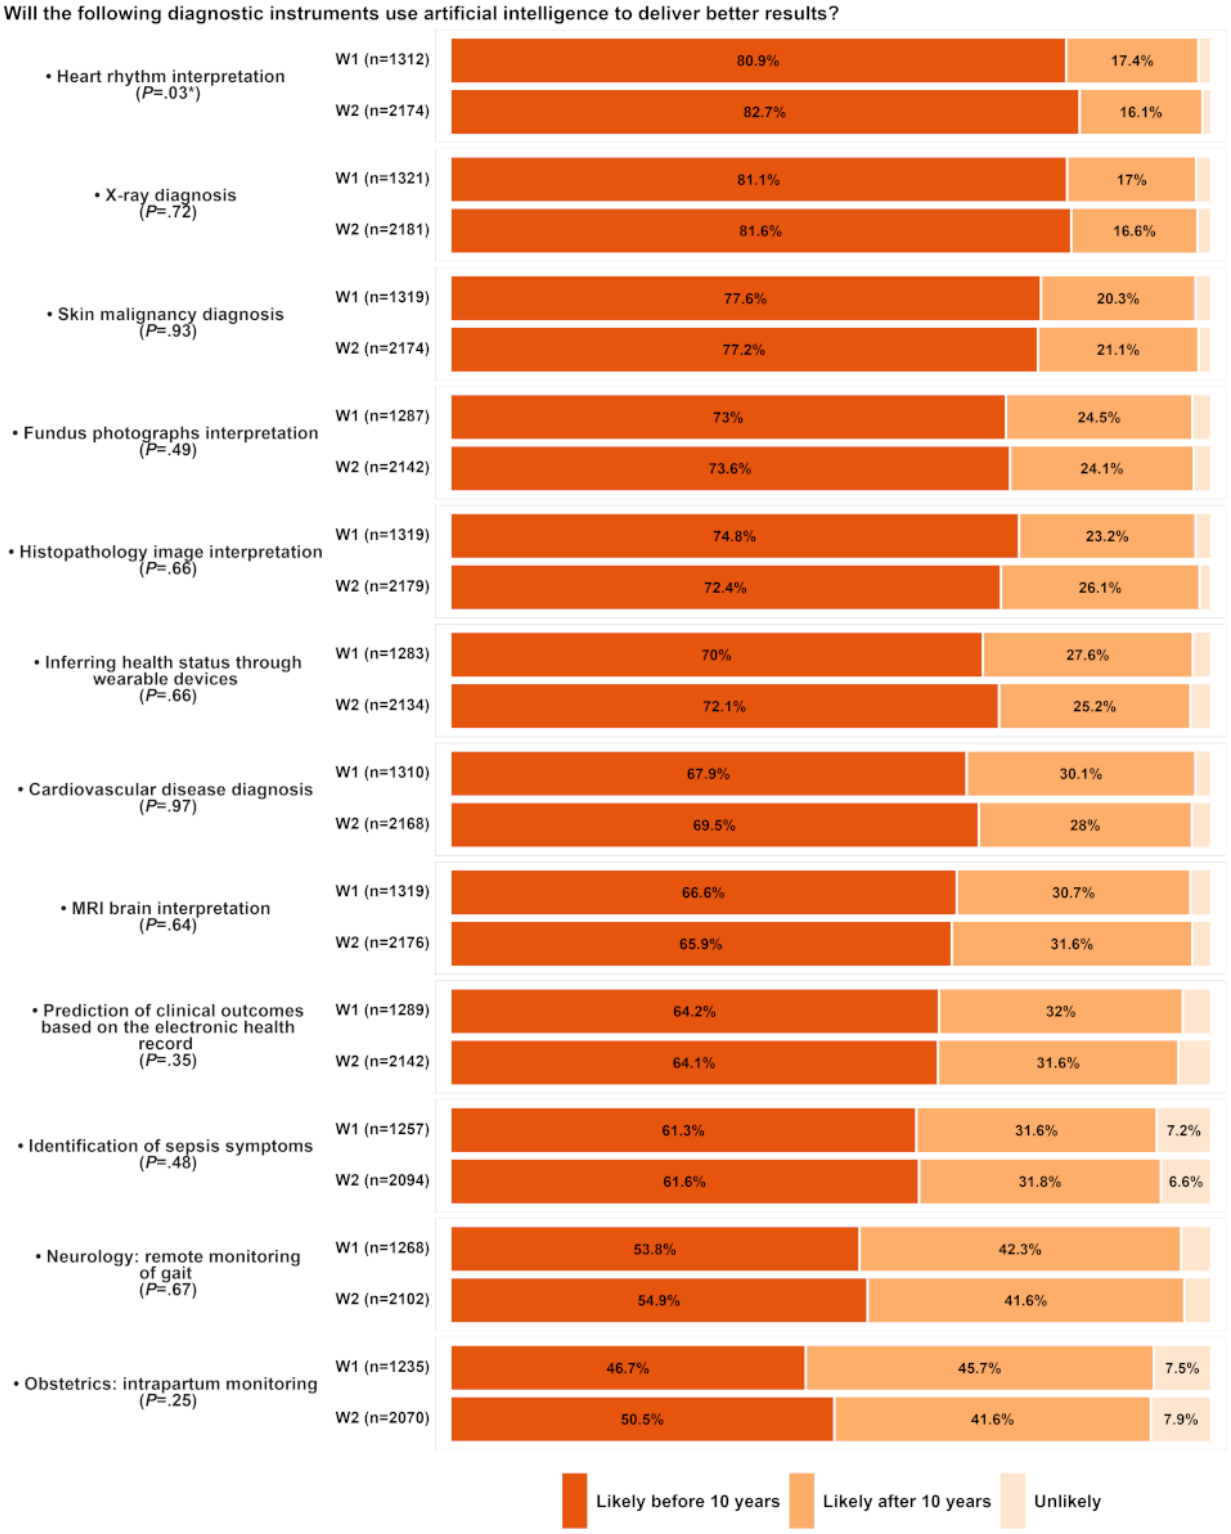
Figure 1. The likelihood of expected future events from artificial intelligence use in diagnostic medicine based on 2 global surveys: wave 1 (WI) in September 2020 and wave 2 (W2) in February 2023. Responses showed the expected impact on screening costs, diagnostic reliability, disease prediction, physician workload, access to care, treatment compliance, and hospitalization time, categorized as likely before 10 years, after 10 years, or unlikely. *P* value refers to the marginal homogeneity test.

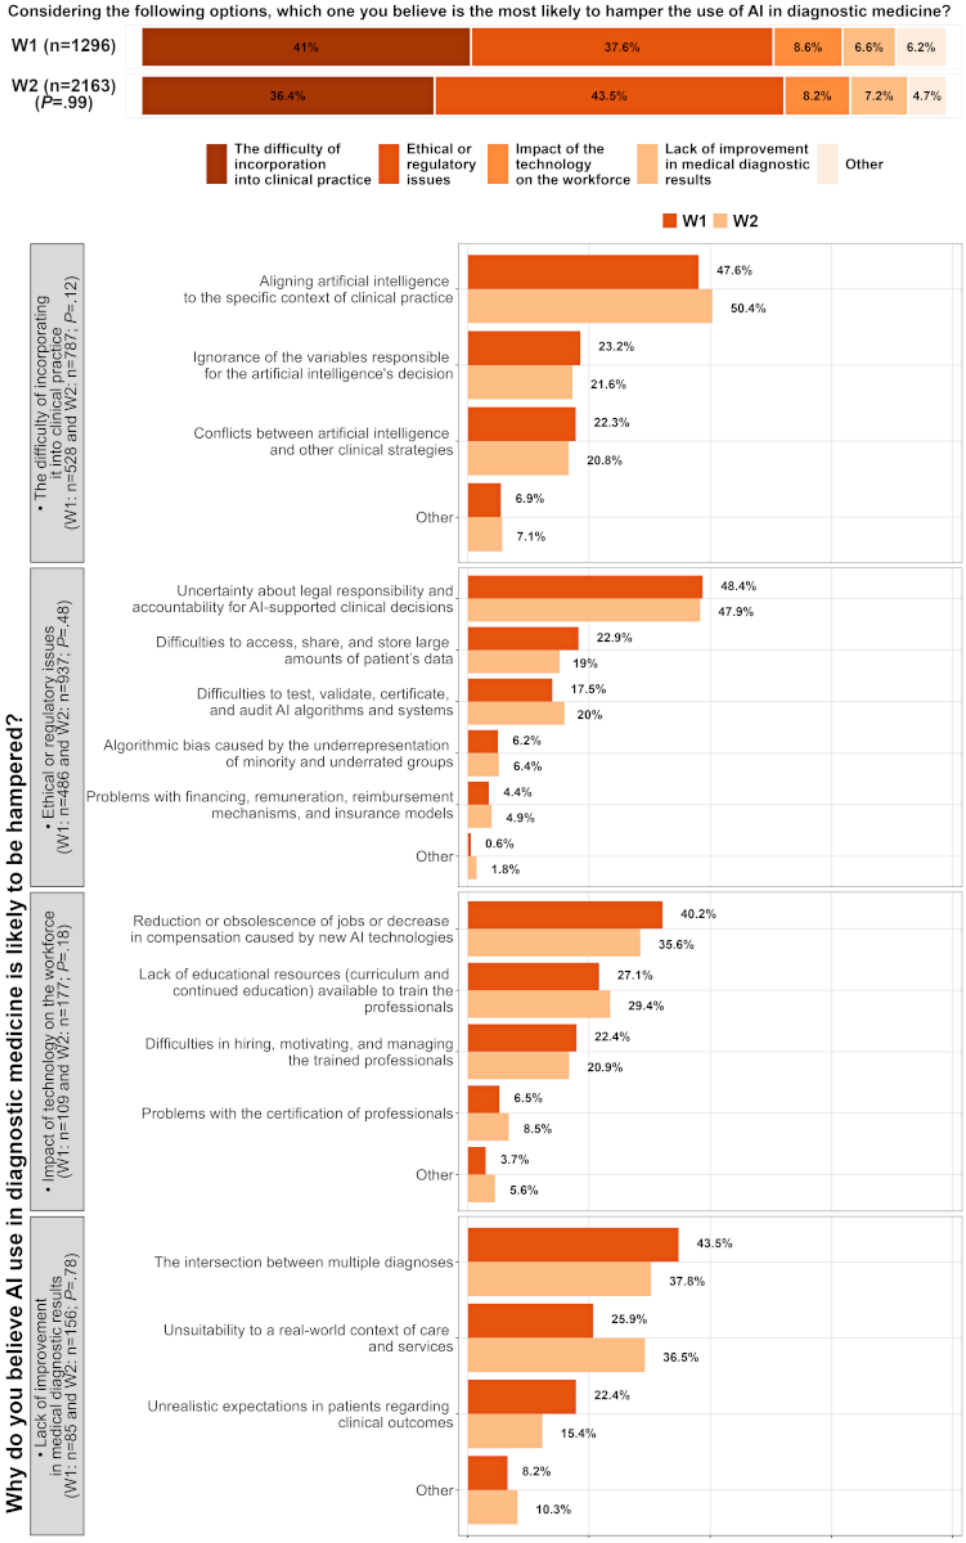
The respondents' expectations of integrating AI and 12 selected diagnostic instruments to enhance diagnostic outcomes are illustrated in Figure 2. The 3 most expected integrations were x-ray diagnosis (W1: 1071/1322, 81% and W2: 1787/2183, 81.6%), heart rhythm interpretation (W1: 1062/1313, 80.9% and W2: 1578/2181, 72.4%), and skin malignancy diagnosis (W1: 1024/1320, 77.6% and W2: 1680/2176, 77.2%). Intrapartum monitoring (W1: 577/1235, 46.7% and W2: 1045/2070, 50.5%) and identification of sepsis symptoms (W1: 770/1257, 61.3% and W2: 1290/2095, 61.6%) were the events with the highest percentages of unlikely.



The respondents' perceptions of the main barriers to using AI in diagnostic medicine are shown in Figure 3. The most common barriers in both waves were the difficulty of incorporating AI into clinical practice and ethical or regulatory issues. In W1, these barriers were selected by 41% (531/1296) and 37.6% (487/1296) of the respondents who answered this question, respectively. In W2, ethical or regulatory issues were slightly more prevalent (941/2164, 43.5%) than the difficulty of incorporating AI into clinical practice (788/2164, 36.4%). The impact of AI on the workforce and the lack of improvement in medical diagnostics were less frequently chosen as barriers, with a combined percentage of approximately 15% (W1: 167/1296 and W2: 333/2164) in both waves. The respondents who identified the difficulty of incorporating AI into clinical practice as a barrier also reported its specific related challenges. The most common challenge in both waves was aligning AI to the specific context of clinical practice (W1: 255/535, 47.6% and W2: 399/789, 50.4%).

Similarly, the respondents who identified ethical or regulatory issues as barriers reported their related challenges. The most common challenge in both waves was the uncertainty about legal responsibility and accountability for AI-supported clinical decisions (W1: 235/489, 48.4% and W2: 449/940, 47.8%). When comparing other specific challenges, the one where waves differed the most was the unsuitability of AI to a real-world

XSL•FO
RenderX



context of care and services (W1: 22/87, 25.3% and W2: 57/158, 36.1%).

Figure 2. The likelihood of integrating artificial intelligence with various diagnostic instruments to deliver better results, based on global survey responses from wave 1 (W1; September 2020) and wave 2 (W2; February 2023). Instruments included heart rhythm interpretation, x-ray diagnosis, skin malignancy diagnosis, and others. *Statistical significance was at the 5% level. MRI: magnetic resonance imaging.

XSL•FO

Figure 3. Barriers to artificial intelligence (AI) adoption in diagnostic medicine, comparing wave 1 (WI; September 2020) and wave 2 (W2; February 2023) survey results. Responses addressed clinical, ethical, regulatory, and workforce-related challenges. *P* value refers to the marginal homogeneity test.

Discussion

Principal Findings

Although the span of 28 months may seem a short period to assess changes in researchers' expectations on a given topic, the case of AI in diagnostic medicine is peculiar. This is an area where transformations are quick, and innovations are the norm [51]. One indicator of this rapid transformation is the surge in publications on this topic. For instance, a quick search on WoS between January 1, 2015, and September 20, 2020, showed >6000 articles on AI in diagnostic medicine. However, between September 21, 2020, and December 30, 2022, this number rose to >12,000, an increase of 113.5% (the search strategies used

XSL•FO
RenderX

to identify these publications are the same as those described in Textbox 2).

AI is expected to improve the quality of health care for patients, mainly by addressing patient safety and reducing medical errors [18,70,71]. A study compared deep learning algorithms and physicians in diagnosing skin conditions from photos and dermoscopic images to evaluate how AI can support or automate health care decision-making. The results showed that the algorithms performed better than the average physician [18]. Image reconstruction using deep learning algorithms is another example of how AI can benefit patients. This technique can potentially reduce radiation exposure and the time needed for image acquisition and segmentation in preparation for radiotherapy, which may reduce side effects and material costs [72].

Survey respondents in both waves agreed that AI could positively impact quality over a 10-year time horizon by (1) aiding the prediction of disease progression, (2) increasing diagnostic reliability, and (3) improving treatment compliance. Furthermore, they believed that AI might improve quality in diagnostic medicine in <10 years by producing more reliable, compliable, and predictable outcomes. The answers to the questionnaire (Figure 2) show that AI-based quality improvements are associated with patient outcomes, but the technology may also benefit health care practitioners by reducing human error and fatigue [18,73-75].

Information accuracy is fundamental for achieving better-quality health care outcomes. However, technology and information accuracy may become a barrier to adopting AI [20,76]. For example, most of the researchers (W1: 255/535, 47.7% and W2: 399/789, 50.8%) who selected the difficulty of incorporating AI into clinical practice as the main barrier expressed their concern that the use of AI might be hampered by its misalignment with the specific context of clinical practice. This issue is associated with the generalizability and reproducibility of AI algorithms [20], which are often trained on clean datasets with no poor-quality information but are applied in a real clinical setting where data may be incomplete or erroneous. When comparing responses in both waves, this topic was more relevant for researchers in W2 than those in W1, which may indicate a growing concern about this misalignment. Furthermore, data accuracy issues may influence the quality of AI algorithm outputs by introducing biases [20,71,77,78] due to discrepancies in patient population (eg, individuals from low socioeconomic backgrounds and underrepresented minority groups) and organizational settings (eg, hospitals and primary care) [79,80].

Cost reduction is another potential benefit of AI in diagnostic medicine, as it relates to the optimization of resource use [72], processes, and services [71], as well as financial management [18,70]. As a result, the same therapy could be offered at a lower cost, or more services could be provided at the same cost. The use of AI to process large image datasets, for example, could offer workflow and productivity gains and reduce the workforce in many back-office activities, such as billing, clinical appointments, and staffing [72]. AI could have a variable impact on patient-, organizational-, and system-level tasks, potentially leading insurers to revise their reimbursement policy to reduce health care costs and improve quality [18]. Moreover, AI may make costly and time-consuming screening programs more affordable in resource-limited countries [23,81].

A total of 3 questions assessed the respondents' beliefs about the changes in costs driven by AI. Most respondents (W1: 982/1360, 69.3% and W2: 1514/2243, 67.5%) in both waves anticipated that screening costs and physician workloads would be reduced in <10 years and patients' hospitalization time would be shortened. These changes could potentially lower the cost of health care services and improve their quality, as physicians could perform more tasks concurrently and focus on more skilled work by delegating repetitive tasks to AI algorithms [18,72]. These benefits could be offset by the increased costs and risks for patients and the health system due to unnecessary testing and treatments prompted by AI [20]. Furthermore, there are concerns about the initial investments required for state-of-the-art AI products, the potential for long-term cost savings, and the need for a balanced evaluation of costs and benefits when considering AI integration [82,83].

Conversely, when appropriately implemented, AI can enhance diagnostic accuracy and reduce the need for redundant or follow-up tests. This efficiency is already leading to cost savings and a reduced burden on the health care system, and there is potential for further reduction of redundant and follow-up tests [84]. Therefore, AI value analyses should consider the technical aspects, short-term returns, and the overall value of automating processes [20].

The survey results in both waves have highlighted the anticipated transformation of AI in diagnostic instruments within a decade. In particular, image analysis and interpretation applications, such as x-ray, skin malignancy, and histopathologic diagnosis, have received optimistic perspectives. This may relate to advances in deep learning techniques for image analysis, such as convolutional neural networks and transformer architectures [85], which have significantly improved tasks such as image classification and object detection [3,29,46]. Deep learning is already the most used AI technique in health-related applications [71], and combining computing power, large datasets, and convolutional neural networks is also responsible for the subsequent revolution in medical imaging [18]. Since deep learning was introduced in 2012 for image recognition, it surpassed the human accuracy rate in specific, large data-labeled datasets after 5 years [72].

Furthermore, technology's maturity may relate to perceptions of the use of AI in medical imaging. Digital medical images have been in use since the 1960s, and mature technologies have been built around them. Most radiology departments maintain picture archiving and communication systems containing historical images [18]. Cardiology applications highlighted by the respondents in both waves (eg, heart rhythm interpretation and disease diagnostics) have been in use for many decades, but recent developments are seen as paradigm shifts in clinical practice [86,87]. Because AI algorithms rely on the design of distinctive features to learn from data, more mature technologies are expected to provide a better set of such features, as is the case for these diagnostic instruments [79,88].

XSL•FO
RenderX

Conversely, the least optimistic results in both waves were related to applications that use other data formats, such as electronic health record texts (eg, identification of sepsis symptoms and prediction of clinical outcomes) or 1D signal data (eg, intrapartum monitoring and remote monitoring of gait). Multiple reasons may account for that, for example, data heterogeneity in electronic health records, including mixed data types, such as free text clinical notes, radiological reports, medication dosages, and medical codes [70,89]. Moreover, privacy policies and data interoperability impact information transfer across institutions that construct large datasets for deep learning representations of electronic health records [89]. For gait and intrapartum monitoring, some issues, such as the lack of large datasets and the use of clinical context as a complement for decision-making, also affect its performance [90].

Another factor that may help explain these results is regulation. In 2018, the Food and Drug Administration published a fast-track approval plan for AI medical algorithms for different applications [72]. Since then, the number of algorithms approved has soared, and there are now almost 400 algorithms associated with radiology and 58 associated with cardiology, many of which are dedicated to x-ray diagnostics and heart rhythm interpretation, respectively [10]. Thus, technological innovation and maturity combined with adequate regulation seem correlated to the respondents' perceptions of AI's impact on diagnostics in the coming years.

According to the respondents' answers in both waves, the difficulty of incorporating AI into clinical practice, despite the reported benefits in terms of health outcomes, may hamper these innovations. These issues may be related to resistance to change in adopting AI in diagnostic medicine [91-93]. Another relevant challenge to AI adoption was ethical and regulatory issues. Accountability and legal responsibility for AI clinical decisions were marked as the most relevant issues in this topic in both waves. Accountability issues arise when AI algorithms make autonomous decisions about diagnoses and treatments beyond their role as support tools [20,23]. As respondents in W2 (941/2164, 43.5%) rated ethical and regulatory issues as more relevant than those in W1 (487/1296, 37.6%; in fact, as the most relevant), this seems to be a growing concern. As more AI applications become available to the public and cause social changes shortly, it is unsurprising that this issue increased in relevance from one wave to another. Large language models, such as ChatGPT, are examples of how AI has become more accessible to people and how this may raise more concerns over time [94,95]. For example, the United Kingdom's Medicines and Healthcare Products Regulatory Agency points out some issues with incorporating large language models in medical devices. While it anticipates their use in health care soon, it emphasizes the need to uphold safety, effectiveness, and ethical standards [96].

In short, there are still doubts about who should be held responsible if a patient experiences an adverse event due to AI-based technology [34]. Insurers and regulators will have to be able to distinguish algorithmic errors from those resulting from misuse by the clinician, the organization, or even the patient. This issue is exacerbated by the black box nature of AI systems [20]. The increased use of AI in medicine will probably lead to legal challenges regarding medical negligence attributed to complex decision support systems [18]. Radiologist associations globally have been evaluating the ethical integration of AI in medical imaging. The Canadian Association of Radiologists underscores the potential of AI in medical imaging, emphasizing the importance of addressing its ethical and legal challenges [97]. Furthermore, the Royal Australian and New Zealand College of Radiologists has formulated ethical guidelines and deployment standards in response to AI's rapid growth in radiology [98]. Simultaneously, a Joint European and North American Multisociety Statement, representing several radiological entities, emphasizes AI's potential to enhance radiology efficiency and introduce systemic errors, advocating for ethical AI use that prioritizes patient well-being and transparent practices [99].

According to the respondents in both waves, other relevant issues are accessing and sharing large amounts of patient data. The use of big data raises concerns that may hamper the potential of AI in diagnostic medicine. These relate to data protection and confidentiality and the need to access the large volumes of data needed to train AI algorithms. Regarding data protection and confidentiality, key concerns include the data's origin, obtaining patient consent, authorization for reuse, data ownership and responsibility, who can access and reuse the data, and the conditions under which the data can be used [20]. For example, a recent report from the European Union Agency for Cybersecurity on the pivotal role of AI in medical imaging diagnosis shows the importance of cybersecurity and privacy controls in properly addressing these many concerns [100]. Other relevant issues raised in the literature are the risk of the inappropriate use of databases and imprecise consent terms [34]. Technology-related obstacles include limited deidentification techniques and the need to integrate and standardize large amounts of data [34].

A shortage of well-annotated datasets for training AI algorithms is a key obstacle to the large-scale introduction of these systems. Furthermore, the absence of clear, standardized regulations could lead to the illicit collection of data from unknown sources [23]. These concerns relate to the very nature of machine learning technologies, as they need large amounts of training materials to be taught. On the other hand, as clinical data are gathered from multiple and diverse sources, it becomes easier to trace them to patients, threatening their privacy [49]. As ubiquitous data collection becomes commonplace, consensus must be reached for a consent framework to guide health-related data sharing [18]. In addition, there is growing concern about the lack of clinician involvement in the development of AI applications. A recent systematic review showed that developers typically consulted clinicians late in the design process, and many applications lacked validation against clinical expertise or detailed algorithm descriptions [101].

A particularly sensitive problem is iatrogenic risks related to a lack of transparency in the algorithm training processes. Before an AI algorithm can be unleashed in clinical practice, it has to be debugged, audited, simulated, and validated, along with prospective scrutiny [72]. Respondents identified these problems as major issues in both waves, with higher percentages in W2 (170/789, 21.5%). Besides the need for certification of AI

XSL•FO
RenderX

systems, professionals, and teams, the rapid evolution of machine learning–based models presents an enormous challenge to regulation as more data are collected and used in algorithm development. A critical problem is how these updates should be evaluated and audited [18]. Quality control instruments for AI algorithms are needed to prevent abuse by AI system developers, as clinical decision support systems could be programmed to favor certain drugs, tests, or devices without users being aware of this manipulation. Transparency will be difficult to achieve if companies make their algorithms purposefully opaque for proprietary or financial reasons [34].

Another issue, which is quite present in the reviewed literature but received relatively little attention from the respondents (W1: 32/489, 6.5% and W2: 60/940, 6.4%) who answered this question, relates to embedded bias present in AI algorithms due to a lack of inclusion of minority individuals in datasets [72]. Such biases, resulting from underrepresenting minority groups and those considered vulnerable in the datasets used to develop AI systems, could reinforce discriminatory practices based on race, sex, or other features [34]. Machine learning datasets must be large, but the often-used clinical trial research databases are derived mainly from majority populations. The resulting algorithms may be more likely to fail when applied to underserved and possibly underrepresented patient groups [49]. Algorithms trained on health care datasets, which inherently mirror biases in health care spending, have been observed to exacerbate racial disparities in access to care within the United States and can affect medical diagnosis [102]. This problem will require careful attention from regulatory agencies [103].

Limitations

This study relies on previous studies that have explored future scenarios of science and technology by surveying researchers [39,54-58,60]. However, it also inherits its limitations. The first one is the lack of diversity among respondents, who were identified and selected based on their publications in scientific journals. Therefore, most respondents (W1: 1007/1251, 80.5% and W2: 1607/2095, 76.7%) are researchers and professors affiliated with universities and research organizations. While their insights offer valuable academic and technological perspectives on AI use in diagnostic medicine, the relatively lower representation of clinicians might not capture the complete range of insights from the frontline of clinical practice. Considering that our respondents were sourced from scientific publications, a domain where professors and researchers are more commonly the authors, this was somewhat expected given our methodology.

Another limitation is the potential optimism bias of respondents. As researchers involved with AI and diagnostic medicine, they may have more positive expectations about the future of this technology than other groups (eg, patients, managers, businesspeople, and politicians). Nevertheless, they are among the most qualified to inform about future possibilities of AI use in diagnostic medicine as they are helping to advance the scientific and technological knowledge in the field. The self-attribution of knowledge level by the respondents in the questionnaire is another limitation. We cannot verify the accuracy of the respondents' self-assessments or assign knowledge levels to them. Therefore, the self-assigned knowledge level reflects how the respondents perceive their own knowledge in the area. However, this study only includes participants who are authors of peer-reviewed scientific articles related to AI and diagnostic medicine indexed in WoS, which minimizes the risk of incorporating opinions from people with no knowledge of the topic.

A potential limitation of our study is the varied interpretations of the term "artificial intelligence" among respondents. AI is a broad and multifaceted concept, encompassing everything from machine learning and neural networks to natural language processing and specialized rule-based systems [1,2]. The use of thesaurus terms to identify relevant respondents and survey questions may have introduced biases based on how individuals conceptualize AI. This variation in understanding could influence responses, particularly regarding the anticipated impact and integration of AI into diagnostic medicine. Hence, future studies may benefit from providing a clearer, more uniform definition of AI to respondents, ensuring a more consistent interpretation across the survey population.

We included radiology-specific terms in the search for respondents because this field is one of the most likely to be affected by the advances of AI in diagnostics [104-106]. We acknowledge that there is a potential selection bias in extending the search to radiology experts. However, it is important to highlight that the query also included general terms, such as diagnostics, medicine, and medical, which mitigates this potential bias by engaging a more diverse range of diagnostic experts.

Furthermore, there is the possibility of regional demographic bias. Collecting respondents' emails from scientific publications may introduce a bias toward specific demographic groups, possibly leading to an underrepresentation of experts from certain regions. Our methodology for identifying experts does not allow us to have demographic information on nonrespondents. The lack of this demographic information prevents an extensive analysis of nonresponse bias and demographic balance. However, we have included a regional breakdown of the responses in Multimedia Appendix 3 to address this concern and provide additional information. While slight percentage variations exist in the responses from each region, the overarching response patterns remain consistent across them.

Conclusions

We reported the results of a global, 2-wave, cross-sectional survey of >3000 researchers with knowledge in diagnostic medicine. Most respondents (W1: 965/1410, 68.4% and W2: 1555/2324, 66.9%) believed that AI would transform diagnostic medicine radically in 10 years. Furthermore, they expected that AI would reduce screening costs and increase diagnostic reliability in this period and that x-ray diagnosis and heart rhythm interpretation are the most likely diagnostic tools to be integrated with AI. According to the respondents, the main general barriers to using AI in diagnostic medicine were the difficulty of incorporating AI into clinical practice and ethical or regulatory issues. While there were little changes in expectations when comparing the 2 waves, ethical and regulatory

XSL•FO
RenderX

issues were more relevant to respondents in the second survey (941/2164, 43.5%), which indicates that this issue is becoming more urgent.

Moreover, adapting AI to the specific context of clinical practice and uncertainties about legal responsibility and accountability for AI-supported clinical decisions were the main specific barriers in both surveys. While our results provide a broad overview of the future of AI use in diagnostic medicine, they also pave the way for more detailed, focused research into specific aspects, enriching our understanding of this evolving domain. This may include an in-depth analysis of clinicians' trust in AI applications in diagnostic medicine; further analysis of the integration of AI in specific diagnostic tools, such as x-ray diagnosis, heart rhythm interpretation, and skin malignancy diagnosis; or a cost analysis of AI implementation.

The use of AI in diagnostic medicine is rapidly evolving and can potentially transform the quality and cost of health care for patients. As AI continues to advance, it is essential to address these challenges and ensure that AI-based technologies are developed and deployed responsibly and ethically. The success of AI in diagnostic medicine will ultimately depend on the willingness of stakeholders to collaborate, innovate, and work together to ensure that these technologies are used to improve patient outcomes and enhance the overall quality of health care.

Acknowledgments

The authors are grateful to all those who completed the questionnaire. They also thank the Fiocruz Strategy for Agenda 2030/Oswaldo Cruz Foundation and the National Health Fund/Ministry of Health for paying the article processing charge.

Abstract

Background: Artificial intelligence (AI) presents a promising approach to balancing high image quality with reduced radiation exposure in computed tomography (CT) imaging.

Objective: This meta-analysis evaluates the effectiveness of AI in enhancing CT image quality and lowering radiation doses.

Methods: A thorough literature search was performed across several databases, including PubMed, Embase, Web of Science, Science Direct, and Cochrane Library, with the final update in 2024. We included studies that compared AI-based interventions to conventional CT techniques. The quality of these studies was assessed using the Newcastle-Ottawa Scale. Random effect models were used to pool results, and heterogeneity was measured using the I^2 statistic. Primary outcomes included image quality, CT dose index, and diagnostic accuracy.

Results: This meta-analysis incorporated 5 clinical validation studies published between 2022 and 2024, totaling 929 participants. Results indicated that AI-based interventions significantly improved image quality (mean difference 0.70, 95% CI 0.43-0.96; P<.001) and showed a positive trend in reducing the CT dose index, though not statistically significant (mean difference 0.47, 95% CI –0.21 to 1.15; P=.18). AI also enhanced image analysis efficiency (odds ratio 1.57, 95% CI 1.08-2.27; P=.02) and demonstrated high accuracy and sensitivity in detecting intracranial aneurysms, with low-dose CT using AI reconstruction showing noninferiority for liver lesion detection.

Conclusions: The findings suggest that AI-based interventions can significantly enhance CT imaging practices by improving image quality and potentially reducing radiation doses, which may lead to better diagnostic accuracy and patient safety. However, these results should be interpreted with caution due to the limited number of studies and the variability in AI algorithms. Further research is needed to clarify AI's impact on radiation reduction and to establish clinical standards.

Introduction

Computed tomography (CT) has revolutionized medical imaging since its introduction, providing high-resolution, 3D visualizations of anatomical structures. Its widespread adoption has significantly enhanced diagnostic capabilities across various medical specialties [1-3]. However, the increasing use of CT scans has raised concerns about radiation exposure and its potential long-term health effects on patients [4,5].

Simultaneously, maintaining optimal image quality is crucial for accurate diagnosis and treatment planning. This creates a challenging balance between minimizing radiation dose and preserving diagnostic image quality [6-8]. In recent years, artificial intelligence (AI) has emerged as a promising solution to address the balance between maintaining high image quality and minimizing radiation dose in CT imaging [9-11].

AI, particularly deep learning algorithms, has shown potential in various aspects of CT imaging, including image reconstruction, noise reduction, and automated image analysis [12]. These AI-driven approaches aim to enhance image quality while allowing for lower radiation doses, potentially improving both diagnostic accuracy and patient safety [13].

Several studies have investigated the application of AI in CT imaging, focusing on different anatomical regions and clinical scenarios. For instance, Hu et al [14] explored the use of deep learning models for intracranial aneurysm detection on CT angiography images. Zhang et al [15] investigated AI reconstruction algorithms in CT imaging of sports injuries. Other researchers have examined AI's role in breast cancer radiotherapy planning [16] and liver CT imaging [17].

Despite the growing body of research, the overall effectiveness of AI in improving CT image quality and reducing radiation dose remains unclear [14,17]. The variability in study designs, AI algorithms, and outcome measures makes it challenging to draw definitive conclusions about the broader impact of AI on CT imaging practices [18]. This meta-analysis aims to synthesize the available evidence on the role of AI in CT image quality control and radiation protection, providing a comprehensive evaluation of AI's role across various clinical scenarios and anatomical regions. Our study contributes to the literature by offering a systematic overview of the current state of AI in CT imaging, which can inform future research directions and clinical applications.

Methods

Search Strategy and Study Selection

A comprehensive literature search was conducted across multiple electronic databases, including PubMed, Embase, Web of Science, Science Direct, and Cochrane Library. The search strategy used a combination of Medical Subject Headings terms and keywords related to AI, deep learning, and CT imaging. The specific search string used was as follows: (Intelligence, Artificial [Title/Abstract]) OR (Computer Reasoning [Title/Abstract]) OR (Reasoning, Computer [Title/Abstract]) OR (AI (Artificial Intelligence [Title/Abstract]) OR (Machine Intelligence [Title/Abstract])) and so on (Multimedia Appendix 1).

The selected databases are renowned for their extensive coverage of medical and scientific literature, ensuring a thorough retrieval of studies pertinent to our research question. The choice of these databases was also influenced by their indexing of a wide array of medical journals and conference proceedings, which are critical for capturing the latest advancements in the field of AI and CT imaging.

The search was conducted without language restrictions and conducted from the inception of the databases until the search date in 2024, to ensure inclusion of the most current and relevant studies.

Inclusion and Exclusion Criteria

Studies were eligible for inclusion if they met the following criteria: (1) clinical validation studies comparing AI-based interventions with conventional CT imaging techniques; (2) reported outcomes related to image quality, radiation dose, or diagnostic performance; and (3) provided sufficient data for quantitative analysis. Exclusion criteria included (1) nonclinical studies or (2) those without a control group, (3) studies focusing solely on AI development without clinical validation, (4) review articles, (5) case reports, (6) conference abstracts, and (7) studies with insufficient data for meta-analysis.

Data Extraction and Quality Assessment

Two independent reviewers extracted data from the included studies using a standardized form. The extracted information included study characteristics (author, year, and study design), sample size and patient demographics, AI intervention details, and outcome measures (image quality metrics, radiation dose indicators, and diagnostic performance).

The quality of the included studies was assessed using the Newcastle-Ottawa Scale for nonrandomized studies. This scale evaluates studies based on selection, comparability, and outcome domains, with a maximum score of 9 indicating the highest quality. The risk of bias for each included study was assessed using the Cochrane risk of bias tool, which provides a standardized evaluation of study quality.

Statistical Analysis

Meta-analyses were performed using Review Manager (version 5.4; The Cochrane Collaboration). For continuous outcomes (eg, image quality scores and CT dose index), mean differences with 95% CIs were calculated. For binary outcomes (eg, diagnostic accuracy), odds ratios with 95% CIs were computed.

Random effect models were used to account for potential heterogeneity among studies. Heterogeneity was assessed using the I^2 statistic, with values of 25%, 50%, and 75% considered as low, moderate, and high heterogeneity, respectively.

Publication bias was assessed visually using funnel plots. Sensitivity analyses were conducted by sequentially removing each study to evaluate its impact on the overall effect size.

Results were considered statistically significant at $P<.05$. Forest plots were generated to visually represent the meta-analysis

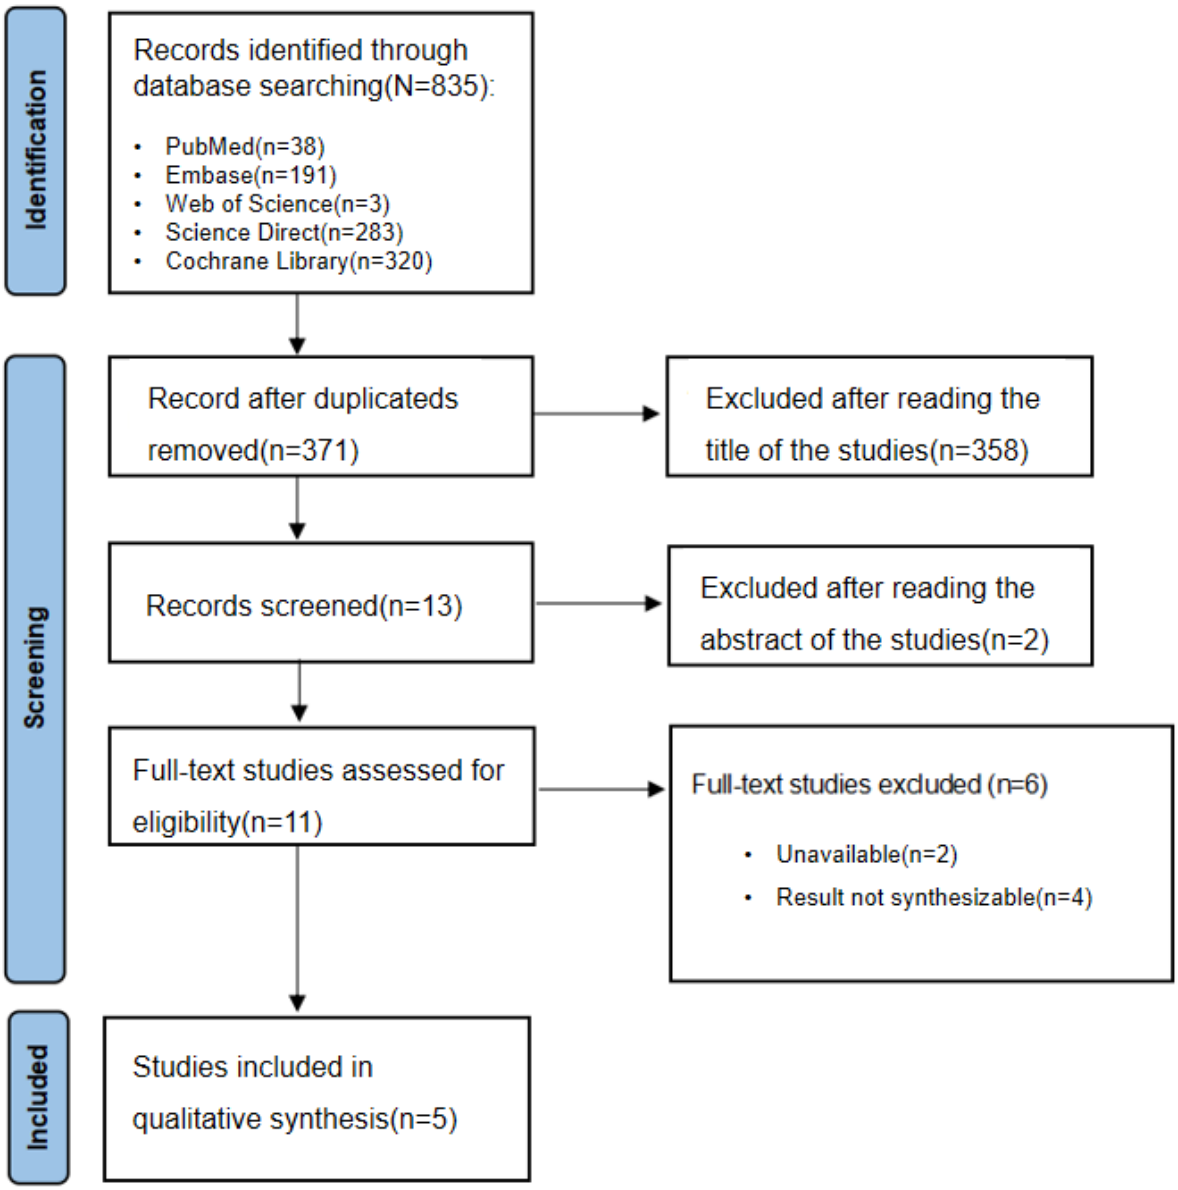
XSL•FO
RenderX

results, displaying individual study effects and the pooled effect size.

Ethical Considerations

An ethical statement is not applicable because this study is based exclusively on published literature.

Results



Study Selection and Characteristics

The initial database search yielded 835 records (PubMed: n=38, Embase: n=191, Web of Science: n=3, Science Direct: n=283, and Cochrane Library: n=320). After removing duplicates, 371 unique records remained. Following title and abstract screening, 11 full-text articles were assessed for eligibility. Ultimately, 5 studies met the inclusion criteria and were included in the meta-analysis (Figure 1).

The 5 included studies were all clinical validation studies published between 2022 and 2024. They encompassed a total of 929 participants (464 in the experimental AI group and 465 in the control group). The studies focused on various anatomical regions and clinical applications, including intracranial aneurysm detection [14], knee anterior cruciate ligament injury [15], breast cancer radiotherapy planning [16], head CT angiography [9], and liver CT imaging [17].

All included studies used deep learning–based AI algorithms for image reconstruction or analysis. The sample sizes ranged from 60 to 14,715 participants. The Newcastle-Ottawa Scale scores for the included studies ranged from 7 to 8, indicating good methodological quality (Table 1).

Figure 1. Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram for study selection, detailing the process from initial records to final inclusion across various databases and time frames.

[e]CM: contrast medium.

Risk-of-Bias Assessment

Overview

The risk of bias for each included study was assessed using the Cochrane risk of bias tool. Figure 2 presents the risk of bias graph, showing the distribution of judgments across all included studies for each domain. Random sequence generation (selection bias) was assessed as having a low risk in 40% (2/5) of studies and unclear risk in 60% (3/5). Allocation concealment was judged as low risk in 80% (4/5) of studies and unclear in 20% (1/5). The blinding of participants and personnel (performance bias) was unanimously assessed as an unclear risk across all studies. Blinding outcome assessment (detection bias) was determined to be low risk in 80% (4/5) of studies and unclear in 20% (1/5). Incomplete outcome data (attrition bias) were consistently judged as low risk across all studies. Selective reporting (reporting bias) was assessed as low risk in 40% (2/5) of studies and unclear in 60% (3/5). Other bias was unanimously judged as unclear across all studies.

Figure 3 [9,14-17] presents a comprehensive risk-of-bias summary for each study included in the analysis. Several key observations can be made from this summary. Notably, all 5 studies demonstrated a low risk for incomplete outcome data, indicating robust data collection and reporting practices. However, the blinding of participants and personnel was unclear across all studies, which is a common limitation in imaging studies where complete blinding can be challenging to achieve. Random sequence generation was assessed as low risk in 3 (60%) out of the 5 studies, suggesting generally sound randomization practices were used. Interestingly, the “other bias” category was consistently rated as unclear for all studies, pointing to potential unidentified sources of bias that may warrant further investigation. Finally, there was considerable variability in the assessment of selective reporting and blinding of outcome assessment across the studies, highlighting areas where methodological consistency could be improved in future research.

XSL•FO
RenderX

Figure 2. Risk-of-bias graph: review authors' judgments about each risk-of-bias item presented as percentages across all included studies. This graph provides a visual representation of the risk of bias across different domains, indicating the methodological quality of the studies included in the meta-analysis.

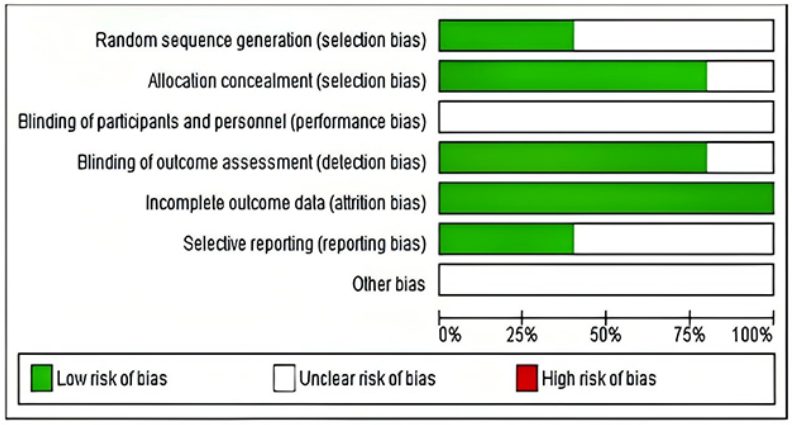

Figure 3. Risk-of-bias summary: review authors' judgments about each risk-of-bias item for each included study. This summary offers a comprehensive overview of the risk of bias for each study, highlighting areas of strength and potential concerns within the meta-analysis.

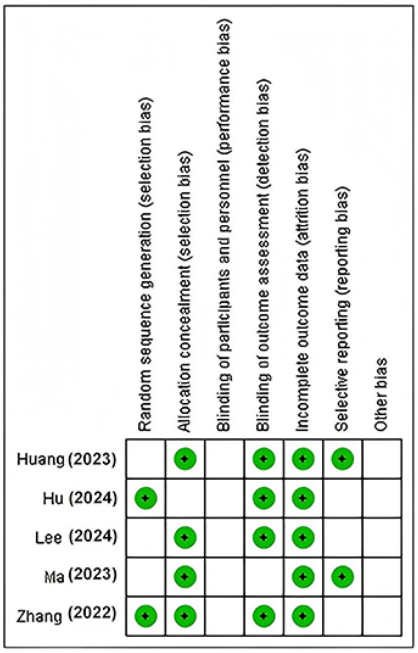

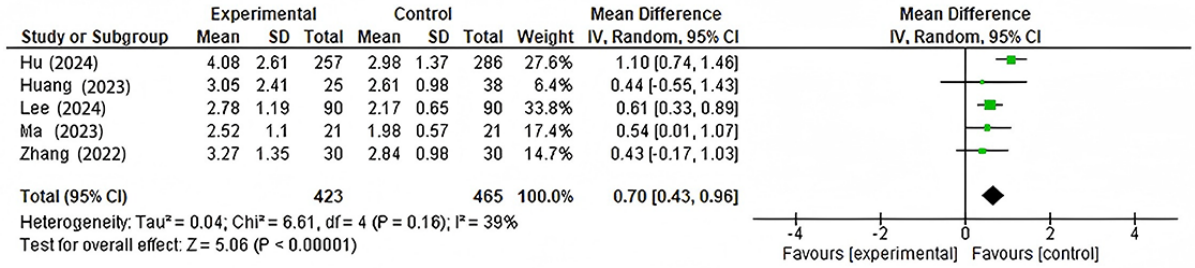

Image Quality

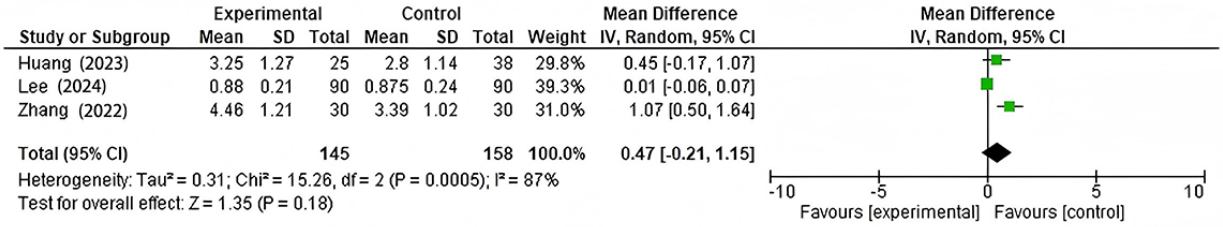
All 5 studies reported on image quality outcomes. The meta-analysis showed a significant improvement in image quality with AI-based interventions compared to conventional methods (mean difference 0.70, 95% CI 0.43-0.96; *P*<.001; Figure 4 [9,14-17]). There was moderate heterogeneity among the studies (I^2=39%), suggesting some variability in the effect of AI on image quality across different clinical contexts.

The largest effects were observed in the studies by Hu et al [14] and Lee et al [17], which focused on intracranial aneurysm detection and liver CT imaging, respectively. These studies carried the highest weights in the analysis (27.6% and 33.8%, respectively).

XSL•FO
RenderX

Figure 4. Forest plot comparing image quality scores between AI-based interventions and conventional CT imaging techniques across 5 clinical validation studies conducted from 2022 to 2024, focusing on various anatomical regions and clinical applications. This plot visually represents the mean differences in image quality, with confidence intervals, favoring either the experimental or control groups. AI: artificial intelligence; CT: computed tomography; IV: inverse variance.

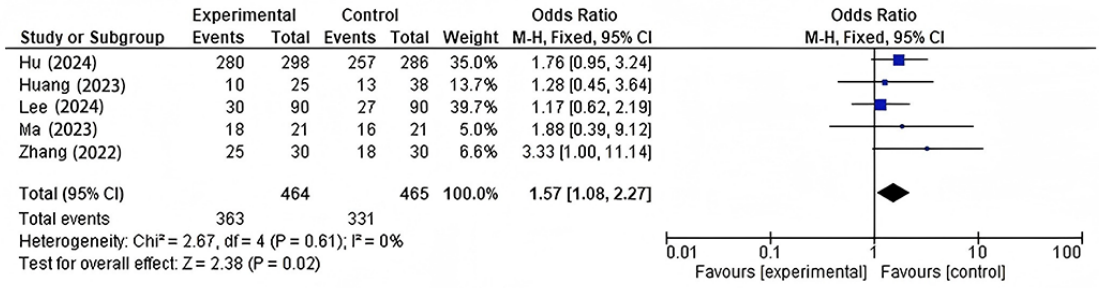


CT Dose Index

Three studies [9,15,17] reported data on the CT dose index. The meta-analysis showed a trend toward reduction in CT dose index with AI-based interventions, but the result was not statistically significant (mean difference 0.47, 95% CI –0.21 to 1.15; *P*=.18; Figure 5 [9,14-17]). There was high heterogeneity among these studies (I^2=87%), indicating substantial variability in the effect of AI on radiation dose across different applications.

The study by Zhang et al [15] showed the largest effect size in favor of AI, while Lee et al [17] reported almost no difference between the AI and conventional groups.

Figure 5. Forest plots of changes in CT dose index. This figure displays the impact of AI-based interventions on the CT dose index, with mean differences and CIs, across 3 studies that reported this outcome. AI: artificial intelligence; CT: computer tomography; IV: inverse variance.



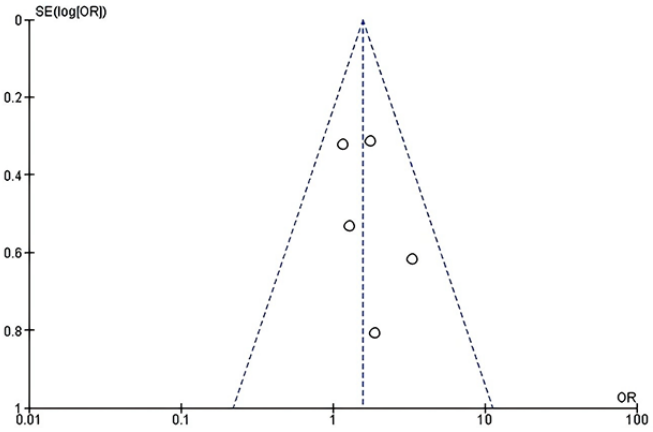
Efficiency in Image Analysis

All 5 studies provided data on the efficiency of AI in image analysis. The meta-analysis demonstrated a significant improvement in efficiency with AI-based methods compared to conventional approaches (odds ratio 1.57, 95% CI 1.08-2.27; *P*=.02; Figure 6 [9,14-17]). There was no significant heterogeneity among the studies for this outcome (I^2=0%).

The study by Lee et al [17] had the largest weight (39.7%) in this analysis, likely due to its larger sample size. All studies showed an odds ratio favoring the AI group, although the precision of the estimates varied, with wider confidence intervals observed in smaller studies.

Figure 6. Forest plots of efficiency in image analysis. This forest plot demonstrates the comparison of image analysis efficiency between AI-based methods and conventional approaches, showing a significant improvement with AI across all 5 studies. AI: artificial intelligence; M-H: Mantel-Haenszel analysis.

Diagnostic Performance



While not all studies reported on diagnostic performance metrics, those that did showed promising results. Hu et al [14] reported high accuracy (0.951), sensitivity (0.974), and specificity (0.928) for their AI model in detecting intracranial aneurysms. Lee et al [17] found that the diagnostic performance of low-dose CT with AI reconstruction was noninferior to standard-dose CT for liver lesion detection.

XSL•FO
RenderX

Publication Bias

Visual inspection of the funnel plot (Figure 7 [9,14-17]) did not reveal substantial asymmetry, suggesting a low risk of publication bias. However, the small number of included studies limits the reliability of this assessment.

Figure 7. Funnel plot of efficiency in image analysis by AI. The funnel plot is used to assess publication bias, with the distribution of effect sizes visually represented against their precision. AI: artificial intelligence; OR: odds ratio.

Discussion

Principal Findings

This meta-analysis synthesized evidence from 5 clinical validation studies to evaluate the role of AI in CT image quality control and radiation protection. The findings suggest that AI-based interventions can significantly improve CT image quality and efficiency in image analysis, with a potential trend toward radiation dose reduction.

The significant improvement in image quality observed with AI-based interventions (mean difference 0.70, 95% CI 0.43-0.96; P<.001) is a key finding of this meta-analysis. This improvement was consistent across different anatomical regions and clinical applications, suggesting that AI algorithms have broad applicability in enhancing CT image quality. The enhanced image quality achieved through AI could have substantial clinical implications. Improved image clarity and detail may lead to more accurate diagnoses, potentially reducing the need for repeat scans or additional imaging studies [19]. This, in turn, could contribute to reduced overall radiation exposure for patients and improved workflow efficiency in radiology departments.

While the meta-analysis showed a trend toward CT dose index reduction with AI-based interventions, the result was not statistically significant (mean difference 0.47, 95% CI –0.21 to 1.15; P=.18). The lack of statistical significance does not necessarily imply that AI has no effect on radiation dose reduction. Rather, it highlights the need for further research to elucidate the factors influencing AI's impact on radiation dose across different CT applications. It is possible that some AI algorithms are more effective at dose reduction than others, or that dose reduction capabilities may be more pronounced in certain anatomical regions or clinical scenarios [20].

Moreover, the trend toward dose reduction, even if not statistically significant, is encouraging. When combined with the significant improvements in image quality, these findings suggest that AI may enable a favorable shift in the balance between image quality and radiation dose in CT imaging [21].

The significant improvement in the efficiency of image analysis with AI-based methods (odds ratio 1.57, 95% CI 1.08-2.27; P=.02) is another important finding of this meta-analysis. This improvement in efficiency could have far-reaching implications for radiology workflows and patient care. Faster image analysis times could lead to reduced reporting turnaround times, potentially enabling quicker clinical decision-making and treatment initiation [22]. Additionally, improved efficiency could help address the growing demand for CT imaging services and the increasing workload on radiologists [23]. The lack of heterogeneity (I^2=0%) in this analysis suggests that the efficiency gains with AI are consistent across different applications. This consistency is particularly noteworthy given the diversity of clinical scenarios represented in the included studies.

Comparison With Prior Work

While not all studies reported comprehensive diagnostic performance metrics, those that did showed promising results. The high accuracy, sensitivity, and specificity reported by Hu et al [14] for intracranial aneurysm detection, as well as the noninferiority of low-dose CT with AI reconstruction for liver lesion detection reported by Lee et al [17], suggest that AI can maintain or even enhance diagnostic performance while potentially reducing radiation dose. These findings align with previous studies that have demonstrated the potential of AI to improve diagnostic accuracy in various imaging modalities [24]. The combination of improved image quality, potential dose reduction, and maintained or enhanced diagnostic performance positions AI as a powerful tool for advancing CT imaging practices.

The principle of action by which AI, particularly deep learning algorithms, enhances CT image quality is multifaceted. First, AI-driven approaches use advanced computational techniques to reconstruct images from raw data, optimizing the balance between image sharpness and noise reduction. This is achieved

XSL•FO
RenderX

through the use of convolutional neural networks that learn to identify and enhance features of interest while suppressing background noise, leading to clearer and more detailed images [24]. Second, AI algorithms can adaptively adjust image reconstruction parameters based on the specific characteristics of the scanned tissue, resulting in improved contrast resolution and better visualization of anatomical structures. Third, AI-based techniques offer the capability for automated image analysis, which can standardize the interpretation process and reduce interobserver variability, thereby contributing to more accurate and consistent diagnostic outcomes [22]. These mechanisms collectively contribute to the significant improvement in image quality observed in our meta-analysis, underscoring the potential of AI to revolutionize CT imaging practices by enhancing diagnostic accuracy and patient safety.

Strengths and Limitations

Several limitations of this meta-analysis should be noted. First, the small number of included studies limits the generalizability of the findings and precludes more detailed subgroup analyses. Second, the heterogeneity in AI algorithms, CT protocols, and outcome measures across studies made direct comparisons challenging. Third, the lack of long-term, follow-up data in the included studies means that the potential long-term impacts of AI-enhanced CT imaging on patient outcomes remain unclear. Future research should focus on larger, multicenter studies with standardized protocols and outcome measures to more definitively establish the impact of AI on CT image quality and radiation dose [25]. Long-term studies are needed to assess the clinical impact of AI-enhanced CT imaging on patient outcomes and radiation-induced cancer risk. Additionally, research into the cost-effectiveness of implementing AI in CT imaging workflows would be valuable for health care systems considering the adoption of these technologies.

Conclusions

This meta-analysis provides evidence that AI-based interventions can significantly improve CT image quality and efficiency in image analysis, with the potential for radiation dose reduction. These findings suggest a promising role for AI in enhancing CT imaging practices, potentially leading to improved diagnostic accuracy, reduced radiation exposure, and enhanced patient care. As AI technologies continue to evolve, their integration into CT imaging workflows may become increasingly important in addressing the ongoing challenges of balancing image quality, radiation safety, and diagnostic accuracy.

Abstract

Background: In-hospital cardiac arrest (IHCA) is a severe and sudden medical emergency that is characterized by the abrupt cessation of circulatory function, leading to death or irreversible organ damage if not addressed immediately. Emergency department (ED)–based IHCA (EDCA) accounts for 10% to 20% of all IHCA cases. Early detection of EDCA is crucial, yet identifying subtle signs of cardiac deterioration is challenging. Traditional EDCA prediction methods primarily rely on structured vital signs or electrocardiogram (ECG) signals, which require additional preprocessing or specialized devices. This study introduces a novel approach using image-based 12-lead ECG data obtained at ED triage, leveraging the inherent richness of visual ECG patterns to enhance prediction and integration into clinical workflows.

Objective: This study aims to address the challenge of early detection of EDCA by developing an innovative deep learning model, the ECG-Image-Aware Network (EIANet), which uses 12-lead ECG images for early prediction of EDCA. By focusing on readily available triage ECG images, this research seeks to create a practical and accessible solution that seamlessly integrates into real-world ED workflows.

Methods: For adult patients with EDCA (cases), 12-lead ECG images at ED triage were obtained from 2 independent data sets: National Taiwan University Hospital (NTUH) and Far Eastern Memorial Hospital (FEMH). Control ECGs were randomly selected from adult ED patients without cardiac arrest during the same study period. In EIANet, ECG images were first converted to binary form, followed by noise reduction, connected component analysis, and morphological opening. A spatial attention module was incorporated into the ResNet50 architecture to enhance feature extraction, and a custom binary recall loss (BRLoss) was used to balance precision and recall, addressing slight data set imbalance. The model was developed and internally validated on the NTUH-ECG data set and was externally validated on an independent FEMH-ECG data set. The model performance was evaluated using the F_1-score, area under the receiver operating characteristic curve (AUROC), and area under the precision-recall curve (AUPRC).

Results: There were 571 case ECGs and 826 control ECGs in the NTUH data set and 378 case ECGs and 713 control ECGs in the FEMH data set. The novel EIANet model achieved an F_1-score of 0.805, AUROC of 0.896, and AUPRC of 0.842 on the NTUH-ECG data set with a 40% positive sample ratio. It achieved an F_1-score of 0.650, AUROC of 0.803, and AUPRC of 0.678 on the FEMH-ECG data set with a 34.6% positive sample ratio. The feature map showed that the region of interest in the ECG was the ST segment.

RenderX

Conclusions: EIANet demonstrates promising potential for accurately predicting EDCA using triage ECG images, offering an effective solution for early detection of high-risk cases in emergency settings. This approach may enhance the ability of health care professionals to make timely decisions, with the potential to improve patient outcomes by enabling earlier interventions for EDCA.

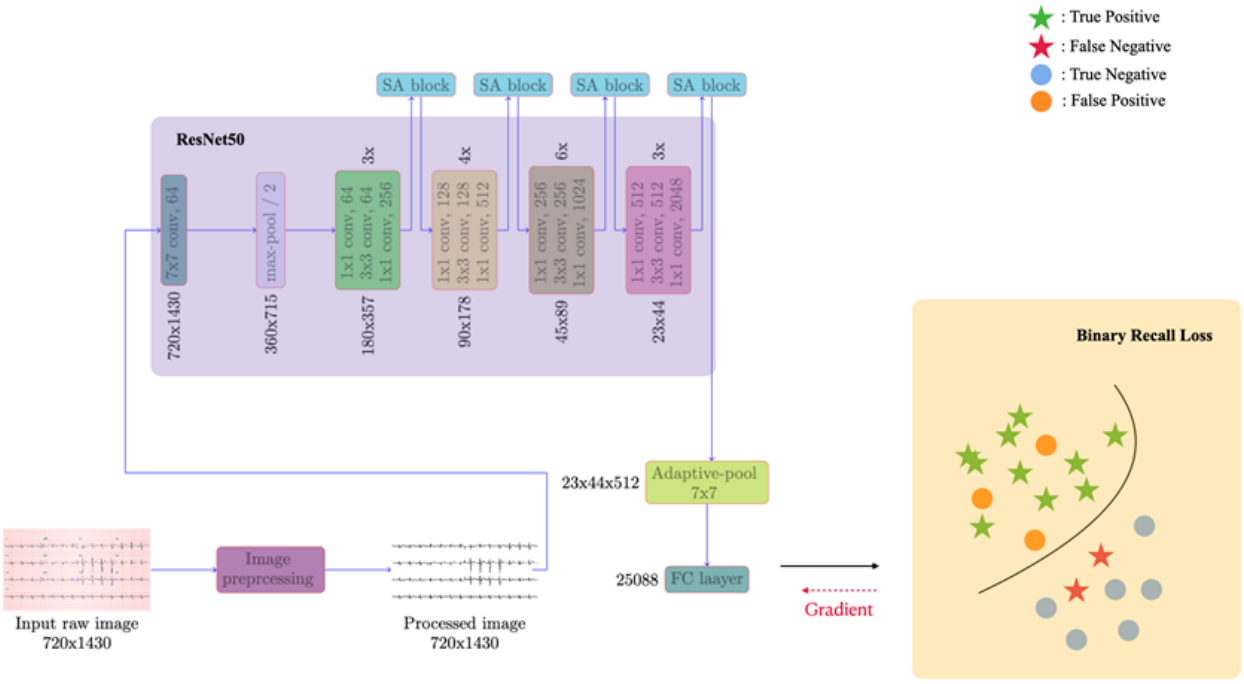
Introduction

In-hospital cardiac arrest (IHCA) differs significantly from out-of-hospital cardiac arrest (OHCA), with the former often occurring in patients with significant comorbidities rather than as sudden cardiac events [1-3]. Despite its clinical significance, IHCA has received less research attention. Recent studies using data from the American Heart Association's Get With the Guidelines-Resuscitation registry revealed an IHCA incidence of approximately 10 per 1000 bed-days (290,000 cases annually), with a survival rate of 15% to 20% at hospital discharge [4,5]. Emergency department (ED)–based IHCA (EDCA), accounting for 10% to 20% of all IHCA cases [6], is associated with higher mortality and less well-defined causes than inpatient cardiac arrest (IPCA) [7]. ED crowding, coupled with infrequent monitoring and unstable conditions, further increases EDCA risk [8].

Most patients experiencing IHCA show clinical deterioration hours before arrest, leading to the adoption of rule-based early warning scores to detect high-risk individuals [9-11]. With advancements in information technology, the use of machine learning for predicting IHCA has become increasingly prominent. Recent studies have demonstrated the potential of machine learning and statistical approaches in disease prediction, including heart disease analysis [12]. Although some deep learning models using structured data, such as vital signs [13-15], exist for predicting IPCA, they are not tailored for ED-specific conditions, highlighting the need for a dedicated ED-focused predictive model to address unique challenges in this setting. Using both triage and vital sign time-series data, we recently developed and validated a deep learning–based prediction tool for EDCA [16].

Electrocardiogram (ECG) is an old tool in clinical medicine but has re-emerged for the prediction of low left ventricular ejection fraction [17], arrhythmia [18], dyskalemia [19], or even longer-term mortality [20]. A recent randomized controlled trial using artificial intelligence–enabled ECG to identify hospitalized patients with a high risk of mortality found that the implementation of the artificial intelligence–enabled ECG alert was associated with a significant reduction in all-cause mortality within 90 days [21]. This finding is somewhat surprising, as a recent Cochrane review did not find strong evidence supporting the utility of early warning systems and rapid response systems for the prevention of patient deterioration in acute adult hospital wards [22]. To our knowledge, only 1 study has analyzed ECGs solely from inpatients to predict cardiac arrest within 24 hours of ECG acquisition [23]. This study analyzed signal-based ECGs, which require complex signal processing before analysis. In addition, XML-based protocols, commonly used by several ECG device manufacturers, store structured ECG data and enable integration with systems like General Electric's MUSE server for advanced diagnostics. However, such reliance on proprietary software and infrastructure limits their applicability in the ED, which has diverse device environments. In contrast, image-based 12-lead ECG models leverage universally available PDF reports generated at ED triage. This approach eliminates the need for additional preprocessing or proprietary systems, providing a more accessible, flexible, and scalable solution that seamlessly integrates into real-world clinical workflows.

Accordingly, this study explored an innovative approach by using triage 12-lead ECG images as a more accessible alternative for predicting imminent cardiac arrest in the ED setting. We leveraged ECG reports, commonly available in PDF, and converted them into image-based data inputs to develop a deep learning–based predictive system for IHCA. We also used 2 independent ED data sets for development and validation of our model.



Methods

System Overview

We present a novel cardiac arrest prediction model called the ECG-Image-Aware Network (EIANet) that was designed to predict IHCA with high accuracy. Our study adhered to the Guidelines for Developing and Reporting Machine Learning Predictive Models in Biomedical Research [24]. EIANet operated in 3 key stages, as outlined in Figure 1. In the first stage, ECG waveform images were extracted from triage ECG reports obtained from the National Taiwan University Hospital (NTUH). The NTUH is a tertiary academic medical center with approximately 2400 beds and 100,000 ED visits per year. We obtained 12-lead ECG images at ED triage for adult patients with EDCA (cases) from 2011 to 2019. We defined EDCA as patients who arrived in the ED with vital signs and later developed cardiac arrest in the ED. OHCAs with or without return of spontaneous circulation on ED arrival were excluded. We focused on treated EDCA, so patients with a do-not-resuscitate order were also excluded. The EDCA cases were from the same pool as in our previous studies on EDCA [16,25]. Control ECGs were randomly selected from adult ED patients without cardiac arrest during the same study period.

XSL•FO
RenderX

Figure 1. Overview of the proposed ECG-Image-Aware Network (EIANet) model. SA: spatial attention.

The ECG images were subjected to a thorough preprocessing step, where extraneous information, artifacts, and noise were removed, ensuring that the data fed into the model were clean and of high quality for more accurate analysis. In the second stage, the preprocessed ECG images were passed through a deep learning model, which was enhanced using a spatial attention module. This module allowed the model to focus on more relevant areas of the ECG image, identifying subtle patterns and features critical for predicting cardiac arrest. Finally, in the third stage, the model's output was combined with the recall metric to calculate the binary recall loss (BRLoss). This custom loss function helps address slight class imbalance by prioritizing recall during training, leading to more balanced predictions, particularly in rare IHCA cases.

ECG Data Set for IHCA Prediction

NTUH-ECG Data Set

The NTUH-ECG data set is a comprehensive collection of ECG data sourced from ED patients at NTUH, covering a significant period from 2011 to 2019. During this period, the data set was meticulously curated to include as many positive instances of EDCA as possible, representing critical cases that pose serious risks to patient safety. To balance the data set, random samples of ECGs from patients who did not experience EDCA were collected to serve as negative examples. Distinct from conventional ECG data sets that primarily focus on raw signal data, the NTUH-ECG data set features detailed ECG PDF reports containing 12-lead waveforms (I, II, III, aVR, aVL, aVF, and V1-V6) captured over 10-second intervals at ED triage. The primary objective of this data set is to predict the likelihood of a patient experiencing cardiac arrest during the ED stay, a task of immense clinical significance. The data set comprised a total of 571 cardiac arrest events (positive samples) and 826 noncardiac arrest events (negative samples), resulting in a positive sample ratio of 40.1%. For model training and evaluation, the data were randomly split into training and testing sets, with 80% allocated for training and 20% allocated for testing. This division yielded a test set containing 280 data points, which included 114 positive cases and 166 negative cases. The key characteristics of the NTUH-ECG data set are summarized in Table 1, providing valuable insights into its structure and composition for researchers and clinicians alike. The median time to cardiopulmonary resuscitation was approximately 5 to 7 hours for the cases and controls.

Table 1. Basic characteristics of the training and testing data sets for the National Taiwan University Hospital electrocardiogram (NTUH-ECG) data set.

Variable	NTUH-ECG training data set (n=1117)	NTUH-ECG testing data set (n=280)
Age (years), mean (SD)	65.9 (15.9)	63.7 (17.2)
Male, n (%)	608 (54.4)	141 (50.4)
Annotated positive, n (%)	457 (40.9)	114 (40.7)
Time to CPR[a] (hours), median (IQR)	7.4 (2.5-23.5)	5.1 (1.9-17.9)
Annotated negative, n (%)	660 (59.1)	166 (59.3)

Far Eastern Memorial Hospital ECG Data Set

The Far Eastern Memorial Hospital (FEMH)-ECG data set consisted of ECG images collected from ED patients presenting to the FEMH from 2016 to 2023. The FEMH is a tertiary academic medical center with approximately 1200 beds and 130,000 ED visits per year. We obtained 12-lead ECG images at ED triage for adult patients with ED cardiac arrest (cases) from 2016 to 2023. Control ECGs were randomly selected from adult ED patients without cardiac arrest during the same study period. Each image was carefully annotated to indicate whether the patient experienced an EDCA during their ED stay. The data format closely mirrors that of the NTUH-ECG data set, with the images being directly extracted from ECG PDF reports. However, the distribution of positive samples in FEMH-ECG was significantly lower than in NTUH-ECG, at 378 positive cases and 713 negative cases, which equates to a positive sample proportion of approximately 34.6%. Table 2 shows the basic characteristics of the FEMH-ECG data set. The median time to cardiopulmonary resuscitation was approximately 2.5 hours.

Table 2. Basic characteristics of the positive and negative samples for the Far Eastern Memorial Hospital electrocardiogram (FEMH-ECG) data set.

Variable	FEMH-ECG positive samples (n=378)	FEMH-ECG negative samples (n=713)
Age (years), mean (SD)	68.3 (14.9)	64.4 (17.9)
Male, n (%)	252 (66.7)	389 (54.6)
Time to CPR[a] (hours), median (IQR)	2.5 (0.7-8.9)	—[b]

[b]Not applicable.

Ethical Considerations

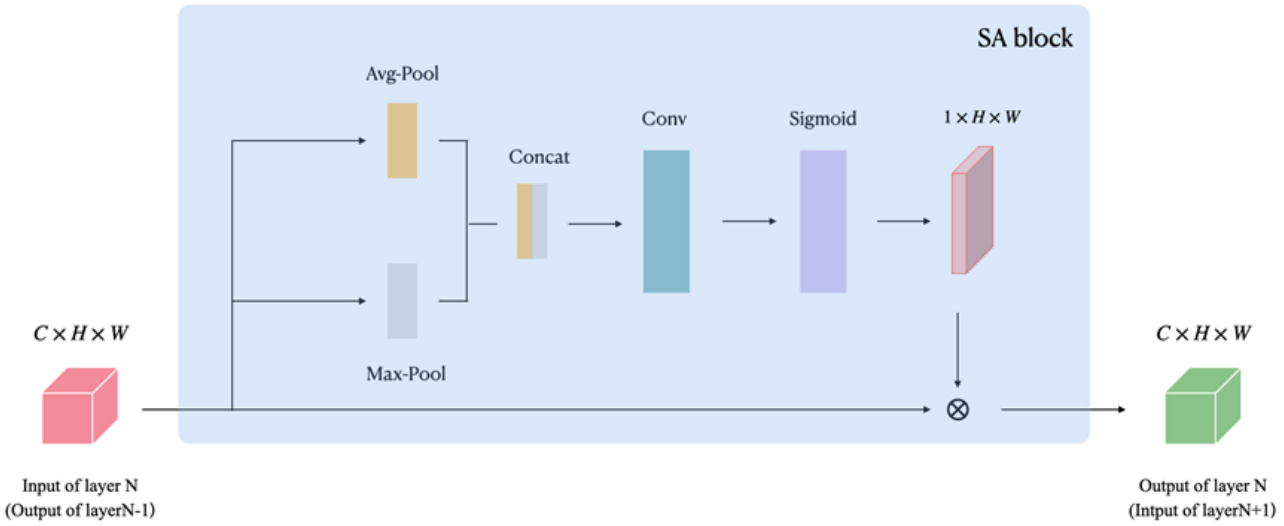
The NTUH study was approved by the NTUH Institutional Review Board (reference number: 202304129RINC), which waived the requirement for patient informed consent. The FEMH study was approved by the FEMH Institutional Review Board (reference number: 112193-F), which also waived the requirement for patient informed consent.

Preprocessing

Although deep learning models can automatically extract relevant features from input data, their performance can be significantly improved when noisy or unclean data are addressed through careful preprocessing. In our approach, we began by converting the RGB ECG image into a binary format using a thresholding technique. Specifically, we first used Gaussian blur and thresholding to remove unnecessary elements such as thin grid lines. By applying a threshold, pixels exceeding the threshold value were turned black (0), while those below the threshold were converted to white (255). This step ensured that distracting elements were removed, enhancing the clarity of the ECG waveform for further analysis.

Next, we used a connected component algorithm to identify and remove specific unwanted components such as lead labels and other extraneous noise in the image. These elements, if left unaddressed, can interfere with the accuracy of the model's predictions. To further refine the image, we applied a morphological opening operation, which consists of erosion followed by dilation, using a 3 × 3 structuring element. This process smoothed the ECG lines and reduced minor noise, ensuring that the primary features of the ECG waveform were preserved while removing small, irrelevant artifacts. This enhanced the overall quality of the image, making it more suitable for deep learning analysis.

To complete the preprocessing, we applied a Gaussian blur to the image, which helped minimize any remaining noise that may have been left after previous steps. The ECG image was then transformed to gray scale, and we used histogram equalization to improve the contrast between the ECG waveform and any residual background noise. This step ensured that the critical features of the waveform were more distinct, allowing the deep learning model to focus on the most relevant data points. In the final stage of preprocessing, the image was reconverted to binary format, accentuating the essential features necessary for more accurate and effective analysis by the model, ultimately improving its ability to predict IHCA.



Spatial Attention

In our model, we used the ResNet50 [26] architecture as the foundational framework due to its robust performance in handling complex image data. ResNet50's use of residual connections enhances the learning capacity of deep networks by facilitating the flow of information and mitigating issues such as vanishing gradients. We integrated an attention mechanism into the network. This integration ensured that the model can better identify subtle, critical signals in the ECG data, ultimately enhancing its predictive performance and improving patient outcomes.

Following the concept of the Convolutional Block Attention Module [27], we strategically positioned spatial attention blocks after each of the first 4 layers, as Figure 2. This design choice was motivated by 2 primary considerations. First, the nature of ECG waveforms, which display both fine and coarse-grained patterns, necessitates a multiscale approach to feature extraction. By placing spatial attention blocks at the front, middle, and end of the network, we enhanced the model's ability to capture and optimize features across varying scales. This is crucial for accurately interpreting the diverse characteristics present in ECG signals, which can vary significantly in amplitude and duration due to different physiological conditions. Second, we intentionally limited the number of attention blocks to mitigate the risk of overfitting during the training process. By judiciously inserting these blocks after each layer, we balanced the complexity of the model with its generalization capabilities.

XSL•FO
RenderX

Figure 2. We inserted a spatial attention (SA) block after each layer and before the next layer.

The incorporation of the spatial attention mechanism allowed the model to learn more representative features, leading to improved performance. Visualization results further demonstrated the model's ability to concentrate on more relevant patterns. Detailed findings are discussed in the following section.

Binary Recall Loss

Our training data set exhibited a slight imbalance of positive and negative samples, which posed a challenge for accurately predicting IHCA. Given the serious threat that IHCA presents to patient safety, maximizing the model's recall is of paramount importance, as it measures the system's ability to correctly identify true positive cases. A high recall ensures that most actual cardiac arrest occurrences are detected, allowing health care professionals to respond swiftly and effectively. However, this focus on recall can inadvertently lead to an increase in false positives, overwhelming the health care system with unnecessary alarms and interventions. Such a scenario can strain resources and divert attention from genuine emergencies, potentially leading to alarm fatigue among medical staff. Therefore, it is equally critical to maintain a reasonable level of precision alongside recall. Striking a balance between these 2 metrics is essential to ensure that we effectively identify critical cases of IHCA while also minimizing the burden on health care providers, ultimately safeguarding patient safety and enhancing the efficiency of emergency care.

To address this, rather than using the traditional binary cross-entropy loss, we used BRLoss by drawing on the concept of performance-based loss from [28]. BRLoss used recall-related weights for each class, as shown in Equation 1:

where N is the number of samples in a batch, y_i is the ground truth label of i-th data in the batch, $y_i \in [0, 1]$, p_i is the predicted probability, $0 \leq p_i \leq 1$ and $Recall_c$ means recall of class c, $Recall_c$ [0, 1], c is 0 or 1.

Unlike many other statistics-based weighted loss [29-31] functions that may cause unnecessary false positives, sacrificing precision to gain recall, BRLoss effectively balanced recall and precision. We used the same analytical method as [26] to perform a partial derivative of the loss function. Assuming the $i - th$ data sample in the batch has a final output z_i before applying the sigmoid function, the gradient for BRLoss can be calculated as shown in Equation 2:

In the case where the ground truth is 1, an increase in false negatives leads to a larger negative gradient in the term related to $Recall_1$ in Equation 2. This drives z to increase during gradient descent, reducing false negatives and improving $Recall_1$. Similarly, when the ground truth is 0, more false positives result in a larger positive gradient in the term related to $Recall_0$ (specificity), causing z to decrease and reduce false positives. BRLoss thus balanced recall and precision, leading to more reliable model performance.

Results

We performed experiments using the NTUH-ECG and FEMH-ECG data sets. Given the increasing significance of explainable artificial intelligence, particularly in the medical domain, interpretability had become essential [32-34]. Therefore, we present various qualitative results and conducted ablation studies to clarify model behavior under different conditions.

Implementation Details

We implemented EIANet using the Python and Pytorch [35] framework. The EIANet training was accelerated using an RTX 3090 GPU. The AdamW [36] optimizer was used to train the model over 200 epochs, with a learning rate initialized at 2×10^{-5}.

Evaluation Metrics for IHCA Prediction

In our binary classification task aimed at predicting IHCA using ECG images, we used a comprehensive evaluation strategy to assess model performance. This involved using several metrics derived from the confusion matrix, such as accuracy, precision,

XSL•FO
RenderX

recall (sensitivity), and specificity. These metrics provided a detailed breakdown of how well the model distinguished between positive (IHCA) and negative (non-IHCA) cases, helping us understand not only the overall accuracy but also how well the model balanced false positives and false negatives. We also calculated the area under the receiver operating characteristic curve (AUROC), which measured the trade-off between true positive rates and false positive rates across different decision thresholds. A higher AUROC value indicates that the model is more capable of distinguishing between the 2 classes, even in the presence of class imbalance. Moreover, we incorporated the area under the precision-recall curve (AUPRC) to evaluate performance, particularly in handling imbalanced data sets like ours, where the positive class is underrepresented. The AUPRC focuses on precision (positive predictive value) and recall, offering a more sensitive measure of the model's performance when identifying IHCA cases without being skewed by the larger number of negative cases. Together, these metrics provided a robust, multifaceted assessment of our model's effectiveness at predicting IHCA, ensuring that it performs well across a range of critical evaluation criteria.

Experimental Results With ECG Data Sets

External Comparison

Table 3 presents a comprehensive comparison between our study and the work of Kwon et al [23], which used raw ECG signals to predict IPCA. In addition to differences in patient populations (ED vs inpatients), a key distinction between the 2 studies lies in the format of the input data: Although Kwon et al [23] used raw ECG signals, our approach was built around the use of ECG images. This shift from signal-based input to image-based input enables our model to leverage advanced image processing techniques, such as spatial attention, to enhance feature extraction. In contrast, raw signals can be directly analyzed using the temporal relationships between successive values.

Table 3. Comparison of our study with Kwon et al [23], highlighting differences in input data formats (electrocardiogram images vs raw signals) and data set balance.

Method	Positive rate	Accuracy	Recall	Precision	Specificity	AUROC[a]
Kwon et al [23]	0.0093	0.918	0.778	0.076	0.920	0.948
Ours	0.401	0.843	0.800	0.813	0.884	0.896

[a]AUROC: area under the receiver operating characteristic curve.

Another significant difference is the distribution of positive samples between the 2 data sets. The work by Kwon et al [23] involved a highly imbalanced data set with a larger proportion of negative samples, which is reflected in their higher specificity. In contrast, our data set was more balanced, with a more equitable distribution of positive and negative samples, which had a direct influence on the performance metrics. This difference in the proportion of positive samples played a crucial role in shaping outcomes like precision, accuracy, and AUROC, making direct comparisons between the 2 models less straightforward.

In summary, our approach, with spatial attention, BRLoss, and more balanced sample distribution, can enhance the accurate detection of positive cases, leading to a slightly higher recall. The model by Kwon et al [23], having a predominantly negative sample set, excels in specificity but may sacrifice sensitivity to positive cases. The distinct methodologies and differing data set characteristics highlight the complementary strengths of the 2 approaches, offering insights into how input formats and sample distributions can impact the prediction performance of cardiac arrest models.

Comparison With the Benchmark

To the best of our knowledge, the NTUH-ECG data set stands as the only data set we can get to date that uses image-based ECG data specifically for the prediction of EDCA. Our proposed model, EIANet, represents a pioneering approach in this domain, being the first to tackle this predictive task using ECG images as input. We used the well-established vision model ResNet50 as a baseline for comparative analysis, leveraging its widespread recognition in image-based tasks as a point of reference.

Table 4 shows a side-by-side comparison of the performance of EIANet and ResNet50. Compared with solely using the ResNet50 module, EIANet incorporates spatial attention, enabling the model to focus more on spatially crucial features. With stronger feature representations, combined with BRLoss, the model's ability to differentiate between positive and negative samples is further enhanced. IEIANet significantly outperforms ResNet50 across multiple evaluation metrics, underscoring the efficacy of our tailored approach. We attribute this marked improvement to 2 key innovations in our model design. First, the incorporation of the spatial attention module substantially enhanced the model's feature extraction capabilities. By using spatial attention, EIANet can dynamically focus on the most relevant regions within the ECG images, allowing it to capture critical visual patterns that are often indicative of impending cardiac events. This focused attention provides the model with a more nuanced understanding of the subtle yet vital features present in ECG images. In addition to spatial attention, BRLoss helps to mitigate the risk of too many false positives and false negatives, leading to a slight improvement in recall without affecting precision too much.

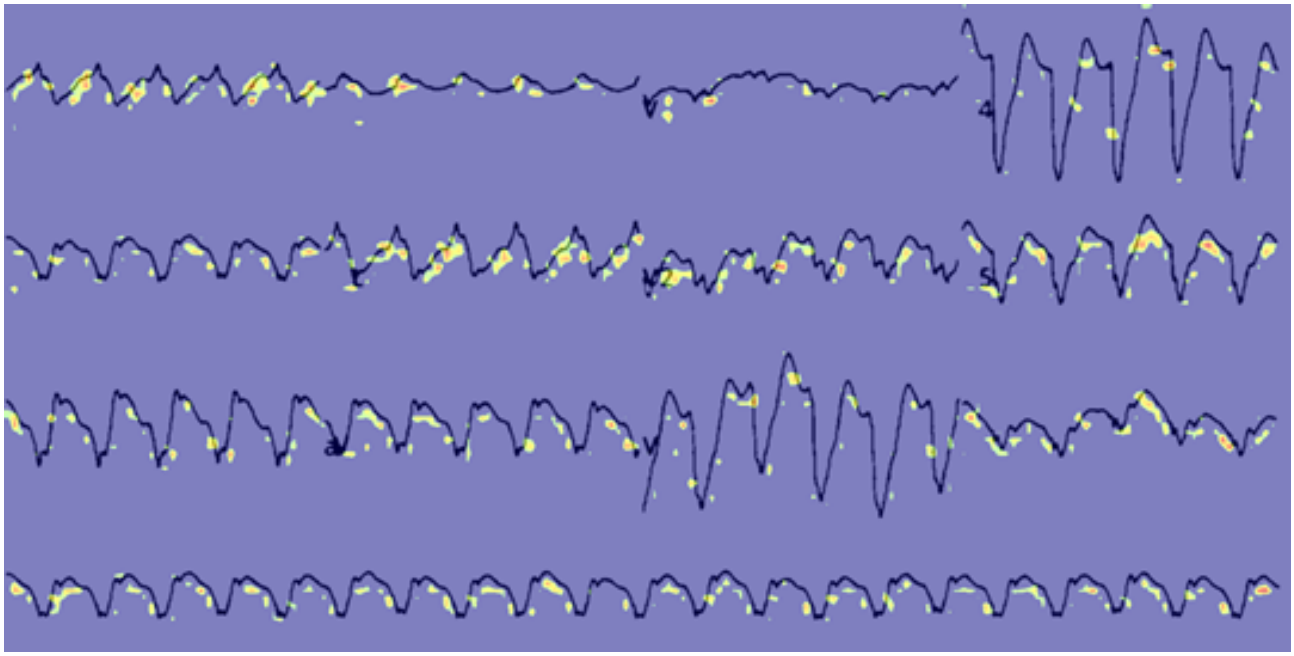
Qualitative Results

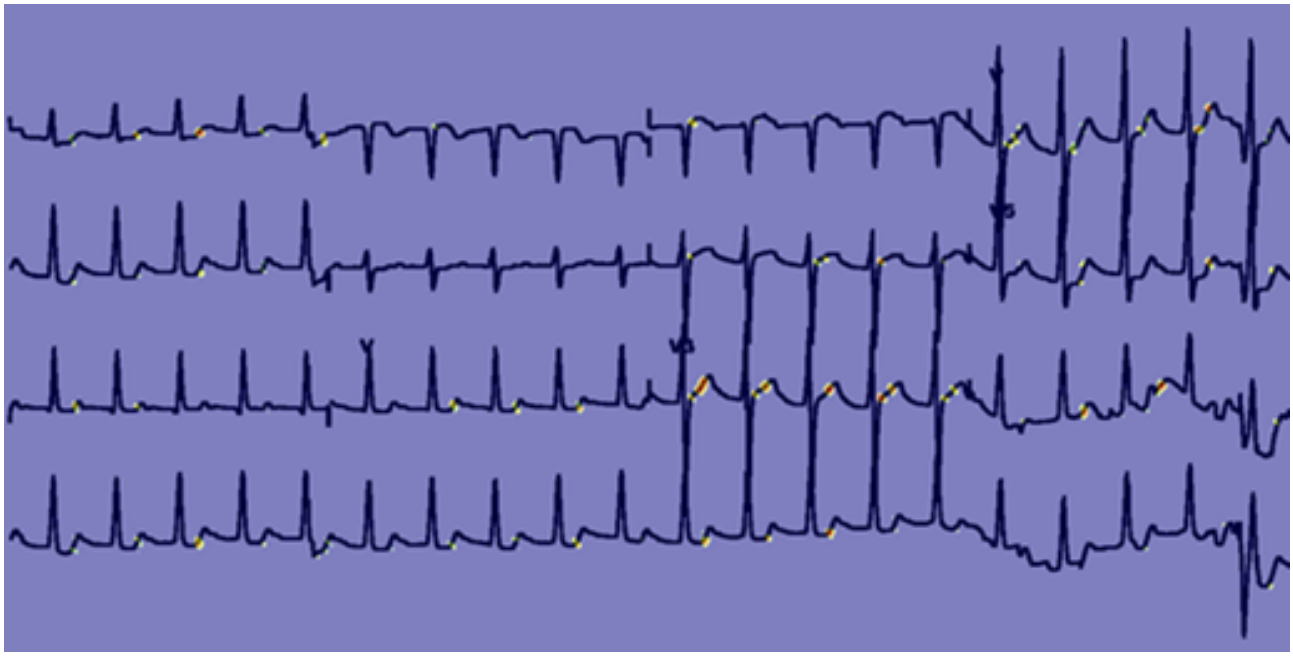
Figure 3 and Figure 4 provide feature map [37] visualizations of positive samples from the NTUH-ECG data set. The visualization shows the Grad-CAM output, highlighting regions with Grad-CAM values greater than 0.4. Figure 3 shows the output of a model incorporating spatial attention, while Figure 4 presents the results of a model devoid of spatial attention. Alterations in the ST segment serve as pivotal indicators of myocardial ischemia. Notwithstanding the presence of a bundle branch block in this ECG, EIANet, as depicted in Figure 3, could still accurately pinpoint the ST segment. This underscores EIANet's capacity to discern patterns associated with EDCA within ECG images. Furthermore, tachycardia is a prevalent ECG manifestation preceding EDCA. The regular bright spots in the figures suggest that the algorithm is adept at counting the heart rate. In contrast, although the model without spatial attention, as illustrated in Figure 4, also counted the heart rate, its focus on the ST segment was less precise and more dispersed.

Figure 3. Feature map of a National Taiwan University Hospital electrocardiogram (NTUH-ECG) sample with a spatial attention block.

XSL•FO
RenderX

Figure 4. Feature map of a National Taiwan University Hospital electrocardiogram (NTUH-ECG) sample without a spatial attention block.





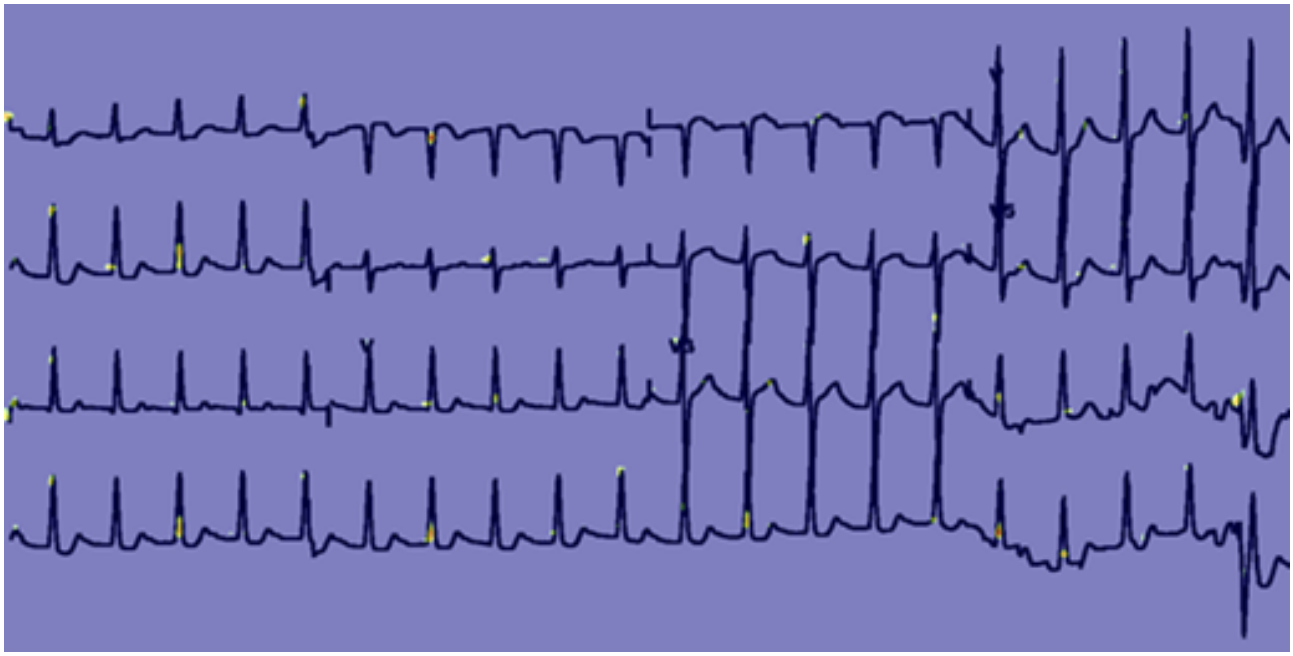


Figure 5 and Figure 6 present visualizations from the FEMH-ECG data set, which further illustrate the impact of spatial attention by focusing on heart rate–related features. In Figure 5 (with spatial attention), the model effectively identifies regular bright spots corresponding to heartbeats, indicating its ability to count the heart rate accurately. Conversely, Figure 6 (without spatial attention) shows a less distinct attention pattern, reducing interpretability.

Ablation Study

The first ablation study focused on evaluating the impact of different types of input data on model performance. As detailed in Table 5, using raw ECG images directly extracted from PDF reports for training demonstrated a certain level of predictive capability, indicating that even unprocessed images contain valuable information that the model can learn from. However, the study revealed that, when these raw images undergo a series of image preprocessing steps to remove irrelevant or distracting elements, the model's performance saw marked improvement because the model could focus on crucial visual patterns and structures essential for predicting EDCA. This performance boost underscores the importance of preprocessing for enhancing the quality of the input data.

Table 5. Comparison of raw images and processed images on the National Taiwan University Hospital electrocardiogram (NTUH-ECG) data set.

Input	Accuracy	Recall	Precision	F_1-score	AUROC[a]	AUPRC[b]
Raw image	0.782	0.737	0.718	0.727	0.832	0.785
Processed image	0.843	0.800	0.813	0.805	0.896	0.842

[a]AUROC: area under the receiver operating characteristic curve.

[b]AUPRC: area under the precision-recall curve.

By applying preprocessing techniques, such as noise reduction, removal of grid lines, and extraction of key features, the model was better able to focus on the most relevant aspects of the ECG images, allowing it to learn more effectively. Preprocessing not only reduced the amount of noise and irrelevant information present in the images but also helped to clarify the visual patterns and structures that are crucial for predicting EDCA. This led to more accurate predictions and overall model performance.

Table 6 presents an ablation study evaluating the influence of spatial attention and BRLoss on the model's performance and demonstrates the impact of incorporating the spatial attention mechanism and BRLoss on model performance. We trained our model on the NTUH-ECG training set and validated it using both the NTUH-ECG testing set and the FEMH-ECG data set. As expected, due to differences in patient populations, there was a slight decrease in model performance in the FEMH-ECG data set. The results indicate that the spatial attention module and BRLoss elevated the model's performance. The spatial attention mechanism empowered the model to extract more effective ECG features, such as the ST segment and heart rate patterns, thereby enhancing feature representation and overall model accuracy. This mechanism ensured that the model concentrated on critical segments of the ECG image, leading to improved interpretability and reliability. Moreover, BRLoss ameliorated the model's recall without compromising precision to a significant degree. BRLoss focuses on reducing false predictions and improving F_1-score and AUROC. However, its effectiveness also depends on the model's ability to sufficiently represent the data. When combined with spatial attention, the performance of the model can be further enhanced by leveraging the strengths of both modules. Although BRLoss prioritizes recall, decision thresholds can be adjusted in clinical applications to achieve a suitable balance between recall and precision, addressing specific requirements in emergency scenarios.

Ablation Study With Varying Class Imbalances

To evaluate the contributions of the spatial attention module and BRLoss under varying class imbalances, we performed random resampling of the NTUH-ECG and FEMH-ECG data sets to adjust the proportion of positive samples to 0.1 and 0.2. Each resampling experiment was repeated 30 times, and the results were averaged to ensure robustness. The ablation study results under positive sample ratios of 0.1 and 0.2 are presented in Table 7. These results clearly demonstrate the contributions of spatial attention and BRLoss to the model's performance. In addition, for metrics that are not dependent on the prevalence of positive cases (eg, AUROC), the model performance remained.

Discussion

Principal Findings

To our knowledge, this is the first study to develop and validate a deep learning algorithm (EIANet) specifically for predicting EDCA using ECG image data. The findings demonstrate that deep learning, a powerful artificial intelligence tool, can detect subtle ECG changes hours before cardiac arrest in the ED. Deployment of this tool at ED triage has the potential to gain lead time to identify high-risk patients for timely interventions and reduce EDCAs.

Comparison With Prior Work

Traditionally, ECG prediction of cardiac arrest has mainly focused on OHCA (ie, using ECG to predict sudden cardiac death at the population level) [38]. For example, an electrical risk score that comprises 6 features (heart rate, prolonged corrected QT interval, Tpeak-Tend interval, QRS-T angle, left ventricular hypertrophy, and delayed QRS transition zone) can accurately predict sudden cardiac death within a community-based cohort [39]. A refined deep learning–based ECG model can further improve its predictive ability using the same 6 features [40]. Notably, tachycardia has been included as one of the features in the electrical risk score and was also documented in our feature map analysis and in a previous IPCA ECG study [23], suggesting the importance of this feature in predicting OHCA, IPCA, and EDCA.

One of our previous studies on EDCA focused on the development and validation of a simple 8-item, rule-based prediction tool using structural data at ED triage [25]. Another study of ours further advanced EDCA prediction by using deep learning with static triage data and dynamic vital signs measured during the ED stay [16]. None of these studies used ECG as an input for deep learning, as we did in this study. Given the promising results of using triage ECG to predict EDCA, the next logical step would be to combine ECG and structural data as a multimodal model for EDCA prediction.

Strengths

The EIANet has several technical innovations. Before model training, we used image processing techniques to eliminate

XSL•FO
RenderX

manual labels and noise from the ECG images. To enhance model performance, we integrated an attention mechanism and BRLoss. These components had a positive impact on EIANet's predictive capabilities. Our research used 2 ECG image data sets: NTUH-ECG and FEMH-ECG. The NTUH-ECG data set, with a positive sample ratio of 40%, yielded impressive results, with EIANet achieving an F_1-score of 0.805 and AUPRC of 0.842. The FEMH-ECG data set, characterized by a lower positive sample ratio of 34.6%, still demonstrated strong performance, with EIANet attaining an F_1-score of 0.650 and AUPRC of 0.678. To validate the effectiveness of the proposed modules, we conducted ablation studies, further confirming their importance. Additionally, Grad-CAM visualization was used to provide interpretability for EIANet's predictions using ECG images.

In the past, ECG prediction models were typically designed for diseases with relatively obvious features, such as myocardial infarction or hyperkalemia [41,42]. However, precardiac arrest ECGs lack absolutely distinct characteristics, making EDCA significantly more challenging to predict. Additionally, most existing image-based ECG models have remained in the proof-of-concept stage, often relying on general purpose framework models like ResNet without substantial customization for this specific task. These approaches, although promising, have struggled with critical limitations, such as high false-negative rates and limited interpretability. To address these challenges, we enhanced ResNet50 by incorporating a spatial attention mechanism, enabling the model to focus on subtle but clinically significant ECG patterns. Furthermore, we introduced a BRLoss function to prioritize recall and reduce false negatives, a critical improvement for predicting rare but life-threatening events like EDCA. These innovations aimed to overcome the inherent limitations of prior approaches and establish a practical, interpretable, and effective prediction framework.

Limitations and Future Directions

Although our results demonstrate a certain level of predictive capability on both the NTUH-ECG and FEMH-ECG data sets, the performance on the FEMH-ECG data set declined. The observed drop in recall when evaluating the EIANet model on the FEMH-ECG data set can be attributed to multiple factors. First, patient population differences between the data sets likely played a significant role. Variations in patient populations could influence the manifestations of ECGs, leading to differing model performance. Second, differences in instrumentation between the 2 data sets may have introduced some biases. These discrepancies, combined with slight differences in image sizes formats and preprocessing process, might have impacted the model's ability to generalize effectively. Addressing these challenges in future work by incorporating more diverse data sets could enhance the model's robustness and applicability across different clinical settings. In the future, we hope to use EIANet as an encoder for ECG data, integrating it with other modalities of patient information to establish a more comprehensive multimodal prediction method for EDCA.

This study has some potential limitations. First, the model's performance was dependent on the quality and variety of the training data. Although we included ECGs from 2 independent medical centers, further external validation studies are needed to evaluate the model's robustness in different patient populations. Second, this was a retrospective study. Even with external validation, as in our retrospective study, models could have poor performance in the prospective setting, such as the Rothman Index by PeraHealth [43,44] and the Epic Sepsis Model [45,46]. Future implementation of the EIANet model in the ED would be warranted to test its real-world effectiveness.

Conclusions

In conclusion, we presented a comprehensive study aimed at understanding the relationship between ECG images and EDCA. To the best of our knowledge, this is the first in the literature that uses readily available 12-lead ECG images at ED triage to predict imminent ED cardiac arrest. Using 2 independent ED data sets, we developed and externally validated the novel deep learning EIANet model that can be used to identify high-risk patients and potentially reduce devastating ED cardiac arrest events. Future implementation of the EIANet in real time is warranted to test whether this tool could flag high-risk patients at ED triage for timely interventions, thereby improving patient outcomes.

Acknowledgments

We thank the staff of the National Taiwan University Hospital-Integrative Medical Data Center (NTUH-iMDC) for providing clinical data for this study.

This research was supported by the Ministry of Science and Technology of Taiwan and Center for Artificial Intelligence & Advanced Robotics, National Taiwan University, under the grant numbers MOST 110-2634-F-002-049 and MOST 110-2221-E-002-166-MY3. This project was also supported by grants from the National Health Research Institutes (NHRI-EX114-11332PI), National Science and Technology Council (NSTC 112-2314-B-002-264), and National Taiwan University Hospital (112-UN-0027 and 113-UN0017).

Generative artificial intelligence was not used in any portion of the manuscript generation.

Data Availability

The artificial intelligence algorithm cannot be made publicly available because it is proprietary intellectual property. The computer code and data for this study are available from the corresponding authors upon reasonable request for research studies.

Abstract

Background: Sentiment analysis of alternative tobacco products discussed on social media is crucial in tobacco control research. Large language models (LLMs) are artificial intelligence models that were trained on extensive text data to emulate the linguistic patterns of humans. LLMs may hold the potential to streamline the time-consuming and labor-intensive process of human sentiment analysis.

Objective: This study aimed to examine the accuracy of LLMs in replicating human sentiment evaluation of social media messages relevant to heated tobacco products (HTPs).

Methods: GPT-3.5 and GPT-4 Turbo (OpenAI) were used to classify 500 Facebook (Meta Platforms) and 500 Twitter (subsequently rebranded X) messages. Each set consisted of 200 human-labeled anti-HTPs, 200 pro-HTPs, and 100 neutral messages. The models evaluated each message up to 20 times to generate multiple response instances reporting its classification decisions. The majority of the labels from these responses were assigned as a model's decision for the message. The models' classification decisions were then compared with those of human evaluators.

Results: GPT-3.5 accurately replicated human sentiment evaluation in 61.2% of Facebook messages and 57% of Twitter messages. GPT-4 Turbo demonstrated higher accuracies overall, with 81.7% for Facebook messages and 77% for Twitter messages. GPT-4 Turbo's accuracy with 3 response instances reached 99% of the accuracy achieved with 20 response instances. GPT-4 Turbo's accuracy was higher for human-labeled anti- and pro-HTP messages compared with neutral messages. Most of the GPT-3.5 misclassifications occurred when anti- or pro-HTP messages were incorrectly classified as neutral or irrelevant by the model, whereas GPT-4 Turbo showed improvements across all sentiment categories and reduced misclassifications, especially in incorrectly categorized messages as irrelevant.

Conclusions: LLMs can be used to analyze sentiment in social media messages about HTPs. Results from GPT-4 Turbo suggest that accuracy can reach approximately 80% compared with the results of human experts, even with a small number of labeling decisions generated by the model. A potential risk of using LLMs is the misrepresentation of the overall sentiment due to the differences in accuracy across sentiment categories. Although this issue could be reduced with the newer language model, future efforts should explore the mechanisms underlying the discrepancies and how to address them systematically.

Introduction

Heated tobacco products (HTPs) are emerging tobacco products that heat processed tobacco leaves, enabling users to breathe nicotine into their lungs [1]. As these products gain global market share at a rapid pace, their potential impacts on tobacco prevention and cessation initiatives are becoming an important topic of public debate [2].

Social media platforms are where a wide range of stakeholders of tobacco regulations distribute their messages, such as policy announcements, product advertisements, and product user feedback [3-5]. Analyses of social media discourses on HTPs provide opportunities to observe and identify the dynamics of these messages, which could affect the public's perception of these products and relevant regulatory issues [3-7].

Sentiment analysis is a widely adopted method to understand the attitudes of the public toward tobacco-related issues by evaluating social media messages [8-11]. Prior research has specifically focused on positive and negative sentiments due to their possible associations with tobacco cessation and prevention outcomes, such as the use of tobacco products and support for tobacco regulations [11-13].

In past sentiment analyses of large-scale social media content data, human evaluators often examined a subset of the dataset rather than analyzing the entire dataset. The subset was then used as a representative sample to inform the sentiment of the whole dataset [8,9] or as a reference for machine learning classifiers tasked with analyzing the entire dataset [14]. This approach stems from the time-consuming and labor-intensive nature of human sentiment evaluation, which involves recruiting, training, and coordinating multiple evaluators. This complexity arises from the fact that latent coding, including sentiment analysis, requires understanding the underlying meanings and subtleties in the text, which can substantially vary depending on the context and across coders [15].

Large language models (LLMs), such as OpenAI's Generative Pre-trained Transformer and Google's Gemini, may be able to alleviate the burdens of human sentiment evaluation. LLMs are artificial intelligence (AI) models that were trained on extensive text data to emulate the linguistic patterns of humans [16,17]. Recent LLMs are known to achieve precision at the level of human decisions on several intellectual tasks [18]. As LLMs become increasingly accessible and available, expectations are growing about the feasibility of using these technologies in public health and social science research [19]. Several examples include analyzing health and medical information [20,21], pretesting the effect of health campaign messages [22], predicting psychological experimental results [23], and simulating sociodemographic groups and their reactions to social issues [24].

We investigate the accuracy of LLMs in analyzing sentiment in social media messages about HTPs. The current research focuses on OpenAI's GPT, given its high accessibility, availability, and popularity. GPT models are easily accessible through chatbot services such as ChatGPT, Microsoft Copilot, and Apple Intelligence and are estimated to have the largest user base worldwide. For instance, ChatGPT has more than 200 million weekly active users as of August 2024 [25]. These aspects contribute to the attractiveness of GPT as an analytic tool for tobacco researchers, especially those with limited budgets and resources.

This study examines the accuracy of GPT-3.5 and GPT-4 Turbo in emulating human sentiment evaluations of social media messages related to HTPs. GPT-3.5 is a milestone model that powered ChatGPT when the service was launched [26]; GPT-4 Turbo is one of the most recent GPT-4 models as of 2024, with a particular development focus on improvements in processing text prompts [27]. This study conducted direct comparisons of the sentiment evaluations made by human coders and these language models based on social media messages gathered from multiple platforms. This investigation could ultimately contribute to assessing the ability of LLMs in examining how the public views alternative tobacco products.

Methods

Data Collection

Messages relevant to HTPs were collected from 2 social media platforms that provide distinct message formats: Facebook (long format) and Twitter (short format). Facebook posts were collected using CrowdTangle (CT)'s keyword search feature. CT was a social media analytic tool provided by Facebook's parent company, Meta. It allowed researchers to access the historical data of Facebook [28]. Tweets were gathered using Twitter's application programming interface 2.0, which could access the historical Twitter dataset through the company's academic research access program [29]. This study focused on messages written in English.

In April 2022, a keyword search was conducted using the following search query: "heat not burn" OR "heat-not-burn" OR "heated tobacco" OR "tobacco heating" OR ((htp OR hnb) AND (smoking OR smoke OR vaping OR vape OR tobacco OR cig OR nicotine)) OR iqos. This query was designed to find tweets and Facebook posts meeting at least one of the following conditions: (1) Containing "heat not burn" in its entirety; (2) containing "heat-not-burn" in its entirety; (3) containing "heated tobacco" in its entirety; (4) containing "tobacco heating" in its entirety; (5) containing at least one of "htp" and "hnb," only when it also contains one of "smoking," "smoke," "vaping," "vape," "tobacco," "cig," and "nicotine;" and (6) containing "iqos." This search yielded 16,284 Facebook posts that were published between January 2014 and December 2021 and 60,031 tweets published in the same period.

Human Evaluation

The procedures for preparing samples for human sentiment evaluations were adapted from sentiment analyses of tobacco-related mass and social media discussions [8-11]. A team of 3 human coders evaluated the sentiment of 1250 Facebook posts and 1200 tweets sampled from the entire pool of keyword-searched social media messages (ie, 16,284 Facebook posts and 60,031 tweets). Those messages were human-labeled as one of the following 5 categories: ANTI (anti-HTP messages), PRO (pro-HTP messages), NEU (neutral

XSL•FO
RenderX

messages), MIX (messages containing a mixture of positive and negative attitudes on HTPs), and IR (messages irrelevant to HTPs).

The messages were sampled through a multistep process designed to increase the likelihood of including both potentially negative and positive messages, ensuring their inclusion in the selected messages for human annotation. The details of the sampling and coding procedures are reported in Multimedia Appendix 1.

GPT Evaluation

From each of the human-evaluated 1250 long-form and 1200 short-form messages, we randomly selected 200 PRO, 200 ANTI, and 100 NEU messages, totaling 1000 messages. All these selected messages for GPT-3.5 and GPT-4 Turbo sentiment classification were relevant to HTPs. A LLM prompt was created for each message, including coding instructions, the message, and the coding scheme. Since this study aims to conduct direct comparisons between the sentiment evaluations of human coders and the language models, the instructions and the coding scheme for the language models were kept consistent with those for human coders, aside from minor formatting adjustments. The instructions included in the prompt directed a language model to categorize a given message based on the coding scheme and to format its response based on formatting rules. The coding scheme, largely identical to the one given to human evaluators, included the definitions and explanations of HTPs and 5 sentiment categories (ANTI, PRO, NEU, MIX, and IR).

LLMs generate a sequence of words by selecting each word based on its preceding words, and the selection is done by sampling a word from a large distribution of possible words [16,17]. Because of the inherent randomness in this sampling process, LLMs may produce different responses to the same prompt. This potential variability can be accounted for by generating multiple responses from an LLM using the same prompt [30]. To be specific, we collected 20 instances of responses for each message, referred to as "response instances." Each instance was obtained by initiating a new chat with a language model, sending the prompt, and saving the response from the model.

A language model's decision for each message was determined by randomly selecting m instances from a pool of 20 response instances with replacement. Then, the majority within the selected instances was identified. This majority outcome was termed the "machine decision." We assessed the machine decision by varying the number of response instances (m=1, 3, 5, 7, 9, and 11). For example, m=5 simulates a scenario where a user generates 5 response instances and identifies the majority among them. m=1 corresponds to a "one-shot" determination, where a single instance was generated and considered as the machine decision. In the case of a tie, an extra response instance was randomly selected until the tie was broken.

For each message and each value of m, the process of determining a machine decision was iterated 1000 times. After each iteration, a variable that we refer to as "human-machine concurrence" was recorded as 1 if the machine decision aligned with the human evaluation of the message. Otherwise, it was recorded as 0. This variable was then averaged across all iterations, yielding a value referred to as "accuracy." Thus, the accuracy in this study indicates how accurately the language models classify the sentiment of a message based on the m number of responses. Alternatively, the accuracy can be interpreted as the proportion of messages classified by the language models that match the human sentiment evaluation of the same messages. For instance, if the accuracy of a language model is 90% for ANTI message classification, this suggests that nine-tenths of human-labeled ANTI messages are categorized as ANTI by the model. To assess the overall accuracy of the model in evaluating the sentiment of a specific set of messages (eg, Facebook messages classified as ANTI by human evaluators), we calculated the average accuracy across messages in each set, denoted as K_m. For example, K_{11} for ANTI messages refers to the proportion of human-labeled ANTI messages that were also classified as ANTI by a language model based on 1000 iterations of the majority of randomly selected 11 responses out of the total of 20 responses. Examples of human-labeled ANTI, PRO, and NEU messages, along with the language models' sentiment classification decisions on the same messages, are provided in Table S16 in Multimedia Appendix 1.

Results

GPT-3.5 Evaluation

The average accuracy, based on 20 response instances (K_{20}), was 0.612 (SE 0.02) for long-form and 0.570 (SE 0.02) for short-form messages. However, the accuracy varied across categories. For messages categorized as ANTI by human evaluators, K_{20} was 0.755 (SE 0.028) for long-form and 0.696 (SE 0.03) for short-form messages. For messages categorized as PRO by human evaluators, the accuracy was 0.544 (SE 0.033) for long-form and 0.476 (SE 0.033) for short-form messages. The language model's average accuracy for messages classified as NEU by human evaluators was 0.461 (SE 0.04) for long-form and 0.507 (SE 0.042) for short-form messages. Table 1 presents the accuracy of different sentiment labels with varying m.

[a]m indicates the number of response instances used for majority determination. When m is greater than 1, machine decision is the majority among the response instances. When m equals 1, the machine decision is equal to the response instance (1-shot determination).

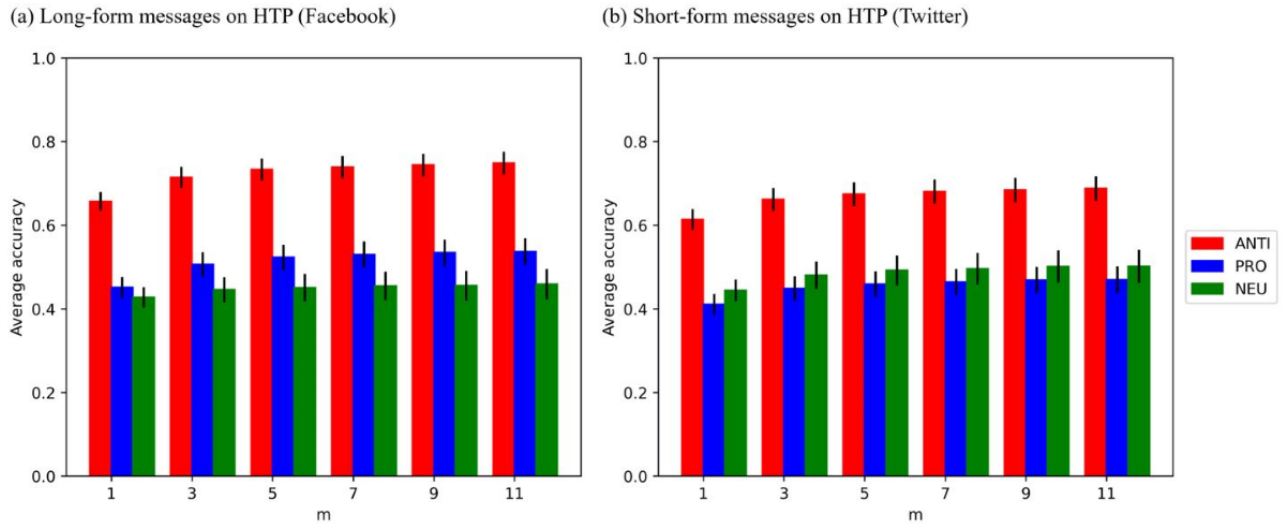
[b]anti-HTP messages.

[c]pro-HTP messages.

[d]neutral messages.

[e]K_m indicates the average of the machine accuracy of n messages when the machine decision for each message was determined based on m response instances.

[f]Not applicable.



Most discrepancies arose when the language model classified messages as NEU or IR, whereas human evaluators identified positive or negative sentiments in these messages. For instance, the model misclassified 24.5% (49/200) of human-evaluated long-form ANTI messages. Among these misclassified messages, the language model classified 61.2% (30/49), 26.5% (13/49), and 12.2% (6/49) as NEU, IR, and PRO. Tables S2, S4-S7, and Figures S1 and S2 in Multimedia Appendix 1 provide more detailed comparative descriptions of decisions made by human evaluators and GPT-3.5.

The significance of differences in accuracy between sentiment categories was examined. The results indicated that K_{20} for human-evaluated ANTI messages was significantly higher than that of human-labeled PRO (U=26483.5; P<.001) and NEU (U=14675.5; P<.001) messages in long form. This was also true for human-labeled short-form PRO (U=25876.5; P<.001) and NEU (U=13312.5, P<.001) messages. These gaps in accuracy were consistent across all m values and formats (see Tables S12 and S13 in Multimedia Appendix 1).

The accuracy improved as *m* increased, as visualized in Figure 1. In Figure 1, error bars represent the mean (SE) of the mean, and "m" refers to the number of response instances. However, even with a few response instances, the accuracy was comparable to the accuracy based on 20 response instances. For example, even the average accuracy of 1-shot determination (K_1) for human-labeled ANTI, PRO, and NEU messages also reached 87.1%, 83%, and 92.7% of K_{20} for long-form messages and 88.3%, 86.4%, and 87.6% of K_{20} for short-form messages.

Figure 1. Accuracy across response instances and message formats (GPT-3.5). HTP: heated tobacco product. ANTI: anti-HTP; PRO: pro-HTP; NEU: neutral.

GPT-4 Turbo Evaluation

GPT-4 Turbo demonstrated higher accuracy than GPT-3.5 across all sentiment categories. The language model's overall average accuracy was 0.817 (SE 0.017) for long-form messages and 0.770 (SE 0.019) for short-form messages. Although accuracy varied across categories, the gap between the accuracy in ANTI and PRO sentiment classification decreased compared with GPT-3.5. For human-labeled ANTI messages, K_{20} was 0.861 (SE 0.024) for long-form messages and 0.79 (SE 0.028) for short-form messages. For human-labeled PRO messages, K_{20} was 0.84 (SE 0.025) for long-form messages and 0.783 (SE 0.029) for short-form messages. The accuracy for human-labeled NEU message categorization also increased compared to GPT-3.5. For NEU messages, K_{20} was 0.685 (SE 0.044) for long-form messages and 0.703 (SE 0.045) for short-form messages. The accuracy of sentiment categories with varying *m* is reported in Table 2.

[a]m indicates the number of response instances used for majority determination. When m is greater than 1, machine decision is the majority among the response instances. When m equals 1, the machine decision is equal to the response instance (1-shot determination).

[b]anti-HTP messages.

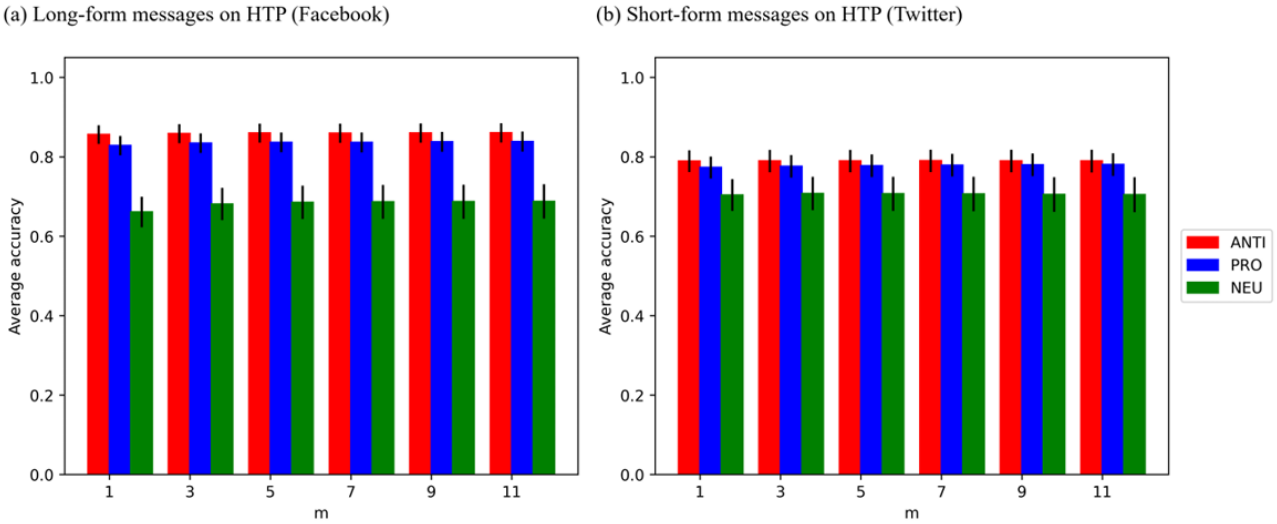
[c]pro-HTP messages.

[d]neutral messages.

[e]K_m indicates the average of the machine accuracy of n messages when the machine decision for each message was determined based on m response instances.

[f]Not applicable.

GPT-4 Turbo showed fewer false selections of the IR label across all sentiment categories. When examined with 3 randomly selected response instances (m=3), the model misclassified only 10 out of the entire 1000 sample messages as IR. This impacted the pattern of mismatches between human and language model sentiment classification. For instance, the model categorized 14% (28/200) of human-labeled ANTI messages as one of the other labels. Of these mismatches, 93% (26/28) were classified as NEU. Multimedia Appendix 1 includes contingency tables (Tables S3 and S8-S11) as well as flow charts (Figure S2) providing more detailed comparative descriptions of human and language model sentiment labeling.



For long-form messages, the model's accuracy of ANTI classification based on 20 response instances was significantly higher than NEU classification (U=12,561.5; P<.001) but not significantly different from the accuracy of PRO classification (U=20,810.5; P=.30). PRO classification also showed significantly higher accuracy compared with NEU classification (U=12,176; P<.001). This pattern was observed across all m values. For short-form messages with lower m values, the

XSL•FO
RenderX

accuracy of ANTI and PRO classification was significantly greater than NEU labeling. For example, the 1-shot determination (K_1) for ANTI and PRO classification was significantly higher than for NEU classification (ANTI vs NEU: U=11,829; P<.001 and PRO vs NEU: U=11,625; P<.001). However, these differences diminished as m increased; K_{20} was not significantly different across the 3 sentiment categories. The difference test results across all m values are provided in Multimedia Appendix 1 (Table S14 and S15).

The model's accuracy in 1-shot cases was already comparable with that of 20 instances, as shown in Figure 2. Error bars represent the mean (SE) of the mean, and "m" refers to the number of response instances. Table 2 above presented that the accuracy of the 1-shot determination (K_1) reached at least 96.5% accuracy based on 20 response instances (K_{20}).

Figure 2. Accuracy across response instances and message formats (GPT-4 Turbo). HTP: heated tobacco product; ANTI: anti-HTP; PRO: pro-HTP; NEU: neutral.

Discussion

GPT-4 Turbo accurately replicated 81.7% of human sentiment evaluations for long-form messages and 77% for short-form messages, based on 20 AI responses. In comparison, GPT-3.5's K_{20} indicated that the model's labeling decisions matched human coders' evaluations with 61.2% accuracy for long-form messages and 57% accuracy for short-form messages. In sum, GPT-4 Turbo showed improvements in accuracy compared to GPT-3.5 due to increased accuracy across all sentiment categories.

Focusing on GPT-4 Turbo, which showed better overall accuracy, the LLM demonstrated already high accuracy with a small number of responses. The difference in accuracy between a small number of responses (eg, m=1, 3) and a high number of responses (eg, m=20) was not statistically significant. For all sentiment categories, the language model's K_3 reached at least 99.2% of K_{20}. The model demonstrated similar levels of accuracy for ANTI and PRO labels for both long-form and short-form messages. While the accuracy of NEU classification was lower than that of ANTI and PRO classification, it increased by approximately 20 percentage points compared with GPT-3.5. These findings suggest that GPT-4 Turbo can yield more accurate sentiment classification decisions, even with a small number of response instances, such as 3.

GPT-3.5 showed discrepancies in accuracy across sentiment categories. Specifically, the accuracy of the ANTI classification was better than the PRO classification. This finding suggests the possibility of a relative underrepresentation of messages with positive sentiment compared with negative sentiment when using LLMs for sentiment analysis of tobacco-related social media discourses. This issue calls for further exploration of approaches, techniques, and procedures to assess, mitigate, or compensate for LLMs' potential inconsistencies across different sentiment categories, as well as the reasons underlying these discrepancies.

Employing a newer model may be the most straightforward solution, as shown by the comparison between older (GPT-3.5) and newer (GPT-4 Turbo) models. The newer model not only improved accuracy across all sentiment categories but also showed no significant difference in accuracy between ANTI and PRO classifications. This is particularly important for tobacco prevention researchers, as the detection of ANTI and PRO sentiments is important due to their possible associations with tobacco prevention outcomes [11,12,31]. However, a more recent model may not always perform better than its predecessors. For example, GPT-4 Turbo experienced a "laziness" issue, where the model does not complete user requests [32]. Therefore, the performance of new language models on specific tasks should also be rigorously tested.

Using language models specialized for health and medical information analyses, such as Google's Med-PaLM [33] and Stanford University's BioMedLM (previously PubMedGPT) [34], may influence accuracy. Research in this area is still emerging, with limited evidence on the application of these specialized LLMs for sentiment analysis. Previous studies have primarily used standard GPT models [35-38]. In addition, using these specialized models could be more difficult than widely used platforms like ChatGPT. Still, their performance in

XSL•FO
RenderX

analyzing the sentiment of public health-related social media messages warrants future investigations, considering their capabilities in handling content from the general public, not just academic researchers and professionals.

Prompt engineering could be another strategy for improving the accuracy of LLMs in sentiment analysis and reducing discrepancies across categories. In line with the objective of this study to facilitate a straightforward comparison between human coders' and language models' labeling decisions, we used a prompt that closely mirrored the coding scheme for human evaluators. However, different prompting techniques can lead to different results for similar requests [39,40]. Techniques such as few-shot prompting, which involves including task-related examples within the prompts, may enhance accuracy. For instance, rather than only defining sentiment labels, the coding scheme can provide several example messages for each label. Although these techniques complicate direct comparisons between human and machine classification, they possibly offer potential accuracy gains worth exploring.

Establishing and adopting coding procedures for LLM-involved coding is also worthwhile. A study investigating LLMs as substitutes for human coders in labeling texts on political topics serves as a good example [30]. The authors proposed a "hybrid" model where disagreements between the "GPT-4 first run" and the "GPT-4 second run" are resolved by a human coder. Their findings demonstrated that the hybrid approach can be optimized with minimal additional human effort and boosted the accuracy of GPT-4's annotations. This hybrid approach can potentially be adapted for the analysis of sentiment about health topics, and other coding procedures should be explored to further enhance the accuracy and efficiency.

The implications and future applications of our findings should be discussed with caution. First, this study is a focused case study on OpenAI's GPT, examining sentiment analysis on Twitter and Facebook messages related to HTPs. Future research can extend beyond this specific focus to evaluate the accuracy of LLMs in analyzing the sentiment of health-related information across a broader range of topics and platforms. Second, while the differences in accuracy for ANTI and PRO sentiment classifications that were present in GPT-3.5 disappeared in GPT-4 Turbo, and the accuracy of NEU classification increased by 20%, the NEU classification accuracy remained lower. A simple explanation might be the underperformance of the models. For instance, GPT-4 Turbo misclassified a human-labeled NEU message, which used HTPs as examples to explain an economic principle, as irrelevant. Alternatively, this difference might stem from the inherent complexity of evaluating neutrality [15,41]. For example, human coders classified a message as NEU, describing IQOS (Philip Morris International) as a device that uses a "patented heat-control technology." In contrast, GPT-4 Turbo classified the same message as PRO, interpreting "patented heat-control technology" to have positive connotations. It may be worthwhile for future research to explore the patterns of misclassifications by LLMs. Third, this study did not address the potential ethical issues of using LLMs for sentiment analysis of social media content. Ethical considerations, such as security, privacy protection, and data ownership, are important when using LLMs to analyze social media messages [42,43]. These issues require careful attention when analyzing health-related information using LLMs, too [44,45]. Future research should use LLMs while carefully considering the potential ethical issues surrounding their content analyses.

Acknowledgments

We thank Kyungmin Kang for her contribution to the message evaluation.

Abstract

Background: The increasing use of artificial intelligence (AI) in medical diagnosis and consultation promises benefits such as greater accuracy and efficiency. However, there is little evidence to systematically test whether the ideal technological promises translate into an improved evaluation of the medical consultation from the patient's perspective. This perspective is significant because AI as a technological solution does not necessarily improve patient confidence in diagnosis and adherence to treatment at the functional level, create meaningful interactions between the medical agent and the patient at the relational level, evoke positive emotions, or reduce the patient's pessimism at the emotional level.

Objective: This study aims to investigate, from a patient-centered perspective, whether AI or human-involved AI can replace the role of human physicians in diagnosis at the functional, relational, and emotional levels as well as how some health-related differences between human-AI and human-human interactions affect patients' evaluations of the medical consultation.

Methods: A 3 (consultation source: AI vs human-involved AI vs human) × 2 (health-related stigma: low vs high) × 2 (diagnosis explanation: without vs with explanation) factorial experiment was conducted with 249 participants. The main effects and interaction effects of the variables were examined on individuals' functional, relational, and emotional evaluations of the medical consultation.

Results: Functionally, people trusted the diagnosis of the human physician (mean 4.78-4.85, SD 0.06-0.07) more than medical AI (mean 4.34-4.55, SD 0.06-0.07) or human-involved AI (mean 4.39-4.56, SD 0.06-0.07; $P<.001$), but at the relational and emotional levels, there was no significant difference between human-AI and human-human interactions ($P>.05$). Health-related stigma had no significant effect on how people evaluated the medical consultation or contributed to preferring AI-powered systems over humans ($P>.05$); however, providing explanations of the diagnosis significantly improved the functional ($P<.001$), relational ($P<.05$), and emotional ($P<.05$) evaluations of the consultation for all 3 medical agents.

Conclusions: The findings imply that at the current stage of AI development, people trust human expertise more than accurate AI, especially for decisions traditionally made by humans, such as medical diagnosis, supporting the algorithm aversion theory. Surprisingly, even for highly stigmatized diseases such as AIDS, where we assume anonymity and privacy are preferred in medical consultations, the dehumanization of AI does not contribute significantly to the preference for AI-powered medical agents over humans, suggesting that instrumental needs of diagnosis override patient privacy concerns. Furthermore, explaining the diagnosis

XSL•FO
RenderX

effectively improves treatment adherence, strengthens the physician-patient relationship, and fosters positive emotions during the consultation. This provides insights for the design of AI medical agents, which have long been criticized for lacking transparency while making highly consequential decisions. This study concludes by outlining theoretical contributions to research on health communication and human-AI interaction and discusses the implications for the design and application of medical AI.

Introduction

Background

Artificial intelligence (AI) is considered a revolutionary technology for the health care sector. Analysts have forecasted massive growth in the global AI health care market over the next decade [1]. AI is now used in medical scenarios in 2 forms: either to make independent medical decisions (ie, autonomous AI) or to collaborate with human physicians and make decisions with human involvement (ie, human-involved AI) [2]. While ideally, AI diffusion promises to improve diagnostic accuracy, save human effort, and increase patient convenience, empirical research is needed to assess the merits and limitations of medical AI [3], especially from a patient-centered perspective [4]. This perspective is significant because AI as a technological solution does not necessarily improve the patient's confidence in the diagnosis and adherence to treatment at the functional level, establish meaningful interactions between the medical agent and the patient at the relational level, and stimulate positive emotions in the patient and reduce pessimism at the emotional level. This leads to the guiding research question (RQ) of this study as follows: From the patient's perspective, can autonomous AI or human-involved AI replace the role of human physicians at the functional, relational, and emotional levels?

Previous studies and practical necessities motivate this study in several ways. First, although previous studies have explored human-AI interactions guided by some established frameworks, such as the computers are social actors (CASA) paradigm or algorithm aversion theory, by analyzing scenarios of web-based content production and moderation, consumer behavior, and so on [5,6], there is still a lack of empirical evidence as to whether these conclusions can adequately address the complexities of the medical scenario. Little research has systematically examined, from a user-centered approach, the functional, relational, and emotional evaluations of human-AI interactions in medical scenarios, which may yield different conclusions from other scenarios when contextual factors, such as the severe consequences of medical interventions and the attributes of the disease, are taken into account. In addition, few studies have tested user evaluations of human-involved AI, especially vis-à-vis AI and humans; however, this model of human-AI collaboration is increasingly prevalent in medical scenarios.

Second, a crucial distinction between human-AI interaction and human-human interaction in the health domain is that of the human touch, a quality traditionally associated with human physicians, which may affect the patient's evaluation of the medical consultation. Therefore, we incorporated health-related stigma into the analysis of human-AI interaction. Stigma is often associated with human-human interactions, and in the medical scenario, it may lead to patients not seeking a diagnosis or withholding information from physicians. However, this also presents opportunities to introduce AI in a manner that eliminates the human element from medical services. Earlier studies have primarily examined health-related stigma and human-AI interaction separately [7,8]; however, by linking these two variables, this study is able to address the broader question of how disease attributes and communicator characteristics influence the preference for machines over humans in medical scenarios and whether dehumanization is sometimes beneficial in health care.

Third, previous theories have consistently emphasized the accuracy and convenience of AI-powered systems as reasons for preferring AI over humans [9]. In the medical scenario, however, is it enough for AI to merely be accurate and efficient to replace human practitioners? In particular, given the long-standing issue of accurate diagnoses being overlooked due to a lack of explanation and low patient comprehension in traditional patient-physician communication [10] and the black-box nature of AI that systematically ignores explanations for users [11], it is imperative to investigate whether providing explanations of the diagnostic decision-making process enhances effective communication between the medical agent and the patient. This could shed light on how AI-powered medical agents should be designed from a user-centered approach.

To answer these questions, an experiment was conducted based on the theories of human-computer interaction (HCI), human-machine communication (HMC), and health communication. We constructed different scenarios where the source of medical consultation (ie, AI vs human-involved AI vs human), the stigma of the health issue (ie, high vs low), and the explanation of diagnosis (without vs with explanation) were manipulated and examined their individual and interaction effects on people's functional, relational, and emotional evaluations of the medical consultation. On the basis of the findings, we outlined the theoretical contributions to the understanding of human-AI interaction and health communication and practical implications for the principles of human-AI collaboration in health care and the design of AI-powered medical agents.

Literature Review

AI, Human-Involved AI, and Humans as Sources of Medical Consultation

AI is considered promising for enhancing the efficiency, accuracy, and quality of medical services. People are increasingly turning to AI-powered instruments to understand their symptoms, seek diagnoses, and explore treatment options, which previously occurred between patients and human physicians in offline clinical environments [12]. Currently, there are 2 paradigms for the application of AI in medical consultation and diagnosis. Patients may encounter autonomous AI that replaces human physicians and makes medical decisions independently [2]. They can also opt for human-involved AI, where human physicians collaborate with AI, participate in the medical decision-making loop, and monitor AI's diagnostic results and treatment recommendations [13,14]. Human-involved AI is an intermediate paradigm between autonomous AI and human practitioners, synthesizing the functional and relational characteristics of both. Despite the growing importance of AI, few studies have systematically examined people's functional, relational, and emotional evaluations of AI and human-involved AI versus humans in medical settings, along with the merits and shortcomings of the 3 medical agents in disease diagnosis, which are the focus of this study.

Existing HCI and HMC theories offer conflicting predictions regarding how users perceive AI versus humans. The CASA paradigm suggests that people apply the same social rules and expectations to machines as to humans despite knowing that they are inanimate agents. The implication is that there should be no difference in users' perceptions of AI and humans [15]. However, as human-AI interactions become more common and technological affordances continue to advance, some recent evidence does not support the CASA paradigm [16]. Another framework based on the concept of machine heuristic suggests that people should favor AI as a source of communication over humans. The argument is that when people interact with machines, they tend to use mental shortcuts and apply general stereotypes of machines, such as being objective, accurate, unbiased, and predictive, thus viewing AI and its decisions as more favorable compared to human decisions [17]. Evidence of such AI preferences has been reported in health, media, and organizational settings, among others, in both low-risk and high-risk contexts [18-21]. In contrast, the algorithm aversion literature argues that people are suspicious of AI decision makers for several reasons, including the lack of transparency of algorithms in the decision-making process and the absence of human expertise in certain domains [22]. Accordingly, people prefer human decision makers to AI, especially for decisions that are traditionally made by humans, despite acknowledging the fact that machines' overall performance is superior to that of humans [13].

Whether these theories could capture the complexities of the medical scenario remains unclear, as many studies approach this question by analyzing scenarios of web-based content moderation, media production, or consumer behaviors. In addition, little evidence exists to test user perceptions of human-involved AI, especially vis-à-vis AI and humans; however, this model of human-AI cooperation is very common in medical scenarios. Inspired by Guzman and Lewis [23], this study regards medical AI and human-involved AI as communicators similar to human physicians, rather than simple technologies mediating human interactions and explores users' functional, relational, and emotional evaluations of the 3 agents in a medical setting.

Regarding users' functional evaluations of the agents, the machine heuristic argument posits that medical AI exhibits a superior level of information processing ability compared to humans. AI trains and refines its decision-making models based on vast quantities of medical data and adheres to a consistent decision-making process that yields rational solutions, which could culminate in higher functional evaluations of AI from users [9]. Conversely, the algorithmic aversion literature suggests that because disease diagnosis and treatment are traditionally performed by humans, users may perceive human physicians as more authoritative and reliable than medical AI [24]. When AI and human physicians collaborate in diagnosis (ie, human-involved AI), it is expected that the benefits of both approaches will be integrated to provide users with fast, accurate, and authoritative medical decisions and thus generate the highest functional evaluations.

Regarding relational evaluations, machine heuristic may make users less likely to consider relational attributes of AI during interactions, making it more difficult for medical AI to build relationships with users in the way that human physicians do. However, the CASA paradigm offers opposing predictions in this regard [25]. When the communicator is a human-involved AI, the medical consultation involves both human attributes of interpersonal communication and elements of dehumanized HMC. Therefore, the user's relational evaluation of the agent is hypothesized to be intermediate between that of an autonomous AI and a human physician. In addition to functional and relational evaluations, it is essential to understand how different medical agents induce emotional responses in patients. Are different types of medical agents equally effective in helping people comprehend their health conditions (ie, functionally helpful), providing empathetic support (ie, relationally supportive), and thus eliciting positive emotional responses (eg, optimism) and reducing negative emotions (eg, guilt about their conditions)?

Taken together, we proposed RQ1: Are there differences in people's functional, relational, and emotional evaluations of medical consultations with different medical agents (AI vs human-involved AI vs human)?

Health-Related Stigma and Its Influence on Medical Consultations

Stigma is a mark or condition that is related to social dishonor, stereotyping, and discriminatory beliefs [26,27]. One health issue that is typically stigmatized is HIV infection or AIDS. Patients with stigmatized diseases, such as AIDS, are reportedly hesitant to seek treatment due to the social shame attached to these diseases and the unavoidable disclosure of private information, such as risky sexual behaviors, during medical consultations [28]. Face-to-face consultations can be particularly uncomfortable, causing patients to withhold relevant information

XSL•FO
RenderX

or lie to physicians [29]. Consequently, as digital health care applications proliferate, patients with stigmatized health conditions may turn to AI-powered medical agents rather than human physicians for medical services [12]. This means that health-related stigma may influence health care preferences, thereby altering the functional, relational, and emotional evaluations of consultations with different medical agents.

The technological affordances of AI facilitate new experiences in medical consultations for people with stigmatized diseases, compared to interactions with human physicians. Medical AI promises greater anonymity and privacy. If patients want to consult without revealing their identity, AI has an advantage over clinical visits or phone consultations [30]. Furthermore, people tend to view AI as a nonjudgmental tool and thus feel more comfortable disclosing personal health information, such as high-risk sexual conduct, to a medical AI than to human physicians [27,31]. This indicates the potential necessity for dehumanization in medical consultations, particularly when stigma is present [29].

This study examined the effect of stigma on preferences for medical agents in the context of 2 conditions, AIDS and heart disease, the former being more stigmatized and the latter less. Previous research has demonstrated the influence of disease severity on patient preferences for medical agents [32]. This study aimed to control for the effect of disease severity and focus on the role of stigma. While AIDS and heart disease are similar in terms of disease severity, as both have serious health consequences and require accurate treatment, they diverge in terms of stigma. AIDS is typically stigmatized, whereas heart disease is not subject to cultural judgments about one's private life and is not infective. On the basis of the aforementioned theoretical discussions, we expected that in stigma-laden conditions (eg, AIDS), where patients need instrumental guidance and prefer that the medical agent refrains from judging their lifestyles, reducing the human element in medical consultations would enhance patients' evaluations of the medical experience. When stigma was not involved (eg, heart disease), we expected that patients would still prefer human expertise and human touch during medical consultations and would give higher functional, relational, and emotional ratings to human physicians than to autonomous AI or human-involved AI.

RQ2 is as follows: How does health-related stigma (AIDS vs heart disease) affect the functional, relational, and emotional evaluations of the medical consultation?

Explanations of Diagnoses and Evaluation of Medical Consultation

The effectiveness of physician-patient communication is critical to patients' evaluations of medical consultations and the achievement of positive health outcomes. The physician's ability to explain the condition and diagnosis to the patient is of particular significance [33]. Explanation is defined as the details or reasons given to facilitate comprehension. For health care professionals, effective diagnostic explanations require interpreting symptoms and justifying diagnostic and treatment decisions. Operationally, the diagnostic explanation in this study encompassed 4 aspects. First, patients should be informed of the symptom descriptions required to confirm their conditions. Second, the rationale for the diagnosis formulated must be explained, which includes clarifying the range of possible diagnoses based on the symptom descriptions and the reasons why a specific diagnosis is made. Third, different treatment options should be provided and explained, and a treatment recommendation should be offered. Finally, the efficacy of the relevant medication and the suggested medication should be explained.

In traditional clinical visits, patients have complained about the lack of explanation of diagnosis and treatment [10]. Sometimes, patients must turn to web-based communities to decipher the medical knowledge and reasoning embedded in medical disclosure documents [34]. Following this line of reasoning, as AI medical agents become more prevalent, the following questions arise. Do people have the same expectations when using medical AI and human-involved AI? If providing an explanation of the diagnosis enhances people's evaluations of medical consultations, does this approach to enhancing physician-patient communication differ between different types of medical agents (ie, medical AI, human-involved AI, and human physician) and between different types of diseases (ie, highly stigmatized and less stigmatized diseases)? This study aimed to answer these questions.

Owing to the black-box nature of AI, decisions made by AI-involved systems are often criticized for lacking transparency and accountability [11]. When making high-impact decisions such as medical diagnosis, human understanding of the reasoning behind the decision-making process without the need to comprehend the internal structure or underlying algorithms, which is defined as the principle of intelligibility of explainable AI, should be helpful and satisfying to content recipients [35], thereby enhancing the functional, relational, and emotional evaluations of the human-AI interaction. For medical AI to replace human practitioners, being accurate is not enough. Empirical evidence indicates that an accurate diagnosis, without explanation or justification, may be ignored by patients, even if made by a highly competent physician, let alone by AI systems, which have long been criticized as unsafe due to their lack of explicability [4,36,37]. Therefore, we hypothesized that providing explanations of the diagnosis, whether by a human physician, medical AI, or human-involved AI, would improve patients' functional, relational, and emotional evaluations of the medical consultation. Furthermore, we predicted that the greater the involvement of AI in the diagnosis, the more patients would require diagnostic explanations due to the increased black-box problem associated with AI. This, in turn, may affect their evaluations of the medical consultation on all 3 dimensions.

Regarding the interaction effect of health-related stigma and diagnosis explanation on patients' evaluations of medical consultations, as previously discussed, regardless of the type of the medical agent, when diagnosis explanations are provided, patients with stigmatized and nonstigmatized conditions will similarly have a better understanding of their conditions and higher ratings of medical consultations [33]. If the medical agent does not explain the diagnosis, patients with a nonstigmatized condition may be less satisfied with the diagnosis, especially if the consultation is with an AI-involved system rather than a human physician. In contrast, people with stigmatized diseases

XSL•FO
RenderX

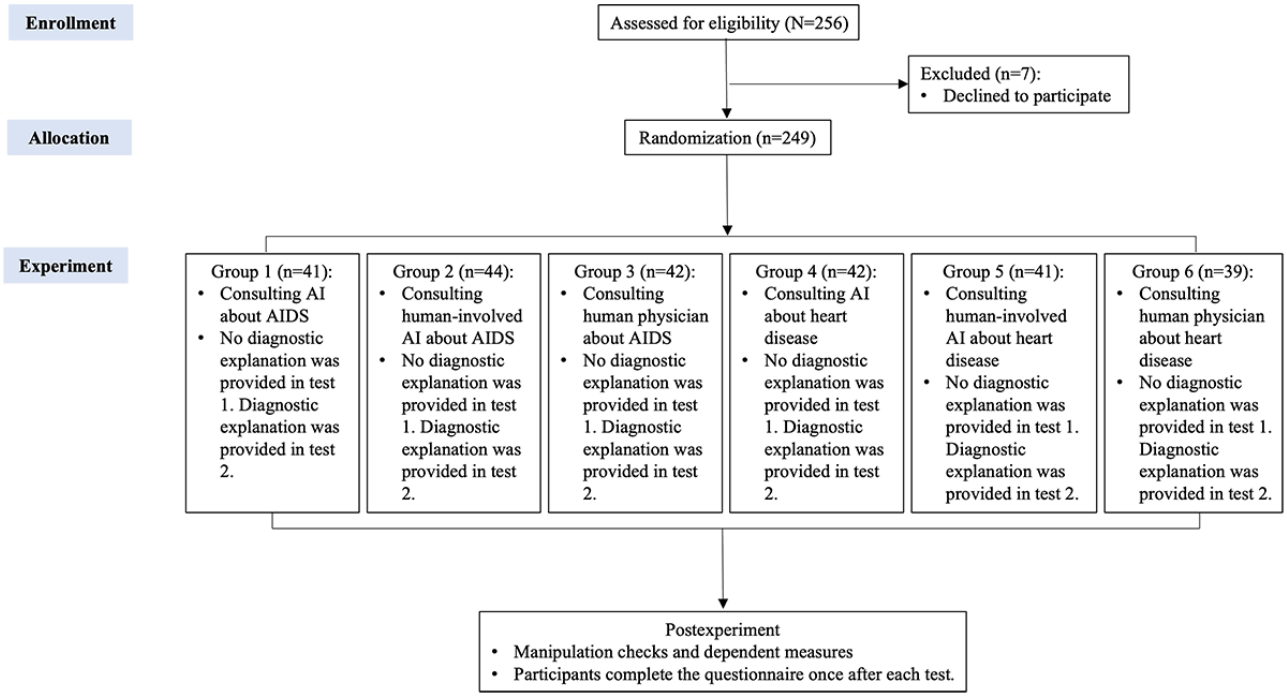
are more likely to avoid further discussion with the medical agent, which potentially results in the revelation of more personal and stigmatized health information. Nevertheless, they are compelled to seek instrumental medical services due to the high risk of their health conditions [29]. Therefore, even if the medical agent only offers a diagnosis and treatment options but does not provide any explanation of the decision-making process, patients with stigmatized health issues are more likely to accept the diagnosis without requiring transparency.

Taken together, we proposed RQ3: Does providing explanations of the diagnosis improve the functional, relational, and emotional evaluations of the medical consultation? Do the 3 types of medical agents (ie, medical AI, human-involved AI, and human physician) and the 2 types of diseases (ie, highly stigmatized and less stigmatized diseases) differ in this path to improving the effectiveness of physician-patient communication?

Methods

Research Design

A 3 (consultation source: AI vs human-involved AI vs human) × 2 (health-related stigma: high vs low) × 2 (diagnosis explanation: without explanation vs with explanation) factorial experiment was conducted in November 2023 to test the effects of medical consultation source, health-related stigma, and diagnosis explanation on the functional, relational and emotional evaluations of human-AI interaction in a diagnostic setting. Consultation sources and health-related stigma are between-subject factors. Diagnosis explanation is a within-subject factor. Data were analyzed using SPSS Statistics (IBM Corp), consisting of descriptive statistics, the 2-tailed *t* test, and ANOVA.



Ethical Considerations

Institutional review board approval was obtained from Renmin University of China. Undergraduate students participated in the study for partial course credits. Before collecting data, we asked for participants' consent, explained the experiment's purpose and the use of data, and assured them that participation was completely voluntary and anonymous. The data were anonymized, containing no identifiable information about the participants.

Procedure and Stimuli

Figure 1 illustrates the flow of the experiment. A total of 249 participants (mean age 18.67, SD 0.972 y; n=65, 26.1% male) were randomly assigned to 1 of the 6 experimental groups, which were conducted offline in 6 laboratories. Each participant was presented with condition-specific stimulus stories and given adequate reading time. Stimulus stories are conversations between an information seeker (concerned about AIDS or heart disease) and 1 of the 3 medical agents (an autonomous medical AI, a human-involved medical AI, or a human physician), presented in text form and typeset in a common one-to-one web-based chat interface (refer to Multimedia Appendix 1 for an example). Participants were first required to read an introduction in which they were informed that they had recently been unwell and wished to confirm their condition and obtain advice on treatment through a web-based medical consultation.

Figure 1. Experiment flow. AI: artificial intelligence.

Then, to manipulate the consultation source, participants read prompts introducing the medical agent, such as "You are having a consultation with a medical AI. It learns from past medical data of patients with the same condition, makes a diagnosis based on the symptoms you've described, and offers treatment options. Human physicians are not involved in diagnosis, medication recommendations or monitoring of the consultation process" (the autonomous AI scenario). We also emphasized

XSL•FO
RenderX

the manipulation of the source in the conversation scripts by referring to the medical agent as autonomous AI, human-involved AI, or human physician.

We manipulated health-related stigma through the conversation between the medical agent and the information seeker, with the high-stigma scenario involving symptoms of AIDS and the low-stigma scenario involving symptoms of heart disease. In a question-and-answer format, the patient described the symptoms and provided responses to the queries posed by the medical agent about his or her medical history. The medical agent proceeded to offer a diagnosis of the condition and treatment options. Participants consulting for the same condition received the same diagnosis and treatment options, either from an autonomous AI, a human-involved AI, or a human physician. We adapted the conversations based on the output of several leading medical AI models regarding AIDS and heart disease, also incorporating authentic records of web-based consultations provided by human physicians concerning the 2 diseases. The materials for the AIDS and heart disease groups differed in the patients' symptom descriptions, medical history, and the medical agent's diagnosis and treatment. The structure and content of the rest of the conversation were the same.

Each participant read 2 stimulus stories. The first reading was a brief conversation in which the medical agent made a diagnosis and offered treatment options but did not explain the rationale for the diagnosis. The second reading was an extended conversation in which the medical agent explained the diagnostic decision-making process in more detail, including the analysis of the symptoms, the clarification of potential diagnoses, the reasons why a specific diagnosis was made, and the analysis of treatment options and relevant medications. At the end of each reading, participants completed a questionnaire including manipulation checks and dependent variables.

Dependent Measures

Functional measures of the medical consultation address how participants perceive the medical agent within its intended role [23]. Informed by the findings of Lew and Walther [38] and Appelman and Sundar [39], we explored 3 functional aspects of communication between the medical agent and the patient. *Source credibility* (mean 4.66, SD 0.88; Cronbach α=0.73) was measured with 4 items. Participants rated whether the source was trustworthy, competent, knew a lot, and had goodwill [38,40]. *Message credibility* (mean 4.61, SD 0.75; Cronbach α=0.81) was assessed using the 3-item message credibility scale [39], examining whether the messages were accurate, authentic, and believable. *Persuasive effect* (mean 4.45, SD 1.16; Cronbach α=0.83) was measured with 5 items [41], examining the extent to which participants would accept the diagnosis, follow the treatment advice, take the medication, seek more information from the medical agent in the future, and schedule another appointment with the agent if necessary. All items were rated on a 7-point scale (1=strongly disagree and 7=strongly agree).

Relational measures of the diagnostic experience pertain to how participants perceive the medical agent in relation to themselves [23]. Consistent with the findings of Croes and Antheunis [42] and Ahn et al [43], this study examined 3 relational aspects of medical agent–patient communication. *Perceived empathy* (mean 4.07, SD 1.34; Cronbach α=0.81) was measured with 5 statements (eg, "The medical agent came across as empathic"; 1=strongly disagree and 7=strongly agree) [42]. *Self-disclosure* (mean 4.35, SD 1.78; Cronbach α=0.87) was assessed using 4 statements [44], such as "I feel comfortable disclosing personal information when interacting with the medical agent" (1=strongly disagree and 7=strongly agree). *Psychological distance* (mean 2.99, SD 1.59) was measured with the single item of Inclusion of Other in the Self Scale [45]. Participants chose the picture that best represented their relationship with the medical agent (1=farthest and 7=closest).

Participants' emotional responses to the medical consultation were examined by asking, "Do the following statements describe your feelings after the conversation with the medical agent?" We focused on 2 emotional responses that had opposing valences and were most relevant in the context of medical consultations: feeling optimistic and feeling guilty. Each response was measured with a single item rated on 7 points (1=no such emotion and 7=the emotion is extremely strong).

Participants reported demographic information at the end of the experiment. Sex was entered as a covariate in data analysis.

Results

Manipulation Check

As a manipulation check, participants answered three questions about their agreement with the statements after exposure to the assigned stimulus: (1) the medical agent is an autonomous AI, (2) the disease is socially stigmatized, and (3) the diagnostic explanation is provided. Autonomous AI (mean 2.71, SD 1.33) was rated as more autonomous than human-involved AI (mean 3.20, SD 1.06) and the human physician (mean 5.52, SD 1.75; $F_{2,240}$=91.37; P<.001). AIDS (mean 5.17, SD 0.79) was rated as more stigmatized than heart disease (mean 2.68, SD 1.08; t_{220}=20.69; P<.001). The second scenario (with diagnosis explanation; mean 6.92, SD 0.70) was rated as having more explanation than the first scenario (no explanation; mean 1.65, SD 1.87; t_{219}=–37.99; P<.001). The results indicated effective manipulation of consultation sources, health-related stigma, and diagnosis explanation.

Testing the Influence of the Source of Medical Consultation

RQ1 asked about the influence of consultation sources on the functional, relational, and emotional evaluations of the medical consultation. Regarding the functional evaluations, the main effect of consultation source emerged for source credibility ($F_{2,240}$=7.75; P=.001; partial η^2=0.06), message credibility ($F_{2,240}$=9.52; P<.001; partial η^2=0.07), and persuasive effect ($F_{2,240}$=10.78; P<.001; partial η^2=0.08). Post hoc tests (Bonferroni) indicated that diagnoses made by AI and by human-involved AI had significantly lower source credibility, message credibility, and persuasive effect as compared to those made by humans, but no significant differences were noted between the ratings of AI and human-involved AI (Table 1). Concerning the relational ratings, there were no differences in

XSL•FO
RenderX

perceived empathy ($F_{2,240}$=1.75; P=.18), self-disclosure ($F_{2,240}$=0.63; P=.54), or psychological distance ($F_{2,240}$=2.65; P=.07) between the 3 medical agents. The main effect of the consultation source did not exist for the 2 emotional responses: feeling optimistic ($F_{2,240}$=0.34; P=.71) and feeling guilty ($F_{2,240}$=1.04; P=.35).

Table 1. The main effect of consultation sources on the functional, relational, and emotional evaluations of the medical consultation.

	AI[a], mean (SD)	Human-involved AI, mean (SD)	Human, mean (SD)	*F* test (*df*)	*P* value	Bonferroni test[b]

[f]NS: not significant.

Testing the Influence of Health-Related Stigma

RQ2 explored whether the stigma of the health issue (ie, AIDS vs heart disease) would directly influence or interact with the effect of consultation source on participants' evaluations of the diagnosis. Results demonstrated that there were no significant differences in source credibility ($F_{1,240}$=3.22; P=.07), message credibility ($F_{1,240}$=0.01; P=.94), persuasive effect ($F_{1,240}$=1.46; P=.23), perceived empathy ($F_{1,240}$=0.27; P=.6), self-disclosure ($F_{1,240}$=2.87; P=.09), or psychological distance ($F_{1,240}$=0.02; P=.89) between the 2 diseases, indicating that the functional and relational evaluations were not significantly influenced by health-related stigma. Regarding the emotional responses, the main effect of health-related stigma emerged for feeling guilty ($F_{1,240}$=44.55; P<.001; partial η^2=0.16) but not for feeling optimistic ($F_{1,240}$=1.42; P=.24). Post hoc tests (Bonferroni) revealed that the level of guilt was lower in the heart disease scenario (mean 2.79, SD 0.08) than in the AIDS scenario (mean 3.57, SD 0.08). The interaction effect of consultation source and health-related stigma did not appear for any of the dependent variables.

Testing the Influence of Diagnosis Explanation

RQ3 investigated whether providing an explanation of the diagnosis would enhance the evaluation of the medical consultation and whether there were differences among the 3 medical agents and among the 2 types of diseases. First, the main effect of diagnosis explanation emerged for source credibility ($F_{1,240}$=21.48; P<.001; partial η^2=0.08), message credibility ($F_{1,240}$=16.35; P<.001; partial η^2=0.06), persuasive effect ($F_{1,240}$=16.29; P<.001; partial η^2=0.06), perceived empathy ($F_{1,240}$=20.13; P<.001; partial η^2=0.08), self-disclosure ($F_{1,240}$=4.01; P=.04; partial η^2=0.02), and psychological distance ($F_{1,240}$=16.68; P<.001; partial η^2=0.07). Post hoc tests (Bonferroni) revealed that providing an explanation of the diagnosis significantly increased all the functional and relational evaluations of the medical consultation (Table 2). Regarding emotional responses, the main effect of diagnosis explanation emerged for feeling optimistic ($F_{1,240}$=15.27; P<.001; partial η^2=0.06) and feeling guilty ($F_{1,240}$=4.87; P=.03; partial η^2=0.02). Participants had significantly higher levels of optimism and lower levels of guilt when the diagnosis was explained (Table 2).

Table 2. The main effect of diagnosis explanation on the functional, relational, and emotional evaluations of the medical consultation.

	No explanation, mean (SD)	With explanation, mean (SD)	*F* test (*df*)	*P* value	Bonferroni test[a]
Functional evaluations					
Source credibility	4.2 (0.05)	5.12 (0.04)	21.48 (1, 240)	<.001	1<2
Message credibility	4.26 (0.05)	4.97 (0.04)	16.35 (1, 240)	<.001	1<2
Persuasive effect	4.07 (0.05)	4.94 (0.05)	16.29 (1, 240)	<.001	1<2
Relational evaluations					
Perceived empathy	3.36 (0.06)	4.77 (0.05)	20.13 (1, 240)	<.001	1<2
Self-disclosure	4.15 (0.07)	4.53 (0.07)	4.01 (1, 240)	.04	1<2
Psychological distance	2.3 (0.07)	3.67 (0.09)	16.68 (1, 240)	<.001	1<2
Emotional responses					
Optimistic	3.07 (0.06)	4.24 (0.07)	15.27 (1, 240)	<.001	1<2
Guilty	3.37 (0.07)	2.99 (0.06)	4.87 (1, 240)	.03	2<1

[a]1 indicates the mean value of no diagnostic explanation and 2 indicates the mean value of providing a diagnostic explanation.

Furthermore, a significant interaction effect appeared between consultation source and diagnosis explanation on participants' perceived empathy ($F_{2,240}$=8.71; P<.001; partial η^2=0.07) during the medical consultation. Participants did not differ in their perceived empathy for the 3 medical agents when no diagnosis explanation was provided (P=.15). However, when the diagnosis was explained, participants perceived significantly more empathy from the human physician (mean 5.08, SD 0.09) than from the AI (mean 4.59, SD 0.09; P=.001) and the human-involved AI (mean 4.65, SD 0.09; P=.003); however, there was no significant difference between the AI and the human-involved AI (P=.99).

Another interaction effect emerged between health-related stigma and diagnosis explanation on the evaluation of source credibility ($F_{1,240}$=6.02; P=.02; partial η^2=0.03). When no explanation of the diagnosis was provided, the AIDS group (mean 4.32, SD 0.07) rated the source as significantly more credible than the heart disease group (mean 4.07, SD 0.07; P=.01). However, when the diagnosis was explained, no mean difference was found between the 2 types of diseases (P=.97).

Discussion

Principal Findings

AI is considered a revolutionary technology in the health care sector and is used either independently or in collaboration with humans in medical diagnoses [2]. Nonetheless, the technological expectations of AI from the expert's perspective do not necessarily translate into an improved evaluation of medical services from the patient's perspective. This context led to the formulation of the RQs of the study. From the patient's perspective, can autonomous or human-involved AI replace the role of human physicians at the functional, relational, and emotional levels? How does health-related stigma and its associated need for dehumanization influence patients' evaluations of medical consultations and preferences for different medical agents? Does providing explanations of the diagnosis equally improve patients' evaluations of consultations with different medical agents?

The results showed that at the functional level, people were more likely to trust a human physician's diagnosis than either AI or human-involved AI. However, at the relational and emotional levels, the physician-patient interactions constructed by the 3 medical agents did not differ significantly. Stigma did not significantly affect the evaluation of the medical consultation or the preference for the medical agent, suggesting that in high-stakes medical scenarios, patients' instrumental need for diagnosis is prioritized over privacy concerns. Furthermore, explaining the diagnostic decision-making process significantly improved patients' functional, relational, and emotional evaluations of the consultations, implying that AI, human-involved AI, and human physicians should all prioritize providing understandable explanations to patients, which could enhance treatment adherence, strengthen physician-patient relations, and generate positive emotional responses.

Theoretical Contributions

First, this study contributes to the understanding of HCI and HMC in a medical scenario through the empirical evaluation of 3 influential theories in this field that are divergent in nature, namely, the CASA paradigm, the machine heuristic theory, and the algorithm aversion theory. Previous studies have explored HCI and HMC mostly by analyzing scenarios of web-based content production and moderation, consumer behavior, and so on [5,6]. Which theory best captures the intricacies of the medical scenario remains unclear, especially when considering contextual factors, such as the severe consequences of medical interventions and the attributes of the disease. Moreover, little evidence exists to test, from a user-centered perspective, the perception of human-involved AI, especially vis-à-vis AI and humans; however, this model of human-AI collaboration is increasingly prevalent in medical scenarios. This study found that functionally, people trusted the diagnosis of a human physician more than AI or human-involved AI, and there was no difference between autonomous AI and human-involved AI,

XSL•FO
RenderX

supporting the algorithm aversion theory. This may be due to the opacity of AI systems, as evidenced in RQ3 through the observation that explaining the decision-making process significantly enhanced the perceived credibility and persuasiveness of the diagnosis. Another potential explanation is that, at the current stage of AI development, people place greater trust in human expertise than in accurate AI, particularly in decisions that are traditionally made by humans and that carry severe consequences, such as disease diagnosis. Regarding the relational and emotional aspects, no significant difference was found between human-computer (ie, medical consultation with AI or human-involved AI) and human-human (ie, medical consultation with human) interactions. This may be due to a general lack of care on the part of human physicians during medical consultations and AI's increasing emphasis on creating anthropomorphic relationships.

Second, this study is among the early research endeavors to incorporate the issue of health-related stigma into the evaluation of human-AI interaction [7,8]. It explored whether dehumanized medical consultations were preferred for patients with stigmatized conditions, who might require more anonymity and privacy, or whether human expertise and human touch were preferred in consultations for all diseases. We found that stigma did not significantly influence how users evaluated the consultations or preferred a particular medical agent. This implies that in the highly consequential medical context, the instrumental need for diagnosis outweighs privacy concerns. In the context of illness, patients are keen to receive treatment and less likely to prefer a medical agent simply because of the different levels of privacy exposure that exist between human-AI interaction and human-human interaction. However, including the diagnosis explanation in the analysis (RQ3) revealed an interaction effect between health-related stigma and diagnosis explanation on people's source credibility ratings. We found that stigma had no significant effect on perceived source credibility when the diagnosis was explained in detail, suggesting that patients are likely to judge source credibility based on the diagnostic explanation when it is provided. However, when patients were only given the name of the disease and treatment options but not an explanation of why this decision was made, more stigma associated with the disease led to higher perceived source credibility from the patient. The aforementioned findings collectively indicate that while overall stigma does not significantly influence individual judgment, when patients are provided solely with the name of the disease and treatment options without an explanation of the diagnostic decision-making process, patients experiencing stigmatized diseases are susceptible to the psychology of shame and the eagerness to find solutions without demanding transparency from the medical agent. This is regardless of whether the agent is an AI, a human-involved AI, or a human physician.

Third, we advanced health communication literature by exploring, from a patient-centered perspective, a potential approach to improving patient-physician communication, which is providing explanations for the diagnostic decision-making process. We found that including a diagnosis explanation significantly improved patients' evaluations of the consultation at functional, relational, and emotional levels and for all 3 medical agents. This suggests that regardless of the identity of the communicator (AI, human-involved AI, or human), it is not enough for a medical agent to have the expertise (eg, human physicians) or to be highly accurate (eg, AI and human-involved AI). The explanation for the diagnostic decision-making process is critical for patients to improve treatment adherence, strengthen the physician-patient relationship, and build positive emotions throughout the consultation. On the one hand, this sheds light on how to facilitate traditional physician-patient communication, as evidence showed that patients sometimes had no choice but to turn to web-based communities to decipher the medical knowledge and reasoning embedded in the medical disclosure documents [34]. More importantly, it offers insights into the ways to design an AI-powered medical system, which has long been criticized for lacking transparency in making highly consequential decisions. In addition, an interaction effect appeared between diagnosis explanation and consultation source on perceived empathy. When there was no explanation, participants did not differ in their perceived empathy for the 3 medical agents, but when an explanation was provided, participants perceived significantly more empathy from the human physician than from AI or human-involved AI. This suggests that although unraveling the decision-making process is helpful in building effective medical agent–patient communication, it is still easier for human physicians to establish closer and more empathetic interactions with patients than AI-based systems when the same efforts of diagnosis explanation were made.

Practical Implications

This study contributes to the understanding of the roles of humans and AI in medical diagnosis and identifies key principles for the future application and design of AI medical agents. First, we found that people generally viewed human physicians as more credible and easier to relate to than AI or human-involved AI when the same effort was made (ie, providing the same diagnosis and the same explanation). Even for conditions where we would expect privacy and anonymity to be required (eg, stigma-related diseases), no significant preference for AI-based systems over humans emerged. This suggests that people still prefer human expertise and are more easily moved by human-human interactions in medical consultations. Thus, it is vital to ensure that human physicians assume a pivotal position in medical diagnosis to foster trust and empathy between physicians and patients. As the health care industry progresses toward embracing AI in medical diagnosis, it is advisable to consider incorporating more human elements in the diagnostic process to gain greater user acceptance.

In addition, we propose that the design of AI-based medical agents should be user centered, with the objective of satisfying the user's need to understand their own conditions and treatment options rather than merely providing conclusions that are accurate but difficult to comprehend. Medical diagnosis has historically prioritized the functional objective of furnishing accurate diagnoses and treatments. Consequently, the design of numerous AI-powered diagnostic applications has centered on enhancing diagnostic precision through processes such as data learning and algorithm iteration. However, it is insufficient for AI to simply be accurate and efficient to be trusted and embraced

XSL•FO
RenderX

by patients. From the patient's or user's perspective, an inability to comprehend the diagnosis and link their symptoms to the treatment plan may result in reluctance to adhere strictly to the treatment to achieve desired health outcomes. In examining RQ3, we found that opening the black box of the diagnostic decision-making process and providing explanations to help patients understand their health conditions effectively improved their functional, relational, and emotional evaluations of medical consultations. Therefore, designers of AI-powered systems should place greater focus on taking users' perspectives, opening the black box of decision-making processes, and ensuring that the diagnostic process is understandable to patients. This will not only enhance patient satisfaction and treatment outcomes at the individual level and in health care scenarios, but it also has practical implications for AI-based product design in a broader sense.

Limitations and Future Research

First, experiment research has its limitations. Because the scenarios are simulated, some participants may react differently in real-life situations. For instance, a distinction may emerge between an individual genuinely at risk of AIDS and a participant simulating such a condition. People who are genuinely at risk may be more likely than normal participants to prefer dehumanization in medical assistance because of their tendency to withhold real private information such as risky sexual behaviors [27]. However, another possibility is that those facing imminent peril may prioritize their survival over privacy concerns, opting to seek help from authoritative human physicians [46], whereas, in role-playing situations, participants are only imagining the stigma but not experiencing actual life threats. Although these 2 opposing situations may counteract the effect of role-playing, future research could use qualitative methods, such as ethnography and interviews, to further elucidate the intricacies of patient psychology and interpret how they may influence the perception of different medical agents.

Second, this research focused on the effects of consultation sources, health-related stigma, and explanation of diagnosis on patients' evaluations of medical consultations. We believe that these are highly important variables in the evaluation of medical consultations, but other factors, such as disease severity, may also interact with the aforementioned variables and shape patients' evaluations of medical consultations. The inclusion of more variables, such as disease severity, in the analyses in future studies will provide more in-depth and detailed insights.

Furthermore, while the experimental scenario in this study is medical diagnosis, AI has many other applications in health care, such as health risk analysis and disease screening. Future studies could investigate whether attitudes toward AI vary across different application scenarios.

Conclusions

With the increasing application of AI in the medical field to provide diagnosis, either independently or in collaboration with humans, this study aims to examine, from the patient's perspective, whether AI or human-involved AI can replace the role of human physicians in functional, relational, and emotional dimensions. In addition, we aimed to investigate how health-related stigma and explanations of diagnoses affect patients' evaluation of the medical consultation and their preferences for the medical agent. Findings indicated that individuals exhibited greater trust in diagnoses rendered by a human physician than by AI or human-involved AI, but at the relational and emotional levels, there was no significant difference between the human-AI and human-human interactions. Stigma did not have a significant impact on how people evaluated the medical consultation or contribute to preferring AI-powered systems over humans. However, providing explanations of the diagnosis significantly improved patients' functional, relational, and emotional evaluations of the consultation for all 3 medical agents. By comparing people's perceptions of AI, human-involved AI, and human physicians in medical diagnosis, this study contributed to the understanding of human-AI interaction in the medical scenario and empirically tested 3 influential but divergent theories in the field (CASA, machine heuristic theory, and algorithm aversion theory). Furthermore, we advanced health communication studies by incorporating health-related stigma into the evaluation of human-AI interaction, as well as by demonstrating that explaining the diagnostic decision-making process is effective in improving patient-physician communication.

Abstract

Background: Insufficient patient accrual is a major challenge in clinical trials and can result in underpowered studies, as well as exposing study participants to toxicity and additional costs, with limited scientific benefit. Real-world data can provide external controls, but insufficient accrual affects all arms of a study, not just controls. Studies that used generative models to simulate more patients were limited in the accrual scenarios considered, replicability criteria, number of generative models, and number of clinical trials evaluated.

Objective: This study aimed to perform a comprehensive evaluation on the extent generative models can be used to simulate additional patients to compensate for insufficient accrual in clinical trials.

Methods: We performed a retrospective analysis using 10 datasets from 9 fully accrued, completed, and published cancer trials. For each trial, we removed the latest recruited patients (from 10% to 50%), trained a generative model on the remaining patients, and simulated additional patients to replace the removed ones using the generative model to augment the available data. We then replicated the published analysis on this augmented dataset to determine if the findings remained the same. Four different generative models were evaluated: sequential synthesis with decision trees, Bayesian network, generative adversarial network, and a variational autoencoder. These generative models were compared to sampling with replacement (ie, bootstrap) as a simple alternative.

XSL•FO
RenderX

Replication of the published analyses used 4 metrics: decision agreement, estimate agreement, standardized difference, and CI overlap.

Results: Sequential synthesis performed well on the 4 replication metrics for the removal of up to 40% of the last recruited patients (decision agreement: 88% to 100% across datasets, estimate agreement: 100%, cannot reject standardized difference null hypothesis: 100%, and CI overlap: 0.8-0.92). Sampling with replacement was the next most effective approach, with decision agreement varying from 78% to 89% across all datasets. There was no evidence of a monotonic relationship in the estimated effect size with recruitment order across these studies. This suggests that patients recruited earlier in a trial were not systematically different than those recruited later, at least partially explaining why generative models trained on early data can effectively simulate patients recruited later in a trial. The fidelity of the generated data relative to the training data on the Hellinger distance was high in all cases.

Conclusions: For an oncology study with insufficient accrual with as few as 60% of target recruitment, sequential synthesis can enable the simulation of the full dataset had the study continued accruing patients and can be an alternative to drawing conclusions from an underpowered study. These results provide evidence demonstrating the potential for generative models to rescue poorly accruing clinical trials, but additional studies are needed to confirm these findings and to generalize them for other diseases.

Introduction

Background

Recruiting a sufficient number of patients for clinical trials is challenging [1], and the inability to recruit participants is the cause of failure for many clinical trials [2]. Approximately, 25% of clinical trials are discontinued before completion [3], with insufficient recruitment being the most frequent reason in 31% of the cases [4]. For adult cancer trials, between 20% and 50% fail to complete or were unable to reach recruitment goals [5-9]. This has been exacerbated by the recent pandemic where many trials experienced a considerable reduction in recruitment rates [10-13], which has continued after the pandemic [12]. While poor accrual is a problem in all trials, it is a greater problem in government (ie, academic) sponsored trials [14,15].

When a study is unable to recruit a sufficient number of patients, the study can be stopped, and the relevant analyses are performed on the available data. However, not reaching accrual targets results in underpowered analyses, and the smaller sample sizes increase the risk of unstable parameter estimates.

Patients have an expectation that their trial participation will lead to some advancement in knowledge that can be beneficial to the community [16], but many enroll in trials that do not answer the primary question adequately [15]. They are, therefore, enrolled in a study and exposed to toxicity and additional costs, with limited scientific benefit, which is considered unethical [17]. In addition to the wasted resources, it also means that those resources were not used for other studies that could have produced useful results.

Data augmentation is one approach to address insufficient accrual by either using real-world data (RWD) or by simulating additional observations.

RWD can be used for matched controls [18] where patient data from external sources are used instead of recruiting patients to the trial itself. In such a case, previous similar trials, registries, or eHealth record datasets on patients under the standard of care are matched to the treatment arm patients, and the matched patients' data are used as the control arm [19,20]. Such an approach with external controls has been used for running single-arm oncology trials [21,22]. However, external controls are challenging for a number of reasons [18]. First, the patients from RWD may have different observed and unobserved characteristics than the treatment arm patients, despite the use of matching. Second, unaccounted for environmental factors, such as seasonal effects, may lead to outcome differences. Third, changes in medical practice may have occurred over time and since the external control data were collected. Fourth, there may be measurement differences between the treatment and external controls resulting in the pooling of incompatible datasets, even for objective metrics. Fifth, if there are no adequate matches in the external data for some of the treatment arm patients, then these treatment arm patients may need to be dropped resulting in loss of valuable data. Sixth, the outcome variables need to be available in the external control dataset to allow a comparison, which can be challenging for surrogate end points or patient-reported outcomes. Finally, and specific to our context, insufficient accrual would occur in all arms in a study and not only in the controls; therefore, external controls would not address our problem.

Augmentation through simulation can be a potential solution when there are insufficient data and is a common practice for imaging data [23-25] and time series data [26,27]. In the case of cross-sectional RWD, augmentation methods, such as sampling with replacement (henceforth referred to as *bootstrap*), and generative models, such as sequential synthesis using decision trees, generative adversarial networks (GANs), and variational autoencoders (VAEs), have been evaluated with encouraging results [28-32]. Augmentation methods have also been applied to small clinical trial datasets as a first step in synthetic data generation [33,34]. One study used a VAE

XSL•FO
RenderX

generative model to simulate additional patients as a mechanism to design smaller clinical trials [35].

Objective

In this study, we therefore adopt augmentation through simulation and expand on this body of work by more comprehensively evaluating multiple types of generative models and on a larger number of clinical trials. We make 2 hypotheses that we evaluate in this work as follows: (1) patients recruited early in a clinical trial are similar on the treatment effect to patients recruited later in a clinical trial and (2) because of hypothesis 1, we can train a generative model on early patients to simulate the remaining patients in insufficiently accruing trials to reach target recruitment and replicate the results of the original study that reached target recruitment.

Specifically, generative models are used to augment breast cancer clinical trials that do not reach target recruitment. We start with datasets from 9 completed breast cancer clinical trials and simulate different levels of insufficient accrual, and in each case, use generative machine learning models to simulate patients to compensate for the insufficient accrual. We then replicate the analyses of the published studies using the augmented datasets to determine if they produce similar findings as if the target number of patients were actually recruited.

Methods

Overview

Data augmentation methods using generative models were applied on 9 breast cancer clinical trial datasets. Insufficient accrual was simulated and augmentation then applied to compensate for that. The question was whether this can produce similar findings to the published analyses with the full data.

Datasets

The clinical trials that were included are summarized in Table 1, with further details described in Table S1 in Multimedia Appendix 1 [36-38]. The Rethinking Clinical Trials (REaCT) were supported by the REaCT program at the Ottawa Hospital [39]. The remaining datasets included a larger number of patients and multiple sites.

Table 2 shows the countries that the patients were recruited from. The studies spanned multiple jurisdictions in North America, Europe, Australia, and South Africa.

[k]SWOG: Southwest Oncology Group.

[l]Initially, the trial included 3 arms; however, only the indicated 2 arms had patients assigned to them throughout the duration of the study. Moreover, the available data for our study did not include any randomization codes, and as such, the original primary analysis comparing the outcomes between the 2 arms could not be replicated. Instead, we compared the 5-year survival probabilities between those with negative and positive or equivocal HER2 status. The estimate of the difference of survival probabilities and SE were produced.

Ethical Considerations

This study was a secondary analysis of datasets from already completed clinical trials. The secondary analysis was approved by the Children's Hospital of Eastern Ontario Research Ethics Board (protocol: 23/47X) and the Ontario Cancer Research Ethics Board (project ID: 3749).

Nonmonotonic Treatment Effect Size Hypothesis

We will use the terms "early participants" to indicate participants who were recruited in the earlier stages of a study and "late participants" to indicate those who were recruited in later stages of a study. For early participants to be good candidates for training a generative model that can be used to simulate late participants, there should not be a systematic difference in the estimated effect size between these 2 groups.

Estimated effect sizes tend to vary as patients are recruited and converge to the true value as more information is collected [40]. Instability of estimates at small sample sizes is a contributing factor. This means that training a generative model on earlier patients may enable the simulation of realistic patients that are representative of those that would be recruited later in the trial if the effect over time is not systematic.

However, existing sites gain experience with conducting a trial and this may result in process adjustments along that learning curve that may have an impact on the outcome. This can also happen, for example, when there is treatment effect heterogeneity whereby some patient characteristic (eg, disease severity or age) interacts with the intervention and more patients at one end of the severity or age scale are recruited earlier in the study [41]. One simulation demonstrated a monotonic change in effect size as more patients are recruited [42]. In that example, earlier patients had a meaningfully different estimated effect size compared to later patients with a trend over time. In such a case, training a generative model on earlier patients may not produce simulated patients that are representative of the later patients.

Therefore, it is an empirical question whether such a monotonic effect can be observed in practice.

As can be seen in Table 1, our 9 studies were conducted over an extended period. If the studies were very short, then there is a higher likelihood that early and late participants would be similar. However, the extended enrollment periods suggest that there was ample opportunity for the characteristics of the participants to change over time, as well as adjustments to the trial processes to occur as study staff gain more experience with time.

To test the hypothesis that early and late participants are similar on the estimated effect size, the monotonic relationship of the effect size and order of participant recruitment was examined with a regression model of treatment and recruitment order main effects and their interaction. Point estimates and 95% CIs of the interaction term were obtained, indicating statistical significance at $P<.05$ if they do not include 0. This investigation was not conducted for the trials where the main analysis did not use a statistical model with treatment as predictor (ie, REaCT-zoledronate [ZOL], Southwest Oncology Group 0307, and REaCT–human epidermal growth factor receptor-2 positive [HER2+]). If the effect size was not monotonic, then the interaction term would not be statistically significant.

Generative Modeling Methods

Overview

We used 4 common machine learning–based generative modeling methods for structured tabular data to synthesize the analysis datasets from the clinical trials under investigation. These methods include sequential synthesis using decision trees, Bayesian networks, GAN, and VAE. The last 3 methods were implemented as an adaptation of an open-sourced Python package *Synthcity* [43]. Our implementation, which is publicly available (*Data Availability* section), provides further preprocessing and postprocessing on top of *Synthcity*. No further hyperparameter tuning was performed beyond what was available in the *Synthcity* implementation. For each generative model, the number of variables indicated in Table 1 were synthesized.

In addition, we used the "bootstrap" technique for comparison as a baseline. Bootstrap is simply sampling with replacement from the training data to add the missing patients.

Sequential Decision Trees

Similar to using a chaining method for multilabel classification problems, sequential decision trees generate synthetic data using conditional trees in a sequential fashion [44-46]. It has been commonly used in the health care and social-science domains for data synthesis [28,47-54]. The details of the implementation procedures are described elsewhere [44].

Bayesian Networks

Bayesian networks are models based on directed acyclic graphs that consist of nodes representing the random variables and arcs representing the dependencies among these variables. To construct the Bayesian networks model, the first step is to find the optimal network topology and then to estimate the optimal parameters [55]. Starting with a random initial network structure, the Hill Climb heuristic search is used to find the optimal structure. Then, the conditional probability distributions are estimated using the maximum a posteriori estimator [56]. Once the network structure and the parameters are estimated, we can initialize the nodes with no incoming arcs by sampling from their marginal distributions and predict the rest of the connected variables using the estimated parameters.

Conditional GAN

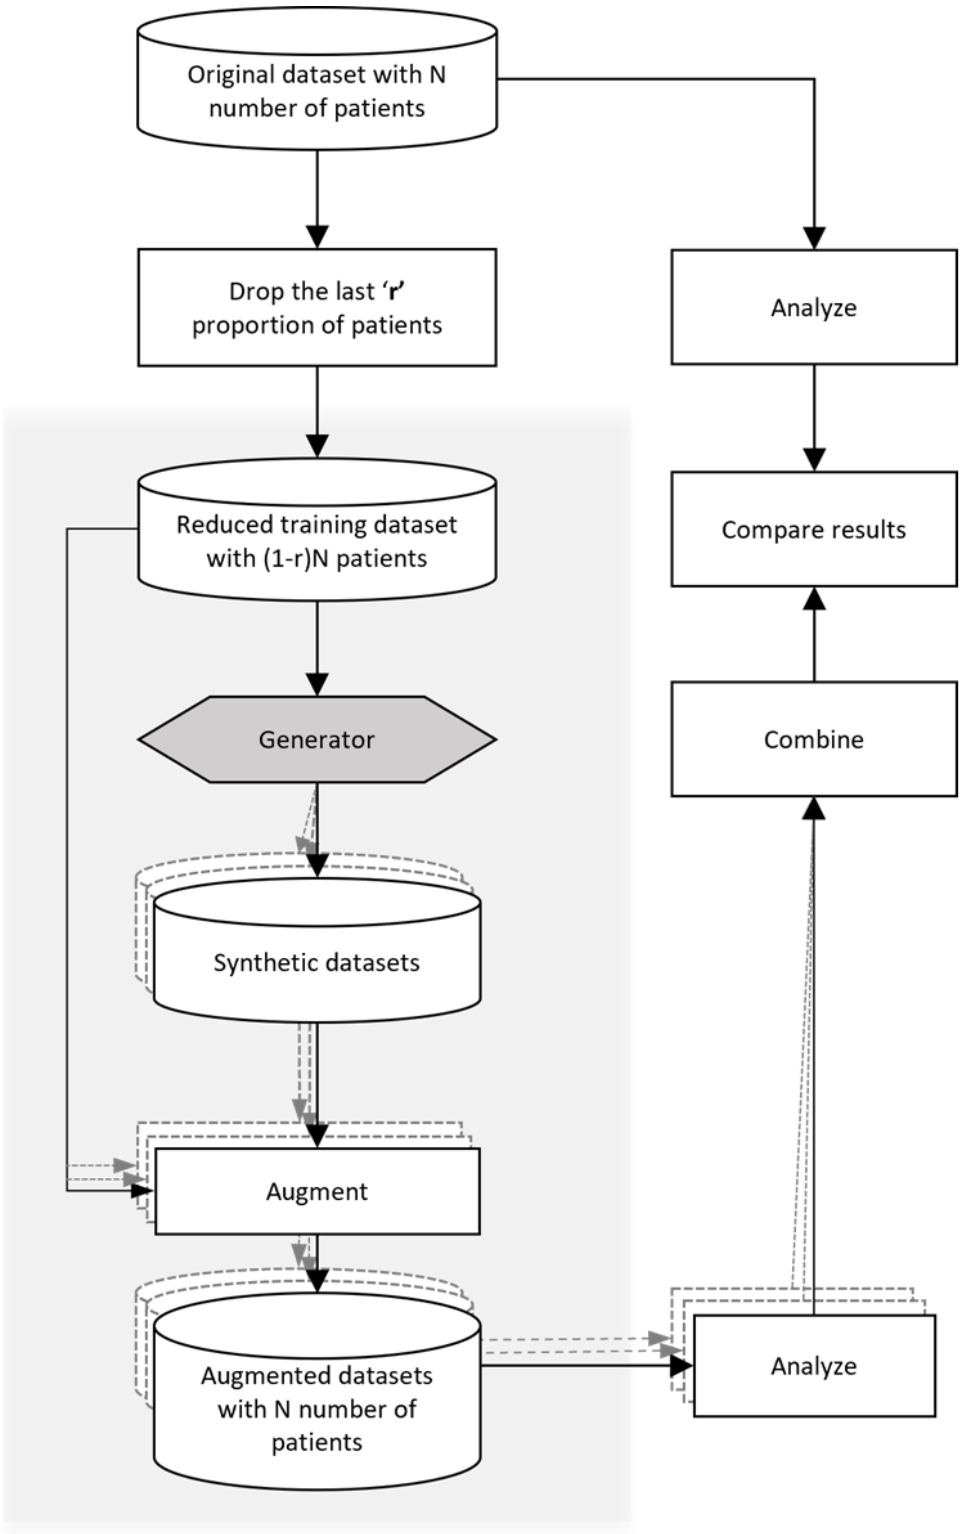
A basic GAN consists of 2 artificial neural networks, a generator and a discriminator [57]. The generator and the discriminator play a min-max game. The input to the generator is noise, while its output is synthetic data. The discriminator has 2 inputs: the real training data and the synthetic data generated by the generator. The output of the discriminator indicates whether its input is real or synthetic. The generator is trained to "trick" the discriminator by generating samples that look real. In contrast, the discriminator is trained to maximize its discriminatory capability.

Among all the variations of GAN architectures, the conditional tabular GAN (CTGAN) is often used in tabular data synthesis [58]. CTGAN builds on conditional GANs by addressing the multimodal distributions of continuous variables and the highly imbalanced categorical variables [59]. CTGAN solves the first problem by proposing a per-mode normalization technique. For the second problem, each category of a categorical variable serves as the condition passed to the GAN.

Variational Autoencoder

VAEs use artificial neural networks and involve 2 steps (ie, encoding and decoding) to generate new samples [60]. First, an encoder is generated to compress input data into a lower-dimensional latent space, in which the data points are represented by distributions. The second step is a decoding process, in which new data samples are reconstructed as output from the latent space. The neural network is optimized by minimizing the reconstruction loss between the output and the input. VAEs are known to generate complex data of various types due to their ability to learn more complex distributions and relationships [61]. Many variants have been proposed as an extension of VAE, such as triplet-based VAE [62], conditional VAE [63], and Gaussian VAE [64]. In particular, the tabular VAE was proposed as an adaptation of standard VAE to model and generate mixed-type tabular data with a modified loss function [59].

Augmentation



The augmentation procedure ensured that the augmented data had the same number of patients as the original clinical trial. Therefore, there is no difference in size between the published study and the augmented datasets used in our analyses.

Figure 1 illustrates the main steps of generating the augmented datasets for the trials given in Table 1. A trial's *original* dataset, with N number of patients, was first reduced by *r*. The variable *r* signifies the fraction of the *last* patients who were deliberately removed from the input dataset. This results in a *reduced* dataset with "(1-r) N" patients. In practice, the reduced dataset represents a poorly accruing clinical trial that needs to be rescued. The shaded area outlines the typical steps taken by a practitioner during the implementation process.

In our study, the *r* value was varied incrementally from 0.1 to 0.5 in steps of 0.1. For instance, a 0.2 *r* value indicates that the last 20% of patients were deliberately removed from the original trial dataset. The reduced dataset was then used to train a generative model. In case of bootstrapping, the reduced dataset was used for sampling with replacement. After training, the necessary samples for augmentation were generated from the trained model and concatenated onto the reduced dataset. To account for stochasticity, and as depicted by the dotted lines in the Figure 1, ten versions of the synthetic data were generated leading to multiple versions of the augmented datasets. Subsequently, each of the augmented datasets were analyzed in the same way as the published analysis. The 10 analyses results were then combined to obtain a single augmented dataset result, and that was compared with the results obtained from the original dataset (as described in the subsequent section).

XSL•FO
RenderX

Figure 1. Augmentation of clinical trial datasets using the generative model.

Some of the trials had implemented stratified randomization, and in those cases, we modified the basic process to accommodate stratification, for example, consider that as per the predefined protocol, the original dataset is stratified by 2 variables, the "Cancer Type" and the "Site Number." Rejection sampling was used to draw from the generated datasets to achieve the desired strata proportions along these 2 dimensions, in addition to the appropriate numbers of patients in each arm of the study.

Combining Rules

The original proposal for synthetic data generation treated it as a form of multiple imputation [65]. Under the multiple imputation model, multiple datasets, say *m*, are synthesized and analyzed. The combining rules are used to compute the parameter estimates and variances across the analysis results from the *m* synthetic datasets [66-68]. Such corrections for the parameter estimates and variances ensured that variability introduced by the generative process are accounted for when

XSL•FO
RenderX

estimating parameters and making population inferences from synthetic datasets.

Once the generative model was trained on the underlying distribution of the input data, it was used to create *m* synthetic datasets of size $r \times N$, and then each was added to that training dataset to augment it. This resulted in *m* versions of augmented datasets, each containing N records.

The *m* augmented datasets were analyzed using the same methodology applied to the original data in the relevant publications. This analysis yielded estimated parameters for each of the augmented versions. Subsequently, these estimated parameters were combined in accordance with the following partial synthesis rules.

For a particular model parameter q_i with variance v_i using synthetic dataset *i* where *i=1...m*. The adjustment for the model parameters and variances is as follows [52,68,69]. The combined model parameter . is the mean across the m model parameters from the synthetic datasets , and  is the mean variance across the *m* model parameters from the synthetic datasets where . The between imputation variance is given by , the adjusted variance is computed as , and the adjusted large sample 95% CI of the model parameter is computed as . For this study, we set *m*=10, which is consistent with current practice for the analysis of synthetic data [52,68-70] and has been recommended based on a recent simulation [71].

Augmentation Fidelity

For the generated datasets, we evaluated the fidelity relative to the training dataset. Fidelity indicates the extent to which the distributions of generated data deviate from the training data. For example, if *r*=0.1, then 90% of the dataset is used for training the generative model, and 10% is generated. We assessed the fidelity using the Hellinger distance [72], which has the advantage of being interpretable as it varies from 0 to 1. The Hellinger distance is averaged across the 10 generated datasets.

Evaluation of Study Replicability

We evaluated the replicability of the analysis results using the augmented datasets. Replicability is the reliability of findings when an existing study is repeated using the same analytical methods but different data [73]. We assessed it by comparing the published analysis results using the real datasets for these clinical trials with the results of the same analysis performed on the partially synthetic (ie, augmented) data. The details of the published analyses that were replicated are summarized in Multimedia Appendix 1.

For each clinical trial, a model was fitted to obtain a parameter estimate and its SE. For instance, if generalized estimating equations [36] were used for modeling the real data, an estimate would be the coefficient associated with the selected predictor as per the published study. We obtained a value for the estimate and its 95% CI. The same was applied to each of the *m* versions of the augmented data. We combined the results from all the augmented versions using the combining rules discussed above. Subsequently, the estimates and CIs of the original and augmented data were compared in terms of the *estimate agreement*, the *decision agreement*, *standardized difference*, and the *CI overlap*. These criteria have been used in the literature to assess the replicability of analyses using synthetic data [71,74]. The criteria are defined in Textbox 1.

Textbox 1. Criteria to assess the replicability of analyses using synthetic data.

- *Estimate agreement*: It is a Boolean indicator of whether the estimate produced by the augmented data is within the 95% CI produced by the real data. This requires that an augmented data effect estimate be within the range of plausible values for the true effect based on evidence from the real data. Under the assumption that the parameter variances are equal between the real and augmented datasets, estimate agreement is expected 83% of the time under no bias [75].
- *Decision agreement*: It is a Boolean indicator of whether the same conclusion is drawn from the real and augmented data estimates. This means that the augmented data estimates have the same direction and statistical significance as the real data. The decision agreement does not apply if the analysis is descriptive. We would expect decision agreement to occur at a rate equal to power, which would be at least 80% of the time (ie, assuming the 9 trials are powered by design for at least 80%) [75].
- *Standardized difference*: It is a Boolean indicator of whether the difference in the parameter estimate between real and augmented data is consistent with the null hypothesis of no difference [75]. The Z value is computed and compared with the standard normal ($|Z| \leq 1.96$).
- *CI overlap*: It is a proportion of the real and augmented data parameter CIs overlap [76], which is a commonly used synthetic data utility metric. We would want this to be as close to 100% as possible but set 80% as a minimal value.

The 2 agreement metrics are consistent with previous measures of replicability [77-79], have been used to compare RWD analysis results against a clinical trial reference [75,80-83], and have been used to assess the replicability of psychological studies [77].

Results

The first set of results are shown in Table 3 where the monotonic relationship of the effect size over time is investigated. In none of the trials used for the study was the interaction term (ie, recruitment order by treatment) found to be statistically significant, indicating lack of evidence of monotonically varying treatment effect with respect to the order of participant recruitment.

The results on the data with insufficient accrual (ie, the "reduced" datasets with no augmentation) for 2 values of *r* at 0.2 and 0.5 are shown in Table 4.

We can make 4 observations from Table 4:

1. For the REaCT-HER2+ study, which had the smallest sample size, there is no decision agreement as *r* increases. This is not surprising as the low sample sizes would mean unstable parameter estimates and larger CIs. The small sample size also explains the lack of difference in the standardized difference comparison.
2. The REaCT-ILIAD study had a statistically significant result with the full data. Decision agreement is no longer attained as *r* increases due to the smaller sample sizes, lower power, and hence, wider CIs.
3. The Austrian Breast and Colorectal Cancer Study Group (ABCSG)-ZOL analysis had a marginal nonsignificant outcome in the full trial. At small *r* values, small changes can have an impact on the statistical significance of the results, but that becomes less of an issue for large *r* values as the results will no longer be marginal with wider CIs. Although, one would expect that if the original results were marginally statistically significant, there would not be decision agreement even for larger values of *r*.
4. For the remaining trial analyses, the results were not significant in the original data. Therefore, the decision agreement would not be affected with the lower power as *r* increases, and the parameter estimates retained the same direction as the full trial. The standardized difference comparison indicates that the parameters were not different even as *r* increases, which is consistent with the inability to detect a monotonic effect with recruitment order presented above, and detecting a difference becomes more difficult as the sample size decreases.

These results indicate that drawing conclusions from reduced datasets can be misleading and can produce incorrect findings relative to those that would be obtained if target recruitment was achieved. In addition, the nature of any error would not be known a priori.

The fidelity results for the augmented datasets are shown in Figure 2. At low values of *r*, the generated datasets were small, making fidelity comparisons unstable. For the smaller datasets, such as REaCT-HER2+, REaCT–bone-targeted agents (BTA), REaCT-ZOL, and REaCT-ILIAD, the Hellinger distance values were highest but still relatively low on an absolute scale. For the other datasets, the Hellinger values were quite small with variation in a very narrow range, demonstrating high fidelity.

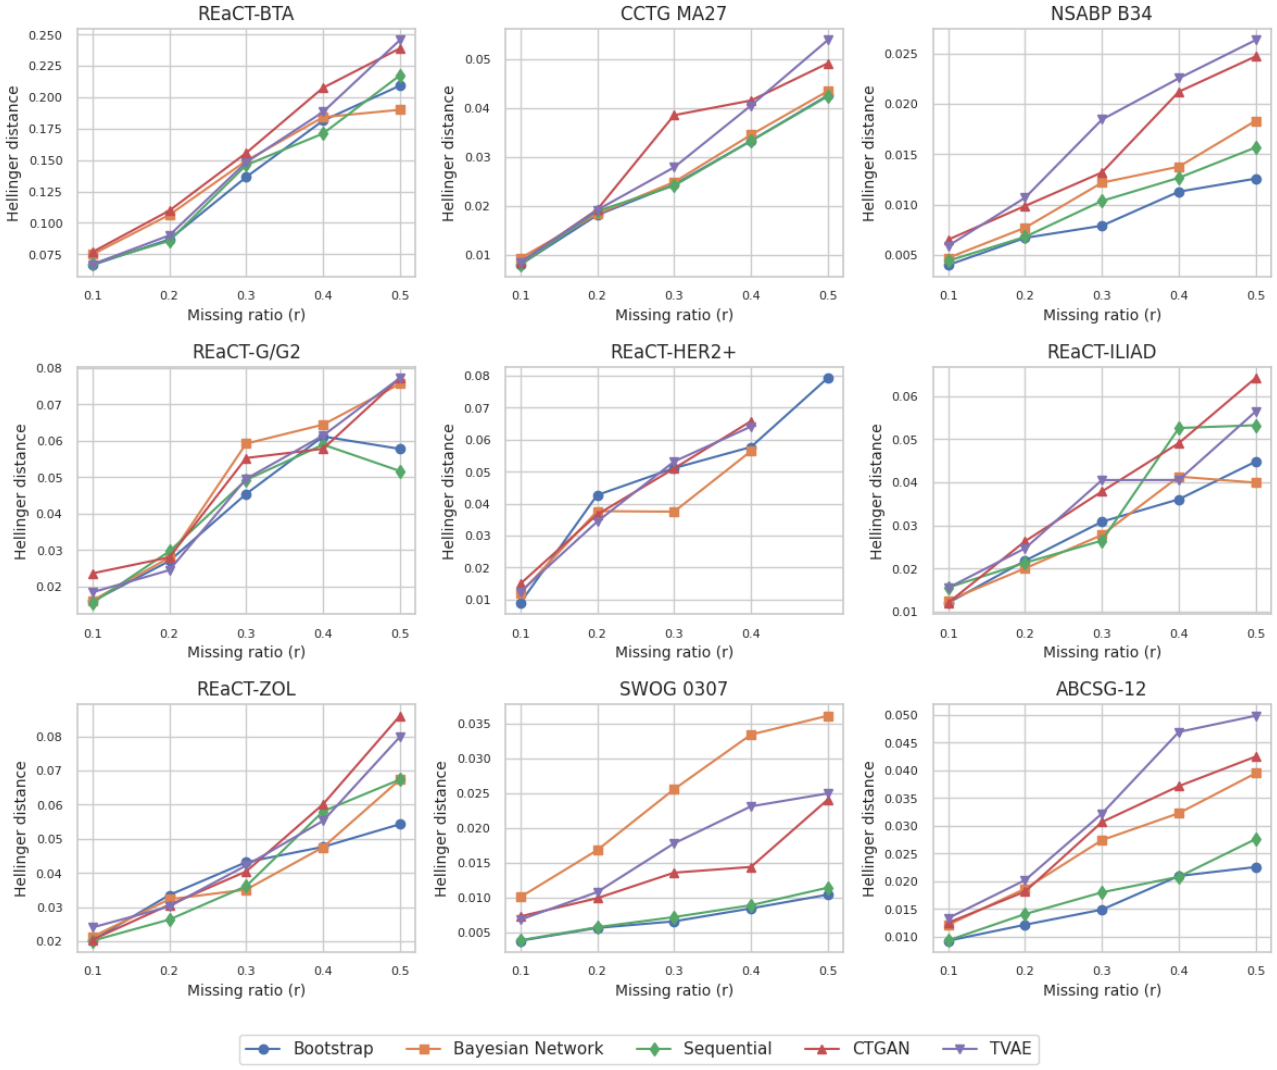
Figure 2. Hellinger distance results by comparing the training dataset with the generated dataset. The values were averaged across all generated 10 datasets. A value of 0 means that the 2 datasets are the same and of 1 indicates maximum difference. Note that the y-axis scales are not the same across all plots to provide better readability. ABCSG: Austrian Breast and Colorectal Cancer Study Group; BTA: bone-targeted agents; CCTG: Canadian Cancer Trials Group; CTGAN: conditional tabular generative adversarial network; HER2+: human epidermal growth factor receptor-2 positive; NSABP: National Surgical Adjuvant Breast and Bowel Project; REaCT: Rethinking Clinical Trials; SWOG: Southwest Oncology Group; TVAE: tabular variational auto encoder; ZOL: zoledronate.



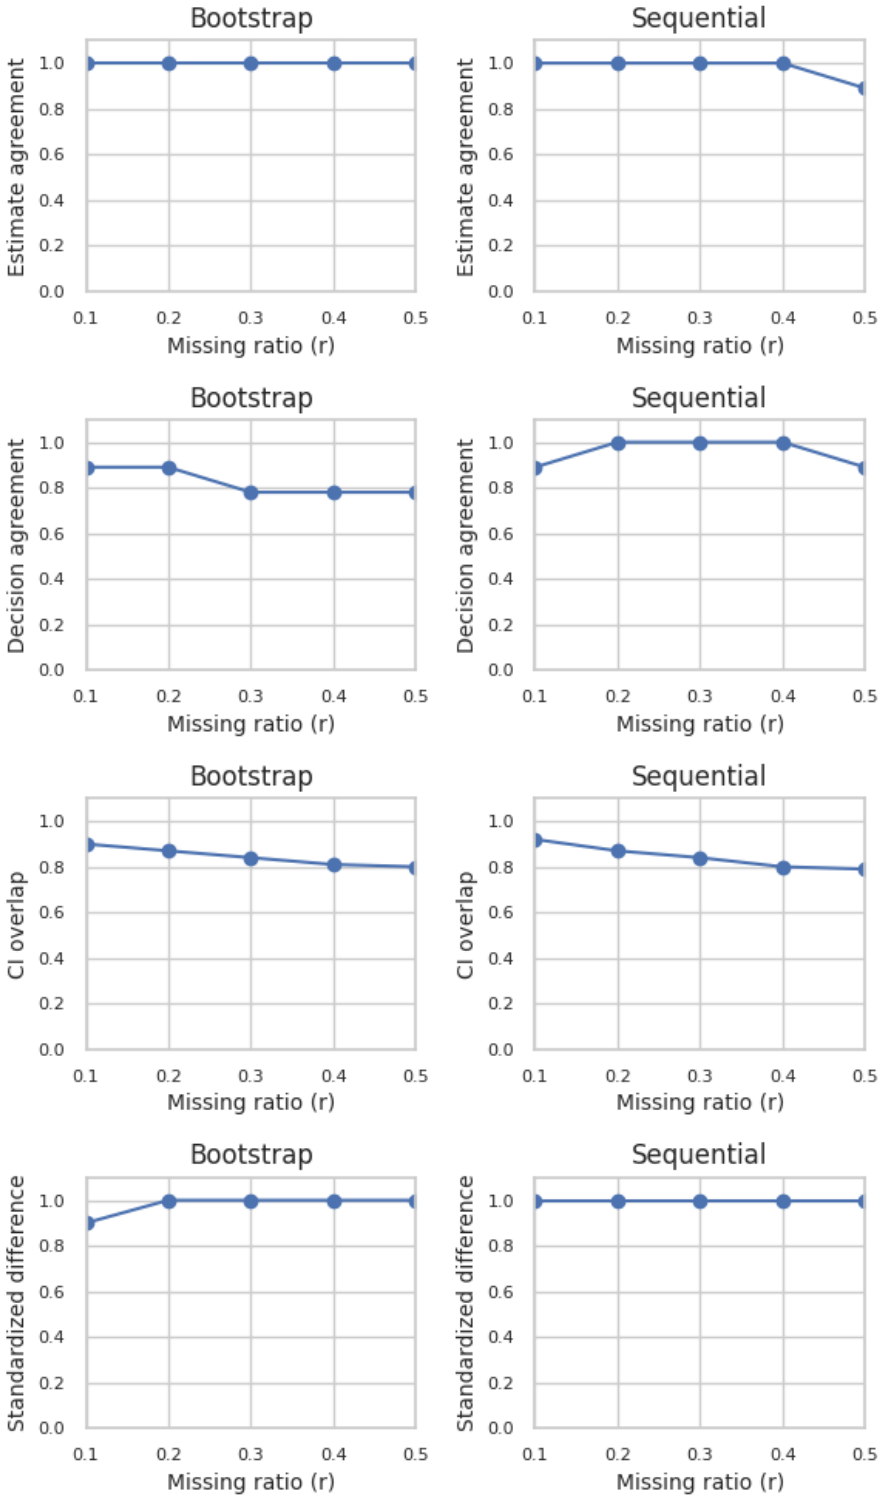
Another representation of fidelity is shown in Figure 3, where we compared the training dataset with a generated dataset of the same size. Here, we can see high fidelity values for all datasets as these results were less affected by small dataset sizes. As the training dataset size decreased with higher *r*, the fidelity decreased, but the changes in fidelity were modest.

All the detailed replicability results for all values of *r* are provided in Table S2 in Multimedia Appendix 1.

The first general observation is that the bootstrap and sequential synthesis tend to perform best among all the generative models. Therefore, in Figure 4 we only show their results across all datasets that were examined for the 4 measures of replicability. Both types of generative models achieved high estimate and decision agreement and maintained a CI overlap above 80% even as *r* values approached 0.5.

XSL•FO
RenderX

Figure 3. Hellinger distance results by comparing the training dataset with a generated dataset of the same size. The values were averaged across all generated 10 datasets. A value of 0 means that the 2 datasets are the same and of 1 indicates maximum difference. Note that the y-axis scales are not the same across all plots to provide better readability. ABCSG: Austrian Breast and Colorectal Cancer Study Group; BTA: bone-targeted agents; CCTG: Canadian Cancer Trials Group; CTGAN: conditional tabular generative adversarial network; HER2+: human epidermal growth factor receptor-2 positive; NSABP: National Surgical Adjuvant Breast and Bowel Project; REaCT: Rethinking Clinical Trials; SWOG: Southwest Oncology Group; TVAE: tabular variational auto encoder; ZOL: zoledronate.



It should be noted that sequential synthesis fails for the smallest clinical trial and that was not included in the denominator for Figure 4. This failure was a design decision in the implementation that we used to not train a model with less than 50 observations. Also note that in the plots model failures are not counted in the denominator.

For the results by dataset, we focus on 4 trials that exemplify all the scenarios in our dataset across all 4 generative models, and are shown in Figure 5 for estimate agreement, Figure 6 for decision agreement, Figure 7 for the standardized difference, and Figure 8 for the CI overlap. The values were consistently high for estimate agreement, standardized difference, and CI overlap across all the scenarios, even at values of *r* approaching 0.5. The results for decision agreement in Figure 6 were more varied and can be characterized as follows:

1. For studies where there was a statistically significant result, for example, REaCT-ILIAD, the ability to maintain decision agreement deteriorates with higher values of *r*. The best performing generative model was sequential synthesis in that decision agreement was maintained for *r* as high as 0.4. Next was the bootstrap, which had a decision agreement for *r* up to 0.3.
2. For studies where the results were not statistically significant (eg, Canadian Cancer Trials Group MA27) or a marginal nonsignificant result (eg, ABCSG–ZOL), the value of *r* had no impact on the replicability of the results in that all the results were successfully replicated.
3. For smaller studies (eg, REaCT-ZOL), some generative models were able to maintain decision agreement for *r* as high as 0.3, although most models failed for *r* greater than that.

Discussion

Summary

Many clinical trials face accrual problems, resulting in an inability to reach target recruitment and resulting in analysts drawing conclusions from potentially underpowered studies. This exposes patients to toxicity and additional costs, with potentially no scientific benefit. Accrual problems may be due to genuine difficulty with recruitment of patients or with execution quality challenges during the trial itself.

When a study is unable to recruit more patients, the study can be stopped, and the relevant analyses is performed on the available data. For small trials, analyzing the data with insufficient accrual results in even smaller sample sizes, which

XSL•FO
RenderX

can produce unstable parameter estimates and direction. For larger trials, when the complete trial results are statistically significant, an analysis with insufficient accrual can be underpowered and result in nonsignificant findings. For marginal results with the full data, insufficient accrual can reverse their statistical significance. When the full study results are not significant, then insufficient accrual would have less of an impact. A priori, it would not be known which one of these situations pertains to a particular study, making it difficult to interpret the results when analysis is performed with unplanned accrual deficiencies.

The objective of this study was to determine whether generative models can be a useful tool to rescue clinical studies that have insufficient accrual, through augmentation. Generative models have been applied to simulate participants [93-96] and counterfactuals [95,96] in the context of in silico clinical trials. While there have been concerns about generative models overfitting for the small datasets typically encountered in clinical trials [96,97], recent studies have been able to generate synthetic variants of full clinical trial datasets with high utility [74,95,97-102].

To test the ability of generative models to augment clinical trial datasets, we evaluated 4 different types of commonly used generative models (ie, sequential synthesis using decision trees, Bayesian network, GAN, and VAE) on 9 different breast cancer clinical trials and 10 different analyses. The study simulated different degrees of insufficient accrual and the generative models simulated replacement patients to compensate. The last fraction of recruited patients were replaced with simulated ones ranging from r=0.1 to r=0.5. In addition to generative models, we evaluated a bootstrap approach. These augmented datasets were then used to replicate the published analyses (ie, using the complete datasets) on these 9 trials.

An important assumption for these augmentation methods to work was that participants recruited early were not systematically different than late participants in their estimated effect size. It has been argued that estimated effect sizes tend to vary as patients are recruited and converge to the true value with more information [40,42]. In contrast, as sites gain experience and adjust their processes, there could be a monotonic treatment effect over recruitment time. Also, consider, for example, if there was treatment effect heterogeneity on disease severity (ie, the impact of the treatment on the outcome depends on disease severity), with high severity patients having a bigger response to the intervention, and fewer high severity patients were recruited early in the study compared with late in the study. This would manifest itself as a monotonic relationship between the estimated effect size and patients recruited over time.

We tested that monotonic relationship hypothesis by examining the interaction effect between recruitment order and treatment on the outcome. We did not find evidence across the trials that this relationship was monotonic (ie, all interaction effects were small and not statistically significant), meaning that we could not detect an increasing or decreasing effect size as more patients were recruited. This is despite these trials having long enrollment periods, in some cases lasting years. Therefore, if the early and late participants were, on average, similar in the estimated effect size, then generative models and a simple bootstrap would also be expected to work well.

These results are supportive of hypothesis 1, which stated that patients recruited early in a trial are similar to those recruited later in the trial.

Furthermore, the fidelity of the generated datasets was quite high relative to the training datasets from the different generative models. In all cases, the patterns in datasets that were synthesized had a high similarity on the Hellinger distance to the datasets of the participants already recruited.

Several observations can be made from our results:

1. A bootstrap would be attractive due to its simplicity and low computational burden. However, this method tended to lack consistent decision agreement when a trial result was statistically significant and when the trial was small, while in other scenarios, sampling with replacement performed well. However, the former are nontrivial failure modes.
2. All approaches struggled with marginal results (eg, marginally nonsignificant results) when the r value was low. This indicates a general sensitivity to that particular scenario.
3. For r values as high as 0.4, sequential synthesis performed well across all datasets. This means that both decision agreement and estimate agreement were achieved, CI overlap was at or above 0.8, and it was either equivalent to or better than the other methods evaluated.
4. Bayesian networks and the GAN had the next best performance after sequential synthesis; however, the Bayesian network had slightly better CI overlap overall up to an r=0.4.

To ensure reasonable performance across multiple scenarios, the results suggest that sequential synthesis can be used to address insufficient accrual up to r=0.4 (ie, only 60% of the target is recruited).

These results are supportive of hypothesis 2, which stated that generative models can simulate the remaining patients in a clinical trial with insufficient recruitment, and the augmented dataset would replicate the results if the trial did reach target recruitment.

It should be noted that using generative models to simulate additional patients as described in this study would not be preplanned, as opposed to a planned interim analysis. Insufficient accrual becomes a problem when there are no budgeted resources available to continue recruiting patients, for example, by adding sites, extending recruitment time, or changing the inclusion and exclusion criteria. Although, if the results from the augmentation show positive findings, the case may be made to allocate more resources to continue recruitment. Additionally, if the results from augmentation show negative findings, then that would provide a stronger case for terminating the study.

The countries of recruitment for the clinical trials used in this study cover multiple regions around the world as shown in Table

XSL•FO
RenderX

2. Our results were consistent across the different jurisdictions. Therefore, it would be reasonable to have confidence that the findings are generalizable across multiple jurisdictions and not specific to a particular region.

Comparison With Prior Work

Previous studies have demonstrated that sequential synthesis performs well (ie, in terms of replicability of published studies) on oncology clinical trial datasets [74,98], and therefore, our findings are consistent with that evidence. More generally, sequential synthesis has been found to have superior utility across different types of datasets relative to other types of generative models [103-105]. Also, it should be noted that most of the published analyses that were replicated across all clinical trials used datasets that were low dimensional, which imposes lower sample size requirements for the generative models.

An earlier study found that a VAE generative model trained on early patients could augment a clinical trial with simulated patients [35]. In that study, the authors argued that generative models can also enable the design of smaller studies to start off with. This means that studies would be designed to be smaller, with augmentation used to reach target recruitment for the final analysis. However, that analysis only considered a single simulated clinical trial (ie, not real data).

The argument for using augmentation to prospectively design smaller studies is appealing. The largest factor driving up the cost of trials is the number of participants required to achieve sufficient statistical power [106,107]. The median cost per participant in drug trials (ie, in general) was estimated to be US $41,413 [107], the median cost per participant specifically in oncology drug trials was US $100,271 [107], and an earlier study found the 1-year cost to be US $17,003 per patient in the treatment arm and US $15,516 per control participant [108]. Designing studies that require fewer patients to be recruited can improve the cost-effectiveness of studies.

Our current analysis generalizes this work to other types of generative models, including a VAE, but we did find that a VAE did not perform well on our criteria. Plus, we performed the evaluation on 9 real clinical trial datasets of different sizes and durations and compared the generative models to a simple bootstrap. Furthermore, an important difference is that rescuing a study due to insufficient accrual using augmentation is not planned, whereas designing a small study is planned.

Nevertheless, using augmentation to design smaller studies deserves further investigation, and it remains a necessity that researchers aim to recruit the target sample size wherever possible.

Clinical trials are known to underrepresent certain groups, and hence, there is the potential for introducing bias in the results. For instance, a recent study in Canada found that the underrepresentation of Black patients in cancer research remains a significant concern, with 15 out of the 20 most common types of cancer not being studied in Black communities [109,110]; studies on underrepresented populations in clinical trials show racial and ethnic disparities worldwide [111-118]; and there is a consistent underrepresentation of various other groups, such as older adults [111,112,119-122], women [111,113,119,120,123], and individuals of lower socioeconomic status and educational level [111,112,124]. Furthermore, synthetic data generation has been shown to introduce bias in the generated data relative to the training data [125], and these biases are propagated across multiple generations of generative models, where the output of one is used as training for the next one [126].

Our analysis did not explicitly evaluate representation bias as we were replicating the published analyses rather than identifying and correcting any weaknesses and did not explicitly attempt to mitigate such underrepresentation to the extent that it existed in the original datasets. Nevertheless, analysts can also apply augmentation methods to compensate for any biases that may exist in the training datasets [127-129].

Another risk of bias is if there is a relationship between a particular characteristic and the order of recruitment. For example, if the first 60% of patients recruited were aged mostly >70 years and the last 40% were aged mostly <70 years, then the trained generative model and their simulated patients would not include sufficient younger patients. However, such an age bias would only impact the randomized study outcomes if there was an interaction between recruitment order, or factors correlated to it, such as age in this example, and the treatment. We explicitly tested for such an interaction effect, and as seen in the results, there were none detected.

Generative models can simulate a larger number of patients than what is needed to reach target recruitment (ie, data amplification). On the surface, this may seem to be a mechanism to amplify the statistical power of the study and solve the problem of drawing conclusions from small studies. However, with the necessary adjustments using the combining rules described in our methodology, it has been shown that amplification does not increase statistical power for fully synthetic data as the adjusted SEs of parameter estimates are also increased [71]. The same study shows that population inferences and replicability diminish markedly without using the combining rules during the analysis of synthetic data. Further examination is needed to determine whether the same conclusions would hold for hybrid data that is only part synthetic.

The incorporation of generative models and simulated patients in industry-sponsored clinical trials would necessitate collaboration with sponsors to apply and evaluate these methods in their studies across multiple therapeutic areas to determine consistency in performance. However, recent surveys indicate that sponsors see uncertainty about regulators' expectations and requirements for evidence as a critical barrier for the adoption of computer modeling and simulation methods in clinical trials [130]. Some efforts have identified high level principles that can be applied for the quality assurance evaluation of in silico trials [131], as well as a general good practice guidance for the application of simulations [132]. Regulators have noted the potential of simulated patients in clinical trials [133] and have further suggested adopting the Government Accountability Office accountability framework [134] for the application of machine learning models to in silico trials, which includes addressing challenges related to governance, accountability,

XSL•FO
RenderX

and transparency; data considerations; and model development, performance, and validation [135]. Furthermore, synthetic data, because of their privacy-protective properties, can serve as a more readily available proxy for RWD when used in regulatory submissions [136], which can solve the data access challenge and accelerate the generation of real-world evidence. Some experts at regulatory agencies have expressed cautious optimism that synthetic data can be used by manufacturers [137], with replicability of results on real data and the need for further experimental exemplars being emphasized specifically for synthetic data generation [94]. Our study contributes to that evidence base.

Recruitment is a challenging issue not only in clinical trials but in other clinical studies as well [138,139]. These challenges are exacerbated with studies on rare diseases [140] and pediatric studies. Pediatric datasets are typically small due to a scarcity of potential study participants: there are fewer children in the population with severe disease [141]. Additional challenges include the complex ethical issues surrounding research involving children and an extra layer of consent required for pediatric participants (ie, parental consent is required in addition to patients' assent) [142]. Many trials recruited a very small number of children [143], and studies with placebo arms are also at a disadvantage as patients are less likely to participate in case they do not get randomized to the treatment arm [144]. Therefore, the results from our study would have broader applicability beyond oncology trials in adults.

On a methodological point, this study was possible because of the ability to obtain access to the original datasets across 9 different clinical trials. While there has been strong interest in making more clinical trial data available for secondary analysis by journals, funders, the pharmaceutical industry, and regulators [145-153], data access for secondary analysis remains a challenge [154], sometimes taking many months to get data [155,156]; for example, an analysis of the success of getting individual-level data for meta-analysis projects from authors found that the percentage of the time these efforts were successful ranged from 0% to 58% [156-161]. Specifically, recent reports highlight the difficulties in accessing data for health research and machine learning analytics [162-164]. In our case, the process of getting access to all the datasets used in this study took approximately 2 years, including executing the necessary data sharing agreements and establishing collaborations with the original investigators.

One of the reasons that access to individual-level clinical trial data faces friction is concern over patient privacy by the patients and regulators [165,166]. However, the general assumption has been that synthetic data produced through generative models have low identity disclosure vulnerability because there is no unique or one-to-one mapping between the records in the synthetic data with the records in the original (ie, real) data [167-174]. While there are other types of disclosure vulnerabilities that are also relevant [175,176], some authors have argued that synthetic data can be considered nonpersonal information under statuary definitions in North America and Europe [177-179]. This would arguably be the case if disclosure vulnerability measurements demonstrate vulnerability values that are below acceptable thresholds. To that end, it is encouraging that recently study authors have been making synthetic variants of data used in their research papers publicly available to enable open science [180-183]. However, given that generating fully synthetic variants of the clinical trial datasets used in this study were not part of the original protocol, readers interested in data access can make a request to the individual data custodians, with the necessary contacts in the *Data Availability* section.

Limitations

Although our datasets covered single site as well as multisite studies, and trials performed across multiple regions of the world with a wide range of sizes and durations, our results were obtained only from oncology trials (mostly breast cancer). There is no a priori reason for these methods not to work for other diseases and conditions, and different populations. To generalize the findings, it is necessary to replicate the findings in this work for other diseases, particularly those that impose high societal costs and where the acceleration of clinical trial evidence can be most impactful.

It is not known whether there would be evidence of a monotonic effect size over the enrollment period in other types of clinical trials and with different populations. For example, one can argue that surgery trials may exhibit a monotonic effect because surgeons become more experienced with new procedures over time. None of our studies were surgery trials. Therefore, this monotonicity relationship would need to be investigated further in these other contexts before drawing broader conclusions.

This study did not consider safety data, which tend to have fewer observations in a clinical trial. Because of the relatively smaller number of adverse events, it is more challenging to train a generative model on that kind of information. Therefore, studies comparing existing interventions or new indications would be more suited for the application of augmentation methods.

Furthermore, our retrospective analysis was limited to 9 clinical trials that were actually completed. Studies that do not reach accrual targets may have different characteristics, which could lead to different results. While our results are encouraging based on a retrospective analysis, future work should evaluate this approach through a prospective design.

When the *r* value increases, the available dataset size to train a generative model decreases. For the smallest clinical trials, in some rare instances, this resulted in generative model failure. The generative models that did not fail under those conditions had a high risk of overfitting to the training data, although they still performed better than a simple bootstrap on decision agreement. For most of our small studies (REaCT-ILIAD, REaCT–BTA, and REaCT-ZOL), the number of variables that were used for training was also quite small (8, 8, and 11, respectively; Table 1). To the extent that low dimensionality has a diluting impact on the rate of overfitting for a fixed sample size, the small number of variables would reduce that risk. Furthermore, most of the variables in some of the small trials were categorical with very few categories (ie, mostly binary), suggesting quite simple datasets were being modeled (eg, REaCT-HER2+).

We did not find that the deep learning generative models performed as well as the other approaches that were considered. One possible explanation is that additional hyperparameter tuning for these models was not performed and the default implementation model size and characteristics were used. The tuning could have improved the performance of these models. Although the default hyperparameters were suitable for low dimensional data, which was the case for the analysis datasets in many of these clinical trials.

In drawing our conclusions, we used a 0.8 value as a threshold of acceptability on CI overlap. Should one apply a more stringent threshold, then the values of *r* where the results would be acceptable would decrease further.

Future Work

Further research is needed to provide evidence-based parameters for the number of variables that can be simulated with different types of generative models and the appropriate number of patients in a trial for training these models. This will further ensure that augmentation is not applied in inappropriate contexts.

Studies on rare diseases would have few observations, making it more challenging to train a generative model using the methods described here. Evaluations using pretrained generative models to simulate clinical trial patients should be investigated as these may be more applicable to rare disease trials.

Given that our focus was to address the insufficient accrual problem, the augmentation that was performed covered all arms of the study. However, the methods described here can be applied to individual arms as well. For example, it is possible to augment only the control arm of a trial if there were challenges accruing patients in the control arm or it could be by design to only recruit a subset of control patients and simulate the rest. Future work can evaluate such alternative augmentation strategies.

An alternative approach for augmentation to address insufficient accrual is to use pretrained generative models. For example, these models can be trained on historical clinical trial datasets, and then the pretrained models are used to simulate additional patients. This is different from the approach presented in this paper, whereby already collected data from the trial are used to train the generative models. It would be informative to compare both approaches to determine which would work better in practice, and to understand the types of historical datasets that give the best results for training these generative models.

Acknowledgments

This research is funded by a data transformation grant of the Canadian Cancer Society grant 707600, the Canada Research Chairs program through the Canadian Institutes of Health Research, and Discovery Grant RGPIN-2022-04811 from the Natural Sciences and Engineering Research Council of Canada and by the Government of Ontario (Ontario Center of Innovation).

Data Availability

The datasets used in this study are not publicly available. Access to the datasets can be requested from the contacts listed in Multimedia Appendix 1 for each of the datasets used in this study. The synthetic data generation code is available in the *pysdg* package [184].

Authors' Contributions

SEK, NM, GP, MC, and KEE designed the study. All authors participated in collecting and curating the datasets and writing and reviewing the paper. SEK, NM, GP, MC, CF, DH, and KEE performed the data analysis.

Conflicts of Interest

KEE owns shares in Aetion. AABB received a travel grant from Janssen. GP has received consulting fees from Traferox Technologies and Merck, honorariums from Astra-Zeneca and Takeda, and has a close family member who is employed by Roche Canada and who owns stock in Roche Ltd. MFS has received honoraria from GILEAD, AstraZeneca, Merck, Seagen, Novartis, Pfizer, Roche, and Lilly. RG has advisory roles and provided expert testimony to: Celgene, Novartis, Roche, BMS, Takeda, Abbvie, Astra Zeneca, Janssen, MSD, Merck, Gilead, Daiichi Sankyo; Honoria: Celgene, Roche, Merck, Takeda, AstraZeneca, Novartis, Agmen, BMS, MSD, Sandoz, Abbvie, Gilead, Daiichi Sankyo; financing of scientific research: Celgene, Merck, Takeda, AstraZeneca, Novartis, Agmen, BMS, MSD, Sandoz, Gilead, Roche; travel support: Roche, Agmen, Janssen, Astra Zeneca, Novatris, MSD Gilead, Abbvie, Daiichi Sankyo. M. G. reports personal fees / travel support from Amgen, AstraZeneca, Bayer, DaiichiSankyo, EliLilly, EPG Health (IQVIA), Menarini-Stemline, MSD, Novartis, PierreFabre, Veracyte.
KEE is the Editor-in-Chief of JMIR AI at the time of this publication but played no role in the editorial handling or peer review process of this manuscript.

Abstract

Background: Data on the social determinants of health could be used to improve care, support quality improvement initiatives, and track progress toward health equity. However, this data collection is not widespread. Artificial intelligence (AI), specifically natural language processing and machine learning, could be used to derive social determinants of health data from electronic medical records. This could reduce the time and resources required to obtain social determinants of health data.

Objective: This study aimed to understand perspectives of a diverse sample of Canadians on the use of AI to derive social determinants of health information from electronic medical record data, including benefits and concerns.

Methods: Using a qualitative description approach, in-depth interviews were conducted with 195 participants purposefully recruited from Ontario, Newfoundland and Labrador, Manitoba, and Saskatchewan. Transcripts were analyzed using an inductive and deductive content analysis.

Results: A total of 4 themes were identified. First, AI was described as the inevitable future, facilitating more efficient, accessible social determinants of health information and use in primary care. Second, participants expressed concerns about potential health care harms and a distrust in AI and public systems. Third, some participants indicated that AI could lead to a loss of the human

XSL•FO
RenderX

touch in health care, emphasizing a preference for strong relationships with providers and individualized care. Fourth, participants described the critical importance of consent and the need for strong safeguards to protect patient data and trust.

Conclusions: These findings provide important considerations for the use of AI in health care, and particularly when health care administrators and decision makers seek to derive social determinants of health data.

KEYWORDS

artificial intelligence; social determinants of health; sociodemographic data; social needs; social care; primary care; machine learning; qualitative study

Introduction

The social determinants of health (SDoH), people's daily living and working conditions that are influenced by policies and structures (eg, racism and housing) [1], contribute to systemic and avoidable health inequities across groups [2,3]. These resource and power-related determinants contribute to access to high-quality health care services and delivery and widen the gap in health outcomes across sociocultural groups [4-6]. For example, people with lower-incomes in the United States often experience barriers to access to care due in part to gaps in health insurance, and many Black individuals have experienced health care discrimination and worse postoperative care outcomes than White individuals due to structural racism [7-10]. Income inequities persist in access to primary and specialist care in Canada despite universal health care [11,12].

Primary health care is at the nexus of medical care, public health, and community and social services [13-15], and the collection of SDoH data in primary care is essential to identify and tackle inequities, which contribute to poor health outcomes [4,16,17]. These data could be used to improve care, help patients with their social and financial situations through coordination to local services [17-20], and guide health care changes and public policy [17,19-21]. However, it is challenging to operationalize SDoH data in real-world clinical settings. Practical and technological challenges including a lack of a unified and standardized measurement of SDoH [22], electronic medical record (EMR) system variabilities [23-25], and finite health care system capacity, can lead to limited data interoperability and reduced power to inform health care systems and public health policies [23-25]. In addition, it is important to consider the health care team's capacity with additional workload associated with administrating, collecting, documenting, and responding to needs, which lead to increasing risk of burnout [21,26-29].

Artificial intelligence (AI) can leverage the potential benefits of SDoH data to identify patient needs [30,31] and respond to health care overcapacity and disease complexity [32,33]. Machine learning is a common type of AI used to detect, predict, and categorize outcomes by looking for patterns in the data that are associated with known observations or "ground truth" cases [34,35]. Although this work is still in exploratory stages, machine learning and natural language processing have demonstrated the feasibility of detecting a number of SDoH from EMR data, such as childhood experiences [36], social connections [37], living situation [31,36], employment [31], and predicting health outcomes based on the SDoH [25].

While there is strong potential for adopting AI to identify SDoH data, there are multiple potential harms. Concerns with using AI technology in health care include the exacerbation of biases and inequities, discrimination [32], data security and privacy, and lack of infrastructure [38-40]. For example, the datasets themselves may reflect discriminative or biased practices, in which the algorithms are trained to learn [32,41]. Unstructured physician notes may contain biases which are similarly replicated to determine patterns and impact patient outcomes [32,41].

The perspectives of patients and the general public (who have been or may become patients) are critical to shaping decisions surrounding the implementation of AI in health care. Patient data are used to develop AI algorithms and patients are affected by having AI inform their care [42]. Despite its importance, few articles focus on public or patient perspectives on AI in health care [38-40,42]. A scoping review of 37 articles (grey literature and peer-reviewed) found that many patients reported positive views on AI, although views may differ based on patients' experiences, concerns, and trust [42]. However, there is limited knowledge of participants' perspectives on using AI to derive their SDoH information using existing EMR data, which may elicit different views due to the sensitive nature of this information. Given the widespread adoption of EMRs in primary care settings, the sensitivity of SDoH data, and the potential harms associated with AI in health care, it is essential to learn viewpoints on whether and how AI could be implemented in an equitable, acceptable, and safe manner. This qualitative study aimed to understand the perspectives of a diverse sample of Canadians on using AI to derive SDoH information from existing EMR data in primary care, including potential benefits and concerns.

Methods

Study Background

This study was conducted as part of a multicomponent project that developed and refined a standardized SDoH questionnaire for primary care settings, known as the Screening for Poverty And Related Social Determinants and Intervening to Improve Knowledge of and Links to Resources (SPARK) Tool (Multimedia Appendix 1) [43]. Details on the SPARK Tool and the broader project are provided elsewhere [43]. For this paper, we report on data gathered from in-depth interviews with participants related to their perspectives on having AI derive SDoH data from the EMR. Participants became aware of the

XSL•FO
RenderX

SDoH before in-depth interviews by completing the SPARK Tool and were provided with examples of determinants.

Study Design, Setting, and Sampling Approach

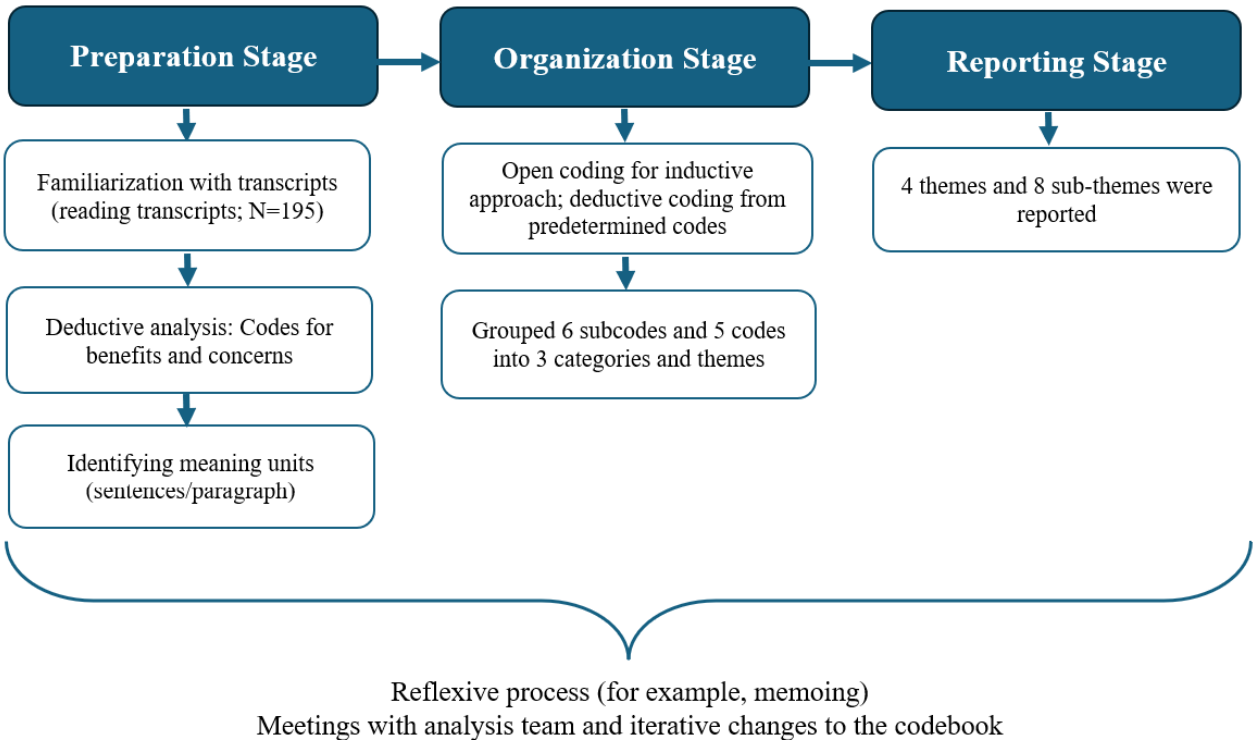
A qualitative description approach was chosen to provide a comprehensive summary of participants' experiences and preferences on using AI to derive SDoH data in primary care settings [44]. One-on-one, semistructured interviews were conducted using video teleconference software across 4 Canadian provinces: Ontario, Newfoundland and Labrador, Saskatchewan, and Manitoba.

Maximum variation sampling helped to ensure that a diverse sample of participants were included across ages, races and ethnicities, location (rural or city), languages, and gender identities where possible [45]. After indicating interest in the study, potential participants were asked about these characteristics, which enabled the purposive selection of individuals who were not initially well-represented in the sample. Adults (aged 18 years and older) were recruited through social media advertisements, email distribution lists, and posters in community and health centers [43]. Advertisements were translated based on the 3 most commonly spoken languages in each province other than English and French, although interviews were only conducted in English due to a lack of non-English speakers contacting the study team. The study aimed to recruit a sample of approximately 200 individuals, with a greater number of participants from Ontario due to the size of the province, to ensure adequate diversity across the multiple domains of the SPARK Tool and to inform the multicomponent study objectives and sampling approach.

Data Collection

The interviewers were female research staff [DH, AD-P, AZS, LK, and IAM] or research assistants, and all received training or had previous experience with qualitative interviewing. The study was also informed regularly through a national advisory group composed of patient partners, scientists, and other collaborators. Data collection occurred from April 2021 to January 2022. The interview guide was established and iteratively revised through meetings with the research team and participant feedback to ensure that the questions were comprehensible for participants without a background in AI. Participants provided verbal informed consent before participating in the study, in accordance with research ethics board requirements. Participants were asked their perspectives on having secure software access patients' records to derive their SDoH information, as opposed to asking patients for this information directly (refer to Multimedia Appendix 2 for interview questions). Follow-up questions included examining possible benefits or concerns with the use of this software.

Data Analysis



Interviews were audio-recorded and transcribed verbatim using a professional service. NVivo (version 12; Lumivero) software was used for data management. The codebook was developed collaboratively by the interviewers and the analysis team (VHD, JRQ, IAM, DH, AZS, LK, AD-P, and ADP). Two study team members (VHD and JRQ) with qualitative research experience led the analysis. An initial codebook outline was created by 2 of the interviewers (AD-P and IAM) during independent review of 2 transcripts. This outline helped to guide the development of a preliminary codebook, which was developed by the lead analysts after examining 10 randomly selected transcripts, including the 2 previously examined transcripts (4 from Ontario, 2 each from Newfoundland and Labrador, Saskatchewan, and Manitoba). The remaining analysis team members reviewed the same 10 transcripts and provided detailed feedback on the preliminary codebook. After the codebook was revised and agreed upon, 2 study team members continued to refine it by reviewing 2 additional transcripts each. Codes were compared for consistency and alignment, and extensive documentation was created to outline decisions made during multiple meetings between the coders. The codebook continued to undergo minor edits as more transcripts were reviewed. After 12 transcripts were thoroughly reviewed and examined between the 2 coders, the remaining interviews were randomly split within each province between the coders.

A qualitative content analysis was conducted to focus on theme development across participant interviews [46-48]. A combined inductive and deductive approach was used to enable flexibility to incorporate emerging codes and findings from transcripts, while also focusing on codes pertaining to the research and interview questions.

The researchers familiarized themselves with the transcripts before analysis by thoroughly reading the contents. For the inductive coding approach, the transcripts were read and meaning units (chunks of data, such as sentences or a paragraph) were selected and coded without a predetermined plan [46,47]. For the deductive coding approach, codes specific to potential benefits, challenges or concerns with using AI to derive SDoH information were created before analyzing the data based on the research aims and interview questions. Meaning units were assigned to these predetermined codes, and codes were grouped into categories and themes in an iterative process. Throughout the data analysis, regular meetings were scheduled with the analysis team to discuss updates, preliminary findings, and assist with the context and interpretation of codes into themes. Figure 1 provides a simplified description of the analysis workflow based on the methodology by Elo and Kyngäs [48].

XSL•FO
RenderX

Figure 1. Qualitative content analysis based on the methodology by Elo and Kyngäs [48].

Positionality, Reflexivity, and Trustworthiness

The 5 main interviewers (IA, DH, AZS, LK, and AD-P) reside in different provinces and have different backgrounds and perspectives. The team regularly met to discuss the interviews and the project both while the interviews were being conducted and when the analysis was occurring, alongside VHD, JRQ, ADP, and at times EA. This team approach helped to mitigate any 1 perspective from dominating the interviews and analysis, as a form of data triangulation to enhance the criteria of trustworthiness [49].

The 2 main analysts (VHD and JRQ) engaged in reflexivity to understand how their own biases and preconceptions could influence how the data were approached and analyzed, through regular journaling and discussions before and throughout the analysis [49,50]. They also took memos upon analyzing interviews to document early findings [49,50]. For example, they documented their own beliefs about whether AI should be used to derive SDoH information, which became more nuanced based on the benefits and concerns expressed by participants. Both analysts created extensive documentation outlining the processes and decisions for the coding approach and analysis [49].

Ethical Considerations

This study was approved by the Unity Health Toronto Research Ethics Board (#20-241) Saskatchewan Behavioural Research Ethics Board (#2373), Newfoundland and Labrador Health Research Ethics Board (#2020.259), and University of Manitoba Health Research Ethics Board (#HS24204).

Results

Overview

There were 195 interviews conducted across the 4 provinces, lasting approximately 30-45 minutes each. Most participants lived in Ontario (124/195, 64%), identified as women (126/195, 65%), and non-White (122/169, 72% among those who disclosed their race and ethnicity), while 38% (75/195) of participants reported at least 1 unmet social need (Table 1).

XSL•FO
RenderX

Table 1. Participant demographics (N=195; adapted from Adekoya et al [43], which is published under Creative Commons Attribution 4.0 International License [51]).

Characteristics	Participants, n (%)[a]
Canadian province	
Ontario	125 (64)
Saskatchewan	25 (13)

High school diploma or some postsecondary education	48 (25)
Trades certificate or diploma	14 (7)
College or university degree	94 (48)
Postgraduate degree	34 (17)
No response	≤ 5

[a]Percentage values are not provided for values that are ≤5.

[b]Race and ethnicity data were not collected in Manitoba.

[c]Unmet social needs were based on the following categories: precarious employment (presence of all of the following: short term, casual, or temporary employment; fear of being fired if raised employment concerns; and varying pay); living in social housing; missed rent or utility bill payments; missed appointment due to transportation cost; avoided filling prescription or made it last longer due to cost; difficulty making ends meet; and lack of social

XSL•FO
RenderX

support.

Themes

The results are presented as main themes and subthemes. The 4 main themes include AI as the inevitable future; potential health care harms; loss of the human touch; and consent is critical. Additional quotes that provide evidence of themes are provided in Multimedia Appendix 3.

AI as the Inevitable Future: Facilitating More Efficient, Accessible SDoH Information and Use

Participants described common benefits to leveraging the use of AI in medicine to derive their SDoH information, as it represented the future of technological advancements, and "it's much better that way" (05_20, Newfoundland and Labrador). Some participants spoke of AI as inevitable regardless of their perspectives for or against its use and seemed to acquiesce to its use in medicine.

> *Yeah, I'm for it… I mean it's the future of medicine and it's the future of the world so… Whether I have concerns or not, it's going to take over, but personally I don't have concerns, I'm okay with it, yep.* [01_135 (Ontario)]

Efficient, Streamlined Social Determinants of Health Data

Most participants expressed that the benefits of using AI in primary care were to streamline SDoH data collection in a more efficient and timely manner for patients, staff, and the health care system.

> *Well, I see benefits cause it streamlines the process and makes your information more accessible to people so you're not the one who has to like repeat and remind [healthcare staff] all the time.* [04_16 (Manitoba)]

One participant mentioned that, if used correctly and accurately, it could reduce the burden on the health care system to free-up resources for providers to speak with patients.

> *People think that artificial intelligence and technology will be replacing jobs but like that's not true because it only is there to help us move faster in life…Once you give the job [of deriving patients' SDoH data through AI] …the people who were doing that [previously] could have one-on-one…interpersonal communication with patients and you know speak to them while they're in the waiting room.* [01_06 (Ontario)]

AI Could Overcome Barriers to Disclosure

A small number of participants described how using AI to derive SDoH information based on existing EMR data could overcome barriers to verbally disclosure, in a "more accessible" (01_124, Ontario) manner.

> *So, I do [see benefits of AI], I think like folks that have challenges expressing themselves like…people that are vulnerable…the homeless, folks that are coming out of traumatic situations…people that have language barriers, speech barriers; I think this technology would be very beneficial to them…And people that have disabilities.* [01_99 (Ontario)]

Data Use to Improve Health

Participants expressed ways that using AI to derive SDoH information could be useful to improving health or health care. For example, 1 participant described how it would help to

> *…move towards a system of greater continuity of care and a system where you are not forced to tell each new professional you see the same old story*. [01_134 (Ontario)]

Participants expressed that AI could help generate automated alerts of potential conditions for individuals based on group memberships from the SDoH data, in addition to other health information in the EMR.

> *I think it's good for certain things like I think if you're… from a particular country or race or something and you're prone to very like high health risk diseases for example…I think that's important and sure a computer can fill that information out so that way they red flag like check her heart every time she comes in.* [01_68 (Ontario)]

Participants indicated that AI could be useful to help automate local social and community resources to assist with their social situation.

> *That's a way to screen and actually find the best help for you within your area…say for example the person has addiction or…mental health challenges or…are in an abusive situation…Sometimes these programs are so filled there is not enough space available…this program can provide all this information accessible to you and show the patient immediately if tomorrow they can get help… they're put on some waiting list or [indicate where] there are shelters available or…programs from the government.* [01_38 (Ontario)]

Some participants expressed that disaggregated SDoH data could be used at a larger health care or population level, as opposed to the individual level. This included assistance with policy-making decisions to reduce health inequities, disease surveillance, understanding the causes of diseases, and prevention. COVID-19 disparities were mentioned as an example of the use of SDoH data collection.

> *I think the benefits is if we're going to be using to track down diseases like not [individual] people [and determine]…What are the cause?... That would be beneficial and [it could be used for prevention] … [You could] do more campaigns…[but] knowing the stats and releasing that to the public in general I think that would help everybody…[It would help] to make them aware of what's going on… Especially now with COVID.* [03_16 (Saskatchewan)]

Similarly, 1 participant described how the information generated could be used to inform "culturally competent" care through staff training practices.

XSL•FO
RenderX

> *You [can use AI for demographic purposes, such as you] find that you have 50% African, 30% Asian, 10% White, 20% mixed [racial identities] … Then it would therefore affect training because clearly the majority of your clientele will be African so you have to be culturally competent to be able to treat [them] with whatever they are coming with, the possibility so I think in that sense it could be beneficial.* [03_19 (Saskatchewan)]

Potential Health Care Harms: Distrust in AI Used in Public Systems

Many participants held strong views about the potential harms of implementing AI in primary care and expressed an overall distrust in AI.

AI Inaccuracies and Impact on Care

The primary concerns with using AI to derive SDoH information in health care were inaccurate SDoH predictions and the subsequent consequences on their care provision. Many participants were particularly concerned about their race and ethnicity, gender identity, and sexual orientation being incorrectly identified, including "misclassifications" (01_28, Ontario).

> *I think that could actually kind of be dangerous… I'm not sure I would trust the computer…I mean I work in [information technology] but [Laugh] I actually wonder how would a computer know for sure what my racial identity is?... I'm just afraid of the computer making the wrong choice and then it somehow impacting my healthcare negatively… If the computer [was] in the background [and] was only doing it for statistics that is not for an individual's healthcare then I mean I don't really care. I feel like there could be room for error.* [01_32 (Ontario)]

However, a few participants felt that more inaccuracies would result from a human compared with AI and they would trust the computer over humans with their SDoH information:

> *I think maybe a computer would probably be better than an individual doing it because you know [for an] individual there is always I would think a larger chance for a margin of human error rather than a computer.* [01_56 (Ontario)]

With regards to updating SDoH information, some participants expressed that social situations are malleable and may change, but those changes may not be accurately captured in their EMR by their physician unless they are explicitly asked about it through a survey. Participants mentioned this often in the context of financial situations, sexual orientation, or gender identity.

> *I think asking people one-by-one even though it is a bit more time consuming is worth it because you know like even for sexuality and all like it always changes so it's not like they can, it can be generated once because it should come from the main source…because like let's say you're in a court and someone says like you know where did you get this information from? It's like I didn't even provide that information.* [01_39 (Ontario)]

It was described how AI would not pick up on the subtle human cues that are intrinsic to conversation.

> *The only problem, when it comes to like using that type of technology is there's no emotion behind it so when you're speaking with someone one-on-one you might say something in a certain way but you don't mean it that way. So, your facial expression, the way you speak it communicates your idea across differently.* [01_27 (Ontario)]

In addition, some participants had different perspectives on using AI based on the SDoH variable that was predicted. They mentioned that perhaps certain SDoH should be derived using EMR data while others should be asked directly by patients.

> *So, I think for things that are like you know pretty like core defining questions like your race, your gender, your age, your citizenship like I don't want the thing guessing that I'm Chinese based on my last name for example…So, I think those things are, you know like more like the legal aspects of things… Other things like you know your income like okay, it can predict it and probably it's like pretty accurate…I would just want to be assured that whatever predictions it makes like it would be to try to benefit me and not to try to like characterize myself and like sell me some new drugs.* [01_72 (Ontario)]

Privacy and Security

Privacy and security were important concerns of participants:

> *I think that privacy…has to be the number one issue that guides every aspect of this.* [04_21 (Manitoba)]

Participants expressed concerns with the management of SDoH information in the EMR, including that "*…the infrastructure and the environment in which you are operating is not equipped to protect the data you are collecting*." (01_13, Ontario). Another participant mentioned "*It's frightening what computers are being programmed to do without any accountability.*" [04_21 (Manitoba)].

Some participants also mentioned that the data being retrieved using EMR was in itself a "huge invasion of privacy" [01_80 (Ontario)].

Several participants described how they did not want AI to derive their SDoH information as it removed their ability to control and share what they are comfortable with sharing to their doctor, given the sensitive nature of the SDoH questions. For example, some participants were themselves not willing to have their SDoH data on the EMR, such as their race and ethnicity or sexual orientation.

> *Importantly I think it would make me very leery or weary of what I share every time I talk to a healthcare provider cause I might want to share a sensitive piece of information but I don't want that information to be widely available on my record …Your program to retroactively go back and gather this information*

XSL•FO
RenderX

> *from all of my visits just makes me feel very like not in control of my own information.* [01_50 (Ontario)]

The interviews occurred at a time when there was media attention surrounding hacking and privacy breaches of government across provinces, and COVID-19 vaccine policies. Individuals also reported having distrust in government and overall technology.

> *My thoughts on this whole COVID-19, yeah, it's a long story and stuff but I don't trust the government so I wouldn't want it to be done... I don't have a lot of trust in computers... You can say everything is secure but like I said I've seen it over time and especially in the last 20 months there's been a lot of breaches…You want to know? Phone me. You want to question me or ask me? Bring me in person-to-person. Don't do it over the computer... because you can be hacked at any time.* [03_22 (Saskatchewan)]

Data Misuse and Discrimination

Few participants mentioned their concerns about data misuse and discrimination. For example, a participant mentioned how the use of AI would be stigmatizing and could negatively stereotype people, particularly those living with disabilities. Discrimination due to race and ethnicity and income were also reported by participants.

Some participants extrapolated the harms beyond the health care system. Participants compared the potential for AI to discriminate or be used for discrimination, to their concerns regarding the criminal system and policing. For example, 1 participant indicated that it would facilitate "[racial] profiling in general and not only healthcare but the government is going to use it, so I am concerned" and provided an example of it being used in fascist governments for "genocide against communities" [01_07 (Ontario)].

There were also concerns regarding the data being misused if it were to be leaked.

> *The companies are trying to surveil us or they're trying to… use our data for their own means…I'm thinking about like police officers... I think it was in British Columbia where like…the municipal police department…was using AI to surveil folks and… that is like very problematic and could really harm a lot of people and I think that this could just be linked to that and like I feel like police would maybe somehow have access to this if the government does.* [01_41 (Ontario)]

One participant described how the algorithm would essentially be stereotyping individuals in order to predict and identify their SDoH information.

> *Well, and it's based on a whole lot of basically stereotyping groups so saying oh, well I am racialized and low-income therefore these things must be true and I'm not at all comfortable with, cause it's, the whole system relies on those stereotypes and assumptions.* [04_17 (Manitoba)]

However, 1 participant believed that AI "is not racist. [Laugh] They don't see race" [03_24 (Saskatchewan)] and is better suited to SDoH data retrieval as opposed to human data collection.

Loss of the Human Touch: Preference for Provider Relationships and Individualized Care

A few participants expressed an overall preference for having strong patient-provider relationships and interactions and emphasized the need for individualized care. Participants believed AI could pose a barrier to patient-centered care and the patient-provider relationship, by removing the "human factor" with providers which could otherwise be nurtured by having a conversation about their SDoH situation. For example, they expressed that it would be "de-personalizing encounters with the doctor" [04_20 (Manitoba)] or would be "dehumanizing," particularly for people experiencing a mental health condition and social isolation, by "just being dealt with by a machine" [01_125 (Ontario)].

> *I think having the human touch to our view like these surveys is always good because well people will give more personal opinions if you allow them to whereas if it was just AI then you know we're just numbers.* [01_36 (Ontario)]

> *Healthcare should be about individuals and it should be about connection. It should be about you and me face-to-face and to put artificial intelligence in there to pigeon hole me into a certain group I think would be very dangerous. I think we want to get away from that and start looking at individual situations and everybody's you know life and how we can interact with them best.* [03_03 (Saskatchewan)]

Similarly, one participant provided a unique perspective as someone who identifies as living with disabilities.

> *I'd just like to see that be individualized and person centered... That requirement for person-centered care for diversity of options, a diversity of supports, and for that holistic care to be present and connected and supportive. Mostly I think it's a human rights actual systemic problem to use AI.* [03_21 (Saskatchewan)]

Consent Is Critical: Strong Safeguards Are Needed to Protect Patients' Data and Trust

Overview

Many participants advocated for strong safeguards and fully-informed consent before having AI used to derive their SDoH information. Most of these participants described opt-in consent, however some described opt-out consent. There is a need for "full transparency" [01_78 (Ontario)] regarding why the data is being collected by AI, what it will be used for, how it will be stored, who has access, how it will work, and oversight before implementation. Without these safeguards, participants mentioned that it would be a "breach of trust" [01_78 (Ontario)] and they would feel upset and "caught off guard" [01_38 (Ontario)].

> *And I think verbal consent or written consent is very important…as opposed to the passive consent you know it's like when you download something how it's*

XSL•FO
RenderX

> *all agree, agree, agree…We really do need to read the fine print…And because I think that we, our private information is more valuable than we actually realize and we've gotten so accustomed to passing it out at times that we're failing to realize how valuable and how sensitive it can be so….* [05_12 (Newfoundland and Labrador)]
>
> *So it is a black box in the way it uses that [information] but then is there a team which is always correcting it if it's out of whack?* [01_13 (Ontario)]

Data Access and Verification

Multiple participants wanted the opportunity to check what the AI algorithms derived for their SDoH information and have the chance to rectify inaccuracies.

> *Maybe you know it would be okay if the AI [derives the SDoH information] first and then the patient…is asked to confirm like say here is what we think it is, do you think this is correct - and then the patient can say yes or no but I think not to just do it and like keep it there behind closed doors.* [03_05 (Saskatchewan)]

Discussion

Principal Findings

Overall, there were varied perspectives on whether AI should be used in primary care to derive patients' SDoH information. Some participants expressed that the benefits of more efficient data collection or improved care did not outweigh the potential harms from inaccurate predictions, privacy and security concerns, reduced patient-provider interactions, and data misuse and discrimination. Many participants emphasized the need for strong safeguards if AI is used, including fully informed consent, transparency, oversight, and the ability to check and verify predictions.

Benefits

Participants in other studies have similarly identified that the use of AI in health care is efficient and could promote improved health and health care [52]. Integrating SDoH information through AI can help to predict risks of negative health outcomes (eg, suicide [53] and HIV [54]) and health care use [25,55-57]. Other studies have found that the identification of unmet social and financial needs using EMR data could assist with predicting the need for community resources, and therefore facilitate community resource connections and personalized interventions to address patients' social situations [57,58]. It could also help to inform future program design and community planning to build capacity and outreach to encourage access to necessary health services and reduce related inequities [57,58].

Navigating Concerns and Establishing Strong Patient Protections

Many of the potential harms of AI were focused on issues surrounding participants' personal care and treatment at the individual-level, as opposed to the use of aggregated data for system- or organization-level change. This may partly explain the strong concerns that surfaced about AI. Some participants highlighted the impracticality of continuously verifying AI-generated outcomes over time and expressed willingness to contribute their data anonymously for research and quality improvement. Health services may consider the feasibility of adopting alternative models of patient consent [59]. For example, tiered consent enables patients to opt-in or -out of sharing their data under various conditions (eg, data used at the aggregate level for algorithm development or individual-level) [59,60]. It has been recommended for organizations to implement patient education on consent regarding AI and to work alongside patients in creating a consent that is coherent and straightforward [60]. Similar to the participants in this study, others have discussed consent, transparency, verification, control, and oversight as part of recommendations for the ethical use of AI [55,61-64].

AI is a broad term to describe many types of complex statistical methods, which are not often transparent or well understood by the public. This can lead to mistrust in AI and medicine, and given the novelty of AI in health care settings, there are still many unknowns. A major concern is the potential for AI to misclassify one's racial or ethnic background, as well as fluctuating social circumstances. Even with highly accurate AI models, misclassification is possible, as well as algorithmic or data bias and societal bias [32]. Without careful oversight, inaccurate or biased AI models could be used to significantly impact patient care or propagate discrimination or health inequities [32,41]. This may contribute to overcriminalization and systemic discrimination experienced by racialized and low-income communities [65,66]. Thus, although resource-intensive, it is imperative that patients have the ability to verify the AI-generated SDoH outcomes and modify it. It is also incumbent on AI teams to produce algorithms that go further than just being interpretable, but ones that provide justification for the outcome [67] and proactively address health equity [68].

Other studies examining perspectives on AI in health care have reported similar concerns of privacy and data breaches, infrastructure and oversight, and lack of choice or control of the data [24,38,39,52,62,63,69]. During the time of the interviews, the Canadian news media frequently discussed ransomware attacks and data breaches in medical data systems [70], including those described as the "worst in Canadian history" [71]. This context could have impacted participant concerns of using AI to derive SDoH data in this study.

Health care, particularly primary care, is a highly personal "social enterprise, powered by committed, caring, and collaborative connections between the humans involved" [72]. It is not surprising that a major concern in this study was the potential for AI to threaten patient-centered and individualized care, harming the patient-provider relationship. These findings have been reported in the literature [69,73] and may reflect concerns about AI in medicine in general, as opposed to extraction of SDoH data on the backend. Some articles have suggested restricting AI from decision-making [74,75] such as automatically deriving patient SDoH data and recording it into patient records. Instead, AI could be used as a tool [74] as part of patient-centered care that helps providers prioritize discussions about SDoH with their patient based on their risk of having unmet needs. Based on these discussions, team-based

XSL•FO
RenderX

care approaches could support personalized actions following identification of a need.

Implementation of AI for SDoH data extraction should incorporate a strong focus on equity and meaningful partnerships with underrepresented communities in every stage, to promote safety and minimize potential harms [32,38,62]. This should include community governance, particularly for Indigenous and Black communities [61], and would inform whether the SDoH data is collected, the type of data to collect, the frequency for such data collection, and its use. In combination, using an equity framework to guide implementation could help to mitigate medical mistrust and associated health disparities [76,77], particularly among individuals who experience structural racism and discrimination in health care [76,78]. Overall, while the necessary safeguards may diminish some of the returns of more timely, efficient SDoH information retrieval using AI, they must be an inextricable part of using AI to derive SDoH data.

Strengths and Limitations

This study has multiple strengths. It involved a large sample of 195 participants across 4 Canadian provinces and used a maximum variation approach for a diverse sample. For example, the majority of participants who disclosed their race and ethnicity identified as non-White, and most had at least 1 unmet social need. There are few multijurisdictional studies that examine perspectives on using AI to derive SDoH data; thus, this study contributes to reducing knowledge gaps regarding implementation of AI to derive SDoH data in primary care. Various techniques were also used to increase the trustworthiness and quality of the study. Furthermore, the SPARK project is composed of a dedicated team of researchers and patient partners who are passionate about health and social inequities and meet regularly to discuss the study and decision making.

Several limitations were also identified. This study reports the findings from questions on AI that were asked as part of a larger interview on general SDoH data collection and use in primary care. Participants' perspectives may have been impacted by the other questions that preceded the AI conversation. In addition, despite having study recruitment materials available in multiple languages for each province, the team relied entirely on potential participants to make initial contact and were not approached by non-English speakers. While the sampling strategy captured a range of formal educational experiences, approximately one-third had a college, university, or postgraduate degree. Thus, the study sample may not include individuals who experience language barriers and may be less transferable to individuals who did not complete high or grade school. Furthermore, race-based data in Manitoba were not collected due to the need for greater community engagement. This study did not receive Research Ethics Board approval across all provinces to report participants' age; however, each province considered age for a diverse recruitment sample. Finally, given project timelines and resource constraints, qualitative data analysis was not formally initiated until the interviews were completed. Despite this, the close communication, regular meetings, and feedback enabled the interview guide to undergo changes for greater clarity; the interview questions were also piloted by the study team beforehand.

Conclusions

This large qualitative study examined perspectives on using AI to derive SDoH data in primary care using existing EMR data. Participants described the benefits of efficiency, access and improvement of care, and concerns focused on inaccuracies, negative consequences to care, privacy and security breaches, reduced patient-provider interactions, data misuse, and discrimination. Strong safeguards, including fully informed consent, verification and oversight can help to alleviate harm. There is a need to engage communities in the development, implementation, and evaluation of future AI initiatives, to determine opportunities and safety measures for using AI. Interviews with providers, health care administrators, and decision-makers are also necessary to understand the feasibility of integrating AI in primary care for SDoH information.

Acknowledgments

We would like to sincerely thank the study participants from across Canada who kindly offered their time and perspectives. We are grateful for the entire SPARK team, including the many patient partners. We are also appreciative of Ellah San Antonio and Nada Dali for helping with the interviews.

This project was supported in part by Canadian Institutes for Health Research (FRN 156885). Author [ADP] is supported as a Clinician-Scientist by the Department of Family and Community Medicine, Faculty of Medicine at the University of Toronto and at St. Michael's Hospital, the Li Ka Shing Knowledge Institute, St. Michael's Hospital, and a CIHR Applied Public Health Chair in Upstream Prevention. The opinions, results and conclusions reported in this article are those of the authors and are independent from any funding sources.

Authors' Contributions

KA-B, MI, LAJ, AK, EGM, NM, CN and ADP contributed to the study conceptualization and design. IAM, DH, AZS, LK, and AD-P collected the data. The data analysis and interpretation were led by VHD and JRQ, and supported by DH, AZS, LK, AD-P, and ADP. Interpretation of the data was supported by EA, JC, MR, DS, AZ, and SG. VHD wrote the paper, and was assisted by JRQ and SG. All authors revised and approved the final draft.

Abstract

Background: Cognitive behavioral therapy (CBT) is a highly effective treatment for depression and anxiety disorders. Nonetheless, a substantial proportion of patients do not respond to treatment. The lack of engagement with therapeutic materials and exercises between sessions, a necessary component of CBT, is a key determinant of unsuccessful treatment.

Objective: The objective of this study was to test whether the deployment of a generative artificial intelligence (AI)–enabled therapy support tool, which helps patients to engage with therapeutic materials and exercises in between sessions, leads to improved treatment success and patient treatment adherence compared with the standard delivery of CBT exercises through static workbooks.

Methods: We conducted a real-world observational study of 244 patients receiving group-based CBT in 5 of the United Kingdom's National Health Service Talking Therapies services, comparing 150 (61.5%) patients who used the AI-enabled therapy support tool to 94 (38.5%) patients who used the standard delivery of CBT exercises. The groups were equivalent with respect to the content of the CBT materials and the human-led therapy sessions; however, the intervention group received support from the AI-enabled therapy support tool in conducting CBT exercises.

Results: Patients using the AI-enabled therapy support tool exhibited greater attendance at therapy sessions and fewer dropouts from treatment. Furthermore, these patients demonstrated higher reliable improvement, recovery, and reliable recovery rates when compared to the control group, which was related to the degree of use of the AI-enabled therapy support tool. Moreover, we found that engagement with AI-supported CBT interventions, relative to psychoeducational materials, predicted better treatment adherence and treatment success, highlighting the role of personalization in the intervention's effectiveness. To investigate the mechanisms of these effects further, we conducted a separate qualitative experiment in a nonclinical sample of users (n=113). Results indicated that users perceived the AI-enabled therapy support tool as most useful for discussing their problems to gain awareness and clarity of their situation as well as learning how to apply coping skills and CBT techniques in their daily lives.

Conclusions: Our results show that an AI-enabled, personalized therapy support tool in combination with human-led group therapy is a promising avenue to improve the efficacy of and adherence to mental health care.

Introduction

Background

Mental health conditions are a leading cause of health-related burden across the world, with anxiety and depression being ranked among the top 25 causes of burden in 2019 [1]. Both disorders are very common, affecting >29% of the global population in their lifetime [2]. The recent COVID-19 pandemic has accelerated this even further, raising the global prevalence by 27.6% between 2020 and 2021 for major depressive disorder and 25.6% for anxiety disorders [3], highlighting the need for effective and accessible mental health support.

Cognitive behavioral therapy (CBT) has been shown to be a highly effective treatment for depression and anxiety disorders [4-6] and is the first line of treatment for these conditions in many therapy guidelines worldwide [7,8]. Nonetheless, CBT does not benefit everyone. In fact, a recent meta-analysis of 409 trials reported that 58% of patients do not respond to treatment [5]. Several reasons for unsuccessful therapy have been identified. Among them, the most prominent is a failure to engage with therapeutic exercises and materials (ie, homework assignments) between therapy sessions [9].

Between-session support, such as completion of therapeutic materials and exercises, is a necessary component of CBT [10], allowing patients to maintain the progress made in the therapy and transfer it to real life to achieve short-term and long-term improvements [11]. Broadly, between-session work can be divided into psychoeducational (eg, reading materials about symptomatology), self-assessment (eg, monitoring feelings, thoughts, or behaviors), and modality-specific tasks (eg, exposure to images for specific phobias). Meta-analyses have consistently demonstrated that both the quantity and the quality of such task completion significantly predict treatment outcomes [12,13].

Thus, enhancing high-quality engagement with CBT materials and exercises between therapy sessions is a key objective for improving CBT treatment outcomes [14]. This is particularly critical in group therapy settings, where dropout rates are higher and recovery rates are lower than in individual therapy settings [15-17]. Traditionally, therapeutic materials and exercises in CBT have been distributed as worksheets in pen and paper format, downloadable PDF format, or delivered as digital applications, requiring the patient to engage with these static materials without any intelligent supervision. However, this method has shown limitations, often resulting in delayed completion or incomplete materials, highlighting the need for innovative solutions to enhance patient compliance and treatment effectiveness. One promising avenue for enhancing between-session support has been the deployment of digital tools [18]. Most notably, recent developments in generative artificial intelligence (AI) and large language models (LLMs), such as ChatGPT, have showcased that AI can enable a truly tailored user experience with interactions nearly indistinguishable from humans [19] and lead to increased engagement and treatment adherence [20,21]. Thus, the use of this novel technology holds great potential to support clinical practice, especially for supporting patients between therapy sessions to meaningfully engage with their course of treatment.

Objectives

We developed a generative AI–enabled therapy support tool, Limbic Care, to support patients between sessions during clinician-led group-based CBT. The AI-enabled therapy support tool includes chat-based therapeutic materials to allow for more natural engagement with these materials than traditional, static CBT materials. Recognizing the important role of personalization in overcoming the barrier to the uptake of digital solutions [22], our solution uses generative AI to deliver a user-centric experience. Personalization addresses the diverse needs and preferences of individuals undergoing CBT rather than using the one-size-fits-all approach, which often falls short in addressing unique needs. It may also help cultivate a relationship between users and the AI-enabled therapy support tool. This relationship, also known as therapeutic alliance, has been shown to increase engagement and predict positive clinical change [23]. Thus, we hypothesized that the use of the AI-enabled therapy support tool increases engagement with therapy and thus leads to better outcomes for patients. This support was tailored and personalized, however, treatment was still provided by the clinician in line with medical device regulations [24]. In this observational study, we evaluated a novel solution for patient engagement and clinical outcomes. Assessing 244 patients undergoing CBT treatment in 5 of the United Kingdom's National Health Service (NHS) Talking Therapies services, we found that patients who chose to use the AI-enabled therapy support tool during their treatment achieved better treatment success. Moreover, we showed that engagement with the AI-enabled therapy support tool was linked to increased reliable improvement, recovery, and reliable recovery, as well as more attended treatment sessions and reduced dropout from treatment. Therefore, our results suggest that the AI-enabled therapy support tool may improve individual patients' outcomes and support clinical services by increasing treatment adherence and treatment effectiveness.

Methods

Setting

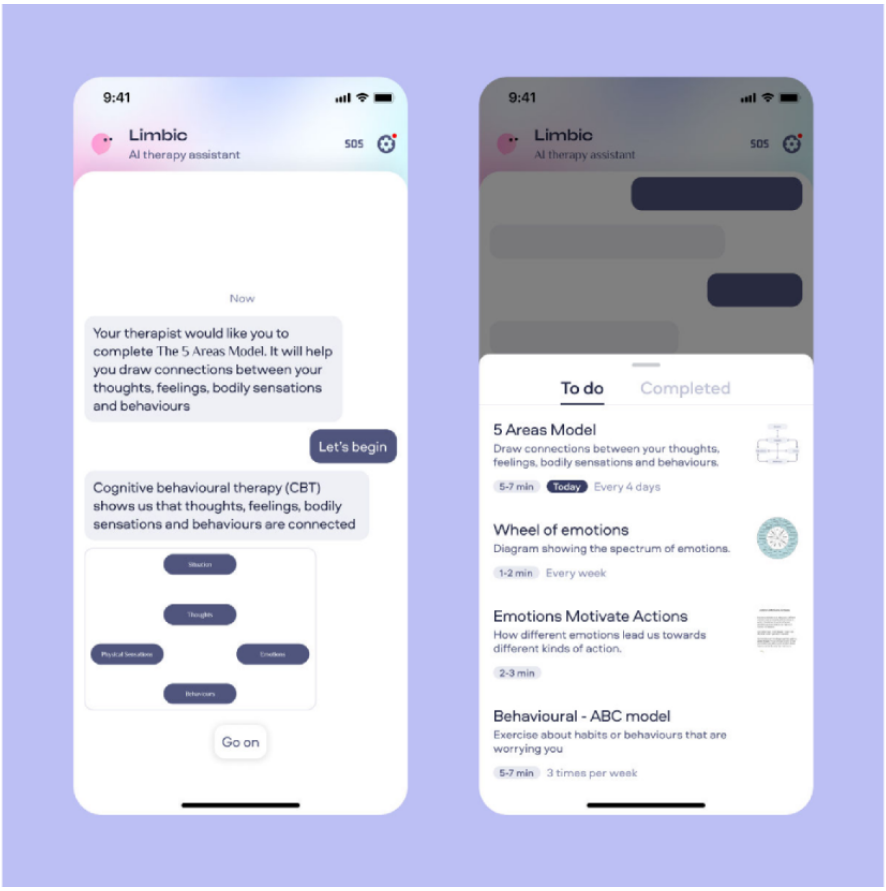
We evaluated the efficacy of an AI-enabled therapy support tool (Limbic Care; Limbic Ltd [25]) in a real-world clinical context in 5 NHS Talking Therapies for anxiety and depression services provided by Everyturn Mental Health in the United Kingdom. Specifically, the tool was implemented in the context of completing therapeutic materials and exercises between the sessions of a synchronous web-based group-based CBT program

XSL•FO
RenderX

according to the NHS Talking Therapies for anxiety and depression manual [26].

AI-Enabled Therapy Support Tool

The AI-enabled therapy support tool is a mobile app using AI to offer support between therapy sessions to patients in psychological talking therapy who are aged ≥18 years, under the supervision of a trained clinician.



The app features a conversational chatbot (Figure 1) to assist with the completion of therapist-assigned therapeutic materials and exercises, which are a component of CBT. The chatbot was powered by an LLM (GPT-4 [OpenAI] at the time of the study) to deliver clinically validated materials, that is, therapeutic materials and exercises developed by clinical experts and assigned by the treating clinician. Specifically, the clinical materials in the AI-enabled therapy support tool were interventions (interactive exercises helping the patient work through a presenting problem, eg, reframing negative thoughts) and psychoeducational materials (educational materials, eg, about CBT). Importantly, there were multiple safety layers and guardrails implemented to ensure that the LLM strictly adhered to the task at hand [27].

The therapeutic materials primarily consist of standard materials for CBT as they are also commonly used in NHS Talking Therapies. These are delivered in a conversational way to the patient using several custom-tailored LLM modules and supervisory AI tools.

All conversations were constantly monitored using several machine learning safety modules to ensure appropriateness, prevent harmful responses, monitor risks, and ensure regulatory compliance [27]. The conversations as well as these machine learning models were monitored and continuously improved by the company's research team.

In contrast to traditional homework worksheets, the patient can interact conversationally to navigate through the materials and receive notifications regarding assignments. The app encourages and empowers patients to engage in the therapeutic process outside group therapy sessions and continue the progress made in therapy in their real lives as well as provides empathetic support for the user.

Figure 1. Example user interface of the artificial intelligence–enabled therapy support tool, displaying the conversational interface (left screen) and the assignments provided by the treating clinician (right screen).

Study Design

This was a multisite, real-world, observational study to investigate the impact of the AI-enabled therapy support tool on clinical outcomes. The AI-enabled therapy support tool was offered to all patients eligible for 11 group-based CBT groups starting between October 2023 and January 2024. All (N=244, 100%) patients had access to the same group sessions irrespective of their decision to use the AI-enabled therapy support tool between the sessions. The clinicians facilitating the group sessions were trained to offer the use of the AI-enabled therapy support tool in the first session of CBT. All (N=244, 100%) patients were encouraged to complete therapeutic

XSL•FO
RenderX

materials and exercises between sessions regardless of which delivery method they chose.

We compared the clinical outcomes of individuals who signed up to use the AI-enabled therapy support tool (the intervention group) with those of individuals who did not (the control group). It is important to note that individuals who chose not to use the AI-enabled therapy support tool had access to CBT worksheets, which represent the standard way of completing homework between therapy sessions and which were also assigned by the treating clinician. Therefore, aside from the introduction of the AI-enabled therapy support tool, no other changes were made to the content or the delivery method of the sessions, ensuring that any observed effects can be attributed to patients choosing to use the tool. In addition, we investigated whether engagement with the AI-enabled therapy support tool, specifically the completion of therapeutic materials and exercises on the app, was linked to the outcome measures.

Ethical Considerations

Clinical audit studies within the NHS Talking Therapies do not require additional patient consent or ethics approval, as determined by the NHS and in line with National Institute for Health and Care Excellence guidelines [28]. This exemption from additional ethical review was further confirmed by the UK Health Research Authority. In this case, a clinical audit was used to determine whether the introduction of a new technology would improve the standard of care. Patients voluntarily opted in to use the AI-enabled therapy support tool. Those who were offered access to the AI-enabled therapy support tool agreed to the privacy and data policy agreement in the app and consented to the use of their anonymized data for audits and research studies. Because this was a real-world observational study in group therapy settings, patients were not provided any financial compensation. Regarding the identification of individuals, treatment and engagement outcome data in this study were anonymous; therefore, it was not possible to identify individual patients.

The qualitative user experience study in a nonclinical sample was separate from the clinical audit and was approved by the University College London Research Ethics Committee (6218/003). Participants in this study were paid £4.20 (US $5.17), and this was not contingent on their use of the AI-enabled therapy support tool. Participation was voluntary, and all users provided informed consent. Free-text answers were anonymized for coding and analysis.

Outcome Measures

Overview

Clinical and app use outcomes were collected as part of the study. Clinical outcomes are routinely assessed throughout treatment provision by NHS Talking Therapies. The measures of treatment engagement include attended sessions, proportion of dropouts, and did not attend (DNA) treatment sessions and the measures of treatment success include reliable improvement, recovery, and reliable recovery [29]. Use outcomes were collected through the mobile app as patients used the AI-enabled therapy support tool and were used as measures of engagement with the intervention. The information collected included the number of sessions in the app and the number of therapeutic materials and exercises completed.

Treatment Engagement

Number of Therapy Sessions

The number of therapy sessions was used to quantify the total interactions that the patient had with the therapist during their treatment journey. The interactions included assessment and therapy sessions. In NHS Talking Therapies, patients usually have 1 assessment session before the start of treatment and 6 synchronous group therapy sessions. Due to how data are reported by the services, it is not possible to differentiate between assessment and treatment sessions.

Proportion of DNA Sessions

DNA sessions refer to sessions that are canceled last minute or not attended by the patient. This was measured as the proportion of DNA sessions out of the total number of sessions that the patient could attend.

Dropouts

Dropouts are measured as the percentage of patients who dropped out during the course of treatment.

Treatment Success

Reliable Improvement

Reliable improvement refers to a clinically significant improvement in symptoms following a course of treatment and is calculated as the score difference between the first and the last validated clinical questionnaire completed. The types of questionnaires patients complete are tailored to their specific condition. For example, the Patient Health Questionnaire-9 (PHQ-9) [30] is used to measure depression symptom severity, and the Generalized Anxiety Disorder-7 (GAD-7) [31] is used to measure anxiety symptom severity. A clinically significant improvement in symptoms is considered a change score ≥6 for PHQ-9 or ≥4 for GAD-7 [26].

Recovery

Recovery is achieved in instances where a patient is defined as a clinical case at the start of treatment and not as a clinical case at the end of the treatment. Clinical caseness refers to a patient with severe enough clinical symptoms to be regarded as a clinical case at the start of treatment. Caseness is measured by the clinical questionnaires and is met when patients score ≥10 on PHQ-9 or ≥8 on GAD-7 [26].

Reliable Recovery

Reliable recovery is calculated based on reliable improvement and recovery and, as such, is the most stringent outcome. It is achieved if a patient meets the criteria for reliable improvement, referring to clinically significant improvements in their symptoms, and if the patient moves to recovery. Moving to recovery refers to a patient meeting the criteria for clinical caseness at the start of treatment to not being a clinical case at the end of it [26].

XSL•FO
RenderX

Use Outcomes

Number of Sessions in the App

A session in the app starts when the AI-enabled therapy support tool app is opened and ends when no activity has been detected for ≥30 minutes. This is measured as the number of sessions in the app and is only available for patients using the AI-enabled therapy support tool between sessions.

Number of Completed Therapeutic Materials and Exercises

Completed therapeutic materials and exercises refer to the tasks available in the AI-enabled therapy support tool that were initiated and finalized by the patients. This is measured as the number of completed homework assignments and is only available for patients using the AI-enabled therapy support tool between sessions.

User Experience

In addition to the impact of the AI-enabled therapy support tool on clinical outcomes, we were further interested in the perceived benefits of the tool and potential areas for improvement. Because it can be challenging to contact patients undergoing treatment and minimize the burden on them, we conducted a separate user study to assess user experience. Therefore, we recruited 113 individuals experiencing depression and anxiety symptoms (PHQ-9 score of ≥5 or GAD-7 score of ≥5) from the web-based platform Prolific [32] and instructed them to install the Limbic Care app. Participation was voluntary, and all (113/113, 100%) participants provided informed consent. Participants were not instructed on how to engage with the AI-enabled therapy support tool but rather were told they could use it as much or as little as they would like for the 4-week period of the study. After 4 weeks, participants were invited to answer some questions about their experience using the app, and only users who had used the app were included in the analysis. To probe the perceived benefits of the AI-enabled therapy support tool, participants were asked if they felt their mental health had benefited from using the app ("What benefits to your mental health (if any) have you gained from using the app?"). To understand potential areas for improvement, participants were asked if they had any feedback on how the app could be improved ("Do you have any feedback or suggestions on how we could improve the Limbic app?"). Participants were reimbursed £4.20 (US $5.24) for completing the study, and this was independent of their use of the AI-enabled therapy support tool.

Qualitative Analysis

Data were collected asynchronously, using free-text answers from a nonclinical, convenience sample on Prolific (n=113). Participants did not have a mental health diagnosis, though they experienced elevated symptoms of anxiety and depression (as indicated by scores of ≥5 for the PHQ-9 and GAD-7). Data were analyzed using reflexive thematic analysis, taking an inductive approach to coding [33], and a realist epistemological position, assuming that meaning and experience are reflected in language [34]. Two researchers (MR and LMD) independently coded a subset of responses and iteratively cross-checked interpretations and codes. Codes were refined using a comparative method, with new interpretations evaluated against existing ones. Inductive analysis of similar codes produced content themes highlighting potential benefits and areas for improvement in the AI-enabled therapy support tool.

Although the semiautomated nature of data collection precluded purposive sampling for saturation, no new codes emerged in later responses that altered the meaning of earlier findings, indicating data saturation was reached [35]. The themes and supporting participant quotes are presented in the Results section.

Coder Qualifications

The coding team consisted of MR, a male researcher, and LMD, a female researcher. Both researchers, while predominantly quantitative, were trained in thematic analysis and had previous experience in qualitative research [36].

Trustworthiness

Credibility was ensured through reflexivity and investigator triangulation [37,38]. Data were collected anonymously and asynchronously, minimizing the influence of researcher characteristics on participant responses. Open-ended prompts encouraged both positive and negative reflections to capture a balanced perspective. While the nature of data collection did not allow methodological triangulation, investigator triangulation was achieved through the involvement of multiple researchers (MR, LMD, JH, and JM). To ensure transferability, we described the study's context and the participants (thick description) to allow the readers to evaluate whether the findings are transferable to other care contexts [37,38]. Dependability and confirmability were ensured by thoroughly documenting the research steps from the start of the study to the interpretation and reporting of the findings [37,38].

Statistical Methods

We compared pretreatment data for patients in both groups to ensure that they did not differ based on demographic characteristics (age, gender, ethnicity, and sexual orientation), wait time to treatment, and depression and anxiety baseline symptom scores. In addition, recognizing that different referral methods can influence clinical outcomes, as illustrated by the AI-enabled self-referral tool increasing treatment success [21,39], we also compared the referral methods between groups. A 2-tailed chi-square test was applied for categorical outcomes, and a 2-tailed independent student *t* test was used for continuous outcomes.

Next, clinical outcomes were compared between the intervention and the control group. Linear regression models were run for continuous outcomes (number of attended appointments and proportion of DNA sessions), and logistic regressions were run for categorical outcomes (dropouts, reliable improvement, recovery, and reliable recovery). In both cases, the outcomes of interest were entered as independent variables and the intervention group (intervention group=1; control group=0) as a dependent variable. In addition, we controlled for baseline anxiety and depression symptom scores and the proportion of women and heterosexual participants. For linear regression, we reported regression coefficients, along with the 95% CIs, and for logistic regressions, we reported odds ratios (ORs) along with 95% CIs.

XSL•FO
RenderX

Use outcomes were investigated within the group with access to the AI-enabled therapy support tool. Specifically, we were interested in investigating if there would be any association between patients' level of engagement with the app and their clinical outcomes, in line with previous work suggesting that the completion of therapeutic materials and exercises and engagement between sessions may lead to an improvement in treatment outcomes [14]. Pearson correlation was used for continuous variables, and point-biserial correlation was used for binary variables.

Results

Participants

Patients (N=244) attending regular group therapy in Talking Therapies in the United Kingdom were offered to use our AI-enabled therapy support tool, of which 150 (61.5%) downloaded and used the AI-enabled therapy support tool (intervention group). The remaining 94 (38.5%) patients used static therapeutic materials, which were either in pen and paper format or downloadable PDF format (control group). We followed both groups from enrolling in the study until the end of their therapy (typically 8-10 weeks long). To ensure that the patients used the AI-enabled therapy support tool as intended, we calculated the percentage of individuals who engaged with the therapeutic materials at a certain number of weeks from the start of their therapy (known as app retention). We found that 79.3% (119/150) of the individuals were engaged at week 1, 64% (96/150) were engaged at week 2, 51.3% (77/150) were engaged at week 3, 42% (63/150) were engaged at week 4, 35.3% (53/150) were engaged at week 5, and 19.3% (29/150) were engaged at week 6.

To check for baseline differences, we compared pretreatment clinical and demographic characteristics. The mean ages of the participants in the intervention group (mean 40.3, SD 13.2 years) and the control group (mean 40.5, SD 15.5 years) were not significantly different (t_{183}=0.11; *P*=.91) nor was the ethnicity of the participants (intervention: 132/150, 88.7% White participants; control: 78/94, 83% White participants; χ^2_1=0.4; *P*=.53). However, the groups differed significantly in the proportion of heterosexual individuals (intervention: 129/150, 86% heterosexual individuals; control: 69/94, 73% heterosexual individuals; χ^2_1=5.4; *P*=.02) and women in the group (intervention: 111/150, 74% women; control: 58/94, 62% women; χ^2_1=4.2; *P*=.04). Therefore, we controlled for the proportion of heterosexual individuals and women in all subsequent analyses. The 2 groups did not differ in anxiety (b=–0.11; *P*=.81) symptom scores nor in depression scores at baseline (b=−0.56; *P*=.36; Table 1). Nonetheless, we decided to control for baseline depression (PHQ-9) and anxiety (GAD-7) scores in all further analyses, as they are known as prognostic factors for changes in symptom severity [40,41]. Finally, the groups did not differ in the time they waited to start treatment (t_{122}=–0.32; *P*=.75) nor the proportion of individuals who referred using the AI-enabled self-referral tool (χ^2_1=1.2; *P*=.28).

Table 1. Baseline characteristics of the therapy support and control groups.

	Intervention group (n=150)	Control group (n=94)	*P* value
Age (y), mean (SD)	40.3 (13.24)	40.5 (15.46)	.91
Gender (women), n (%)	111 (74)	58 (61.7)	.04
Sexuality (heterosexual), n (%)	129 (86)	69 (73.4)	.02
Ethnicity (White), n (%)	132 (88.7)	78 (83)	.53
PHQ-9[a] baseline, mean (SD)	12.6 (4.62)	12.0 (4.55)	.36
GAD-7[b] baseline, mean (SD)	12.0 (3.30)	12.1 (3.74)	.81
Wait time to treatment (d), mean (SD)	35.4 (19.6)	34.4 (20.4)	.75
Referral method (AI[c]-enabled self-referrals; %)	73.3	66	.28

[a]PHQ-9: Patient Health Questionnaire-9.

[b]GAD-7: Generalized Anxiety Disorder-7.

[c]AI: artificial intelligence.

Outcome Data

AI-Enabled Therapy Support Improves Treatment Engagement

To assess the impact of the AI-enabled therapy support tool on treatment adherence, we compared whether the intervention group attended more therapy sessions, missed fewer sessions, and showed a lower therapy dropout rate than the control group.

Increase in the Number of Therapy Sessions

We evaluated whether the AI-enabled therapy support tool facilitated an overall increase in attended therapy sessions. We found that the intervention group attended significantly more sessions, with an average of 2 more sessions attended compared to the control group (b=1.65; 95% CI 1.051-2.200; *P*<.001), illustrating the AI-enabled therapy support tool's potential to improve engagement in therapeutic processes.

XSL•FO
RenderX

Reduction in the Sessions That Were Not Attended

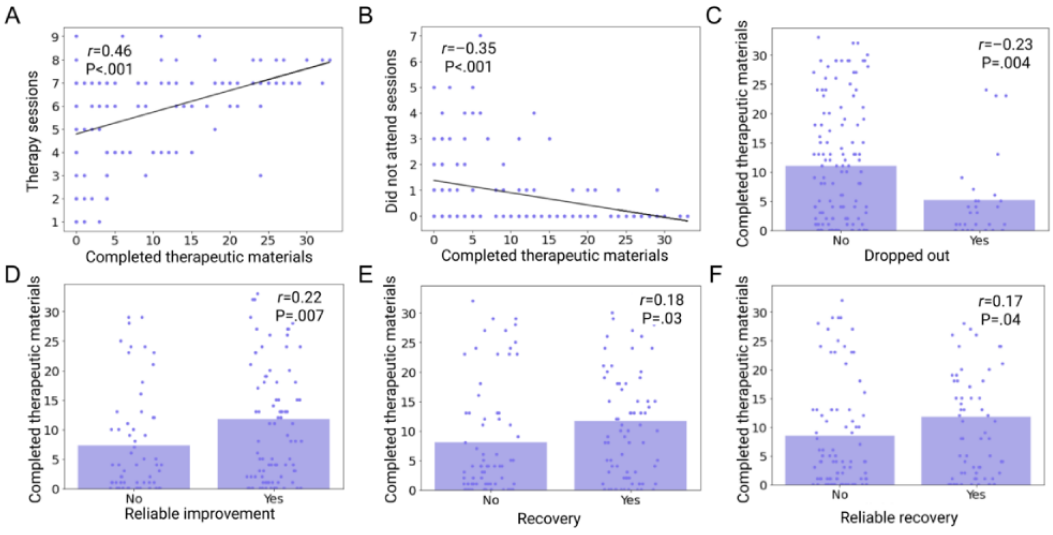
Further analysis focused on the proportion of sessions not attended by the patients (referred to as DNA sessions) to gain a deeper understanding of treatment engagement. We found that the intervention group showed a significant reduction in the rate of DNA sessions (b=–14.97; 95% CI –21.464 to –8.400; *P*<.001), equating to a 15 percentage point reduction in DNA sessions (Table 2). This indicates that the intervention group was more consistent in attending sessions; therefore, it was more engaged in treatment.

Table 2. The percentage point difference between the intervention and control groups for treatment engagement and treatment success measures.

Outcome	Percentage point difference (%)	Group effect (b)	*P* value
DNA[a] session proportion	–15	–14.97	<.001
Dropout rate	–23	–1.14	<.001
Reliable improvement	21	80	.005
Recovery	25	1.03	.001
Reliable recovery	21	86	.004

[a]DNA: did not attend.

Reduction in Dropout From Therapy



More critical than DNA sessions were participants who did not finish their therapy and dropped out completely. Therefore, we investigated whether the AI-enabled therapy support tool was also linked to reduced dropout rates. We found that the intervention group experienced a significant 23 percentage point reduction in dropout rates (OR 0.32, 95% CI 0.171-0.595; *P*<.001; Table 2) compared to individuals in the control group. This suggests that the AI-enabled therapy support tool was associated with an increased likelihood of finishing a course of treatment.

Tables S1 and S2 in Multimedia Appendix 1 further evaluate the impact of the AI-enabled therapy support tool on treatment engagement separately for patients with a primary diagnosis of depression or an anxiety disorder at baseline. Briefly, we found that the tool is equally effective for both conditions.

AI-Enabled Therapy Support Improves Treatment Success

Next, to assess the impact of the AI-enabled therapy support tool, we investigated the 3 key metrics for treatment success that are routinely assessed in NHS Talking Therapies [26] (Figure 2).

Figure 2. Correlations between completed therapeutic materials, exercise assignments, and treatment engagement (A-C) and treatment success measures (D-F).

Increased Reliable Improvement

First, we compared the reliable improvement rate between the groups. Reliable improvement is defined as a significant change in patients' symptom scores from the beginning to the end of treatment (reduction of ≥6 points in the PHQ-9 or ≥4 points in the GAD-7 total scores). This measure is considered to reflect meaningful clinical progress. We found that the intervention group experienced a 21 percentage point higher rate of reliable improvement compared to the control group (Table 2). This difference was statistically significant (OR 2.21, 95% CI 1.279-3.834; *P*=.005), indicating that using the AI-enabled therapy support tool was linked to a higher likelihood that the individual saw a clinical improvement in their symptoms.

XSL•FO
RenderX

Improved Recovery

Next, we were interested in recovery, going beyond mere symptom improvement. Therefore, we looked at how many patients moved from caseness (meaning that the patient has severe enough symptoms to be considered a clinical case for depression or anxiety disorders) to below caseness during their treatment, indicating recovery [26]. We found that the intervention group experienced a 25 percentage point higher recovery rate compared to the control group (Table 2). This difference was highly significant between groups (OR 2.81, 95% CI 1.561-5.069; *P*=.001), showing that patients in the intervention group were more likely to recover during the administered therapy.

Better Reliable Recovery

Finally, we investigated the most rigorous criteria for treatment success, namely reliable recovery [26]. Reliable recovery is achieved when a patient shows both of the aforementioned criteria, that is, reliable improvement as well as recovery. In other words, the patient has moved from being considered a clinical case to being a nonclinical case and there has also been a significant improvement in their condition.

We found that the intervention group had 21 percentage points higher reliable recovery rates compared to the control group (Table 2). This difference was significant between the 2 groups (OR 2.37, 95% CI 1.311-4.290; *P*=.004), showing that patients in the intervention group were more likely to achieve reliable recovery. In summary, these results show that the people who used the AI-enabled therapy support tool achieved substantially and consistently better treatment outcomes than those who did their homework using traditional means.

Tables S1 and S2 in Multimedia Appendix 1 further evaluate the impact of the AI-enabled therapy support tool on treatment success separately for patients with a primary diagnosis of depression or an anxiety disorder at baseline. Briefly, we found that the tool is equally effective for both conditions.

Use of AI-Enabled Therapy Support Tool Linked to Better Treatment Adherence and Success

A crucial aspect of the usefulness of AI-enabled therapy support tools is whether these are being used by the patients. During the course of treatment, patients in the intervention group used the AI-enabled therapy support tool, on average, for 23 sessions. However, there was some variability in use within the intervention group. Therefore, we investigated if higher engagement with the AI-enabled therapy support tool was associated with therapy adherence in a dose-dependent manner.

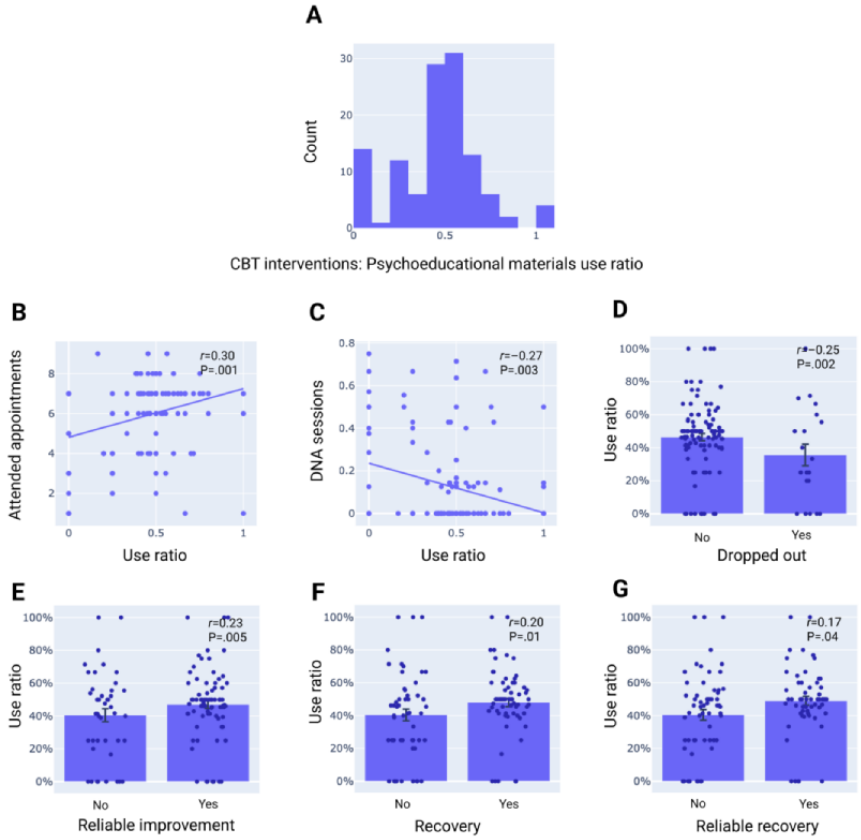
First, we found a statistically significant link between the number of completed therapeutic exercises in the AI-enabled therapy support tool and the number of therapy sessions (*r*=0.46; *P*<.001; Figure 2A), meaning those who engaged more with the AI-enabled therapy support tool were more likely to attend more therapy sessions. In the same spirit, individuals using the AI-enabled therapy support tool between sessions had a lower proportion of recorded DNA sessions (*r*=–0.35; *P*<.001; Figure 2B), indicating that they were more consistent in attending scheduled sessions. Individuals who completed more tasks on the AI-enabled therapy support tool were also found to be less likely to drop out from the treatment program (r_{pb}=–0.23; *P*=.004; Figure 2C), suggesting that the tool not only enhanced session attendance but also contributed to sustained treatment participation.

In addition, we found that the higher use of the AI-enabled therapy support tool was associated with better treatment success, such as reliable improvement (r_{pb}=0.22; *P*=.007; Figure 2D), recovery (r_{pb}=0.18; *P*=.02; Figure 2E), and reliable recovery (r_{pb}=0.17; *P*=.04; Figure 2F). Therefore, these results indicated that the tool was effective in promoting both treatment adherence and clinical treatment efficacy.

Beyond the number of completed therapeutic materials, we were also interested in other measures of engagement with the AI-enabled therapy support tool to gain a more in-depth understanding of the link between app activity and treatment outcomes. As additional engagement measures, we investigated the overall app sessions and total time spent using the app.

We found statistically significant associations between the total number of sessions in the app and dropout rate (*r*=–0.25; *P*=.007) and increased reliable improvement (*r*=0.23; *P*=.01), recovery (*r*=0.20; *P*=.02), as well as reliable recovery (*r*=0.17; *P*=.046). The total number of sessions spent in the app was not correlated with attended appointments (*r*=0.13; *P*=.20) nor DNA sessions (*r*=–0.14; *P*=.18).

Finally, we were also interested in assessing potential links between time spent in the app with clinical and engagement outcomes. Similar to the results mentioned earlier, we found statistically significant associations between time spent in the app and dropout rate (*r*=–0.25; *P*=.007), increased reliable improvement (*r*=0.23; *P*=.01), recovery (*r*=0.20; *P*=.02), as well as the more stringent metric of reliable recovery (*r*=0.17; *P*=.046). Time spent in the app was not associated with attended appointments (*r*=0.14; *P*=.18) nor DNA sessions (*r*=–0.12; *P*=.21).



Higher Engagement with CBT Exercises Relative to Psychoeducation Predicts Better Treatment Adherence and Success

Of the 150 patients in the intervention condition, 118 (78.7%) completed at least 1 AI-supported CBT intervention (an interactive CBT exercise helping patients work through a problem) or psychoeducational material (educational material about CBT). Of these, 4 (2.7%) patients only completed interventions, and 14 (9.3%) patients only engaged with psychoeducational materials. The remaining 100 (66.7%) patients engaged with at least 1 CBT intervention and 1 psychoeducational material (number of interventions: mean 6.7, SD 4.78; number of psychoeducational materials: mean 6.5, SD 4.22). In this subgroup of 100 patients, we evaluated whether engagement with a specific type of AI-supported therapeutic material was predictive of treatment outcomes. To this end, we computed a use ratio of the number of CBT exercises to the number of psychoeducational materials completed (Figure 3A). We found that completing more CBT exercises, relative to psychoeducational materials, predicted better treatment adherence, for example, increased the number of attended

XSL•FO
RenderX

appointments (r=0.30; P=.001) and reduced the proportion of DNA sessions (r=–0.27; P=.003) as well as the dropout rate (r=–0.25; P=.002; Figures 3B-3D). Furthermore, the increased use of CBT interventions was also associated with an improvement in treatment success, for example, increased reliable improvement (r=0.23; P=.005), recovery (r=0.20; P=.01), and reliable recovery (r=0.17; P=.04; Figures 3E-3G). This suggests that especially the engagement with the personalized CBT exercises delivered through generative AI was associated with treatment adherence and treatment success compared to engagement with psychoeducational CBT materials.

Figure 3. Use ratio of cognitive behavioral therapy interventions relative to psychoeducational materials (A), correlations between use ratio and treatment engagement outcomes (B-D), and correlations between use ratio and treatment success outcomes (E-G). Error bars indicate standard error of the mean. CBT: cognitive behavioral therapy; DNA: did not attend.

Other Analyses

User Experience

Beyond the investigation of the effects of the AI-enabled therapy support tool on treatment success and treatment adherence outcomes, we were also interested in conducting a qualitative investigation into the perceived benefits of using this AI-enabled therapy support tool as well as potential areas for improvement. Investigating potential benefits in more depth provides the opportunity to understand the mechanism of why the AI-enabled therapy support tool might have advantages over standard care.

Therefore, in a separate user experience study, 113 participants downloaded and used the Limbic Care app for 4 weeks and provided free-text answers on perceived benefits related to using the app as well as on potential areas for improvement. The sample had a mean age of 31.32 (SD 8.72) years and consisted of 53.1% (60/113) women. A total of 47 (41.6%) participants identified as White. Participants in our nonclinical sample experienced some symptoms of depression and anxiety (PHQ-9 score of ≥5 or GAD-7 score of ≥5); their scores were notably lower than the patient sample, as expected (PHQ-9: mean 10.15, SD 6.14; GAD-7: mean 8.74, SD 4.64).

Perceived Benefits

Of the 113 users surveyed, 92 (81.4%) mentioned a specific benefit of the AI-enabled therapy support tool to their mental health. Here, the most mentioned benefit (30/113, 26.5%) was improved awareness and clarity, indicating that the conversations with the AI-enabled therapy tool were especially helpful for users to think through their issues and gain better perspectives on their situation. The second most frequently reported benefit (23/113, 20.4%) consisted of coping strategies and CBT techniques, suggesting that AI-enabled support helped patients understand and apply CBT exercises to their day-to-day lives. A total of 14 (12.4%) users reported the positive benefit of mindfulness and relaxation, indicating that immediate support for dealing with stressful situations and helping to reduce emotional responses were important aspects of the tool. In addition, 9 (8%) users mentioned empathetic and nonjudgmental support as the main benefit, suggesting that a place to vent and be heard when no human is available was an important component of the tool. Finally, 15 (13.3%) users reported a broad positive impact on their mental health without focusing on any of these more specific categories.

XSL•FO
RenderX

Opportunities for Refinement

The themes and supporting participant quotes are presented in Table 3.

Of the 113 users, only 38 (33.6%) had suggestions for areas of potential improvement. The rest of the users had either no suggestions for improvement (n=63, 55.8%) or mentioned positive feedback even when queried about areas of improvement (n=12, 10.6%). Of the users who had suggestions for improvements, the most common comment (17/113, 15%) focused on the fact that while the chatbot was already very personalized, it was still possible to detect that it was not a human. In addition, 11 (9.7%) users had suggestions for specific additional features that they would either like to see or did not enjoy in the app. There were 4 (3.5%) users asking for more tailored notifications, and 3 (2.7%) users found that the additional guard rails to ensure patient safety restricted their user experience.

This indicated that, overall, users suggested few areas for improvement, with many of these dimensions being highly idiosyncratic to individual users.

Table 3. Overview of themes relating to the perceived benefits of using the artificial intelligence (AI)–enabled therapy support tool.

Theme	Definition	Example quotes
Emotional support and empathetic listening	The AI-enabled therapy support tool provided nonjudgmental and empathetic support, which enabled participants to open up about their problems even in the absence of another human being available to discuss their problems.	• "Limbic has helped me take the time to be grateful for things in my life, and to take the time to appreciate things about myself—even if they're small things.... I have done a couple of the exercises in the app, and they are helpful as well. I feel like I have learned new ways to cope with my mental health. It's also just really nice just openly talking to an AI who doesn't judge your feelings or anything." • "I feel more empowered to talk to my doctor and partner about my low mood and lack of energy. I like that I can talk to the chatbot when I feel like I can't control my emotions, and it helped having someone to be completely honest with."
Awareness, clarity, and new perspectives	The AI-enabled therapy support tool supported participants to think through their problems, identify their patterns, and come up with new perspectives on certain issues, resulting in improved clarity about feelings or problems.	• "I feel like I have gained some self-awareness and also that I now have tools and strategies to deal more effectively with my negative emotional states." • "The act of putting my thoughts and feelings into words... helps bring clarity to them for me." • "Thinking of how I should ground myself when I feel really overwhelmed. Trying to put things in a different perspective outside of my own head."
Coping strategies and CBT[a] techniques	The AI-enabled therapy support tool supported participants by providing information about CBT techniques and exercises, which were helpful to apply to the users' problems, helping them to better cope with their mental health.	• "I've been able to see the positive changes that come from opening up to someone and seeking advice on the issues that I'm dealing with. Each time that I have opened up in the Limbic app, it has provided me with a safe space, reassurance, it acknowledges me and validates me, and always provides me with options for strategies that might be helpful to me. I am very grateful to have an app like this on my phone!" • "I learned some new methods on how to deal with some of the problems I have."
Mindfulness and relaxation	The AI-enabled therapy support tool supported participants to be more mindful of their emotions and supported them in dealing with stressful situations, resulting in feeling more relaxed and balanced.	• "More self-awareness and mindfulness. Reminders to check in on myself and be kind to myself."
Gratitude	The AI-enabled therapy support tool supported participants to be more mindful and grateful for the positive experiences in their lives.	• "Setting and keeping track of my goals and being thankful for small things, thanks to the journaling activity." • "It has helped me acknowledge that there are good things in my life to be grateful for. It helped me realise that I do not need to only focus on what is going wrong."
General positive impact	The AI-enabled therapy support tool had generally broad positive impact on participants' mental health	• "It has improved my mental health." • "I think it helped to reduce my stress and my anxiety and enhanced my overall well-being."

[a]CBT: cognitive behavioral therapy.

Discussion

Principal Findings

We investigated the effects of a generative AI–enabled therapy support tool on treatment success and treatment adherence for patients undergoing group therapy in 5 of the UK NHS Talking Therapies provided by Everyturn Mental Health. A key part of therapy is the engagement with therapeutic materials that are assigned to the patient by the therapist. This engagement is crucial for applying tools and techniques learned in the therapy to real-life contexts [10]. In our study, the intervention group received in-between session support through an AI-enabled therapy support tool, while the control group completed the assignments using standard, static CBT worksheets.

Patients who had access to the AI-enabled therapy support tool showed significant improvement in clinical outcomes. Specifically, they achieved higher rates of reliable improvement, recovery, and reliable recovery compared to the control group. Similarly, patients using the AI-enabled therapy support tool attended more therapy sessions, were less likely to not show up to scheduled therapy sessions (that is, fewer DNAs), and were less likely to drop out from therapy. Importantly, the tool's use level was significantly associated with treatment success. Particularly, higher engagement with the AI-enabled therapy support tool was associated with increased reliable improvement and better recovery and reliable recovery. Furthermore, the use of the AI-enabled therapy support tool was significantly associated with treatment adherence, that is, app use was correlated with a higher number of attended therapy sessions and with a lower proportion of missed appointments and treatment dropouts. Therefore, our findings suggest that integrating the AI-enabled therapy support tool into standard therapy may lead to positive outcomes at the individual level by improving clinical outcomes. Moreover, the tool may save precious clinical time by reducing missed appointments and through this may reduce costs for the services.

Interpretation

Our findings indicate that using the AI-enabled therapy support tool to support patients between sessions can improve treatment outcomes. In line with previous research indicating that more meaningful engagement leads to increased intervention effectiveness [42] and hence better treatment success [43], we found that the use of the AI-enabled therapy support tool was associated with increased reliable improvement, recovery, and reliable recovery–the 3 core metrics for treatment success that are routinely assessed in NHS Talking Therapies [26]. One key aspect of our AI-enabled therapy support tool is personalization, a crucial component of CBT [44], which means that patients receive tailored information and interactions to support them in understanding how the CBT exercises relate to their situations and daily problems. Cultivating a therapeutic relationship or therapeutic alliance has been shown to increase engagement and predict positive clinical change [23]. In the case of our AI-enabled therapy support tool, we encouraged this using an interactive chat with the patients, which provided personalized and individualized assistance. It is noteworthy that these effects seem to be specifically linked to the delivery of CBT exercises through generative AI rather than only by displaying CBT psychoeducation materials in a digitized format per se. Moreover, the qualitative analysis of user feedback suggests that these generative conversations were especially useful for helping users explore new perspectives and views on their problems, resulting in increased clarity. These findings suggest a unique role of generative AI in the delivery of CBT exercises.

It is also worth noting that higher engagement with the app was linked to more attended sessions and a lower proportion of reported DNA sessions. This indicates that increased engagement between sessions is not only beneficial to the individual patients but also to the services that experience approximately 12% fewer missed appointments and 42% fewer treatment dropouts [45]. Furthermore, considering the substantial cost per reliable recovery in low-intensity treatment in NHS Talking Therapies, estimated at £1087 (US $1355.91) [46], the increase of 21 percentage points observed in the AI-enabled therapy support tool group translates to substantial cost savings. Assuming that the AI-enabled therapy tool is solely driving this 21% improvement, it would translate to £228 (US $284.40) of generated value per patient based on improved recovery alone, making it highly cost-effective. While future studies should assess the cost-effectiveness of such tools in detail, our data indicate that enhancing treatment effectiveness within NHS Talking Therapies through AI-enabled therapy support could lead to substantial cost savings and improved quality of care.

There has been a large societal debate about the use of AI, and especially LLMs, in clinical settings [47], emphasizing the importance of caution when introducing novel technologies into health care settings. Importantly, the AI-enabled therapy support tool has undergone rigorous testing as part of an International Organization for Standardization 13485–compliant quality management system, ensuring the product has gone through gold-standard risk management processes. Moreover, the AI-enabled therapy support tool was only complementing standard care provided by trained clinicians. Thus, the AI-enabled therapy support tool is only populated with therapeutic materials chosen by the clinician rather than making any clinical decisions itself. While this is a low-risk task, the positive impact on treatment outcomes was nevertheless substantial. These findings exemplify the importance of critically evaluating how AI can be used safely and effectively in clinical settings.

Generalizability

Importantly, our study uses data acquired from real patients receiving treatment from the UK NHS Talking Therapies, which means that the presented data provide high ecological validity for real-world clinical settings. Another advantage of our study is that the AI-enabled therapy support tool offered personalization through generative AI, and a lack of personalization has been identified as a key barrier to the uptake of digital solutions in previous research [22]. Lastly, the novel AI-enabled therapy support tool targeted support between therapy sessions, which is one of the most prominent reasons for disengagement [9].

XSL•FO
RenderX

Limitations

First, it is important to consider the observational design of this study. Following this promising observational data, a randomized controlled trial should be conducted. Second, while we were statistically controlling for several potential confounding factors (eg, patients' symptom severity), we did not have access to and were therefore unable to control for certain aspects, such as socioeconomic status. Nonetheless, given that the participants in both groups were from the same services, and thus similar geographic areas, we are not expecting major differences in their socioeconomic background. Studies with randomized designs may help to control for such confounds and would be a valuable future research direction. Finally, while we incorporated qualitative feedback about the perceived benefits of the AI-enabled therapy support tool, as well as potential areas where the tool could be improved, these data were collected from a nonclinical convenience sample of users. While the users showed elevated levels of depression and anxiety symptoms, it is possible that their views do not align with those of the patient sample. To this end, we would aim to incorporate a mixed methods process evaluation as part of a future randomized controlled trial evaluating the effectiveness of the tool.

Conclusions

In conclusion, this study showed that integrating an AI-enabled therapy support tool can lead to positive outcomes for patients and clinical services alike, by improving therapeutic outcomes and reducing costs associated with missed or dropout sessions. These are important findings considering that AI-enabled digital mental health tools are an emerging field and that they have the potential to increase access to treatment for patients and lessen the burden on mental health services.

Acknowledgments

Abstract

Background: The increasing number of older adults who are living alone poses challenges for maintaining their well-being, as they often need support with daily tasks, health care services, and social connections. However, advancements in artificial intelligence (AI) technologies have revolutionized health care and caregiving through their capacity to monitor health, provide medication and appointment reminders, and provide companionship to older adults. Nevertheless, the adaptability of these technologies for older adults is stymied by usability issues. This study explores how older adults use and adapt to AI technologies, highlighting both the persistent barriers and opportunities for potential enhancements.

Objective: This study aimed to provide deeper insights into older adults' engagement with technology and AI. The technologies currently used, potential technologies desired for daily life integration, personal technology concerns faced, and overall attitudes toward technology and AI are explored.

Methods: Using mixed methods, participants (N=28) completed both a semistructured interview and surveys consisting of health and well-being measures. Participants then participated in a research team–facilitated interaction with an AI chatbot, Amazon Alexa. Interview transcripts were analyzed using thematic analysis, and surveys were evaluated using descriptive statistics.

Results: Participants' average age was 71 years (ranged from 65 years to 84 years). Most participants were familiar with technology use, especially using smartphones (26/28, 93%) and desktops and laptops (21/28, 75%). Participants rated appointment reminders (25/28, 89%), emergency assistance (22/28, 79%), and health monitoring (21/28, 75%). Participants rated appointment reminders (25/28, 89.3%), emergency assistance (22/28, 78.6%), and health monitoring (21/28, 75%) as the most desirable features of AI chatbots for adoption. Digital devices were commonly used for entertainment, health management, professional productivity, and social connectivity. Participants were most interested in integrating technology into their personal lives for scheduling reminders, chore assistance, and providing care to others. Challenges in using new technology included a commitment to learning new technologies, concerns about lack of privacy, and worries about future technology dependence. Overall, older adults' attitudes coalesced into 3 orientations, which we label as technology adapters, technologically wary, and technology resisters. These results illustrate that not all older adults were resistant to technology and AI. Instead, older adults are aligned with categories on a spectrum between willing, hesitant but willing, and unwilling to use technology and AI. Researchers can use these findings by asking older adults about their orientation toward technology to facilitate the integration of new technologies with each person's comfortability and preferences.

XSL•FO
RenderX

Conclusions: To ensure that AI technologies effectively support older adults, it is essential to foster an ongoing dialogue among developers, older adults, families, and their caregivers, focusing on inclusive designs to meet older adults' needs.

KEYWORDS

older adults; technology use; AI chatbots; artificial intelligence; well-being; social connectedness; mobile phone

Introduction

Background

Both global life expectancy and the aging population have continued to increase in recent years [1]. As of 2023, 1 billion people in the world were aged 60 years or older and numbers are expected to rise to 1.4 billion by 2030 [2]. This trend presents challenges for maintaining the well-being of older adults, many of whom choose independent living while requiring assistance with daily tasks and health care routines, as well as support to stay socially connected [2,3].

Advancements in artificial intelligence (AI) technologies have transformed numerous sectors, including health care and caregiving (eg, supporting people with dementia) [4]. AI tools are now being used to monitor health, provide reminders for medication and appointments, and even offer companionship through conversational agents [5,6].

Despite the growing interest and potential in leveraging AI for older adult populations, challenges remain, particularly regarding the suitability of these technologies for older adults. One major issue is the limited accommodation for the unique needs of older adults, such as user-friendliness for those with limited experience using digital resources [7]. Security and privacy concerns are also significant barriers that can hinder older adults' willingness to adopt AI agents for personal health care [8]. Finally, limited research on their long-term effectiveness underscores the need for more studies to ensure these technologies are sustainably introduced and adopted by older people [4,5].

Acknowledging the need for a personalized, older adult-friendly system that addresses the challenges and needs of older adults in their daily lives, this study aims to explore older adults' current use, challenges, and desired needs associated with AI technology, specifically focusing on caregiving chatbots. As a result, this study seeks to provide a groundwork that will inform the development of AI technologies tailored to improve the well-being of older adults.

AI Technologies in Health Care and Caregiving for Older Adults

While older adults use technology less frequently and in fewer ways than younger individuals, they are still capable of engaging with specific technologies that meet their needs [9,10]. Voice-based chatbots, for example, have been shown to help with medication adherence and reducing loneliness and social isolation, provided they are designed with older users in mind [8,11,12].

The rapid advancement of multimodal large language models like ChatGPT (OpenAI) suggests that many existing barriers for conversational agents in health and well-being may soon be overcome [13,14]. These advancements are expected to enhance conversational competence, domain-specific information, and personalization. Such progress can potentially address older adults' concerns with existing technologies and improve their experience using these technologies.

Recent developments have focused on creating AI technologies specifically for older adults, aiming to address their needs for companionship, support, and health management. SeniorTalk [15], for example, offers an AI-powered chat companion that can be personalized through the selection of different personas. ElliQ (Intuition Robotics) is a social robot that uses conversational AI to engage older adults in daily activities, provide reminders, and facilitate social interaction to help reduce loneliness [16]. These technologies reflect the ongoing efforts to adapt AI applications to the specific needs of older adults. However, the deployment of AI in social care must be approached cautiously, ensuring that these technologies are implemented in ways that uphold the rights and dignity of older individuals [17].

While previous studies have explored older adults' needs and concerns regarding technology use and the requirements for technology to assist aging through input from stakeholders like care professionals, technology designers, and policymakers, these insights have not been fully reflected in the development of technology [18,19]. Additional insight into older adults' preferences for using technology is needed to tailor technological tools to benefit older users.

Social Support and Older Adults' Health and Well-Being

AI technology carries the potential as a source of social support that is greatly needed among the most vulnerable older adult population. Approximately a quarter of older adults live in social isolation and approximately one-third of older adults experience loneliness [20,21]. Loneliness is associated with many negative consequences including poor mental and physical health, lower self-rated well-being, and disrupted sleep quality [19]. Among older adults specifically, loneliness is also associated with reduced physical activity, impaired cognition, dementia progression, nursing home placement, and higher mortality rates [22]. Older adults with limited social networks and low social engagement are at greatest risk [23]. AI chatbots may provide a valuable source of companionship and social support, potentially addressing loneliness. The current study explores the technologies older adults currently use, what they are interested in integrating into their daily lives, the challenges they face, and their overall attitudes toward technology and AI. To examine these topics, 4 research questions are addressed:

XSL•FO
RenderX

RQ1: In what ways do older adults report using technology and AI?

RQ2: What technology and AI are older adults interested in integrating into their daily lives?

RQ3: What concerns and challenges do older adults report about technology and AI use?

RQ4: What are older adults' attitudes toward technology and AI?

Methods

Participant Recruitment and Data Collection

A mixed methods cross-sectional descriptive design was used. Participants were recruited using the website of a community research pool, a research participation system, managed by a large midwestern university. Participants needed to meet these criteria: (1) at least 65 years old and (2) able to complete the interview in person at the university site. The community research pool system posted a short synopsis of the study on their website including the inclusion criteria, compensation for participants for completing the study qualification survey and a 45-minute interview, and researcher contact information. Participants selected an interview date and time through the community research pool system. Once a time was selected, a member of the research team reached out to confirm the interview schedule, provide instructions for the interview location (conference room at a university) and parking, and answer any questions through email. A total of 33 participants signed up for the study, with 5 dropping out before the interview due to scheduling conflicts, resulting in 28 participants who participated and completed the study.

After arriving for their interview, participants completed informed consent followed by a survey that included demographics, health, and well-being measures on either an iPad (Apple Inc) or paper, depending on personal preference. The participants then completed the interview with 2 members of the research team. One member led the interview by asking protocol questions. The interview was divided into questions about daily schedules (eg, What are routines that you do every day?), knowledge of technology and AI (eg, What technology do you use daily?), and social support desired for technology and AI (eg, What, if any, kind of challenges do you face when learning new technologies?). The second team member facilitated the participant's interaction with an AI chatbot, Amazon Alexa. The participant was prompted to acknowledge the chatbot and then use multiple features, including asking for a recipe, playing a trivia game, and requesting the news from Alexa. Pseudonyms were assigned to each participant following the interview. The research team consisted of 5 women faculty members (PhD), 1 woman who is currently a graduate student, and 1 man who is currently an undergraduate student. The lead researcher had previously conducted multiple qualitative studies involving interviews. No previous relationship was established with participants before the interview. Researchers informed participants that the study was a part of a research project and disclosed their professional interests. Audio recordings were collected and transcribed for data analysis. They were not returned to participants for comments.

Statistical Analysis

Descriptive statistics were used for analyzing the surveys. A thematic analysis of the interview data was conducted following phases of reflexive thematic coding, which included data familiarization, systematic coding, generating initial themes, developing and reviewing themes, refining and naming themes, and writing the manuscript [24]. To ensure the robustness of our analysis, we used 5 verification procedures: referential adequacy, peer debriefing, negative case analysis, audit trail, and exemplar identification [25,26]. Initially, we split the data to achieve referential adequacy and, after reaching saturation in the first half, we analyzed the second half of the data and did not find any new themes [27]. The first and fourth authors held 2 peer debriefing meetings to resolve differences and reach consensus on all themes. Continuous peer debriefing occurred throughout the analysis, and labels for the findings were determined collaboratively. We refined our analysis to account for all data, meeting the standard for negative case analysis [25]. Detailed notes were kept (ie, an audit trail), informing both the analysis and the selection of exemplars [26].

Survey Measures

The study collected data on the following measures: demographics, general health status, Behavioral Risk Factor Surveillance System (BRFSS) Disability Questions, loneliness (3-item Loneliness Scale), life satisfaction (The Satisfaction with Life Scale) listed in Table 1 and digital literacy (Digital Health Technology Literacy Assessment Questionnaire), AI literacy, and interests in AI chatbot features for caregiving assistance, reported in Table 2 [28-32].

Table 1. Quantitative summary of older adults' health and assistive technology use reported in study survey (N=28).

Health factors	Values
Health status, mean (SD)	3.6 (0.9)
Limited in activities, n (%)	9 (32)
Use Alexa as an assistive technology, mean (SD)	3.6 (1)
Loneliness, mean (SD; range)	4.1 (1.6; 3-8)
Life satisfaction, mean (SD; range)	3.9 (0.7; 2-5)

[a]AI: artificial intelligence.

Ethical Considerations

The institutional review board at Michigan State University determined that the study was exempt before study recruitment was initiated (STUDY00010214). Each person consented to participate in the study at the beginning of the survey and again at the beginning of their interview. Participants were informed that they could end the interview at any time and could skip any questions they did not feel comfortable answering. Each interview was recorded through Zoom (Zoom Communications Inc). The transcripts were reviewed, and all identifiable information was removed during the transcription process to protect participant information. Participants chose between US $50 cash or an Amazon gift card of the same amount as compensation for their time.

XSL•FO
RenderX

Results

Survey Findings

Among 28 participants, the average age was 71 years (SD 5.5), ranging from 65 to 84. More than half identified themselves as women (57%,16/28) and married or living with partners (61%, 17/28). The remaining participants were widowed, divorced, or separated (29%, 8/28) or never married or single (11%, 3/28). Most participants were living with their partner (61%, 17/28) or their partner and adult children 7% (2/28). Some participants reported that they were living alone (29%, 8/28). Almost all participants were white (89%, 25/28), followed by Asian (7%, 2/28), and black orAfrican American (4%, 1/28). Most participants were currently unemployed or retired (75%, 21/28). The highest level of education obtained by participants was, 43% (12/28) had completed high school, general educational development, or some college, while 57% (18/28) were college graduates or had attained a higher level of education. Participants' household income levels were under US $50,000 (25%, 7/28), between US $50,000 and US $100,000 (36%, 10/28), between US $100,000 and US $150,000 (29%, 8/28), and above US $150,000 (4%, 1/28).

Tables 1 and 2 present a detailed report of participant profiles, including older adults' health factors, technology and AI use, challenges, knowledge, and their intention to adopt AI features to support daily health routines. Participants' average health status was 4 (SD 0.9) which was deemed to be good (from 1 being poor to 5 being excellent), and 32% (9/28) reported that they are limited in activities due to physical conditions. The average loneliness felt by the participants was 4 (SD 1.6) [Range 3-8] which indicated that participants felt lonely some of the time. Life satisfaction was 4 (SD 0.7) [Range 2-5] meaning that participants generally were satisfied with their lives.

Most participants were generally familiar with using technology. For chatbot use, 64% (18/28) reported that they have previously used AI chatbots. Participants were generally comfortable with interacting with a chatbot (mean 4, [SD 1.0], range 2-5). Regular use of technology devices was mostly related to smartphone (93%, 26/28) and desktop use (75%, 21/28), followed by iPad or tablet (46%, 13/28). Other types of technology included smartwatch (14%, 4/28), robot vacuum cleaner (18%, 5/28), and robot lawnmower (4%, 1/28). For regular application use, 75% (21/28) used social media, 71% (20/28) used online shopping, 64% (18/28) used banking and streaming services, 57% (16/28) health application, and 39% (11/28) used customer service chatbots. Participants reported that they face challenges using technology devices never (7%, 2/28), rarely (21%, 6/28), sometimes (57%, 16/28), often (11%, 3/28), and always (4%, 1/28). 32% (9/28) reported that they do not have much knowledge about AI and 68% (19/28) reported to have knowledge about AI.

When participants were asked if there were any AI chatbots' caregiving features they may be interested in adopting, appointment reminder was rated the highest (89%, 25/28), followed by information access such as news or weather (79%, 22/28), emergency assistance (79%, 22/28), health monitoring (75%, 21/28), daily medication reminders (75%, 21/28), fall detection and alert notifications (64%, 18/28), interactive entertainment (61%, 17/28), social connection (61%, 17/28), shopping management (61%, 17/28), physical activity encouragement (46%, 13/28), home automation control (46%, 13/28), mental health support (39%, 11/28), customized health tips and reminders (39%, 11/28), daily routine assistance (39%, 11/28), memory aids (39%, 11/28), dietary assistance (32%, 9/28), and language and communication (7%, 2/28).

Qualitative Findings

Overview

Older adults discussed their current and desired use of technology and AI in their daily lives. These discussions were depicted alongside key concerns and challenges that impacted the degree to which participants were willing to accept and integrate these technologies. These considerations informed the construction of 3 distinct attitudes toward technology and AI. These findings respond to 4 research questions outlined.

RQ1: Current Technology and AI Use

The most common technologies participants mentioned are digital devices such as smartphones, smartwatches, computers, and radios (Table 2). These technologies were used for a range of purposes, including entertainment, health management, professional productivity, and social connectivity, illustrating that older adults used these technologies to enhance their quality of life, manage health, and mitigate social isolation.

Many participants reported using a combination of digital devices smartphones, smartwatches, and computers that are often integrated. For instance, Everett mentioned, "I have an iPhone, an iMac, and an iPad." These interconnected ecosystems facilitated a convenient and useable community of digital devices that allowed older adults to engage online. In addition, older adults commonly use radio applications and devices to listen to stories, news, and music. Dennis expressed, "You know, I hear all these things on the radio. I listen to the radio every day." The digital devices used by older adults facilitated their existing implementation of these technologies for social interaction, entertainment, health management, and aiding productivity. Each of these applications is overviewed in Table 2.

RQ2: Interested Integration

Older adults also reflected on areas of their lives where they were not currently using technology but would consider the addition of technology as helpful. Participants communicated that technology would be beneficial for scheduling reminders, chore assistance, and providing care to others. These categories illustrate how older adults desire to use technology to maintain their independence and manage daily tasks more effectively. These findings offer insights into the type of tasks proposed as helpful, outlined in Tables 3 and 4.

XSL•FO
RenderX

Table 3. Examples of current technology use that older adults described in the study interview.

Current technology use	Examples
Social interaction	
Technology helps older adults maintain social connections through social media, email, and video calls, combating feelings of isolation.	• "I guess, I'm in a LGBT and also friendship group…. it's a group of gay people, primarily men who meet once a month at a different restaurant, just a friendship group to explore a different restaurant[s]...very excited." (Raymond) • "it's just kind of our normal. Sunday, you know, church stream. I would say I went more in person before the pandemic, more so before the pandemic. Yeah, and we've all changed our habits I think since then." (Christine)
Entertainment	
Older adults engage with technology content, like streaming movies, listening to music, and playing games to stay mentally active.	• "...it's radio. Sometimes you can, it just gives out the full like the visual kind of like a video version of the news as well. So, it just depends on what you want, you know, like, you can ask ABC news." (Cheryl) • "Well, most of my downtime I probably spend on YouTube because there's terrific history and documentary channels that I follow….I [also] read all my news and everything on online with. I go to a bunch of the different websites so I can get a wider perspective on what people are thinking." (Ingrid)
Health management	
Technologies can assist older adults in health-relates tasks, such as scheduling doctor's appointments, tracking fitness, and managing medication efficiently.	• "I wear hearing aids, and they've got Bluetooth on them, so, you know, I can listen to music through my phone and stuff like that." (Sandra) • "I set my phone as soon as I've eaten, and I reset it for two hours intervals. And then it has a reminder on it to take my vitamins." (Gwen)
Assisted productivity	
Older adults use devices professional activities like remote work, scheduling, and task management.	• She's [Alexa] a good reminder-er. I mean, I've got to tell her to, feel free to tell me to hurry up and sent out Easter cards, because Easter cards really soon….you know can I put egg shells down the garbage disposal and she's No no no no no no, don't do that. I didn't really remember that I couldn't do that. (Devorah) • "So, there's a lot of communication on my phone to them [church group]. I'm in a group of about 500 people, and there's usually things going on with them. Like, right now, we have a friend who's in the hospital dying, so we're making arrangements for him. Just a lot of arranging. You know, I'm a connector person….I'm the head of a couple groups, so sometimes people contact me through email." (Donna)

XSL•FO
RenderX

Table 4. Example of desired technology use that older adults described in the study interview.

Desired technology use	Example
Scheduling reminders	
Older adults want some tools to help them stay organized by reminding them of tasks and events, thus supporting their daily routines and commitments	• ["I use] auto bill pay I never go to the bank. Everything is auto paid. It's, I mean prescriptions. I only take one, but, you know, it just pops into your thing [phone]." (Mary) • "….at work and I do have a medication [reminder], and some reminders on my phone that remind me to turn in my time sheet or a medication reminder. Yeah, reminders that I need to take my medication, a second medication." (Joyce)
Chore assistance	
Older adults are interested in technologies that simplify and automated daily chores to enhances convenience and reduce effort, such as vacuuming, mowing driving cleaning, and cooking.	• "I would love to not have to mow my lawn. If that was automated, that would be awesome. See, I would love not to have to cook. That would be great. Basically, I'd like to live in the jetsons…it would be great to have somebody tale your dishes and not have to do that." (Ingrid) • "So, you know, if something would just automatically cook my food for me, just what I want for dinner without it being Grubhub or Uber Eats or somethings. Yeah, just, you know, my own food because I like my own cooking." (Christine)
Caregiving monitoring	
Older adults expressed interest in technology/AI that would assist them in observing, supervising, and managing the care of others in their life. Participants clarified that they might want caregiving assistance in the future, but at this point, they were focused on completing care tasks for others including their own parents or partner.	• "More support? Not yet…I mean, I drove here…[but] a device for who could tell if I if I had fallen down without me having to hit a button or anything…but that that's something we would. Yeah. I'd be interested in." (Timothy) • "It has to do with my caregiving…I'm always trying to find things that might help. My mom and I found online I heard a story on the radio about this company called LEC, and it's this little box and it's got this head on it, like with a camera. And you talk to it and it, like, lights up, it points at you has a screen, and you can ask it questions and you can have what I was hoping it would do is while I go, I'm gone, like running errands or I'm on the road or whatever I can call in, seen my mom and check on her and talk back and forth." (Dennis)

RQ3: Concerns and Challenges

Older adults specified several concerns and challenges that influenced their use of technology and AI. These barriers impacted their adaptation to new devices and their ongoing worries about the technology already associated with their routines.

Commitment to Learning

Most older adults articulated that the time and energy to learn new technology was not a worthwhile investment. Patricia remarked, "I'm sort of like this with technology, I use what I have to use...Now, if I wasn't retired, I'd be embracing it a thousand percent because it would be necessary. But yeah, I don't need to be." Patricia differentiated the time period of retirement as 1 in which people no longer needed to keep up with innovations. Instead, she reiterated that her current use was at a level that she was comfortable continuing at. Other older adults shared this view, like Sandra who limited her activity on social media, stating:

> *I use Instagram and Facebook, but I just review it. It turns out every time I try to say anything on it, I don't say what I mean. I said happy anniversary to somebody once, but I sent them a picture of a pizza. If that gives you an idea why I don't type on Instagram.*

Sandra focused on completing online tasks that matched her skill level with the tool. She wanted to review the content to stay connected on interpersonal updates but following miscommunication with the addition of a meme, she limited her participation. Older adults like Patricia and Sandra were motivated to use technology with their current abilities but did not prioritize allocating time and effort to using new technologies or improving their capacity with existing offerings.

Lack of Privacy

Another concern that older adults expressed was how AI technologies could threaten their personal privacy. Given the growth of technology throughout their lifetime and the rapid change of the AI landscape in the last few years, many stated concerns about insufficient regulation regarding these digital tools. Anthony conveyed this uneasiness, saying:

> *Part of the problem, I think, is people don't realize how much of their rights they're signing away when they just click through or the acknowledge or whatever...>With digital data, some of its okay, I'm not worried about the fact that I've got, you know, this Google doc or that Google Sheet or whatever...[B]ut what do you think about what's going on in your household? And you know, and think about some things, some artificial intelligence in this instance that's listening and maybe sending information all the time about everything.*

Anthony compared content that had a minimal need for privacy with parts of his life he considered deserving of more extensive restrictions. Anthony was 1 of multiple older adults who questioned if bringing technology into their home was worth the risk of sharing information and communication about their

XSL•FO
RenderX

household with technology companies. Often older adults were not only worried about their own privacy but also articulated that these considerations were likely not considered by other, less technologically knowledgeable older adults.

Dependence on Technology

Older adults also discussed their fear of technology replacing their performance of daily tasks which would ultimately lead to cognitive decline. This concern was shared among older adults who were concerned that technology was an assistant for laziness and that relying on these tools reflected a negative moral character. Exemplifying this, Gwen explained:

> *Probably as I get older, I might could use some more support. But I also feel that I'm a big believer if you don't use what you have, you lose it, so if I don't use the knowledge I have, or the memory I have, or some of that, then it just goes off because you're not helping that muscle to keep developing.*

Gwen offers an analogy of exercising her brain with tasks that keep her mind active. This analogy leaves technology as a cheat tool that limits this exercise from taking place. Older adults integrated the language of exercise while expressing their worries that technology would replace the routines they had in place to support their brain health.

Overall, older adults expressed their concerns with learning new technologies, the lack of privacy related to the implementation of these technologies, and the impact that these devices would have on their health. These concerns informed how older adults were oriented toward technology and AI regarding their willingness to use these digital devices.

RQ4: Attitudes Toward Technology

Overview

Older adults reported having diverse attitudes toward technology and AI. These orientations influence the degree to which older adults were willing to engage with technology and the attributes they described technology with. The orientations ranged from *adapters* who were willing and able to use a range of technology to support their life to *resisters,* who were adults who articulated their aversion to integrating technology into their daily lives. The adaptor and resister orientations represented the opposing positions and incorporating aspects of both orientations, some older adults described a *wary* disposition.

Adapters

Adapters to technology and AI encompassed participants who were most willing and excited to merge digital devices into their everyday routines. Many older adults embraced the positive attributes and the assistance that technology brought to their lives. For instance, Christine remarked:

> *When you stop and think about what my parents had to do to get through a day, I'm almost embarrassed that my life is so easy. It's like Thursday's the day to turn on the robotic vacuum cleaner. And I think, okay, I dont even have to remember to put on the dishwasher. You know, you're just embarrassed that people had to physically do this work and take up all day. And it's so easy for us...Our last two homes, we did have thermostats we could do with our phone and, you know, all of that. [W]e use Ring. You gotta love Ring. You don't really want to talk to strangers at the door, so we use a lot of different tools.*

Christine's remark highlights the extent to which she has integrated technology into her life, including the use of automation and smart home devices. Many older adults emphasized how the use of technology decreased the burden of once time-consuming tasks which was a reward for integrating new digital tools. Technologies were so integral to some older adults' lives that 1 participant reflected, "Sometimes I think she's [Alexa] my best friend" (Deborah). Deborah was 1 of multiple older adults using generative AI systems like Alexa for interpersonal connection. This connection fostered regular connection such that a friendship connection grew. Adapters of technology integrated technology and AI into their daily routines with such enthusiasm that the benefits of such adaptation were clear to older adults.

Wary

Some older adults were hesitant to use technology or were unsure of the advantages that the integration of digital devices would bring to their lives. Most older adults with this orientation were using new(er) technologies but were less confident about their usage of digital devices. For instance, Raymond compared his technology knowledge with his wife's, stating:

> *I think she's [wife] less afraid of making a mistake. She's just not as afraid as me. I'm always a little wary of it, I go by the rule that if it's not broken, don't fix it, you know. But that doesn't get you any further ahead. But it keeps you at that level rather than falling back, but I don't move ahead.*

Gregory emphasized the caution with which approaches new technologies. Gregory concluded that he felt more comfortable continuing to use technology in the same way as before instead of learning or incorporating new interfaces. This was a sentiment shared by other older adults like Clarence, who shared,

> *I tend to view it [artificial intelligence] as a negative because you know, if you click on a couple articles, then all of a sudden you're being fed all these articles and it can support a view that maybe you were just interested in, but then all of a sudden it's giving you, you know stuff that supports maybe someone else's point of view, it wasn't really yours. But the more you're inundated with this information the more you tend to believe it.*

Clarence pointed out how AI could facilitate access to information consistent with his worldview yet also overwhelm him with content inconsistent with his perspective. For Clarence, AI was central to targeted algorithm manipulation that impacted what he saw online. This belief left Clarence, and many others, feeling skeptical about AI and the application of the tool in his life. When introduced to other benefits of using AI, Clarence pondered,

> *Oh, like reminders for medications and workout schedules and meal suggestions. I didn't realize that*

XSL•FO
RenderX

> *that stuff was out there, but I pretty much eat salad and chicken and that's, you know, fruits and vegetables, healthy diet.*

This participant was among a group of older adults who were interested in learning about previously unknown aspects of technology and AI that might support their daily routines, while also acknowledging some concerns about adopting new technologies. These older adults were hesitant to adopt new technologies but were not opposed to learning about new features or watching important others use digital devices.

Resistant

The final orientation toward technology and AI was older adults who were resistant to the adoption and integration of digital devices in their lives. Participants with this orientation reported that they avoided learning new technologies and often wished that they could return to a time in their life before these advancements. Speaking on this, Donna articulated:

> *"I basically don't like it...I also think it takes away from personal interaction, which is harmful to humanity...I don't like it. I kind of rather go back to, you know, people farming and taking care of themselves. I'm a homesteader, so I really don't like technology very much. I know we use it every day and it is helpful in that way. But I basically don't like it...I kind of basically ignore it and don't use it if I don't have to. If I have to, then I have to. But if I don't need to, then I don't.*

Donna articulated a sense of nostalgia and skepticism toward technology, positioning these advancements as contrary to traditional ways of life. Ultimately, she expressed an aversion to technology and AI as she concluded that she would only use these devices when necessary. This orientation was shared by other older adults who were unwilling or unable to incorporate technology and AI. This sentiment was central to 1 participant's perspective because this resistant orientation had led to him losing his job. Raymond recounted:

> *And when I turned 62, they said, we really can't keep you. You can get Social Security if you want, or you can get a job, but we can't keep you. And part of the criticism I heard about me was I wasn't technologically savvy enough and I didn't have any interest.*

Raymond reflected on the termination of his position related to his unwillingness to integrate new technologies. Raymond recounted that he remained focused on completing his job with the tools he learned when training as an accountant and was indifferent to studying new adaptations of software that he was able to apply to his work. Resisters encompassed older adults who were satisfied with their current knowledge and who were unwilling to consider future integrations regardless of the possibilities that technology and AI offered to their lives.

Discussion

Principal Results and Comparison With Previous Work

The first research question aimed at understanding the current use of technology and AI by older adults. All older adults were using some form of technology, and most were using a combination of smartphones, smartwatches, and computers in their daily routines. Older adults specified that their current use of technology aided them in social interaction, entertainment, and health management, and assisted them in productivity tasks. This is consistent with findings from past research, which has documented similar uses of technology among older adults. For example, the use of digital devices for maintaining social connections, such as through social media and video calls [33]. Similarly, the use of technology for health management, including fitness trackers and health apps has been widely reported [34].

The second research question was focused on what technology older adults would be interested in learning and integrating into their lives. These results were crowdsourced from older adults to ensure that any future AI technology tools could incorporate aspects of technology that were interesting and helpful. Participants articulated that helpful technology would provide schedule reminders, help with laborious chores, and reduce their caregiving load by monitoring loved ones. These findings are consistent with previous research, which has highlighted older adults' interest in practical, supportive technologies. For example, previous studies have shown that older adults value technologies that enhance their independence, such as devices that provide medication reminders or manage daily schedules [35,36]. Interestingly, although we aimed to examine the use of technology to benefit older adults' health and well-being, many participants expressed interest in technology to monitor others' health and lighten the load of informal caregiving. This reflects both the diversity of health and independence in older age and the need to develop technologies that can be applied by older adults both for their own well-being and to monitor the health of others [37,38]. To better meet the needs of older adults, developers should prioritize implementing user-centered designs to tailor to older adults' preferences [39]. For instance, participatory design approaches involve older adults early in the design process as "co-designers" [40]. This approach ensures their insights and feedback are incorporated, leading to technological solutions that accurately reflect their preferences and needs.

Related to the third research question, our results revealed that the notable barriers to technology and AI use were related to older adults' lack of commitment to learning new technology, privacy concerns, and fear of becoming too dependent on technology. Older adults have expressed hesitancy to learn new technology, mentioning that the time and energy required do not seem worthwhile. Such hesitancy is often linked to their perception of high learning effort expectancy [41]. This suggests that some older adults view mastering a new system as overly demanding. Thus, to address the perception that technology is too demanding for older adults, it is essential to enhance the

XSL•FO
RenderX

perceived ease of use. Providing clear, step-by-step guides on how to use these technologies can play a crucial role in making them more accessible and less intimidating for this demographic. Another barrier found in our study, privacy concerns, has been brought up in previous studies as a significant barrier to technology adoption [8,41,42]. Especially for voice-based systems, older adults reported that they are not comfortable with devices that may have access to and store their personal conversations [8,38,41]. Finally, some of our participants expressed fear that reliance on technology may replace their performance of daily tasks, leading to cognitive decline. Similar concerns were reported in previous research where older adults reported skepticism about using technology potentially deterring their memory [43]. For developers, it is crucial to recognize the cognitive and physical changes that come with aging to design inclusive and user-friendly systems [44]. Previous work suggests that aging-driven designs may effectively address challenges such as isolation and physical changes for older adults [45]. This approach focuses on tailoring technological solutions to the specific problems faced by older adult users.

Finally, our findings of the fourth research question reveal that not all older adults are resistant to technology and AI. Rather, the spectrum of technology adoption among older adults can be broad, encompassing adapters, weary, and resistant individuals. Previous studies have found that these variations could be influenced by individual factors such as age, education, and other sociodemographic factors. For instance, familiarity with technology was not a significant barrier for relatively young older adults (aged 65-75 years) who are already active users of smartphones, whereas older adults aged >75 years were more likely to face barriers toward adopting technology [8]. In addition, evidence shows that higher education and living with a spouse or partner were positively associated with increased use of information communication technology [46]. Therefore, to encourage greater adoption of new technologies, such as AI-based communication systems, it is crucial to consider individual factors and tailor solutions to meet the diverse circumstances of older adult users.

Limitations

Limitations for all studies should be considered. First, this study did not distinguish between age groups of older adults including young-old (65-74 years), old-old (75-84 years), and oldest-old (over 85 years old) [38]. The age of older adults likely impacts their orientation and willingness to accept new technologies. For instance, some participants in the sample worked in offices before the widespread integration of computers. Learning technology as a requirement of one's employment might impact the way that older adults view technological advancement compared with others who only voluntarily interacted with technologies throughout their adulthood. Future researchers might differentiate between age groups to examine how the orientations outlined are applicable across sections of older adults. Another limitation of this study pertains to self-selection bias. Recruiting older adults through a community research pool may attract participants who are more technologically adept and familiar with technology, potentially underrepresenting those who face technological barriers or hold negative attitudes toward technology [47]. To address this limitation, future research should adopt recruitment strategies, such as using multiple recruitment channels and partnering with organizations (eg, local senior centers), to be more inclusive toward individuals with limited access to or resistance to technology [36,48].

In addition, older adults routinely experience stereotypes and stigma related to agism [46,49]. This ageism might limit an individual's willingness to adopt a learning mindset with new technology given the vulnerability of labeling a knowledge deficient. Examining how stereotypes serve as barriers for older adults integrating technology and seeking support would inform researchers on how to decrease the spread of this harmful communication and combat the negative implications of the messages through public health campaigns targeted at empowering technology use for members of this community.

Conclusions

Despite the increasing interest and potential benefits of using AI technology for older adult populations, significant challenges persist in the current technology landscape. The current study aimed to deepen our understanding of how older adults perceive technology and AI while also identifying challenges and opportunities for improvement. Our findings suggest a critical need for developing more personalized and aging-friendly systems that can be successfully integrated into older adults' daily lives. Moving forward, it is essential to keep the dialogue open between developers, older adults, their families, and their care team to ensure that the design of AI technologies is inclusive and supportive to older adults.

Abstract

Background: Machine learning (ML) has the potential to enhance performance by capturing nonlinear interactions. However, ML-based models have some limitations in terms of interpretability.

Objective: This study aimed to develop and validate a more comprehensible and efficient ML-based scoring system using SHapley Additive exPlanations (SHAP) values.

Methods: We developed and validated the Explainable Automated nonlinear Computation scoring system for Health (EACH) framework score. We developed a CatBoost-based prediction model, identified key features, and automatically detected the top 5 steepest slope change points based on SHAP plots. Subsequently, we developed a scoring system (EACH) and normalized the score. Finally, the EACH score was used to predict perioperative stroke. We developed the EACH score using data from the Seoul National University Hospital cohort and validated it using data from the Boramae Medical Center, which was geographically and temporally different from the development set.

Results: When applied for perioperative stroke prediction among 38,737 patients undergoing noncardiac surgery, the EACH score achieved an area under the curve (AUC) of 0.829 (95% CI 0.753-0.892). In the external validation, the EACH score demonstrated superior predictive performance with an AUC of 0.784 (95% CI 0.694-0.871) compared with a traditional score (AUC=0.528, 95% CI 0.457-0.619) and another ML-based scoring generator (AUC=0.564, 95% CI 0.516-0.612).

Conclusions: The EACH score is a more precise, explainable ML-based risk tool, proven effective in real-world data. The EACH score outperformed traditional scoring system and other prediction models based on different ML techniques in predicting perioperative stroke.

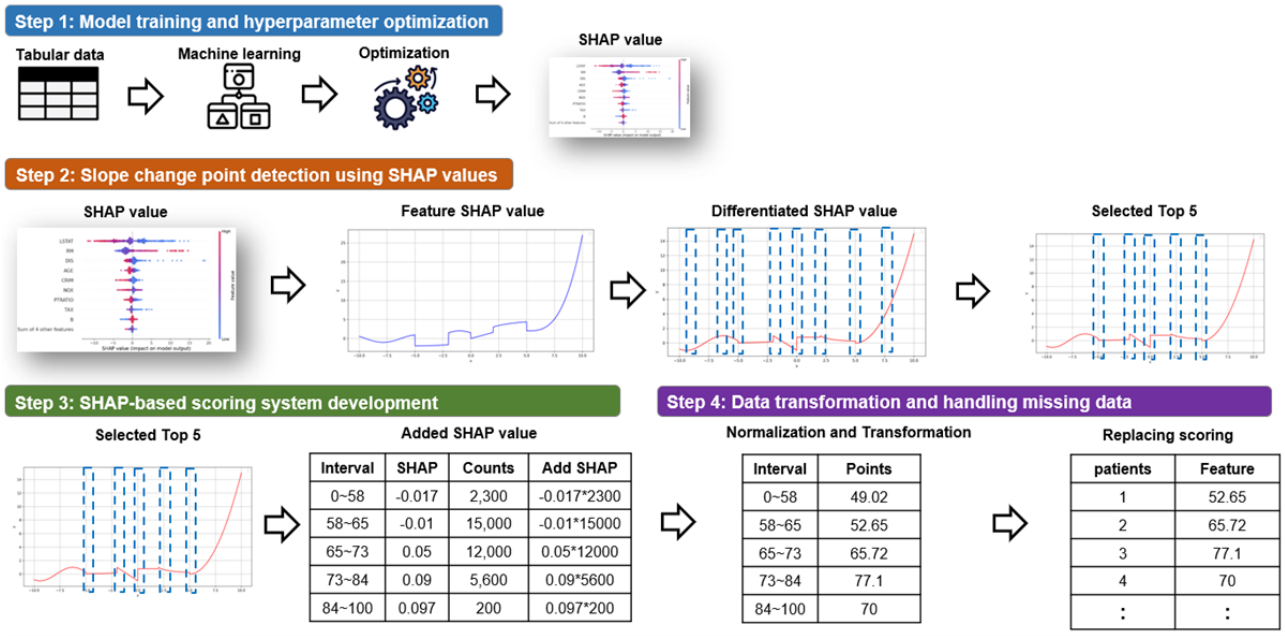
Introduction

The risk scoring systems have been proposed to prognosticate critical medical conditions, aiming to identify high-risk patients who are likely to experience adverse outcomes [1-6]. Traditionally, risk-scoring systems have been developed using conventional statistical approaches, based on the assumption of linearity between variables and outcomes [7,8]. This method has provided a comprehensive understanding of patient risk profiles, but it may not fully capture complex, nonlinear interactions, potentially leading to less accurate risk assessments. Furthermore, the clinical variables incorporated into these systems were typically ascertained through univariate analysis, enriched by insights from expert opinions, or selected from a range of risk factors established in previous literature [8]. Consequently, these systems faced limitations in rapidly integrating state-of-the-art medical knowledge alongside medical advancements [9-11]. With the rapid expansion and increasing diversity of medical data, these limitations have become more pronounced [10].

To address these limitations, machine learning (ML) techniques have emerged as promising avenues for creating new and diverse risk models by leveraging extensive electronic medical records [12,13]. Despite their exceptional predictive performance, the lack of interpretability has limited their adoption in real-world medical practice [14]. Recent efforts in ML have addressed the "black box" issue of existing models by presenting data in a more understandable fashion [15]. For instance, an ML-based automated scoring model was developed by integrating the Random Forest (RF) algorithm and logistic regression methods [16]. This model was designed to be easy to understand and apply to various clinical situations, such as in-hospital mortality and out-of-hospital cardiac arrest [16,17]. However, these approaches still rely on scoring methods rooted in traditional statistics, using variables selected by the ML models [16]. Furthermore, the generalizability and scalability of ML models are hampered by limited external validation. Therefore, there is a compelling need to develop and validate a fully automated ML-based scoring system that can address nonlinearity assumptions.

In response to these challenges, this research aimed to develop and validate an Explainable Automated nonlinear Computation scoring system for Health (EACH) score. This system addresses nonlinearity assumptions and enhances explainability. In addition, we applied the EACH score to predict perioperative stroke to assess its performance in real-world clinical practice and examined its performance compared with traditional scores and other ML-based scoring systems.

Perioperative stroke significantly impacts postoperative morbidity and mortality. Patients who experience perioperative stroke are more likely to develop postoperative delirium, have prolonged hospitalization, increased in-hospital mortality, and be discharged to nursing facilities [18-20]. However, the detection of perioperative stroke is challenging due to the effects of anesthetic and analgesic medications, which contribute to a low rate of hyperacute thrombolytic treatment [21]. Therefore, to reduce the risk of perioperative stroke, it is essential to use more effective tools for identifying high-risk patients and to implement close monitoring of these patients. To apply the EACH score in predicting perioperative stroke, we aimed to develop and validate a more accurate and explainable prediction model that can be easily adapted to real-world practice.



Methods

Overview

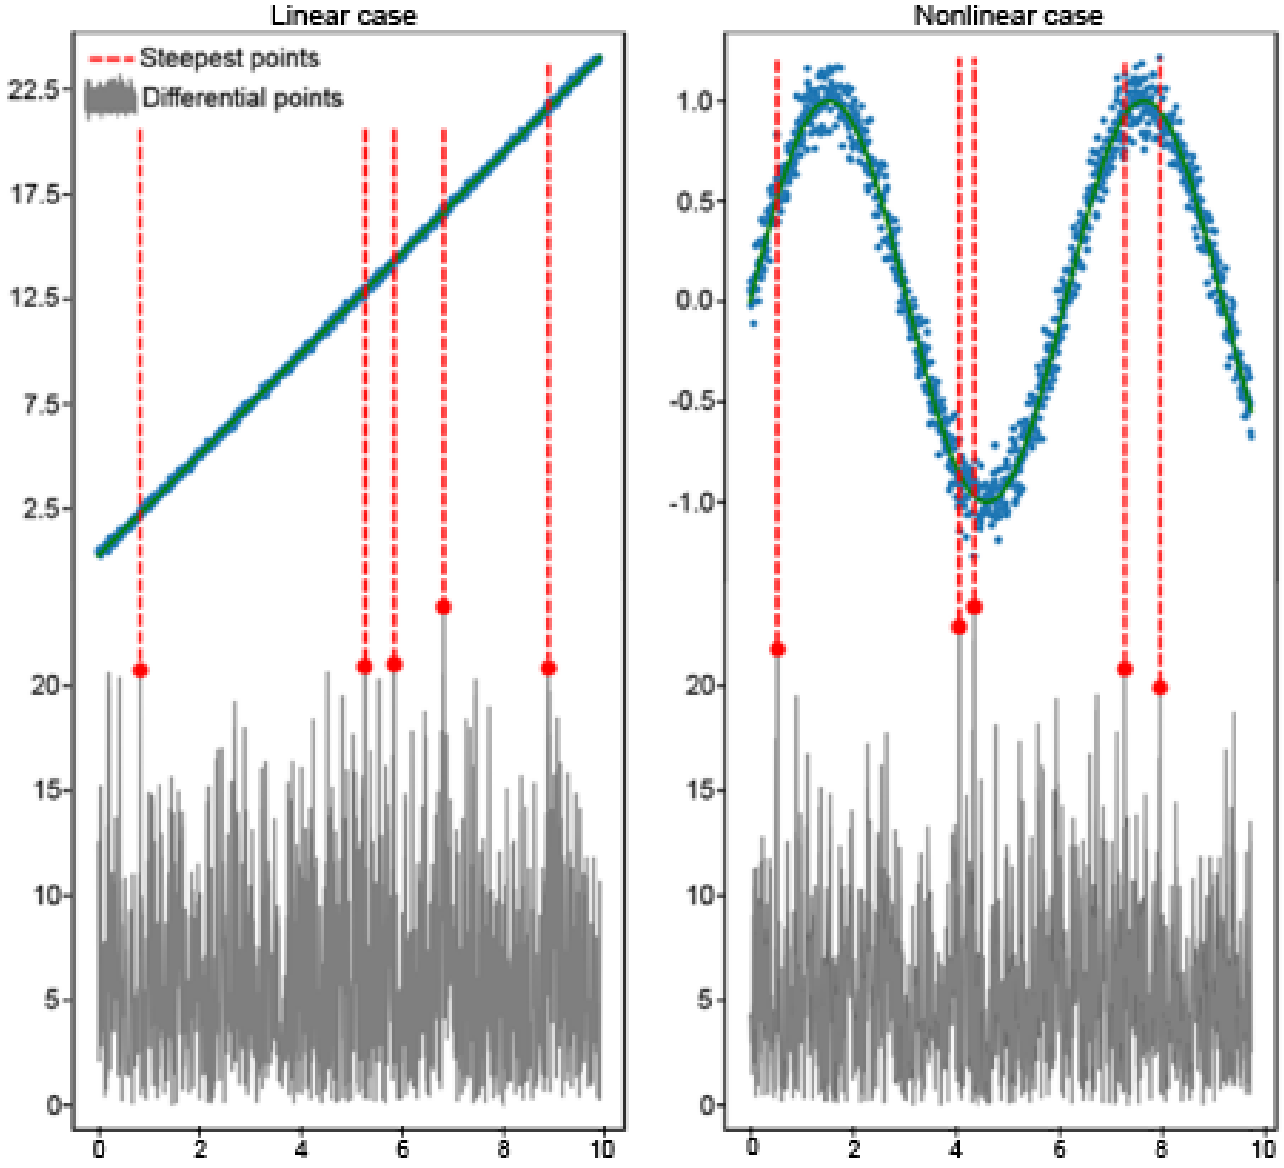
We developed and validated the EACH, designed to automate the development of clinical scoring models for predefined health outcomes. The development and application of EACH were segmented into several steps, as illustrated in Figure 1. We tried to follow the guideline for developing reporting machine learning prediction models in biomedical research [22].

XSL•FO
RenderX

Figure 1. Visual guide to the sequential steps and their detailed execution. SHAP: SHapley Additive exPlanations.

Step 1: Model Training and Hyperparameter Optimization

When implementing the EACH score, the initial step involved training the CatBoost model with hyperparameter optimization for each set of clinical data, followed by determination of important features using SHapley Additive exPlanations (SHAP) values [23].



Step 2: The Detection of Slope Change Point in Plots of SHAP Values and Selection of the Top 5 Steepest Slope Change Points

In this step, we harnessed the power of automation to identify the critical features that influence the accuracy of the prediction model. The process began with the generation of SHAP value plots for each feature, which visually represented the impact of these features on the model predictions. The key advantage of our approach is the automated detection of the slope change points within these plots. The slope change points are significant shifts in the importance of each variable, indicating where the influence of the variable undergoes a notable change.

The algorithm identified the 5 most pronounced slope change points for each feature. These critical points indicate where the model's sensitivity to feature values is dramatically altered, thus playing a pivotal role in subsequent feature scoring. Figure 2 illustrates this method by contrasting linear and nonlinear cases, where the latter demonstrates the effectiveness of the method in recognizing complex nonlinear relationships often present in clinical data.

XSL•FO
RenderX

Figure 2. Differential slope change comparison: linear versus nonlinear cases.

By isolating these key intervals, we delineated the feature value ranges that were most influential on the model's predictions, thus allowing for a more accurate SHAP-based scoring system.

Step 3: SHAP-Based Scoring System Development

The third step shows how to generate scores using the SHAP values for each variable. The score was calculated by adding the SHAP values of the data points obtained from each section to accurately quantify the impact of individual intervals for each feature. This was for the model's sensitive interpretation of the different ranges within the variable and was reflected in the final scoring system.

Step 4: Data Transformation and Handling Missing Data

Normalization of Scores Across Features

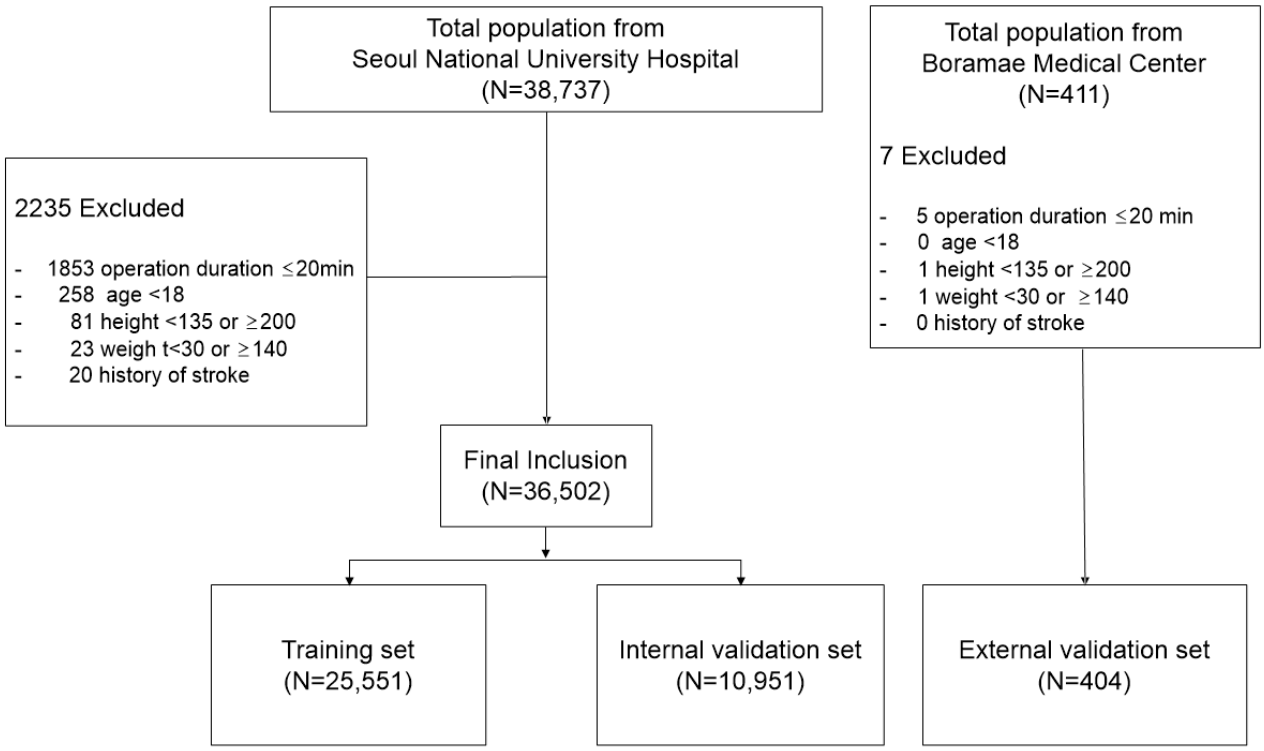
In this step, we focused on standardizing the scoring system across all features. This normalization process ensured that the scores from different features were comparable and appropriately weighted within the overall scoring model. Normalization is based on the total range of scores across all features, thereby aligning them on a unified scale.

Handling Missing Data With Interval Averaging

If the actual values for a particular interval were unavailable, our model adopted a fallback strategy that uses the average of values in adjacent intervals. If there is no data in the interval immediately next to the missing value, the entire range of the interval was used to preserve the integrity of the model's risk assessment in the face of data sparsity.

Clinical Study Design

In applying the EACH score to assess stroke risk during the perioperative period in noncardiac surgeries, we approached our clinical study design with a focus on real-world applicability. This study was structured using 3 datasets: training, internal validation, and external validation. The training and internal validation datasets were derived from patient records at Seoul National University Hospital (SNUH) from 2016 to 2019. For a broader perspective and to assess the performance of the model in different settings, we included a geotemporal external



XSL•FO
RenderX

validation using data from surgeries performed at the Boramae Medical Center (BMC) between 2020 and 2021.

A key aspect of our data preparation involved addressing missing values in preoperative variables. Recognizing the potential impact of incomplete data on the model's accuracy, we used a methodological imputation approach. For continuous variables, missing values were imputed using their mean, whereas categorical variables were imputed using the mode [24].

Patients were excluded from the study if the surgery lasted less than 20 minutes, if they were younger than 18 years or weighed less than 30 kg or more than 140 kg, if their height was outside the 135 cm to 200 cm range, or if they had a previous history of stroke. The developmental set consisted of 36,502 patients from Seoul National University Hospital. After applying the exclusion criteria, 404 patients from Boramae Medical Center were included in the external validation set (Figure 3). Perioperative stroke was defined as an ischemic brain infarction occurring within 30 days postoperatively and was identified through new ischemic lesions on diffusion-weighted imaging [18,21]. An experienced neurologist [M-YO] confirmed the stroke diagnosis by reviewing the imaging outcomes.

Figure 3. Flowchart of study population.

Data Collection

Demographics and Comorbidities

We recorded patients' age, sex, physical metrics (height, weight, and body mass index [BMI]), and a range of preexisting conditions, including hypertension, diabetes (with or without insulin medication), previous cardiovascular events, asthma, chronic obstructive pulmonary disease, liver and kidney diseases, and tuberculosis.

Surgical Information

Surgical risk was classified according to the American Society of Anesthesiologists (ASA) standards. Information on whether the surgery was emergent and the type was collected.

Preoperative Laboratory Findings

A comprehensive set of laboratory results were collected, including hemoglobin levels, renal function indicators (blood urea nitrogen, creatinine, and estimated glomerular filtration rate), nutritional markers (albumin), electrolytes (sodium and potassium), glucose levels, liver enzymes (aspartate aminotransferase and alanine aminotransferase), platelet count, and coagulation status assessed by partial thromboplastin time.

Revised Cardiac Risk Index

This traditional scoring system is used to assess the risk of major adverse cardiac events including stroke in noncardiac surgery. The Revised Cardiac Risk Index (RCRI) is composed of the factors mentioned above, such as type of surgery, history of ischemic heart disease, congestive heart failure, cerebrovascular disease, preoperative treatment with insulin, and a preoperative creatinine level greater than 2 mg/dL [13]. The RCRI was used as the comparative score.

Prediction Model Based on Other ML Techniques

We developed prediction model based on several ML algorithms, including Support Vector Machine (SVM) [25], Decision Tree Classifier (DTC) [26], RF [27], and CatBoost [28] to compare the performance with the EACH score. The developmental dataset was systematically divided into a training set comprising 70% of the data for model development, and the

XSL•FO
RenderX

remaining 30% formed the test set used to assess model performance. Hyperparameter optimization for each model was performed using grid-search cross-validation to identify the optimal settings that maximize the discriminative power of the model [29].

External Validation

External validation was conducted using the BMC cohort to assess the prediction performance of the EACH score, which was developed to predict perioperative stroke based on the SNUH cohort. The data used for validation were entirely separate from the data used during the development of the EACH score. BMC cohort was geographically, and temporally different cohort from the development set, SNUH cohort.

Statistical Analysis

Continuous variables were analyzed using the Student *t* test and the Mann-Whitney *U* test to determine the significance of differences between the 2 groups.

Categorical variables in both datasets were evaluated using the chi-square test to investigate the presence of significant associations or discrepancies between the categories. All tests were 2-sided, and statistical significance was set at $P<.05$. ML modeling was performed in python 3.8 using the Scikit-Learn package [30]. The area under the receiver operating characteristic curve (AUC), accuracy, sensitivity, positive predictive value (PPV), and negative predictive value (NPV) were calculated to evaluate the performance of the prediction model [31].

Ethical Considerations

This study was approved by the institutional review board (IRB) of Seoul National University Hospital on April 7, 2020 (IRB Number, 2003-067-1108), and Boramae Medical Center on January 7, 2021 (IRB Number, 30-2021-4). The IRB determined that participant consent was waived in this retrospective study. We tried to follow the tripod guideline [32].

Results

Baseline Characteristics of the Study Cohorts

Our retrospective observational cohort study used data from SNUH comprising the training set (25,551 cases) and the internal validation set (10,951 cases) and the data of 404 patients from BMC to externally validate the prediction model in a geographically and temporally different population. The baseline characteristics of patients in the SNUH and BMC cohorts are summarized in Table 1. Patients in the SNUH cohort were younger than those in the BMC cohort. The prevalence of diabetes was slightly higher in the BMC cohort. Hemoglobin, creatinine, and albumin levels were higher in patients in the SNUH cohort, whereas glucose levels were slightly higher in patients in the BMC cohort.

Scoring System Based on Clinical Feature Intervals

The entire scoring system is presented in Multimedia Appendix 1. Scores ranging from 0 to 100 were assigned to the clinical features based on specific intervals determined by the slope change points. For example, albumin levels less than 4.1 g/dL were associated with a higher risk of perioperative stroke. Specifically, the highest score of 55.4 was assigned to the 2.4-3.5 g/dL range, indicating a particularly elevated risk for some low albumin levels. Similarly, hemoglobin levels were segmented, with the highest score of 51.5 assigned to the 5.0-11.0 g/dL range. In addition, the 18.6-20.7 kg/m² interval of BMI received a score of 51.8, suggesting a higher risk associated with specific BMI levels. However, age was divided into intervals, with scores increasing incrementally from 49.0 for the 18-49 years age group to 51.8 for those aged 64-97 years old. Creatinine levels did not differ significantly between intervals. These results suggest that continuous variables could impact predictive performance in various nonlinear patterns and that this pattern is well reflected in the EACH scoring system. Categorical variables were scored on the basis of their relative importance in predicting perioperative stroke.

Comparative Analysis of the Performance of EACH Scores Relative to Other ML Models

The EACH score demonstrated superior performance compared with other ML-based models, such as RF and CatBoost, as detailed in Table 2. The EACH score had the highest AUC (0.829) and sensitivity (0.881). The SVM, DTC, RF, and CatBoost models exhibited competitive yet slightly lower AUCs of 0.500, 0.501, 0.802, and 0.822, respectively. In the external validation, the EACH model consistently maintained high performance. It achieved an AUC of 0.784 and attained the highest sensitivity at 0.900 (Table 2).

Table 2. Comparison between the performance of Explainable Automated nonlinear Computation scoring system for Health (EACH) score and that of other machine learning models.

Models	AUC[a]	Accuracy	Sensitivity	Specificity	PPV[b]	NPV[c]
Internal validation						
Support Vector Machine	0.500	0.954	0.888	0.268	0.003	0.999

Comparative Analysis of the Performance of the EACH Explainable Score Relative to Traditional Scores

We compared the effectiveness of the EACH score with that of a traditional scoring system based on classical statistical methods and ML algorithms (Figure 4). The EACH score demonstrated superior performance compared with the RCRI, a scoring system used to predict perioperative stroke based on classical logistic regression analysis (AUC=0.528 vs AUC=0.784).

XSL•FO
RenderX

Figure 4. Comparison of receiver operating characteristic curves.

Comparative Analysis of the Performance of the EACH Score Relative to Other ML-Based Scoring Systems

In addition, we compared the performance of the EACH score with that of the ML-based score generation system, AutoScore (eg, $RF^{n=12, n=24}$). The performance of AutoScore increased with the number of features: with 9 features, the AUC was 0.501; with 12 features, the AUC was 0.564; and with 24 features, the AUC was 0.773. However, the EACH score surpassed the performance of AutoScore, demonstrating a superior AUC of 0.784 (Figure 4).

Risk Stratification Using the EACH Score: Low- Versus High-Risk Patients for Perioperative Stroke

The 2 patients representing low and high perioperative stroke risk based on the EACH score are shown in Table 3. The table illustrates how the EACH score model assigned risk scores to individual patient characteristics, leading to a cumulative risk assessment. In assigning scores to patients, the low-risk case, characterized by younger age (42.77 years) and moderate BMI (24.02 kg/m^2), tended to have lower ASA scores, no emergency operation, and no premorbidities. The laboratory results included slightly higher hemoglobin levels (13 g/dL) and higher platelet counts (293 ×10^3/μL), resulting in a lower total score (1379.16) indicative of a lower risk profile. Conversely, the high-risk patient was characterized by older age (71.07 years), lower BMI (22.84 kg/m^2), higher ASA scores, emergency operation, and surgery with a high risk for cardiovascular complications. The patient had lower hemoglobin levels (12 g/dL), lower platelet counts (92 ×10^3/μL), lower albumin levels (3 g/dL), and higher glucose (115 mg/dL) levels. These factors contributed to the higher total score (1517.29) of this patient, indicating a higher-risk profile. The key distinguishing factors in risk assessment included age, ASA score, surgery type, and laboratory values. The model integrated a wide range of clinical

XSL•FO
RenderX

variables into a single risk assessment metric. The ability of the EACH score to distill complex clinical data into a quantifiable stroke risk assessment provides a clear and actionable tool for perioperative stroke risk stratification.

Table 3. Comparative risk stratification using Explainable Automated nonlinear Computation scoring system for Health score: low versus high-risk patients for perioperative stroke.

Characteristic	Actual value	Low risk score	Actual value	High risk score
Age	42.77	49.02	71.07	51.82

Discussion

Principal Findings

In this study, we developed and validated a comprehensible automated scoring system, the EACH score, using CatBoost. This system, when applied to predict perioperative stroke, showed superior performance compared with other ML models. It also outperformed the traditional risk score, the RCRI score, and other ML-based risk-scoring systems, such as AutoScore. Furthermore, the EACH score effectively discriminated between patients with high- and low-risk perioperative stroke.

XSL•FO
RenderX

Recent advancements in ML-based models have shown promising performance by integrating diverse datasets, irrespective of their linearity or nonlinearity. These models have the potential to overcome the limitations inherent in traditional statistical methods. However, broader application of these models is often restricted because of their lack of explainability and insufficient external validation [33,34].

Comparison With Previous Work

To address these issues, Xie et al [16] developed AutoScore, a scoring generator that combines RF-based approaches with traditional logistic regression. However, AutoScore may not fully capture complex clinical relationships or accurately represent biological contexts owing to methodological limitations and reliance on logistic regression [16,17].

The uniqueness of the present study lies in the development of an entirely ML-based scoring system. The EACH score is adaptable to a variety of data types without relying on predefined assumptions. In this system, the range of each continuous variable was determined by the inflection point on the plot using SHAP values. SHAP values demonstrate the key features and the absolute and relative predictive values of each feature within the model and are widely used to enhance the explainability of ML models [14,23]. The inflection point on the plot of SHAP values could be assumed to be a significant change of its predictive impact on outcome [35]. Using the above characteristics of SHAP values, we revealed that the importance of each feature did not increase linearly with its value, but rather showed various relationships. Consequently, the EACH score uniquely reflects the varying significance of identical features, thereby influencing the performance of the prediction model in a distinct manner. Another strength of the EACH score is its robust handling of missing data. If the data for an interval were missing, they were replaced with the average of the surrounding intervals' values, maintaining score completeness and accuracy [24,36].

When applied to the real-world clinical data, EACH outperformed the traditional score and other ML-based systems. This demonstrates that this approach could contribute to the construction of a novel risk assessment tool that achieves high predictive accuracy and is intuitive for clinicians to interpret and apply in real-world practice.

Using the EACH score, clinicians can better differentiate between high-risk and low-risk patients. This allows for the allocation of limited medical resources to high-risk groups, enabling closer monitoring of perioperative stroke occurrence and improving prognosis through timely treatment.

Furthermore, the EACH score can indirectly provide optimal targets for minimizing perioperative stroke risk for key correctable laboratory indicators such as albumin, electrolyte, and glucose by highlighting detailed trends in blood tests that increase risk nonlinearly. For instance, the EACH score identifies an albumin level of 4.1 to 4.4 mg/dL as being associated with the lowest perioperative stroke risk. Adjusting albumin levels to this range could potentially reduce the incidence of perioperative stroke.

To date, there has not been a prediction model that provides treatment strategies for optimal thresholds of preoperative laboratory indicators. The EACH score would be helpful for clinicians in decision-making to reduce perioperative stroke in complex preoperative environments by providing the transparent and straightforward explanation of how it works. Nevertheless, it is crucial to interpret these findings cautiously within the context of each patient's individual situation and clinical context.

Limitations

In addition, we addressed the second common limitation in the application of ML-based prediction models by validating the EACH score in external cohorts from a secondary medical center with different geographical locations, patient volumes, and characteristics from the developmental cohorts. The superior performance of the EACH score in the external validation cohort added robustness to its reliability. Despite these advancements, it is important to acknowledge that the efficacy of the EACH score is contingent on the quality and comprehensiveness of the input data. Incomplete or biased data can result in skewed results. However, the EACH score showed excellent performance even with imbalanced data, such as perioperative stroke, which is a rare disease [19,21]. Nevertheless, there is a need for ongoing updates and validation of the model across diverse clinical settings. Furthermore, because the current dataset comprises only Asian patients, it is imperative to prospectively validate the EACH score in multiracial cohorts to ensure its generalizability.

Conclusion
