Methods: A total of 74 patients scheduled for surgery across 4 hospitals in 3 European countries were enrolled in this study from September 2021 to March 2022. Surgeries included cardiopulmonary and coronary artery bypass surgeries, cardiac valve replacements, prostate or bladder cancer surgeries, hip and knee replacements, maxillofacial surgery, and scoliosis procedures. After assessment for eligibility, participants were randomized into 2 groups: the intervention group (n=23) received the Adhera CARINAE DH intervention in addition to standard care, while the control group (n=27) received standard care alone. Psychological metrics such as self-efficacy, self-management, and mental well-being were assessed before and after the intervention, alongside physiological markers of stress.

Results: The intervention group demonstrated significant improvements across several psychological outcomes. For example, Visual Analogue Scale Stress at the hospital improved at admission by 5% and at hospital discharge by 11.1% and Visual Analogue Scale Pain at admission improved by 31.2%. In addition, Hospital Anxiety and Depression Scale Anxiety after surgery improved by 15.6%, and Positive and Negative Affect Scale-Negative at hospital admission improved by 17.5%. Overall, patients in the intervention study spent 17.12% less days in the hospital. Besides these individual scores, the intervention group shows more

XSL•FO
RenderX

positive relationships among the psychological dimensions of self-efficacy, self-management, and mental well-being, suggesting that the CARINAE solution could have a positive effect and impact on the reduction of stress and negative emotions.

Conclusions: Our results provide an important first step toward a deeper understanding of optimizing DH solutions to support patients undergoing surgery and for potential applications in remote patient monitoring and communication.

Introduction

Patients undergoing surgical operations commonly experience symptoms of severe stress, anxiety, and fear due to the potentially threatening nature of surgeries [1,2]. Family caregivers, who play a crucial role in caring for these patients, also face emotional distress and physical challenges [3]. Surgeons and health care professionals use various stress coping strategies, as stressors can affect surgical performance and lead to complications [4]. Psychological support and patient education have proven effective in reducing stress and anxiety in surgical settings [5,6]. Providing information about the surgical procedure is essential for both patients and caregivers, as it helps decrease anxiety levels and surgical complications [7,8]. Patient empowerment, where patients actively participate in managing their diseases, leads to better self-care management and improved outcomes in terms of satisfaction, cost, health status, and function [9,10]. Addressing caregiver strain is also vital for pediatric patients [11] and those with special health care needs [12].

Being in unfamiliar surroundings and facing preoperative requirements can add to feelings of confusion and stress. It is common for individuals anticipating surgery to experience uncertainty, fear, hesitation, and anxiety. These emotions can affect patients' well-being and their ability to adhere to instructions throughout their perioperative journey. Research shows [13] that patient experience is closely tied to emotional health and surgical outcomes. Failure to address anxiety and stress adequately can lead to unnecessary discomfort, prolonged hospital stays, higher costs, and suboptimal clinical results.

Preventing presurgical anxiety can significantly contribute to positive outcomes in terms of health and well-being. Various strategies and techniques have been used to manage preoperative stress and anxiety, ranging from simple methods like listening to music and basic relaxation techniques to more involved approaches such as providing information, consulting with nurses, and using advanced interventions like patient education programs and modern information and communication technology tools [14,15].

For instance, allowing preoperative patients the opportunity to listen to music before surgery can prove to be an effective intervention in reducing anxiety and aiding patients in coping with what could potentially be a challenging or stressful procedure. Music has demonstrated its ability to alleviate anxiety among preoperative patients on numerous occasions [8]. However, it is noteworthy that only a small fraction of patients receive adequate stress relief support before undergoing surgery.

Digital health (DH) interventions have significantly supported enhancing health condition awareness and mental health management, using both nonimmersive systems, for example, mobile apps, and immersive systems, for example, virtual reality (VR) [16]. These interventions have shown promise in supporting patients in managing anxiety, stress, and pain [17-19]. Especially for VR, studies [20-23] have demonstrated benefits in various health care areas, including stress and pain reduction [23,24], medical practitioner training, patient counseling, cognitive rehabilitation, physical therapy, dentistry, mental health management, and surgery, as well as in managing pain and anxiety in pediatric patients [21,22,25]. VR's distractive properties make it an efficient tool for stress relief and pain management [26]. In addition, VR has been shown to reduce perceptions of anxiety in preoperative patients [27].

On the other hand, DH interventions generate vast amounts of data that can be used for personalization through artificial intelligence techniques [28-33]. These techniques capitalize on remote activity recognition and monitoring in order to provide recommendations, enabling the personalization of patient interventions based on their unique behavioral and health needs [34,35]. Perioperative stress varies greatly among patients, depending on the severity of their illness and the type of surgery required. Personalized interventions targeting stress management should take these individual differences into account, incorporating health behavior theories. Health Recommender Systems, like the I-Change model, guide the personalization of educational and behavioral interventions [36,37].

Independent of the progress in the domain, the feasibility of combining VR with mobile-based technologies as the primary means of delivering a DH intervention remains poorly understood [38]. This study aims to explore the feasibility of a DH intervention named CARINAE, which combines evidence-based perioperative stress management, anxiety, and pain relief techniques grounded in behavioral science. The intervention leverages mobile and VR technologies to help patients manage stress and anxiety during surgery, promoting healthy recovery, extensively reported already in another paper [39]. Through self-reported measurements and a control group,

XSL•FO
RenderX

the study assesses the impact of the CARINAE platform on perioperative stress, aiming to determine the effectiveness of the intervention.

Methods

Overview

In this section, we summarize the design and the protocol followed for the intervention. For more information on the details of the protocol and the technological solution, the interested reader is forwarded to the relevant paper [39].

Ethical Considerations

This study was approved by the Institutional Review Board of the four hospitals participating in the study (Hospital Universitario Reina Sofia, Spain; Instituto di Ricovero e Cura per Anziani, Italy; Sant Joan de Déu Hospital, Spain; and Fundació Parc Taulí, Spain) and with the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards. Informed consent was obtained from all individual participants included in the study. Additionally, measures were taken to ensure the confidentiality and anonymity of patient data throughout the study. The study posed no significant risks to participants, and they were free to withdraw at any time without affecting their standard of care. Finally, no financial compensation was provided to the participants of the study.

Study Setting

The study, following ethical boards' approval, was conducted at the following European hospitals: (1) Hospital Universitario Reina Sofia (SAS; Spain)—Cardiothoracic Surgery Department; (2) Instituto di Ricovero e Cura per Anziani (INRCA; Italy)—Urology Department; (3) Sant Joan de Déu Hospital (SJD; Spain)—Orthopedics and Traumatology Department for Children; and (4) Fundació Parc Taulí (Parc Taulí; Spain)—Orthopedics and Traumatology Department for Adults. A fifth hospital had granted ethical approval to conduct the study; however, due to external reasons, no patients were recruited from this hospital, and so it did not participate.

The recruitment process started in September 2021 and finished in March 2022.

Clinical investigators prescreened the eligibility of the participants that they had available in their pool of participants that were proposed for one of the surgeries in the inclusion criteria that are reported in the sequel. Whenever a potentially eligible participant was identified, he or she was invited to the study, either by phone or during the routine consultation, whatever was more convenient. As soon as the patient showed interest in taking part in the study, she or he was referred to the research coordinator of the study who facilitated him or her by providing the patient information letter and the informed consent form and who solved any questions and concerns that the patient might have. Upon the signature of the informed consent, the patient was considered recruited for the trial.

Study Design

The CARINAE DH platform was tested in a multicentric trial conducted in 4 clinical settings across two European countries. The trial used a stratified randomized controlled design and aimed to address two main research questions.

RQ1: The first question seeks to determine the extent to which CARINAE impacts patients' stress, anxiety, and pain levels compared to those who receive the standard of care only. Additionally, the study investigated the effects on secondary outcomes, such as well-being and overall quality of life. As a side effect, the study investigated the impact of CARINAE on caregivers' stress and anxiety based on the groups they were assigned to.

RQ2: The second research question focuses on evaluating the overall usability of the CARINAE solution based on feedback and experiences from patients, caregivers, and health care professionals involved in the trial.

Eligibility Criteria

Inclusion Criteria

Participants aged 12 to 65 years who underwent various surgeries, including cardiopulmonary bypass surgery, coronary artery bypass surgery, cardiac valve replacement, prostate, kidney, or bladder cancer surgery, hip or knee replacement, maxillofacial surgery, orthognathic surgery, or scoliosis. Adult participants were required to have an Android smartphone and demonstrate basic digital literacy, while children's caregivers also needed to have an Android smartphone and basic digital literacy.

Exclusion Criteria

Participants who could not provide informed consent, communicate effectively in the native language, demonstrate basic digital literacy, exhibited symptoms of dementia, had allergies to dedicated wearable materials like steel and silicone, were pregnant, or were already enrolled in another clinical trial.

Interventions

Overview

The eligible participants were randomly allocated to either the experimental group or the control group using block randomization with a block size of 4. The randomization process was facilitated through the Sealed Envelope web-based tool [31]. The DH solution consisted of three distinct components: a mobile app, a VR component, and a clinical web application. Participants in the experimental group used the first and second components, while the third component was exclusively used by health care professionals for those patients. Both the control and experimental groups underwent the same visit schedule.

Control Group

The control group received standard care, which included four visits with the health care provider. During these visits, patients in the control group received instructions on diet and healthy lifestyle habits. In current health care settings, it is not common to provide patients with stress and anxiety relief support during the perioperative period. Assessments for the control group took place during the following visits: (1) the initial visit, where the health care provider communicated the need for surgery to the patient (2-4 weeks before the surgery); (2) hospital admission,

XSL•FO
RenderX

which occurred 1-3 days before the surgery; (3) hospital discharge, approximately 1 week after the surgery; and (4) remote follow-up 14 days after the surgery. After each visit, patients were administered several questionnaires capturing primary and secondary outcomes, as well as covariates.

Experimental (Intervention) Group

The participants in the experimental group received the digital solution CARINAE during the first visit, along with training on how to use the tool effectively. They were allowed to take CARINAE home and use it as frequently as desired. Following each of the 4 standard care visits, the experimental group completed the same questionnaires as the control group.

Sample Size Calculation

The study was a feasibility clinical trial, with the number of participants established before the beginning of the project by the clinics. According to the study protocol reported by Kondylakis et al [39], participants were randomized to achieve a balance between the 2 groups (intervention and control groups) according to the type of surgery and baseline characteristics (covariates). Considering a 1:1 random allocation, significance level of .05 (2-sided), and 80% power, 60 participants were needed to detect a 10% difference in stress, anxiety, and pain between the intervention and control groups. Sample size calculations are estimated using G*Power (version 3.1.9.2; University of Dusseldorf).

Outcome Variables

The primary outcome variables in this study were stress, anxiety, and pain, which were measured using paper-and-pencil questionnaires. The secondary outcome variables included overall quality of life, emotional status, mental well-being, self-efficacy perception, and patient activation during and after the hospital stay.

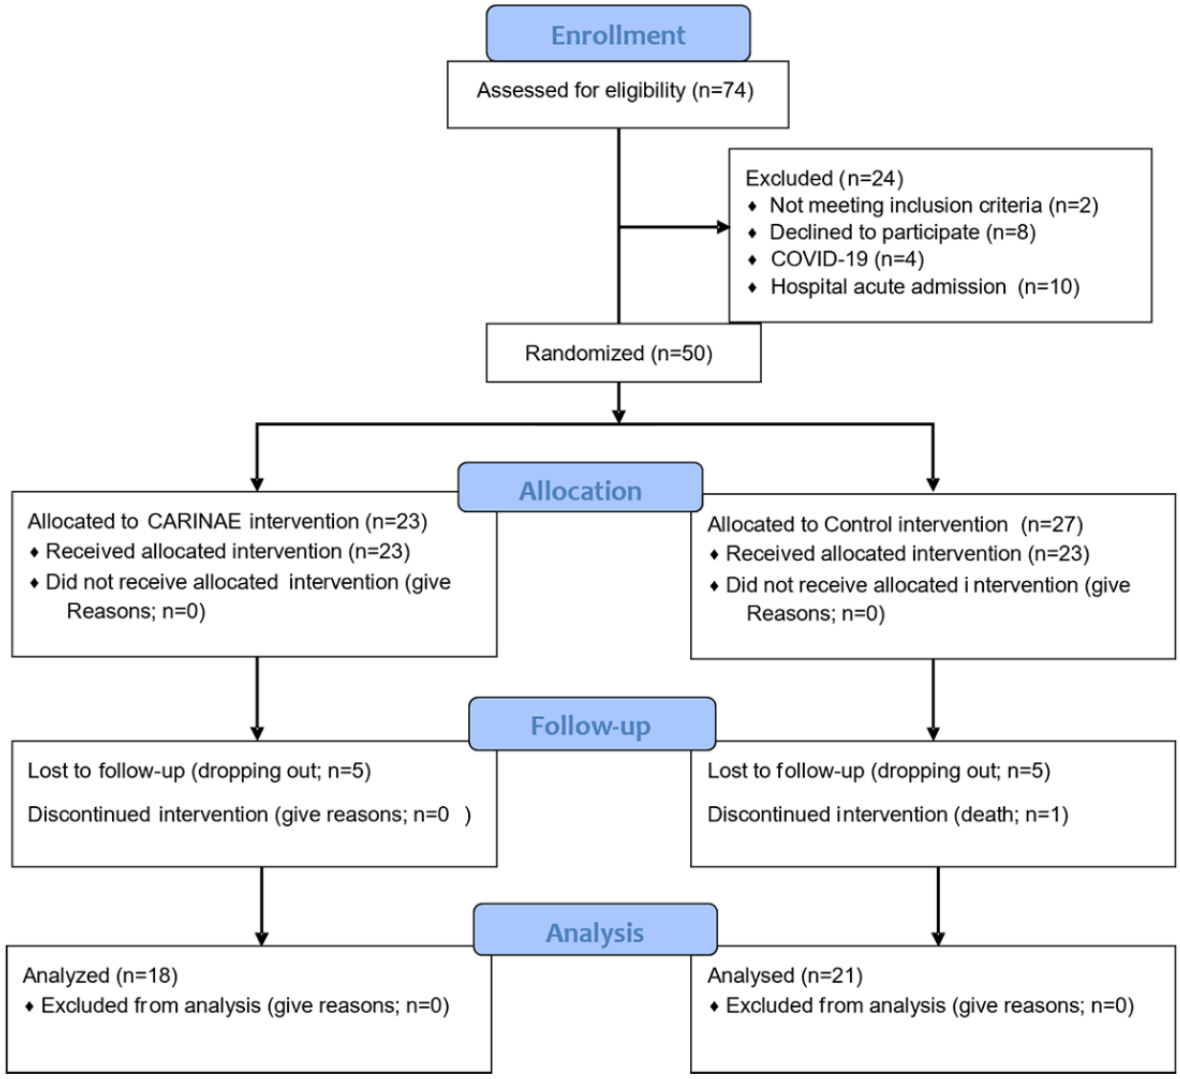
For assessing the primary outcome variables, the following questionnaires were used after each standard care visit and administered on paper:

- Patients' and caregivers' self-reported stress measured using a Visual Analogue Scale (VAS) at baseline, admission for surgery, hospital discharge, and 2 weeks after surgery [40].
- Patients' self-reported pain measured using a VAS at baseline, admission for surgery, hospital discharge, and 2 weeks after surgery [41].
- Patients' Hospital Anxiety and Depression (HADS) measured at admission for surgery, hospital discharge, and 2 weeks after surgery [42].

For assessing the secondary outcome variables, the following questionnaires were used after each standard care visit and administered on paper:

- Patients' health-related quality of life measured using the EQ-5D-3L questionnaire at baseline, admission for surgery, and clinical discharge [43].
- Patients' emotional status measured using the Positive and Negative affect Scale (PANAS) at baseline, admission for surgery, hospital discharge, and 2 weeks after surgery [44].
- Patients' and caregivers' mental well-being measured using the "Short Warwick Edinburgh Mental Well-Being Scale" (SWEMWBS) at baseline and 2 weeks after surgery [45].
- Patients' and caregivers' self-efficacy measured using the General Self-Efficacy in short form (GSE) questionnaire at baseline and 2 weeks after surgery [46].
- Patients' activation status measured using the Patient Activation Measure short form (PAM-13) at baseline, admission for surgery, and 2 weeks after surgery [47].

All these questionnaires have proven to be reliable and effective in measuring the respective variables.



Results

Overview

The diagram of the study is shown in Figure 1. From September 2021 to March 2022, a total of 74 patients were assessed for eligibility and 24 patients were excluded according to the following: (1) not meeting inclusion criteria (n=2); (2) declined to participate (n=8); (3) COVID-19 urgency (n=4); and (4) hospital acute admission (n=10). A total of 50 patients participated in the study, 23 patients were allocated to the CARINAE group (intervention group) and 27 participants were allocated to the control group. In total, 10 patients dropped out of the study (5 patients in the intervention group and 5 patients in the control group). In addition, 1 control group patient died during the surgery. A total of 39 patients finalized the trial and their data have been analyzed (21 patients in the control group and 18 patients in the intervention group; see the CONSORT [Consolidated Standards of Reporting Trials] flowchart in Figure 1 and CONSORT checklist in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram of the trial.

The intervention group consisted of 18 patients (10 male and 8 female patients; mean age 45.38, SD 26.2, range 12-91 years) and the control group consisted of 21 patients (11 male and 10 female patients; mean age 56.66, SD 27, range 12-91 years). Furthermore, intervention group surgeries included 1 patient undergone coronary bypass, 1 cardiac valve replacement, 4 scoliosis, 2 hip and 2 knee replacements, 3 prostate cancer, 2 bladder cancer surgeries, and 3 maxillofacial surgery types (see Multimedia Appendix 2 for sociodemographic characteristics).

The control group consisted of 3 patients undergone cardiac valve replacement, 2 scoliosis, 2 hip replacements, 4 knee replacements, 2 prostate cancer, 4 bladder cancer, and 4 maxillofacial surgery types (see Multimedia Appendix 2 for sociodemographic characteristics). The baseline table highlights a potential bias with regard to the age of the participants in both intervention and control groups (ca. 10 years), see the impact of that in the Discussion/Limitations section.

In addition, 22 caregivers participated in the study (11 in the control group and 11 in the intervention group). A total of 5 caregivers dropped out of the study (4 in the control group and 1 in the intervention group). A total of 17 caregivers finalized the trial and their data have been analyzed. This difference in drop out might be resulting from the lack of incentive to stay in the control group.

Finally, 12 health care professionals answered the three questionnaires (VAS, SWEMWBS, and Caregiver GSE), and their data were analyzed; 5 health care professionals belonged to INRCA—Italy, 4 to the SAS—Cordoba, Spain, 2 to the HSJD—Barcelona, Spain and 1 to the Parc Taulí, Spain.

Descriptive Statistics

Multimedia Appendix 2 presents descriptive statistics for the most important sociodemographic characteristics such as age, sex, digital expertise, educational level, type of medication, type of surgery, and previous comorbidities. Most of the participants had basic (n=13) or advanced digital skills (n=17) and 8 of them considered themselves experts. Regarding previous comorbidities, 11 of them had cancer in the past, 7 of them had cardiovascular disease, 1 had diabetes mellitus, 1 had renal disease, and 4 of them had mental diseases.

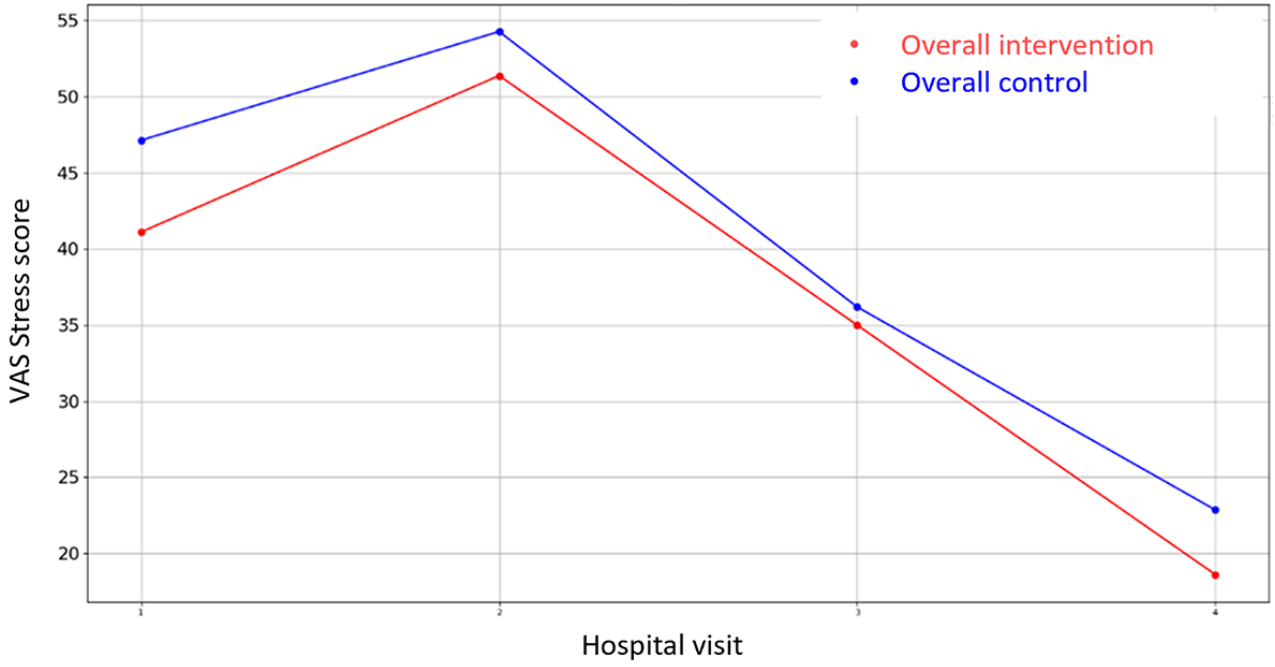
Clinical Outcome Parameters

Regarding the clinical variables, descriptive statistical metrics along with results of univariate analysis between intervention and control groups by *t* test method are presented in Multimedia Appendix 3.

XSL•FO
RenderX

Among all the variables in Multimedia Appendix 3, the VAS values for stress were lower for the intervention groups in all the overall cases (prehospitalization, hospitalization, and discharge) but they did not reach significance. There is only one that demonstrates statistical differences between control and intervention groups: HADS Depression Score during hospital admission in Parc Taulí. For the rest variables, the hypothesis of equal mean between intervention and control groups cannot be rejected due to the high *P* value outcome of the statistical tests. In addition, the mean VAS Stress, VAS Pain, HADS Depression, HADS Anxiety, PANAS Positive, and PANAS Negative score evolution throughout the 4 hospital visits follow-up period are illustrated in Figures 2-7.

Figure 2. Evolution of mean VAS Stress score during the 4 hospital visits (initial visit, hospital, hospital discharge, and 14 days postsurgery). VAS: Visual Analogue Scale.



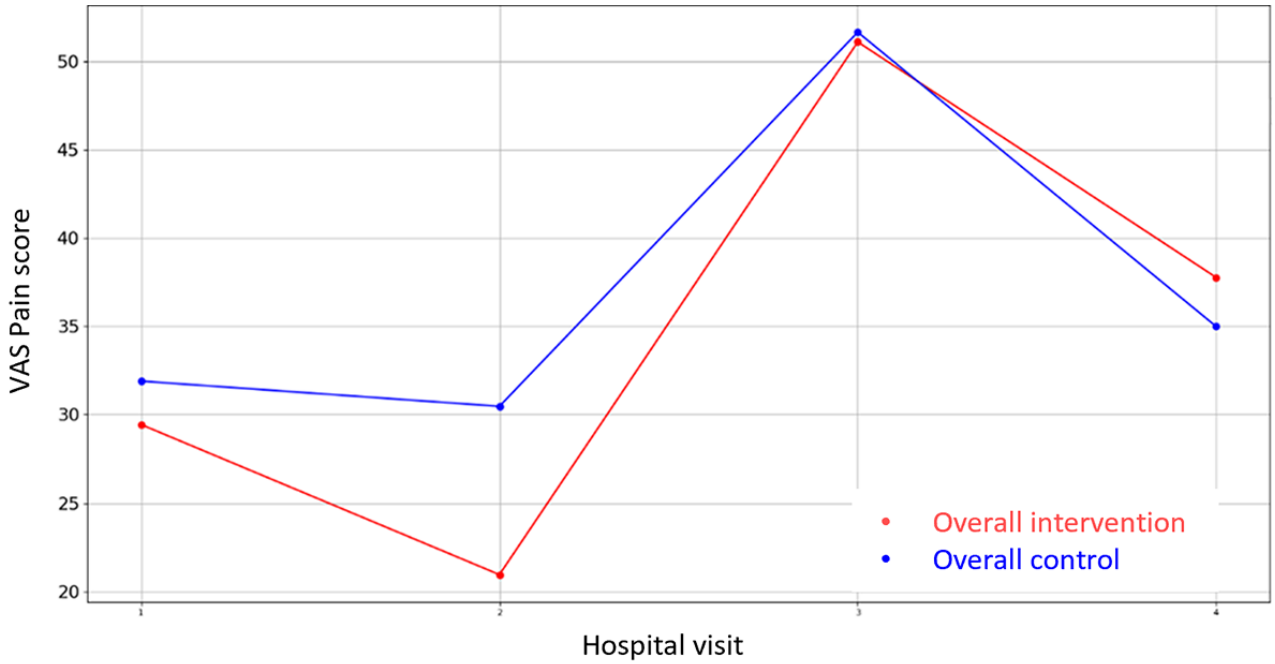


Figure 3. Evolution of mean VAS Pain score during the 4 hospital visits (initial visit, hospital, hospital discharge, and 14 days postsurgery). VAS: Visual Analogue Scale.

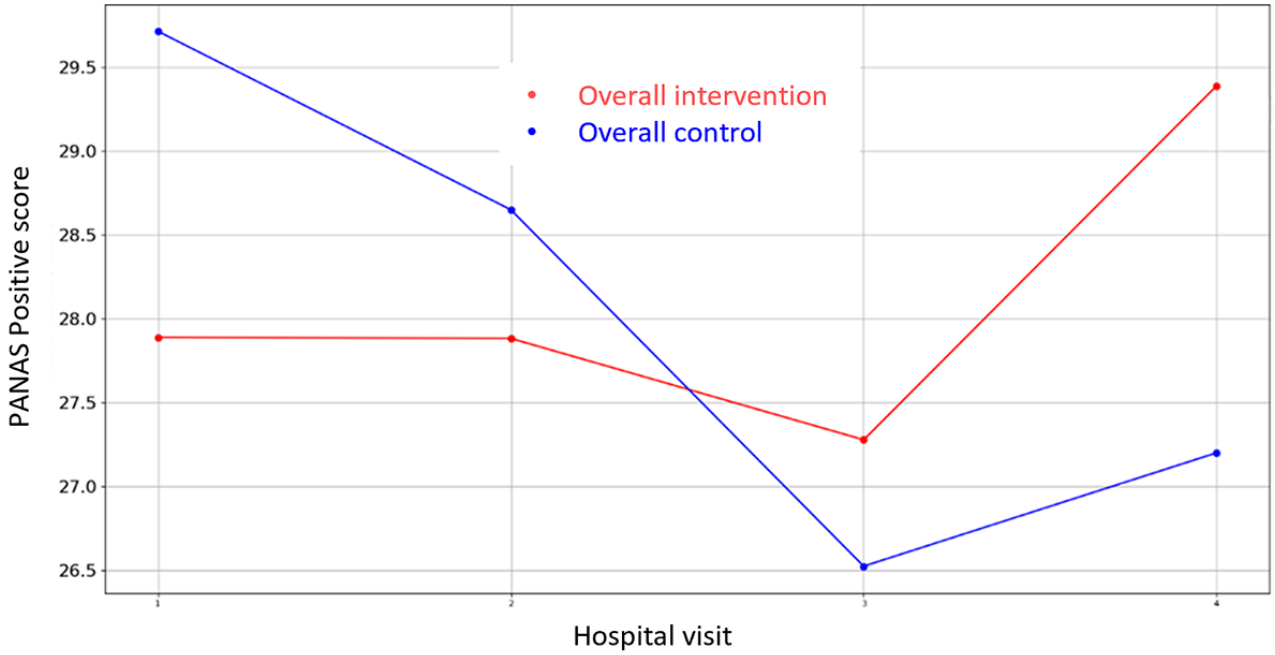

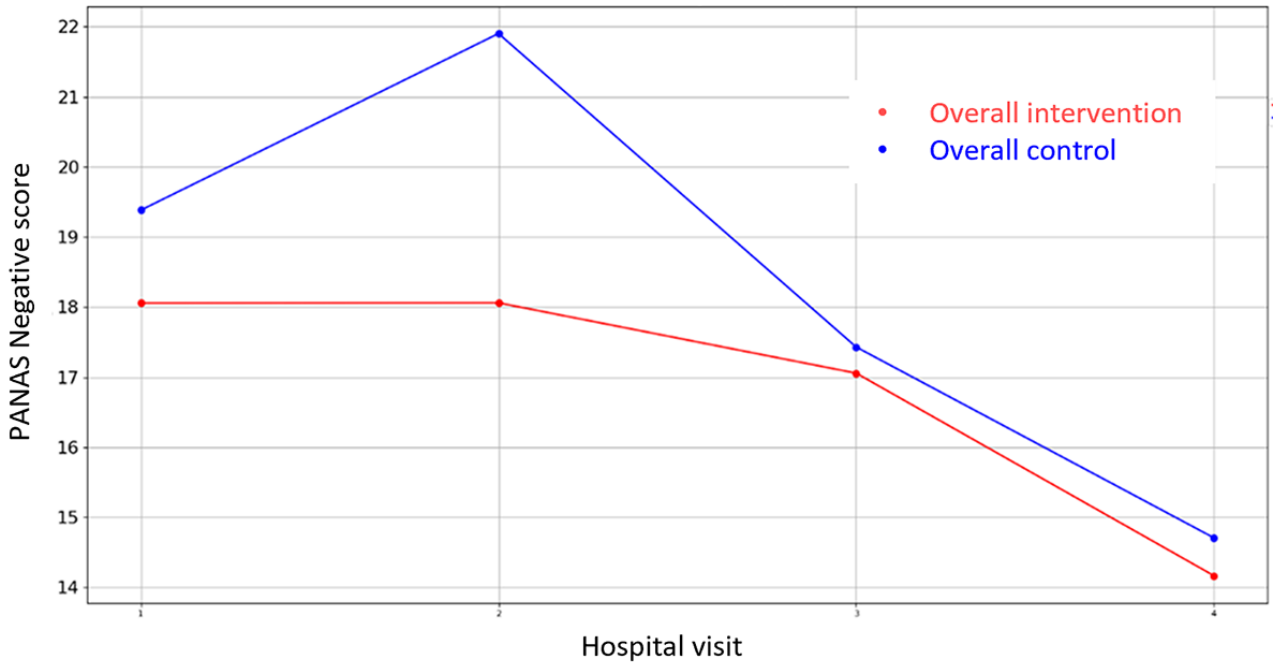

Figure 7. Evolution of mean PANAS (Positive and Negative Affect Scale) Negative score during the 4 hospital visits (initial visit, hospital, hospital discharge, and 14 days postsurgery).

Likewise, regarding the nonclinical outcome parameters of Multimedia Appendix 4, the same statistical methodology has been designed and executed to identify the most statistically significant variables. In this case, there are three variables where the hypothesis of equal means can be rejected (P<.05), that is, PAM-13 Hospital Admission item 13, VAS Stress—hospital discharge, GSE, and the corresponding questionnaires' (PAM-13, GSE, SWEMWBS, QOLmean, VAS Stress Caregiver, SWEMWBS Caregiver, and GSE Caregiver) score evolution graphics are presented in Figures 8-16.

Surgery's Exploratory Analysis

ANOVA Analysis

This section aims to investigate any possible statistical effect of the type of surgery on the patients between the intervention and control groups. It uses the mixed-ANOVA statistical tests applied to each unique surgery type group. Thus, depending on the surgery, ANOVA results are as follows:

- Hip replacement surgery: $F_{29,29}$=1.38; P=.19; η_p^2=0.58
- Knee replacement surgery:$F_{29,116}$=259; P=.06; η_p^2=0.27
- Maxilofacial surgery: $F_{29,145}$=0.67; P=.89; η_p^2=0.11
- Cardiac valve replacement surgery: $F_{29,58}$=0.8, P=.73; η_p^2=0.28
- Bladder surgery: $F_{29,116}$=0.38; P=.99; η_p^2=0.08
- Prostate surgery: $F_{29,87}$=0.73; P=.82; η_p^2=0.19
- Scoliosis surgery: $F_{29,116}$=0.13; P=.007; η_p^2=0.32

The P value obtained from ANOVA analysis in scoliosis is significant (P<.05), and therefore, we conclude that there are significant differences among intervention and control patients undergone that type of surgery.

Tukey Approach

For further investigation of the scoliosis data, an essential pair-wise correlational analysis has been implemented to specify the exact pair of variables whose statistics are significantly different between the intervention and control groups. One of the most commonly used post hoc tests is Tukey's test, which allows us to make pairwise comparisons between the means of each group while controlling for the family wise error rate.

Thus, we would conclude that there is a statistically significant difference (P<.05) between the means of groups: VAS Stress (hospital discharge) – VAS Pain (postoperation day) VAS Stress (hospital discharge) – HADS Depression (enrollment) VAS Stress (hospital discharge) – HADS Depression (hospital admission) VAS Stress (hospital discharge) – HADS Depression (hospital discharge) VAS Stress (hospital discharge) – HADS Depression (postoperation day) VAS Stress (hospital discharge) – HADS Anxiety (enrollment) VAS Stress (hospital discharge) – HADS Anxiety (hospital admission) VAS Stress (hospital discharge) – HADS Anxiety (hospital discharge) VAS Pain (enrollment) – VAS Pain (postoperation day) VAS Pain (hospital discharge) – VAS Pain (postoperation day) VAS Pain (hospital discharge) – HADS Depression (enrollment) VAS Pain (hospital discharge) – HADS Depression (hospital admission) VAS Pain (hospital discharge) – HADS Depression (hospital discharge) VAS Pain (hospital discharge) – HADS Depression (postoperation day) VAS Pain (hospital discharge) – HADS Anxiety (enrollment) VAS Pain (hospital discharge) – HADS Anxiety (hospital admission) VAS Pain (hospital discharge) – HADS Anxiety (hospital discharge) HADS Depression (enrollment) – PAM (enrollment).

Linear Mixed Models

Apart from ANOVA tests, to identify any connections between the input data clustered by type of surgery, another statistical approach has been tested, the linear mixed modeling technique.

In this exploratory analysis VAS Stress, VAS Pain, HADS Depression, HADS Anxiety and PANAS questionnaires' scores have been submitted to a linear mixed models (LMM) analysis wherein "time," "group (intervention vs control)," their interaction (time × group), age, and sex have been included as fixed factors. On the other hand, "subjects" and "surgery" have been submitted as random factors. The most significant LMM model's results appear to be the ones with dependent variables the questionnaire VAS Stress and VAS Pain. The corresponding results are presented in Tables 1 and 2.

XSL•FO
RenderX

Table 1. Results of the linear mixed models for the VAS[a] Stress.

	Coefficient	SE	*P* value
Hospital admission score	8.59	5.7	.13
Hospital discharge score	–8.72	5.7	.13
Postoperation visit score	–23.46	5.7	<.001
Sex (female)	11.92	5.06	.02
Groups (intervention/control)	–8.99	4.616	.05
Age	–1.58	0.448	.001

Groups (intervention/control)	–2.22	4.2	.59
Age	–0.28	0.349	.42

[a]VAS: Visual Analogue Scale.

Feature Importance Analysis

Feature importance refers to techniques that calculate a score for all the input features for a given model—the scores simply represent the "importance" of each feature. A higher score means that the specific feature will have a larger effect on the model that is being used to predict a certain variable. The following figures correspond to the computation of the most important factors linked to the principal questionnaires of this study (VAS Stress, VAS Pain, HADS Depression, HADS Anxiety, PANAS) using the XGBoost Regressor. The results are shown in the Multimedia Appendices 5-10.

Adherence and Engagement Analysis to CARINAE App

Adherence to VAS Pain and Stress, as well as to Wound Healing questionnaires into the CARINAE app have been analyzed to show the actions performed by the patients and the results show an overall adherence on VAS Pain of 47.23%, on VAS Stress of 68.41%, and Wound Healing of 2.5%. In the following table (Table 3), the adherence rates are also presented per hospital.

Further, the engagement table to the CARINAE app is presented in Table 4 for the various hospitals showing the total amount of interactions and patient sessions.

Table 3. Mean adherence to VAS[a] Pain, VAS Stress, and Wound Healing questionnaires into the CARINAE app.

Hospital	Days in hospital	Days in study	Completed VAS Pain	VAS Pain rate	Completed VAS Stress	VAS Stress rate	Wound Healing rate
INRCA[b]	3	33	23.33	73%	23	71.13%	3%
Parc Taulí	4	37	12.33	24.15%	15.6	30.50%	0%

Discussion

Principal Findings

The main aim of this study was to test the feasibility and efficacy of a personalized stress and anxiety patient empowerment DH solution (CARINAE) on patients undergoing surgery compared to a control group. Furthermore, this study aimed to show the impact of the CARINAE solution on quality of life, emotional status, mental well-being, and self-efficacy, activation status on patients' knowledge, skills, and confidence for self-management. Besides, the CARINAE solution has been assessed by health care professionals and patients and caregivers allocated to the intervention group, in terms of engagement.

According to our results, at baseline, patients of both groups reported generally normal levels of pain and stress, with higher levels of stress. Patients undergoing coronary bypass and cardiac valve replacement surgeries indicated higher levels of stress before the surgery (VAS>80), followed by hip and knee replacement surgeries in both pain and stress (VAS>60) compared to the other patients' surgeries. Similar stress values can be observed by caregivers. Regarding depression, patients of both groups reported general normal levels but they indicated to experience anxiety (HADS score between 7 and 10). In detail, depression is primarily observed by older patients undergoing prostate and bladder cancer removal surgery, with values between the abnormal range (HADS depression abnormal range 11-21) and secondarily, with borderline values (HADS depression borderline range 8-10), by patients undergoing coronary bypass and cardiac valve replacement surgeries. In contrast, anxiety is more generalized among various patients, and the results showed that older patients undergoing an operation to remove prostate or bladder cancer report very high values, in the abnormal range (HADS anxiety >11), followed by the youngest undergoing scoliosis and maxillofacial surgeries (HADS anxiety=10), and hip and knee surgeries, as well as coronary bypass and cardiac valve replacement surgeries with borderline levels of anxiety (HADS anxiety borderline range 8-10). Regarding positive and negative affect scores, patients of both groups showed normal levels of positive affect (mean scores normal levels 33.3, SD 7.2) and higher values regarding negative affect (mean scores normal levels 17.4, SD 6.2). Regarding patients' knowledge, skills, and confidence for self-management, no patient of either group found it important to take action with respect to the situation and the self-efficacy perception resulted quite high in most patients and caregivers (GSE>25). Finally, with respect to mental well-being and quality of life, at baseline patients and caregivers of both groups present quite high rates of mental well-being and quality of life. With respect to the latter two measures, it can be emphasized that patients who are older and have undergone more delicate surgeries, such as coronary bypass and cardiac valve replacement surgeries showed lower levels than other surgeries and age. A potential bias is the difference in age between the control and intervention groups, the control group has on average 10 years more. In a small sample, this bias might have occurred inevitably, but it might be indicative of a selection bias. In future studies, we should consider the possibility of including a "control intervention" that also requires the use of some simple mobile-based technology (eg, watching educational videos on YouTube).

Looking at the relationship between the variables, overall patients show most strong associations between negative emotions, anxiety, and stress, especially in the preoperative phase (recruitment and hospital admission), which in some cases are also maintained in the postoperative phase (hospital discharge and postoperative follow-up visit), but nevertheless, the presence of a strong inverse relationship between mental well-being and anxiety at the postoperative follow-up visit suggests that as anxiety decreases, patients' mental well-being increases again.

Examining the 2 groups separately, the control group shows greater relationships between the more negative psychological dimensions, such as anxiety, stress, negative emotions, and depression, whereas the intervention group shows more positive relationships between the psychological dimensions of self-efficacy, self-management, and mental well-being, suggesting that CARINAE solution could have a positive effect and impact on the reduction of stress and negative emotions. In detail, the control group showed levels of stress, depression, anxiety, and negative emotions that remained constant throughout the entire perioperative process, and only at the end of the process could changes in the perception of greater mental and physical well-being be observed. There were positive trends in the intervention group, although not significant from a statistical point of view. The intervention group shows a greater perception of mental well-being, self-efficacy, and self-management during the entire perioperative process and not only at the end of the process. Considering the clinical

XSL•FO
RenderX

outcome parameters on pain, stress, anxiety, and depression, a significant difference between the two groups has been found in the depression subscale regarding the hip and knee surgeries, still showing values within the normal range. Although no other statistically significant differences were found, it can be seen how the values with respect to pain remain low at the time of hospitalization and how they increase after the operation and then decrease again at the follow-up visit. Pain is known to be related to stress levels. The highest postoperative pain values are perceived more in those patients who underwent a more invasive operation (eg, coronary bypass and cardiac valve replacement surgeries) than in those whose operation was less invasive (prostate and bladder cancer). As expected, as far as stress was concerned, no significant differences were found, but the values increased at hospital admission, compared to baseline, and these values decreased at discharge and more so at the follow-up visit. Looking at the individual operations, the cardiac valve replacement surgeries and hip and knee replacement surgeries on admission to the hospital are the ones that cause the most stress for patients. Finally, the values of anxiety and depression remained within the normal ranges, and with respect to the baseline, it can be observed that in patients undergoing prostate or bladder cancer removal surgery who had high levels, the levels of both parameters steadily decreased at various stages of the perioperative process. We should notice that the project and the intervention aim at reducing stress levels, and not clinical anxiety disorder or major depression. This is quite important since a narrower focus on major mental health disorders might reduce the applicability of the intervention to most of the population who undergoes surgery. We should be aware that the exploratory analyses might, due to multiple testing, be subject to type 1 error, and cautious interpretation of the analysis is warranted.

Regarding the nonclinical outcome parameters, no significant differences have been found. However, the positive effect values remain stable and in the normal range during the perioperative process, increasing more after the hospital discharge, while negative values decrease after the operation and at the follow-up visit. Regarding patients' knowledge, skills, and confidence for self-management, no patient of either group found it important to take action with respect to the situation, and the self-efficacy perception resulted higher in patients and caregivers after the surgeries than the baseline (GSE>30). Finally, with respect to mental well-being and quality of life, in the follow-up visit, patients and caregivers of both groups presented higher rates of mental well-being and lower rates of quality of life than baseline, suggesting a faster recovery process of mental well-being in terms of recovery of feeling relaxed, optimistic, thinking clearly, and dealing with problems well and a slower recovery of quality of life in terms of recovery of mobility, autonomy, and usual activities. These results are not conclusive, and a bigger study might be needed to identify the level of effectiveness of the intervention. However, major aspects deserve further attention prior to a larger study. The low awareness about the importance of self-management might be an indicator of low health literacy levels. It might be wise to consider strategies that as part of the intervention address awareness of lifestyle factors for recovery even before the intervention itself.

The founded differences between the two groups may be linked to the young age of the participants and consequently to the related hormonal and neurodevelopment changes. Indeed, these changes are currently conceptualized in terms of imbalance between systems supporting reactivity and regulation, specifically nonlinear changes in reactivity networks and linear changes in regulatory networks [48].

In addition, as identified by LMMs, stress and pain showed other statistical differences in accordance with other parameters, showing that experiences of stress seem to differ according to age and sex. The level of stress rises with aging and is higher in female patients than in male patients. In addition, both stress and pain also differed depending on the phase of the perioperative process in which patients find themselves. In detail, pain presented more effect and impact at hospital discharge, showing the highest levels of the perioperative process, and stress at the end of the entire process (at follow-up visit), showing the lowest levels of the perioperative process. Further analyzing the importance of the various features using XGBoost revealed that stress, anxiety, pain, and negative affect measures are interrelated as expected and that physical activity is also important.

Finally, according to the adherence to the psychometric questionnaires in the CARINAE app, we observed that younger and older participants were more involved in the self-evaluation regarding stress with 79% and 71%, respectively. On pain, older participants were involved more than younger with 73% of responses by the older and 40% by the younger. These data are also reflected in the use of the CARINAE app, where the greatest interactions were found among older and younger patients. These data suggest, on the one hand, a greater provision of time by older people, and on the other hand, extensive use of technology by younger people and overall high involvement in the use of CARINAE for both ages.

Comparison to Literature

Although no significant differences have been found between groups, advances in DH interventions are playing great support in enhancing awareness about health conditions and for the management of mental health by relying on both nonimmersive (eg, such as mobile apps) and immersive systems (eg, VR) [16]. These include support for patients in the management of anxiety, stress [37], and pain [18]. On one hand, mobile apps for perioperative processes are becoming a hot topic, allowing to provide psychoeducational contents, mental well-being activities to reduce pain and stress, up-to-date information, tracking personal health data, reminding and engaging patients, and communicating in a cost-effective way. On the other, VR has been used in multiple health care applications including reducing stress and pain, training medical practitioners, patient counseling, cognitive rehabilitation, physical therapy in medicine, and for diagnostic and treatment needs in dentistry, mental health management, and surgery [19]. A multiuser immersive VR system was developed and used during presurgical discussions in a prospective patient cohort undergoing cerebrovascular surgery [20]. An immersive VR intervention adopted in pediatric patients to manage pain and anxiety provided a new, easy, and cost-effective intervention

XSL•FO
RenderX

that can be applied to other painful and stressful medical procedures [49]. Pain is a highly distressing symptom for patients in all clinical settings and stress and anxiety levels influence it. VR applications have proven to be efficient in stress relief and pain management, mainly due to their distractive properties [22].

In the literature, there is a lack of understanding of the feasibility of combining VR with mobile-based technologies as the main channel of the provision of a DH intervention [36]. In this study, what is explored is the feasibility of a DH intervention that leverages the latest mobile and VR technologies within the use case of helping patients manage stress and anxiety during surgery while promoting healthy recovery.

The findings of this project, reveal the importance of addressing this type of intervention as a service design approach with a strong focus on implementation aspects. A recent guideline by the World Health Organization in DH reinforces the importance of addressing training and supporting the environment as key success aspects in DH implementations [50]. In addition, infrastructure was a key element (eg, connectivity issues). The workforce is not only crucial from a service delivery point of view, but also a key channel to facilitate patient DH literacy which in this very complex setup with multiple devices and features is especially important.

Strengths and Limitations

Several strategies and techniques have been proposed to manage preoperative stress and anxiety that can be effective in supporting patients to cope with a wide range of stressful health situations. In the current health care settings, however, it is not very common to provide patients with stress and anxiety relief support prior to a surgical procedure. Usually, VR-enhanced solutions focus only on providing informative content, neglecting the importance of patient empowerment with a more robust educational curriculum. This study has been among the first to evaluate the potential effectiveness of a comprehensive technology in reducing perioperative stress and anxiety. CARINAE provided a unique combination of endpoints and the integration of knowledge deriving from several domains, including stress or anxiety management, patient empowerment, communication with medical professionals, adaptation to illness, self-regulation and self-management, and adaptation to medical procedures. The study has been successful in terms of identifying the key impacts of such type of intervention and provided enough exploratory insights to redesign the intervention and establish a new randomized controlled trial design to provide more conclusive data on efficacy. At the same time, this study allowed us to identify implementation issues that need to be addressed prior to larger studies and implementations. For example, larger trials with more participants are advisable for future work, which will facilitate the application of ANCOVA analysis.

This solution allowed participants to receive constant feedback to improve their appraisal and coping skills in an entertaining and motivating manner. It focuses on patient empowerment through active participation in the process and is dynamically adapted according to operation type, patient preferences, needs, and medical history all the way through the preclinical phase, admission, and discharge, in a continuous and personalized way. At the same time, it facilitated effective interactions between patients and health care professionals, through user-friendly and intelligent communication. It used the spaced learning methodology to help patients understand and learn the diverse aspects of their surgical process, from presurgery requirements to recovery steps with stress management all along the process, and provides multichannel anxiety and stress relief personalized content.

CARINAE solution, combining mobile health and VR technologies with a web app, provided positive preliminary results in reducing perioperative stress and creating effective collaborations between physicians or surgeons and their patients whilst supporting them in improving their knowledge in related domains. CARINAE has shown the potential to improve physical and emotional reactions to a stressor, such as surgical operations, to increase the levels of calmness to promote a sense of well-being and to empower patients in preoperative conditions. Information provided through the platform advances and enhances health literacy and digital competence and increases the participation of the patient in the decision-making process. Integration with third-party applications has facilitated the exchange of important information between patients and physicians, as well as between personal applications and clinical health systems.

While the findings of this study are interesting and valuable, it has some limitations. First, the small sample size, as well as the high variability of the ages and surgeries might limit the generalizability of the results. Given the pragmatic nature of this feasibility study, its small sample size was anticipated, further compounded by emergent challenges amid the COVID-19 crisis. The study did not aim to have a conclusive answer in terms of effectiveness, but to gather insight on whether it can be done as suggested in related literature [51]. As such, this study provides insights to support the design of a future randomized controlled trial. While a prospective observational design was considered, its susceptibility to confounding due to temporal changes prompted the inclusion of a control group, albeit with a heightened risk of limited significance. Moving forward, future research should prioritize more robust, adequately powered clinical studies to offer comprehensive insights.

Furthermore, pain and anxiety management guidelines might differ from one clinical setting to another, thus providing limited evidence based on raw cross-comparisons between different health care providers. Finally, the different durations of each surgery and each process limited the engagement data to the DH solution. Third, no data about use have been gathered from the VR app, limiting the quantitative performance rates and engagement to the VR component.

Recommendations for Future Research, Development, and Clinical Practice

An area of future improvement that both this feasibility study and other DH solutions demonstrate the need for is long-term patient engagement. Indeed, according to the literature, as mobile health apps grow more prevalent, many have low attrition rates, reducing the relevance of data collection for the

XSL•FO
RenderX

study [51]. Potential hurdles to long-term involvement include the patients' functional condition and the workload associated with performing in-app tasks. Our findings are aligned with those studies. This is especially true for procedures such as cancer and cardiac surgeries, where the target population is older and potentially more functionally constrained than younger patient populations. To address the issue of long-term engagement, potential solutions include developing even more simplified versions of the solution that are easier to use for those unfamiliar with technology, using SMS text messaging–only modes of communication, and using shorter surveys that take less time to complete. For younger patients, on the contrary, more videos and images instead of text could engage more. Additionally, it may empower patients further if they are shown the outcomes of their data and are able to visualize and quantify in real-time, how their condition has improved. Previous studies have noted that patients provided positive feedback when presented with their study results and often noted reluctance to participate because they had not received personalized feedback from their care teams in previous app-based studies [51]. In this study, differences across sites might be due to differences in populations but also on how the solutions were promoted or introduced in each site. When integrating new technology into any health care setting, provider input may significantly streamline the integration of applications into already complex clinical workflows. Continually enhancing the experience and usability, from both the patient and provider perspectives, will allow the realization of the full potential of DH solutions for patients undergoing interventional procedures.

Conclusions

We evaluated the feasibility of using CARINAE, a comprehensive DH solution, for patients undergoing surgery. This study examined the user experience and engagement with the solution, as well as the ability to collect patient-reported outcomes. Our results provide an important first step toward a deeper understanding of optimizing DH solutions to support patients undergoing surgery and for potential applications in remote patient monitoring and communication. This study highlighted how DH may be integrated into major procedures to improve patient education, emotional management, and engagement, and serve as a versatile clinical and research tool. Future studies will aim to test CARINAE in a larger cohort to establish its potential impact on health care resource utilization.

Acknowledgments

This study was part of the STARS-EU-PCP project that has received funding from the European Union's Horizon 2020 Research and Innovation Program (grant: 727585).

Data Availability

The datasets generated during or analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

IACG, HA, SH-F, PLG-S, FJN-B, and LF-L developed the patient view of the digital solution and coordinated clinical studies across all hospitals. In addition, they performed the initial data analysis. HK, DK, and AK developed the clinician view of the digital solution and contributed to the analysis of the results and their interpretation. RMB-R focused on the analysis of the results from the psychological perspective. GP, PZ, KA, and CS focused on the development of the virtual reality technology of the solution and contributed to the analysis of the results. All authors contributed to the writing of the manuscript, and reviewed, edited, and approved the final manuscript for submission.

Conflicts of Interest

IACG, HA, SH-F, and PLG-S are employees of Adhera Therapeutics, which owns the Adhera CARINAE DH Program. LF-L and SH-F were co-founders of Salumedia Labs, which was acquired by Adhera Therapeutics. All other authors declare no conflicts of interest.

Abstract

Background: Home spirometers have been widely implemented in the treatment of people with cystic fibrosis (CF). Frequent spirometry measurements at home could lead to earlier detection of exacerbations. However, previous research indicates that the long-term use of home spirometry is not well maintained by people with CF.

Objective: We aimed to gain insight into the long-term uptake of home spirometry in regular multicenter CF care.

Methods: Home spirometers combined with a remote monitoring platform were introduced in the treatment of people with CF in 5 Dutch CF centers starting in April 2020. Usage data from April 2020 to December 2022 were analyzed retrospectively. Survival analyses were conducted to assess use consistency over time, and *t* tests were used to evaluate the impact of increased pulmonary symptoms on home spirometry frequency. The effect of the initiation of a new treatment, Elexacaftor/Tezacaftor/Ivacaftor, on use frequency over time was assessed in a subgroup of participants with repeated measures ANOVA.

Results: During the observation period, a total of 604 people with CF were enrolled in the remote monitoring platform and 9930 home spirometry measurements were performed. After the initiation of home spirometry use, the number of users declined rapidly. One year after the initiation, 232 (54.2%) people with CF stopped using home spirometry. During the observation period, 67 (11.1%) users performed more than 20 measurements. Furthermore, the number of consistent home spirometry users decreased

XSL•FO
RenderX

over time. After 600 days, only 1% of users had measured their lung function consistently every 31 days. Use frequency slightly increased during periods with increased pulmonary symptoms (ΔMean=0.45, $t_{497.278}$=–4,197; P<.001) and showed an initial rise followed by a decrease after starting treatment with Elexacaftor/Tezacaftor/Ivacaftor (ΔMean=0.45, $t_{497.278}$=–4,197; P<.001).

Conclusions: Consistent uptake of home spirometry in people with CF is low but increases around periods of changing symptoms. A clear strategy for the organization of remote care seemed to improve the long-term uptake of home spirometry. Nevertheless, home spirometry and its intensity are not a goal on their own but should be used as a tool to reach individual goals within local contexts.

Introduction

Cystic fibrosis (CF) is a recessive autosomal disease caused by dysfunction of the CF transmembrane conductance regulator (CFTR) channel. Dysfunction of the CFTR channel leads to increased pulmonary mucus viscosity that causes chronic inflammation and predisposes to recurrent infections [1]. Early detection and treatment of pulmonary decline is essential to prevent mortality and morbidity in people with CF. The forced expiratory volume in 1 second (FEV1) measured by spirometry is the most reliable clinical outcome for this end [2,3].

Portable home spirometers that measure FEV1 have been available for multiple years. However, they have recently become more accessible thanks to advances in digital patient environments, the widespread availability of smartphones to operate them with, and a pivot toward home monitoring driven by the COVID-19 pandemic [4,5]. In theory, home spirometers allow people with CF to identify lung function decline sooner which could help them seek timely medical intervention and thus reduce mortality, morbidity, and health care costs [6].

Early detection of pulmonary decline with home spirometry would require regular self-monitoring of people with CF over extended periods, also when their condition is stable. In recent work, we found there is little incentive for people with CF to frequently self-monitor during periods of well-being, or when there is no reduction in therapy burden elsewhere [7]. This is in line with findings from previous prospective studies that reported declines in monitoring adherence to study protocols over time, especially in adults [6,8-11].

Understanding how people with CF incorporate home spirometry into their treatment routine is crucial for evaluating its added value. There is a specific need for more insights into the long-term uptake of home spirometry in regular CF care. This study aimed to examine the uptake of home spirometry in regular CF care in 5 Dutch CF centers over 2.5 years. From previous work, we hypothesized that the uptake of home spirometry is not well-maintained over time, that home spirometry uptake increases during periods with increased pulmonary symptoms, and that home spirometry uptake declines after the initiation of treatment with a new drug that specifically targets the CFTR channel (Elexacaftor/Tezacaftor/Ivacaftor) [7].

Methods

Study Design

This was a retrospective, multicenter, observational study conducted in 5 Dutch CF centers (Radboud University Medical Center Nijmegen, University Medical Center Groningen, Maastricht University Medical Center, Amsterdam University Medical Center, Haga Hospital, The Hague).

Remote Monitoring Platform

Home spirometry testing combined with a remote monitoring platform (RMP) was implemented on April 1, 2020, to prevent unnecessary outpatient visits during the COVID-19 pandemic in 5 Dutch CF centers. Details of the RMP have been published elsewhere [7]. In short, the RMP was used in addition to regular care in order to reduce physical hospital visits when possible. Considering the turbulent period of the COVID-19 pandemic, no formal implementation period or protocols were used. Instead, the implementation of the RMP and its use varied between departments based on their local settings, capacities, and needs. Therefore, RMP implementation across the 5 centers and enrollment of individual users occurred gradually during the COVID-19 period [7]. As a general rule, people with CF were asked to measure their lung function monthly, but health care professionals and users had the freedom to deviate from this based on individual contexts.

Home spirometry was performed with the Spirobank Smart (Medical Internet Research). Home spirometers were donated by the Dutch Cystic Fibrosis Foundation. In addition, 4 of the 5 CF centers used a digital symptom questionnaire based on the Modified Fuchs criteria to track symptoms indicative of a pulmonary exacerbation. How often this questionnaire was used varied between centers and people with CF. If 2 or more symptoms were reported, automated feedback provided the advice to measure the lung function and contact the CF team as needed [12].

Study Population

This study included all people with CF who measured their lung function at home with the RMP. Home spirometry and symptom survey data of all users of the RMP were extracted anonymously. As this was a retrospective observational trial with anonymous data, no formal eligibility criteria were used. In practice, eligibility for enrollment on the RMP is decided by the treating

XSL•FO
RenderX

health care professionals and patients themselves based on whether the user is able and willing to measure their lung function at home. In general, children had to be older than 6 years old to be considered for enrolment on the RMP. Individual start dates of Elexacaftor/Tezacaftor/Ivacaftor were available for a subgroup of people with CF who participated in a previous study and who gave informed consent for additional data collection [7].

Primary and Secondary Outcome Measures

Primary outcomes included (1) the median number of days between each consecutive home spirometry measurement day during the observation period (time-to-next lung function [TTN]) and (2) the proportion of users who continued self-monitoring with consistent frequencies (ie, monthly, 2-monthly, or quarterly) over time. Secondary outcomes included (1) the difference in the average intra-person frequency of home spirometry measurements between periods of increased pulmonary symptoms (ie, a symptom survey score ≤5) and few pulmonary symptoms (ie, a symptom survey score ≥6) and (2) the difference in the average intra-person frequency of home spirometry following initiation of Elexacaftor/Tezacaftor/Ivacaftor.

Statistical Analysis

All statistical analyses were conducted using IBM SPSS Statistics (version 27). User characteristics were described for all users and user groups based on home spirometry uptake categories (ie, 0, 1-20, and >20 unique measurement days). User characteristics of the group without measurements and the group with >20 unique measurement days were compared with each other using the Pearson chi-square test for proportions. To compare uptake categories with CF departments the Monte Carlo method was used to estimate the Fisher exact test. As data of users were gathered anonymously, only age, sex, and treating CF centers could be described. Treating CF centers were anonymized.

Consistent uptake of home spirometry was assessed using the Kaplan-Meier estimator. A total of 2 different definitions of consistent uptake were used in 2 separate analyses. First, we examined the number of users who self-monitored every 31, 62, or 93 days without breaking this pattern (ie, TTN remained below 31, 62, or 93 days). A break in this pattern was considered a loss of survival. Second, we allowed 1 break in the pattern after every 2 measurements following the pattern of 31 or 62 days. The break could be no longer than twice the number of the pattern (ie, 62 or 124 days, respectively). Users who had never measured their lung function or only once were excluded from the analyses. Separate subgroup analyses were performed for age categories at the first measurement, CF centers, and the adult and pediatric CF departments of the CF centers.

An independent *t* test was used to compare the mean number of home spirometry measurement days within 28 days of all symptom surveys with a score ≤5 (ie, a period of increased symptoms) with those taken within 28 days of all symptom surveys with a score ≥6 (ie, a period of few symptoms). In a sensitivity analysis, the intraindividual change in home spirometry use related to the number of symptoms was examined. A dependent *t* test was used to compare the number of home spirometry measurement days during the first period of increased symptoms of an individual after the initial 100 days of use with the closest period of few symptoms.

Changes in use frequency after the introduction of Elexacaftor/Tezacaftor/Ivacaftor were examined in a subgroup of people with CF. Data on Elexacaftor/Tezacaftor/Ivacaftor use was only available for a subgroup of 81 users who participated in a previous study [7]. Change in frequency of use was assessed with repeated measures ANOVA between multiple intervals around the initiation of Elexacaftor/Tezacaftor/Ivacaftor: the 30 days before initiation of Elexacaftor/Tezacaftor/Ivacaftor; and 0-30 days, 30-60 days, 60-90 days, and 90-120 days after initiation of Elexacaftor/Tezacaftor/Ivacaftor. Users were only included if they started Elexacaftor/Tezacaftor/Ivacaftor at least 120 days before the end of the study period.

Ethical Considerations

Local ethical committees waived formal approval considering the negligible burden of participation and absence of imposed risks (file number local ethical committee Arnhem-Nijmegen region: 2021-13214). A subgroup of people with CF provided electronic informed consent for the use of additional pseudonymized data to answer the research questions of this study.

Results

Patient Characteristics

A total of 604 people with CF were included in the analysis. Demographics are presented in Table 1. The median time people with CF were enrolled on the RMP during the observation period was 816 (IQR 716-856, range 37-998) days. Throughout the 998-day observation period, a total of 9930 home spirometry measurements were performed of which 5104 were unique day measurements. Overall, 428/604 (70.1%) people with CF performed at least 1 home spirometry measurement, 365/604 (60.4%) had 2 or more unique home spirometry measurements days, and this number decreased further with more unique measurement days (Table 1). One year after the initiation of home spirometry, 232 (54.2%) people with CF stopped using home spirometry. For users with 2 or more unique home spirometry measurement days (N=365), the median participant TTN was 25 (IQR 12-76, range 1-541) days for the total period. The median number of days between the first and last unique home spirometry day was 334.5 (IQR 59.25-632.75, range 0-966).

[h]Not applicable.

Long-Term Use

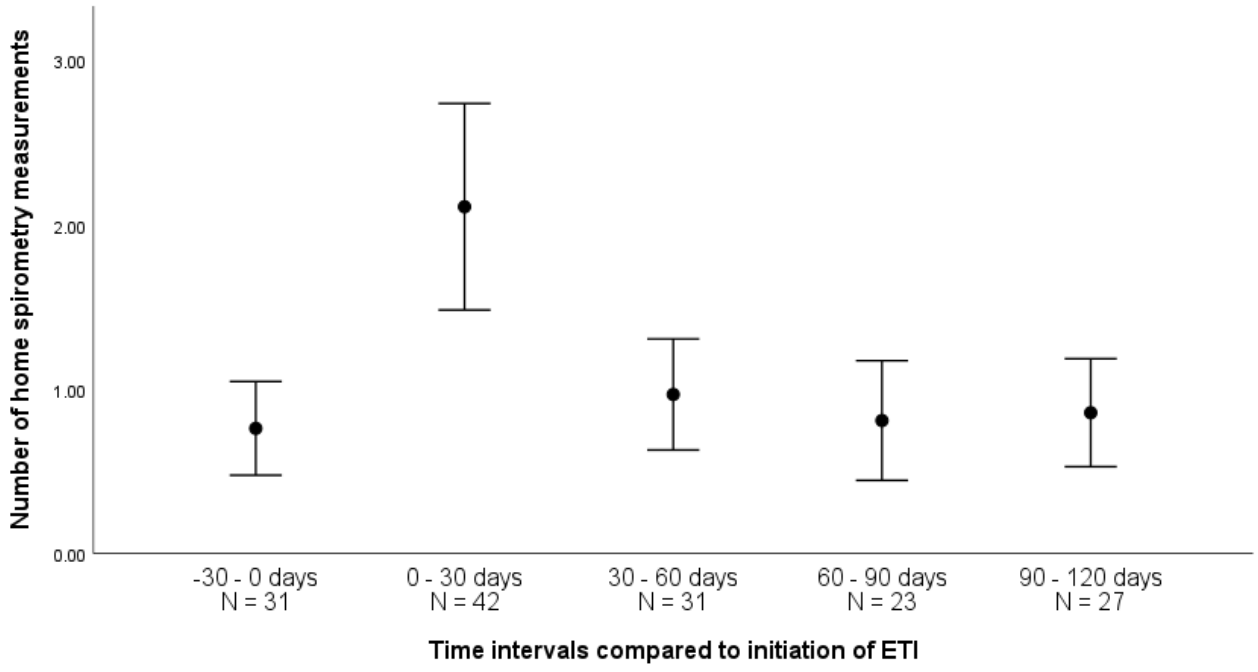
At 600 days, only 1% of users had measured their lung function at home consistently every 31 days. The decline was largest during the first 150 days across all intervals. For the more lenient criteria, the decline was less steep but followed a similar curve. Figure 1 shows Kaplan-Meier curves for the different uptake patterns. On average, consistent use frequency patterns were broken after 41 days (95% CI 31-51 days) for the 31-day interval, after 105 days (95% CI 86-123 days) for the 62-day interval, and after 172 days (95% CI 95-118 days) for the 92-day interval. After 150 days, 93% of users had broken the 31-day pattern, 79% had broken the 62-day pattern, and 68% had broken the 93-day pattern (Figure 1).

XSL•FO
RenderX

Figure 1. Kaplan-Meier survival curve of the consistency of home spirometry use (n=365). Upper panel: Consistent users with every FEV1 measurement performed with a maximum time-to-next lung function of 31, 62, or 93 days. Lower panel: consistent users with a more lenient approach, where one FEV1 measurement can be performed with a longer time-to-next lung function if two subsequent measurements are taken with a maximum time-to-next lung function of 31, or 62 days. People with cystic fibrosis who are consistent users at the end of the observation period are censored with dots. Yellow: 93-day interval; green: 62-day interval; blue: 31-day interval.

Multimedia Appendix 1 shows Kaplan-Meier curves for the strict use frequency patterns with subgroups based on age categories (6-12 years, 12 -18 years, ≥18 years; Figure S1 in Multimedia Appendix 1), sex (Figure S2 in Multimedia Appendix 1), treating CF center (Figure S3 in Multimedia Appendix 1), and age categories within treating CF center (<18 years within treating CF center vs ≥18 years within treating CF center; Figure S4 in Multimedia Appendix 1). There was no difference between long-term use consistency and sex. Children and teenagers generally seemed to use their home spirometer consistently longer than adults. Average consistent use frequency patterns were maintained longer in one CF center than in the others with a mean survival of the strict 31-day pattern of 125 days (95% CI 70-179 days). Both the pulmonary and pediatric pulmonary departments of this CF center had better maintained consistent use rates than all other departments (Figure S3 in Multimedia Appendix 1).

XSL•FO
RenderX



Impact of Increased Pulmonary Symptoms on Home Spirometry Use Frequency

A total of 381 periods with increased symptoms and 1340 periods with few symptoms were compared. There was a small, but significant difference between the mean number of home spirometry tests performed during periods of increased symptoms (mean=1.33) and those with few symptoms (mean=0.88; ΔMean=0.45, $t_{497.278}$=–4,197; *P*<.001). In the sensitivity analysis, periods of increased and few symptoms could be compared for 76 users. Dependent *t* test showed no significant difference between the number of home spirometry tests performed between these periods (ΔMean=0.37, t_{75}=–1.843; *P*=.07). Of the users in the sensitivity analysis, 14 (18.4%) measured only during periods of increased symptoms, 5 (6.6%) only during periods with few symptoms, and 44 (57.9%) measured their lung function in both periods. A total of 13 (17.1%) of all users did not measure their lung function in both periods. In an exploratory analysis, the FEV1 during the first period with increased symptoms after 100 days of use was compared with the nearest period with few symptoms for 44 users with a Wilcoxon signed rank test. The FEV1 was significantly lower during the period with increased symptoms (median=1.75, IQR 1.41-2.59) compared with the period with low symptoms (median=1.97, IQR 1.52-2.89; ΔMedian=0.22; *Z*=–3.46; *P*<.001).

Influence of Elexacaftor/Tezacaftor/Ivacaftor Treatment Initiation on Use Frequency

A total of 63 out of 81 (78%) people with CF for whom additional data were available started Elexacaftor/Tezacaftor/Ivacaftor treatment during the observation period. More users measured their lung function at home within 30 days after initiation of Elexacaftor/Tezacaftor/Ivacaftor (N=42/63, 67%) compared with the other time intervals (Figure 2). The mean number of home spirometry measurements for the consecutive time intervals were 0.76, 2.11, 0.97, 0.81, and 0.86, respectively. Repeated measures ANOVA with Greenhouse-Geyser correction showed a significant effect of time in relation to Elexacaftor/Tezacaftor/Ivacaftor initiation on the number of home spirometry measurements ($F_{2.36,146.26}$=13.73, *P*<.001). Tests of within-subjects contrasts showed a significant difference between the month before initiation and 0-30 days after initiation ($F_{1.62}$=19, *P*<.001) and between 0-30 days and 30-60 days after initiation ($F_{1.62}$=15.37, *P*<.001) but not between 30-60 days and 60-90 days, or 60-90 days and 90-120 days after initiation of Elexacaftor/Tezacaftor/Ivacaftor treatment.

Figure 2. Mean number and 95% CI values of home spirometry measurements per user in the month before and months after initiation of Elexacaftor/Tezacaftor/Ivacaftor treatment. N indicates the number of users who measured their lung function at least once during the intervals.

Discussion

Principal Findings

This study aimed to examine the use of home spirometry in regular CF care for 2.5 years in 5 Dutch CF centers. Our results showed a fast decrease in both use frequency and the number of users of home spirometry over time. Only a small group of people with CF continued to use home spirometry consistently during the study period. We observed a small but significant increase in the absolute number of home spirometry measurements during periods of increased pulmonary symptoms on a group level as well as shortly after initiation of Elexacaftor/Tezacaftor/Ivacaftor treatment. Moreover, during increased symptoms, up to a fifth of users measured their lung

XSL•FO
RenderX

function at home whereas they did not during periods of few pulmonary symptoms.

Comparison With Literature

Low adherence to home spirometry protocols has been identified as a recurring problem in many prospective trials [8-11,13]. Our results show that the frequency of home spirometry monitoring might be even lower in routine care. This discrepancy could partly be attributed to differences in study designs. First, selection bias is inherent to trials as they select highly skilled and motivated patients or patients with few comorbidities for whom preventing a decline in pulmonary function is the highest priority. Second, this was a retrospective study in the time frame of the COVID-19 pandemic and during the introduction of Elexacaftor/Tezacaftor/Ivacaftor treatment in the Netherlands. These enormous changes in CF care and the lack of a home spirometry protocol might have limited the uptake of home spirometry in our study.

In previous work, we identified multiple incentives (eg, changes in the physical condition and positive psychosocial effects) and disincentives (eg, technical difficulties and lack of perceived need) for regular home monitoring of lung function [7]. Regular use of home spirometry requires patients to allocate time and effort to perform the measurements and this increases the already high treatment burden of people with CF [14-16]. When there are no clear benefits from home spirometry or reductions in overall treatment burden, people with CF might have little motivation to keep measuring their lung function at home regularly [7]. This is emphasized by our findings that an increase in pulmonary symptoms and initiation of Elexacaftor/Tezacaftor/Ivacaftor temporarily increased both the number of users and the number of home spirometry tests. Increases in symptoms and new modulator therapies provide clear incentives and a perceived necessity for people with CF to measure their lung function, but during stable periods these incentives may be less evident.

A previous study showed prolonged uptake in home spirometry in children compared with adults, but the authors also reported that increased supervision of health care professionals in pediatric care might have attributed to this difference [11]. In our study, younger people with CF had just slightly better uptakes of home spirometry than adults. However, we found large differences between CF centers, with much more consistent users in the adult and pediatric departments of one CF center. Interestingly, in this CF center, CF nurses cared for both the adult and pediatric populations. These CF nurses had created a clear strategy for the organization of remote care with policies for the initiation, follow-up, and administration of remote monitoring [7]. This strategy was likely used for both the adult and pediatric populations, whereas similar strategies were not necessarily present in other centers due to the turbulent period of the COVID-19 pandemic [7]. We already know that CF nurses play an important role in the successful implementation of home monitoring interventions, and these findings suggest that differences in uptake might not be due to the age of patients but rather due to the differences in the organization of care and policies regarding home spirometry across CF centers and departments [7]. This strengthens the conclusion that clear agreements within departments and with patients as well as clear policies for the initiation and follow-up of home spirometry may enhance its sustainability.

Strength and Limitations

To our knowledge, this is the first long-term study into the uptake of home spirometry in a real-world clinical setting. Moreover, our study benefited from the large number of participants, the multicenter setting, and the long follow-up time that increases generalizability to other settings. As stated earlier, the time of initiation of home spirometry was turbulent due to the COVID-19 pandemic and the introduction of Elexacaftor/Tezacaftor/Ivacaftor treatment. This may have affected the implementation of home spirometry and therefore use frequency. Moreover, CF departments were provided with spirometers and access to the RMP but were allowed to implement home spirometry according to their preferences. The uptake of home spirometry differed between CF departments and this may limit our overall findings. But these differences between centers also allowed us to hypothesize about the underlying causes of varying uptake such as the availability of motivated CF nurses and clear policies. Finally, because this study used anonymized data, we were unable to study the frequency of home spirometry within individual contexts such as treatment, health care consumption, socioeconomic background, and other important determinants for digital health use. In addition, due to the use of anonymized data, data on Elexacaftor/Tezacaftor/Ivacaftor treatment use was only available for a small number of users.

Future Directions

The role of home spirometry in the field of CF and other pulmonary diseases is becoming increasingly evident. However, to ensure that home spirometry does not become an inefficient and underused tool, it is imperative that we regard it as a means to an end instead of a goal on its own [17]. Goals should be tailored to individual needs and contexts, and the intensity of home spirometry monitoring should be adjusted accordingly. Centers should create clear policies for the organization of remote care that address how to set, initiate, follow up, and evaluate these goals on an individual basis to ensure successful implementation.

We previously identified four “Sensible Strategies for Remote Monitoring” as a set of predefined goals that can be adopted in CF care [7]. In our study, CF centers mostly seemed to adopt symptom-driven strategies where home spirometry was used to quantify symptoms when needed rather than at regular intervals. However, the positive attitude from our questionnaire results implies that it is not just the frequency of use that creates the benefits [7]. Nevertheless, some people with CF might benefit from regular home monitoring within patient-driven strategies that address individual needs, but a widespread application seems limited.

There is an increasing interest in prediction-driven strategies that use regular home spirometry to predict a decline in pulmonary function or other clinical outcomes [9,10,18]. However, these strategies only work when people with CF monitor themselves frequently over extended periods of time,

XSL•FO
RenderX

also during periods of stability. Our results show these strategies are likely not feasible for the long term or the majority of users. To mitigate this, studies will have to devise solutions to solve the problem of low adherence many of these studies face. They will have to devise solutions and address the lack of perceived necessity for people with CF to measure their lung function during periods of stability. This could include limiting their studies to people with CF who deteriorate often or reducing treatment burdens elsewhere to ensure that home spirometry is not just an additional burden (eg, care-driven strategies that replace regular care with remote monitoring) [15,19].

Hence, there should be a stronger emphasis on whether home spirometry can support individual patients and what intensity of home monitoring best fits individual goals. The frequency of home spirometry on its own is meaningless when not coupled with clear strategies. This approach will not only prevent the introduction of new "monitoring-adherence discussions" in our clinics, but it will also ensure that remote monitoring remains value-driven.

Conclusion

Consistent uptake of home spirometry in regular long-term multicenter CF care is low but appears to increase around periods of changing symptoms. A clear strategy for the organization of remote care seems to stimulate long-term uptake of home spirometry. Nevertheless, frequent and regular home spirometry monitoring might not be feasible for all patients and all the time. Instead, home spirometry and its intensity are not a goal but should be used as a tool to reach individual patient goals within local contexts.

Acknowledgments

We would like to thank the Dutch CF Foundation for donating the portable spirometers. This research did not receive any specific grant from funding agencies in the public, commercial, or not-for-profit sectors. Anonymized data from this study will be made available upon reasonable request. No generative AI was used at any stage of this study.

Abstract

Background: Early intervention during the first 3 years of life is crucial for children with developmental disabilities to optimize developmental outcomes. However, access to such services is often limited by geographical distance and resource constraints. Telehealth can be part of a solution for overcoming these barriers, enabling the delivery of early intervention services. However, a comprehensive understanding of the efficacy and implementation of telehealth in early interventions remains elusive, particularly for children aged 0-3 years.

Objective: This systematic review aims to synthesize existing research on the effectiveness and implementation of telehealth interventions in infants and toddlers (aged 0–3 years) who are at risk of or diagnosed with developmental disabilities. The primary objective of the study is to evaluate the ways that telehealth compares to conventional in-person interventions in improving developmental outcomes for children and supporting family well-being.

Methods: A systematic search was conducted of 4 electronic databases (PubMed, Embase, CINAHL, and Web of Science), focusing on studies published between 2010 and 2024. The inclusion criteria were studies involving telehealth interventions for children aged 0-3 years who were at high risk or had developmental disabilities, which involved active interactions between the providers and the families. Study quality was assessed using the mixed methods appraisal tool, and a narrative synthesis was used to analyze the data.

Results: Eighteen studies met the inclusion criteria: 12 single-case designs, 4 randomized controlled trials, and 2 nonequivalent control group designs. All studies involved caregiver-child dyads, with child ages ranging from 5 to 37 months and having or at risk of autistic spectrum disorder (n=10, 56%), cerebral palsy (n=4, 22%), and other conditions (n=4, 22%). Synchronous videoconferencing was the primary modality for caregiver training and coaching (n=17, 94%) while 1 intervention used an Internet of Things system. Outcomes were identified in child communication (n=9, 50%), physical (n=6, 33%), social or emotional (n=6, 33%), and adaptive behavior (n=4, 22%), as well as caregiver implementation (n=12, 66%). Telehealth demonstrated comparable or superior effectiveness to traditional in-person methods in 2 studies. However, the focus on specific conditions and limited research on cognitive development were notable gaps.

Conclusions: Telehealth can be a viable alternative to traditional in-person early interventions for young children who have developmental disabilities and their families. It enhances accessibility and interactions between families and providers at a distance while promoting family-centered care. Challenges exist, including those of technological literacy, and the lack of research on cognitive outcomes must be addressed. Future work should explore more comprehensive interventions, including multidisciplinary approaches and expanded family outcomes, to solidify the role that telehealth plays in early intervention.

KEYWORDS

developmental disabilities; developmental delay; early intervention; telehealth; digital intervention; autistic spectrum disorder; cerebral palsy; family-centered care; multidisciplinary care; systematic review

Introduction

Child mortality rates have decreased dramatically in recent decades, but the prevalence of developmental disabilities in children is gradually increasing [1,2]. Developmental disabilities are a group of conditions due to an impairment in physical, learning, language, or behavior areas, including but not limited to autistic spectrum disorder (ASD), down syndrome (DS), attention-deficit/hyperactivity disorder, cerebral palsy (CP), and learning disabilities [3]. These generally manifest during the developmental period, and their effects typically persist throughout life [3].

Historically speaking, developmental disabilities have been predominantly recognized for their negative impacts on the physical and psychosocial health of affected individuals [4]. Indeed, developmentally disabled children and their families can expect to encounter an endless series of daily challenges that can undermine the overall functioning of the entire family [5,6]. However, positive experiences have also been reported by parents raising children who have developmental disabilities, such as their feelings of appreciation, improved tolerance and sensitivity toward others, opportunities for learning, and deeper familial connections [7,8]. Effective advocacy, including promoting family-centered interventions and socioeconomic support, can reinforce well-being and resilience in such families [9,10].

Early intervention is an umbrella term encompassing a range of services and support that are provided for developmentally vulnerable infants, toddlers, and their families to enable them to achieve their optimal competencies and quality of life [11,12]. Robust neurological evidence supports the strong recommendation to provide early intervention in the first 3 years of life, which is a period of high brain plasticity [13-19]. This addresses 5 critical domains of development—the cognitive, physical, adaptive behavioral, social or emotional, and communication domains—to mitigate developmental challenges and maximize children's developmental potential [13]. In addition, in that multidisciplinary and family-centered care (FCC) are critical principles for early intervention [14-18], the positive effects of early intervention extend to family outcomes including parents' competency and appraisal, family relationships, and family quality of life [19-21].

In spite of substantial research that has demonstrated the positive effects of early interventions on children who have developmental disabilities and their families [4,22], several factors continue to impede the accessibility of such services, including complex referral and provision systems, long wait times, and geographical distances [23,24]. The COVID-19 pandemic has only exacerbated the challenges faced by these families, reducing their access to in-person services [25]. Rural areas and underdeveloped societies tend to be more vulnerable to these issues, aggravating existing health disparities [26,27]. In response to these challenges, telehealth has emerged as a solution that can help address the limitations of traditional early intervention methods, such as accessibility issues and resource shortages.

For several decades, telehealth has been extending its sphere of influence and making remarkable advancements [28]. Recently, the COVID-19 pandemic has accelerated its growth, going beyond a proper alternative to becoming an essential method of global health care [29]. While the terminology of telehealth is often used interchangeably with other terms, including telemedicine, telepractice, and teleintervention, telehealth is the broadest term that encompasses all types of remote health care services delivered via technology, as suggested in multiple definitions of telehealth [30-32]. World Health Organization defines it as any method of delivering "health care services, where patients and providers are separated by distance," so long as they use "information and communication technologies for the exchange of information" [32]. Medicaid suggests a narrower definition of telehealth as permitting "2-way, real-time interactive communication between the patient and the physician or practitioner at the distant site" via audio or video components [30].

Previous research has investigated the effectiveness of telehealth across health conditions and health care settings [33,34]. Telehealth is a promising means of overcoming distance, contributing to the prevention of infections, and narrowing health disparities between urban and rural areas, as well as between developed and underdeveloped societies [28].

Young children who have developmental disabilities are among the populations that benefit from telehealth. Previous research has found that telehealth is as effective as or better than traditional methods of delivering rehabilitation, parent-mediated intervention, and parent coaching to children who have developmental disabilities [35-37]. A few reviews have demonstrated the success of early interventions via telehealth. Still, these include a wider range of ages, up to 7 years [38,39], despite the heterogeneity in children's developmental stages. Further, these reviews tend to limit their focus to specific diagnoses (eg, ASD, CP) or particular types of intervention (eg, mobile apps, websites) [40,41]. To understand the implementation and effectiveness of early intervention via telehealth precisely, it is indispensable to focus on children aged 0-3 years and not to limit types of developmental disability or delay and telehealth modalities.

This systematic review compiled and synthesized the literature on early intervention via telehealth for children who have a high risk of developmental disabilities and their families, focusing on evaluating the implementation process and the effectiveness of these interventions. The main research question, structured in Patient, Interested Intervention, Comparison, Outcome (PICO)

XSL•FO
RenderX

format, was "Is early intervention via telehealth (I) effective in improving outcomes (O) for infants and toddlers aged 0-3 years with or at high risk for developmental disabilities and their families (P), relative to conventional in-person intervention (C)?"

Methods

Methodology

The review was conducted and reported using systematic review methodologies from the Joanna Briggs Institute [42].

Selection Criteria

The inclusion and exclusion criteria are described in Textbox 1. In this study, early intervention via telehealth was defined as using information and communication technologies to enable active interactions between children or families and service providers, either synchronously or asynchronously. This definition reflects the nature of early intervention, which involves active engagement and collaboration of families and providers [13]. Thus, studies adopting telehealth modalities only for recording, monitoring, self-management, assessment, or diagnosis were excluded, as they do not involve the interactive process integral to early intervention practices.

Textbox 1. Inclusion and exclusion criteria for study selection.

Inclusion criteria

- Population: children aged 0-3 years with or at high risk of developmental disability
- Intervention: telehealth interventions involving interactions with a health care provider
- Outcomes: results including child or family outcomes
- Study design: empirical studies
- Year: January 2010 to April 2024
- Language: available in English

Exclusion criteria

- Population: children older than 3 years of age
- Intervention: adoption of telehealth modalities only for recording, monitoring, self-management, assessment, or diagnosis without interaction or feedback from health care providers
- Outcomes: results not reporting child outcomes
- Study design: nonempirical studies (eg, editorials, study protocols, or review studies)

Search Strategy

A comprehensive literature search of 4 bibliographic databases (PubMed, Embase, CINAHL, and Web of Science) was conducted to identify studies using free keywords and the index vocabulary tailored for each database. The search strategy adopted was developed in collaboration with a librarian expert in the field. The search terms were a combination of three categories: (1) developmental disabilities, (2) telehealth, and (3) early intervention (Multimedia Appendix 1).

Study Selection

For the study selection, all search references were imported into Covidence (Veritas Health Innovation), a management tool used to review studies. After the exclusion of duplicates, 2 reviewers independently screened the title and abstract, followed by a full-text review. Disagreements were resolved by the corresponding author. For data extraction, a template was developed using the software program Microsoft Excel to collate specific information from the included studies.

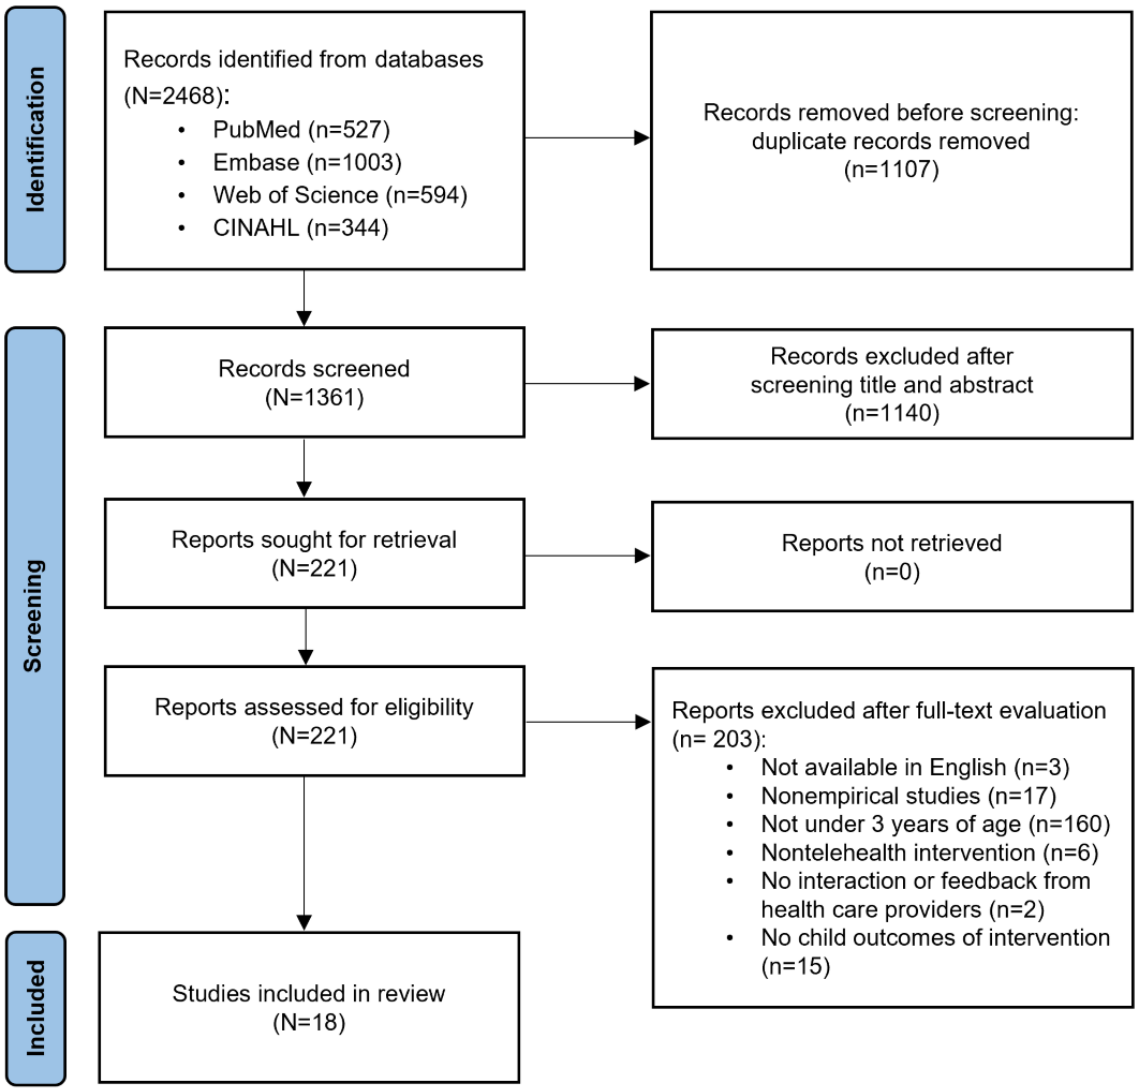
Quality Assessment

Quality assessment was conducted using the mixed methods appraisal tool [43] to ensure the methodological quality of the studies included (Multimedia Appendix 2 [44-61]). This tool includes 5 distinct checklists for empirical studies across categories. Each criterion could be assigned to "yes," "no," or "can't tell." The total quality score for each article ranged from 0% to 100%, where higher scores indicated higher methodological quality. Two researchers independently appraised each study, and conflicts or criteria that were answered as "can't tell" were discussed with the corresponding author. The threshold for inclusion was 60% or more.

Data Extraction and Synthesis

Due to the heterogeneity of the populations, interventions, and outcome measures across studies, a narrative synthesis was conducted following the guidance of Popay et al [62]. Two researchers investigated the selected studies thoroughly to develop a standardized tabular form for the extraction and synthesis of the data. The synthesis included (1) the general characteristics of the studies that were included (authors, study location, study design, target functions, and technological modalities); (2) their population characteristics (diagnosis or condition, sample size, age, and sex); (3) the intervention characteristics (program title or theoretical base, provider or profession, description, control, and duration), and (4) the outcome characteristics (variables, measurements, and main findings). The frequency of the technological modalities and target functions across the included studies were described in independent matrix tables. Minor disagreements that arose during the process were resolved by consensus between the

XSL•FO
RenderX



investigators. The corresponding author was brought in when consensus could not be reached.

Results

Overview

An electronic search yielded 2468 studies, of which 18 were ultimately included in the review. The screening process is detailed in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) diagram, shown in Figure 1.

Figure 1. Flow diagram of study selection following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guideline.

Quality Assessment

Of the 18 selected studies, 4 studies were evaluated using the checklist for quantitative randomized controlled trials, all scoring 100% (Multimedia Appendix 2). A checklist for quantitative non-randomized research was used to assess 13 studies. Of these, 7 studies scored 100%, 5 studies scored 80%, and 1 study scored 60%, due to an unclear indication of participant eligibility (n=3, 50%), an incomplete exhibition of outcome data (n=2, 33%), or an inadequate consideration of potential confounders (n=2, 33%). One study was categorized as a mixed methods study and scored 100% on the quality assessment.

General Characteristics of the Reviewed Studies

Of the 18 studies included, 13 were published between 2020 and 2024, following the onset of the COVID-19 pandemic (Multimedia Appendix 3 [44-61]). The studies were primarily conducted in the United States (n=10, 56%), with others from Canada (n=2, 11%), Brazil (n=3, 17%), Italy or Denmark (n=1, 6%), Iran (n=1, 6%), and Sweden (n=1, 6%). The designs of the studies were varied, including single-case designs (n=11, 61%), randomized controlled trials (n=4, 22%), and nonequivalent control group designs (n=3, 17%). The sizes of the samples ranged from single cases to 82 participants, including 8 studies featuring 6 or fewer participants.

XSL•FO
RenderX

Participant Characteristics

Most studies focused on children at risk for or diagnosed with ASD (n=10, 56%; Multimedia Appendix 3 [44-61]). Other studies included children at risk for CP (n=4, 22%), born preterm (n=1, 6%), with DS or developmental delays (n=1, 6%), with DS and visual impairment (n=1, 6%), or with a hearing impairment (n=1, 6%). Among the 12 that specified the sex of the child participant, 147 were boys (62.3%), and 89 were girls (37.7%). The ages of the children ranged from 5 to 37 months.

All studies, with the exception of one, which included a child and both of her parents [44], recruited participants as caregiver-child dyads. In all, 14 studies specified the caregiver's sex; 170 (88.1%) were female, and 23 (11.9%) were male. Although none of the studies purposefully recruited mother-child dyads, seven ended up having 100% female caregivers, all of whom were the child's mothers, except for 1 grandmother [45]. Eight studies reported the ages of the caregivers, which ranged from 20 to 48 years.

Intervention Characteristics

Technological Modalities

Videoconferencing using devices such as smartphones, tablets, or personal computers was predominantly used (n=17, 94%) to deliver interventions (Table 1). The only exception was Sgandurra et al [46] who used an Internet of Things (IoT) baby gym, which enabled remote, highly personalized rehabilitation and monitoring. Websites or multimedia modules (n=2, 11%) and data sharing platforms or clouds (n=8, 44%) were used to facilitate data sharing between providers and families. Two studies used an IoT system or a wearable device to monitor children's functioning [46,47].

Intervention Contents

The intervention characteristics are given in Multimedia Appendix 4 [44-61]. Among the 17 studies that used videoconferencing, all but 1 study [45], which included both individual and group sessions, conducted one-on-one sessions to provide parent training, coaching, or both. In the sessions, the providers delivered knowledge of strategy, answered questions, monitored caregiver-child interactions, and provided real-time feedback.

Nine out of 17 studies had children participate in live sessions to observe caregivers' strategy implementation, monitor their progress, and provide coaching at the moment [44,47-54]. The remaining 8 studies involved only researchers and caregivers, focusing on the delivery of strategies so that caregivers could apply them to their children later. Four studies prescribed dosage for caregivers' self-practice outside of the videoconferencing sessions [54,55,57, 60], where 3 required caregivers to log their progress, whether online or offline. In addition, 7 studies individually tailored the goals and plans of the programs as a result of discussions conducted between providers and caregivers, which increased the extent of the individualization of the interventions offered [49,51,54,55,57,58,61].

XSL•FO
RenderX

In addition to videoconferencing, in 5 studies, the caregivers [53,54,56-58] received training in multimedia modules provided through web platforms or DVDs, primarily containing video and written instructions. The caregivers were instructed to use the modules for self-teaching in a predetermined sequence or at their own pace. The IoT baby gym system that was used by Sgandurra et al [46] provided daily goal-directed activities based on the child's condition monitored through video cameras, wearable sensors, and other sensorized components, such as mats and toys.

The interventions for all 18 studies were provided by researchers who had relevant experience with the target population. Nine studies indicated the professions or professional qualifications of service providers, which included special educators (n=3, 17%), physiotherapists/occupational therapists (n=3), behavior analysts (n=2, 11%), and psychologists (n=1, 6%). The average intervention was approximately 10.2 weeks long, ranging from 4 to 29 weeks, except for 1 study, which only stated the number of sessions (42-57 sessions) [48]. The average frequency was approximately 1.6 sessions per week, with the 4 aforementioned studies including additional self-practice components [52,53,55,60]. Each session continued for an average of approximately 54.3 minutes, with a range of 15 to 90 minutes.

Effectiveness of Interventions

All of the included studies suggested the overall effectiveness of the interventions on child outcomes, with some degree of variability (Multimedia Appendices 3 and 4 [44-61]). In each of the 18 studies, the interventions targeted one or more domains of child development (Table 2). Among the 5 early-intervention domains, the development of communication was most frequently addressed (n=9, 50%), as measured through variables such as communicative behaviors (eg, initiation, response, and vocal imitation) and the number of words used. Studies targeting social/emotional development (n=6, 33%) assessed social behaviors, including joint attention, social turn-taking, and behavior imitation. General or specific motor skills were measured for physical development (n=6, 33%). The development of adaptive behavior (n=4, 22%) was evaluated with flexible and inflexible behavior, repetitive and restricted behaviors, instrumental turn-taking, and daily activities. It should be noted that cognitive development was not specifically targeted as part of any of the included studies.

Table 2. Frequencies of child functions targeted in the reviewed studies based on early intervention domains [13].

More particularly, among the child outcomes, the communication skills of children with or at risk for ASD were the most frequently reported (n=7, 39%), followed by the motor function of infants having or at biological risk for CP (n=4, 22%). The adaptive behavior of children with or at risk for ASD has been assessed in 3 studies [50,59,60]. Six studies included control groups, three of which provided in-person or traditional care to the control groups. Two studies reported nonsignificant differences between the invention (telehealth) and the control (in-person or traditional care) groups.

The outcomes for caregivers and families were reported in 12 studies, among which 10 demonstrated increased or appropriate levels of caregivers' implementation fidelity for learned

XSL•FO
RenderX

strategies. Implementation-related outcomes, such as acceptability, feasibility, satisfaction, and cost efficiency were also measured. In addition, interventions were reported to improve clinical outcomes for caregivers and families, including parenting stress (n=2, 11%), caregiver engagement (n=1, 6%), self-efficacy (n=1, 6%), and home environment (n=1, 6%), although these did not consistently reach statistical significance.

Discussion

Principal Findings

This review synthesized the existing literature on early interventions through telehealth for young children who have developmental risks and examined their implementation and effectiveness. A distinguishing feature of this review is that the child participants were restricted to the ages of 0-3 years, strictly following the extensively recommended criteria for early intervention. Thereby, this study enabled a concrete inspection of current practices in telehealth interventions that were precisely aimed at young children during their first 3 years and their impact.

Effectiveness

This review identified the overall effectiveness of early interventions via telehealth for both children and their families. In particular, children showed improvement in their targeted abilities and behaviors, in general, corresponding to the caregivers' enhanced or sufficient fidelity for implementing learned strategies. The effectiveness was comparable to those of in-person approaches. This finding is consistent with previous studies that have addressed the effectiveness of telehealth interventions for children and youths with developmental disabilities [35]. McCarthy et al [63] and Bharat et al [40] suggested a potential for telehealth or mobile apps in delivering early intervention for children aged under 6 with ASD or hearing difficulties. For older children and adolescents, multiple reviews have indicated that telehealth interventions for ASD [41,64,65] and CP [66] are at least as effective as traditional methods. Telehealth interventions demonstrate sustained effectiveness throughout childhood in children who have developmental challenges.

Scope of Child Conditions and Target Outcomes

However, early interventions through telehealth included in the studies were less comprehensive, with limited populations or target functions relative to traditional in-person interventions. Most interventions targeted either communication development in children who have ASD during their second or third years of life or motor development in infants with CP; none of the included studies targeted or examined child outcomes in relation to the cognitive domain. Cognitive ability serves as the foundation for early childhood development, and it affects overall health and socioeconomic status during the later stages of life [67,68]. This underscores the importance of early intervention for enhancing cognitive development [69,70], highlighting further attention to this omission. The alienation of cognitive outcomes is also observed in telehealth interventions for children who have developmental disabilities and are aged more than 3 years [41,65,71]. This suggests that adopting telehealth in comprehensive interventions including the cognitive domain for children having developmental disabilities or delays could accompany difficulties. Some conditions require specialized skills that are difficult to deliver virtually [72], and certain assessments require long periods or physical materials that may not be feasible using telehealth [73,74].

Despite these challenges, a comprehensive approach is uncompromisable for early intervention for children with developmental disabilities [75,76]. As a result of the interrelated nature of all aspects of development, such that the growth or deficiency in 1 area influences that of others, thereby either promoting or hindering overall development [13]. Thus, the study of early intervention for young children with developmental challenges has consistently striven to encompass cognitive, physical, adaptive behavior, social or emotional, and communication domains, and it has even expanded to include sensory integration, nutrition, and sleep [75,77-80]. To establish telehealth as a viable method for the delivery of early intervention, future research is encouraged to cover a more comprehensive range of developmental challenges.

Telehealth Modalities

The most widely used form of early intervention through telehealth was synchronous caregiver training or coaching through videoconferencing, engaging caregivers as the main implementers. The caregivers generally reported satisfaction with telehealth care. Real-time videoconferencing sessions between providers and caregivers produced positive feedback, in particular when it was combined with multimedia modules.

Telehealth interventions commonly meet certain barriers, including technological issues, lack of digital literacy, and negative perceptions of telehealth [81,82]. In pediatric care, telehealth assigns extra responsibility to caregivers for delivering interventions and maintaining an optimal environment for remote communication, which some find burdensome [83,84]. The caregivers in the included studies reported occasional internet issues and discomfort in moderating the home setting; however, these did not critically reduce their satisfaction with telehealth modalities.

Consistent reports of decent social validity could be attributed to the participants' ages and locations. Youths, internet access, and technological competency facilitate the use of telehealth, while old age, technological disconnection, and insufficient understanding of telehealth pose barriers [81,85]. Studies of early-intervention studies typically involve young individuals who have high digital literacy [86] and are often conducted in environments having stable internet connections, which likely contributes to positive feedback on telehealth. Future research should account for the digital divide according to age and region, as it prevents the generalizability of the results.

Family-Centered Care

The concept of early intervention is grounded in the principle of FCC, as has been established in key definitions and purposes emphasizing enhancements to parental capacity and supporting parent-mediated interventions [11,13]. The integration of telehealth into early intervention strengthens home-based family

XSL•FO
RenderX

participation and caregiver competence [87-89], promoting active family engagement within a natural environment, and leading to favorable outcomes for both child and family [39].

While the included studies incorporated FCC, there is potential for further improvement in its application in early intervention, in particular through telehealth [90]. Dyad-recruiting and caregiver coaching/training, the most common strategies used by the included studies, are reported to be effective in child development, caregiver implementation, and child-caregiver interaction [13,22,91-93]. However, a notable sex imbalance was seen in caregivers who were participating in the studies, with mothers predominantly participating. This inclination toward the mother aligns with prior FCC research, which attributes it to traditional sex roles, lack of tailored services, and limited awareness of both families and providers [22,94-97]. Nonetheless, fathers' engagement is linked to the improved cognitive, emotional, behavioral, and psychopathological development of young children [98-100], and involving siblings as playmates or models is associated with enhanced peer relationships and social skills [101,102]. Future research should explore strategies to increase father and sibling involvement in FCC interventions.

In addition, most included studies had family outcomes that were limited to caregivers' implementation in the absence of clinical outcomes, underscoring the need for further exploration of caregiver and family outcomes to develop and evaluate FCC-based early interventions through telehealth. Research indicates that parents' physical and mental health directly affects their ability to provide care and support for their children, which, in turn, impacts children's developmental progress and overall well-being [103,104]. By contrast, the severity of children's developmental disabilities can also affect parental health, producing an interplay within families [105-107]. Therefore, more comprehensive research is required to explore the whole family's outcomes when evaluating the effects of telehealth early interventions.

Multidisciplinary Approach

A multidisciplinary approach should also be considered, as each intervention in the included studies was conducted by individuals from a few professions, including physiotherapists, behavior analysts, and special educators. While the focused expertise of the providers could allow for intensive interventions in particular areas, collaboration among diverse professions fosters a comprehensive understanding of conditions, integrative problem-solving, and effective risk management, ultimately enhancing the quality and outcomes of the intervention [108-110]. A multidisciplinary team, including education, medical care, rehabilitation, community service, and family, can reflect the holistic nature of children who have developmental disabilities and their families [111,112]. In particular, thanks to early intervention, a multidisciplinary approach can be posited as an essential principle for the promotion of individualization and family engagement and achieving optimal development [113].

Limitations

To the best of our knowledge, this is the first systematic review to synthesize the use of telehealth in early intervention for young children aged 0-3 years and their families, involving developmental challenges. However, this study has some limitations.

First, a large portion of the included studies used single-case designs, which pose challenges in generalizing findings to broader populations. This limitation hindered our analysis to compare the overall effectiveness of telehealth interventions to traditional methods or evaluate variability in effectiveness across different groups based on factors such as participants' age, sex, and developmental disabilities of the children.

Consequently, we were unable to calculate effect sizes for a statistical synthesis, limiting our ability to draw definitive conclusions about the effectiveness of early intervention delivered through telehealth.

While our search terms were meticulously developed in collaboration with an institutional librarian specializing in medical research, the scope of our search could be further refined. The exclusion of gray literature may have omitted informal data or professional experiences beyond traditional research settings. Additionally, limiting the review to published studies introduces a potential risk of publication bias, as studies with positive results are more likely to be published. Future research incorporating a wider range of integrative works, including gray literature, could enhance the generalizability and provide a more comprehensive understanding of telehealth's impact on early intervention.

Finally, the findings predominantly come from developed, primarily Western countries. This limitation may be due to restricting the search to English-language studies, as well as the concentration of related research in these regions. In many low- and middle-income countries, early intervention remains a lesser-known concept [114], and the necessary infrastructure for telehealth delivery is often lacking [115]. These considerations may explain the geographic biases of this review; nonetheless, the findings serve as a foundation for guiding future research and policies to expand access to early intervention via telehealth in underserved communities.

Conclusions

This review highlights the potential that telehealth has for early intervention for young children having developmental challenges and their families. By synthesizing the existing literature, we observed that telehealth, mainly in the form of synchronous caregiver training or coaching, can effectively enhance child and family outcomes across various areas. Despite its limitations, the adoption of telehealth technologies in early intervention is a promising direction for researchers, clinicians, and educators to deliver holistic, FCC for young children with developmental disabilities at a distance. This integrative approach will ultimately benefit children who have developmental challenges and their families in remote or underserved areas by improving developmental outcomes and the quality of life within families. Finally, we call for additional high-quality research that expands the scope of telehealth early

XSL•FO
RenderX

interventions and ensures a comprehensive, multidisciplinary approach for children with developmental disabilities and their families, which can generate robust and generalizable evidence.

Abstract

Background: Cognitive deterioration is common in multiple sclerosis (MS) and requires regular follow-up. Currently, cognitive status is measured in clinical practice using paper-and-pencil tests, which are both time-consuming and costly. Remote monitoring of cognitive status could offer a solution because previous studies on telemedicine tools have proved its feasibility and acceptance among people with MS. However, existing smartphone-based apps include designs that are prone to motor interference and focus primarily on information processing speed, although memory is also commonly affected.

Objective: This study aims to validate a smartphone-based cognitive screening battery, icognition, to detect deterioration in both memory and information processing speed.

Methods: The icognition screening battery consists of 3 tests: the Symbol Test for information processing speed, the Dot Test for visuospatial short-term memory and learning, and the visual Backward Digit Span (vBDS) for working memory. These tests are based on validated paper-and-pencil tests: the Symbol Digit Modalities Test, the 10/36 Spatial Recall Test, and the auditory Backward Digit Span, respectively. To establish the validity of icognition, 101 people with MS and 82 healthy participants completed all tests. Of the 82 healthy participants, 20 (24%) repeated testing 2 to 3 weeks later. For each icognition test, validity was established by the correlation with its paper-and-pencil equivalent (concurrent validity), the correlation and intraclass correlation coefficient (ICC) between baseline and follow-up testing (test-retest reliability), the difference between people with MS and healthy participants, and the correlation with other clinical parameters such as the Expanded Disability Status Scale.

Results: All icognition tests correlated well with their paper-and-pencil equivalents (Symbol Test: r=0.67; P<.001; Dot Test: r=0.31; P=.002; vBDS: r=0.69; P<.001), negatively correlated with the Expanded Disability Status Scale (Symbol Test: ρ=–0.34; P<.001; Dot Test: ρ=−0.32; P=.003; vBDS: ρ=−0.21; P=.04), and showed moderate test-retest reliability (Symbol Test: ICC=0.74; r=0.85; P<.001; Dot Test: ICC=0.71; r=0.74; P<.001; vBDS: ICC=0.72; r=0.83; P<.001). Test performance was comparable between people with MS and healthy participants for all cognitive tests, both in icognition (Symbol Test: U=4431; P=.42; Dot

XSL•FO
RenderX

Test: *U*=3516; *P*=.32; vBDS: *U*=3708; *P*=.27) and the gold standard paper-and-pencil tests (Symbol Digit Modalities Test: *U*=4060.5, *P*=.82; 10/36 Spatial Recall Test: *U*=3934; *P*=.74; auditory Backward Digit Span: *U*=3824.5, *P*=.37).

Conclusions: icognition is a valid tool to remotely screen cognitive performance in people with MS. It is planned to be included in a digital health platform that includes volumetric brain analysis and patient-reported outcome measures. Future research should establish the usability and psychometric properties of icognition in a remote setting.

Introduction

Background

Medicine is increasingly digitalizing, and there are compelling reasons to stimulate this trend. Clinicians can more easily access and share electronic health records, and storing data in a digital format facilitates visualization and organization in research databases, yielding new insights into pathology and disease management. Moreover, electronic health records drive artificial intelligence research [1], while artificial intelligence, in turn, further stimulates storing records digitally [2], closing a positive feedback loop. Far from being a mere "nice to have," digital medicine was crucial during the COVID-19 pandemic [3], enabling telemedicine services to be provided when social distancing was essential.

Telemedicine provides practical solutions for people with multiple sclerosis (MS), a chronic disease characterized by inflammation and degeneration of the central nervous system [4]. Telemedicine tools are well accepted by patients, and their feasibility and cost-effectiveness have been established previously [5]. Moreover, patients tend to objectively benefit from the use of these tools, which can, for example, aid in fatigue management [6] and improve cognitive function [7]. The latter is important because nearly half of the people with MS have cognitive impairment [8], which has significant repercussions on daily life activities, societal participation, employment, and susceptibility to psychiatric disorders [9].

Telemedicine could also facilitate cognitive monitoring of people with MS. First, it would allow increasing temporal resolution of cognitive trajectories because cognitive tests are usually performed during routine follow-up sessions that are months apart. This is problematic because cognitive decline can be sudden, unexpected, and severe (eg, in case of a relapse) [10,11]. Remote testing could help detect minimal changes early, enabling timely intervention. Second, it would unburden clinicians because current practice relies on paper-and-pencil tests administered under the supervision of a trained examiner.

Smartphones especially provide a window of opportunity, with an estimated 6.7 billion subscriptions worldwide (69% of the population) [12]. However, current smartphone-based cognitive assessments focus primarily on information processing speed (IPS) [13]; yet, besides slowed IPS, the hallmark cognitive problem in MS is impaired memory [14], for which the first smartphone test was only recently introduced by Podda et al [15]. Memory assessments emerged earlier on tablet devices [16] but are less suitable for consistent follow-up because tablet devices are used far less frequently than smartphones. Furthermore, smartphone tests might be prone to motor interference. They are predominantly digital versions of the Symbol Digit Modalities Test (SDMT) [17], which is a popular test in clinical practice to measure IPS and has excellent psychometric properties [18]. Digitalizing the SDMT allows randomizing its key, which could reduce practice effect as reported in the study by Pereira et al [19]. However, creating an exact digital replica of the SDMT requires patients to choose from 9 small buttons on the screen, which could cause motor interference because fine motor skills are commonly affected in MS [20].

Objectives

To tackle these limitations, in this study, we aim to validate a new smartphone-based cognitive screening battery called "icognition." It is a quick, smartphone-based screening tool for remote follow-up of the 2 most commonly impaired cognitive domains in MS: IPS and memory [14]. It is intended to be part of the recently established icompanion app, a digital diary for people with MS [21]. Regular remote screening could enable faster confirmation of cognitive deterioration by a neuropsychologist and prompt intervention by the patient's neurologist.

Methods

Study Design

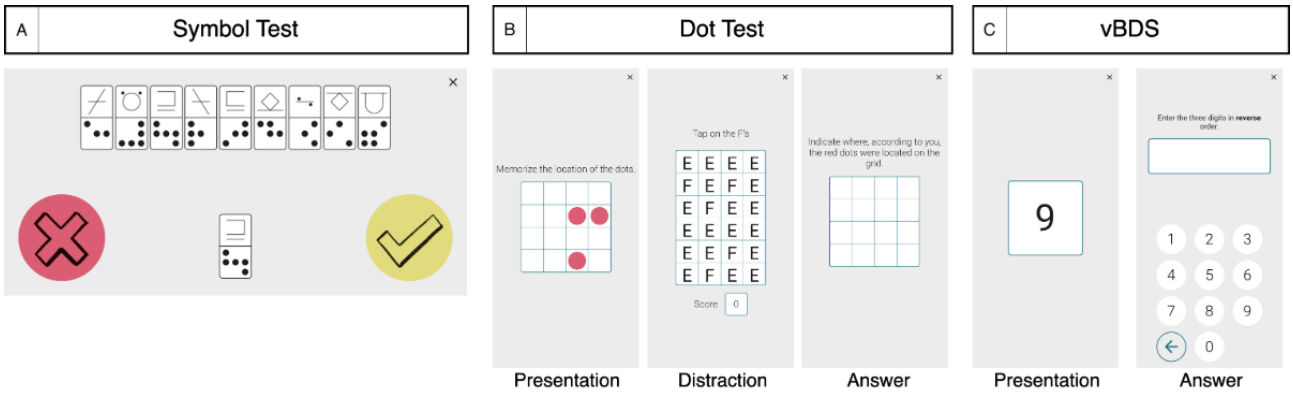
This is an observational case-control study designed to validate the icognition smartphone app.

Participants

Study participants were recruited between June 17, 2021, and January 3, 2023. People with MS were enrolled from the outpatient clinics of the neurology department at Universitair Ziekenhuis Brussel (secondary care) and the National MS Center at Melsbroek (tertiary care). They were recruited by the local study nurse during their follow-up visit. Healthy control participants were recruited via leaflets and the social networks of the researchers involved. Inclusion criteria for people with MS were a confirmed diagnosis of MS according to the McDonald criteria [22]. People with MS were excluded if they had been hospitalized for reasons other than rehabilitation or if they had experienced a relapse within the past month. Both people with MS and healthy control participants were excluded if they had any other neurological or psychiatric disorder or learning disorder. A total of 101 people with MS and 82 healthy control participants (matched on age, sex, and education level)

XSL•FO
RenderX

met the inclusion and exclusion criteria for this study. All participants were either Dutch-speaking or bilingual, including Dutch, and were aged ≥18 years.



Ethical Considerations

This study was approved by the medical ethics committee of Universitair Ziekenhuis Brussel (BUN 143201940335) and the National MS Center at Melsbroek. All participants signed informed consent (in Dutch) before inclusion. Data were pseudonymized and stored in the protected OneDrive cloud service (Microsoft Corporation) of Vrije Universiteit Brussel. When publicly shared via GitHub, as explained in the Data Availability section, the data will be anonymized. This manuscript presents the primary analysis of these data. Participants did not receive compensation for taking part in the study.

icognition Screening Battery

The icognition cognitive screening battery consists of 3 tests (Figure 1).

Figure 1. Screenshots of the icognition tests (although the instructions were in Dutch during testing, they are presented here in English). (A) The Symbol Test for information processing speed (score=number of correct responses [does the symbol combination occur in the key?] in 90 s). (B) The Dot Test for visuospatial short-term learning and memory (score=total number of correctly indicated dots across 10 trials [maximum score=30]). (C) Visual Backward Digit Span (vBDS) for working memory (score=sum of span lengths of correct spans [correct inversion of shown span]).

The Symbol Test is based on the computerized Digit Symbol Substitution Test presented in the study by Rypma et al [23]. In the Symbol Test, a combination of symbols is presented to the participants, one at a time. A key, consisting of 9 pairs of symbols, is displayed at the top and is shuffled for each trial. For each trial, the participant needs to indicate whether the presented combination appears in the key. The total score is the number of correct answers provided in 90 seconds. This test is designed to assess IPS.

The Dot Test consists of 3 phases. In the first phase, a participant is presented a 4×4 grid in which 3 dots are shown for 3 seconds. Next, as a distractor task, the participant is shown a 4×6 grid of "E" and "F" shapes and must identify as many "F" shapes as possible in 4 seconds. In the last phase, the participant must indicate in an empty 4×4 grid where the 3 dots of the first phase were located. The Dot Test is inspired by the Dot Memory Test presented in the study by Sliwinski et al [24], with all grids reduced in size compared to their version (5×5 grids). We also implemented a criterion for the distractor task, requiring the participant to identify at least 3 "F" shapes. If this criterion was not met, the trial was restarted. The 3 dots could not be aligned on 1 line or form an L-shape within a 2×2 block of cells. The total score is the number of correctly indicated dots across 10 trials. This test is designed to assess visuospatial short-term memory and learning.

In the visual Backward Digit Span (vBDS), a series of digits is presented on the screen one by one, each for 1 second, as described in the study by Hilbert et al [25]. The participant must then list the digits in reverse order. Spans were randomly generated with digits between 0 and 9, with the following constraints: a digit can appear only once in the span, and a chain of ≥3 digits cannot have a fixed increment or decrement of 1 or 2 digits, in accordance with Woods et al [26]. Scoring is based on the sum of all correct span lengths; for example, if a participant correctly recalls 2 spans of length 3 and 1 span of length 4, the total score is 10. This test is designed to assess working memory.

All tests were performed on a Samsung Galaxy A10 smartphone (6.2-inch screen size) and were supervised by a test examiner. Each test was directly preceded by a practice phase to familiarize the participants with the respective test. This phase consisted of 5 trials for the Symbol Test, 3 for the Dot Test, and 4 (2 of length 3 and 2 of length 4) for the vBDS. The Symbol Test is performed with the smartphone in landscape orientation, whereas for the Dot Test and vBDS, the smartphone must be in portrait orientation. In the design of icognition, careful consideration was given to the potential biasing influence of fine motor impairment in MS [20]. Motor interference was minimized by using 2 large buttons for the Symbol Test (in contrast to digital SDMT variants where participants must choose from 9 smaller buttons [27]) and not placing any restrictions on the response time in the other icognition tests.

Validation Procedure

The procedure to validate icognition is based on the study by Benedict et al [28] and involves assessing 4 criteria, as outlined in the following subsections.

Concurrent Validity

We assessed how well each icognition test correlates with its paper-and-pencil equivalent. For the Symbol Test, the equivalent

XSL•FO
RenderX

was the SDMT [17]. In the SDMT, a sheet is presented to the participant with a key of 9 symbol-digit pairs at the top and a list of symbols without corresponding digits. In 90 seconds, the participant must convert as many symbols to digits as possible from the list, reading them out loud to the examiner, using the key. The Dot Test is based on the 10/36 Spatial Recall Test (SPART) [29]. In the SPART, the participant is shown a 6×6 grid with a pattern of 10 dots for 10 seconds. Subsequently, the grid is removed, and the participant is asked to replicate the pattern using 10 checkers. This process is repeated 3 times. The final score is the total number of correctly placed checkers across all trials. Finally, for the vBDS, a modified version of the Wechsler Adult Intelligence Scale, Fourth Edition, auditory Backward Digit Span [30] was used. In the auditory Backward Digit Span, digit spans are read out loud to the participant, who is asked to repeat them in reverse order. The original test consists of 2 trials for each span length, starting with a span of 2 digits and increasing by 1 digit each time the participant correctly completes at least 1 of the 2 trials. As discussed in Woods et al [31], in the original Wechsler Adult Intelligence Scale, Fourth Edition, design, participants with the same score can have a different number of correct spans. To mitigate this, we used a fixed number of spans, ranging from 3 to 7 digits in length (Table S1 in Multimedia Appendix 1). The complete list was always administered for each participant. The scoring metric is the same as described earlier for the icognition Backward Digit Span.

Test-Retest Reliability

Benedict et al [28] mention that test-retest reliability should be assessed on a "small sample" of either people with MS or healthy controls [28]. We aimed to retest the healthy controls 2 to 3 weeks after baseline testing. We used the intraclass correlation coefficient (ICC) to assess agreement between baseline and retesting, which is explained in more detail in the Statistical Analyses subsection.

Comparison of Performance

For each test, we compared the performance of people with MS to that of age-, sex-, and education level–matched healthy controls using the Mann-Whitney *U* test. The analysis was then repeated after correcting test performance for age, sex, and education level (Figure S1 in Multimedia Appendix 1). Details of the correction methodology are presented in the Statistical Analyses subsection.

Assessment of Correlations

Finally, we assessed the correlation of each icognition test with the Expanded Disability Status Scale (EDSS) [32], disease duration, the Beck Depression Inventory (BDI) [33], the Fatigue Scale for Motor and Cognitive Functions (FSMC) [34], education level, and age.

Data Curation

Data were entered independently by 2 researchers (SD and DVL). Conflicts in data entry were resolved through mutual discussion.

Statistical Analyses

We used an α level of .05 for all analyses. Participants with missing data on a certain test were only excluded for that specific test. We used the Spearman correlation for nonlinear and categorical variables (EDSS, BDI, FSMC, and education level), whereas the Pearson correlation was used otherwise. Mann-Whitney *U* tests were used for between-group distribution comparisons.

To assess test-retest reliability, following the approach of van Oirschot et al [35] and the guidelines by Koo and Li [36], we used the following ICC type: "two-way mixed effects, absolute agreement, single rater/measurement" (ICC[A,1]). In this study, the smartphone app served as the sole "rater," which is why we used a 2-way mixed effects model, appropriate when the "selected raters are the only raters of interest" [36]. For the same reason, the "type" of ICC was "single rater/measurement," while for "definition," we used "absolute agreement," reflecting the extent to which 1 rater's score (in our case, baseline testing) equals the other rater's score (in our case, retesting). The decision process is illustrated in the decision flowchart in the study by Koo and Li [36]. To interpret the magnitude of the test-retest reliability, we used the guidelines by Koo and Li [36]: poor (<0.50), moderate (0.50-0.75), good (0.75-0.90), and excellent (>0.90).

The magnitude of correlations was interpreted using the classification by Portney and Watkins [37]: small (<0.25), fair (0.25-0.50), moderate to good (0.50-0.75), and excellent (>0.75).

Finally, for each cognitive test, we fitted a regression equation with age, sex, and education level as independent variables and test performance as dependent variable on the healthy control data. This allows calculation of the expected score of a participant, given their age, sex, and education level, and subsequently comparison with the actual score of the participant, resulting in a *z* score. The technical details of the procedure, including the required values for performing *z* normalization on other data, are presented in Multimedia Appendix 1, while Table S2 in Multimedia Appendix 1 presents the values necessary to perform the procedure. Test performance was considered impaired if the *z* score was ≤−1.5, based on the study by Benedict et al [38].

Results

Overview

Participant characteristics are presented in Table 1.

Number impaired, n (%)	8 (7.9)	9 (11)	.65[d]

[a]The following variables had missing values: Expanded Disability Status Scale (n=7), 10/36 Spatial Recall Test (people with multiple sclerosis: n=1; healthy controls: n=1), Beck Depression Inventory (people with multiple sclerosis: n=2; healthy controls: n=1), Fatigue Scale for Motor and Cognitive Functions (people with multiple sclerosis: n=2; healthy controls: n=7), Dot Test (people with multiple sclerosis: n=3; healthy controls: n=1), and visual Backward Digit Span (people with multiple sclerosis: n=1). An additional 3 participants were excluded from the Dot Test analyses because they had been tested with an earlier version of icognition where a larger grid size was used. We reduced the grid size after these 3 participants were tested because we deemed this test to be too difficult. However, these 3 participants were included when the mean (SD) and number of participants considered impaired was calculated.

Concurrent Validity

Figure 2 shows the scatterplot of each icognition test with its paper-and-pencil equivalent. The Symbol Test showed a significant moderate to good correlation with SDMT performance (healthy controls: r=0.68; P<.001; people with MS: r=0.67; P<.001). There was also a significant fair correlation between the Dot Test and the SPART (healthy controls: r=0.30; P=.007; people with MS: r=0.31; P=.002) and a moderate to good correlation between the vBDS and its auditory equivalent (healthy controls: r=0.69; P<.001; people with MS: r=0.69; P<.001).

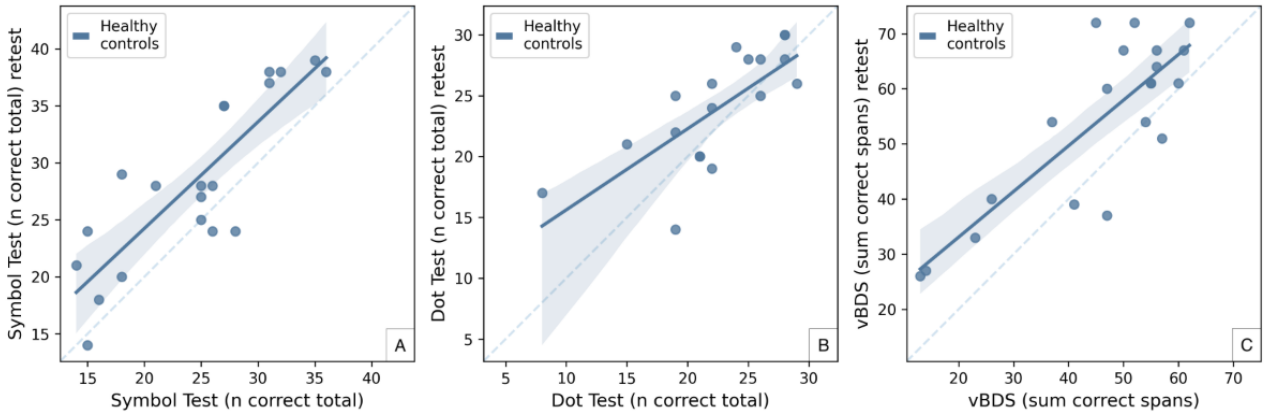

Figure 2. Concurrent validity. Scatterplots comparing the scores of each icognition test (x-axis) with those of its corresponding paper-and-pencil equivalent (y-axis). Correlations for both people with multiple sclerosis (MS) and healthy controls were (A) moderate to good, (B) fair, and (C) moderate to good. aBDS: auditory backward digit span; SDMT: Symbol Digit Modalities Test; SPART: 10/36 Spatial Recall Test; vBDS: visual Backward Digit Span.

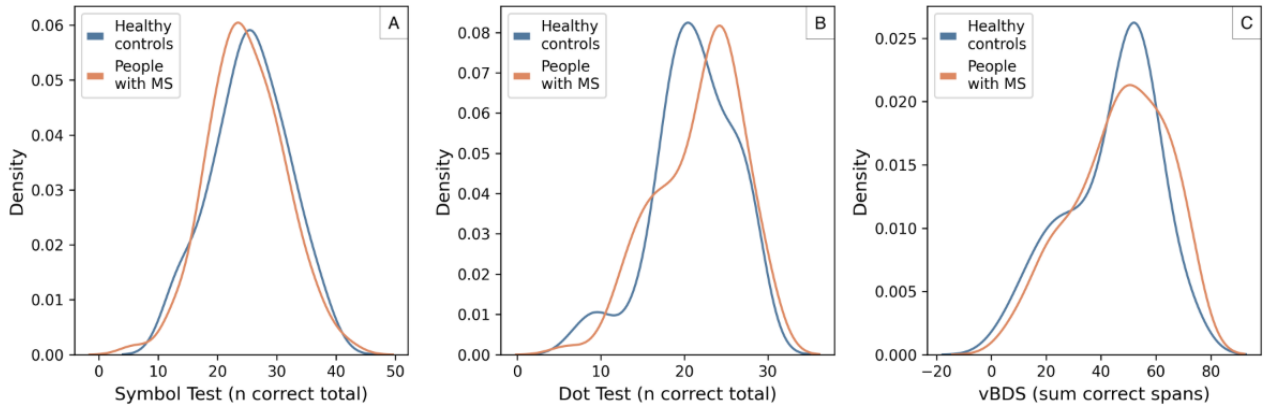
Test-Retest Reliability

In total, 20 healthy controls were retested with an average intertest interval of 18 (SD 3, range 14-23) days after initial testing to establish test-retest reliability. For the Dot Test, there was 1 missing value at baseline testing (n=19). Test-retest reliability (Figure 3) was moderate for the Symbol Test (ICC=0.74, r=0.85; P<.001), moderate for the Dot Test (ICC=0.71, r=0.74; P<.001), and moderate for the vBDS (ICC=0.72, r=0.83; P<.001).

Figure 3. Test-retest reliability. Scatterplots comparing the scores of each icognition test at baseline (x-axis) with the retest scores an average of 18 (SD 3) days later (y-axis). All tests demonstrated moderate test-retest reliability. vBDS: visual Backward Digit Span.



XSL•FO
RenderX

Difference Between People With MS and Healthy Controls

For all icognition tests, there was no significant difference in performance between healthy controls and people with MS (Symbol Test: U=4431; P=.42; Dot Test: U=3516; P=.32; vBDS: U=3708; P=.27; Figure 4). The results were similar for all paper-and-pencil tests (SDMT: U=4060.5; P=.82; SPART: U=3934; P=.74; auditory Backward Digit Span: U=3824.5; P=.37; Figure S2 in Multimedia Appendix 1).

Figure 4. Comparison of the performance of healthy controls and people with multiple sclerosis (MS) on the icognition tests. Test performance was not significantly different between people with MS and healthy controls for all icognition tests. vBDS: visual Backward Digit Span.

Correlations With Clinical Parameters

A correlation matrix between the icognition tests and different clinical tests is presented in Table 2. In general, higher scores on the icognition tests were associated with less physical disability (measured using the EDSS), younger age, and a higher education level. Furthermore, all tests except the Symbol Test showed a correlation with disease duration, whereas fatigue (measured using the FSMC) was negatively associated with Dot Test performance. No correlation was found between any icognition test and depression (measured using the BDI). Correlation magnitudes were small or fair, with the exception of the moderate to good correlation between the Symbol Test and age ($|r|$=0.52).

Table 2. Correlation matrix of icognition tests with clinical variables. The Spearman correlation was used for the Beck Depression Inventory (BDI), Fatigue Scale for Motor and Cognitive Functions (FSMC), Expanded Disability Status Scale (EDSS), and education level, while the Pearson correlation was used for age and disease duration.

	Symbol Test		Dot Test		vBDS[a]	
	Correlation	*P* value	Correlation	*P* value	Correlation	*P* value
Age	−0.52	<.001	−0.29	.004	−0.27	.008
Education level	0.20	.04	0.37	<.001	0.22	.03

[a]vBDS: visual Backward Digit Span.

Discussion

Overview

In this paper, we present the results of the validation process of a smartphone-based screening battery for cognitive problems in people with MS. All tests correlated with their paper-and-pencil equivalents (concurrent validity), although correlation between the Dot Test and the SPART was only fair, most likely due to the fact that the SPART—the gold standard—lacks a distractor phase. The distractor phase was initially added to avoid ceiling effects and increase sensitivity in detecting cognitive decline. However, other test differences between the Dot Test and the SPART, such as grid size and the number of trials, could also cause the correlation to be weaker. Furthermore, all tests correlated with various clinical variables (age, education level, and EDSS) and showed moderate test-retest reliability. These findings indicate the suitability of the battery for routine remote screening of cognitive problems, a condition that many people with MS are likely to develop over time [8].

State of the Art

We performed a systematic search (Multimedia Appendix 1) to identify smartphone-based cognitive tests for MS, which are summarized in Table 3. In brief, these apps began to emerge in 2020 and predominantly use a typical SDMT design. In this format, the mobile phone is held in landscape orientation, and

XSL•FO
RenderX

a key of 9 symbol-digit pairs is displayed at the top. For 90 seconds, 1 symbol at a time is shown in the center of the screen, and the participant selects as quickly as possible the matching digit from 9 digit buttons located at the bottom of the screen. These tests are primarily designed to measure IPS, although they are also used to measure cognitive fatigability [39,40]. Other tests designed to measure specific cognitive domains include the smartphone version of the Trail Making Test Part B [41] for executive function and the Auditory Test of Processing Speed for IPS [42]. Furthermore, smartphone keystroke analysis [43,44] and various cognitive training games [45] were not designed for a specific cognitive domain, but their relationships with multiple cognitive domains was assessed. Recently, the first smartphone-based cognitive screening battery (DIGICOG-MS [15]) was introduced, marking an important next step in smartphone-based cognitive assessment.

XSL•FO
RenderX

Table 3. Summary of the state of the art in smartphone-based cognitive tests for people with multiple sclerosis (MS). The "Target domain" column indicates the specific cognitive domain assessed by each cognitive test.

Name	Summary	Target domain
MCT[a] [46]	The MCT, part of MSCopilot, is a digital version of the SDMT[b]. In the MCT, a key displaying 9 symbol-digit pairs is presented at the top of the screen, with an exit button located in the top right corner. One symbol at a time is presented below the key. No details pertaining to the length of the test or scoring method are provided in the paper.	Information processing speed
sSDMT[c] [35]	The sSDMT, part of MS Sherpa, is a digital version of the SDMT. In the sSDMT, a symbol-digit key (with 9 pairs) is presented at the top of the screen. A single symbol is then presented in the center of the screen, and participants must quickly tap the correct matching digit from 9 digit buttons presented at the bottom. The total score is the number of correct digits selected in 90 s. A timer is displayed, and the key is randomized at each trial.	Information processing speed
Voice-controlled DSST[d] [47]	The voice-controlled DSST is part of the elevateMS app. Although limited details are provided, the app seems to be a variant of the SDMT, in which responses are collected via microphone.	Information processing speed and working memory
sSDMT [27]	The sSDMT, part of the Neurological Functional Test Suite, resembles the sSDMT (described previously). However, 3 differences are noteworthy. First, no timer is provided. Second, the test duration is 75 s; a 90-s performance score is calculated by multiplying the result by 90/75. Finally, the app also supports vocalized responses using a microphone and voice recognition to test participants with severe motor impairments.	Information processing speed
Mobile Trail Making Test Part B [41]	The app displays 13 circles, 6 containing a letter and 7 containing a number. The goal of the test is to connect the circles as quickly as possible in order, alternating between numbers and letters (1-A-2-B and so on, up to 7). The smartphone test was introduced by Ross et al [48] and assessed in people with MS in the study by Chen et al [41].	Executive function
Neurokeys [43]	Neurokeys is an alternative keyboard that records typing events (press and release) and subsequently calculates a range of features such as press duration and time interval between 2 presses.	No specific cognitive domain
BiAffect [44]	Similar to Neurokeys, the BiAffect app features a custom keyboard that temporarily replaces the smartphone's default keyboard and is used to collect keystrokes and subsequently calculate various features.	No specific cognitive domain
cFAST[e] [40]	The cFAST is similar to the sSDMT but includes an exit button and a progress bar to indicate the remaining response time. Unlike the 90-s duration of the sSDMT, the cFAST test lasts 5 minutes because the goal is to assess cognitive fatigability rather than information processing speed.	Cognitive fatigability
eSDMT[f] [49]	The eSDMT, part of Floodlight, is an electronic version of the SDMT. Although few details are provided, the app seems to use a similar design to the sSDMT [39,50]. However, no timer or randomization of the key is mentioned.	Information processing speed
Cognitive games in the dreaMS app [45]	Several cognitive games were included in the dreaMS app featured in the study by Pless et al [45].	No specific cognitive domain
Auditory Test of Processing Speed [42]	Participants are presented auditory digits between 1 and 99 across 3 trials (20 digits each), with each trial involving different questions for the participants to answer (ie, trial 1: is the digit greater than 50? Trial 2: is the digit greater than 50 or odd? Trial 3: is the digit greater than 50 and odd?). The test examiner records the participants' responses, and response time is calibrated before testing.	Information processing speed
MS Care Connect [51]	The MS Care Connect app is freely available for remote health assessments, including cognitive tests, in people with MS. Although limited information is available about the cognitive tests, a scoping review by Michaud et al [52] mentions it contains an SDMT-like test. According to a video on the app's website, the test is administered in portrait orientation, with the key (9 symbol-digit combinations) at the top of the screen, a symbol presentation field below it, and a 3×3 answer keypad at the bottom [53].	Information processing speed
Konectom [54]	The test is designed to measure cognitive processing speed, with the smartphone held in portrait orientation. A symbol-digit key (with 9 pairs) is displayed at the top of the screen and remains fixed for the 90-s test duration. Symbols are presented in the center of the screen, and a 3×3 answer keyboard (digits 1-9) is located at the bottom. To correct for visuomotor interference, a separate test is included in which participants are asked to tap, in the same 3×3 answer keyboard and for 20 s, as many numbers as possible that are consecutively displayed in the center of the screen.	Information processing speed
DIGICOG-MS [15]	This is a smartphone-based cognitive battery with tests for memory, semantic fluency, and information processing speed. All tests seem to be designed for use in portrait orientation. A symbol-digit key (with 9 pairs) is presented at the top of the screen and remains fixed for the 90-s test duration. Four symbols are shown at a time in the center of the screen, and a 3×3 answer keyboard (digits 1-9) is located at the bottom.	Visuospatial memory, verbal memory, semantic fluency, and information processing speed

[e]cFAST: Cognitive Fatigability Assessment Test.

[f]eSDMT: electronic Symbol Digit Modalities Test.

The icognition screening battery differs from the state of the art in 2 ways. First, fine motor and visual problems are frequently reported in people with MS [55,56]. These symptoms are likely to interfere with time-based digital processing speed tests and could be affected by design considerations, as seen in the common digital SDMT design. This design includes multiple answer buttons (typically 9), and if configured in portrait orientation may result in a small symbol-digit key, especially on smaller devices. Although the problem is recognized by Woelfle et al [50] and the Scaramozza et al [54], the latter implementing a separate test to quantify motor interference, we opted to minimize motor and visual interference through design. Specifically, we used a simplistic design in landscape orientation, featuring 2 large answer buttons (Figure 1). Second, rather than a single test, icognition features a battery of tests designed to capture a broader cognitive profile because cognitive problems in people with MS are not limited to slowed IPS [14]. To the best of our knowledge, only Podda et al [15] have recently published a smartphone-based cognitive battery for people with MS. Moreover, icognition will be included in a digital care platform assessing symptoms, imaging biomarkers, and patient-reported outcomes [21] to provide a holistic picture of a patient's well-being.

A Cognitively Preserved Sample of People With MS

People with MS scored equally well on all tests compared to healthy controls. However, as can be observed in Table 1 and Figure S2 in Multimedia Appendix 1, this was also the case for the paper-and-pencil tests. Indeed, we seem to have included a sample of people with MS with relatively preserved cognition. We tested this in a post hoc analysis using the ANOVA method described by Anders [57], comparing the SDMT performance scores of our sample of people with MS (mean 58.5, SD 10.0; n=101; Table 1) with those reported in previous studies. López-Góngora et al [58] report an average SDMT performance score of 54.3 (SD 13.4; N=237), while Sousa et al [59] mention an average SDMT performance score of 53.51 (SD 11.76; n=115). We found that the people with MS included in this study performed significantly better (comparison with López-Góngora et al [58]: $F_{1,336}$=8.01; P=.005; comparison with Sousa et al [59]: $F_{1,214}$=11.1; P=.001).

The underlying reason for having selected a cognitively preserved sample is most likely the sampling bias resulting from the limited inclusion and exclusion criteria and the recruitment of patients during outpatient consultation in secondary and tertiary MS care settings. In these settings, participants are tested cognitively at least annually, which might enhance their familiarity with typical cognitive tests for MS, with a carryover effect to derivative tests, such as those in icognition. Moreover, people with MS who were able and willing to participate might (1) have better cognitive abilities, (2) be better at handling a smartphone, and (3) be familiar with scientific studies. The reason for being less strict on inclusion was to be able to offer the screening battery to any patient with MS who is regularly followed up in an outpatient setting. Future studies should confirm the validity of icognition in people with MS who are cognitively impaired. Moreover, combined with the publicly available data underlying this study, the sensitivity of icognition in detecting cognitive impairment could be established.

To investigate the impact of cognitive impairment on our results, we performed a post hoc analysis excluding participants who were considered impaired on at least 1 paper-and-pencil test (Figures S3-S5 and Table S3 in Multimedia Appendix 1). Compared to the original analysis, the most notable differences were observed in the correlations with clinical parameters, where the correlation between the Symbol Test and disease duration became significant (P=.04), while significance dropped for the relationship between the vBDS and education level (P=.06), the Dot Test and FSMC (P=.18), and the vBDS and EDSS (P=.20). Results for concurrent validity, test-retest reliability, and the difference between people with MS and healthy controls were comparable.

The Benefits of Regular Digital Follow-Up

Proper and regular follow-up of cognitive function is important to capture fluctuations in cognitive state, such as those caused by a disease exacerbation or a relapse. Although Giedraitiene et al [60] show that a short cognitive screening tool such as the Brief International Cognitive Assessment for Multiple Sclerosis [18] can detect these cognitive fluctuations [60], the cognitive dip is likely missed in reality because cognitive assessments are usually performed only once or twice a year during clinical follow-up visits. The icognition screening battery allows for more frequent cognitive assessments. Furthermore, testing can be performed wherever and whenever a patient feels ready for it, reducing biasing effects such as fatigue [61]. Moreover, digitalization facilitates data collection and allows the extraction of more information from a cognitive test. As icognition associates every response with a 13-digit time stamp (with millisecond precision), cognitive fatigue or other performance metrics such as the "maximum gap time between correct responses" [39] can be tracked with high temporal resolution. For the Symbol Test, analogous examples are provided in the studies by Ganzetti et al [39] and Barrios et al [40].

Implementing icognition in a health care platform that includes fine motor assessment [62], symptom logging, and patient-reported outcome measures [21] enables patients to take an active role in their disease management; they can provide the individual information that complements the professional knowledge of the treating physician [63]. Moreover, collecting confounding variables, such as fatigue [21], at cognitive assessment improves the interpretation of cognitive scores.

Limitations and Future Work

This study has some limitations. This validation study used a cross-sectional design, aside from the assessment of test-retest reliability. Therefore, we were unable to map the cognitive

XSL•FO
RenderX

evolution of people with MS over time. These and other validated digital cognitive tests could considerably facilitate longitudinal testing in future studies, analogous to the 1-year follow-up study by Lam et al [64].

Popular screening batteries such as the Brief International Cognitive Assessment for Multiple Sclerosis also include a measure of verbal memory, which is indeed commonly impaired in MS [14]. However, we chose not to implement a digital test of verbal memory in icognition because such tests usually rely heavily on language, which complicates international use with the need for language-specific validation. Moreover, this introduces new technological difficulties, such as variations in microphone and speaker quality or the accuracy of speech recognition software. Although the aim of this study was to create a quick, home-based cognitive screening assessment, we acknowledge the importance of more in-depth multidomain cognitive assessment, including the assessment of verbal memory.

In the initial version of the Dot Test, the final 5 trials included remembering the position of the 3 dots on a 5×5 grid, but, after testing 3 participants with MS, we decided to consistently use a 4×4 grid, given the difficulty of the task, and excluded these participants from the Dot Test analyses. However, including these 3 participants in a post hoc analysis yielded similar results.

Furthermore, we tested consistently on the same Android smartphone (Samsung Galaxy A10) to avoid a biasing influence of model-specific factors, such as screen size, weight, and responsiveness, because these factors might impact performance and user experience. Although we expect our results to be applicable to other smartphone models, this limits the study findings to this smartphone model. However, as icognition has been designed using the Flutter framework (Google LLC), it can also be deployed on operating systems other than Android. An external validation study is planned to show the robustness of the app on different devices in a home setting.

To test concurrent validity, we used the SPART as the ground truth test for visuospatial memory because this closely resembled the Dot Memory Test presented in the study by Sliwinski et al [24]. Although recent evidence suggests that the SPART is among the most sensitive memory assessments in MS [65], Strober et al [66] found the Brief Visuospatial Memory Test–Revised to be more sensitive than the SPART. One might argue that the sole criterion of the ground truth test is that it measures visuospatial memory, regardless of its similarity to the digital test. In this context, using the Brief Visuospatial Memory Test–Revised would have been justified. Although the concurrent validity of the Dot Test was only fair, it demonstrated an acceptable test-retest reliability and correlated with several clinical variables, underscoring its value for clinical practice. Unlike the Symbol Test, which can be seen as a digital alternative to its paper-and-pencil reference test (SDMT), more research is necessary to establish the ground truth reference for the Dot Test. Furthermore, future research could subject icognition to a real-world (referred to later in this subsection), longitudinal study to establish its sensitivity to change at the individual level.

Test-retest reliability was assessed only in the healthy controls as per the recommendations of Benedict et al [28], who stated that test-retest reliability “can be investigated in a small sample of MS and/or healthy volunteers over 1-3 weeks.” Although we deem this to be a good indication for test-retest reliability in people with MS, substantiated by similar ICC reliability scores in the smartphone SDMT study by van Oirschot et al [35], test-retest reliability is not guaranteed to be similar for the cognitive tests in icognition. As we strove to perform test-retest reliability in similar circumstances (eg, location), assessing it for people with MS was difficult because they were tested during a 1-time visit to the outpatient MS clinics for consultation. Furthermore, we acknowledge that, although we followed the recommendations of Benedict et al [28], the sample sizes for testing test-retest reliability were small (Symbol Test and vBDS: n=20; Dot Test: n=19).

By recruiting a cognitively preserved sample of people with MS, this study was unfortunately unable to provide a realistic assessment of the sensitivity of the app to discriminate between (1) people with MS and healthy controls and (2) people with MS who are cognitively impaired and people with MS who are cognitively preserved. As the goal of icognition is not the diagnosis of MS but to screen for people with MS who are cognitively impaired, we especially recognize the latter as a limitation of this study. Indeed, of the 101 participants with MS, only 7 (6.9%), 8 (7.9%), and 9 (8.9%) presented impairment on the Symbol Test, Dot Test, and vBDS, respectively, resulting in a substantial class imbalance with respect to preserved test performance. However, because we make our data publicly available, this analysis can be conducted by future studies evaluating icognition on a sample of people with MS who are cognitively impaired.

This study validated the icognition app in controlled laboratory conditions under the supervision of a test examiner. However, we acknowledge that future studies should confirm psychometric properties such as test-retest reliability in remote, unsupervised settings. Furthermore, as recently demonstrated by Podda et al [15], the usability of cognitive apps should be assessed to assure a smooth transition to a real-life setting. A usability study is planned for icognition as well.

Conclusions

This study established the reliability and validity of a newly developed smartphone app, icognition, for remotely screening cognitive impairment in terms of IPS and memory in people with MS. This allows for regular screening of cognitive performance to more quickly detect and respond to potential deterioration.

Abstract

Background: An effective primary treatment for obsessive-compulsive disorder (OCD) in children and adolescents as well as adults is exposure and response prevention (ERP), a form of intervention in the context of cognitive-behavioral therapy. Despite strong evidence supporting the efficacy and effectiveness of ERP from studies in research and real-world settings, its clinical use remains limited. This underuse is often attributed to access barriers such as the scarcity of properly trained therapists, geographical constraints, and costs. Some of these barriers may be addressed with virtual behavioral health, providing ERP for OCD through video teletherapy and supplemented by app-based therapeutic tools and messaging support between sessions. Studies of teletherapy ERP in adults with OCD have shown benefits in research and real-world settings in both small and large samples. However, studies of teletherapy ERP in children and adolescents thus far have been in small samples and limited to research rather than real-world settings.

Objective: This study reports on the real-world effectiveness of teletherapy ERP for OCD in the largest sample (N=2173) of child and adolescent patients to date.

Methods: Children and adolescents with OCD were treated with live, face-to-face video teletherapy sessions, with parent or caregiver involvement, using ERP. Assessments were conducted at baseline, after 7-11 weeks, and after 13-17 weeks. Additionally, longitudinal assessments of OCD symptoms were performed at weeks 18-30, 31-42, and 43-54. We analyzed longitudinal outcomes of OCD symptoms, depression, anxiety, and stress using linear mixed models.

Results: Treatment resulted in a median 38.46% (IQR 12.50%-64.00%) decrease in OCD symptoms at 13-17 weeks, and 53.4% of youth met full response criteria at this point. Improvements were observed in all categories of starting symptom severity: mild (median 40.3%, IQR 8.5%-79.8%), moderate (median 38.4%, IQR 13.3%-63.6%), and severe (median 34.1%, IQR 6.6%-58.5%). In addition, there were significant reductions in the severity of depression, anxiety, and stress symptoms. The median amount of therapist involvement was 13 (IQR 10.0-16.0) appointments and 11.5 (IQR 9.0-15.0) hours. Further, symptom improvements were maintained or improved upon in the longitudinal assessment periods of weeks 18-30, 31-42, and 43-54.

Conclusions: These results show that remote ERP treatment, assisted by technology, can effectively improve both core OCD and related depression, anxiety, and stress symptoms in children and adolescents with OCD in a real-world setting. Notable outcomes were achieved in a relatively small amount of therapist time, demonstrating its efficiency. Demonstrating the usefulness of a delivery format that overcomes several traditional barriers to treatment, these findings have implications for widespread dissemination of accessible, evidence-based care for children and adolescents with OCD.

digital behavioral health; youth; cognitive-behavioral therapy; exposure and response prevention; CBT; ERP; OCD; psychiatry; clinical trial; psychology; video therapy; teletherapy; e-therapy; e-counseling; cyber-counseling; adolescents; adolescence; obsessive-compulsive disorder; retrospective study; longitudinal study; observational study; ERP therapy

Introduction

Obsessive-compulsive disorder (OCD) is a common and often disabling mental health condition that affects 0.25%-4% of children and adolescents [1-3]. Without treatment, OCD can persist into adulthood. Further, it can significantly interfere with a young person's development, education, and relationships. Fortunately, OCD in young people can be effectively managed through psychotherapy, medication, or a combination of the two. Exposure and response prevention (ERP), a form of intervention in the context of cognitive-behavioral therapy (CBT), is particularly effective for treating OCD in children and adolescents. It has been extensively tested in clinical trials [4-6] and is recommended as the first-line treatment for OCD [4,7-10].

However, accessing ERP can be challenging due to a shortage of therapists trained in this specialized technique, along with the costs and geographical limitations of attending in-person therapy sessions [11-13]. Therapists with adequate training in ERP for children and adolescents are even more scarce [14,15]. Remotely delivered ERP, for example, therapy that delivers ERP via the phone or video, can potentially overcome many of these obstacles by increasing access to specialized providers, reducing travel time and costs for families, and enabling therapists to work with patients in their natural environments that trigger OCD symptoms.

Meta-analyses of remotely delivered CBT with ERP for OCD have shown benefits in studies for adults and children or adolescents [16-18]. The largest meta-analysis (22 studies; N=1796) that included studies of both adults and children or adolescents (9 studies) found that remote ERP resulted in superior reduction of OCD symptoms compared with control conditions (Hedges g=0.94, 95% CI 0.60-1.27; P<.001), and there was no significant difference in efficacy compared with in-person CBT or ERP (g=–0.104, 95% CI –0.391 to 0.184; P=.479) [17]. The majority of these studies have included mostly self-referred participants, those with any severity of OCD, concurrent psychiatric medications, and comorbidities such as depression and anxiety disorders. Further, in several countries, remote ERP, delivered both with and without therapist support, has been implemented in routine care and found to be safe and efficacious, with medium to large effect sizes [19-21]. Remote video telemedicine treatment, in general, has shown noninferiority to traditional in-person treatment for OCD, anxiety, and depression in a head-to-head study in adults [22]. Non-inferiority of remote CBT delivered by telephone compared with face-to-face CBT has also specifically been demonstrated in adolescents with OCD [23]. Remote treatments have the added benefit of allowing therapy to take place in the patient's everyday environment. This can be especially helpful for younger patients, as it enables therapists to work with them in the settings that trigger their OCD symptoms, such as at home or school.

The convenience of teletherapy, coupled with the widespread ownership of smartphones, makes this form of treatment a promising option for families seeking help for OCD. NOCD is a virtual behavioral health provider that specializes in the delivery of evidence-based treatments, including ERP, for obsessive-compulsive and related disorders. NOCD has created a virtual therapy program that delivers ERP through video teletherapy. The program aims to maximize therapeutic impact while minimizing the time required from therapists by eliminating travel time and allowing for more efficient, remote delivery sessions. The program uses treatment design elements from an open clinical trial in adults that demonstrated the effectiveness of combining the NOCD app with face-to-face therapy sessions in reducing OCD symptoms significantly and efficiently while achieving good patient satisfaction [24]. To extend the reach of its treatment and enhance its effectiveness, NOCD provides one-on-one video sessions with a therapist, along with additional support through messaging with their therapist, a web-based OCD community, and peer support. We previously reported clinical outcomes from 3552 adults with OCD treated with ERP [25]. In this retrospective observational study, the median improvement was a 45% reduction in OCD symptoms. Further, 62.9% met the criteria for a full response.

The treatment for children and adolescents at NOCD follows a similar structure as for adults, although it includes involvement of parents and other caregivers. This comprehensive model aims to improve access to effective OCD treatment for children and adolescents, thereby addressing a significant gap in mental health services for young people. The goal of this retrospective observational longitudinal study was to determine clinical outcomes in a large naturalistic sample of children and adolescents with a primary diagnosis of OCD who received ERP treatment via video teletherapy.

Methods

Research Design

This was a retrospective, observational longitudinal analysis of clinical data from children and adolescents with a primary OCD diagnosis who received ERP treatment at NOCD from July 23, 2020 (when NOCD began offering child and adolescent treatment), to May 3, 2024, when we froze the data for analysis.

Population and Sample

From the total pool of child and adolescent patients who received treatment at NOCD between July 2020 and May 2024, our analytical sample included 2173 patients who met the following criteria: (1) primary diagnosis of OCD according to *DSM-5* (*Diagnostic and Statistical Manual of Mental Disorders*

XSL•FO
RenderX

[5th Edition]) criteria and Diagnostic Interview for Anxiety, Mood, and OCD and Related Neuropsychiatric Disorders (DIAMOND) assessment, (2) completion of baseline Dimensional Obsessive-Compulsive Scale (DOCS) assessment, and (3) completion of at least one DOCS assessment during weeks 13-17 of treatment.

As part of the general clinical enrollment at NOCD, parents or legal guardians initially reached out to the intake team as self-referrals or received a referral from their insurance or medical provider. Therapists trained by NOCD in OCD assessment and treatment conducted the initial diagnostic evaluations. These evaluations occurred over the first 2 sessions and included a thorough clinical review covering the biopsychosocial aspects of the individual's history and a semi-structured diagnostic interview using the DIAMOND [26]. Those diagnosed with OCD as their primary concern, according to *DSM-5* criteria [27] and the DIAMOND, received treatment. The majority of candidates with an “extreme” rating on the DIAMOND clinician-rated severity scale were directed to more intensive treatment options, such as intensive outpatient programs, partial hospitalization programs, or residential treatment programs. Exceptions to referring patients with an “extreme” DIAMOND rating to more intensive treatment were made on a case-by-case basis, based on clinician judgment. Factors considered included, for example, the patient's level of motivation to engage in outpatient ERP treatment, the presence of comorbidities that might interfere with treatment, as well as the availability and involvement of supportive family members or caregivers who could assist with the treatment process. Referrals for other significant psychiatric or substance use issues, if they were deemed to potentially interfere with ERP treatment, were also made as needed (eg, to child and adolescent psychiatrists or other specialty providers). NOCD generally provides services to individuals aged 5 years and older, although exceptions were made for some 4-year-old patients.

Treatment Approach

The treatment plan included weekly or twice-weekly 60-minute ERP sessions via video for the first 3 weeks for most, followed by, typically, 10-14 weeks of weekly 60-minute sessions to support the continuation of ERP exercises. During this phase, some transitioned to 30-minute check-in sessions based on their clinical progress. The decision to transition patients to 30-minute check-in sessions was based on clinical judgment considering factors such as symptom reduction, demonstrated mastery of ERP principles, and consistent engagement with between-session exposures. Therapists, while aiming to adhere to this structured approach, could adjust the number or frequency of sessions to meet clinical needs and accommodate patients’ and their parents’ or caregivers’ schedules. Family therapy sessions were scheduled when the therapist deemed them necessary. Treatment duration, number of visits completed, and total therapist contact hours were obtained for each patient. Additionally, patients and their parents or caregivers could engage in asynchronous in-app messaging with their therapists for guidance on homework assignments or for support. App usage (number of app opens) and messaging activity between therapists and patients were tracked to measure treatment engagement. NOCD also offered continuously available support through online monitored community groups. Patients and their parents or caregivers also had access to the NOCD app for tools to set up ERP exercises with their therapist, record the results of their ERP exercises, and access and interact with the online NOCD community. The NOCD app’s ERP tools include ways to set up exposures with instructions, images, scripts, audio recordings, and external links; means to record obsessions and track distress reduction associated with exposure exercises (with graphical depictions); and response prevention tips (see Multimedia Appendix 1 for example screenshots of the NOCD app's key features). Parents or caregivers and caregivers of youth with OCD were able to access weekly support groups facilitated by a trained clinician to receive ongoing support and guidance in reducing accommodation of OCD in the home. Lastly, parents or caregivers received personalized psychoeducation on OCD symptoms in youth and on the maintaining role of familial accommodation and were given guidance in developing a plan to progressively reduce and eventually eliminate any accommodation behaviors.

Technology Platform

All sessions used a secure, US HIPAA (Health Insurance Portability and Accountability Act)-compliant (and compliant with other countries’ health information privacy regulations) version of Zoom, accessible via personal computing or mobile devices, with live technical support available during business hours to address connectivity issues.

Therapist Qualifications and Training

Study therapists held master’s or doctoral degrees and were licensed in the states of patients to whom they provided treatment or were associate clinicians who were supervised by licensed therapists. Therapists underwent comprehensive ERP training from NOCD. This included multiple days of focused instruction on OCD and ERP techniques. This was followed by evaluations, including written tests and mock diagnostics, education, and ERP treatment sessions. Therapists were required to pass these written and practical evaluations before starting to treat patients. Additionally, clinicians received further training and guided practice opportunities in the following areas: (1) providing psychoeducation to youth using age-appropriate language and examples, (2) tailoring ERP for OCD in youth, and (3) addressing familial accommodation. Ongoing consultation was provided, including weekly group sessions and periodic case reviews.

Data Collection and Assessment Instruments

Patients completed self-report assessments to avoid therapist bias. These included the DOCS, which was the primary OCD outcome measure, and the Depression, Anxiety, and Stress Scale (DASS-21) to measure commonly occurring comorbid depressive, anxiety, and stress symptoms. Links to these assessments were sent to patients or parents or caregivers via the NOCD app every 3 weeks. Assessments were completed collaboratively between the patient and their parent or caregiver. Therapists also completed the DIAMOND severity scale, a clinician-rated measure of OCD severity.

XSL•FO
RenderX

DOCS

The DOCS [28] is a 20-item self-report measure of OCD symptom severity across 4 domains: contamination, responsibility for harm or mistakes, unacceptable thoughts, and incompleteness or symmetry. Respondents rate the severity of their symptoms on a scale from 0 (no symptoms) to 4 (extreme symptoms) across 5 items: time occupied, avoidance behavior, associated distress, functional interference, and difficulty disregarding obsessions or refraining from compulsions. The 4 subscale scores (range 0-20) can be summed to produce a total DOCS score (range 0-80). A DOCS total score of 18 or above optimally distinguishes someone with OCD from someone without a psychiatric diagnosis [29]. The DOCS has shown good psychometric properties, including strong convergent validity with the Yale-Brown Obsessive Compulsive Scale (r=0.54) and the Obsessive-Compulsive Inventory-Revised (r=0.69), and is sensitive to the effects of treatment. Further, it shows strong correlations with the Obsessive-Compulsive Inventory-Children's Version Revised (OCI-CV-R) [30] at baseline (r=0.77), at 3 weeks (r=0.80), and at 9 weeks (r=0.80) of treatment [31]. For the purposes of this analysis, a full response was defined as a ≥35% reduction in DOCS scores and a partial response as a 25%-35% reduction, aligned with recommended criteria for treatment response and remission in OCD [29,31].

DIAMOND

The DIAMOND severity scale [26] is a 2-item clinician-rated assessment of the overall severity of an individual's emotional distress and functional impairment related to OCD symptoms. The clinician makes separate ratings of an individual's emotional distress and functional impairment on a scale ranging from 1 (normal) to 7 (extreme), and the higher of the 2 ratings is taken as the total severity score. On the DIAMOND clinician-rated severity scale, a score of 7 indicates an "extreme" level of OCD symptoms and functional impairment.

DASS-21

The DASS-21 [32] is a 21-item self-report measure of symptoms of depression, anxiety, and stress. It has been widely used in previous research and has consistently shown good psychometric qualities.

Statistical Analysis

Data, pseudoanonymized before analysis, were examined using a linear mixed model approach, with time points as fixed factors and patients as random factors. This statistical method allowed us to include all available data points while accounting for the repeated measures structure of the data. The time points for rating scale scores included ratings at baseline, the most recent rating obtained between weeks 7-11, and the most recent rating obtained between weeks 13-17. The primary measurement of interest was DOCS score changes from baseline to week 13-17. Since there was some degree of flexibility in the treatment, not everyone had rating scales done at precisely the same session or week of their treatment. Thus, these windows allowed us to measure symptom improvement at approximately a midpoint in treatment (weeks 7-11) and at the end of the active treatment period (weeks 13-17). We only included patients who had data from at least both of these time points. Of the patients who completed both baseline and week 13-17 assessments, a subset also completed assessments during weeks 7-11.

The primary (DOCS scores) and secondary (DASS-21 depression, anxiety, and stress scores) outcome measures were analyzed using linear mixed models, with time points as fixed factors and patients as random factors and with statistical significance set at an α of 0.05. We calculated effect sizes using Hedges g. Descriptive statistics, including treatment duration and mean and median symptom improvements, were calculated for those who had a baseline and at least one subsequent rating at 13-17 weeks. The primary analysis included data from both children and adolescents together, with subsequent post hoc analyses examining the effect of age group (children: ages 4-12 years, and adolescents: ages 13-17 years). The model included time (assessment_bin), age group, and their interaction as fixed effects. Similarly, we analyzed the effect of racial and ethnic category with a model including time (assessment_bin), racial and ethnic category, and their interaction as fixed effects. We also analyzed the effect of therapy over time on individual OCD domains, with the respective DOCS subscore as the outcome variable. The model included time (assessment_bin), OCD subtype (subscore_name), and their interaction as fixed effects. A random intercept for each user accounted for individual variability. Analyses were conducted in R.

Ethical Considerations

The analyses in this study did not require research ethics board review, as this does not meet the criteria for human subject research as defined by federal regulations for human subject protections, 45 CFR 46.102(e); this is a secondary analysis of de-identified data from clinical records, obtained and analyzed retrospectively, and was not the result of a research intervention or interaction. The University of California, Los Angeles (UCLA) institutional review board (IRB) office confirmed that this study did not meet the criteria for human subject research (PRE#20-008583) and thus did not require approval. Compliance with data protection laws was ensured through NOCD's privacy policy, which all patients agreed to, outlining data use and protection measures.

The UCLA IRB determined that analyses conducted in this study did not meet criteria for human subject research (PRE#20-008583) as defined by federal regulations for human subject protections, 45 CFR 46.102(e). This determination was made because this is a secondary analysis of de-identified data from clinical records, obtained and analyzed retrospectively, and was not the result of a research intervention or interaction. Regarding informed consent, since this was a secondary analysis of existing clinical data, additional research consent was not required beyond the original consent provided for receiving clinical care. All patients agreed to NOCD's privacy policy and terms of service during their clinical care, which included provisions for the use of deidentified data for research purposes. Patients had the ability to opt out of data sharing. Data privacy and confidentiality were maintained through comprehensive de-identification procedures. All direct identifiers were removed from the dataset before analysis. The de-identified data was stored and analyzed on secure, HIPAA-compliant servers with

XSL•FO
RenderX

restricted access limited to authorized clinical and research personnel. No direct participant compensation was provided for this retrospective analysis, as it did not involve any additional participation beyond standard clinical care.

Results

[a]This sample includes individuals with DOCS assessments available at least at baseline and at 13-17 weeks.

[b]DOCS: Dimensional Obsessive-Compulsive Scale.

[c]DASS-21: Depression Anxiety and Stress Scale-21.

[d]As some individuals were on more than one psychiatric medication and had more than one comorbidity, the total across categories is greater than 100%.

[e]SSRI: selective serotonin reuptake inhibitor.

[f]ADHD: attention-deficit and hyperactivity disorder.

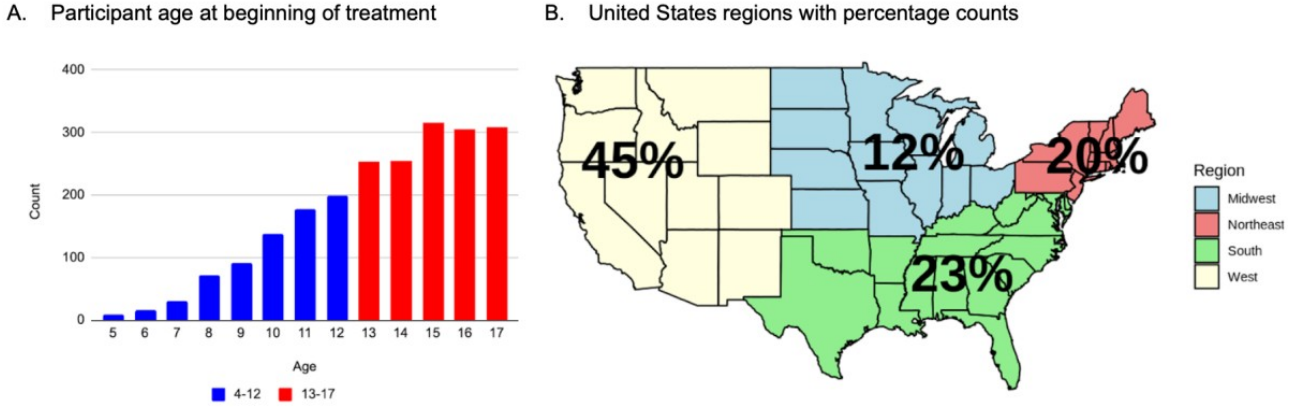
[g]ADHD medications included stimulants (eg, methylphenidate, amphetamine derivatives), non-stimulants (eg, atomoxetine), and alpha-2 adrenergic agonists (eg, clonidine and guanfacine).

[h]Anti-anxiety or sedative-hypnotics included non-benzodiazepine anti-anxiety agents (eg, hydroxyzine, and buspirone), benzodiazepines (eg, clonazepam and lorazepam), and beta blockers (eg, propranolol).

[i]Antipsychotics included both typical and atypical antipsychotics (eg, aripiprazole, quetiapine, risperidone, and ziprasidone).

[j]Other antidepressants included norepinephrine-dopamine reuptake inhibitors (eg, bupropion), serotonin antagonist and reuptake inhibitors (eg, trazodone), and tetracyclic antidepressants (eg, mirtazapine).

[k]SNRI: serotonin–norepinephrine reuptake inhibitor.



[l]Anticonvulsant or mood stabilizers included anticonvulsants (eg, lamotrigine, gabapentin, and oxcarbazepine) and non-anticonvulsant mood stabilizers (eg, lithium).

[m]TCA: tricyclic antidepressant (eg, clomipramine).

Sample

The total sample size of individuals who had at least a baseline and weeks 13-17 DOCS completed was 2173. The number of individuals who had a baseline, weeks 7-11, and weeks 13-17 DOCS completed was 1797. As shown in Figure 1A, the age distribution of participants at treatment initiation included both children and adolescents. The sample represented diverse geographic regions across the United States (Figure 1B).

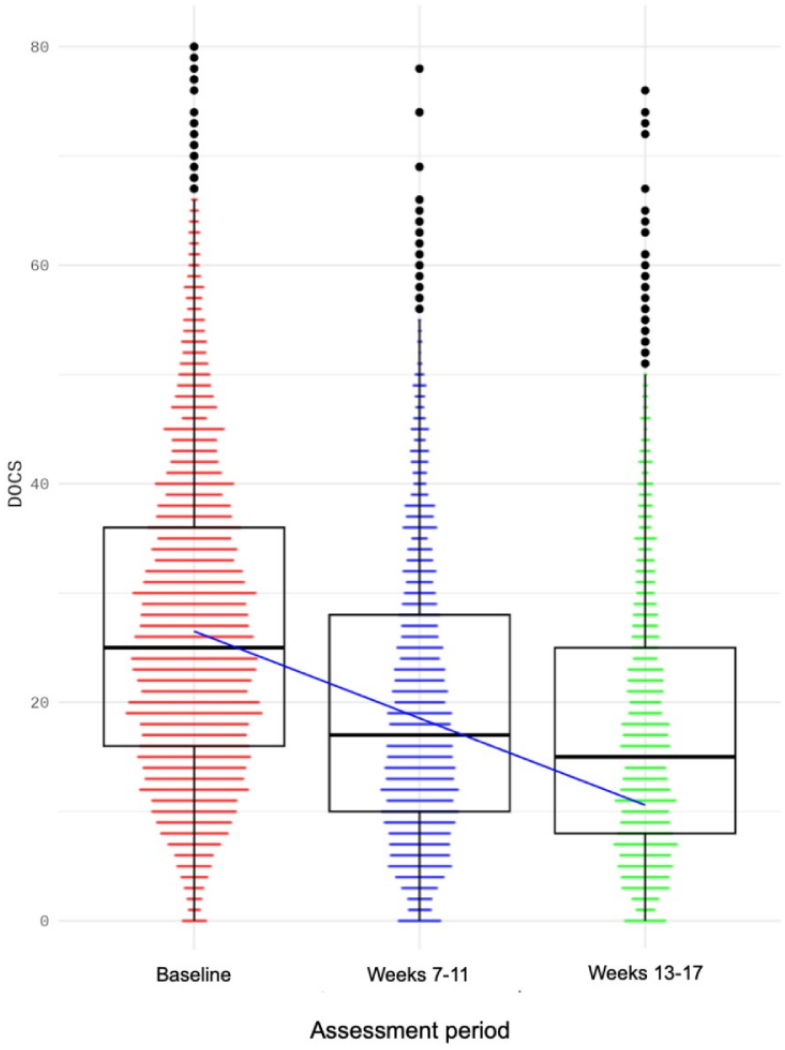
Figure 1. Age and US geographic distributions for the total sample. (A) Participants' age at the beginning of treatment. Blue indicates children, and red indicates adolescents. (B) Percentages of patients by US geographic location of residence.

App Use and Messaging

In terms of app usage, 2129 (97.98%) opened the app more than 10 times. In total, 2127 (97.88%) had at least one chat message with their therapist, while 1835 (84.45%) had 10 or more chat messages. The mean number of chat messages for those who had at least one message was 53.53 (SD 87).

Treatment Duration

The mean treatment duration was 15.12 (SD 7.96, median 15, IQR 1-.86-17.00, mode 16) weeks, the mean number of visits was 13.70 (SD 5.83, median 13, IQR 10.00-16.00, mode 13), and the mean number of therapist hours was 12.60 (SD 5.58, median 11.50, IQR 9.00-15.00, mode 10.50).



XSL•FO
RenderX

OCD Symptom Results

NOCD treatment resulted in a significant decrease in patient-rated OCD symptoms over time (DOCS scores; effect of time: $F_{1,6927.7}$=2785, P<.001; $t_{6927.69}$=–52.77, P<.001; initial to endpoint Hedges g=–0.65: "medium" effect size, 95% CI –0.59 to –0.70). From baseline to week 7-11, DOCS scores decreased from a mean of 28.16 (SD 13.50) to a mean of 20.58 (SD 13.00), representing a mean –7.7 (95% CI –7.1 to –8.2) point decrease (27.3%) among participants who completed the forms at the midpoint. By week 13-17, DOCS scores improved to a mean of 17.94 (SD 12.9), representing a mean –10.22 (95% CI –9.7 to –10.7) point decrease (38.4%; see Figure 2 and Table 2). On the individual patient level, median DOCS score improvement was 38.46% (IQR 12.5%-64%). Further, 54.0% had a ≥35% reduction in OCD symptoms and were categorized as full "responders" [33]. A total of 64.6% achieved either partial (25%-35% reduction) or full response.

An additional analysis using the assessment time period as a categorical fixed effect (rather than ordinal, as was done in the main analysis) confirmed the overall effect of duration on scores ($F_{2,6545.5}$=1610.4, P<.001). Specifically, there was a significant decrease in scores between baseline and week 7-11 of 7.58 points (SE .179, t_{6805}=44.707, P<.001). There was an additional significant decrease in scores between weeks 7-11 and weeks 13-17 of 1.94 points (SE .224, t_{6310}=8.674, P<.001). Thus, longer treatment duration is associated with continued significant improvements in OCD symptoms.

Figure 2. Changes in obsessive-compulsive disorder symptoms as assessed by the Dimensional Obsessive-Compulsive Scale (DOCS) with treatment. Median and interquartile ranges are indicated in the box-and-whisker plots. P<.001 for the effect of assessment period.

[a]DOCS: Dimensional Obsessive-Compulsive Scale.

[b]Missing data at weeks 7-11 for DOCS and DASS-21 scales were due to the patient not completing the rating scale(s). Missing data for DOCS at weeks 18-30, 31-42, or 43-54 were due to either the patient not completing the rating scale or the patient having left treatment.

[c]DASS-21: Depression Anxiety and Stress Scale-21.

[d]Not applicable.

Post Hoc Analysis of Treatment Outcomes by Age Group and Racial and Ethnic Categories

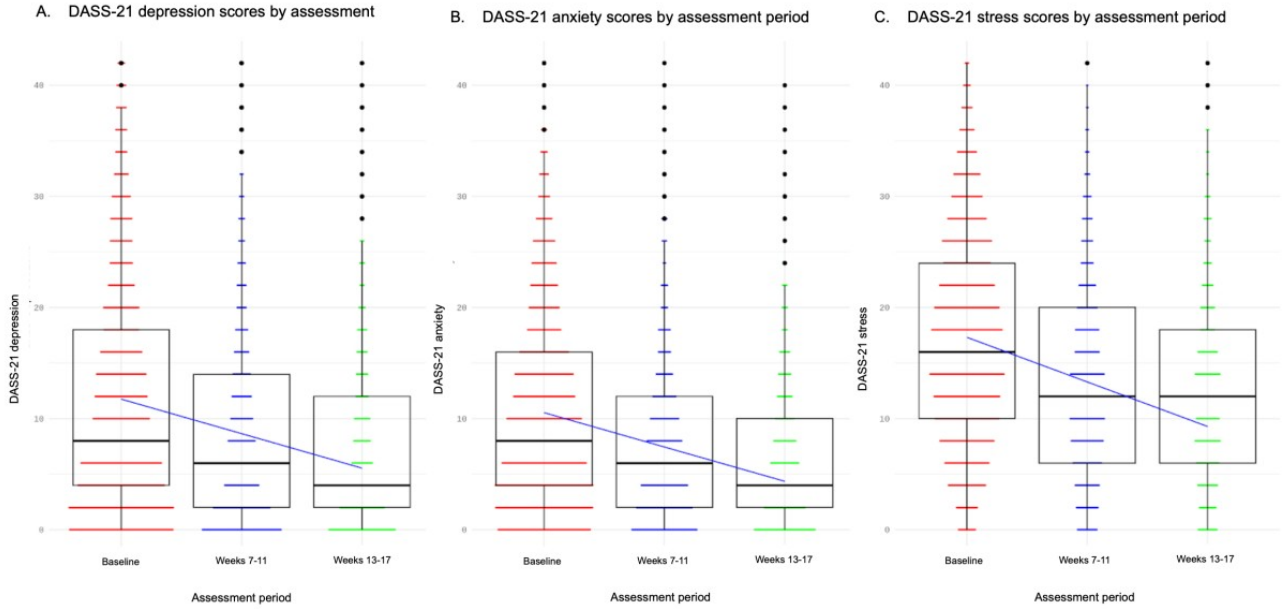
Adolescents had higher baseline scores compared to children (β=4.52, $t_{6045.16}$=11.09, P<.001). However, the interaction between time and age group was not significant (β=–0.21, $t_{5127.48}$=–0.80, P=.42), indicating that the rate of improvement over time was not significantly different between the 2 age groups. An additional analysis of responses in children (ages 4-12 years) and adolescents (ages 13-17 years), separately, revealed similar results: in children, the effect of time on DOCS scores: β=–5.10, $t_{2132.88}$=–27.06, P<.001; in adolescents, the effect of time on DOCS scores (β=–5.39, $t_{4071.89}$=–40.99, P<.001).

An analysis testing the effects of racial and ethnic categories did not reveal any significant effects of these categories on the overall outcomes (all P values≥.10).

OCD Subtype Results

Treatment resulted in a significant decrease in patient-rated OCD symptoms (DOCS subscores) over time. With the "contamination" subtype taken as the reference group, the reported main effect of time was significant ($F_{1,52,742}$=2213.70, $t_{48,510}$=–16.31, P<.001). A significant main effect of OCD subtype ($F_{3,45,585}$=564.98, P<.001) indicated that baseline symptom severity differed across subtypes. Patients with the "thoughts" subtype had the highest baseline scores, followed by "responsibility," "symmetry," and "contamination."

The interaction between time and subtype was significant ($F_{3,45,585}$=68.85, P<.001), indicating that the rate of symptom improvement varied by subtype. The "thoughts" subtype showed the steepest decline in symptoms over time, changing by –1.85 points per assessment time point window ($t_{48,510}$=–13.81, P<.001), followed by "responsibility" (–1.49 points per assessment time point window, $t_{48,510}$=–8.77, P<.001) and "symmetry" (–1.20 points per assessment time point window, $t_{48,510}$=–4.80, P<.001). The "contamination" subtype, serving



XSL•FO
RenderX

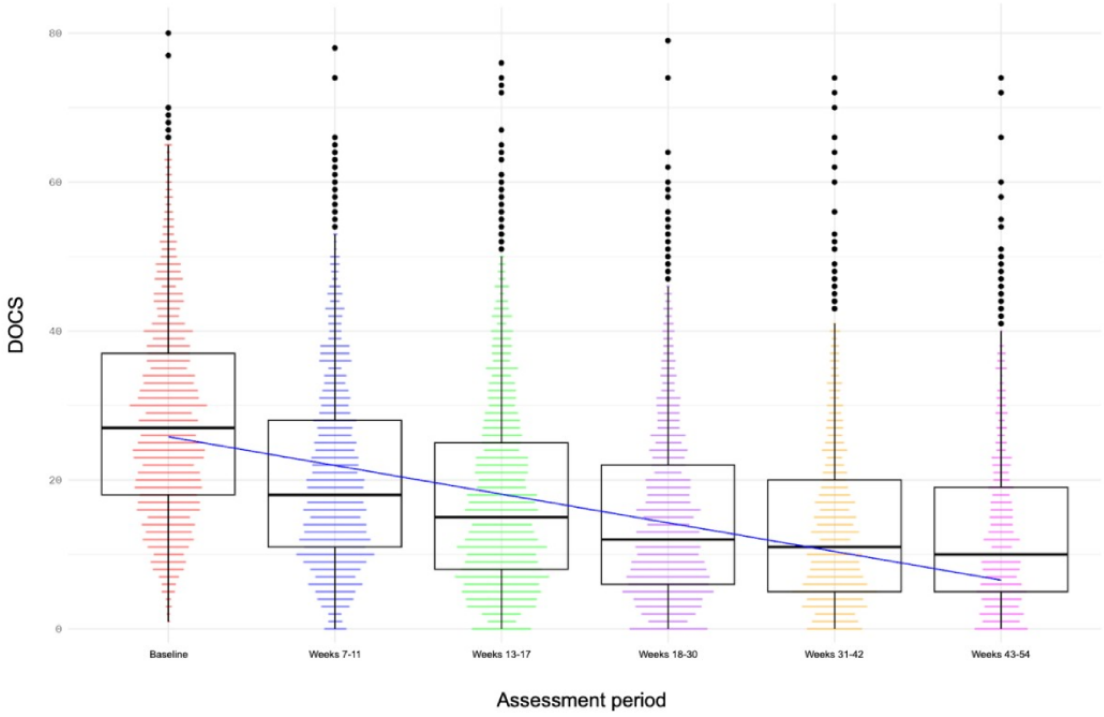
as the reference group, experienced the slowest decline (–0.86 points per assessment time point window, $t_{48,510}$=–16.31, P<.001). These results suggest that NOCD treatment is effective across all OCD subtypes, with different magnitudes of improvement over time.

Depression, Anxiety, and Stress Results

Treatment resulted in significant improvements on the DASS-21 depression ($t_{6415.03}$=–30.55, P<.001; initial to endpoint Hedges g=–.37, 95% CI –0.32 to –0.42), DASS-21 anxiety ($t_{6571.91}$=–34.05, P<.001; initial to endpoint Hedges g=–.43, 95% CI –0.38 to –0.49), DASS-21 stress ($F_{7123.66}$=–36.66, P<.001; initial to endpoint Hedges g=–.52, 95% CI –0.47 to –0.57; Figure 3 and Table 2).

Figure 3. Changes in (A) depression, (B) anxiety, and (C) stress symptoms with treatment, as assessed by the Depression Anxiety and Stress Scale (DASS-21). Median and interquartile ranges are indicated in the box-and-whisker plots. P<.001 for the effect of assessment period.

Post Hoc Analysis of Outcomes Stratified by Starting Clinician-Rated Severity Level



To determine how treatment response differed by different initial severity levels of OCD, we used the DIAMOND clinician-rated severity scale at the initial assessment to stratify patients into 3 groups of severity ratings: “Mild” (severity score of 2 or 3), “Moderate” (severity score of 4 or 5), or “Severe” (severity score of 6 or 7) (n=4 had missing DIAMOND data). For DOCS scores, on the individual patient level, the mild group (n=264) had a median 40.31% (IQR 8.51%-79.80%) reduction, the moderate group (n=1761) a median 38.36% (IQR 13.33%-63.64%) reduction, and the severe group (n=144) a median 34.07% (IQR 6.56%-58.52%) reduction. Response rates from the DOCS were 55.3% for mild, 54.23% for moderate, and 49.30% for severe. A chi-square test showed that these response rates did not differ significantly between severity groups (χ^2_2=1.49, P=.47), suggesting that treatment was similarly effective regardless of initial severity level.

Longitudinal Follow-Up

We conducted an analysis of longitudinal follow-up of OCD symptom scores after the active treatment period (weeks 13-17). At the follow-up windows of weeks 18-30, 31-42, and 43-54, most patients maintained their gains or made further improvements (effect of time: $t_{7970.47}$=–61.99, P<.001; Figure 4 and Table 2). From baseline to week 18-30 (n=1779), DOCS scores decreased from a mean of 28.16 (SD 13.50) to a mean of 15.26 (SD 12.01), representing a mean –12.9 (95% CI –12.11 to –13.7) point decrease (45.81%; Hedges g=–1, 95% CI –0.94 to –1.07). By weeks 31-42 (n=1257), DOCS scores improved to a mean of 14.04 (SD 11.71), representing a mean –14.12 (95% CI –13.27 to –14.99) point decrease (50.14%; Hedges g=–1.09, 95% CI –1.02 to –1.17). By weeks 43-54 (n=859), DOCS scores improved to a mean of 13.51 (SD 11.87), representing a mean –14.65 (95% CI –13.68 to –15.63) point decrease (52.02%) from baseline (Hedges g=–1.12, 95% CI –1.04 to –1.2).

Discussion

Principal Findings

The aim of this retrospective observational longitudinal study was to assess the clinical outcomes of a large, naturalistic sample of children and adolescents with a primary diagnosis of OCD who received ERP treatment using video teletherapy. Children and adolescents exhibited significant reductions in their symptoms, demonstrating the effectiveness of this approach for younger populations. Specifically, symptom reduction was notable with a median 38.5% reduction, 54.0% of participants achieving a full response, and 64.6% showing either a partial of full response. The treatment also led to improvements in commonly co-occurring symptoms such as depression, anxiety, and stress symptoms from baseline to end point (weeks 13-17).

There were similar outcomes for children as for adolescents, and outcomes did not significantly differ by racial and ethnic categories. Moreover, the results were largely maintained, or improved upon, for those in long-term follow-up. These outcomes underscore the potential of targeted OCD treatment to alleviate a range of severe and distressing symptoms that stem from their primary OCD diathesis. This is particularly important given that an estimated 50%-87.5% of OCD cases onset before the age of 21 [34,35], and OCD is a chronic condition if left untreated. Further, individuals often endure symptoms for an average of 11 years before receiving treatment [36].

The results highlight the substantial impact and efficiency of this treatment model for OCD and associated symptoms, offering both time and cost savings. The rapid timeframe of these improvements, achieved in a median of 13 sessions and 11.5 hours, represents a significant reduction in both therapist time and treatment duration compared to what has been observed in treatment-as-usual outpatient CBT (37.0, SD 45.0 sessions) [37]. This efficiency has implications for considerable cost reductions for families and insurance providers.

Comparison to Prior Work

Meta-analyses of remotely delivered CBT with ERP for OCD have consistently shown benefits across studies of both adults, adolescents, and children. The earliest meta-analysis [16] (N=420) found that technology-delivered CBT demonstrated a moderate effect size (d=0.82) for OCD symptom reduction compared to control conditions (although this analysis primarily focused on adults, without specifying results for children or adolescents). A subsequent meta-analysis [18] (N=823) similarly reported a large effect size (g=1.17) for remote treatment of OCD symptoms compared to control, including both children and adults in their analysis but without segregating effect sizes by age group. The most recent and largest meta-analysis [17] (N=1796) found that remotely delivered CBT resulted in significant improvement in OCD symptoms compared to control conditions (g=0.936) and showed no significant difference in efficacy compared to face-to-face CBT (g=–0.104). Notably, this analysis included 9 studies specifically examining children and adolescents, representing 36.8% of the total sample. A pilot study published after these meta-analyses, focusing specifically on video-based CBT for pediatric OCD [38], demonstrated promising results, with a 90% response rate in a small sample (N=29) of children and adolescents. While encouraging, this high response rate may reflect the carefully controlled conditions typical of pilot investigations. Additionally, Weidle's study used clinician-rated outcomes rather than patient-reported metrics.

Importantly, to date, no other studies have examined the real-world effectiveness of video teletherapy for treating OCD in children and adolescents. The current retrospective

XSL•FO
RenderX

observational analysis represents the largest naturalistic examination of this treatment approach, with over 2000 patients receiving care within a community-based online clinical practice. Comparison of these results with results from controlled studies is hindered by multiple factors, including differences in sample size, self-selection (in controlled studies), treatment protocols, and outcome measures used, which may have contributed to differences in response rates. These data were from patient-reported OCD symptom scale (DOCS) rather than clinician-rated assessments, are retrospective or observational rather than a prospective study, and have a longitudinal design to evaluate the durability of treatment gains. Despite these methodological distinctions, the findings from our observational analysis, together with findings from previous research studies, suggest video-based delivery of exposure-based therapy is both effective and efficacious for treating OCD in younger populations. Our large-scale, real-world investigation provides promising evidence for the viability of this innovative service delivery model.

The treatment methodology for children and adolescents, as for adults, was influenced by a previously developed and evaluated approach to provide evidence-based ERP treatment efficiently in terms of therapist time [24]. The symptom reduction achieved in this study aligns with that found in earlier research, although direct comparisons are somewhat limited due to differences in setting (real-world clinical versus controlled research environments) and outcome measures used (patient-rated DOCS versus clinician-rated Yale-Brown Obsessive-Compulsive Scale) [36]. Additionally, the use of face-to-face teletherapy distinguishes this treatment from in-person methods previously studied.

In terms of comparison with previously-reported adult outcomes [25], the results in this child and adolescent cohort show a slightly lower magnitude of symptom reduction (median 7.7% lower). This may be due to several factors. Children and adolescents may not as readily comprehend the rationale behind ERP, which might result in some resistance in completing all required homework. In general, the idea of intentionally experiencing distress in the interest of overcoming symptoms may be highly counterintuitive, especially for children. The concepts of habituation with repeated exposures and interruption of compulsions as a way to break the cycle of obsessions and compulsions are abstract concepts that may exceed the cognitive developmental capacities of some. These potential barriers are partially mitigated, however, by parental psychoeducation and their involvement in the treatment.

Further, in this cohort, symptom improvements were relatively consistent across mild, moderate, and severe cases. This indicates the treatment model's broad applicability and effectiveness across different severity levels of OCD, even in those with severe OCD, who achieved a median of 34.07% symptom reduction. This finding emphasizes the treatment's capacity to address the needs of a diverse group of young patients in a time-efficient manner.

The treatment also resulted in decreases in depression, anxiety, and stress symptoms from baseline to endpoint (weeks 13-17). This was unsurprising as, for many with OCD, these symptoms are secondary to their core OCD symptoms; thus, as the OCD symptoms improve, improvements in the secondary symptoms often follow. This can occur to a certain extent even without specific treatments directed at them.

An innovative aspect of the NOCD model was the inclusion of additional patient support mechanisms, such as between-session SMS messaging with therapists, which was used by about 98% of members and in those who used it at an average of about 54 times. Also available was 24-hour access to NOCD's online support community. It is possible that this might facilitate a sense of belonging and understanding among participants and their parents or caregivers and help normalize their experiences by connecting them with peers facing similar challenges. This peer support, especially from individuals who had successfully completed the NOCD treatment, likely encouraged ongoing engagement and adherence to the therapy process, which is critical given the inherently challenging nature of ERP.

The use of technology, including video teletherapy and integrated communication tools, was pivotal in engaging and effectively treating a wide demographic of young patients across various locations. These technological solutions allowed for the execution of in-session, in vivo exercises tailored to the individual's symptoms and environments, enhancing the relevance and impact of the therapy. Previous research supports the efficacy of remote therapy [17], and the significant symptom improvement rates observed in this study further validate the effectiveness of virtual ERP, comparable to traditional in-person therapy.

Strengths and Limitations

There are several limitations to this analysis that should be considered. First, the use of the DOCS as the primary outcome measure is a limitation, as it was not designed specifically for use in children and adolescents. Nevertheless, we found it to be correlated with a validated self-report child-specific measure (the OCI-CV-R) [30]. However, because we did not use a rating scale that is widely used in children (such as the Children's Yale-Brown Obsessive Compulsive Scale (CY-BOCS) [39], direct comparison of results to prior studies that used other scales to assess OCD symptom severity and treatment response in pediatric populations is hindered. In future work, it would be beneficial to incorporate additional parent- or caregiver-completed assessments, such as the CY-BOCS Parent Version [40]. Second, there was a high percentage of missing data for the DOCS for weeks 13-17 and in the longitudinal follow-up periods and for the DASS-21 for weeks 7-11 and 13-17. Using linear mixed models for analyses allowed us to include all available data points (without having to discard all of a patient's data if, for example, a midpoint assessment was missing). However, the extent of missing data limits our ability to estimate responses for OCD symptoms at midpoint (weeks 13-17), in the follow-up period, and secondary outcomes of depression, anxiety, and stress. Third, this was an observational study design, which inherently precludes making causal inferences about the specific effects of the video teletherapy intervention since there was not a control arm. Relatedly, there were no standardized treatment fidelity checks, typically found in controlled trials, although NOCD therapists received the same

XSL•FO
RenderX

standardized training and were audited for adherence. Finally, while we collected satisfaction ratings after sessions, the response rate was low, limiting our ability to comprehensively assess families' satisfaction with the treatment approach. Despite these limitations, the flexibility allowed within the treatment model provides real-world applicability and potential for adaptation to the highly varied individual patient and parent needs. Additionally, the large sample size and longitudinal design offer substantial evidence for the effectiveness of this innovative service delivery approach in a naturalistic clinical setting.

Conclusions

Overall, ERP delivered via technology-assisted video teletherapy results in clinically significant improvements in OCD, depression, anxiety, and stress symptoms for children and adolescents with OCD. This is achieved in approximately 65% fewer sessions than treatment-as-usual outpatient CBT with ERP. This could translate to lower costs than such lower-intensity approaches and may also translate to reduced costs compared with higher-intensity programs for those with severe symptoms. Further, it is effective for moderate and severe OCD, which for some may prevent the need for higher levels of care such as intensive outpatient, partial hospitalization, residential, or inpatient treatment. Because OCD in this population intimately involves the family, healthier children and adolescents could translate to less stress and better health in family members. In sum, this treatment modality offers a scalable, effective option for accessing evidence-based care, potentially reducing the burden of OCD on young individuals and their families while also presenting an opportunity for significant cost savings compared to traditional treatment methods.

Acknowledgments

The authors would like to thank the NOCD therapists and member advocates for their help in facilitating treatment and care experiences. We would also like to thank Clare Beatty, MA, for her assistance with manuscript preparation. There was no external funding for the analysis.

Data Availability

The datasets analyzed during this study are proprietary business assets of NOCD Inc, and are not publicly available. The data may be available from the corresponding author on reasonable request with appropriate data use agreements in place.

Authors' Contributions

JDF and SS were involved in conceptualization; NL and AR were involved in data curation; formal analysis was done by AR; JDF and AR were involved in investigation and methodology development; JDF and LT contributed to project administration; LT and SS contributed to resources; supervision was done by JDF, NRF, MN, PBM, LT, and SS; visualization was done by AR; JDF, NRF, MN, CWM, and AR were involved in writing—original draft; and JDF, NRF, MN, NL, CWM, PBM, LT, SS, AR were involved in writing—review & editing.

Conflicts of Interest

JDF, NRF, MN, NL, CWM, PBM, LT, SS, and AR report personal fees from NOCD Inc.

Abstract

Background: The COVID-19 pandemic has shifted health care toward virtual and online models, impacting both users and providers. Numerous user concerns and perceived risks related to telemedicine are continually evolving and adjusting in response to the pandemic. In many countries, there has been a substantial increase in the use of virtual health care visits, which offers a unique opportunity for researchers to explore these user concerns.

Objective: This study aimed to first reconstruct the risk dimensions associated with telemedicine, then identify the risk factors affecting users' adoption, and finally propose effective solutions to mitigate these concerns. By integrating the newly constructed perceived risk with the technology acceptance model (TAM), we scrutinized various dimensions of perceived risk and their influence on users' perceptions of ease of use, perceived usefulness, and use intention (UI).

Methods: Our target population consists of adults aged ≥18 years who have used or may use telemedicine services, recruited through an anonymous, voluntary, open, web-based survey. We collected responses and used part of them to reconstruct risk dimensions using exploratory factor analysis. Subsequently, we analyzed the intricate relationship between perceived risk, the TAM, and the acceptance of telemedicine using structural equation modeling with another part of the responses.

Results: A total of 1600 valid responses were collected. Eight distinct risk dimensions were reconstructed, revealing a substantial negative impact of performance risk on UI. The psychological and social risk was the strongest barrier to the ease of using telemedicine. Time risk, provider risk, and privacy risk were not statistically significant to the TAM. The resulting model elucidates a remarkable 66% variance in UI for telemedicine services.

Conclusions: This study substantially advances the field of telemedicine research by reconstructing and redefining 8 risk dimensions and confirming the statistical significance of 5 perceived risks on the adoption of telemedicine services. These insights are poised to facilitate the promotion and enhancement of telemedicine services in the health care sector.

Introduction

Background

During the COVID-19 crisis, telemedicine gained global prominence and became more accessible and applicable than ever before [1]. Social distancing measures necessitated the use of telemedicine as a substitute for in-person health care interactions in many countries. Health care users and providers, who had previously been reluctant to adopt telemedicine, were compelled to embrace it [2]. A substantial disruption such as a pandemic can act as a catalyst for the acceptance of telemedicine services, potentially leading to a shift in users' perceptions and attitudes [3]. Consequently, the current expansion of telehealth has provided an opportunity to explore and reevaluate the concepts of technology acceptance and risk.

Telemedicine is an umbrella term defined as the use of technology to deliver health care and health information to individuals who are located at a distance from health care providers [4]. While the concept of telemedicine is not new, its wide-scale adoption began in the 1990s. However, telehealth is currently operating within a more information-rich environment. Due to the rapid development of telecommunication technologies and the high cost of devices, its adoption continues to face various challenges, particularly in certain regions where the full benefits of telemedicine services have not yet been realized [5,6].

According to Chen et al [7], the impact of technology on the development of telemedicine in Taiwan began with the National Information Infrastructure project, which used various network bandwidths for telemedicine starting in 1995. Before the legalization of telemedicine through an amendment to the Physician Act in 2018, Taiwan's medical laws restricted its practice to remote areas, mountainous regions, and outlying islands [8]. Following this amendment, the Taiwan Ministry of Health and Welfare expanded the nationalized health insurance program to include coverage for telemedicine outpatient consultations across different specialties in remote areas. Despite the technological advancements, use of telemedicine remains limited in Taiwan. Reports indicate a disappointingly low rate of use, with only approximately 5.83% of individuals quarantined at home in Hsinchu City using telemedicine consultations from February to May 2020 [8]. With the onset of the COVID-19 pandemic, the government further promoted telemedicine services, resulting in a larger pool of virtual visits. This expansion provides researchers with a valuable opportunity to better understand user concerns. During the COVID-19 pandemic, telemedicine in Taiwan was primarily used for treating confirmed COVID-19 cases and chronic diseases care. Due to quarantine and social distancing requirements, patients used mobile phones, tablets, or computers to engage in telemedicine consultations with health care professionals from the comfort of their homes.

Telemedicine service is not only a technological innovation but also a sociocultural phenomenon [5]. It transforms the traditional physician-patient relationship, altering both its complexity and essence [5]. A systematic review of telemedicine emphasizes the need for more patient-oriented studies, recognizing it as a complex collaborative process [9]. In addition, Bashshur et al [5] highlight the lack of research on the social, cultural, and psychological dimensions of telemedicine.

This Study

This study aims to approach the impact of risk from psychological and social perspectives, comprehending its influence on telemedicine, and proposing strategies for development, implementation, and acceptance [5].

Perceived risk is a substantial barrier to the adoption of telemedicine services, encompassing social and psychological aspects [10]. Bakshi and Tandon [11] introduced and validated a theory-driven framework that uncovers the facets of perceived risk as barriers to telemedicine acceptance in their study involving physicians in north India. Harst et al [12] argued that user-centered design and theory-guided approaches are crucial in telemedicine development. The impact of risk on the adoption of a technology is undeniable. However, with the increasing stream of literature, many different dimensions of risk have been proposed. Some studies adopt a limited number of risk dimensions, while others introduce risk dimensions from other fields; some risks share similar concepts or have a high degree of overlap. First, there is a shortage of effective categorization and definition among the various risks. Second, there remains a lack of research that comprehensively assesses the multiple dimensions of risk in telemedicine. Therefore, this study addresses substantial gaps in the telemedicine literature related to perceived risk facets and provides solutions. We aim to reconstruct the effective dimensions of perceived risk and explore what primarily influences users' acceptance of telemedicine services. We seek to evaluate the integration of the technology acceptance model (TAM) into the perceived risk dimensions, providing a solid theoretical foundation for telemedicine acceptance during a crisis.

Therefore, we posed the following research questions: (1) What are the evidence-based effective risk dimensions for telemedicine services adoption? and (2) Which risks effectively influence users' intention to use telemedicine during the COVID-19 pandemic?

To address these questions, we will conduct a comprehensive literature review to identify potential risk types in telemedicine from existing literature, providing a strong theoretical foundation. We will then empirically reconstruct these risk dimensions through exploratory factor analysis (EFA) [13]. By applying confirmatory factor analysis (CFA), we will validate and redefine the risk factors identified in the literature. Subsequently, we will integrate these redefined risk dimensions with the TAM and use CFA to explore the relationship between the 2, aiming to provide robust and credible results to strengthen the theoretical framework.

Theoretical Background

TAM Overview

The TAM was designed as a model of users' acceptance of information technologies and systems in 1986, and 3 years later, it was used to understand the attitude of computer users [14,15]. The final version of the TAM, introduced by Venkatesh and

XSL•FO
RenderX

Davis [16] in 1996, eliminated the construct of attitude and found that both perceived ease of use (PEOU) and perceived usefulness (PU) positively influence use intention (UI).

The TAM model included constructs of PU, PEOU, and UI. PU was defined as the degree of users' belief that using a particular system or service would enhance their performance [17]. PEOU means the degree of their belief that using a particular system or service would be free from effort [17]. TAM theorizes that PU and PEOU are antecedents to the adoption of technology determined by external factors [17]. In prior studies on telemedicine, PEOU positively affects PU, and both PU and PEOU positively affect UI [17].

The TAM has been used to explain various forms of computer technology and is also one of the most applied theories in the field of telemedicine [12]. Many studies considered that the TAM is an appropriate model that can be adapted to the study of technology acceptance and use of telemedicine [18,19]. One systematic review by Harst et al [12] indicates that the adaption of telemedicine service can be evaluated by using the theories of TAM and acceptance is predicted by PU, social influences, and attitude. In our study, we used the TAM to evaluate the adoption of telemedicine and hypothesized that it would be influenced by perceived risk.

Perceived Risk

Overview

The perceived risk was developed from the psychological theory proposed by Bauer [20] in 1960 to explore consumer behavior. The perceived risk is defined as a combination of uncertainty plus seriousness of the outcome involved [20]. Featherman and Pavlou [21] also adopted the same definition. Perceived risk refers to an individual's subjective expectation of experiencing a loss in pursuit of the desired outcome [21,22]. Perceived risk consists of individuals' subjective feelings and the self-evaluation of the size of the potential loss [23]. Thereafter, researchers increasingly applied perceived risk to consumer behavior and many dimensions of perceived risk were identified [21,24,25].

Cunningham [23] identified performance and psychosocial elements as perceived risk's 2 major categories and typified perceived risk into 6 dimensions, such as performance, safety, financial loss, time, and social and psychological loss [23]. Then, the importance of privacy concerns has been gradually recognized and the rich literature on consumer risk perception appeared [21]. Provider risk, physical risk, and technology risk have been presented to better understand the adoption of e-services [21]. The fear that has stemmed from the COVID-19 crisis has recently caused psychological changes in terms of consumer behavior. Information on the objective risk of the pandemic is typically scarce and is featured as unpredictable and uncertain. It remains unclear how people perceive infection risks and whether these perceptions influence their decision to adopt telemedicine [26,27].

Perceived risk has been a prominent subject of discussion within the realms of telemedicine and health care in general. In Table 1, we present a comprehensive review of previous studies that have incorporated perceived risk or its related dimensions as variables in telemedicine research, using structural equation modeling (SEM) as the primary analytical approach. The literature on perceived risk suggests different types of risk, which can be flexibly applied according to the characteristics of the product or service [28]. Among these studies, only the work of Bakshi and Tandon [11] attempts to understand the barriers to telemedicine adoption by exploring different facets of perceived risk. It is worth noting that not all risk dimensions have been included in SEM models or assessed for patients in prior studies. However, a substantial number of studies investigating the relationship between telemedicine and perceived risk did not adopt SEM as their chosen research methodology.

In the subsequent sections, we will define each risk construct and provide ample justification for selecting these constructs through the existing literature, supported by theoretical backing. Furthermore, we will reconstruct the risks using EFA and obtain empirical evidence with CFA. This approach will be used to reconstruct the effective risk dimensions and validate the reliability and influence of these risk constructs on UI.

Ten dimensions of risk were selected based on our literature review. We will discuss their relationship with telemedicine in the subsequent sections.

Financial Risk

The financial risk refers to potential monetary loss owing to transaction errors or subsequent maintenance costs of the productor service [11]. Financial risk in telemedicine pertains to insurance, billing, payment system, and equipment costs. Historically, insurance coverage and reimbursement for telemedicine services has been a major barrier to adoption [39]. Before the COVID-19 pandemic, most commercial health insurance plans restricted the types of services covered, and many excluded telehealth services. Users were worried that insurance payment regulations did not allow the coverage of telemedicine, which would cause extra loss of money [39]. Second, the lack of awareness about appropriate service charges and the way of payment is another cause of risk. Because of payment restrictions and complex and diversified billing before the pandemic, users' fear about the perceived risk of monetary loss was caused by transaction errors, though some countries had legalized payment parity for telehealth and more user-friendly payment systems have been developed as of now. Third, the purchasing and maintenance cost of the equipment for telemedicine and as well as the internet is relatively high, particularly in developing countries [39]. Topacan et al [40] opined that users and designers of health services should be concerned about the cost of telemedicine services, which should be even less than the cost of visiting a physician [40]. These factors lead to the following concerns: (1) using telemedicine (video consultations) might involve additional costs (financial risk 1); (2) uncertainty about the fees for telemedicine worries me (financial risk 2); (3) complex online payment systems

XSL•FO
RenderX

during telemedicine could lead to financial losses (financial risk 3); and (4) uncertainty regarding insurance coverage during telemedicine might result in financial setbacks (financial risk 4).

Performance Risk

A performance risk is the potential that a product or service will not deliver as much value and desired benefits as required [25]. Inconsistent service quality and failure to meet expectations contribute to perceived risk and consumer dissatisfaction [41]. Generally, the content of the service should be related to the physicians' professionalism and users' requirements. Deviations from one's expectations of care may result in reduced satisfaction [42]. Topacan et al [40] stated that users attach importance to obtaining accurate, relevant, and quality information in a minimum response time. A cross-sectional survey of 699 German mayors identified misdiagnosis and differences in disease applications as the primary perceived risks of telemedicine [43,44]. Users are concerned that not only would the same patient-physician connection not be established but they would not receive the level of complex care they may require because diseases could not be diagnosed through telemedicine services compared with face-to-face consultations [45,46]. These reviews and observations lead to the following survey questions: (1) telemedicine services might not be able to address my concerns (performance risk 1); (2) telemedicine might not meet my expected standards (performance risk 2); and (3) the effectiveness of telemedicine might not compare to in-person consultations (performance risk 3).

Technology Risk

Technology risk can be defined as a technological failure that disrupts business and increases the users' perceived uncertainty about telemedicine technology. Bakshi and Tandon [11] revealed that technology risk had a negative effect on a group of physicians' intention to adopt telemedicine. Consumers are reported to have the same concern. The most frequently cited barriers among patients on dialysis who use home telehealth services are malfunctioning equipment or trouble with internet connections [47]. In addition, a cross-sectional survey in Australia revealed that factors including ineffective communication, the lack of scope for physical examination, and difficulty obtaining prescriptions or examination results were reasons for perceived risk. Technological limitation is the reason why user's telehealth experiences were poorer than traditional face-to-face consultation experiences [46]. Hence, the survey includes the following questions: (1) I worry that the equipment for telemedicine might not function properly (technology risk 1); (2) I am concerned that physicians might not gather my information thoroughly during telemedicine consultations (technology risk 2); (3) I fear the absence of physical examinations (such as touch, percussion, or auscultation) during telemedicine services (technology risk 3); (4) I am worried about the effectiveness of communication with the physician during telemedicine consultations (technology risk 4); and (5) I am concerned about difficulties in obtaining medications or learning about test results through telemedicine services (technology risk 5).

Psychological Risk

Perceived psychological risk refers to users' perception of any possible psychological frustration or anxiety resulting from the use of telemedicine services, which is relatively complicated and with which users are unfamiliar compared to long-term face-to-face consultation [48]. Thus, users may operate the service system unsuccessfully, which can cause anxiety and psychological pressure, called technology anxiety. The term is derived from studies on computer anxiety in which users hold anxious and negative attitudes toward computers [49]. Previous studies among physicians in Ethiopia have shown that computer systems can bring about anxiety; users tend to have an emotional response and become anxious when they are requested to use the service [50]. The following questions are based on these observations: (1) using telemedicine services might make me anxious (perceived psychological risk 1); (2) using telemedicine services might make me feel uncomfortable (perceived psychological risk 2); (3) using telemedicine services might create stress for me, such as worrying about technical errors (perceived psychological risk 3); and (4) using telemedicine services might negatively impact my self-image and self-esteem (perceived psychological risk 4).

Social Risk

Featherman and Pavlou [21] defined social risk as the "potential loss of status in user's social group as a result of adopting the service, looking foolish, or untrendy" [21]. Social risk and influence may come from subjective norms, social factors, and specific interpersonal agreements [40]. People are influenced by others' opinions and behaviors. Individuals have favorable or unfavorable perceptions of telemedicine that in turn affects their perspectives; alternatively, not adopting telemedicine may also have positive or negative connotations [51]. Harst et al [12] demonstrated that not only the target users but the user's social environment should be considered when planning telemedicine service. This is because of the importance of users' social environment and because individuals' social group can support their use of telemedicine. One worldwide study showed that peer experience is one of the major factors behind the overall adoption of telemedicine, as it seems more attractive to them after seeing their family and friends successfully using it. The following questions are based on these observations: (1) using telemedicine service might lower my self-esteem (social risk 1); and (2) using telemedicine service might lead my family and friends to have negative opinions about me (social risk 2).

Physical Risk

Physical risk means the risk of potential threat to users' safety, physical health, or well-being. Physical risk in telemedicine services is related to the safety and health of individuals within high-risk environments [25,52]. During the COVID-19 pandemic, telemedicine could help mildly ill patients to receive the medical care they need at home while minimizing their exposure to the coronavirus [53]. Therefore, the survey contains the following questions: (1) using telemedicine service might pose risks to my physical health (physical risk 1); (2) using telemedicine service might harm my well-being (physical risk 2); and (3) using telemedicine service might lead to illness or infectious diseases, such as pneumonia (physical risk 3).

XSL•FO
RenderX

Privacy Risk

Privacy risk refers to the possibility of the loss of private data owing to fraud or hacking, which compromises the information security of online users [51]. Privacy concerns are a major barrier to online technology adoption [54]. Issues in telemedicine included substantial concerns about privacy and information security [55]. The users' critical concern about privacy included the maximum protection of personal electronic records and clinical data. Transmission and storage of sensitive information must be transparent [56]. This guarantee must be provided by those who supply the device; they must ensure that the devices are safe and noninvasive so that the users do not feel they were spied on [55]. Studies in the United States suggest that people tend to trust hospitals, which substantially moderate the negative privacy effects [54]. Therefore, the survey contains the following questions: (1) I feel that my privacy might not be secure when using telemedicine service (privacy risk 1); (2) I worry that if health care facilities do not have proper storage and backup, my personal data might be lost during the use of telemedicine service (privacy risk 2); (3) I am concerned that my personal information or medical condition might be leaked during telemedicine service (privacy risk 3); and (4) I fear that my personal data might be stolen or misused during telemedicine service (privacy risk 4).

Provider Risk

Provider risk refers to the degree to which users perceive uncertainty about telemedicine providers, including companies, hospitals, organizations, primary care providers, and physicians [29]. A nationwide survey in the United States emphasizes the importance of providers, stating that respondents become less willing to use telemedicine as they become further detached from their own providers [57]. On the basis of another nationwide survey involving 4345 adults in the United States, most participants expressed hesitation when it came to using telemedicine for consultations with health care providers not affiliated with their current organization. Only a mere 19% indicated a willingness to use it for a provider from an entirely different organization [58]. Therefore, the survey contains the following questions: (1) I worry that the providers of telemedicine service might not be knowledgeable (provider risk 1); (2) I am concerned whether professional medical personnel provide this telemedicine service (provider risk 2); and (3) I fear that the providers (physicians or hospitals) might not have enough capability during telemedicine service (provider risk 3).

Time Risk

Time risk is defined as the loss of time and inconvenience caused by delays in finding appropriate services and in learning to use particular technology [11,21]. Most users do not prefer using medical services that demand more time [40]. During the process, consumers may waste time learning how to use telemedicine services and are forced to switch to face-to-face consultation if it does not meet their expectations. Moreover, in developing economies, inadequate provision of information and communication technology infrastructure and poor internet connectivity are still formidable barriers leading to the wastage of time [57]. In contrast, a worldwide study showed that one of the major factors behind the overall adoption of telemedicine is that it saves time, as telemedicine can reduce physical travel and queue times at the hospital [59]. In addition, in some countries, telemedicine visits usually take less time than in-person visits, which are substantially associated with higher levels of satisfaction [60]. So, the survey contains the following questions: (1) accepting telemedicine service might require additional time (time risk 1); (2) slow internet speeds could potentially waste my time (time risk 2); and (3) If telemedicine service do not meet expectations, it might lead to even more time wastage (time risk 3).

Perceived COVID-19 Infection Risk

There are 2 dimensions in perceived COVID-19 infection risk: the cognitive and affective dimension and the dimension related to fear and general concerns. The cognitive or affective dimension is the qualitative dimension in the perception of COVID-19, such as its severity, controllability, and personal impact. However, the dimension related to general concerns focuses on personal feelings of fear and insecurity. Perceived risk related to COVID-19 does not come under the perceived risk of telemedicine; however, a crisis situation such as the COVID-19 pandemic influences the perceptions of telemedicine [59]. Following these theories, we can expect that people with higher risk perceptions are more likely to adopt telemedicine services. Therefore, the survey includes the following questions: (1) I feel my health is at risk during the COVID-19 pandemic (perceived COVID-19 infection risk 1); (2) I believe it is challenging to control the COVID-19 outbreak (perceived COVID-19 infection risk 2); (3) I worry about severe harm to my body if I contract the virus (perceived COVID-19 infection risk 3); (4) I think the current COVID-19 situation is more serious than before (perceived COVID-19 infection risk 4); and (5) I fear I might get infected by the coronavirus (perceived COVID-19 infection risk 5).

Methods

Instrument Development

The target population in our study were users and potential users of telemedicine services in Taiwan. The questionnaire for the survey was adopted from previous telemedicine studies or studies on fields related to health care. Both constructs suggested by the TAM model and perceived risk dimensions were included in the questionnaire [21]. To improve its quality and clarity, the questionnaire's preliminary version was tested to a pilot group of 60 citizens through the web-based survey and 3 individuals holding master's degree suggested modifications in the wording of items for conciseness. Finally, some questions were deleted owing to their low α reliability. The measurement scales were assessed on a 5-point Likert scale—from 1 for "strongly disagree" to 5 for "strongly agree." Then, it was determined whether the value of Cronbach α in all constructs was >0.65, which meant that the internal consistency and reliability of summated rating scales were acceptable [61].

Ethical Considerations

We conducted a noninterventional questionnaire-based study, using social science methods to gain a deeper understanding of

XSL•FO
RenderX

participants' perceptions. According to the Taiawn Ministry of Health and Welfare's Human Research Act, Article 5, research conducted in public settings involving nonspecific individuals, which is noninterventional, anonymous, and where the collected information cannot be used to identify specific individuals, is exempt from review [62]. At the initial stage of questionnaire distribution, participants were informed of the study's purpose and made aware that their participation was voluntary and anonymous, with no personal or private data being collected. All procedures were conducted in accordance with the ethical guidelines of the Declaration of Helsinki.

Data Collection

The study uses SurveyCake, a widely used and professional questionnaire distribution platform in Taiwan. Our target population includes individuals who have previously used telemedicine services or those who may potentially use them in the future. Recruitment was restricted to adults aged ≥18 years, as they possess medical decision-making autonomy. We primarily used public social media platforms, such as Facebook (Meta Platforms, Inc), to reach a broad audience. To ensure the representativeness of our sample, we extended our outreach to relevant online communities across various geographical regions, aiming to achieve balance in terms of age and urban-rural distribution. In addition, for populations less familiar with the internet, we used local community networks to raise awareness about recruitment. By engaging participants through a diverse range of online and offline platforms, we aimed to ensure that the sample accurately reflected Taiwan's current population, particularly in terms of sex, age, education level, and regional distribution.

Data Management

After the questionnaire collection is complete, we conducted preliminary processing of the results, including the deletion of incomplete responses. In addition, some questionnaires deemed to have low reliability were removed, including those with reverse order questions and extreme outlier values (such as very short response times and selecting the same option for all questions). Next, the collected questionnaires were randomly divided into 2 groups: group A and group B, using simple random sampling in SPSS (version 20; IBM Corp). Subsequently, normality tests were conducted to determine whether the datasets approximated a normal distribution by testing the normality of the data using the Kolmogorov-Smirnov residual method with the appropriate criteria.

The exported data were managed by SPSS and the relationship between variables was evaluated with SPSS Amos (version 26). SEM is the preferred technique among many standard methods in software and enables the evaluation of complex, multiple latent constructs and relationships [63]. Moreover, because the study analyzes the cause and different facets of perceived risk and its effect on technology acceptance, SEM has been preferred over regression. SEM comprises 2 parts, EFA and CFA. The questionnaires from group A, used for EFA, were used to ensure that the variables adequately represented the domains of the factors and to exclude variables from unrelated domains, thereby reconstructing several evidence-based risk dimensions. Meanwhile, the questionnaires from group B were used for CFA to validate the hypothesized model and its paths [64].

EFA, Construct Extraction, and Definition

First, the questionnaires from group A were used to justify the application of EFA by accessing the Bartlett test of sphericity with Kaiser-Meyer-Olkin, which was conducted with Varimax rotation and the results of EFA [65,66]. Next, we redesigned the facets of perceived risk based on eigenvalues exceeding 1.000, as determined by CFA. The EFA aims to extract domains with eigenvalues greater than 1.000, and to name the newly generated dimensions based on a combination of data analysis results (such as factor loadings) and theoretical background. In this step, we reconstructed latent variables of perceived risk, and informed the hypothesis according to the abovementioned literature review.

Bias, Reliability, and Validity

To address common method bias (CMB), we conducted a Harman 1-factor test, which involved performing an EFA on all study variables. The results indicated that the first factor accounted for >50% of the variance among the variables [67]. To mitigate concerns of multicollinearity, we used the variance inflation factor to evaluate the potential bias generated by the measurement design and determine the degree of multicollinearity among the multiple regression variables, with a suggested threshold of <10 [68].

To assess the validity of the model, 2 types of validities were used: convergent and discriminant validities. The convergent validity reflects the extent to which 2 measures capture a common construct [69]. Convergent validity is estimated by using the factor loading of all indicators and the average variance extracted (AVE). If the value of the factor loading of all items is >0.50, it is considered substantial. In addition, if the AVE is >0.5 and composite reliability is not <0.7, it indicates adequate convergence [70]. Moreover, the discriminant validity reflects the degree to which items are discriminated against amid constructs or individual conceptions are assessed for the measurement model. Two criteria are used for the estimation of discriminant validity. The first one is that the AVE itself is greater than correlations in a given construct's column or row [71]. The second one is that the square root of AVE of the corresponding construct exceeds any correlation with another construct, which means the discriminant validity is considered to be established [72].

Model Fit

To ensure the fit between the data and the measurement model or to assess the goodness of fit, 4 different measures were used, including chi-square—the ratio of the chi-square statistic to the respective *df* (χ^2/df), the goodness of fit index (GFI), root mean square error of approximation, and the comparative fit index. The chi-square is an absolute fit index, with a low chi-square value relative to the df indicating a better model fit. However, the chi-square fit statistic is affected by large samples and a ratio is <5 for the χ^2/df is preferred for acceptable model fit evaluation [73-75].

XSL•FO
RenderX

Hypothesis Testing

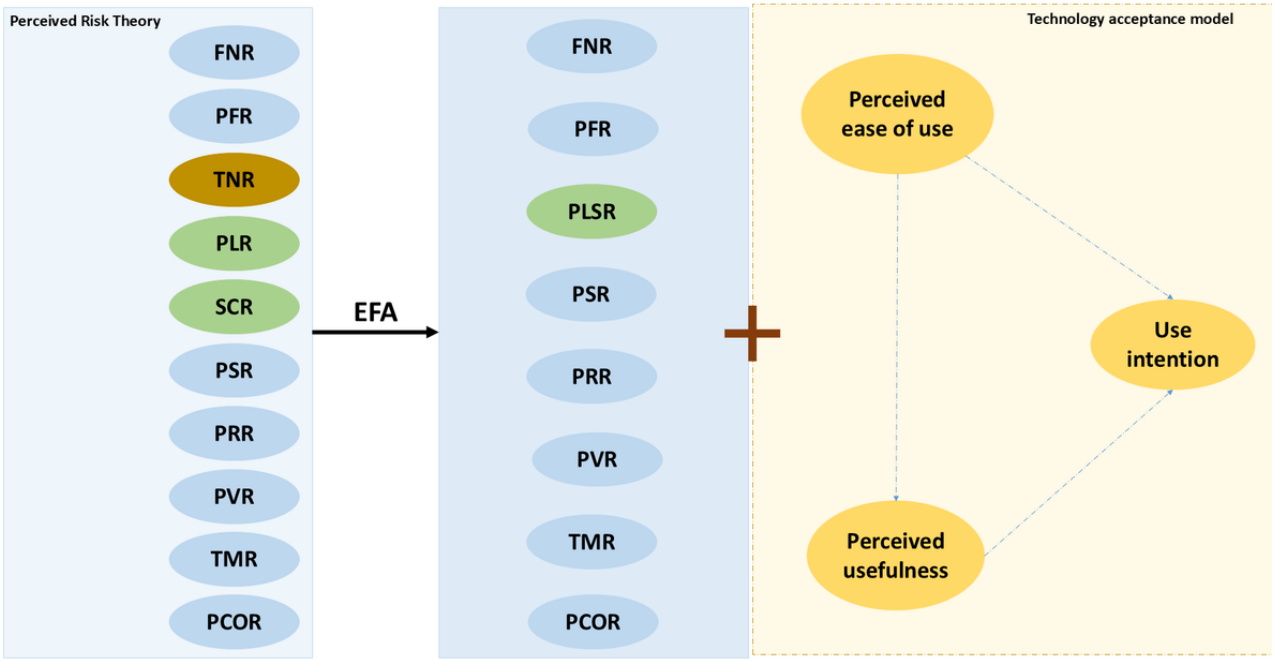
After the measurement model was confirmed, we used the structural model to explain the relationship among the variables and discover the connection between constructs followed by hypothesis testing. Then, bootstrapping resampling technique was used to examine model paths in the structural model—the *P* values <.05 were considered statistically significant [76].

Results

Overview

The web-based survey of our study was open to the public in Taiwan from June 13 to 30, 2022. A total of 1638 responses to the questionnaire were received, of which 38 were deleted owing to incompletion or low reliability caused by short use of answer time. Therefore, 1600 valid responses were collected for the analysis with a valid response rate of 98.2%. Using simple random sampling, all the questionnaires were divided into 2 groups: group A (600 questionnaires, 37.5%) and group B (1000 questionnaires, 62.5%). Table 2 reports the characteristics of all respondents in more detail, including reasonable representations of sex, age, and educational qualifications. Normality was assessed using the 1-sample Kolmogorov-Smirnov test, with significance values for group A and group B recorded as 0.200 and 0.550, respectively. Because both values exceed 0.05, we conclude that the data are normally distributed.

Table 2. Sample demographic of the respondents.



Characteristics	Group A (n=600)	Group B (n=1000)	Total (N=1600)
Sex, n (%)			
Male	301 (50.1)	474 (47.4)	775 (48.4)
Female	299 (49.9)	526 (52.6)	825 (51.6)
Age (y), n (%)			
18-29	213 (35.5)	318 (31.8)	531 (33.2)
30-39	116 (19.3)	169 (16.9)	285 (17.8)
40-49	98 (16.4)	214 (21.4)	312 (19.5)
>50	173 (28.8)	299 (29.9)	472 (29.5)
Education level, n (%)			
High school	71 (11.8)	129 (12.9)	200 (12.5)
Bachelor	357 (59.5)	607 (60.7)	964 (60.3)
Master	155 (25.8)	241 (24.1)	396 (24.7)
Doctoral	17 (2.8)	23 (2.3)	40 (2.5)
Experience of telemedicine, n (%)			
None	510 (85)	839 (83.9)	1349 (84.3)
1-3 times	85 (14.1)	147 (14.7)	232 (14.5)
>3 times	5 (0.9)	14 (1.4)	19 (1.2)
History of chronic disease, n (%)			
None	477 (79.5)	801 (80.1)	1278 (79.8)
Yes	123 (20.5)	199 (19.9)	322 (20.2)

Thus, group A were used to justify the application of EFA by accessing the Bartlett test of sphericity with Kaiser-Meyer-Olkin value was 0.925 and the Bartlett test of sphericity was significant (*P*<.001) [65,66]. The test was conducted with Varimax rotation and the results of EFA indicated that 8 different factors, with eigenvalues being superior to 1.000, accounted for 69.9% of the cumulative variance. Technology risk 1, technology risk 2, technology risk 4, and perceived COVID-19 infection risk 3 were deleted owing to lower factor loading, wrong concept of contrast, or the crossing of 2 different contrasts during the EFA process.

According to the results of EFA, 2 risk facets, namely "technology risk" and "social risk," were removed from the analysis. In addition, the facet originally labeled as "perceived psychological risk" was renamed "psychological and social risks" because the 2 items related to social risk were classified under the same category as perceived psychological risk by the EFA. As a result, a total of 8 facets related to perceived risk were identified (Figure 1) and details including factor loading are presented in Table 3. To sum up, 8 risk dimensions were reconstructed, including financial risk, performance risk, psychological and social risk, physical risk, privacy risk, provider risk, time risk, and perceived COVID-19 infection risk.

Definition of Factors of Risk

The definitions of the 8 facets of perceived risk and constructs of TAM are provided in Table 4. The 8 risk dimensions included financial risk, performance risk, psychological and social risk, physical risk, privacy risk, provider risk, time risk, and perceived COVID-19 infection risk.

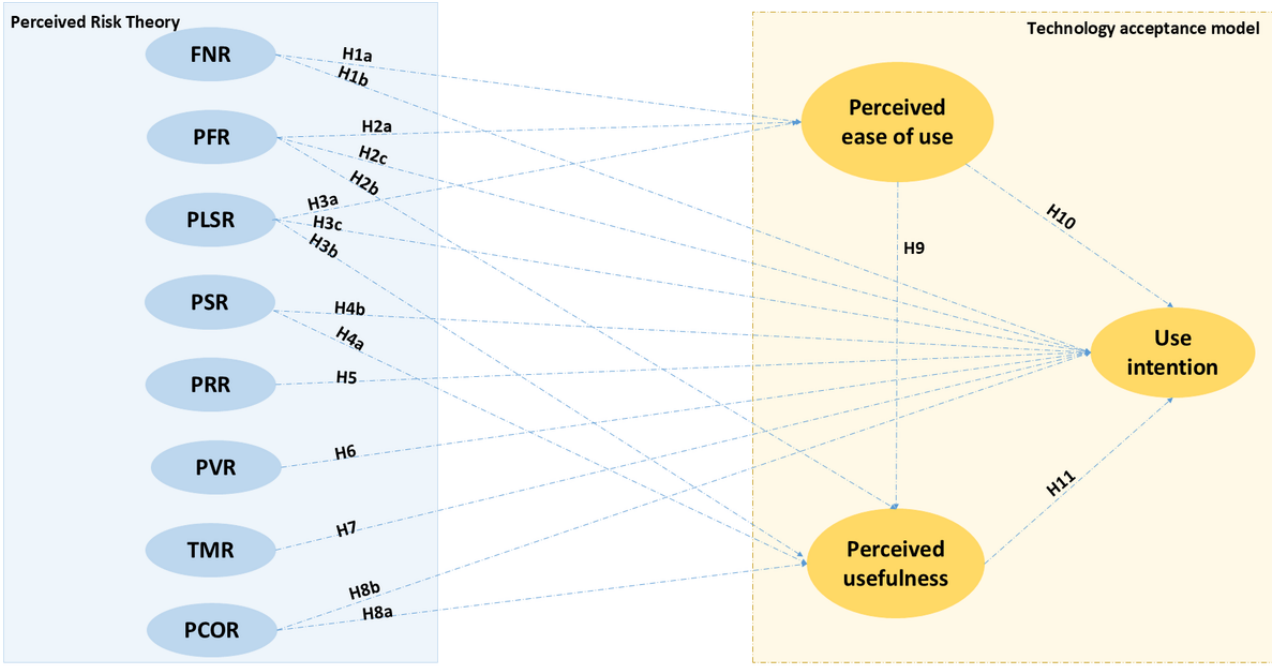
Table 4. The definition of the constructs.

Constructs	Operational definition	Reference
Financial risk	Potential for financial loss due to online payments, limited insurance coverage, and maintenance costs for products like mobile phones and the internet.	[39,77]
Performance risk	The result does not match the desired benefits.	[21,48,78]
Psychological and social risks	The risk that lowers the user's self-image, leads to a loss of self-esteem and embarrassment, and generates pressure and anxiety resulting from the use of a service.	[79]
Physical risk	The risk to the user's safety and physical health in using telemedicine.	[78]
Privacy risk	Potential loss of control over personal health information without permission.	[77,80]
Provider risk	The risk of the user's perceived uncertainty about the telemedicine provider.	[29,81]
Time risk	The risk of the user's perception of wastage of time in learning how to use the service.	[21,77]
Perceived COVID-19 infection risk	The fear and general concerns about people's perception of COVID-19 infection.	[82]
Perceived ease of use	The degree of users' belief that using telemedicine service would be free from effort.	[83]
Perceived usefulness	The degree of users' belief that using telemedicine service would enhance their performance.	[83]
Use intention	Users' desire to use telemedicine services in the future.	[10,77]

Hypothesis Formation

According to the aforementioned literature review, 18 hypotheses were derived (Textbox 1).

XSL•FO
RenderX



Textbox 1. Derived hypotheses.

- Hypothesis 1a: financial risk negatively influences the perceived ease of use (PEOU) of telemedicine services.
- Hypothesis 1b: financial risk negatively influences the usage intention (UI) in telemedicine services.
- Hypothesis 2a: performance risk negatively influences the PEOU in telemedicine services.
- Hypothesis 2b: performance risk negatively influences the perceived usefulness (PU) of telemedicine services.
- Hypothesis 2c: performance risk negatively influences the UI in telemedicine services.
- Hypothesis 3a: psychological and social risks negatively influences the PEOU of telemedicine services.
- Hypothesis 3b: psychological and social risk negatively influences PU in telemedicine services.
- Hypothesis 3c: psychological and social risk negatively influences UI in telemedicine services.
- Hypothesis 4a: physical risk negatively influences the PU of telemedicine services.
- Hypothesis 4b: physical risk negatively influences the UI in telemedicine services.
- Hypothesis 5: privacy risk negatively influences the UI in telemedicine services.
- Hypothesis 6: provider risk negatively influences the UI in telemedicine services.
- Hypothesis 7: time risk negatively influences the UI in telemedicine services.
- Hypothesis 8a: perceived COVID-19 infection risk positively influences the PU of telemedicine services.
- Hypothesis 8b: perceived COVID-19 infection risk positively influences the UI in telemedicine services.
- Hypothesis 9: PEOU positively influences the PU in telemedicine services.
- Hypothesis 10: PEOU positively influences the UI in telemedicine services.
- Hypothesis 11: PU positively influences the UI in telemedicine services.

Research Model

The research model (Figure 2) consists of 8 redefined dimensions of risk combined with the TAM, resulting in a total of 18 hypotheses.

Figure 2. Research model and hypothesis. FNR: financial risk; PFR: performance risk; PLSR: psychological and social risks; PSR: physical risk; PRR: privacy risk; TMR: time risk.

Reliability, Validity, and Bias

In CFA for the reliability and validity test (Table 5), financial risk 1 and perceived COVID-19 infection risk 5 were deleted owing to lower standard loading. PU1 was deleted from the subsequent analysis according to the result of modification indices because of a higher correlation with UI and failure of the test of discriminant validity (the square root of the AVE for PU 0.715 is less than PU of the correlations with UI 0.766). After that, the tests indicate adequate discriminant validity. Two criteria regarding discriminant validity showed that not only all AVEs were greater than the correlations in that construct's rows and columns but also the square root of AVE (diagonal) was greater than off-diagonal elements in rows and columns. The two tests mentioned earlier support discriminant validity (Table 6).

In addition, the result of the evaluation showed that all Cronbach α values were >0.7 and the internal consistency of items was considered. Moreover, all item loads on their own factors were >0.5 and the internal consistency reliability for each construct was >0.6. Most constructs' AVE values met the minimum requirement because the constructs exceeded the criterion of 0.50, though the construct—"perceived COVID-19 infection risk"—was 0.394 and "financial risk" was 0.483. However, we could accept AVE<0.5 if the composite reliability was >0.6 because the convergent validity of the construct was still adequate. Therefore, these tests indicate adequate convergent validity [72].

Financial risk, performance risk, psychological and social risk, physical risk, privacy risk, provider risk, time risk, and perceived COVID-19 infection risk had mean scores of 3.33 (SD 0.854), 3.58 (SD 0.783), 2.43 (SD 0.769), 2.49 (SD 0.897), 3.39 (SD 1.00), 3.32 (SD 0.878), 3.37 (SD 0.831), and 3.81 (SD 0.751), respectively. The mean scores of predictors of TAM such as PU, PEOU, and UI, were 4.00 (0.761), 3.81 (SD 0.804), and 3.87 (SD 0.768), respectively.

The values of variance inflation factor for all the latent variables in the model were between 1.107 and 2.241, all of which were lower than the suggested threshold, indicating low concerns about multicollinearity. For addressing CMB, the Harman 1-factor test during the EFA on all study variables showed the first factor accounted for 31% of the variance among the variables, which was lower than the suggested threshold, indicating no CMB issues.

Model Fit

In the following procedure, the measurement model (Figure 3) assessment was done, and a summary of the model fit measurements is presented in Table 7, in which most results surpass the acceptable levels but the value of GFI is 0.840 which is below 0.9. As Doll et al [84] suggest, GFI in the 0.8-0.9 range presents a reasonable fit, particularly for more variance [84]. Overall, the measurement model indicates a satisfactory fit.

After the measurement model was confirmed, we used the structural model (Figure 4) to discover how closely the theory is supported by empirical data and whether the theory is empirically confirmed [85]. The result of the structural model and the summary of the model fit measurement are given in Table 8. The structural model indicates a satisfactory fit. We also tested for second-order factors in multifaceted risk perception. However, the model fit indices were inferior to those of the first-order model. Therefore, we decided to retain the original structural model.

Result of Hypotheses

The hypothesis testing showed that 5 out of 8 redefined risks significantly affect the TAM. The result of the hypotheses testing is shown in Table 9. Three kinds of perceived risk—financial risk, performance risk and psychological and social risk—had significant negative effects on PEOU. The psychological and social risk showed a stronger effect (β=−0.377; *P*<.001) than the financial risk (β=−0.116; *P*=.003) and performance risk (β=−0.091; *P*=.006). PU was affected by 2 types of perceived risk. The performance risk (β=−0.133; *P*<.001) had a significant negative effect, but the perceived COVID-19 infection risk (β=0.120; *P*=.003) had a significant positive effect on PU. Furthermore, performance risk was the only kind of risk that had a significant direct negative impact on all 3 variables: PEOU, PU, and UI. However, time risk, provider risk, and privacy risk did not significantly impact the 3 contrasts of TAM. PU was significantly influenced by PEOU (β=0.511; *P*<.001). Moreover, both PU and PEOU were found to significantly affect UI (*P*<.001). In terms of goodness of fit indicators, the research model explained 66% of the variance in UI of telemedicine service as shown in Figure 5. To further assess the significance of the direct and indirect effects of predictor variables on the UI of telemedicine service, a decomposition of the effects analysis was conducted in Table 10. Overall, among the 8 types of risks, performance risk had the most significant total effect on UI (β=−0.362).

Discussion

Principal Findings

The study developed a theoretical model based on TAM to determine the barriers to UI in telemedicine services. By reconstructing the risk dimensions, 8 facets of perceived risk were extracted through EFA, and 5 facets of perceived risk were considered to substantially affect the TAM of telemedicine services during the COVID-19 pandemic in Taiwan. Three risk dimensions have been adjusted according to the results of EFA. Perceived psychological risk and social risk have been categorized into psychological and social risk, mainly due to their high degree of overlap. Social risk emphasizes the potential for image damage due to lack of recognition by others, while perceived psychological risk highlights the potential for inconsistency with self-identity. Social perceptions may also influence one's self-image, as well as attitudes toward and anxiety about telemedicine. Technology risk, which is not traditionally categorized under risk perception, was included in previous studies primarily from a technological perspective to assess the impact of risks. This inclusion leads to some overlap with the original risk dimensions. For instance, survey questions asked users whether they were concerned about the poor performance of telemedicine due to various technological limitations (such as network, equipment, and physical examination). Although these are technological limitations, they fundamentally address concerns about performance. This was the purpose of EFA—to reconstruct 8 effective types of risk.

The psychological and social risk seems to be the strongest barrier to perceived risk affecting the ease of using telemedicine. Our study supports the effect of technology anxiety and pressure, which have been shown to affect users' resistance to using new technology [10]. Technology anxiety and uncertainty can lead to resistance to change owing to unexpected errors in technology [49]. Therefore, when users are faced with a new telemedicine service, they may be reluctant to switch from a face-to-face service to an alternative one. In addition, our results agree with the past finding that psychological and social risk prevents not only providers but also users from adopting technology [11]. Users care about social pressure from their friends, family members, and work groups with regard to telemedicine service.

According to the results of the total effect, performance risk is the most substantial risk factor affecting UI when Taiwanese individuals consider the adoption of telemedicine. In addition, performance risk was the only risk factor that had a negative effect both on UI directly and on PEOU and PU at the same time. This indicates that PEOU and PU are the mediators that partially explain the association between performance risk and UI. Concerns about the performance, technology, and quality of service have been expressed by stakeholders. For both health care providers and users, performance always plays a vital role. A large number of medical studies on the effectiveness of telemedicine have compared it with traditional in-person visits with regard to different diseases, such as anxiety disorders [2] and chronic kidney diseases [86]. Variations of quality and effectiveness in telemedicine and in-person care may lead to performance risk. Another factor leading to performance risk is distrust and concern regarding the technology. As shown in the previous research, the result provides more empirically grounded evidence for the importance of technology concerns perhaps caused by inadequate communication effects between physicians and patients and by disruptions in communication owing to an unstable broadband connection, which may alter the accuracy of instructed physical examination results and even cause medical error. Therefore, the "digital divide" means that telemedicine service cannot completely substitute for face-to-face visits. Indeed, a substantial concern shared by both physicians and users is the inability to conduct an in-person physical examination [87]. In the study, the item technology risk 3, "I fear the absence of physical examinations during telemedicine services," was classified as a factor related to performance risk during the EFA. This indicates that individuals not only have concerns about the limitations of the technology itself but also about the impact it may have and the resulting performance outcomes. As Nguyen et al [42] mentioned in the review, promoting realistic expectations before the telemedicine visit takes place is essential to effectively improve patient satisfaction [42]. Providers should try to increase technology acceptance and a sense of trust by assuring the users of various technological solutions to reduce the risk or by showing evidence for the similarity between technological use and in-person examination components through virtual assessments [88].

We found that the perceived COVID-19 infection risk has a positive effect on PU with P value of <.001. This is because telemedicine was globally used by force of circumstance and because of social distancing as a substitute for face-to-face interactions in enhancing clinical care, health promotion, and disease prevention. The substantial negative effect of financial risk on the PEOU of telemedicine is notable. In this context, financial risk refers to payment models, personal and governance insurance coverage, and online payment systems. One possible reason for the impact of financial risk could be the general public's understanding of Taiwan's nationalized health insurance program, which may not be fully aware of the extent and scope of insurance coverage for telemedicine services. In addition, users may have concerns about online transactions due to their perception of financial loss risks. Studies on online payment highlight the importance of website security signs and quality information, as these factors can influence customers' perception of financial risk [89]. These results may underscore the importance of trust in online trading platforms and payment systems.

Three facets of perceived risk—time risk, provider risk, and privacy risk—do not appear to be statistically significant to TAM in telemedicine service. In the past, internet privacy concerns were one major barrier to the adoption of digital technologies or online services [90]. However, the absence of a substantial effect of privacy risk on UI in telemedicine in our hypotheses agrees with the findings of the study by Kamal et al [10], in which perceived privacy risk was found to be an insignificant determinant of UI to use telemedicine services. Moreover, as shown by studies among 1059 US residents, just like environmental risks similar to the COVID-19 pandemic, privacy concerns do not negatively impact UI. Another

XSL•FO
RenderX

cross-sectional study in Germany also revealed that data privacy and security concerns were seen as less important in case of an emergency condition [44]. One possible explanation by Kato-Lin and Thelen [54] is that people may be involved in a different decision process when they are facing immediate and severe risks. Another explanation may be the result of a tradeoff during the crisis between the privacy concern and the perceived risk of COVID-19 infection.

In general, telemedicine services were expected to reduce the need for transportation, save travel time, and provide cost-saving for the public [87,91]. However, it is worth noting that the health care system in Taiwan is characterized by good accessibility, comprehensive population coverage, and short waiting times [92]. Compared to the study by Weibel et al found that patients using telemedicine saved an average of 438 driving miles per visit, the study also highlighted the potential risks related to time and distance [42]. In Taiwan, seeking medical services is extremely convenient, with shorter time and distance required for medical visits. These advantages make it less likely for the public to experience time risk.

Regarding provider risk, previous studies found that most patients prefer to use telemedicine with their physician with whom they have an established relationship [58]. One possible explanation for the insignificant hypothesis is that most users in Taiwan primarily used telemedicine services for COVID-19 infection diagnosis and treatment during that period. This is different from the context of general chronic disease management, where the importance of the service provider is comparatively reduced. Therefore, it is the result of tradeoff among provider risk, government policy, and perceived of COVID-19 infection. Consistent with previous research, our study found that PEOU positively influences PU, and both PU and PEOU positively impact UI. However, PU exerts a stronger influence on UI [17].

As >80% of respondents had no prior telemedicine experience, the findings are particularly relevant to nonadopters and may encourage them to consider using telemedicine. Risk perception is a dynamic and continually adjusting process. Nonadopters often perceive increased uncertainty and risks due to their lack of experience with technology, driven by unfamiliarity, fear of the unknown, and privacy concerns [93]. Therefore, these perceived risks have a greater potential for mitigation through awareness campaigns and other adjustments.

Implications and Limitations

In the promotion of telemedicine, addressing psychological and social risk is crucial in influencing user behavior. To alleviate technology anxiety and discomfort, health care providers should prioritize the establishment of emotional bonds and genuine care, particularly when catering to older adult users engaging in mobile health services [94]. Demonstrating empathy and inclusiveness toward users, particularly those experiencing anxiety and discomfort, is essential. Swiftly resolving issues and offering efficient technical support, particularly for new services, can effectively reduce user concerns and mitigate risks associated with social origins. Encouraging users to share positive experiences contributes to diminishing social risk and generating excitement among potential users.

Regarding the main barrier to adoption, performance risk, which may stem from the public's unfamiliarity and lack of knowledge about telemedicine, as well as the unknowns and misunderstandings surrounding its performance. According to consistent evidence from systematic reviews, the quality of care in telemedicine is comparable to, or even superior to, face-to-face consultations [2]. Governments and health care providers play a critical role in informing individuals about this evidence to alleviate concerns of potential users. Close monitoring of telemedicine service quality and providing additional education tailored to underserved users can substantially enhance adoption rates.

There are some limitations to this study. First, the web-based survey using the platform SurveyCake has a methodological limitation. The sample may produce a bias toward individuals more likely to be on the web and have internet access. Second, we focused on users in Taiwan、 and our result for perceived risk may not be representative of other countries. Furthermore, at the time of the study, approximately 80% of the population in Taiwan still did not have experience with telemedicine services, which may limit the applicability of the study's findings. Third, this survey would benefit from longitudinal data, which represents only a single point in time and does not assess trends or tradeoffs in patients' perceived risk over time. In future studies, an examination of user's perceived risk at other time points will help understand the change of tradeoffs among the risks. Second, to understand the effect of experience or age difference on users' perceived risk, future studies can recruit subgroups and compare the findings with those of our study.

Conclusions

This study aimed to enhance previous research efforts by reconstructing the facets of perceived risk at a more granular level and further refining the nomological fit of the TAM with the perceived risk dimensions. Eight effective risk dimensions were reconstructed based on a solid review of the background literature through empirical techniques. Upon analyzing the relationships between perceived risk and the TAM, we determined that performance risk was the most substantial risk factor and substantially influenced telemedicine adoption both directly and indirectly. In addition, performance risk, financial risk, and psychological and social risk substantially impacted PEOU. These findings deepen our understanding of user perceived risk and its impact on telemedicine adoption, highlighting the need for strategies to address users' uncertainties and concerns.

On the basis of the identified factors, including performance risk and psychological and social risk, telemedicine service providers, planners, and policy makers can design better strategies for the successful implementation and adoption of the services in countries that have not yet benefited from telemedicine. To decrease public anxiety and pressure, public awareness about the adoption process should be increased, and the willingness to embrace telemedicine should be instilled in the public as a convenient way to obtain high-quality health care services. Health care providers and governments must also improve the quality of technology and widely disseminate

XSL•FO

evidence related to the effectiveness and safety of telemedicine, which will decrease performance risk and fundamentally promote the public's intention to use telemedicine services.

Authors' Contributions

TCW drafted the manuscript. TCW and CTH revised it critically for important intellectual content. All authors have read and agreed to the published version of the manuscript. This research received no external funding.

Abstract

Background: Digital health adoption in clinical practice has been widespread, yet there remains further potential for optimizing care specifically for chronic obstructive pulmonary disease (COPD). This study therefore conducted qualitative research involving 35 health care professionals from a range of hospitals in Taiwan.

Objective: This study aims to investigate barriers and facilitators related to the implementation of digital health technology (DHT) in the long-term monitoring of individuals with COPD based on clinical experiences in Taiwan. The perspectives of Taiwanese health care professionals provided valuable insights into the challenges and opportunities associated with using DHT for the management and enhancement of respiratory rehabilitation and long-term monitoring of patients with COPD.

Methods: Several key themes related to the development of DHT were identified. Barriers encompassed concerns pertaining to digital safety, insurance coverage, constraints related to medical resources, and the presence of a digital divide. Facilitators included the potential for cost reduction, personalized prescriptions, and instilling motivation in users.

Results: To enhance the acceptance and use of DHT, embracing a user-centered approach that prioritizes the distinct needs of all parties involved is recommended. Moreover, optimizing and leveraging the effective use of DHT in managing the health of individuals with COPD promises to deliver care characterized by greater precision and efficiency.

Conclusions: Overall, the benefits of using DHT for the long-term care of patients with COPD outweigh the disadvantages. After the COVID-19 pandemic, there has been an increased emphasis in Taiwan on the effectiveness of DHT in managing chronic diseases. Relevant studies including this paper have suggested that web-based exercise management systems could benefit patients with COPD in rehabilitation and tracking. Our findings provide meaningful directions for future research endeavors and practical implementation. By addressing identified barriers and capitalizing on facilitators, advancements can be made in the development and use of DHT, especially in overcoming challenges such as information security and operational methods. The implementation of the recommended strategies will likely lead to improved COPD care outcomes.

Introduction

Chronic obstructive pulmonary disease (COPD) is a major public health problem and is the third-leading cause of morbidity and mortality by disease worldwide [1,2]. Indeed, over 328 million people were diagnosed with this disease in 2019 [2,3]. Caused by smoking and air pollution [4,5], COPD is typically associated with reduced physical, emotional, and social functioning, resulting in a decline in overall quality of life [4,5]. Health care professionals have reported that physical activity and effective self-management are strongly correlated with improved lung function [6,7], reduced exacerbations, and significant improvements in the quality of life for hospitalized and discharged patients [7,8]. However, decreased exercise tolerance is linked with dyspnea, which is the primary symptom experienced by individuals with COPD [9-11]. Consequently, this symptom often leads to poor adherence to self-care management and exercise in patients with COPD [12]. Research has shown that lower levels of physical activity are associated not only with increased hospitalization but also with an elevated risk of premature death [13,14]. Thus, respiratory rehabilitation plays a vital role in improving lung function and aiding recovery in patients with lung damage or injury [15].

To enhance adherence to exercise and facilitate health management in patients with COPD, the implementation of digital health (DH) has been suggested as an innovative approach [16,17]. DH models offer opportunities to optimize COPD care by leveraging accumulated big data to assess individual exercise capacity and provide personalized exercise prescriptions, thereby enhancing treatment efficacy [18]. DH primarily involves the application of information and communications technologies, leading to the emergence of concepts such as mHealth or eHealth [19,20]. Digital health technology (DHT) refers to technologies enabling the remote monitoring of physiological markers such as oxygen saturation and the self-monitoring of physical activity using wearable activity trackers. It also encompasses the use of web-based apps to support disease management, facilitate behavioral change, provide medication reminders, and predict personalized exercise prescriptions.

Compared to alternative therapies, digital pulmonary rehabilitation is a cost-effective and beneficial intervention that encompasses various components, including diagnosis, training, and evaluation [21-23]. This comprehensive approach effectively delays the deterioration of lung function and slows the progression of the disease [24,25]. Moreover, digital pulmonary rehabilitation empowers patients to have real-time control over their condition [26,27]. Furthermore, it benefits health care professionals by enabling the collection of longitudinal health data from patients, thereby facilitating informed decision-making and the provision of personalized care [28,29].

However, systematic reviews have found no significant evidence demonstrating the effective impact of digital pulmonary rehabilitation on COPD management [30,31]. This could be attributed to the advanced age or limited motivation for exercise in the majority of patients with COPD, who often have impaired lung function. Additionally, their limited familiarity with digital spaces, devices, and knowledge further contributes to this issue [32,33]. Notably, prior exploration of the needs and preferences of health care professionals and patients as well as careful consideration of intervention design are essential factors that have rarely been addressed in the implementation of digital pulmonary rehabilitation for patients with COPD [34,35]. Failure to consider the needs of health care professionals and patients from a user-centric perspective may lead to user experience issues, such as lack of clinical use, disruption of patients' workflow, and negative engagement experiences with DHT [36,37]. Consequently, users may become unwilling to continue using and adhering to treatment regimens [38-40].

Prior to conducting the primary survey in this study, we conducted informal interviews with health care professionals within the hospital to gather their perspectives on using DHT for managing remote pulmonary rehabilitation. Although the sample size was small (n=10), the majority of health care professionals emphasized that remote rehabilitation is an important development for the future. This was particularly evident during the COVID-19 outbreak when many hospitals faced closures, preventing patients from continuing their rehabilitation programs and hindering their overall recovery progress. Most Health care professionals believed that implementing DH models for respiratory rehabilitation was necessary. However, both health care professionals and patients had limited knowledge about DH. Moreover, despite the advancements in medical technology in Taiwan, the application of DH in the care of patients with COPD remains subject to various barriers, such as information security measures, disparities between urban and rural areas, and the acceptance of digital tools among professional caregivers.

This study explores a broader range of barriers to using DHT in respiratory rehabilitation from the perspective of health care professionals. We also assessed the feasibility of implementing DHT in the management of COPD. Given Taiwan's relatively rich medical resources and its urban-rural disparities, the findings from this research serve as a valuable reference for similar implementations worldwide. This study not only contributes to optimizing clinical rehabilitation designs of DH from a user perspective but also significantly enhances the benefits for patients throughout the treatment process.

Methods

Study Design

A qualitative descriptive methodology was used to investigate the barriers encountered when using DH for managing pulmonary rehabilitation among patients with COPD. A snowball sampling technique was used to recruit 35 diverse health care professionals in this study. The participants included 12 respiratory physiotherapists, 8 respiratory specialist nurses, 5 rehabilitation physicians, 2 thoracic surgeons, 5 physical therapists, and 3 sports medicine specialists. The interviewees were representatives in the field of cardiopulmonary rehabilitation in Taiwan, with an average age of 52 (SD 8) years and a minimum of 6.3 (SD 7.4) years of relevant work experience.

XSL•FO
RenderX

Ethical Considerations

To investigate the key elements of pulmonary rehabilitation for patients across different regions, this study was conducted in the Department of Physical Medicine and Rehabilitation across 6 affiliated hospitals situated in different regions of Taiwan. The research protocol received approval from the Research Ethics Board of Chang Gung Hospital (202200070B0). All participants possessed experience in providing care for patients with COPD. Before the commencement of interviews, participants were provided with physical copies of consent documents. All individuals who participated in the study provided informed written consent. Among these consents, 1 copy was retained by the researcher, while another was retained by the participant. Subsequently, semistructured one-on-one telephone interviews were conducted, each lasting approximately 45 to 60 minutes. The interview data were processed with unique identifiers to ensure participants' rights. All participants voluntarily participated in the study without receiving any compensation, ensuring the fairness of the experiment.

Procedure

The study was conducted in June 2022 and completed in May 2023. All interviews were conducted by the first author (SYC), who is an experienced qualitative researcher. The interviews were carried out in a one-to-one semistructured format. An interview topic guide in Textbox 1, outlined in Tables 1 and 2, was used as a framework for the interviews. The initial version of the topic guide was developed based on relevant literature and consultations with respiratory therapists and rehabilitation physicians. The interviews were designed to gather information through semistructured and open-ended questions, allowing for in-depth discussions on the interview content.

Textbox 1. Interview topic guide (including clinical, home care, and digital health aspects).

Clinical perspective

- Please outline the basic requirements for conducting pulmonary exercise training for patients with chronic obstructive pulmonary disease (COPD).
- Please describe the information and physiological parameters that need to be collected for conducting pulmonary exercise training.
- Please describe the current limitations and challenges in clinical respiratory care.

Self-care management

- Please describe health management and follow-up methods for inpatients and discharged patients.
- Please discuss the key factors influencing patients' self-management abilities.
- Please describe the difficulties of health management for patients after discharge.

Digital health

- Please describe your views on digital health (DH).
- Please describe the benefits and challenges that DH may bring to patients with COPD.
- Please describe your experiences of implementing DH in clinical practice. What are your views on incorporating DH into respiratory rehabilitation?
- Please describe the factors that need to be considered when integrating DH into the workflow of respiratory rehabilitation care.
- Please describe the potential risks of using DH technology in clinical settings.
- Please describe the indicators that clinicians wish to track for patients after discharge.

Table 1. Participant demographics and characteristics (N=35).

	Values
Sex (male:female), n:n	18:17
Age (years), range (mean, SD)	37-67 (52, 8)
Years of experience in pulmonary rehabilitation, range (mean, SD)	5-36 (6.3, 7.4)

XSL•FO
RenderX

Table 2. Health care professionals in pulmonary rehabilitation.

Type of health care professionals	Participants, n (%)
Respiratory physiotherapists	12 (34)
Respiratory specialist nurses	8 (23)
Rehabilitation physicians	5 (14)
Thoracic surgeons	2 (6)
Physical therapists	5 (14)
Sports medicine specialists	3 (9)

Data Analysis

Participants were informed that all study data would be treated anonymously. Each participant voluntarily consented to join the study, with no compensation offered during the research period. The entire interview process was audio-recorded, and unique identifiers were assigned to each participant to ensure confidentiality. The transcripts were generated based on the interview topic guide, and NVivo software (version 12.2; QSR International) was used to conduct a thematic analysis (TA) of the transcripts.

This study follows the reflexive TA method developed by Braun and Clarke [41,42], using a coding-first approach to identify themes that help understand and construct the clinical experiences of health care providers. This approach aims to authentically capture the participants' perspectives on events and uncover the meanings behind surface-level expressions. The TA consists of 6 meticulous steps, ensuring consistency, logic, and comprehensiveness in the research process. It has been demonstrated to possess confirmability, reliability, and credibility [41,42]. Moreover, this descriptive method distinctly articulates the researcher's interpretation of the data, rather than simply reiterating the participants' statements.

The analysis of the interviews followed an inductive and cyclical process. This involved a thorough reading and rereading of each transcript to gain familiarity with the data [43]. The data were then coded with unique labels, and themes and subthemes were generated based on the coded data. To ensure analytical rigor, the first author independently coded the data. Then, 2 experienced researchers were invited to review and validate the coding process.

In reference to the study by Hennink and Kaiser [44] on sample sizes for saturation in qualitative research, this research also considers the work of Rowlands et al [45], which proposes calculating thematic saturation using a lognormal distribution with a selected confidence level. In this study, the data obtained from 35 participants is expected to hold significant reference value, aligning with these methodological guidelines [44,45].

Results

Overview

After nearly a year of duration, this study completed interviews with 35 participants. Based on the interview records, an analysis was conducted, resulting in the generation of themes and subthemes for this study. The analysis has identified several themes: digital safety and reliability, insurance coverage and safety concerns, medical resource constraints, and the digital divide, which are presented as barriers. Additionally, the themes of the advantages of using DHT, reduced health care expenditure, personalized prescribing, and motivation for use are presented as facilitators.

Barriers

Digital Safety and Reliability

The majority of the interviewees (n=21, 60%) expressed concerns about the use of DHT in health care services, particularly in relation to information security and patient privacy. As the primary objective of health care is to ensure patient safety, any potential breach of privacy resulting from seeking medical treatment is considered harmful to patients. Therefore, information security in the health care field is a highly sensitive issue for patients. The promotion of DHT in the health care industry is critically dependent on network security and data protection.

Furthermore, more than half of the interviewees (n=19, 54%) had concerns about the accuracy of the generated data. Inaccurate data have the potential to lead to erroneous medical decisions and in severe cases to even jeopardize the health and safety of patients.

> *Patient information is highly sensitive, and any data breaches or information errors in a hospital can result in significant losses. While I acknowledge the many benefits that DHT can bring, I believe that ensuring information security and data accuracy should be a minimum requirement.* [Thoracic surgeon 26]

> *Technology has been advancing rapidly, especially after the pandemic. Currently, almost every industry relies on the internet to handle various aspects of daily life. However, the healthcare field is different. There are two main concerns. First, there is a fear of data breaches and the potential leakage of sensitive information. Second, there is a worry that if the machines make mistakes, it could jeopardize the safety and well-being of patients.* [Respiratory physiotherapist 3]

> *Regardless of everything, patient safety always comes first for healthcare professionals. Digital health is just starting to thrive, and it seems to bring much convenience. However, I believe there is still room for improvement. For example, how do you prove that it is accurate?* [Thoracic surgeon 27]

XSL•FO
RenderX

The interviewees highlighted the issue of low patient adherence to medical instructions, particularly among patients with COPD, which encompasses various complex aspects such as medication adherence, exercise control, and smoking cessation. Most interviewees emphasized that patients with COPD tend to dislike exercise due to the physical burden it imposes (n=26, 74%), as they believe it may cause discomfort and even pose a threat to their livelihood. Consequently, after being discharged from the hospital, patients often struggle to comply with basic exercise instructions, resulting in a decline in pulmonary function. Even with the use of optimal rehabilitation assistive devices, there remains an insufficient improvement in the pulmonary function of patients. Moreover, the interviewees (n=19, 54%) expressed concerns regarding the long-term observation and accumulation of training hours required to assess patients' recovery progress in pulmonary function training. Consequently, when using DHT, there may be concerns about the reliability of generated medical recommendations if the accumulated data are incomplete or if the duration of data collection is insufficient to provide meaningful results.

> *Patients can be categorized into inpatients and outpatients. Generally, inpatients tend to be more compliant and follow the doctor's treatment instructions. Managing the health of outpatients can be challenging because many patients become difficult to reach once they return home, and it is uncertain whether they are taking medication and engaging in physical activity as prescribed.* [Respiratory physiotherapist 1]

> *Our patients are not very keen on physical activity because it often triggers breathlessness and discomfort. This makes it challenging for them to engage in exercise. Many patients who cooperate well during their hospital stay exhibit different behaviors once they return home. Therefore, for patients with chronic conditions such as COPD, it is crucial that we have digital health technology to assist us in monitoring their condition closely.* [Respiratory physiotherapist 9]

> *After being discharged, patients often resume smoking, engage in unhealthy eating habits, and neglect physical activity due to a lack of supervision. As a result, their lung function deteriorates rapidly, leading to a cycle of readmissions until their unfortunate demise.* [Respiratory physiotherapist 6]

> *After discharge, patients often lack motivation and health awareness, which lead to poor compliance with medical instructions. Some may occasionally follow them, while others resist any form of supervision. Both types of patients are not suitable candidates for digital health technology-based healthcare prescription advice because insufficient information would be collected, which may result in inaccurate prescriptions and potential harm to their health.* [Respiratory specialist nurse 17]

Insurance Coverage and Safety Concerns

Prior to the outbreak of the COVID-19 pandemic, global insurance coverage for telemedicine was subject to stringent limitations. However, as the severity of the pandemic increased, regions including Taiwan gradually relaxed regulations surrounding telehealth. Nevertheless, participants universally emphasized that DHT continues to face multiple constraints and considerations. Specifically, not all medical conditions are suitable for DHT adoption, and a lack of sufficient information impedes health care professionals from making accurate medical decisions. Moreover, vulnerable patients, particularly elderly patients, often face potential risks of falls and emergencies.

> *In the past, telemedicine was not very successful because insurance coverage was limited. Even though there are more flexible rules now due to the pandemic, digital health still has its challenges. Some diseases cannot be diagnosed through video calls alone, and there are also concerns about risks for weaker patients, such as the possibility of accidents or falls.* [Rehabilitation physician 22]

> *I believe digital health technology can play a significant role in managing health information, while the diagnosis and treatment depend on the situation. Of course, conditions vary in different regions, so I think digital health technology should consider factors such as disease type, severity, and the availability of alternative options in diagnosis and treatment.* [Thoracic surgeon 26]

Medical Resource Constraints

The interviewees discussed the challenges of implementing DHT in different hospitals, which stem from variations in health care resources. For urban medical centers, the promotion of DHT is relatively easier compared to regional hospitals located in remote rural or island areas. This is due to the limitations in health care resources, knowledge gaps, and a shortage of health care professionals in rural areas, leading to an increasing disparity in health care between urban and rural regions. However, it is precisely because of the scarcity of health care resources in remote rural and island areas that the introduction of DHT is needed in order to bridge the gap in health care access between urban and rural areas.

> *In my opinion, not every region can implement digital health technology because conditions vary. For example, in rural areas, many places lack internet signal, making it impossible for activities such as video consultations or data transmission to take place.* [Sports medicine specialist 34]

> *Urban and rural areas have different living conditions. In rural areas, apart from limited healthcare resources, there is also a shortage of staff. Additionally, there are disparities in education and professional expertise across different regions. As a result, the acceptance and trust in digital health technology vary among healthcare professionals and patients in different areas.* [Physical therapist 31]

XSL•FO
RenderX

> *Digital health technology can be a valuable tool for rural or island areas, but before considering its use in healthcare services, it is important to assess whether digital health technology is suitable for the specific region. This involves examining what technologies can address the local challenges, improve specific issues, and enhance overall benefits.* [Respiratory specialist nurse 14]

Digital Divide

As mentioned earlier, both health care professionals and patients may face digital disparities. These disparities are more prevalent in rural or island areas due to factors such as economic conditions, educational levels, living environments, and comorbidities, including cognitive impairments, which can potentially impact the opportunities and abilities of individuals to use digital products such as computers or the internet. Consequently, there exists a significant gap in the health care capacity for medical examinations, monitoring, and care between urban and rural areas.

> *Typically, COPD patients do not just have a single condition. They may also experience physical, cognitive, or visual impairments. This means they might face difficulties with tasks such as connecting to or operating computers, or expressing themselves.* [Rehabilitation physician 21]

> *"Based on my past experience, although we use smartphones daily for information, older doctors like us may find it challenging to practice and become proficient with new IT products, let alone the patients.* [Thoracic surgeon 27]

Facilitators

Advantages of Using DHT

Interviewees emphasized the need for an adaptation period when adopting DHT (n=26, 74%), for both health care professionals and patients. They unanimously acknowledged the significant clinical benefits of using DHT to assist patients with COPD in respiratory rehabilitation. Moreover, they recognized the advantages of DHT in facilitating the recovery of emergency inpatients and monitoring discharged patients. For the majority of patients who are unable to remain hospitalized for an extended period due to insurance regulations, continuous monitoring and remote care treatment at home are essential. DHT is regarded as the optimal clinical tool choice in such cases.

> *I believe that every disease requires going through four stages: testing, treatment, monitoring, and health management. It is just a matter of the extent to which each stage is needed. COPD patients, in particular, require them because their condition does not improve, so having long-term tracking and health management tools is crucial to assist us in our clinical work.* [Rehabilitation physician 22]

> *Due to insurance regulations, most hospitalized patients are discharged within a certain number of days. If there are still relevant technologies or tools available for continuous remote monitoring or care of COPD patients after discharge, it would be a significant advancement.* [Respiratory specialist nurse 14]

Reduced Health Care Expenditure

Most interviewees noted that patients with COPD often face limitations in adhering to medical instructions (n=23, 66%), for example, taking medications and following exercise prescriptions, due to factors such as home environment, declining physical function, and transportation difficulties after discharge. The application of DHT is seen as an effective solution to mitigate these limitations.

> *Some patients face challenges in contacting or returning for follow-up care after discharge due to their residential or transportation constraints. If there is technology available to assist us in regularly monitoring discharged patients, their willingness to cooperate would likely be higher.* [Respiratory specialist nurse 20]

Personalized Prescriptions

Most participants highlighted the potential of DHT in enabling personalized prescriptions through the accumulation of data (n=24, 69%). They emphasized that the use of big data and machine learning can facilitate data processing, enabling the identification, inference, and prediction of individuals' health statuses and required rehabilitation interventions based on changes in their health behaviors.

> *To be honest, I have high expectations for big data because humans cannot remember everything, but machines can. Moreover, the larger the data are, the more accurate their judgments become. It is a great clinical tool.* [Thoracic surgeon 26]

> *I believe we should understand that artificial intelligence does not provide a definitive answer, but it is certainly the best supporting evidence for making judgments.* [Sports medicine specialist 35]

Increased Motivation to Participate in Rehabilitation Programs

The motivation of patients to use DHT will be a key determinant of the success of its implementation. Our participants discussed how issues related to hardware and software devices, technology, and operation are likely to affect user motivation. While they generally recognized the convenience and clinical benefits of DHT, many pointed out the difficulties encountered by older health care professionals when learning new technology. Thus, the interface design of DHT must be optimized for users, both patient users and health care professionals. This will increase motivation to participate in remote rehabilitation programs.

> *Learning and adapting to new tools is not easy for us or for patients, so interface design is also a crucial factor.* [Thoracic surgeon 27]

> *I believe motivation plays a significant role in many things. If digital healthcare can help alleviate our*

XSL•FO
RenderX

clinical workload, of course, we are all willing to use it, as are the patients. If they know it is for their own good, I believe they will be more than willing to give it a try. [Rehabilitation physician 23]

Discussion

Overview

This study provides insights into the perspectives of health care professionals on the use of DHT in the care of patients with COPD and explores potential issues faced by both the clinical and patient sides. The findings highlight the urgent need to promote DHT at the clinical level, particularly in the postpandemic era, to reduce interpersonal contact, interaction, and health care costs for hospitals and patients.

Findings

Previous research has often neglected the user-centered perspectives and diverse needs of stakeholders when investigating DHTs. Additionally, the demands and feasibility of DHT vary across regions due to population demographics and contextual differences. Addressing these challenges requires tailored investigations of stakeholder needs, encompassing health care providers and users, considering specific regional characteristics. Collaborative or participatory design approaches can facilitate the development of innovative DHT solutions that are adaptable to different regional contexts, including urban, rural, and island areas, with the ultimate goal of maximizing the benefits of DHTs in health care.

In summary, this study reveals that due to significant individual differences among patients with COPD, a singular treatment approach cannot be universally applicable, and a uniform health care service model cannot be implemented across regions. Respondents preferred personalized prescriptions that consider crucial factors such as patients' health conditions, geographic locations, and educational levels, thus facilitating the provision of diverse DH services.

Furthermore, the aging population and lifestyle changes in the postpandemic era have underscored the importance of pulmonary rehabilitation as a key indicator for DHT development. The findings indicate that both health care professionals and patients have unmet digital literacy needs, emphasizing the importance of considering usability when implementing DHT and constructing pulmonary rehabilitation systems. This study contributes valuable insights into the demands and preferences of health care professionals regarding DHT in the care of patients with COPD. The user-centric design approach not only benefits health care professionals in clinical care for inpatients but also expands the applications of DHT in postdischarge monitoring, observation, and ongoing health care services for patients with COPD.

Despite health care professionals having concerns about the health information obtained from patients using DHT, they still recognize numerous advantages of DHT in clinical practice. For instance, DHT can streamline repetitive clinical tasks and proactively collect patient data through recommended system and device designs, thereby reducing the chances of human errors in documentation and medical decision-making. Simultaneously, simplified hardware and software designs can facilitate the collection and management of patient exercise levels and fundamental physiological data, particularly for discharged patients. Despite the mentioned information security issues, DHT faces additional risks and limitations in clinical applications.

Health care professionals acknowledge that insurance coverage and personal safety have hindered the successful implementation of DHT for many years [19]. Prior to the pandemic, many doctors faced challenges in understanding and navigating the insurance system, resulting in unsuccessful insurance claims. Furthermore, older patients may struggle with using internet-connected devices, making remote consultations difficult. Health care professionals also consider the advanced age of patients with COPD, raising concerns about potential falls during simple rehabilitation exercises at home. Additionally, various constraints in manpower, equipment, and infrastructure within the clinical setting hinder the widespread adoption of DHT. For instance, patients with severe respiratory disease rely on large respiratory devices and specialized personnel for treatment.

Past studies have identified resource constraints as the primary hindrance to the widespread adoption of DH, mainly due to the inability to generate reliable data. However, this investigation reveals that the lack of consideration for local geographical conditions and population structures has impeded the proliferation of DH. This results in a disconnect between health care providers and patients, either due to communication barriers or disparities in digital literacy, thereby reducing acceptance. It is important to acknowledge that different regions, including urban, rural, and island areas, exhibit varying living environments, necessitating the use of different DH tools to ensure the generation of precise, reliable, and trustworthy data. Moreover, given the significant individual differences among patients with COPD, a one-size-fits-all approach is deemed inappropriate. Consequently, emphasizing the significance of personalized prescriptions, this study highlights the potential of big data in achieving tailored and accurate treatments. Finally, contrary to previous research attributing patients' inadequate self-management to a lack of motivation, this study proposes that their inability to effectively engage in health management may stem from practical constraints such as the unavailability of necessary equipment or the complexity of operations. In summary, by adopting a human-centered approach and considering the needs and circumstances of various stakeholders, the development of health care services can be optimized, ultimately enhancing patient adherence to medical instructions.

Future Directions

The survey findings of this study indicate that the majority of health care professionals perceive the potential of DHT to facilitate the care of patients with COPD. However, both health care professionals and patients require a period of time to adapt to and become familiar with the use of digital tools. The novelty of this study lies in proposing that each disease undergoes 4 stages: detection, treatment, monitoring, and health management. However, the distribution of needs across these stages varies for different diseases. For instance, in the context of COPD, a

XSL•FO
RenderX

condition that cannot be clinically cured, patients require long-term monitoring of their condition and self-health management. Therefore, DHT should be designed with individualized approaches for different diseases. Participants widely believed that DHT tools not only assist patients in understanding their own condition but also alleviate the burden of clinical work.

Previous studies have frequently cited inadequate compliance with exercise programs due to a lack of motivation and home environment factors. However, this study posits that the appropriate use of DHT can enhance patient motivation for exercise and reduce health care expenditures. By leveraging DHT, it becomes possible to synchronously execute consultations, treatments, monitoring, and overall health management for patients with COPD.

While the reliability of big data may still be questioned in many studies, the accumulation and learning capabilities of big data over the years will serve as a reference for future health care professionals when making medical decisions, given the inherent limitations of human memory and abilities. The information provided by DHT may not be the sole definitive answer, but it is certainly the best evidence supported by a scientific basis. The personalized prescriptions inferred by DHT are accumulated from individual health behavior changes, enabling the identification, inference, and prediction of individual needs for rehabilitative interventions. This will lead to more accurate health care decisions and provide an additional level of patient safety.

Finally, the issue of low patient adherence to health behaviors is often discussed in many studies. However, this problem also applies to health care professionals. Learning new things is inherently challenging for everyone, especially for older individuals. Therefore, for both patients and health care professionals, the motivation to use and accept DHT is crucial. If the use of DHT can help health care professionals reduce their clinical workload, make more accurate judgments, and lower the rate of medical decision errors, it is expected to increase the chances of clinical acceptance of DHT interventions. On the other hand, if DHT can assist patients in effectively managing and controlling their own health [20] while making the treatment process more interesting and reducing discomfort, it is believed that the majority of patients would be willing to try it. Of course, it is crucial that the devices, systems, or equipment designed for DHT adhere to design principles that are simple and intuitive and minimize errors. With this in mind, popularizing DHT should not be a challenging task.

Study Limitations

Given the global attention to patients with COPD and the increasing demand for care and management of chronic lung diseases, along with the reliance on DHT during the pandemic, particularly in the health care sector, it has been confirmed that DHT can effectively perform the 4 major clinical tasks of diagnosis, treatment, monitoring, and health management even in special circumstances. Despite the rigorous investigation conducted over the course of one year, this study still has some limitations. First, the study used a snowball sampling method, which may introduce information bias and deviation due to the potential similarity of perspectives. Second, the study overlooked the age and work experience differences among health care professionals involved in the care of patients with COPD, resulting in a broad and unfocused information scope. Finally, the research solely relied on interview-based data collection without conducting a questionnaire survey, potentially leading to unverified differences between the interview findings and questionnaire responses.

Based on the above, this study represents a novel postpandemic reevaluation of the clinical applicability of DHT for managing patients with COPD. It aims to explore the potential of using DHT in enhancing health management for patients with COPD while considering the associated obstacles and potential benefits from a clinical perspective. According to the findings of the survey, the majority of health care professionals express concerns regarding the security and reliability of data generated by DHTs. These concerns can be attributed to two primary reasons: (1) apprehension regarding potential privacy breaches for patients; and (2) the lack of a validation platform for DHT, which raises doubts about its accuracy. Many respondents also mentioned incomplete data and potential risks to patient safety due to information security issues. Despite having high expectations for DHT, there is still perceived room for improvement. Existing research suggests poor adherence among patients with chronic diseases, especially patients with COPD who may exhibit reluctance to regular physical activity due to compromised lung function and struggle to maintain complete smoking cessation due to self-discipline challenges. Moreover, they face difficulties related to the absence of effective tracking and management systems. These factors hinder patients' ability to consistently comply with data collection, thereby impacting the accuracy and reliability of health decision-making.

Overall, using DHT for the long-term monitoring of individuals with COPD offers more benefits than drawbacks. In the context of global digital transformation, medical digitalization is an inevitable trend. Therefore, limitations in equipment and urban-rural disparities will improve with advancements in information security and changes in insurance systems. Digitalization will significantly reduce overall health care costs, enhance precision, and transform personal health behaviors and motivations, ultimately achieving a patient-centered vision of health and well-being.

Acknowledgments

The authors wish to express their gratitude to the individuals who dedicated their time, invaluable experiences, and insightful perspectives to enrich the depth of this study. Furthermore, the authors' sincere appreciation is extended to the entire team of health care professionals at Chang Gung Hospital, each of whom contributed to the support of this research initiative. Notably, special recognition is reserved for the Respiratory Therapy Team, whose commitment and collaboration were integral in facilitating

XSL•FO

Abstract

Background: Gender-affirming hormone therapy (GAHT) has shown potential for improving mental health outcomes among transgender and gender-diverse adults. How clinical outcomes change among adults receiving GAHT via telehealth across the United States is not well known.

Objective: This study evaluated the relationship between initiating GAHT via a telehealth clinic and changes in depression, anxiety, and suicide ideation over a 3-month period.

Methods: This cohort study evaluated the relationship between initiating GAHT via a telehealth clinic and changes in mental health over a 3-month period. Data were collected at baseline and 3 months later among adults who had their first GAHT visit between August and November 2023. The study included adults aged 18 years and older initiating GAHT for the first time, with a final sample of 342 adults across 43 states (192 initiated estrogen and 150 initiated testosterone therapy). The primary outcomes were depression symptoms using the Patient Health Questionnaire-9 (PHQ-9), anxiety symptoms using the General Anxiety Disorder-7 (GAD-7), and suicide ideation in the past 2 weeks.

Results: Before GAHT initiation, 40% (136/342) of participants reported depression (PHQ-9 ≥10), 36% (120/342) reported anxiety (GAD-7 ≥8), and 25% (91/342) reported suicidal ideation. By follow-up, significant reductions were observed in PHQ-9 (−2.4, 95% CI −3.0 to −1.8) and GAD-7 scores (−1.5, 95% CI −2.0 to −1.0). Among those with elevated symptoms, 40% (48/120) to 42% (56/133) achieved a clinically meaningful response (≥50% reduction in baseline scores), and 27% (36/133) to 28% (33/120) achieved remission (PHQ-9 or GAD-7 score <5). Of those with suicide ideation at baseline, 60% (50/83) had none at follow-up.

Conclusions: This study highlights the important relationship between telehealth-delivered GAHT and mental health, emphasizing the importance of accessible and timely care.

Introduction

Transgender and gender-diverse (TGD) individuals have poorer mental health outcomes than their cisgender peers, including depression, anxiety, and suicide ideation [1-3]. TGD individuals consistently face significant barriers to accessing gender-affirming medical and surgical treatments, leading many to delay or altogether forgo necessary care [3]. These challenges include difficulty in locating providers who are affirming and knowledgeable, financial barriers to paying for care, and

XSL•FO
RenderX

frequent discrimination in health care settings [4-6]. Despite legislation against gender identity discrimination [7], an unprecedented number of states enacted banned medical care for transgender people between 2021 and 2024, further reducing access to care [8]. These barriers to care can intensify psychological distress and create a syndemic environment that significantly increases the risk of poor mental health for TGD people [6].

Gender-affirming hormone therapy (GAHT), which involves medications such as testosterone, estrogens, and antiandrogens [9], has been associated with improvements in depression, anxiety, suicidality, and overall quality of life for transgender people [4-6]. A 2022 randomized controlled trial (RCT) conducted in Australia found a significant reduction in depression and suicidality within 3 months for patients beginning testosterone therapy compared to those for whom access to care was delayed [10]. However, the study may not represent individuals using estrogen or those outside of Australia, where care barriers differ from those in the United States. For example, TGD individuals in the United States face varied access challenges [10-12] particularly in states [10] where recent legislation led to legal penalties for providers of gender-affirming care [13], clinic closures, and care disruptions. These laws profoundly impact TGD individuals' mental health [14,15]. Studies that include a nationwide population of TGD adults can help ensure that the findings are applicable across the United States.

Further, the rapid expansion of telehealth and acceptance of telehealth-delivered GAHT [7] after COVID-19 has shifted the way this care is provided. Telehealth is a critical modality for primary care [8], mental [16], and behavioral health [15], yet its efficacy in delivering GAHT remains less explored [11,17]. TGD adults report frequent use of telemedicine [10], and express high levels of satisfaction with telehealth-delivered GAHT [12]. Therefore, understanding changes in health outcomes among those initiating GAHT via telehealth is essential to ensure that this increasingly widespread model of care provides effective, equitable, and accessible treatment.

Factors that are associated with improved mental health outcomes for those initiating GAHT are not well understood. Previous research found the mental health of TGD individuals varies based on insurance coverage [13], legal affirmation of gender [14,18], gender-affirming surgery access [19], geography [20], gender identity [21], race and ethnicity [9], employment status, and mental health treatment [22]. Few studies have explored the association between this comprehensive set of factors and changes in mental health outcomes.

We conducted an observational study of adults in 43 states initiating GAHT for the first time at a telehealth clinic to assess changes in depression, anxiety, and suicide ideation over a 3-month period. In addition, we examined whether these changes varied based on demographic factors, insurance coverage, and mental health treatment.

Methods

Overview

Ethical Considerations

This study received an exemption from the Western Institutional Review Board-Copernicus Group (WCG) institutional review board. The study follows the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) reporting guideline.

Study Procedures (Participant Selection and Study Framework)

We conducted a single-arm, observational study at FOLX Health, a telehealth clinic licensed across all 50 US states and the District of Columbia, with adults aged 18 years and older who initiated testosterone or estrogen therapy between August 3, 2023, and November 6, 2023. Participants were required to complete an intake questionnaire before their initial visit and a follow-up assessment 3-4 months later. All had consented to care and were first-time GAHT recipients, and the study did not influence their treatment outcomes.

All participants self-scheduled their initial GAHT visit and completed a comprehensive intake questionnaire before the visit, and a follow-up questionnaire three months later to assess mental health and care satisfaction. Alerts were sent if urgent mental health issues were reported. Initial Zoom visits lasted 30 minutes, with payment options including insurance or cash, and prescriptions could be sent to local pharmacies or delivered directly to homes. Treatment options, such as injectable testosterone cypionate or enanthate, transdermal testosterone gel, estradiol tablets, injectable estradiol cypionate or valerate, and transdermal estrogen patches, were chosen based on standard care practices and patient goals, under clinician guidance [23]. Psychotherapy was not a requirement for initiation of GAHT [23].

Measures

Psychological Outcomes

The primary outcomes of this study were the resolution of suicide ideation, and Healthcare Effectiveness Data and Information Set measures for response and remission from depression and anxiety [24], assessed using the Patient Health Questionnaire-9 (PHQ-9) [25] for depression and the General Anxiety Disorder-7 (GAD-7) for anxiety [24,26]. Elevated symptoms were defined as PHQ-9 ≥10 and GAD-7 ≥8 [27,28]. Response, our primary outcome, was defined as a 50% reduction in these scores [29,30], accommodating patients with various baseline severities [29]. Remission, chosen as a secondary outcome for its correlation with improved daily function and long-term prognosis, was defined as scores below 5 on both tools. Completion of the PHQ-9 and GAD-7 was mandatory at baseline, ensuring that all respondents provided data for these instruments.

Suicidal ideation was evaluated with item 9 of the PHQ-9, "Thoughts that you would be better off dead or of hurting yourself in some way." Consistent with existing research and

XSL•FO
RenderX

the relevance of this measure for gender-diverse populations [2,31], any response other than "not at all" indicated possible suicidal ideation. Resolution was defined as a "not at all" response at the follow-up (refer to Multimedia Appendix 1).

Covariates Plausibly Associated With Changes in Outcomes

We included demographic factors (age, sex assigned at birth, race or ethnicity, and legal change of gender marker on identity document), access factors (insurance coverage, urbanicity of living environment, educational level, and unemployment status), and health care factors (history of a gender-affirming surgery (GAS); use of mental health treatment, including medication for anxiety or depression; use of talk therapy in the year previous [32] to initiating hormones; and use of talk therapy during the study period).

Statistical Analysis

First, we present baseline descriptive statistics, categorizing continuous variables as mean (SD) and categorical variables as frequency (percentage). These statistics are provided separately for individuals seeking testosterone and estrogen therapy.

Second, we calculated the mean changes in PHQ-9 and GAD-7 scores for all participants, along with their 95% CIs. Next, we analyzed the proportion of individuals achieving response and remission from depression and anxiety, and resolution of suicide ideation.

Third, for each group —those with baseline elevated symptoms of depression (PHQ-9 ≥10) anxiety (GAD-7 ≥8), and suicide ideation— we estimated 5 separate models for each outcome: resolution of suicide ideation, and response and remission of anxiety and depression. We used generalized estimating equations with a binomial family and a logit link function to estimate adjusted odds ratios for outcomes while accounting for individual-level clustering. These models estimated the association between outcomes and any mental health treatment, health insurance, education, urbanicity of residence, age, and sex assigned at birth. All models included time to follow-up (in weeks), and because remission does not take into account baseline symptom severity, we also included baseline PHQ-9 and GAD-7 scores in those models. We excluded covariates with a prevalence of <5% and state of residence from the final model to prevent overfitting and ensure the reliability of our estimates.

Participants with missing data on PHQ-9 or GAD-7 scores at baseline or follow-up were excluded from the analysis. For all other variables, missing data were categorized separately and included in the analysis to maintain the integrity and size of the sample.

We conducted a sensitivity analysis in which we reran all models after excluding individuals who had experienced mental health treatment, as well as those who had undergone GAS or legally changed their gender. This approach aimed to help mitigate the effects of unobserved confounders like symptom persistence and perceived need for care, which could influence mental health independently.

Finally, to assess potential differences between participants who completed the follow-up survey and those who did not, we analyzed the association of completing the follow-up survey with baseline PHQ-9 and GAD-7 scores, controlling for time and covariates described previously.

Statistical analyses were conducted using Python (version 3.11.7; Python Software Foundation) in March 2024.

Results

Overview

A total of 669 adults initiated GAHT via telehealth during the dates specified in our study period, with 98% (658/669) completing an initial intake survey; and 52% (342/669) participating in a follow-up survey. A detailed comparison between participants who completed the follow-up and those who did not is available in Multimedia Appendix 2. There were no baseline mental health differences between participants who did and did not complete the follow-up survey.

Our final sample included 342 adults ages 18 years to 67 years (mean 26.5 years [SD 8.5 years]). Among 342 adults, 192 (56.1%) were prescribed estrogen therapy and 150 (43.9%) were prescribed testosterone therapy.

Prescriptions were issued primarily by nurse practitioners (291/342, 85%), and the remainder were primary care physicians (51/342, 15%). Most patients (298/342, 87%) completed their first appointment within 7 days of registration. Prescription fulfillment was split, with 50% (171/342) receiving medications through direct mail and 50% (171/342) through local pharmacies. Estradiol tablets were the predominant form of estrogen therapy, while injectable testosterone cypionate was the most common testosterone therapy (Multimedia Appendix 3).

Overall, 71% (243/342) identified their race as white only, and 12% (42/342) identified their ethnicity as Latinx (Table 1). Geographic distribution showed a concentration in the southern United States (170/342, 50%), and socioeconomic data revealed that 59% (201/342) were uninsured and 6% (18/342) unemployed, with educational attainment distributed as follows: 36% (122/342) with high school education or less, 37% (124/342) with some college education, and 27% (93/342) holding at least a college degree.

[a]*P* values represent the statistical significance of differences between adults prescribed testosterone and estrogen, calculated using appropriate tests for each variable type (eg, chi-square test for categorical variables and *t* test for continuous variables).

[b]Patients resided in 43 states.

[c]PHQ-9: Patient Health Questionnaire-9.

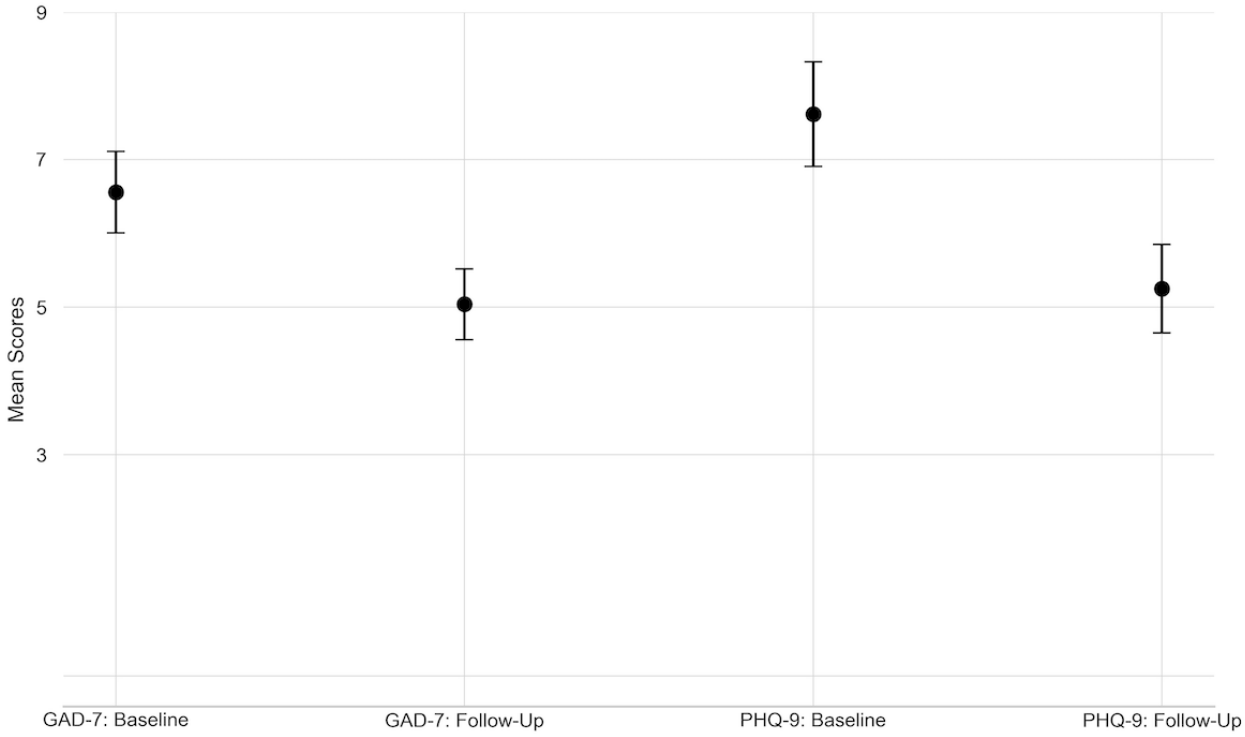
[d]Probable major depression.

[e]GAD-7: General Anxiety Disorder-7

[f]Probably anxiety disorder.

Only 5% (16/342) of participants had legally changed their gender on their license or identification card, and 4% (14/342) had undergone GAS. Meanwhile, 39% (132/342) had consulted a mental health professional in the past year, with an average of six visits, and 24% (82/342) were prescribed medication for anxiety or depression.

Individuals seeking testosterone therapy were younger, used more mental health care services, had higher rates of



XSL•FO
RenderX

prescriptions for anxiety or depression, and were more likely to have undergone one or more GAS compared to those seeking estrogen therapy.

Baseline and Follow-Up Depression and Anxiety Scores

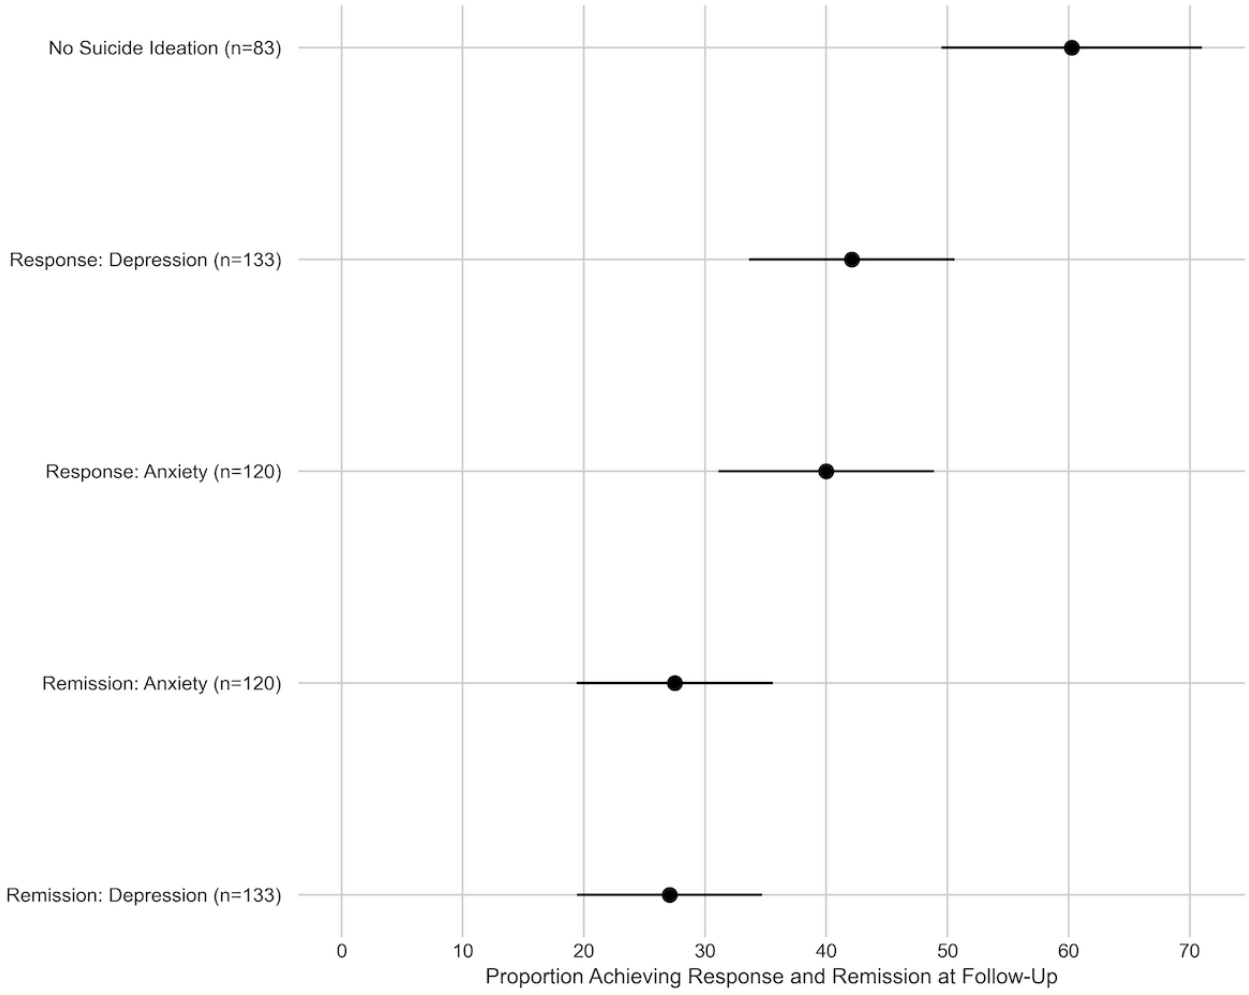
There were 333 individuals who reported depression and anxiety scores at both baseline and follow-up. The mean baseline PHQ-9 score was 7.6 (Figure 1). At follow-up, there was a statistically significant decrease in PHQ-9 scores (mean difference, −2.4 points; 95% CI −3.0 to −1.8 points).

Figure 1. Baseline and follow-up depression (PHQ-9) and anxiety (GAD-7) scores among adults who initiated gender-affirming hormone therapy. GAD-7: General Anxiety Disorder-7; PHQ-9: Patient Health Questionnaire-9.

Mean and 95% CIs are represented for 333 adults who completed baseline and follow-up PHQ-9 and GAD-7 assessments.

In total, 40% (136/342) had elevated symptoms of depression (PHQ-9 ≥10) at baseline. This included 76 individuals who scored moderate (10 to 14), 42 individuals who scored moderately severe (15 to 19), and 18 individuals who scored severe (20 to 27). For those without elevated symptoms, the baseline PHQ-9 score was none/minimal (0 to 4) in 128 individuals (128/342, 37%), and mild (5 to 9) in 78 individuals (78/342, 23%).

The mean baseline GAD-7 score was 6.6. At follow-up, there was a statistically significant decrease in GAD-7 scores (mean difference −1.5 points, 95% CI −2.0 to −1.0 points).



In total, 36% (120/342) had elevated symptoms of anxiety (GAD-7 ≥8). This included 40 individuals who scored mild (8-9), 51 individuals who scored moderately severe (10 to 14), and 33 individuals who scored severe (15 to 21). For those without elevated symptoms, the baseline GAD-7 score was none or minimal (0 to 4) in 127 individuals (127/342, 37%), and mild (5 to 7) in 91 individuals (91/342, 27%).

Response and Remission from Depression and Anxiety

Among the 133 individuals with PHQ-9 ≥10 at baseline, 42% (n=56) achieved response (50% reduction in score), and 27% (n=36) achieved remission (PHQ-9 <5) at follow-up (Figure 2).

XSL•FO
RenderX

Figure 2. The proportion of adults who initiated GAHT (gender-affirming hormone therapy) achieving remission and response from elevated symptoms of depression and anxiety, and resolution of suicide ideation at follow-up.

Among the 120 individuals with GAD-7 ≥8 at baseline, 40% (n=48) achieved response, and 28% (n=33) achieved remission at follow-up.

Resolution of Suicide Ideation

At baseline, 83 individuals (83/342, 25%) reported suicide ideation. Among these individuals, 60% (50/83) did not report suicide ideation at follow-up.

Adjusted Odds of Response and Remission

Use of mental health treatment before or during the period was associated with a 0.43 (95% CI 0.19-0.93) lower odds of depression response and 0.43 (95% CI 0.19-0.98) lower odds of anxiety response. Those who were female sex assigned at birth (FSAB) had a 0.38 (95% CI 0.18-0.82) lower odds of depression response. No statistically significant association was found between depression or anxiety symptom response and age, race or ethnicity, insurance coverage, educational level, or use of mental health treatment (Table 2).

No associations were observed between mental health treatment or other baseline factors and remission of depression, anxiety, and resolution of suicide ideation (Table 3).

XSL•FO
RenderX

Table 2. Association between demographic and treatment factors and mental health response among adults initiating gender-affirming hormone therapy with elevated symptoms of depression or anxiety.

[a]All models use Generalized Estimating Equations with a binomial family and a logit link function, with clustering at the individual level and controlling for time to follow-up. We excluded employment status, change of legal gender, or history of a gender-affirming surgery because of small cell sizes. This model includes those with PHQ-9 ≥10 at baseline. Remission is defined as a PHQ-9 <5 at follow-up

[b]Model includes those with GAD-7 ≥8 at baseline. Remission is defined as a GAD-7 score <4 at follow-up.

[c]Model includes those with suicide ideation at baseline. Remission includes those who do not have suicide ideation at follow-up.

[d]Any mental health treatment was defined as using an antidepressant or using talk therapy a year before or during the study period.

[e]GAD-7: General Anxiety Disorder-7.

[f]PHQ-9: Patient Health Questionnaire-9.

Sensitivity Analyses

After excluding those without mental health treatment, GAS, or a legal gender change, no statistically significant association was observed between FSAB and odds of depression and response or remission (Multimedia Appendices 4 and 5).

Discussion

Principal Findings

Among adults newly initiating testosterone or estrogen therapy via telehealth services with elevated depression and anxiety symptoms, 40%-42% achieved a clinically meaningful response. Of those with suicide ideation, 60% saw resolution within 3 months. These results are consistent with improvements reported in previous studies [4,5,33]; however, most of these studies were conducted outside the United States, inclusive of youth, and before the COVID-19 pandemic, thus telehealth modalities were not specifically explored. Moreover, very few studies have used similar outcome measures. One such example is an observational study of 315 youth aged 13 to 20 from Seattle. This study reported no change in moderate to severe depressive symptoms at 3 or 6 months, with improvements only evident after a year on GAHT [34].

Other US-based studies, including smaller cohorts from New York, California, Boston, and Illinois, also documented mental health improvements in youth initiating GAHT using other measures [6,35]. While comparisons between observational studies and RCTs, may raise concerns due to differences in study design, it is noteworthy that 61% of Australian adults receiving testosterone saw a reduction of five or more points on the PHQ-9 score, and 52% experienced the resolution of suicide ideation within three months [34]. Our study fills a critical gap by providing contemporary insights on hormone therapy via telehealth, demonstrating significant mental health improvements in a setting largely unexplored in previous research.

Although GAHT is not explicitly prescribed for anxiety or depression, its impact on mental health can be profound, and in this study, it compares favorably with treatments that target mental health conditions directly. For instance, antidepressants

XSL•FO
RenderX

typically show an improvement in symptoms for less than 20% of adults with moderate to severe depression [36,37]. Other types of treatments show similar effects, with 13-25% of adults achieving remission from depression in traditional and telehealth-enabled collaborative care models [38,39]. While GAHT is not a replacement for mental health condition–specific treatments, this research strongly suggests that it is an important factor in mental health wellness for TGD adults.

Our finding that individuals who used mental health treatment had lower odds of achieving a depression response, though not remission, suggests that those with a history of mental health treatment may have more persistent symptoms of depression. In contrast, individuals without prior treatment may have more emergent symptoms. Furthermore, engagement in mental health treatment is not randomly assigned; rather, it is heavily influenced by both perceived needs and available resources [36]. Notably, less than 40% of this population had health insurance, which likely limited their access to consistent and comprehensive mental health treatment. Our findings imply that improvements in mental health observed in individuals using hormone therapy occurred independently of their use of other mental health treatments.

Prior studies have reported that adults with multiple marginalized identities are at risk for worse mental health as a result of compounded discrimination [21]. While our findings showed no significant differences in mental health remission based on race, ethnicity, or education, we observed that FSAB had lower odds of depression response than male sex assigned at birth adults. However, this association disappeared when excluding individuals already receiving mental health treatment. The higher rates of mental health treatment among FSAB individuals suggest variations in underlying symptomatology, which our main models could not fully adjust for. Future research should further elucidate how concurrent GAHT and mental health treatment influence mental health symptoms.

Limitations

A primary limitation is the lack of a control group of participants who did not receive GAHT, which would be both infeasible and unethical. This makes our observational study unable to definitively link improvements in mental health to GAHT alone due to potential unmeasured factors. In addition, with only a 3-month follow-up, the long-term effects of GAHT remain unclear. Our reliance on patient-reported outcomes may introduce bias, although baseline mental health was comparable between those lost to follow-up and those retained. Furthermore, the quick scheduling of initial visits within a week, contrasting with the months- to years-long delays at traditional gender specialty clinics, may also influence the generalizability of our results.

The generalizability of our findings may be limited to similar care models, as our cohort was drawn from a specialized telehealth-only clinic—one of a few in the United States providing GAHT. Although telehealth has increasingly been recognized as a way to broaden geographic access to such care [7,40], it remains out of reach for some populations. Compared to other nationally representative samples of transgender and gender-diverse adults, our participants were generally younger, more educated, predominantly white, more rural, and less insured [1,41] Despite these differences, the prevalence of mental health symptoms before GAHT mirror those of other clinics providing in-person care, suggesting that our results may be comparable with other health care settings [2,27].

Conclusions

In this observational study, adults accessing GAHT at a telehealth clinic experienced significant improvements in depression, anxiety, and suicide ideation after 3 months. Although GAHT is not prescribed for mental health, it may be an important part of mental health wellness for TGD adults. Future studies with longer follow-up periods are essential to better understand these findings.

Acknowledgments

Abstract

Background: Health care wearable devices can transform health care delivery by enabling real-time, continuous monitoring that facilitates early disease detection, personalized treatments, and improved patient engagement. The COVID-19 pandemic has heightened awareness of the importance of health technology, accelerating interest in wearables as tools for monitoring health and managing chronic conditions. As we navigate the postpandemic era, understanding the adoption and data-sharing behaviors associated with wearable devices has become increasingly critical. Despite their potential, challenges and low adoption rates persist, with significant gaps in understanding the impact of sociodemographic factors, health conditions, and digital literacy on the use and data-sharing behaviors of these devices.

Objective: This study aimed to explore the usage and data-sharing practices (willingness to share wearable data and actual data-sharing behavior) of wearable devices among US adults specifically during the later phases of the COVID-19 pandemic.

Methods: Using cross-sectional data from the National Cancer Institute's Health Information National Trends Survey 6, conducted from March to November 2022, this study uses responses from 5591 US adults to examine wearable use, willingness to share wearable data with providers, family, and friends, and the wearable data-sharing behavior.

Results: The results indicate an increase in wearable device adoption to 36.36% (2033/5591) in 2022, up from 28%-30% in 2019. We also find a significant discrepancy between the willingness to share data, with 78.4% (1584/2020) of users open to sharing with health care providers, and the actual sharing behavior, where only 26.5% (535/ 2020) have done so. Higher odds of using wearables were associated with female gender (odds ratio [OR] 1.49, 95% CI 1.17-1.90, P<.01) and higher income levels (OR 2.65, 95% CI 1.42-4.93, P<.01 for incomes between US $50,000 and US $75,000, and OR 3.2, 95% CI 1.71-5.97, P<.01 for incomes above US $75,000). However, the likelihood of usage and data sharing declines significantly with age. Compared with African American respondents, Hispanic respondents were more willing to share wearable data with providers (OR 1.92, 95% CI 1.02-3.62, P<.05), though the odds of their actual sharing of wearable data with providers was relatively less (OR 0.44, 95% CI 0.20-0.97, P<.05). Frequency of provider visits (OR 1.23, 95% CI 1.08-1.39, P<.01), and total medical conditions (OR 1.35, 95% CI 1.05-1.73, P<.01) were significant predictors of data-sharing behavior. The study also identified weight, frequency of provider visits, technological self-efficacy and frequent physical activity as predictors for higher wearable use.

Conclusions: Insights from this study are crucial for health care providers and policy makers aiming to leverage wearable technology to enhance health outcomes. Addressing the disparities and barriers identified can lead to more effective integration of these technologies in health care systems, thereby maximizing the potential of digital health tools to improve public health outcomes.

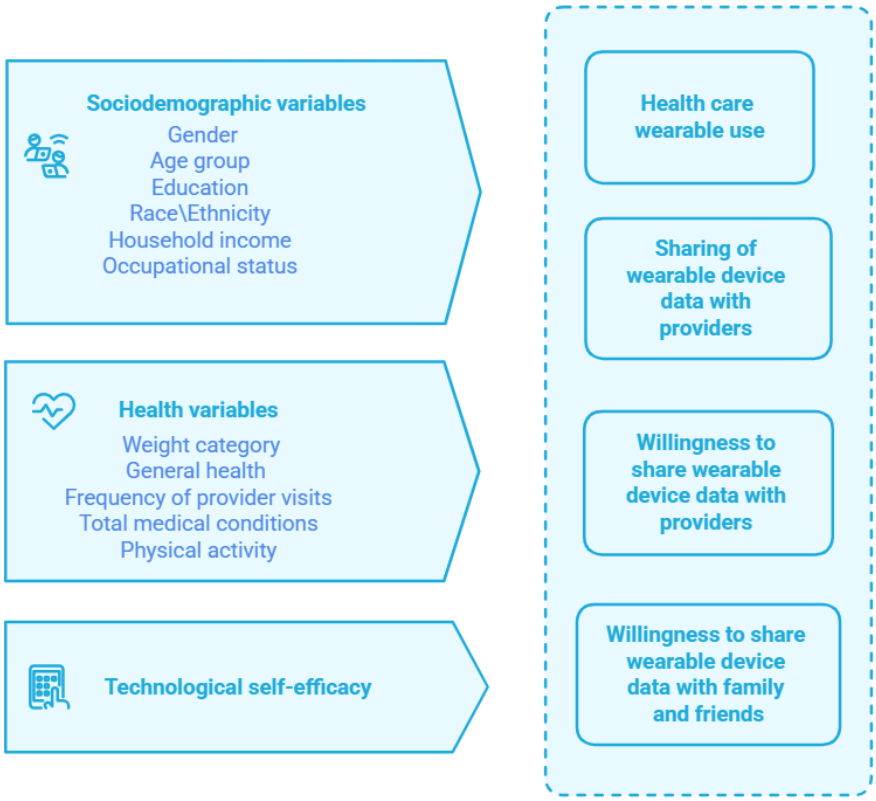
Introduction

Health care wearable devices, encompassing a diverse array of technologies ranging from smartwatches, activity trackers, to biosensors, are revolutionizing the landscape of health care delivery [1]. These devices, which include skin-based wearables, biofluidic-based wearables, and drug delivery systems [2], are typically worn on or close to the body, gather physiological data, and provide actionable insights into an individual's health and well-being. By continuously monitoring vital signs, activity levels, and other biometric parameters, health care wearables offer opportunities for early disease detection, personalized treatment, and remote patient monitoring [3-5]. The potential of these devices to transform health care delivery is underscored by their ability to empower individuals to take proactive measures toward their health [6-8] and to facilitate health care professionals in delivering more personalized and timely interventions [9-11]. Furthermore, the integration of health data generated from wearable devices with mobile apps enhances their use, allowing for real-time tracking, monitoring, and analysis of health metrics [12]. With advancements in sensor technology, miniaturization, and data analytics, the market for health care wearables has witnessed exponential growth in recent years. The global market for health care wearables was valued at US $33.85 billion in 2023 and is projected to reach US $250 billion by 2030 [13], driven by increasing consumer demand for continuous health monitoring and the growing adoption of telehealth services.

Wearable health care devices have been found to be effective in gathering reliable health information for various conditions including cardiovascular diseases [14-17], chronic respiratory conditions like asthma, and chronic obstructive pulmonary disease [18-20], Parkinson disease [21-23], and mental health conditions such as stress, anxiety, depression, and behavioral changes [24-27]. Despite such promising benefits, adoption rates of wearable health care devices have varied across different demographics and health conditions [28-30]. While some individuals enthusiastically embrace these technologies for health monitoring purposes, others remain skeptical or face barriers such as cost, usability issues, and concerns regarding data privacy and security [31-33]. For instance, studies have indicated that older adults [34,35], individuals with lower income [36,37], and those with limited digital literacy [38-40] may experience greater difficulties in accessing and using wearable technology. In addition, questions have also been raised about the accuracy and reliability of data captured by wearable devices [14,41,42]. Therefore, to fully realize the potential benefits offered by wearable health care devices, effective sharing of wearable health data from patients to health care providers is critical.

Many studies have examined individuals' behavioral intentions to use wearable devices [43-46] and their willingness to share health data generated by wearables with health care providers [47,48]. Other studies have documented the willingness of individuals to share the data generated from their wearable health devices for research purposes [49-51]. However, despite documented intentions, there remains a notable gap in understanding the actual, actionable health data-sharing behaviors of users of health care wearable devices. This study aims to address this gap by investigating both self-reported willingness and actual behavior in sharing health data generated by wearable devices. We present findings based on a national survey conducted among US adults to ascertain the current landscape of health care wearable usage. We build upon and extend our earlier work [30] that examined wearable usage in the prepandemic period (2019) by using a recent dataset from 2022 to provide insights into the current use of wearable devices, with a particular focus on wearable data-sharing practices. In addition, we explore potential disparities in wearable use across socioeconomic demographics, health conditions, levels of technological self-efficacy, and engagement in physical activities. Furthermore, we examine whether these factors are associated with variations in individuals' willingness to share health data with health care providers and family or friends. Importantly, we assess the actual data-sharing behavior to identify predictors associated with the willingness-action gap and compare our findings with similar studies to highlight both similarities and differences (Figure 1).



This study leverages the most recent, nationally representative dataset of US adults, gathered in the later phases of COVID-19 pandemic (2022), a period marked by heightened health awareness and evolving health behaviors [52]. As we transition into the postpandemic era, understanding the use and data-sharing behaviors associated with wearable devices has become increasingly critical. The data collected during this period could offer valuable insights into shifts in health behaviors and highlights the role of wearable technology in managing and improving health engagement.

This study aims to answer the following questions:

1. How has wearable device usage among US adults changed since 2019, and what factors are associated with wearable use in the postpandemic era?
2. What are the key sociodemographic, health, and technological factors that influence US adults' willingness to share health data from wearable devices with health care providers, and with their family and friends?
3. How do actual data-sharing behaviors with health care providers compare with individuals' self-reported willingness to share wearable health data, and what are the key predictors of the actual data-sharing behavior?

Methods

Sample and Data Collection

Data for this study were sourced from the sixth cycle of the Health Information National Trends Survey (HINTS 6), conducted by the National Cancer Institute from March through November 2022. HINTS 6 is a nationally representative, probability-based cross-sectional survey. In this cycle, adult, civilian, noninstitutionalized individuals were invited to participate through self-administered questionnaires, with respondents completing the survey either on paper or online. The survey used a nationally representative sampling strategy, targeting areas with high concentrations of minorities and those with lower minority concentrations, in addition to stratification by rural and urban geographic areas.

The survey was designed to collect data in 2 modes, giving respondents the option to complete the questionnaire through paper or through the web, with certain incentives offered for web participation. The sampling method continued to use a 2-stage design, initially selecting a stratified sample of addresses, followed by the selection of 1 adult per household from these addresses. This methodology ensures a broad representation of the US population, though the reliance on self-reported data may introduce certain biases in reporting and recall. To include respondents in the analytic sample, we implemented a 2-step filtering process: (1) respondents must have reported having a smart device, such as a smartphone or tablet, or multiple smart devices, and (2) they must have provided a response to the question regarding their use of a wearable device for tracking health or activity in the past 12 months. Specifically, only those smart device owners who answered the question, “In the last 12 months, have you used an electronic wearable device to monitor or track health or activity? For example, a Fitbit, Apple Watch, or Garmin Vivofit,” were included in the dataset for analysis. This approach resulted in 5591 completed survey responses, ensuring consistency with our research goals pertaining to current usage patterns of wearable health care devices and also into the data-sharing behaviors with health care providers and personal networks.

Variables and Measures

Outcome Variables

The primary focus of this study was on the use of wearable health care devices, assessed through a binary (yes or no) question asking respondents if they had used such an electronic wearable device to monitor or track their health or activity in the past 12 months. In addition, we also explored the responses about the frequency of wearable health care device use in the past month (everyday, almost every day, 1-2 times a week, <1 time a week, never used). In addition, the study explored respondents’ willingness to share data from their wearables with health care providers and with family and friends, also assessed as yes or no responses. To understand actual data-sharing behavior, we examined a survey question about whether respondents had shared health information from a wearable device with a health professional in the last 12 months.

Independent Variables

The study incorporated data from the survey questionnaire to capture respondents’ self-reported characteristics, which

XSL•FO
RenderX

included sociodemographic factors (such as age, gender, race/ethnicity, education, occupational status, and annual household income), health-related aspects (general health status, the total number of medical conditions, frequency of health care provider visits, and weight category), and technology-related factors (technology self-efficacy). General health was evaluated on a Likert scale from 1 (poor) to 5 (excellent). To quantify the total number of medical conditions, we counted 5 self-reported conditions such as diabetes or high blood sugar, hypertension, heart conditions (eg, heart attack, angina, or congestive heart failure), chronic lung diseases (such as asthma, emphysema, or chronic bronchitis), and mental health issues like depression or anxiety disorders. The values for total medical conditions ranged from 0 to 5. The frequency of health care provider visits was measured on a scale based on the number of visits in the past year, with values ranging from 0 (none) to 6 (10 times or more). Weight categories were determined based on BMI values: a BMI under 18.5 indicates underweight, and values between 18.5 and 25 indicates a normal healthy status, 25 to 29.9 is considered overweight, and a BMI of 30 or above is categorized as obese.

Previous research has demonstrated that technological self-efficacy, or comfort with technology, significantly influences the use of wearables [35,53,54]. Building on these findings, we measured respondents' technological self-efficacy based on their engagement in 4 internet-based health activities over the past year: searching for health information, electronic communication with health providers, accessing medical test results online, and scheduling appointments online. Each activity was scored as yes (1) or no (0), with total scores ranging from 0 to 4, indicating increasing comfort with technology.

We also explored the relationship between physical activity exercise routines and wearable device usage. Previous research suggests that individuals who are regularly motivated to exercise and engage in physical activities are more inclined to adopt and use wearable devices [55,56]. To assess the physical activity levels of respondents, we examined a question asking how many days per week they engage in any physical activity or exercise of at least moderate intensity (0-7 days a week). Examples provided included brisk walking, bicycling at a regular pace, and swimming at a regular pace.

Statistical Analysis

All the statistical analyses were performed using STATA software (version 18; StataCorp). We began with a descriptive analysis of our data sample. To explore the associations between the use of wearable health care devices and various sociodemographic predictors, we generated crosstab tables and evaluated them using the Wald chi-square test. This approach was repeated to analyze the willingness to share wearable health data with providers, family, and friends, as well as the actual sharing of such data with health care providers.

Given that our primary variables of interest were all binary, and our predictor variables included both categorical and continuous types, logistic regression analysis was used (Figure 1). We ran 4 survey logistic regression models (using svy: logistic command in STATA) with the following outcome variables: (1) use of wearable health care device (0/1), (2) willingness to share health care wearable data with providers (0/1), (3) willingness to share health care wearable data with family and friends (0/1), and (4) actual sharing of wearable data with providers (0/1). The predictor variables were the sociodemographic factors (gender, age group, education level, race/ethnicity, annual household income, and occupation status), health related variables (weight category based on BMI, self-reported general health, frequency of provider visits, total medical conditions, and extent of physical activity) and technology self-efficacy. We calculated adjusted odds ratios (ORs) and CIs for these predictors. To account for the complex survey design, we applied weights with jackknife replications in our statistical analyses, using *svy:* commands in STATA. Since the svy: logistic model in STATA does not assess multicollinearity, we initially ran standard logistic regressions and examined variance inflation factor values with a cutoff value of 4, before performing svy: logistic regression assessments.

Ethical Considerations

HINTS data are publicly available and collected as deidentified information from participants, specifically designed for research purposes [57]. The HINTS 6 survey was classified as "exempt research" under 45 CFR 46.104 and approved by the Westat institutional review board (IRB) on May 10, 2021 (Project #6632.03.51), with an amendment approved on November 24, 2021 (Amendment ID #3597). It also received a "Not Human Subjects Research" determination from the National Institutes of Health (NIH) Office of IRB Operations on August 16, 2021 (iRIS reference #562715). Therefore, no additional approvals were required from authors' institutions. Further details on the survey instrument, and the methodology and data handling for HINTS 6 can be explored through the National Cancer Institute's official resources [58,59].

Results

Overview

Table 1 describes the characteristics of survey respondents. A total of 5591 respondents had indicated having a smart device that is needed for storing and sharing data from a health care wearable device, in addition to responding to the question about use of a wearable device. A total of 3161 out of 5591 (60.45%) were female, 3405 out of 5591 (61.55%) were aged 50 years or older, 2600 out of 5591 (49.67%) had a college degree or higher, and 2479 out of 5591 (44.34%) were employed full-time. Among the respondents, 2925 out of 5591 (57.97%) identified their race\ethnicity as White, 785 out of 5591 (15.56%) as Black, 893 out of 5591 (17.7%) as Hispanic, and 271 out of 5591 (5.37%) as Asian. Furthermore, 2100 out of 5591 (42.24%) indicated their annual household incomes to be US $75,000 or more.

Health Care Wearable Use and Frequency of Use

Out of 5591 respondents, 2033 (36.36%) reported using a health care wearable device in the past 12 months (Table 2). In the exploratory analysis, we observed statistically significant differences in wearable use (Table 3) across age groups (χ^2_4=261.7, *P*<.01), gender (χ^2_1=25.7, *P*<.01), education (χ^2_3=170.6, *P*<.01), occupation status (χ^2_2=143.1, *P*<.01), race\ethnicity (χ^2_4=13.7, *P*<.01) and income levels (χ^2_4=290.1, *P*<.01; Figure 2). When asked about health care wearable use in the past month, 880 out of 5591 (43.48%) reported daily use, 557 out of 5591 (27.52%) used them almost every day, 217 out of 5591 (10.72%) used them 1-2 times per week, and 156 out of 5591 (7.71%) used them less than once a week. Notably, 214/5591 (10.57%) indicated they had not used their wearables at all in the past month.

Figure 2. Health care wearable use across different demographic segments.

Wearable Data Sharing: Willingness and Sharing Behavior

Out of 2020 wearable users, 1584 (78.4%) expressed willingness to share data from health care wearables with their providers, and 1266 out of 2014 (62.95%) users indicated willingness to share health data with family or friends. Despite this willingness, only 535 out of 2020 (26.5%) users actually shared data from wearable devices with providers within the past 12 months (Table 2). This highlights a significant gap between the intention to share health data and actual sharing behavior. Table 4 reveals demographic disparities in health data sharing behaviors based on exploratory chi-square tests: gender (χ^2_1=4.08, P=.04), age groups (χ^2_4=50.45, P<.01), race/ethnicity (χ^2_4=12.79, P<.01), and occupational status (χ^2_2=18.56, P<.01). Differences in the willingness to share wearable data with health providers were significant only by race/ethnicity (χ^2_4=10.35, P<.03). Similarly, the willingness to share data with family and friends showed significant variation across different age groups (χ^2_4=20.44, P<.01) and occupational status (χ^2_2=5.64, P<.05).

Predictors of Health Care Wearable Use

Table 5 presents results from a logistic regression analysis examining predictors of health care wearable use. Women, compared with men, are more likely to use health care wearables (OR 1.49, 95% CI 1.17-1.9, *P*<.01). The likelihood of using health care wearables declines with age; compared with the 18-34 years age group, the 50-64 years (OR 0.49, 95% CI 0.36-0.67, *P*<.01), 65-74 years (OR 0.37, 95% CI 0.26-0.54, *P*<.01), and over 75 years (OR 0.35, 95% CI 0.20-0.61, *P*<.01) age groups showed significantly lower odds. Higher annual household incomes are also associated with increased likelihood of wearable use, notably in the US $50,000 to US $75,000 range (OR 2.65, 95% CI 1.42-4.93, *P*<.01) and above US $75,000 (OR 3.21, 95% CI 1.71-5.97, *P*<.01). Weight categories, as assessed by BMI significantly influenced wearable use. Overweight individuals (BMI 25-29.9) were more likely to use wearables compared with those with normal weight (BMI 18.5-24.9; OR 1.36, 95% CI 0.98-1.89, *P*<.05). Conversely, underweight individuals (BMI<18.5) were less likely to use wearables (OR 0.31, 95% CI 0.09-1.04, *P*<.05). Obese individuals (BMI≥30) also showed higher odds of use (OR 1.33, 95% CI 0.93-1.90, *P*<.10), though this was only significant at the 10% level.

Among the health-related variables, the frequency of provider visits was significantly associated with an increase in wearable use (OR 1.08, 95% CI 1.02-1.15, *P*<.01), whereas neither self-rated general health nor the number of medical conditions were significant predictors. In addition, our analysis indicated that individuals who exercised more frequently were more likely to use wearables (OR 1.15, 95% CI 1.11-1.20, *P*<.01).

As reported in Table 5, our findings indicated a strong association between technological self-efficacy and wearable use (OR 1.29, 95% CI 1.15-1.44, *P*<.01).

Predictors of Health Data Sharing and Willingness to Share Wearable Data

A series of 3 logistic regressions were used to explore the relationships between various predictors and both the behavior of sharing health data and the willingness to share data from wearable health devices with providers, family, and friends. These findings are detailed in Table 6.

While women were more likely to use health care wearable devices compared with men, they were less likely to share the data from these devices with providers (OR 0.66, 95% CI 0.44-0.99, $P<.05$). No significant associations were found between gender and the willingness to share wearable data with either providers or family and friends.

Health						
General Health	1.16 (0.84-1.60)	.35	1.10 (0.85-1.42)	.46	1.21 (0.97-1.52)	.09
Frequency of Provider Visits	1.23 (1.08-1.39)	.01	1.29 (1.08-1.43)	.04	1.10 (0.98-1.23)	.15
Total Medical Conditions	1.35 (1.05-1.73)	.01	1.06 (0.87-1.29)	.53	1.06 (0.84-1.32)	.54
Physical Activity (Times Exercise)	1.09 (0.98-1.21)	.10	0.99 (0.91-1.07)	.81	1.08 (1.07-1.17)	.05
Technology self-efficacy						
Electronic Usage	1.26 (0.92-1.71)	.14	1.13 (0.94-1.36)	.17	0.94 (0.8-1.11)	.46

Older adults aged 75 years and above showed higher odds of sharing wearable device data with providers (OR 4.14, 95% CI 1.18-14.6, *P*<.01) compared with the younger (18-34 years) age group. Although no significant differences were noted among age groups in their willingness to share wearable data with providers, a negative association was observed in their willingness to share with family and friends. Specifically, individuals aged 50-64 years (OR 0.39, 95% CI 0.22-0.71, *P*<.01), 65-74 years (OR 0.35, 95% CI 0.23-0.93, *P*<.01), and older than 75 years (OR 0.46, 95% CI 0.23-0.93, *P*<.05) were less likely to share health data from wearable devices with family or friends.

XSL•FO
RenderX

Compared with non-Hispanic Black respondents, Hispanic respondents (OR 1.92, 95% CI 1.02-3.62, *P*<.05) and non-Hispanic White respondents (OR 1.74, 95% CI 1.08-3.09, *P*<.05) exhibited higher odds of willingness to share health data from wearables with providers. Furthermore, non-Hispanic White respondents showed a greater tendency to share wearable data with family and friends (OR 1.81, 95% CI 1.04-3.16, *P*<.05). However, in comparison with non-Hispanic Black respondents, actual sharing behavior was lower for Hispanic respondents (OR 0.44, 95% CI 0.20-0.97, *P*<.05). Altogether, these results indicate racial disparities in the actual sharing of health data despite a higher willingness.

No significant differences were observed in the willingness to share health data with providers, as well as family and friends, based on annual household income, yet the likelihood of sharing health data with providers decreased with higher income levels. Those earning between US $50,000 and US $75,000 (OR 0.28, 95% CI 0.08-0.94, *P*<.05), and those with incomes above US $75,000 (OR 0.31, 95% CI 0.09-0.99, *P*<.05) showed lesser odds of sharing.

Frequency of provider visits emerged as a significant predictor for both willingness to share and actual sharing behavior with providers. Those who visited their providers more frequently were more willing to share data from wearable devices (OR 1.29, 95% CI 1.08-1.43, *P*<.05) and more actively engaged in sharing this data (OR 1.23, 95% CI 1.08-1.39, *P*<.01). Individuals with more medical conditions also showed higher odds of sharing data with providers (OR 1.35, 95% CI 1.05-1.73, *P*<.01). A weak association was observed between self-reported general health and the willingness to share data with family and friends (OR 1.21, 95% CI 0.97-1.52, *P*<0.1). In addition, individuals engaging in more exercise and physical activities were found more likely to share wearable health care data with family and friends (OR 1.08, 95% CI 1-1.17, *P*<.05).

Discussion

Principal Findings

Wearable health care devices such as smartphones and activity trackers offer continuous and real-time monitoring of an individual's health metrics. These tools are becoming increasingly popular as they not only empower users to take proactive control over their health but also provide health care providers with invaluable data for better patient care. Despite their potential, significant gaps remain in understanding the predictors that influence wearable device use, and data-sharing behaviors associated with these devices. This study aimed to address these gaps by identifying key factors that influence both the use of wearable devices, the willingness to share the data they collect and actual data-sharing behavior. We observed an increase in wearable device usage from 28%-30% in 2019 to 36.36% in 2022, reflecting a broader trend of heightened health awareness, particularly following the COVID-19 pandemic. In addition, despite a high willingness to share wearable data with health care providers and family or friends, there is a significant gap between willingness and actual sharing behaviors, with only a quarter of users actively sharing data with providers.

Our results highlight a significant uptick in the adoption and use of health care wearable devices, from 28%-30% in 2019 [30,60] and 21% according to a 2020 Pew Research Study [61], to 36.36% in 2022. Our findings from HINTS 6 dataset, collected during a period of accelerating vaccinations and evolving public health measures, reflect how the COVID-19 pandemic has increased the adoption of wearable devices and shifted consumer attitudes toward self-health monitoring. The rise in wearable usage in 2022 signifies a growing health consciousness and commitment to self-health monitoring, suggesting that wearable technology will be crucial in fostering ongoing health engagement and preventive care in the postpandemic landscape [62,63].

Our analysis found that 78.4% of US adults were willing to share data from wearable devices with providers, and 62.95% were willing to share with family and friends. However, only 26.5% actually shared data with providers. This willingness-action gap may stem from factors such as privacy concerns and technological challenges. Notably, there is a decrease in willingness compared with previous years; studies from 2019 reported that 81.85% of respondents were willing to share wearable data with providers, and 69.51% with family or friends [47]. Other studies have reported even higher levels of willingness [30,48], particularly among subgroups such as cardiovascular patients and older individuals [35,64]. This decline in willingness suggests that while interest in wearable technology remains high, barriers to data sharing may have increased, hindering the translation of willingness into actual sharing behavior with providers.

Our analysis also reveals that wearable use is not uniform across demographic segments. Notably, women are more likely than men to use these devices. This trend is partly attributed to women's greater health consciousness and proactive engagement in health monitoring and management activities [65,66]. Previous research has also found that women with one or more chronic conditions are more likely to use wearable devices [67]. However, we also find that women are less likely to share data from wearable devices with health providers. This reluctance, relatively more in women, may stem from privacy concerns, fear of data misuse, and lack of trust in how their health information will be handled [68,69]. It is essential to develop targeted education and intervention programs for women that emphasize benefits of data sharing for personalized health care and improved medical outcomes. In addition, ensuring robust data security measures and transparent communication about how data will be used can help build trust and encourage more individuals to share their health information from wearable devices.

We also find that wearable usage decreases with age, with individuals over 75 showing the least likelihood of using wearables. This finding is consistent with previous studies [35]. This decline could be attributable to varying levels of technological comfort or perceived use and usability of the devices among the older adults [34,70]. Furthermore, older adults could find the devices to be too complex to use and integrate into their daily lives [71]. However, we also found older adults to be less willing to share wearable device data with family and friends but were actually more engaged in

XSL•FO
RenderX

sharing this data with their providers. This behavior suggests that older adults may prioritize sharing health information with professionals for medical oversight and care management, highlighting a trust in professional health care settings over personal networks.

Racial and ethnic disparities also manifest in wearable device use, with Hispanic individuals showing a greater propensity to share data from these devices compared with non-Hispanic Black individuals. This could reflect cultural differences in health management practices or disparities in access to technology. Our findings are consistent with previous studies that have documented increased interest in wearable devices among Hispanic communities, especially after the COVID-19 pandemic [72]. Challenges in obtaining health resources and general distrust in health care infrastructure and systems have also motivated Hispanic individuals to look at wearable devices to better monitor their health care. Hispanic individuals have also been engaging more with electronic tools to acquire health information using online resources and for communicating with providers [73]. While non-Hispanic White and Hispanic individuals showed a higher willingness to share data with providers, their actual sharing rates did not align with these intentions, indicating possible systemic or personal barriers that prevent translating willingness into action.

Our findings reveal that economic factors significantly influence wearable device usage, with individuals having higher annual household incomes being more likely to use these technologies, likely due to greater access to and affordability of emerging health technologies. Interestingly, despite their higher use rates, these individuals are less inclined to share wearable data with health care providers, possibly due to heightened privacy concerns [74,75] or a greater sense of autonomy in managing their health data independently.

Our analysis extends into health-related variables and conditions influencing wearable adoption. Frequent visits to health care providers and the presence of multiple health conditions are associated with higher likelihood of wearable usage and sharing of wearable data with providers, suggesting that individuals more engaged with their health are more receptive to using technology to manage their health. Our findings complement previous studies that have documented wearable use among patients with cardiovascular conditions [76], and diabetes [77,78].

Furthermore, our findings suggest that individuals who regularly engage in physical activities are not only more likely to use wearables but are also more willing to share the data generated, especially with family and friends potentially to monitor their fitness progress or health status more effectively. Many users share their physical activities with a group of friends using fitness and health apps, which helps to boost motivation and receive positive reinforcement [79,80]. These social features and gamification in wearable health apps allow users to join challenges, share achievements, and provide mutual support, significantly enhancing adherence to fitness goals and creating a sense of community [81].

Implications

The findings from this study on wearable health care devices suggest several implications for health care providers, policy makers, regulators, and industry stakeholders. Wearable devices can provide health data relevant to users' specific health needs and concerns, yet access to these benefits is not equally distributed among all users. Those with greater digital literacy and socioeconomic resources tend to have better access to the health monitoring and predictive capabilities of wearable technologies.

Health care providers can enhance wearable data sharing by addressing patient concerns, particularly among women and older adults, through targeted education and communication that underscores the benefits of sharing health wearable data. There is also a need for simplified training programs to increase wearable device use among older adults. Policy makers and regulators should focus on improving accessibility and affordability for lower-income individuals, ensuring robust data protection standards, and promoting interoperability between wearable devices and health systems to build trust and use. For racial and ethnic minorities, culturally tailored programs that address disparities in technology access and use are crucial. In addition, health insurers and technology companies could offer incentives for wearable data sharing and develop features that enhance user engagement through social connectivity and gamification, fostering a community-focused approach to health management. Collectively, these efforts can lead to better integration of wearable technologies in health care, providing valuable insights for preventive health measures and personalized care, thereby maximizing the potential of digital health tools in improving public health outcomes.

Limitations

This study has several limitations. Primarily, it relies on self-reported information by survey respondents, which can be subject to recall bias and social desirability bias. Respondents may not accurately remember past behaviors or may portray themselves in a more favorable light. For some variables, which may introduce inherent biases. In addition, the cross-sectional design of the survey restricts the ability to establish causality between variables. Since wearable usage may change over time, this type of study does not capture the dynamic changes in patterns of wearable use over time. We were also limited by the data already gathered by HINTS. Further research could explore reasons for nonuse or nonsharing of wearable data, and could examine additional questions pertaining to privacy, trust and design issues.

Conclusion

This study highlights critical insights into the use and data-sharing behaviors associated with wearable health care technology. We have detailed the latest trends in the adoption and use of wearable devices, outlining the frequency and demographics of users. In addition, we explored how US adults engage in sharing data from wearable devices, including their willingness to share this information with health care providers and with family and friends. Our study noted major gaps between willingness to share health care wearable data, and the

XSL•FO
RenderX

actual sharing behavior with providers. By identifying the sociodemographic, health and technological factors that influence both the use of wearables and the willingness to share data, our findings underscore the necessity for tailored interventions. Clinicians can enhance patient engagement by addressing the specific barriers identified, particularly among demographics with lower sharing rates. Policy makers should prioritize initiatives that promote accessibility and digital literacy, ensuring equitable benefits from wearable technologies. These targeted approaches can help bridge the gap between users' willingness to share health data and their actual sharing behaviors, ultimately advancing the integration of wearable devices in personalized health care.

Looking forward, this study lays the groundwork for future research aimed at enhancing the design of digital health interventions and improving the integration of wearable technology in clinical practices. By continuing to investigate the evolving dynamics of user engagement and the barriers to data sharing, we can better leverage wearable technology to advance personalized health care and public health outcomes.

Data Availability

The Health Information National Trends Survey 6 (HINTS 6) data is publicly available and seeks to provide a comprehensive view of health communication trends among US adults. Conducted by the National Cancer Institute, this data collection focuses on how people access and use health-related information and behaviors. The complete datasets, including methodological reports and questionnaires, are accessible on the HINTS website [82].

Abstract

Background: China has changed its COVID-19 prevention and control status since 2023. However, what role telemedicine will play post–COVID-19 is still uncertain.

Objective: We aimed to determine the frequency change in health care providers offering telemedicine services before, during, and after COVID-19, as well as the correlation between the frequency change and telemedicine visit time.

Methods: The Telemedicine Informationization Professional Committee of China (TIPC) carried out a nationwide questionnaire survey. We adopted data from part of the questionnaires that answered questions regarding the frequency of offering telemedicine services before, during, and after the COVID-19 explosion. Chi-square tests were applied to compare general differences in the between-group telemedicine frequency. Regression models were performed to analyze correlations between the frequency change and the time spent in online versus in-person visits.

Results: Questionnaires from 428 providers were included. As reported, 39 (9.11%) providers often and 159 (37.15%) always offered telemedicine services before COVID-19 exploded. The component ratio increased to 12.38% (n=53) of providers often and 45.79% (n=196) always offering telemedicine during COVID-19 explosion and 12.62% (n=54) often and 50% (n=214) always offering telemedicine after pandemic control was relaxed. The increase in frequency shown as a difference between the before and during groups (χ2=17.21, *P*.002) and between the before and after groups (χ2=30.17, *P*<.001) was significant, while it was insignificant between the during and after groups (χ2=2.89, *P*.57). Senior professional titles (odds ratio [OR] 4.38, 95% CI 1.72-11.6) and longer (OR 3.87, 95% CI 1.95-7.89) and shorter (OR 2.04, 95% CI 1.11-3.87) online visits were correlated with the increase in frequency during versus before COVID-19. In addition, senior professional titles (OR 3.47, 95% CI 1.46-8.49), longer (OR 3.14, 95% CI 1.64-6.11) and shorter (OR=2.27, 95% CI 1.31-4.07) online visits, and using third-party telemedicine platforms (OR 0.51, 95% CI 0.29-0.86) were correlated with the increase in frequency after versus before COVID-19. No factor was significantly correlated with the frequency change after versus during COVID-19. In stratified analysis, longer online visits were correlated with both during versus before (OR 3.84, 95% CI 1.73-8.83) and after versus before (OR 3.40, 95% CI 1.61-7.34) groups for providers using hospital-run platforms, while shorter online visits were correlated with both during versus before (OR 8.16, 95% CI 1.39-68.3) and after versus before (OR 5.70, 95% CI 1.22-33.6) groups for providers using third-party platforms.

XSL•FO
RenderX

Conclusions: The frequency of telemedicine has increased since the COVID-19 pandemic exploded and is correlated with the time spent in online versus in-person visits. The correlation is different for providers using hospital-run and third party platforms. On a hospital-run platform, providers with longer online visits have a higher frequency of offering telemedicine, while on a third-party platform, providers with shorter online visits are more likely to offer telemedicine.

telemedicine; post–COVID-19; provider's perspective; length of online visit; COVID-19; pandemic; China; prevention; questionnaire; survey; healthcare provider

Introduction

The COVID-19 explosion has made significant changes to health care systems worldwide [1,2]. Telemedicine services, also referred to as virtual care in some studies, are defined in this paper as services that use digital technologies to provide health care at a distance and to connect doctors with each other. These services, mainly including online medical visits, virtual consultations, and remote monitoring and diagnosis, developed rapidly during the COVID-19 pandemic period [3-6]. As proved by former studies, telemedicine or virtual care has many advantages, such as decreased exposure risk to COVID-19 and other infectious diseases, ensuring the sustainability of medical services during quarantine; increased accessibility of medical services; lower costs for patients on both the money and time spent on the way to clinic; lower costs for medical institutes on patient flow management; relatively increased patient compliance, especially in chronic disease management; and early detection of subclinical changes [7-13]. Based on these advantages, telemedicine has been accepted, and both patients and providers are satisfied; it was even promoted by some policies as the pandemic proceeded [1,14-16].

Telemedicine in China developed early since the first remote consultation case in the mid-1980s, and the "Opinions on Promoting Telemedicine Services in Medical Institutions" policy issued in 2014 by the Chinese government accelerated its development [17.] In 2017, telemedicine platforms had been established in 22 of 34 provincial administrative regions in China that covered 13,000 medical institutions, which indicated that a telemedicine service system had been formed already [17,18]. When the COVID-19 pandemic exploded, this telemedicine system was rapidly put into practice. Virtual consultations were performed, live-stream platforms were used to offer health education to patients and the general public, virtual care bills were covered by the national health insurance, and medication-delivering systems were formed as the pandemic proceeded [2,19]. At some places, experts were gathered to offer preliminary screening for community residents with symptoms [20]. In Henan Province, the local telemedicine platform connected 147 COVID-19–designated hospitals, which offered prevention, diagnosis, and treatment of COVID-19 using modules such as real-time monitors, intractable case transfer, and remote guidance [21]. Implementation of telemedicine systems was on an unprecedented scale and pace.

In January 2023, the management of COVID-19 in China was changed from class A to class B, which means no longer isolating patients with COVID-19, no longer identifying close contacts, no longer designating high- and low-risk areas, and adjusting the testing strategy to voluntary testing. However, the pressure on the health care system rapidly increased in a short period after prevention measures were relaxed, which has led to different requirements for the application of telemedicine. Post–COVID-19, it is still uncertain how telemedicine would integrate in the health care system for a long time [22].

As a result, in this study, we aimed to compare the frequency of offering telemedicine services before the COVID-19, during the pandemic explosion, and after China reopened post–COVID-19 and to find out what kind of providers would like to offer more telemedicine services, even after pandemic prevention was relaxed.

Methods

Study Setting and Data Collection

The data for this study were taken from the 2023 Chinese National Survey of Telemedicine Development in Hospitals, conducted from September to October 2023, which used online questionnaires. The Telemedicine Informationization Professional Committee of China (TIPC) and the National Telemedicine Center of China (NTCC) were in charge of data collection for the survey.

A multistage sampling method was used to recruit respondents. Initially, 11 provinces were strategically selected from across eastern, central, and western regions for the survey, considering prior collaborative experiences. Subsequently, a TIPC member was designated to manage the survey operations in each province. They were tasked with overseeing hospital coordination and selection. Following receipt of consent from the chosen hospitals, a dedicated staff member was appointed in each facility by the TIPC members to handle the recruitment of participants, all of whom had undergone training by 3 experienced researchers from the NTCC. Ultimately, electronic questionnaires, accompanied by quick response (QR) codes and detailed instructions, were distributed to health care providers engaged in telemedicine services by the staff member in each hospital. Participation was voluntary, allowing participants to withdraw anytime. Data anonymity and confidentiality were guaranteed, and no monetary compensation was offered. Researchers from the NTCC periodically reviewed the data collected during the survey, offered prompt feedback, and carried out centralized data cleansing to ensure data integrity and effectiveness.

At the end of the survey, 996 questionnaires were received from all TIPC members. After excluding questionnaires with repeated

XSL•FO
RenderX

information, incomplete responses, inconsistency, and other problems (eg, some providers reported having worked in telemedicine longer than their overall working years), there were 831 (83.43%) valid questionnaires left. Data used in this study were from questionnaires filled by health care providers who had ever practiced telemedicine and has answered the question "How frequently did you offer telemedicine services before/during/after the COVID-19 pandemic explosion?" As a result, only 428 (51.5%) questionnaires were included.

The questionnaires included the following demographic items:

- Age, sex, professional title, education, and working experience, especially in offering telemedicine services recorded by year
- Hospital information, such as province, level of the hospital, and which department the provider was from
- The provider's feelings about validity and reliability (scoring from 1 to 10)
- Whether the provider engaged in telemedicine through a hospital self-operated platform or a platform run by a third party, which mainly refers to companies such as Chunyu Doctor
- The provider's feelings about whether the time spent in offering telemedicine services is longer or shorter or not different compared to in-person visits and other offline medical services
- The provider's feelings about how easy it is to acquire patients' tests and examine results during the telemedicine service procedure
- The provider's feelings about the frequency of offering telemedicine services before the COVID-19 pandemic outbreak, during the pandemic explosion and pandemic prevention, and after pandemic prevention control was relaxed

Professional titles included junior, intermediate, and senior. Education recorded doctor, master's, and bachelor's degrees, as well as education below the bachelor level. The province was then classified as the eastern, central, or western region of China. Hospital levels were categorized as tertiary or nontertiary. Departments of providers were sorted as clinic and nonclinic departments. How easy it was to acquire test results online and the frequency of telemedicine at 3 time points were scored on a 5-point Likert scale as "always," "often," "occasionally," "rarely," and "never."

Ethical Considerations

This study was conducted using an online survey method, collecting data that were limited to demographic information, such as age and gender, with no collection of sensitive or individually identifiable biological information. All procedures were approved by the Medical Ethics Committee (2020-KY-0379-002) of the First Affiliated Hospital of Zhengzhou University. Informed consent was obtained from all individual participants involved in the study. For secondary analyses of research data, we confirmed that the original informed consent or Institutional Review Board (IRB) approval included provisions allowing for secondary analysis without additional consent from the participants.

In this study, we prioritized the privacy and confidentiality of participants. The online survey was designed to collect only nonsensitive demographic information, such as age and gender, without any personal identifiers that could compromise the privacy of the respondents. All responses were collected anonymously, ensuring that no individual could be identified using the data.

Participants were not offered any form of compensation for their participation. No images of individual participants or users were included in the manuscript or multimedia appendices that would allow for identification.

Outcomes

The general frequency of offering telemedicine services was calculated at each time point, and the difference in the frequency between the 3 groups was considered the primary outcome of this study. As the frequency was an ordered categorical variable, it was reassigned a score of 1-5 at each time point. A change in the frequency of offering telemedicine services as the pandemic progressed was calculated, via subtraction, as the difference in the frequencies between the 3 time points for each participant, and the change was categorized as an increase or a decrease, depending on whether the result of the subtraction was >0 or <0. Thus, binary variables showing whether the frequency increased from before the pandemic outbreak to during its explosion, increased from during the explosion to after controls were relaxed, and from before the outbreak to after controls were relaxed were calculated as secondary outcomes of this study.

Statistical Analysis

Age was presented as the mean (SD). Other continuous variables were presented as the median (IQR) as their distribution was not symmetric. Categorical variables were described as counts and percentages. Chi-square tests were performed to compare differences in the frequency of offering telemedicine services between all groups. Single-variate and multiple regression analyses were used to explore correlations between the increase in frequency and other questionnaire responses. Stratified analysis was also performed in using the multiple regression model in different groups. A 2-sided *P* value of <05 was considered statistically significant in all analyses. Statistical analysis was performed using R version 4.3.1 (R Foundation for Statistical Computing). Figures demonstrating intergroup distributions and advantages and disadvantages were created in Microsoft Excel.

Results

Participant Details

A total of 428 health care providers (n=199, 46.5%, males and n=229, 53.5%, females) filled in the questionnaires and were included in this study. The general characteristics of participants and their responses to the questionnaires are summarized in Table 1. The participants' mean age was 38.6 (SD 8.51) years. Over half were bachelors (n=257, 60.05%), with a median of 12 (IQR 7-20) years of working experience and 4 (IQR 2-6) years working in telemedicine. The majority were from tertiary hospitals (n=229, 53.5%) and located in central (n=218, 50.93%)

XSL•FO
RenderX

and western (n=151, 35.28%) parts of China. Most providers were engaged in telemedicine through platforms operated by their own institutes (n=317, 74.07%), while the rest were engaged through third-party platforms usually operated by internet companies, such as Chunyu Doctor. Participants reported that test and examination results could be generally acquired (n=125, 29.21%, always; n=191, 44.63%, often) during the telemedicine procedure. Most participants believed that the reliability and validity of telemedicine are high, with a median score of 9 (IQR 8-10) and 9 (IQR 7.75-10), respectively, on a scale of 0-10. Regarding the complexity of the diagnosis procedure, 200 (46.73%) participants indicated online virtual visits are quicker than in-person outpatient visits, 99 (23.13%) participants reported the length of virtual medical service is even longer than an offline visit, and the rest reported that the time spent in the 2 methods is not different.

Outcomes

According to the providers' responses, the frequency of providing telemedicine services, including online visits, generally increased as the pandemic proceeded through the 3 stages: before, during, and after the COVID-19 explosion. As shown in Table 2, approximately 198 (46.26%) providers always or often offered telemedicine before the pandemic outbreak, 249 (58.17%) during the pandemic explosion, and 268 (62.62%) after the pandemic explosion. The differences between these groups, calculated using the chi-squared test, indicated that generally the frequency of providing telemedicine services increased since the pandemic exploded and stayed at similar levels after the explosion (Table 3).

Table 2. Frequency of offering telemedicine before, during, and after the COVID-19 pandemic.

Grade	Before the pandemic outbreak, n (%)	During the pandemic explosion, n (%)	After prevention measures were relaxed, n (%)
Never	29 (6.78)	11 (2.57)	9 (2.10)
Rarely	76 (17.76)	60 (14.02)	46 (10.75)
Occasionally	125 (29.21)	108 (25.23)	105 (24.53)
Often	159 (37.15)	196 (45.79)	214 (50.00)
Always	39 (9.11)	53 (12.38)	54 (12.62)

Table 3. Chi-square test results of differences between the frequencies of offering telemedicine.

Comparison between groups	χ^2 (*df*)	*P* value
Before vs during the pandemic	17.21 (4)	.002[a]
During vs after the pandemic	2.89 (4)	.57
Before vs after the pandemic	30.17 (4)	<.001[a]

[a]*P*<.05.

Regression models were performed in single and multiple variate analyses, and whether offering telemedicine services increased during the pandemic explosion versus before the pandemic outbreak, after the pandemic explosion versus during the explosion, and after the pandemic explosion versus before the pandemic outbreak was considered a dependent variable. As demonstrated in Table 4, age, working experience, telemedicine working experience, and providers' report of the validity of telemedicine were positively correlated or negatively correlated with an increase in the frequency of offering telemedicine services as the pandemic explosion proceeded, with significant correlation but a coeffective value close to 1. The providers' professional titles were significantly correlated with the frequency increase in the single-variate model: they had an increased frequency compared to those with junior titles. Participants from western regions compared to central regions and from nontertiary hospitals compared to tertiary hospitals were less likely to increase telemedicine services as the pandemic exploded. Compared to participants who felt the time spent between online and in-person visits was not different, those who felt online services take longer (during vs before: odds ratio [OR] 4.27, 95% CI 2.30-8.15; after vs before: OR 3.22, 95% CI 1.79-5.92) or shorter (during vs before: OR 2.09, 95% CI 1.19-3.80; after vs before: OR 2.15, 95% CI 1.28-3.72) increased telemedicine services.

[a]OR: odds ratio.

[b]*P*<.05.

In the multivariate analysis, age, professional title, education, years working in telemedicine, region, type of hospital, platform provider engaged in telemedicine, time spent in online versus in-person service, and validity of telemedicine were included as independent variables in regression models. According to variance inflation factor test results shown in Table S1 in Multimedia Appendix 1, working years (during vs before: 10.85; after vs during: 9.99; after vs before: 10.86) and reliability of telemedicine (during vs before: 6.9; after vs during: 6.72; after vs before: 6.85) were not adjusted in the multivariate regression model. As shown in Table 5, providers with senior professional titles compared to junior titles, who were engaged in telemedicine through third party–operated platforms compared to hospital-run platforms, and who felt online visits are shorter

XSL•FO
RenderX

or longer than in-person visits had significant coeffective values. In Tables S2 and S3 in Multimedia Appendix 2, single and multiple regression models involving frequency increases after versus during the pandemic explosion are reported, and no significant correlations were found.

Table 5. Multivariate analysis of telemedicine service frequency increase during versus before the COVID-19 pandemic and after versus before the pandemic.

Characteristics	During vs before the pandemic		After vs before the pandemic

Shorter online visits	2.04 (1.11-3.87)	.02[b]	2.27 (1.31-4.07)	.004[b]
Validity of telemedicine	0.96 (0.83-1.12)	.60	1 (0.86-1.16)	.90

[a]OR: odds ratio.

[b]*P*<.05.

Stratified analysis was performed. The distribution of the online service length between 2 types of platforms (Table S4 in Multimedia Appendix 3) showed that over half of the providers on self-operated platforms (160/317, 50.47%) felt online visits are shorter, while on third party–operated platforms, only 40 (36.04%) of 111 providers felt online visits are shorter. The difference in distribution between the 2 types of platforms was significant. Thus, the correlation of whether online service takes longer and the frequency increase in telemedicine might be different between the 2 types of platforms. As a result, providers were grouped by whether they chose to offer telemedicine on platforms operated by their own hospitals or on third party platforms.

As demonstrated in Table 6, multiple regression analysis was applied, and the variables age, professional title, education, years working in telemedicine, region of hospital, type of hospital, and validity of telemedicine reported by providers were adjusted as covariables in the regression model in each group. In the self-operated platform group, compared to providers who felt the time spent in online and in-person visits is not different, those who felt online visits are longer were significantly more likely to increase offering telemedicine services when COVID-19 exploded (OR 3.84, 95% CI 1.73-8.83) and when pandemic prevention controls were relaxed (OR 3.40, 95% CI 1.61-7.34) compared to before the pandemic. The differences in the telemedicine offer frequency increase for providers who felt online service time is shorter than in-person visits were not significant. In the third party–operated platform group, the increase in telemedicine offer frequency was significant among providers who felt online visits are shorter than in-person visits both when the pandemic exploded (OR 8.16, 95% CI 1.39-68.3) and when prevention measures were relaxed (OR 5.70, 95% CI 1.22-33.6) compared to before the pandemic, while the differences for providers who felt online visits are longer were not significant.

Discussion

Principal Findings

Based on a national survey of telemedicine providers, this study explored the change in the frequency of offering telemedicine services at the time before COVID-19 exploded, during the pandemic explosion, and after prevention measures were relaxed; analyzed the correlation between other factors and the frequency change; and located health care providers who would like to offer more telemedicine services in China even after the pandemic is over.

In general, our study found that the frequency of health care providers offering telemedicine increased both during the pandemic and after prevention measures were relaxed compared to before the pandemic. Specifically, we found that providers' feelings about the online service length compared to in-person visits were correlated with the telemedicine offer frequency increase as the pandemic proceeded. Among providers offering telemedicine through platforms run by their own hospitals, those who felt online visits take longer were more likely to increase offering telemedicine. Among providers engaged through third-party platforms, those who felt online visits are shorter were more likely to increase offering telemedicine.

Comparison With Prior Work

Studies worldwide have already proved that telemedicine technologies were helpful tools during the COVID-19 explosion and were generally welcomed after the pandemic was over [1,3,9,23,24]. Considering the condition changed in China, it was significant that the telemedicine offer frequency was still high after pandemic controls were relaxed [22].

In our study, the difference in the telemedicine frequency change was not significant between different types of hospitals but was significant between the 2 types of platforms. As Chinese telemedicine-promoting policies started early, there were various ways of offering telemedicine services at the time the pandemic exploded [17]. In May 2019, there were 158 telemedicine platforms known as "internet hospitals" operated by local public hospitals around the nation and video-based platforms, such as the Huawei telepresence conference system [18]. Private companies, such as Chunyu Doctor (founded in 2011) and Ping An Health (founded in 2015), established and began operating their teleconsulting and diagnosis platforms even earlier. Some physicians said they would still contact patients through phone calls, text messages, or instant messaging software, such as WeChat, but a few responded that they would offer telemedicine services or only consultations through these ways. As a result, common tools, such as WhatsApp, telephone, or email, were not included as a way of offering telemedicine in this study. The difference in frequency between the 2 kinds of platforms was not the same as the platforms or tools used in former studies [25,26].

The 2 types of platforms in this study included providers engaging in telemedicine publicly or privately. As all our participants were from public hospitals, the self-operated platforms were similar to those run by public hospitals. However, the third-party platforms were mainly run by private companies. Former studies on cognition and telemedicine services between public and private providers are not consistent. Galle et al [27] and Cordioli et al [28] suggested that providers in the private sector or private clinics have a higher frequency of offering telemedicine services. Scheffer et al [29] claimed physicians working in both public and private sectors are the most frequent users. Elhadi et al [30] indicated there are no differences in attitude, cognition, knowledge, or skills in providers between work in public hospitals, private hospitals, or both. Mazouri-Karker et al [31] reported that differences

XSL•FO
RenderX

between public and private providers are only their preference in tools. In our results, public providers reported that a higher frequency increase after pandemic controls were relaxed might be because public hospitals, especially tertiary public hospitals in China, usually have a better reputation, whereas private third-party telemedicine platforms or physicians who work a "part-time job" on these platforms can hardly acquire patient trust.

We also found that some providers feel that online visits take longer, others believe that online visits are shorter, while still others feel that they take the same time as in-person visits. This is consistent with Ly's [32] results that some physicians report telemedicine increases their efficiency and lowers the workload, while other physicians report telemedicine takes more time and increases their workload because of having to learn new techniques and because communication on-screen is difficult. Although some researchers believe that one of the advantages of adopting telemedicine during COVID-19 was that it could save time and increase efficiency, it actually saved patients' traffic-related costs on both time and money and increased efficiency by reducing unnecessary visits through pretriage online [24,30,33]; however, we are still uncertain about whether adopting telemedicine could have saved the providers' time. Naamani et al [34] suggested that telemedicine could save providers' time because of pretriage online. Shaarani et al [26] proved that the average time spent in in-person visits reported by former studies is longer than 15 minutes, while providers in their survey reported a shorter average online visit time. Silver et al [35] found out that providers who spent an average visiting time longer than 14 minutes would prefer offering visits in person instead of virtually. Ramsey et al [36] indicated that providers would have to spend more time on documentation, which made the procedure more complicated and online visits took longer.

Providers in our study who reported that online visits are shorter than in-person visits have a good reason to increase the frequency of offering telemedicine services as these have higher efficiency. Providers who reported that online visits are longer than in-person visits, compared to those who believed there is no difference between the 2 service types, would also like to increase the telemedicine usage frequency. This might be because telemedicine has other advantages as well, such as saving patients' costs, even though it would increase the time spent by providers. As Ramsey et al [36] suggested, the other benefits for clinicians, patients, and quality of care could motivate health care professionals to offer more telemedicine services. In addition, in China, the average outpatient visiting time is much shorter, especially in tertiary hospitals [37]. This indicates that even though online visits take longer, they might still be shorter than average in-person visits in other countries. Providers who feel online visits take more time are not against offering telemedicine according to Silver et al [35], as also shown by our results of stratified analysis. Providers offering telemedicine services through their own hospitals' platforms might be more responsible and attach importance to their reputation. However, providers using third-party platforms might pay more attention to efficiency. As a result, on self-operated platforms, the increase in the telemedicine offer frequency by providers who felt online visits take longer was significant, while on third-party platforms, the increase in the telemedicine offer frequency by providers who felt online visits are shorter was significant.

Limitations

Our study showed that the length of online visits is correlated with the frequency change in offering telemedicine by providers, and the frequency increased for both longer and shorter online visits. However, our questionnaire was not designed to acquire the average number of minutes the providers spent in online and in-person visits. Further studies could focus on this to obtain a more detailed and convincing result. The results from this study were all from a cross-sectional survey, though it was nationwide. Thus, the frequencies of offering telemedicine at the 3 time points and the frequency change data were all obtained from providers' self-reports, which may have led to self-report and selection bias. It would be more accurate after regional online prescription–examining platforms in China are established and we can acquire data on them.

Moreover, some questions in this study were rather subjective. As the questionnaire used a 5-point Likert scale, questions regarding the frequency of offering telemedicine was set with 5 levels from "never" to "always," without specifying the exact time or duration for each level. "What platform do you mainly use to offer telemedicine services?" was set as a single-choice question, which was less suitable for more complicated situations, such as providers using both types of platforms.

Conclusion

The frequency of telemedicine services offered by health care providers has increased since the COVID-19 pandemic exploded and was still high after pandemic prevention controls were relaxed in China. Differences in providers' professional titles, types of platforms, and length of online visits compared to in-person visits are correlated with the increase in frequency. In using hospital-run platforms, providers with longer online visits are more likely to offer telemedicine services, while on third-party platforms, providers with shorter online visits would like to increase telemedicine services.

Acknowledgments

This research was supported by the National Key Research and Development Program of China (grant 2022ZD0160704), the Science and Technology Research Program in Henan Province (grant 242102311021), and the Joint Co-construction Program of Medical Science and Technology of Henan Province (grants LHGJ20220433 and LHGJ20230178). authors and do not necessarily reflect the position of the funding bodies. No artificial intelligence was used in any part of the paper.

Data Availability

The datasets generated and analyzed during this study are not publicly available because they are questionnaire data obtained from a nationwide survey initiated by the Telemedicine Informationization Professional Committee of China, but they are available from the corresponding author upon reasonable request.

Authors' Contributions

JZ, WW, and YC made substantial contributions to the design of this work. WW and YC designed, led, and initiated the survey; conducted data analysis; and drafted the initial paper. FC and XS played an important role in data preprocessing. XZ and DS were involved in the discussion of the paper structure and results. JS reviewed and revised the paper. All authors contributed to writing and revising the manuscript and have approved the final version of the manuscript, as submitted.

Abstract

Background: Telemedicine is an important way to fill in the access gap to in-person health care services during challenging times like pandemics.

Objective: This study aimed to investigate the role that telemedicine played during the COVID-19 pandemic by multicountry comparison of the use of telemedicine prior to and during the pandemic.

Methods: This study analyzes data from the second wave of the International Sexual Health and Reproductive Health study. This included data collected between April 2021 and July 2022 in 8 countries, including Armenia (n=296), Egypt (n=889), Germany (n=138), Moldova (n=311), Nigeria (n=205), Portugal (n=951), Singapore (n=13), and Spain (n=54). This study covered sociodemographics, sexual and reproductive health (SRH), and telemedicine use. Descriptive statistics and multilevel modeling were used to assess the factors influencing the use of telemedicine.

Results: Overall, 2857 participants were recruited. Approximately 57.6% (n=1646) of participants had never used telemedicine prior to COVID-19 measures, while 45.9% (n=1311) of participants required health care but reported not using telemedicine services following the introduction of COVID-19 measures. In high-income countries, the most common mode reported was audio-based telemedicine services, with 283 (71.8%) and 417 (73.5%) participants doing so before and during COVID-19, respectively. This was followed by text-based telemedicine services, with 152 (38.6%) and 173 (30.5%) participants doing so before and during COVID-19, respectively. In low- to middle-income countries, many participants also reported using audio-based

XSL•FO
RenderX

telemedicine services, with 288 (35.3%) and 237 (40.8%) participants doing so before and during COVID-19, respectively. This was followed by chat-based telemedicine services, with 265 (32.4%) and 217 (37.3%) participants doing so before and during COVID-19, respectively. Multilevel modeling revealed that those who were older (adjusted odds ratio [aOR] 0.99, 95% CI 0.99-1.00) and were in countries with a higher gross domestic product per capita (aOR 0.99, 95% CI 0.98-1.00) were less likely to have ever used telemedicine. Participants who were of male sex assigned at birth (aOR 0.79, 95% CI 0.65-0.96) were less likely to use telemedicine during the pandemic. Participants who perceived that they were worse off financially were more likely to have switched to telemedicine during COVID-19 (aOR 1.39, 95% CI 1.02-1.89) and were more likely to report having a poor or fair experience of telemedicine services (aOR 1.75, 95% CI 1.34-2.29). When sexual orientation was included in the model, nonheterosexual individuals were more likely to ever use telemedicine prior to COVID-19 (aOR 1.35, 95% CI 1.08-1.69), more likely to have used telemedicine during COVID-19 (aOR 1.58, 95% CI 1.24-2.02), and more likely to have switched to telemedicine during COVID-19 (aOR 1.55, 95% CI 1.09-2.21).

Conclusions: Telemedicine played a key role in addressing health care needs during the COVID-19 pandemic. Age, sex, economic status, and sexual orientation influenced its use.

(J Med Internet Res 2025;27:e60369) doi:10.2196/60369

KEYWORDS

COVID-19; telemedicine; sexual and reproductive health; pandemic; web-based survey; sexual health; reproductive health; communication technology; medical education; contraception; abortion; health care delivery; care; chronic condition

Introduction

The World Health Organization defines telemedicine as "healing at a distance," enabling the use of information and communication technology tools to improve the quality of medical services while overcoming the obstacles posed by travel [1]. It has also been described as "a branch of e-health that uses communication networks for the delivery of healthcare services and medical education from one geographic location to another" [2]. Telemedicine plays an important role in enhancing or substituting access to health care services, particularly during challenging circumstances like a pandemic or in hard-to-reach areas [3]. Moreover, telemedicine technologies have the potential to address unmet sexual and reproductive health (SRH) needs and improve SRH services. This is especially important as the World Health Organization estimates that everyone of reproductive age would not have access to at least 1 essential reproductive health intervention over the course of their lives [4].

The role of telemedicine in health care has grown rapidly and concomitantly with the expansion of communication technology. The significance of telemedicine was especially underscored during COVID-19 infection control measures and lockdowns. During this time, telemedicine provided the general public with a convenient and secure method to seek guidance from health care professionals regarding COVID-19 symptoms, preventive and treatment measures, psychological concerns, and various other matters [5]. It is estimated that about 116 million people had access to digital doctor consultations worldwide in 2024 compared to 57 million in 2019 [6]. During the pandemic, telemedicine was also recommended to be used for contraception counseling, shared decision-making, and managing potential side effects [7]. It was also used as a means of accessing abortion-related services during the pandemic [8]. Country-specific studies demonstrate that telemedicine was successfully implemented to provide SRH services during the pandemic, and it was a convenient and comfortable approach, especially for young people [9,10].

Telemedicine helped fill several health care service gaps that emerged during the pandemic, especially in the context of SRH [11]. First, telemedicine allowed patients to consult with health care providers remotely, reducing the need for in-person visits to health care facilities [12]. This was particularly important during the pandemic when minimizing physical contact was essential to curb the spread of the virus. Second, telemedicine platforms were used for COVID-19 screening and triage [5]. Patients could use digital visits to discuss symptoms with health care professionals, who could then determine the appropriate course of action, whether it be self-isolation, testing, or in-person care. Third, many routine and nonemergency health care services were disrupted due to lockdowns and restrictions [13,14]. Telemedicine provided a way for patients to continue receiving medical care for chronic conditions, follow-up appointments, medication management, and health services without needing to visit a health care facility. Fourth, the pandemic had a significant impact on mental health, and telemedicine became a valuable tool for delivering mental health services [15]. Digital counseling and therapy sessions allowed individuals to access support from the safety of their homes.

In the past 2021-2022 period, many countries have relaxed COVID-19 restrictions. This provided a unique opportunity to understand how social and behavioral factors related to decreasing COVID-19 restrictions may have influenced sexual behaviors in diverse settings, including the use of telemedicine. The second International Sexual Health and Reproductive Health (I-SHARE)-2 study examined the 2021-2022 period and focused on similar sexual or reproductive health data from I-SHARE-1, over and above the addition of telemedicine-related variables. The aim of this study is to describe the use of telemedicine before and during the COVID-19 pandemic in 8 countries. The data for this study are a part of the cross-sectional multicountry project called "International Sexual Health and Reproductive Health during COVID-19" [16]. The I-SHARE project brought together SRH researchers from different countries to conduct a web-based survey using a standardized instrument. The main aim of this multinational study was to gain insights into SRH

XSL•FO
RenderX

before and during the initial phase of the COVID-19 pandemic in each country.

The I-SHARE, multicountry, web-based, cross-sectional study was developed to assess SRH during and after COVID-19 restrictions. The initial multicountry study examined the 2020-2021 period and compared SRH in the pre–COVID-19 and COVID-19 periods [17,18]. In this study, we found that the pandemic hindered access to SRH care. However, telemedicine-related variables were not measured in the initial study. This study aimed to understand the prevalence of general telemedicine use and correlates of its use during the COVID-19 period as well as prior to COVID-19.

Methods

Study Design and Participants

This study analyzes data from the I-SHARE study. The consortium was developed to better understand SRH during the COVID-19 pandemic. The initial round of data collection (named the "I-SHARE survey") covered the period from July 20, 2020, to February 15, 2021. This I-SHARE-2 survey included data collected between April 2021 and July 2022 in 8 countries, including Armenia (n=296), Egypt (n=889), Germany (n=138), Moldova (n=311), Nigeria (n=205), Portugal (n=951), Singapore (n=13), and Spain (n=54).

Each country included details of SRH resources at the end of the survey. The in-country team translated the survey into local languages, field-tested the survey instrument, and submitted the protocol to a local institutional review committee for review. Field testing included giving the survey to at least 10 individuals who provided feedback about translation and sensitive topics. Some countries organized a second round of field testing using the web-based version of the survey questionnaire. All countries recruited participants on the web and through the help of community organizations. More details of the methods of the initial I-SHARE survey are described in the survey protocol [19]. The survey took approximately 15-20 minutes to complete. Open Data Kit software (version 1.16; Get ODK Inc) was used to collect data from participants on a cell phone, laptop, or other electronic device.

Eligibility criteria for participation included being at least 18 years of age, residing in the country where the survey was conducted, and being able to provide web-based informed consent. Researchers from each country were invited to join working groups focused on analyzing multicountry data. Survey data were included if they had received institutional review board approval and field-tested the survey. The survey questionnaire included domains on sociodemographic characteristics, sexual relationships, compliance with COVID-19 restrictions (eg, social distancing), web-based harassment through digital media, intimate partner violence, and HIV or sexually transmitted disease testing. The complete survey instrument is included in Table S1 in Multimedia Appendix 1.

Measures

Telemedicine use was measured through a series of questions regarding its (1) use prior to the introduction of COVID-19 measures (never, rarely, sometimes, often, and always), (2) use following the introduction of COVID-19 measures (yes, no, and did not need to access health care), (3) the various types of telemedicine modalities used (audio, video, text, chat, or other forms), as well as (4) participants' satisfaction with telemedicine services during COVID-19 (excellent, good, fair, and poor). While this was a survey that focused on SRH, our questions on telemedicine use were not limited to just SRH services, and we were not able to measure the use of telemedicine in the context of specific types of services. We constructed a new variable for participants who never used telemedicine prior to the introduction of COVID-19 measures but needed health care and switched to the use of telemedicine following the introduction of COVID-19 measures (switched to telemedicine).

Individual-level variables included sociodemographic characteristics such as sex assigned at birth, age (in years), sexual orientation, place of residence, educational attainment, employment status, partner living arrangement, perceived changes to one's economic situation as a result of COVID-19, and having children at home. Country-level variables included gross domestic product (GDP) per capita.

Data Analysis

Sociodemographic characteristics as well as frequencies and proportions around the use of telemedicine were summarized using descriptive statistics. Subsequently, we proceeded to conduct multilevel modeling (using Stata, version 16; StataCorp LLC), which included country-level variables. These multilevel models were constructed to assess the odds of ever using telemedicine, of using telemedicine during COVID-19 if health care services were needed, of switching to telemedicine during COVID-19, as well as having fair or poor experiences of telemedicine during COVID-19. We omitted sexual orientation from the main models, as participants in several countries largely omitted responding to this question but provided supplemental analyses including sexual orientation as a variable. Statistical significance was set at $P<.05$.

Ethical Considerations

Each country's ethical review committee approved the respective national web-based study prior to launch. We obtained approval from Ghent University (approval BC-07988) and the University of North Carolina at Chapel Hill (approval 295989) for multicountry analyses based on deidentified data, which allowed for secondary analyses without additional consent. A single data-sharing agreement covered multicountry analyses. In-country leads made final decisions about data sharing and data management practices. Survey participants were required to provide informed consent prior to the survey and were allowed to stop at any point and leave any item blank. We did not collect any personal identifiers and therefore all responses were anonymous. In-country leads also made decisions on the forms of remuneration provided to participants that were appropriate for the respective countries and approved by the local ethics board.

Results

A total of 2857 participants were recruited in the 8 countries of our sample. Most participants identified as cisgender female

XSL•FO
RenderX

(n=1757, 61.5%), were heterosexual or straight (n=1313, 70.8%), reported living in the city (n=1392, 49.7%), had completed college (n=1421, 51%), were formally employed (n=1663, 58.2%), were not partnered or not living with their partners (n=1714, 60%), perceived that the economic situation of their household had remained the same (n=1400, 50.6%), and did not have children (n=1538, 60.1%). The average age of participants was 37.4 (SD 16.0) years, and the average GDP per capita at the country level was US $13,900 (SD US $13,600). Table 1 demonstrates the sociodemographic attributes of the study sample.

We have found that approximately 57.6% (n=1646) of participants had never used telemedicine before the introduction of COVID-19 measures, while 45.9% (n=1311) of participants required health care but reported not using telemedicine services following the introduction of COVID-19 measures. A total of 370 (26.3%) participants who never used telemedicine services prior to the introduction of COVID-19 measures, and required health care services during the pandemic, switched to using telemedicine during the pandemic. A total of 482 participants (33.3%) reported a fair or poor experience with using telemedicine services during COVID-19. Table 2 summarizes the frequencies and proportions for variables regarding telemedicine use before and following the implementation of COVID-19 measures as well as for participants who switched or did not switch to telemedicine use during COVID-19.

Table 2. Use of telemedicine among International Sexual Health and Reproductive Health-2 study participants in 8 countries, April 2021 to July 2022 (N=2857).

Table 3 provides a summary of the proportions of participants by country who reported ever using telemedicine services before COVID-19 as well as telemedicine use following the introduction of COVID-19 measures (excluding participants who did not require health care services during this time). In high-income countries, a majority of participants reported using audio-based telemedicine services, with 283 (71.8%) and 417 (73.5%) participants doing so before and during COVID-19, respectively. This was followed by text-based telemedicine services, with 152 (38.6%) and 173 (30.5%) participants doing so before and during COVID-19, respectively. In low- to middle-income countries, many participants also reported using audio-based telemedicine services, with 288 (35.3%) and 237 (40.8%) participants doing so before and during COVID-19, respectively. This was followed by chat-based telemedicine services, with 265 (32.4%) and 217 (37.3%) participants doing so before and during COVID-19, respectively, as well as text-based telemedicine services, with 265 (32.4%) and 217

XSL•FO
RenderX

(37.3%) participants doing so before and during COVID-19, respectively. Table 4 summarizes the frequencies and proportions of participants who reported using either audio, video, text, chat, or other forms of telemedicine modalities during COVID-19. Country-level data may be found in Figures S1 and S2 in Multimedia Appendix 1.

Table 3. Telemedicine use before and during COVID-19 measures by country among International Sexual Health and Reproductive Health-2 study participants in 8 countries, April 2021 to July 2022 (N=2857).

Country and time frame	Used telemedicine, n (%)	Did not use telemedicine, n (%)
Armenia		
Before COVID-19 (n=296)	168 (56.8)	128 (43.2)
During COVID-19 (n=251)	133 (53)	118 (47)

Before COVID-19 (n=889)	431 (48.5)	458 (51.5)
During COVID-19 (n=723)	261 (36.1)	462 (63.9)
Germany		
Before COVID-19 (n=138)	48 (34.8)	90 (65.2)
During COVID-19 (n=117)	40 (34.2)	77 (65.8)
Moldova		
Before COVID-19 (n=311)	136 (43.7)	175 (56.3)
During COVID-19 (n=280)	127 (45.4)	153 (54.6)
Nigeria		
Before COVID-19 (n=205)	82 (40)	123 (60)
During COVID-19 (n=173)	60 (34.7)	113 (65.3)
Portugal		
Before COVID-19 (n=951)	325 (34.2)	626 (65.8)
During COVID-19 (n=853)	485 (56.9)	368 (43.1)
Singapore		
Before COVID-19 (n=13)	3 (23.1)	10 (76.9)
During COVID-19 (n=12)	5 (41.7)	7 (58.3)
Spain		
Before COVID-19 (n=54)	18 (33.3)	36 (66.7)
During COVID-19 (n=50)	37 (74)	13 (26)

Table 4. Telemedicine modalities used before and during COVID-19 measures by country income groupings among International Sexual Health and Reproductive Health-2 study participants in 8 countries, April 2021 to July 2022 (N=2857).

Types of telemedicine modalities used	High-income countries[a]		Low- to middle-income countries[b]		All countries[c]	
	Before COVID-19, n (%)	During COVID-19, n (%)	Before COVID-19, n (%)	During COVID-19, n (%)	Before COVID-19, n (%)	During COVID-19, n (%)
Audio	283 (71.8)	417 (73.5)	288 (35.3)	237 (40.8)	571 (47.2)	654 (57)
Video	36 (9.1)	116 (20.5)	113 (13.8)	81 (13.9)	149 (12.3)	197 (17.2)
Text	152 (38.6)	173 (30.5)	259 (31.7)	211 (36.3)	411 (33.9)	384 (33.4)
Chat	44 (11.2)	50 (8.8)	265 (32.4)	217 (37.3)	309 (25.5)	267 (23.3)
Other	68 (17.3)	84 (14.8)	58 (7.1)	36 (6.2)	126 (10.4)	120 (10.5)

[a]A total of 394 participants used telemedicine before COVID-19, and 567 participants used telemedicine during COVID-19. Countries included Germany, Portugal, Singapore, and Spain.

[b]A total of 817 participants used telemedicine before COVID-19, and 581 participants used telemedicine during COVID-19. Countries included Armenia, Egypt, Moldova, and Nigeria.

[c]A total of 1211 participants used telemedicine before COVID-19, and 1148 participants used telemedicine during COVID-19.

XSL•FO
RenderX

In Table 5, we have summarized the binomial logistic multilevel model assessing the odds of ever using telemedicine, of using telemedicine during COVID-19 if health care services were needed, of switching to telemedicine during COVID-19, as well as having fair or poor experiences of telemedicine during COVID-19. First, for individuals who ever used telemedicine prior to COVID-19, those who were older (adjusted odds ratio [aOR] 0.99, 95% CI 0.99-1.00) and were in countries with a higher GDP per capita (aOR 0.99, 95% CI 0.98-1.00) were less likely to have ever done so. Second, for telemedicine use during COVID-19, those who were of male sex assigned at birth (aOR 0.79, 95% CI 0.65-0.96) were less likely to use telemedicine.

XSL•FO

[a]aOR: adjusted odds ratio.

[b]*P*<.05.

[c]Values in italics format indicate findings where *P*<.05 (statistical significance).

[d]Not available.

[e]*P*<.001.

[f]*P*<.01.

[g]Please note that sexual orientation was not measured systematically in several countries and therefore was not included as a variable in the main analysis. However, it was an important factor; therefore, we have chosen to display the role of sexual orientation in telemedicine use, adjusted for all of the above variables in a separate model.

[h]Telemedicine use before COVID-19: n=1657, telemedicine use during COVID-19: n=1467, switched to telemedicine during COVID-19: n=881, and poor experience with telemedicine during COVID-19: n=870.

Third, for those who never used telemedicine prior to COVID-19 but switched to using telemedicine during COVID-19, participants who perceived that they were worse off financially were more likely to have switched to telemedicine during

XSL•FO
RenderX

COVID-19 (aOR 1.39, 95% CI 1.02-1.89). For those who reported a fair or poor experience of telemedicine, participants who perceived that they were worse off financially were more likely to report doing so (aOR 1.75, 95% CI 1.34-2.29). When sexual orientation was included in the model, we noted that nonheterosexual individuals were more likely to ever use telemedicine prior to COVID-19 (aOR 1.35, 95% CI 1.08-1.69), more likely to have used telemedicine during COVID-19 (aOR 1.58, 95% CI 1.24-2.02), and more likely to have switched to telemedicine during COVID-19 (aOR 1.55, 95% CI 1.09-2.21).

Discussion

Principal Findings

This study explored the use of telemedicine during COVID-19 through an analysis of the I-SHARE-2 study that took place amid the lifting of COVID-19 restrictions. Slightly over half the participants we surveyed had never used telemedicine prior to the COVID-19 pandemic. However, this proportion increased during the pandemic, with about a quarter of those who never used telemedicine before switching to the use of telemedicine. About a third of participants reported a fair or poor telemedicine experience during this time period. This study extends the literature through an analysis of multiple countries and provides insight into the use of different telemedicine modalities and the factors associated with them during the COVID-19 pandemic. In this section, we discuss these findings considering the available evidence and suggest implications of our data for policy and future research.

Comparison to Prior Work

Our study found that about less than half of the participants had ever used telemedicine services prior to the COVID-19 pandemic. This is lower than estimates published by Ipsos in 2018, which estimated that globally, only 10% of individuals ever reported using telemedicine. Nevertheless, such estimates vary widely across contexts, with Saudi Arabia (31%), India (27%), China (24%), Malaysia (15%), and the United States (15%) being the highest adopters in 2018 [20].

Furthermore, we found that those who were older were less likely to have used telemedicine prior to the pandemic. The finding on the association between older age and lower use of telemedicine has been supported in past studies around the world due to barriers that older patients face in terms of accessing these technological platforms [21-23]. It is worth noting that we did not find an association between age and switching to the use of telemedicine during the pandemic. The findings on this association are mixed. Some contexts find no difference in age and use rates for telemedicine [23]. However, this contrasts with other studies, which found that older adults were less likely to take up telemedicine services compared to younger people during the pandemic [24-26]. Nevertheless, the negative correlation between increasing age and low telemedicine use is not universal and may differ across country settings, disease areas, and types of telemedicine platforms (eg, video, audio, or text-based) [27]. Further nuanced research on different older adult populations, as well as modes of using telehealth, is warranted.

Our study also indicated that individuals who identified as sexual minorities were more likely to have ever used telemedicine services. They were also more likely to have used telemedicine services during the pandemic. These results are unsurprising, given that traditional facility-based health services have often been associated with stigma and suboptimal care for sexual minorities [19,28] and that digital health interventions targeted at sexual minorities have been expanding across most settings [29]. There has also been evidence to show that services for sexual minorities had successfully pivoted to provide telehealth services during the pandemic, thus offering targeted interventions for this population that might have increased their access to telemedicine services.

The adoption of telemedicine during the pandemic, among individuals who previously never used telemedicine, was also influenced by economic circumstances. Our results indicated that those who perceived themselves as financially worse off during the pandemic were more likely to switch into digital care but at the same time also report fair or poor telemedicine experiences. This substantial proportion of individuals reporting fair or poor experiences with telemedicine use is noteworthy, given that a systematic review on telemedicine use in low- to middle-income countries found high patient satisfaction with such services [30]. Another systematic review found high satisfaction across multiple medical disciplines [31]. Ultimately, our data may reflect how some individuals who may have competing financial demands may not have been able to leverage technology effectively to enjoy telemedicine services compared to others who were more financially stable or better off during the pandemic.

Audio-based telemedicine services were the most used platform across both high- and low-income countries in our sample. We noted that more participants in high-income countries switched to the use of video-based telemedicine services (before: n=36, 9.1% and during: n=116, 20.5%) compared to those in low-income countries (before: n=113, 13.8% and after: n=81, 13.9%). We also note that chat-based services were the second most popular platform for the use of telemedicine services in low-income countries in our sample. These findings may reflect disparities in technological and telecommunication infrastructures between high- and low-income settings, which may shape access to telemedicine. Studies have found that chat-based platforms may be preferred over video-based platforms in low- to middle-income countries due to the reduced need for data bandwidth and stability of communications [30].

We are mindful of several limitations of this study. This study relies on self-reported data, which may be subject to recall bias and social desirability bias. Participants might not accurately remember their use of telemedicine or may report what they perceive as socially acceptable answers. There is also the possibility of nonresponse bias of those individuals who did not participate in the survey and might have different experiences or views about telemedicine compared to those who participated. Moreover, the survey was conducted on the web, which might result in a selection bias where respondents who are more technology-savvy or have better access to digital devices or internet services were recruited. Such participants may already have better experiences of telemedicine given their technological

XSL•FO
RenderX

savvy. The cross-sectional design also constitutes a limitation to establish causality. Additionally, the study methodology is basically quantitative, which may not capture the nuanced experiences, perceptions, and challenges faced by users of telemedicine. As only 8 countries have been included, the findings may not be generalizable to all populations and may not represent the global diversity in health care systems, technological infrastructure, and cultural attitudes toward telemedicine. Moreover, the study groups various forms of telemedicine (audio, video, text, and chat) into a single category. The experiences and effectiveness of these different modalities can vary greatly, and lumping them together might oversimplify the analysis.

Conclusions

Most of the participants had never used telemedicine before the pandemic, and a significant proportion did not use it either following the introduction of COVID-19 measurements. Only a quarter of the participants who never used it before switched into it during the pandemic. However, about one-third of the participants reported fair or poor experiences using it during COVID-19. Telemedicine has emerged as a critical tool for expanding access to health care services, particularly in the field of SRH. The COVID-19 pandemic has accelerated its adoption, highlighting the importance of telemedicine during crises, emergencies, or natural disasters. Understanding all the factors that influence the implementation of digital consultations, barriers and facilitators could help not only health care professionals but also policy makers and stakeholders to tailor strategies that improve its accessibility and effectiveness in delivering proper care. Finally, the adoption and implementation of telemedicine may be cost-saving but might also incur costs that vary greatly across different countries and contexts due to diverse health system configurations and digital and telecommunication infrastructures [32]. Future work should therefore consider how telemedicine services can be used to deliver care to people in a cost-effective manner, especially across high-income and low- to middle-income settings.

Acknowledgments

The authors acknowledge the research teams in Armenia, Egypt, Germany, Moldova, Nigeria, Portugal, Singapore, and Spain who contributed data to International Sexual Health and Reproductive Health-2 as well as the International Sexual Health and Reproductive Health-1 team for the initial work on setting up the consortium.

Abstract

Background: The increasing global demand for health care, driven by demographic shifts, the rise of personalized medicine, and technological innovations necessitate novel approaches to health care delivery. Digital remote assessment tools have emerged as a promising solution, enabling hybrid care models that combine traditional and remote patient management. These tools support the quadruple aim of health care by enhancing the monitoring and evaluation of patient-reported data, thereby improving patient care, boosting operational efficiency, reducing costs, and improving the experience of patients and clinicians. This review seeks to understand how remote assessment tools are used for routine consultation substitution in adult tertiary care centers.

Objective: This scoping review aims to evaluate the implementation and health outcomes of digital remote assessment tools used for routine consultation substitutions in adult tertiary care centers. The objectives include assessing the extent of use, types, and effectiveness of these tools in substituting conventional outpatient care.

Methods: A comprehensive scoping review was conducted, adhering to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist. The review focused on studies that used internet-dependent remote assessment technologies for patient data transfer in tertiary care settings. A detailed search strategy was used across multiple databases, with studies selected based on predefined inclusion and exclusion criteria. Data extraction and analysis were performed by independent reviewers, with a focus on the functionalities of the tools and their alignment with the Quadruple Aim of Healthcare.

Results: The review included 12 studies, highlighting a growing interest in remote assessment technologies across diverse clinical settings. The interventions varied in length, from 4 weeks to 12 months, and demonstrated a range of functionalities, including symptom monitoring and postsurgical follow-ups. The use of these tools was associated with improved clinical outcomes, such as timely intervention for clinical deterioration and enhanced clinical protocol adherence. Additionally, a small number of studies identified potential cost savings in terms of reduced unplanned health care contacts and optimized clinical resource use. Patient and clinician experiences were generally positive, with high adherence to remote assessments and an appreciation for the personalized and timely care facilitated by these technologies. Barriers included high initial setup costs for digital technologies, leading to an inflated cost per patient in small sample studies.

XSL•FO
RenderX

Conclusions: Digital remote assessment tools offer significant potential to enhance health care delivery by improving health outcomes, reducing costs, and enriching patient and clinician experiences. Their flexibility and adaptability make them suitable for various clinical contexts, supporting the personalization of care and operational efficiency. While digital remote assessment tools offer significant potential, careful consideration of implementation strategies, equity, cost, and clinician and patient experiences is crucial for successful clinical integration.

Introduction

Background

Globally, the demand for health care services is set to rise due to an increasing population, an aging demographic, the rise of personalized medicine, and the introduction of innovative technologies. Escalating costs, digital disruption, and consumer-centered care are likely to impact the effectiveness and viability of health care systems to meet this demand [1]. Novel approaches to health care are needed.

Well-established digital health interventions, such as telehealth have only marginally enhanced the capacity of public health systems and health care services [2]. Efforts to explore new strategies for enhancing health system sustainability persist, including digital interventions that use data to triage patients to optimal care pathways [3]. Remote management of diagnosed chronic diseases using biometric and wearable technologies is also becoming more common [3]. Such interventions streamline patient screening and triage, center the process around the patient, and in some instances, obviate the need for physical tertiary facility visits [4]. Provider-delivered remote monitoring tools and digital patient-reported outcome measurement tools are becoming prevalent. These approaches enable the introduction of new care models that may alleviate operational health system pressures and the realization of personalized care models [5].

Digital remote assessment tools are an emerging area with the potential to revolutionize traditional patient care approaches. These technologies enable hybrid care delivery models consisting of asynchronous patient-reported follow-up outside of conventional care settings and enable health providers to clinically supervise remotely located patients [5]. Such tools serve to capture, monitor, evaluate, and guide care decisions undertaken by health care professionals using the data reported by the patient, including pain, function, and symptoms.

Remote assessment tools cover a broad range of methods and technologies that can deliver interactive, patient-provider communications remotely through the digital collection of clinical assessment data. The implementation of care substitution using technology could yield benefits for both patients and providers by reducing unplanned health care contact post surgery, decreasing travel and costs, and optimizing workflows and human resources [6,7]. There is also some evidence that substituting postoperative follow-up visits with clinical assessment data collected from smartphone apps is acceptable to patients [6,7]. The broad use of "care substitution" encompasses various technologies that facilitate patient-provider interactions through the digital collection of clinical assessment data, thereby offering an alternative to traditional face-to-face or videoconferencing consultation.

The Quadruple Aim of Healthcare [8] provides a comprehensive framework for evaluating new interventions by focusing on 4 key dimensions: improving population health, enhancing patient and clinician experiences, and reducing health care costs, offering a holistic measure of an intervention's impact and effectiveness. This general approach is particularly valuable in assessing diverse interventions, as it captures a wide range of outcomes and benefits, ensuring a thorough evaluation despite the variability in study designs and methodologies. The integration of innovative technologies to complement or substitute existing clinical pathways warrants further exploration, particularly the use of asynchronous remote consultations to replace routine tertiary facility care. There are no published systematic or broad scoping reviews that assess the outcomes of using only remote assessment tools to substitute routine outpatient care.

This review seeks to understand, through the available literature: How are adult patient interventions using remote assessment tools used, practically, and effectively, for routine consultation substitution in tertiary care centers?

Study Objectives

The objectives of this scoping review are to (1) investigate how many studies have used remote assessment tools as the primary data collection or assessment method for routine care substitution; (2) explore what are the types, frequencies, and durations of interventions using digital assessment tools; and (3) map the published outcomes of interventions using digital assessment tools, including how they are evaluated and measured against the quadruple aim framework. This research can inform health care systems and providers regarding their appropriate use.

Methods

Overview

A scoping review was conducted, following PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) methods [9], because of the broad research questions and the emerging field of digital remote assessments. The PRISMA-ScR checklist,

XSL•FO
RenderX

provided in Multimedia Appendix 1, was used to ensure comprehensive reporting and methodological rigor.

Study Selection and Search Strategy

The intervention of interest for this scoping review was remote assessment tools using digital internet technologies incorporating patient-reported data in a tertiary health setting. The full inclusion and exclusion criterion developed is shown in Textbox 1.

The initial literature search was conducted in April 2023. An updated search was completed in March 2024. The search terms used to describe the intervention were "survey," "telemedicine," "mobile applications," and "tertiary" with synonyms built out from these initial terms. Studies published in the last 10 years in English and indexed in the following databases were searched: PubMed, CINAHL, Embase, Web of Science, and Cochrane. The PubMed search strategy is included in Multimedia Appendix 2.

Textbox 1. Search strategy inclusion and exclusion criteria.

Inclusion criteria

- Study type: Peer-reviewed, full-length studies.
- Language: English
- Study design: Primary intervention studies with or without a control group, including randomized controlled trials, nonrandomized controlled studies, controlled before-after studies, observational cohort studies, and preliminary and pilot studies.
- Population: Study participants aged 18 years or older, who are under management of a hospital or similar tertiary facility.
- Intervention: Remote assessments using internet-dependent technologies to transfer patient-reported data from the patient's home to a hospital institution or tertiary health provider as the primary intervention.
- Comparison: Health facility or hospital where remote patient assessments were compared to standard or routine care, specifically face-to-face or in-person clinical consultations
- Outcome: Hospitalization rate, mortality, quality of life, health service efficiency, economic impact, clinical workflows, patient experience, clinician experience, and access to health services.

Exclusion criteria

- Study type: Systematic reviews, scoping reviews, study protocols, conference abstracts, case studies, or editorials or commentary.
- Language: Languages other than English.
- Study design: Studies without primary data, descriptive studies only, theoretical frameworks, conference abstracts, or posters.
- Population: Pediatric patients and patients managed outside of a tertiary or hospital team setting.
- Intervention: Exclude video consultations and technologies that directly transfer data from biometric or wearable devices; exclude the use of photographic data; and exclude studies that use educational information or content.
- Comparison: Studies assessing rehabilitation, exercise, mobility, or clinical education use and adoption compared to in-person consultations.
- Outcome: Educational outcomes and training effectiveness

All identified citations were uploaded into EndNote (version 20.6/2023; Clarivate Analytics) and initial duplicates were removed. The remaining studies were then imported into Covidence, a web-based literature review platform, where the identification of studies was undertaken by 3 independent reviewers. All 3 reviewers screened the titles and abstracts for eligibility, with any combination of 2 reviewers per study. A study was included if both reviewers agreed that it met the inclusion criteria. Conflicts in study selection were resolved during team meetings. Full-text review of studies was randomly distributed across the team of 3 reviewers, with any combination of 2 reviewers requiring agreement for the study to be included. Extraction of data from the final full-text studies was shared across all reviewers, with all reviewers systematically and independently documenting data as per a previously agreed data extraction format. The data extraction fields were then compared, discussed, and finalized with all reviewers present.

To help understand the functions of the tools used, the data was used to create a functionality score based on the Incidental Medical Services (IMS) Institute for Healthcare Informatics functionality score description [10]. This functionality score consists of 7 functionality criteria and 4 functional subcategories. The complete structure of the IMS Institute for Healthcare Informatics functionality scoring can be found in Table 1. Each intervention was scored using 1 to indicate function was present, and 0 function was not present.

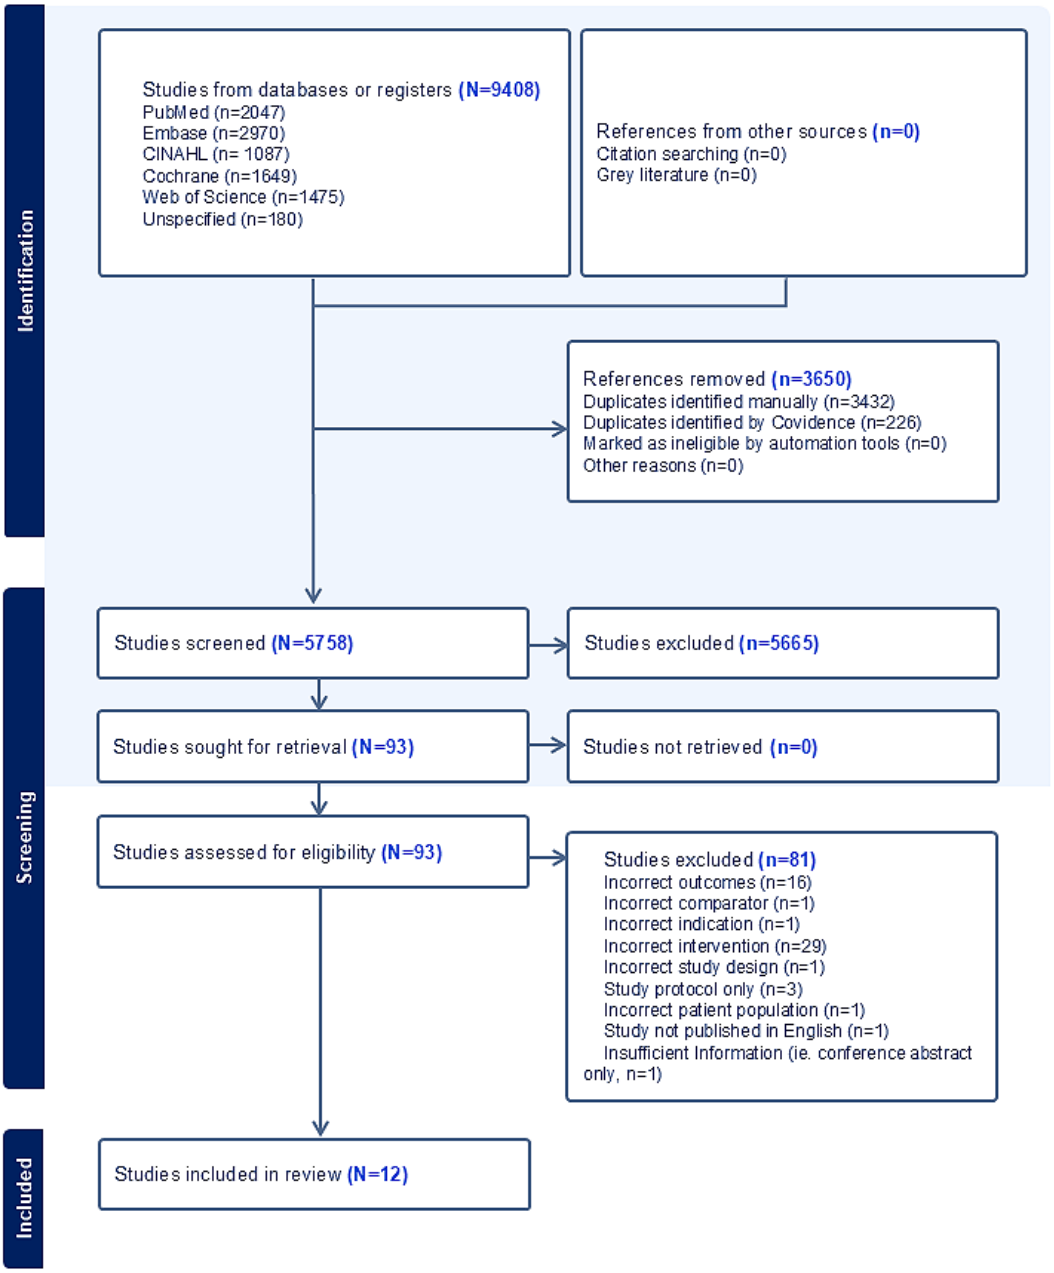
To facilitate consistency across the studies, the results were mapped across the 4 dimensions of the Quadruple Aim of Healthcare to assist in the comparison of benefits and outcomes. The quadrants used were (1) improve population health, (2) enhance patient experience, (3) enhance clinician experience, and (4) reduce health system costs. In the context of this review, factors contributing to the reduction of health system costs under investigation included cost of care or service (overall operational cost to provide a service), workforce use, and reduction in avoidable or unnecessary hospital admissions.

XSL•FO
RenderX

Table 1. IMS[a] Institute for Healthcare Informatics functionality criteria assessment [10].

Functionality criteria	Description
Inform	Provides information in a variety of formats (text, photo, and video)
Instruct	Provides instructions to the user
Record	Capture user entered data
Collect data	Able to enter and store health data
Share data	Able to transmit health data
Evaluate data	Able to evaluate the entered health data by patient and provider, provider and administrator, or patient and caregiver
Intervene	Able to send alerts based on the data collected or propose behavioral intervention or changes
Display	Graphically display user entered data or output user–entered data
Guide	Provide guidance based on user entered information, and may further offer a diagnosis, or recommend a consultation with a physician or a course of treatment
Remind or alert	Provides reminders to the user
Communicate	Provide communication with health care provider or provide links to social network

[a]IMS: Incidental Medical Services.



Results

Overview

The literature searches yielded 5758 unique citations, of which 12 studies were included in the final review. Figure 1 demonstrates the combined search results, with the first search completed in April 2023, and an updated search completed in March 2024.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for combined searches.

Summary of Included Studies

The 12 included studies span a publication period from June 2020 to January 2024, illustrating a growing contemporary interest in the domain of digital remote assessments. Geographically, the research landscape is diverse with studies originating from regions including the United Kingdom [11-13], Europe [13-17], North America [18,19], Asia [20], and Africa [21]. As for clinical focus, the studies encompass a wide range of patient populations, including those undergoing cancer treatment, individuals with cardiac or rheumatoid conditions, and postsurgery patients. Five of the studies included specific participant criteria that included participants who communicated in a specific or native language [12,15-17,19].

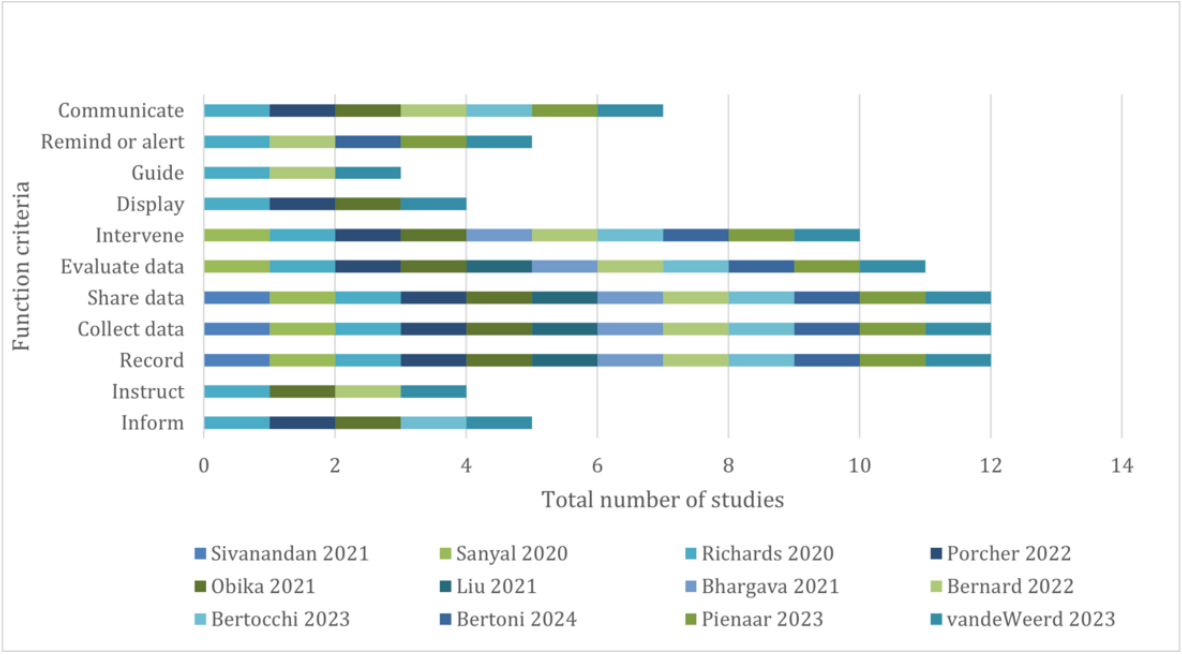
Intervention descriptions are varied, from real-time digital monitoring systems to smartphone apps. While some studies use the term “remote symptom monitoring” explicitly, others refer to “digital health tool,” “mHealth,” or “connected monitoring.” It should be noted that there were a considerable number of conference extracts that were excluded due to insufficient information published. Characteristics of included studies are presented in Multimedia Appendix 3 [11-22].

Types of Remote Assessment Interventions

Observations from the results on interventions involving remote assessment tools in various clinical scenarios reveal certain care models and distinctions. The length of interventions varied across studies, ranging from a period of 4 weeks [14] to a more extended duration of up to 12 months [20], with others such as Sanyal et al [18] remaining unspecified.

Data Sampling

Some studies adopted a weekly sampling approach [13,14,22], while others used more intermittent sampling, evident in Liu et al's method of sampling [20] at 90, 180, and 365 days. Richards



XSL•FO
RenderX

et al [12] introduced a mixed approach, beginning with thrice weekly visits in the initial week and then weekly assessments to the eighth week. The assessments' purpose ranged from symptom monitoring, and feedback collection to postsurgical outcomes and patient experience, with the data collection formats and tools varying accordingly. This included data collected through specific clinical symptom questionnaires designed by local clinical teams or disease-specific assessments, pain scores, patient experience Likert measures, distress thermometers, and disease-specific patient-reported outcome measures in various combinations.

Technology

Interventions leveraged digital platforms, either on computers or smartphone devices. Several studies used digital, web-based questionnaire portals [11,19], with other studies [18,22] using smartphone-native apps, some of which had additional functionalities like real-time alerts for clinical teams based on patient input. Pienaar et al [21] use a "2-way-texting" platform that requires only native SMS text responses from patients. Functional variation of the technology used is described in Figure 2, mapped against the IMS Institute for Healthcare Informatics mHealth functionality criteria [10]. Only 1 study [18] incorporated a dual approach using both SMS and email to communicate with patients. The majority of interventions [11-19,22] used functionalities to trigger specific clinical team alerts or interventions when customized thresholds in symptom reports were reached. Only the functions of recording, collecting, and sharing data were consistent across all interventions reviewed.

Figure 2. Study intervention assessed by digital health function criteria [11-22].

Evaluation of Outcomes Mapped to the Quadruple Aim

With an extensive range of variation across the types of interventions reviewed, there was not a single or consistent evaluation method to measure the outcomes and benefits of the intervention. The themes of the included studies are summarized in Multimedia Appendix 4 [11-22].

Population Health Outcomes

Overall, the use of remote assessment tools to directly manage patient health outcomes indicated positive results, particularly in the management of clinical deterioration, timely clinical intervention, and clinical protocol adherence. Accurate identification of clinical deterioration was achieved in most studies [12-14,19,22], whereby remote clinical review was initiated after interpretation or alert of the data, and patient treatment schedules or pathways were adjusted to prevent harm or further deterioration of health. This included 1 study that reported no patients on the intervention attending an emergency department for symptom management during the study period [19] and a reduction of the 30-day readmission rate for patients with high protocol adherence in a separate study [15]. In another study, quality of life outcomes (quality-adjusted life years) improved by 0.07, on a scale of 0 to 1, for those patients who underwent remote digital assessment as compared to traditional in-person monitoring and consultations [13]. The number of potential adverse events was also tracked over the intervention period in 1 study, where potential adverse events were low on day 1 post surgery and peaking on day 3 of 13-day monitoring [21].

One study explored the consistency of patients' data provided over a telephone interview with a clinician versus patient self-reporting via instant messaging. The results showed up to 10% variance on some symptom assessment data points, which may impact accurate management of health outcomes [20].

Health System Costs

Cost of Care or Service

Two studies [13,19] attempted to understand service costs using cost utility analysis, assessing the overall cost saving of providing care through remote assessment interventions

XSL•FO
RenderX

compared to usual care. While both studies reported a cost saving delivered by the intervention compared to routine care, there was commentary on an inflated cost per patient due to the small sample sizes undertaken, n=13 [19] and n=89 [13], and the baseline costs of establishing the digital technologies for such interventions. The majority of patients in 1 (60%) study indicated that the digital intervention saved them time and money from attending in-person clinic visits [21].

Workforce Use

The impact on the use of clinical resources through the substitution of remote assessment was reported across several studies [12-14,19,20], including the assumed suggestion of potential cost savings for the health service through triaged use of multidisciplinary teams, asynchronous communication, and reduction of routine consultation methods. The ability to effectively use different roles where appropriate was highly dependent on predefined patient pathways and parameters that could be automated through the digital tools and workflows used [12-14,19,22].

Reduction in Avoidable or Unnecessary Hospital Admissions

There was no clear reporting on the reduction in avoidable or unnecessary hospital admissions. The number of hospital readmissions for the intervention group of postsurgical patients was reported, however, no comparator to readmissions for a usual care approach was provided to establish if this was an improvement or otherwise [12]. One study reported a correlation of reduction in readmission rate for patients with high adherence to the digital protocol (P=.004) [15]. A reduction in hospitalization rate over a 6-month period was reported in patients with chronic disease when remotely monitored (rate of hospitalization=1.3) compared to the conventional monitoring group (rate of hospitalization=2.3) [13].

Patient Experience

Patient-experience measures were commonly captured through the use and adherence of the protocol, as well as qualitative surveying of the patient's service experience using Likert scoring.

Overall, there was positive patient acceptance of services using digital remote assessments [13-16,19,21,22], with adherence levels to the assessment reporting ranging between 62%-93% across the full study periods of the relevant interventions.

One study noted that patients with high function and low symptom burden were more likely to withdraw, implying the tool was more beneficial for patients experiencing significant symptoms [19]. It was further noted that there seemed to be other influencing factors to patient use such as physical health, in being able to complete self-reporting assessments [19].

Further thematic analysis of 1 intervention [12] highlighted that most patients valued the advice provided by the technology-enabled system. Key themes included reassurance and the relevance of advice which felt tailored to their specific needs. Patient perception of the usefulness of the interventions varied, with 1 study [17] reporting that 63% of patients thought the intervention was useful to support the management of health and access to services (score of 4.42/7), while another scored above 92% for patients feeling comfortable and safe using the digital service [21].

Clinician Experience

The 2 study interventions where clinical experience measures were reported both strongly indicate positive outcomes [12,19]. Measures indicated a consensus among clinical staff that using digital assessments improved clinical confidence in the delivery of care. Commentary in these studies indicated clinicians' belief that no clinical symptoms were overlooked, and the system was perceived to provide additional safety in highlighting areas of patient health that might not otherwise be reported or escalated by the patient [12,19].

One study highlighted that the clinicians found the ability to access the reported data through the hospitals. Electronic medical record systems useful, however, were contingent upon their accessibility to a computer within the hospital [12].

Additionally, 75% of clinicians from 1 study [19] perceived that the quality of life for their patients had improved owing to the remote assessment system in place.

Discussion

Summary of Evidence

This scoping review seeks to explore how remote assessment tools are used, practically and effectively, for routine consultation substitution in tertiary care centers. The review identifies the risks and benefits of these tools to guide health care systems in adopting technology-assisted models of care. Specifically, it investigates studies using remote assessment tools as the primary method for routine care substitution, the types and durations of these interventions, and how published outcomes align with the Quadruple Aim framework.

The review identified 12 studies, indicating that while digital remote assessment tools may be broadly implemented across health care facilities, limited research has been published on their specific applications for routine care substitution. Despite this small body of literature, these tools appear to be effective in capturing and assessing clinical deterioration, enabling proactive management and personalized treatment pathways. They may influence care pathway stratification and multidisciplinary team use and have the potential to improve health service efficiency.

The geographic distribution of studies suggests a concentrated focus in regions such as the United Kingdom and Europe, where conditions appear favorable for this type of research. However, many studies excluded participants due to language barriers, raising concerns about equity and inclusivity. While digital translation tools are widely available in other industries, health care settings face unique challenges in integrating such solutions effectively [23].

Notably, all studies were published from 2020 onward, highlighting the role of the COVID-19 pandemic as a catalyst for the adoption and evaluation of digital remote assessment tools. This trend underscores the growing interest in leveraging digital health technologies to address emerging pressures on

XSL•FO
RenderX

health care systems. However, the limited number of studies underscores the need for further research to establish robust evidence for the risks, benefits, and broader applicability of these interventions.

Principal Findings

When analyzed using the Quadruple Aim framework, the findings demonstrate an emphasis on measuring population health outcomes and patient experience. However, the neglect of health system costs and clinician experience in many studies reveals a significant gap in literature. To create a sustainable health care system capable of meeting both current and future challenges, balanced attention to all 4 dimensions of the Quadruple Aim is essential [8].

Only 2 studies [13,19] examined health system costs, underscoring the limited focus on this critical area. This neglect may stem from the challenges associated with costing health care delivery comprehensively, particularly in complex, innovative care models like digital health interventions. Traditional costing methods often fail to capture the variability and complexity of care pathways, making it difficult for policymakers to evaluate economic implications accurately [24]. Without robust cost analyses, the ability to optimize resource allocation, reduce unnecessary expenditures, and understand long-term sustainability remains limited [25].

Similarly, only 2 studies [12,19] addressed clinician experience, a surprising finding given the pivotal role clinicians play in the success of digital health technologies. While the focus on patient-centered care is appropriate, neglecting clinician perspectives risks compromising the balance necessary to achieve the Quadruple Aim [26]. Clinicians must be confident that digital remote assessment tools enhance, rather than burden, their workflows and align with their commitment to patient care. Failure to address these concerns could lead to implementation challenges or resistance, undermining the benefits of digital interventions.

Limitations

The study has several limitations. The narrow selection criteria focused exclusively on interventions using remote assessment data as the primary data source, excluding studies that integrated additional data inputs such as biomedical devices, photographic data, or web-based education. As a result, relevant studies incorporating more comprehensive data sources were not included.

Additionally, a substantial number of studies (n=27) were excluded due to insufficient information to answer the research questions, many of which were conference abstracts. The lack of randomized controlled trials or comparator studies further limits the robustness of the findings, potentially introducing bias and inflating the perceived benefits of these interventions. This reflects a broader challenge in digital health research, where the rapid pace of technological development renders traditional randomized controlled trials less feasible. Innovative methods, such as observational studies, may provide more pragmatic and timely approaches for evaluating digital health interventions [27].

Future Research

Future research should prioritize direct assessments of health system costs associated with remote assessment interventions, incorporating time-driven activity-based costing to provide more accurate and comprehensive insights [25]. Understanding funding policies and potential revenue streams from public and private health funders will also be essential to support scalability and sustainability [27-29].

Additionally, research should explore clinician experiences with reduced patient contact due to digital interventions and identify systemic strategies to mitigate burnout and promote health care workers' well-being. This area remains underexplored despite its importance for successful implementation.

Broader Implications

The integration of digital remote assessment tools into health systems holds substantial promise for improving health care delivery. However, their success hinges on addressing critical challenges, including equity, cost analysis, and clinician engagement. Tailoring interventions to specific clinical contexts, integrating them seamlessly with existing workflows, and incorporating patient and clinician feedback are essential steps toward maximizing their impact.

To ensure long-term sustainability, future research and implementation efforts must adopt a holistic approach that balances the dimensions of the Quadruple Aim. This includes developing robust cost analyses, fostering clinician buy-in, and addressing barriers to accessibility. Ultimately, by addressing these factors, digital health interventions can contribute to a more equitable, efficient, and patient-centered health care system capable of withstanding evolving challenges.

Conclusions

This review highlights the broad-reaching potential and adaptability of digital remote assessment interventions. Despite variability in duration and methodologies, these technologies consistently demonstrate accurate data recording, collection, and dissemination. More mature interventions that guide clinical responses offer additional benefits.

Digital health solutions can advance the Quadruple Aim of Healthcare by enhancing population health outcomes, optimizing resource allocation, and improving patient and clinician experiences. Future research should establish standardized measures of health system effectiveness, consider clinician adoption, and investigate the long-term sustainability and impact on access to care.

While digital remote assessment tools offer significant potential, careful consideration of implementation strategies, equity, cost, and clinician and patient experiences is crucial for successful clinical integration.

Abstract

Background: Obtaining informed consent (IC) is vital for ethically and effectively recruiting participants in research projects. However, traditional in-person IC approaches encounter notable obstacles, such as geographic barriers, transportation expenses, and literacy challenges, which can lead to delays in enrollment and increased costs. Telehealth, especially teleconsent, offers a potential way to overcome these obstacles by facilitating the IC process in a digital setting. Nonetheless, there are concerns about whether teleconsent can achieve levels of understanding and involvement that are equivalent to those of in-person IC meetings.

Objective: This study aims to evaluate comprehension and decision-making in participants undergoing teleconsent versus traditional in-person IC. We used validated assessments to determine whether teleconsent is a viable alternative that maintains participants' understanding and decision-making abilities.

Methods: A randomized comparative study design was used, recruiting potential participants for a parent study assessing patient experiences with patient portals. Participants were randomly assigned to 2 groups: teleconsent and in-person consent. The teleconsent group used Doxy.me software, allowing real-time interaction between researchers and participants while reviewing and electronically signing the IC documents. Recruitment involved using an institutional web-based platform to identify interested individuals, who were then contacted to assess eligibility and gather demographic information. The Decision-Making Control Instrument (DMCI) survey was used to assess the perceived voluntariness, trust, and decision self-efficacy. The Quality of Informed Consent (QuIC) was used to measure the comprehension level of the consent form. The validated Short Assessment of Health Literacy-English tool was used to measure participants' health literacy levels.

Results: A total of 64 participants were enrolled in the study, with 32 in the teleconsent group and 32 in the in-person group. Of 64 participants, 32 (50%) were in the teleconsent group, 54 (84.4%) were females, 44 (68.7%) were aged 18-34 years, 50 (78.1%) were White, and 31 (48.4%) had a bachelor degree. The mean SAHL-E scores were different between the teleconsent and in-person groups (16.72, SD 1.88 vs 17.38, SD 0.95; *P*=.03). No significant differences were found between the average scores at baseline and follow-up for QuIC part A (*P*=.29), QuIC part B (*P*=.25), and DMCI (*P*=.38) within the teleconsent and in-person groups. Additionally, there were no significant differences in QuIC or DMCI between subgroups based on age, sex, and ethnicity.

Conclusions: This study assessed the effectiveness of IC processes through telehealth compared to traditional in-person visits. Findings indicate that telehealth offers similar participant understanding and engagement while overcoming geographic and accessibility barriers. As health care adopts digital solutions, these results highlight telehealth's potential to improve recruitment and retention in clinical research, suggesting that policy makers should integrate telehealth practices into regulations for better access and health outcomes.

Introduction

Obtaining informed consent (IC) supports the successful recruitment of participants and the overall success of research studies [1]. However, obtaining IC faces challenges related to the cost and time to travel to and from the study site, geographic barriers in rural or remote areas, and literacy barriers [2]. Lack of obtaining IC leads to delayed enrollment, low retention, and engagement rates, and increased costs for additional resources [3].

Traditional methods of obtaining IC usually involve face-to-face interactions in which health care providers explain procedures, risks, benefits, and alternatives to patients, often using written consent forms [4,5]. These methods facilitate direct communication and allow patients to ask questions, which helps build understanding and trust [5,6]. However, several challenges are associated with this process. Patients often have varying levels of health literacy, and time constraints can prevent thorough discussions [7,8]. Additionally, the use of complex medical jargon can confuse patients [9,10].

Research has shown that many patients are unaware of their rights and may not receive enough information to make fully informed decisions [11,12]. Challenges in decision-making and comprehension of in-person IC are multifaceted. Patients often have varying levels of health literacy, which can significantly impact their understanding of medical information and their ability to make informed decisions [13]. Time constraints during consultations can further hinder thorough discussions, leaving patients with insufficient information [7]. Additionally, the use of complex medical jargon can confuse patients, making it difficult for them to grasp the details of their treatment options [14]. Research has shown that many patients are unaware of their rights and may not receive enough information to make fully informed decisions [11]. Furthermore, the responsibility for obtaining consent can sometimes be unclear, leading to inconsistencies in the process [15,16]. To address these challenges, it is essential to improve communication strategies and ensure that consent forms are clear and comprehensive.

The use of telehealth, namely teleconsent, has the potential to address these challenges by conducting the IC process digitally [17]. Teleconsent involves live video calls during which the researcher and participant can see and interact with each other in real-time [18,19]. There are concerns about the ability of teleconsent to deliver similar levels of comprehension and engagement to in-person IC visits. This noninferiority study aimed to examine the comprehension and decision-making levels for teleconsent versus in-person IC visits using validated comprehension assessment survey instruments in conjunction with health literacy evaluation.

Methods

Study Design

In this randomized comparative study, we obtained the IC of potential participants for a parent study that assesses patients' experience using patient portals. Participants were recruited through an institutional web-based recruitment platform or word of mouth. Participants were randomly assigned to in-person or teleconsent. The teleconsent group used Doxy.me software, which enables the researcher to share the IC document on-screen, collaboratively complete it with the participant and sign it electronically. Individuals in the in-person group met with the study research assistant in a private office.

Recruitment Process

We listed the study on an institutional recruitment platform such that when an individual expressed interest in the study, the research assistant received an automated notification email containing the potential participant's contact information.

The research assistant had initiated contact via email acknowledging the individual's interest and requesting demographic and eligibility information to ensure participant diversity. The research assistant provided a link to a Qualtrics survey and asked qualified individuals to digitally sign a consent form. The research assistant emphasized confidentiality and mentioned an upcoming interview, which could be in person or via teleconsent. Participants would also receive a gift card for their involvement in both the initial interview and a follow-up session.

Participants designated for teleconsent received an email from the research assistant confirming their eligibility for remote participation via computer (microphone and camera required; smartphones and tablets not allowed). They were asked to complete a scheduling form for a 45-minute session, which included the consent process, a semistructured interview on MyChart usability, and follow-up questionnaires. The research assistant also mentioned a gift card incentive for both initial and follow-up sessions.

In cases where participants were scheduled for an in-person session, the research assistant issued a similarly structured email. The message confirmed their eligibility and presented them with the option to choose between 2 locations: a public library or a private office at the University. Participants were encouraged to fill out a scheduling form with their preferred time slots. The research assistant outlined the session's duration and activities, mirroring the information provided for teleconsent, along with the mention of the gift card reward for study completion.

XSL•FO
RenderX

Consent Process

The consent form was 6 pages long, and it outlined the purpose, procedures, risks, and participant rights related to the study. The consent form was designed to inform potential participants about the study, ensuring they can make an informed decision about their involvement. It invited them to ask questions and clarified their rights as research subjects.

This consent form explained the nature of the study to evaluate participants' perceptions of the MyChart patient portal's usability and differences in consent understanding between teleconsent and traditional methods. The participants were adults who were users of MyChart, a prominent web-based patient portal. Participation in this study was voluntary. The form explained the chronological order of events in this study and that it will begin with eligibility questions and the collection of demographic information. Participants will then be randomly assigned to either teleconsent or in-person consent. Following this, they will take part in an interview with a research assistant regarding their experiences with MyChart, which will be recorded for transcription purposes. Additionally, participants will complete questionnaires on consent comprehension and health literacy.

The form also stated that the study will last no more than 1 hour and will be conducted at a designated location either in person or via videoconference. The research assistant also read the section about the potential risks, including confidentiality breaches, which will be minimized by assigning codes to data and ensuring anonymity during analysis. Finally, the form covers that the study is protected by a Certificate of Confidentiality, which prevents the use of identifying information in legal scenarios without consent, with some exceptions such as mandatory reporting laws. To verify the identity of the individuals in the teleconsent group, we asked that they enable their cameras during the entirety of the session. In addition, when signing the consent form, we used a feature in Doxy.me that enables taking a screenshot along with a timestamp to accompany the individual's wet signature obtained live during the session. This feature ensures that the individual who signed the consent form is the intended individual, a necessary step in teleconsent [20].

After the session, participants completed the Decision-Making Control Instrument (DMCI) and Quality of Informed Consent (QuIC) surveys after the consent session (ie, baseline) and 30 days after the session (ie, follow-up). Data collection occurred between April 30, 2019, and June 29, 2021. The institution review board approval was obtained.

We used the DMCI, a 15-item validated instrument, to assess participants' perceived voluntariness, trust, and decision self-efficacy in the consent form [21]. The DMCI assesses participants' feelings of influence over decisions and their confidence in the fairness and transparency of the process. The maximum possible score is 30 and higher scores indicate greater perceived autonomy and trust in decision-making.

We used the QuIC to measure comprehension of the parent study consent form [22]. The QuIC consists of 2 parts: part A (14 items) assesses objective knowledge of study details, testing participants' factual understanding of the consent process; and part B (6 items) measures perceived understanding, evaluating how confident participants feel about comprehending the consent materials. Together, the QuIC thoroughly evaluates both actual and perceived IC quality. The maximum possible score is 80 and higher scores reflect better comprehension and confidence, ensuring that consent is truly informed.

We used the validated Short Assessment of Health Literacy-English (SAHL-E) tool to measure participants' health literacy levels. The SAHL-E is an 18-item tool that assesses functional health literacy by testing participants' ability to understand and apply health-related terms. It uses a word association format to evaluate vocabulary and conceptual knowledge. The maximum possible score is 18, and higher scores indicate better health literacy, which correlates with improved capacity to make informed health decisions (Multimedia Appendix 1).

Ethical Considerations

The University of North Carolina at Chapel Hill institutional review board deemed this study exempt (17-2870). Participants consented to participate in the study and to be assigned to either the control or intervention groups. Participant responses were kept anonymous, and participants were only referred to by subject ID. All data were kept separate from names and housed behind a secure, Health Insurance Portability and Accountability Act (HIPAA)–compliant server. Participants received a US $15 gift card upon completing the baseline surveys and another US $15 gift card upon completing the follow-up surveys.

Data Analysis

We compared the demographic distribution of participants regarding sex, age, race, education, and income between teleconsent and in-person groups. We used a 2-sample, 2-tailed *t* test assuming unequal variances to compare the SAHL-E scores between the teleconsent and in-person groups to compare literacy levels. We compared the scores for the DMCI and QuIC surveys for both the teleconsent and in-person groups between baseline and follow-up using 2-sample *t* tests. We used a 2-sample, 2-tailed *t* test assuming unequal variances to compare the DMCI and QuIC score for subgroups on sex (male and female), age (18-34 years, 35-50 years, 51-64 years, and 65 years and older), and race (Asian, Black or African American, White, and mixed race).

We aimed to enroll 64 participants to provide 80% power to detect modest differences (effect sizes approximately 0.50) between groups with respect to the survey instrument scores. For example, we expect to be able to detect a 3.5-unit difference on the DMCI composite score (which has been reported to have a mean of 46.1, SD 7.0) and a 4.7-unit difference on the QuIC (which has been reported to have a mean of 77.8, SD 9.4).

Results

Overview

Of 64 participants, 32 (50%) were in the teleconsent group, 54 (84%) were females, 44 (68%) were aged 18-34 years, 50 (78%) were White, and 31 (48%) had a bachelor degree. The mean

XSL•FO
RenderX

SAHL-E scores were different between the teleconsent and in-person groups (16.72, SD 1.88 vs 17.38, SD 0.95; *P*=.03; Table 1).

At baseline, the teleconsent group had a higher mean QuIC score than the in-person group for part A (7.38, SD 1.27 vs 6.84, SD 2.46; *P*=.29) and part B (53.88, SD 1.80 vs 53.19, SD 2.79; *P*=.25). Both groups had similar mean DMCI scores (19.44, SD 1.12 vs 19.84, SD 2.31; *P*=.38; Figure 1).

[a]SAHL-E: Short Assessment of Health Literacy-English.

XSL•FO
RenderX

Figure 1. Average scores for (A,B) QuIC: (A) part A (maximum possible score=24) and (B) Part B (maximum possible score=56); and (C) DMCI (maximum possible score=30) at baseline and follow-up for the teleconsent and in-person groups. DMCI: Decision-Making Control Instrument; QuIC: Quality of Informed Consent.

At follow-up, the teleconsent group had a higher mean score than the in-person for the QuIC part A (7.84, SD 1.99 vs 7.03, SD 1.61; *P*=.08) and the DMCI (19.41, SD 1.77 vs 19.09, SD 1.13; *P*=.41). In-person had a higher mean score for the QuIC part B (52.94, SD 3.03 vs 53.50, SD 2.68; *P*=.44).

No significant differences were found between the average scores at baseline and follow-up for QuIC part A, QuIC part B, and DMCI within the teleconsent and in-person groups (Multimedia Appendix 2).

Within the teleconsent group, scores for QuIC part A increased from a baseline average of 7.38 (SD 1.27) to 7.84 (SD 1.99), while QuIC part B showed a slight decrease from 53.88 (SD 1.80) to 52.94 (SD 3.03). The mean DMCI scores remained relatively stable, with a minor decrease from 19.44 (SD 1.12) to 19.41 (SD 1.77). However, none of these changes were statistically significant.

Within the in-person group, the mean QuIC part A scores increased slightly from 6.84 (SD 2.46) to 7.03 (SD 1.61), and QuIC part B scores rose marginally from 53.19 (SD 2.79) to 53.50 (SD 2.68). The mean DMCI scores saw a notable drop from 19.84 (SD 2.31) to 19.09 (SD 1.13). Similar to the teleconsent group, none of these differences reached statistical significance.

DMIC Subgroup Analysis

The results of the teleconsent and in-person consent assessments, measured by the DMCI scores, showed no significant differences, Table 2. However, males exhibited higher baseline scores in the teleconsent group (mean 20.25, SD 1.64) compared to females (mean 19.32, SD 0.97), although both groups showed similar follow-up scores. In-person assessments also indicated male scores were slightly higher at baseline (mean 19.50, SD 0.5) compared to females (mean 19.92, SD 2.54), but follow-up scores highlighted a more significant disparity between the groups.

XSL•FO
RenderX

Table 2. Comparison of DMCI[a] scores by sex, age, and race for teleconsent and in-person consent groups at baseline and follow-up (maximum possible sore=30).

	Teleconsent			In-person		
	Baseline DMCI	Follow-up DMCI	*P* value	Baseline DMCI	Follow-up DMCI	*P* value
Sex, mean (SD)						
Male	20.25 (1.64)	20.50 (1.12)	.83	19.50 (0.5)	19.33 (0.94)	.73
Female	19.32 (0.97)	19.25 (1.79)	.85	19.92 (2.54)	19.04 (1.16)	.12
Age (years), mean (SD)						
18-34	19.52 (1.28)	19.17 (0.64)	.26	20.28 (2.75)	19.09 (1.38)	.09
35-50	19.14 (0.35)	20.14 (3.48)	.51	19 (0)	19.12 (0.33)	.35
51-64	19.5 (0.5)	19.5 (0.5)	≥.99	19 (0)	19 (0)	N/A[b]
65 and older	0 (0)	0 (0)	N/A	19 (0)	19 (0)	N/A
Race, mean (SD)						
Asian	20.33 (1.89)	20 (1.41)	.85	24.33 (5.44)	19.66 (0.94)	.35
Black or African American	19 (0)	19.4 (0.8)	.37	19 (0)	19.5 (0.5)	.50
White	22 (2)	21 (2)	.75	19.5 (0.5)	19 (0)	.50
Mixed race	19.18 (0.39)	19.18 (1.85)	≥.99	19.4 (0.75)	19 (1.2)	.17

[a]DMCI: Decision-Making Control Instrument.

[b]N/A: not applicable.

Age-related trends showed that younger participants (aged 18-34 years) had DMCI scores of 19.52 (SD 1.28) at baseline and 19.17 (SD 0.64) at follow-up via teleconsent, which were not significantly different (*P*=.26). Comparatively, older age groups showed varied results, with the 35- to 50-year-olds' scores being 19.14 (SD 0.35) and 20.14 (SD 3.48) for teleconsent, yielding a *P* value of .51. The 51- to 64-year age group had stable scores of 19.5 (SD 0.5) across both assessments, while there were no participants aged 65 years and older.

Racial comparisons show that Asian participants recorded the highest baseline score in the teleconsent group (mean 20.33, SD 1.89), while White participants presented more stable averages across both modes of consent. Asian participants had mean (SD) DMCI scores of 20.33 (1.89) and 20.00 (1.41) at baseline and follow-up via teleconsent (*P*=.85). Notably, the performance of Black or African American and mixed-race individuals illustrated lesser variability in scores.

QuIC Subgroup Analysis

There were no significant differences in comprehension scores between teleconsent and in-person methods across the sex categories, with males reporting a baseline mean (SD) score of 61.25 (1.92) for teleconsent and 60 for in-person consent, while females scored 61.25 (2.18) and 60.04, respectively (Table 3). However, the *P* values for both sexes were .85 and .36, indicating no statistically significant differences between baseline and follow-up.

XSL•FO
RenderX

Table 3. Comparison of QuIC[a] scores by sex, age, and race for teleconsent and in-person consent groups at baseline and follow-up (maximum possible sore=80).

	Teleconsent			In-Person		
	Baseline QuIC	Follow-up QuIC	*P* value	Baseline QuIC	Follow-up QuIC	*P* value
Sex, mean (SD)

[a]QuIC: Quality of Informed Consent.

[b]N/A: not applicable.

The 18-34 age group had a teleconsent baseline mean (SD) score of 61.30 (1.78) compared to 60.24 (3.28) for in-person, with a *P* value of .87 indicating no significant difference. The 35-50 age group's scores exhibited a teleconsent baseline of 61.14 (3.23) and an in-person score of 59.88 (2.76), with a *P* value of .43, again highlighting a lack of significant differences. The older age groups (51-64 years) demonstrated teleconsent baseline scores of 61 (SD 1) and 58 (SD 2) respectively for in-person, yielding a *P* value of .41.

Regarding race, the Black or African American group exhibited the highest baseline teleconsent score of 62.20 (SD 0.98), while the lowest was seen in the mixed-race category, scoring 60.50 (SD 2.50). Mixed race individuals exhibited a teleconsent score of 60.5 (SD 2.5) and 59 (SD 3) in-person, yielding a *P* value of .96, while White participants had baseline scores of 61.05 (SD 2.33) for teleconsent and 59.92 (SD 3.31) for in-person, with a *P* value of .81. The *P* values across race categories ranged from .25 to .96, indicating a lack of statistical significance in the differences observed.

Discussion

Principal Findings

Our study provides important insights into how participants understand and make decisions during teleconsent sessions compared to traditional in-person IC visits. Notably, our results suggest that telehealth can match or even improve participants' understanding of the consent process in certain situations. This study provides evidence that telehealth can effectively obtain IC for research studies in health. This challenges the common belief that in-person interactions are always better at facilitating informed consent. It also emphasizes the need to reevaluate consent methods in the evolving digital health landscape.

Findings from this study provide evidence that using telehealth to obtain IC is a viable method that allows participants to obtain similar levels of comprehension of the study consent form and make voluntary decisions as the in-person method. In some cases, we found that participants retained information better in the teleconsent group 30 days after the IC session compared to the in-person group. This supports previous findings suggesting that obtaining IC digitally can streamline the IC process compared to in-person methods [23].

The subgroup analysis suggests no significant differences in DMCI or QuIC scores across sexes, age groups, or races when comparing teleconsent and in-person methods. We found no significant differences in teleconsent participants' comprehension levels of perceived voluntariness, trust, and decision self-efficacy from baseline to 30-day follow-up. The lack of significant differences provides evidence that using teleconsent among various populations can yield similar results to in-person IC efforts.

Our findings, aligned with prior studies, suggest the efficacy of telehealth in increasing accessibility and improving participant engagement in clinical research. For example, previous research has demonstrated that telehealth significantly reduces geographic barriers to seeking care [24]. Our findings build on this foundation by specifically targeting the comprehension aspect of the consent process, thereby filling an important gap in current scholarships.

However, teleconsent may also exacerbate health inequities among individuals and communities that lack access to digital tools or lack digital literacy [25,26]. Therefore, it is essential to carefully examine the use of teleconsent by conducting a needs assessment or feasibility study for the target audience to understand if teleconsent is an appropriate IC method.

XSL•FO
RenderX

The implications of our study findings are profound for future clinical research. As health care systems continue to adapt and incorporate telehealth, there is a clear opportunity to standardize teleconsent in many studies. Teleconsent has the potential to streamline participant enrollment and also foster a more inclusive environment where individuals who might otherwise face barriers to participation, such as those in remote areas or those with mobility challenges, can take part in important research without compromising their understanding of the process. Ultimately, this evolution in practice could improve participant understanding and engagement, advancing the goals of ethical, effective, and translational clinical research.

This study had limitations. It is a single-site study, and the diversity in some demographics was limited due to the difficulty of recruiting participants during a public health emergency. Also, we did not collect the duration of the consent session for each group, which would have added more evidence regarding differences in efficiencies between in-person and teleconsent methods. Future research should explore the long-term effects of teleconsent on participant engagement and retention, particularly among different populations. Studying how different technologies, such as smartphone apps, compare to traditional methods could provide valuable insights for optimizing telehealth strategies.

The findings of this study emphasize that study participants using teleconsent and in-person were able to comprehend and make voluntary decisions related to IC alike, that is, comprehension and voluntariness are not negatively impacted by this type of remote IC modality.

Conclusions

This study aimed to assess the comprehension and decision-making effectiveness of IC processes conducted via telehealth compared to traditional in-person visits. Key findings revealed that telehealth maintains comparable levels of participant understanding and engagement, overcoming significant barriers such as geographic limitations and accessibility challenges. As health care increasingly adopts digital solutions, these findings highlight the potential of telehealth to enhance participant recruitment and retention in clinical research. This is particularly relevant for policy makers, who should integrate telehealth practices into regulatory frameworks to promote equitable access and improve health outcomes in diverse populations.

Abstract

Background: Continuous and wireless vital sign (VS) monitoring on hospital wards is superior to intermittent VS monitoring at detecting VS abnormalities; however, the impact on clinical outcomes remains to be confirmed. A recent propensity-matched study of primary surgical patients found decreased odds of intensive care unit (ICU) admission and mortality in patients receiving continuous monitoring. Primary surgical patients are inherently different from their medical counterparts who typically have high morbidity, including frailty. Continuous monitoring research has been limited in primary medical patients.

Objective: This study aims to evaluate the clinical outcomes of primary medical patients who received either continuous or, as a contemporaneous control, intermittent vital monitoring as the standard of care using propensity matching.

Methods: Propensity-matched analysis of a population-based sample of 7971 patients admitted to the medical wards between January 2018 and December 2019 at a single, tertiary United States medical center. The continuous monitoring device measures oxygen saturation, heart rate, respiratory rate, continuous noninvasive blood pressure, and either 3-lead or 5-lead electrocardiogram. Patients received either 12 hours or more of continuous and wireless VS monitoring (n=1450) or intermittent VS monitoring (n=6521). The primary outcome was the odds of a composite of in-hospital mortality or ICU transfer during hospitalization. Secondary outcomes were the odds of individual components of the primary outcome, as well as heart failure (HF), myocardial infarction (MI), acute kidney injury (AKI), and rapid response team (RRT) activations.

Results: Those who received intermittent VS monitoring had greater odds of a composite of in-hospital mortality or ICU admission (odds ratio [OR] 2.79, 95% CI 1.89-4.25; *P*<.001) compared with those who had continuous and wireless VS monitoring. The odds of HF (OR 1.03, 95% CI 0.83-1.28; *P*=.77), MI (OR 1.58, 95% CI 0.77-3.47; *P*=.23), AKI (OR 0.74, 95% CI 0.62-1.02; *P*=.06), and RRT activation (OR 0.94, 95% CI 0.75-1.19; *P*=.62) were similar in both groups.

Conclusions: In this propensity-matched study, medical ward patients who received standard of care intermittent VS monitoring were at nearly 3 times greater odds of transfer to the ICU or death compared with those who received continuous VS monitoring. Our study was primarily limited by the inability to match patients on admission diagnosis due to limitations in electronic health record data. Other limitations included the number of and reasons for false alarms, which can be challenging with continuous monitoring strategies. Given the limitations of this work, these observations need to be confirmed with prospective interventional trials.

Introduction

Vital sign (VS) monitoring is routine practice on the general medical wards and is typically performed as an intermittent "spot check," at 4 to 8-hour intervals [1]. However, this intermittent VS monitoring may fail to detect VS abnormalities [2-5], and perturbations in VS may be sustained for long periods between spot check intervals [6,7]. The failure to detect abnormal VS or their trends has significant implications for clinical care [8]. For example, transient hypotension is associated with worse outcomes [9-14]. Furthermore, the failure to act on or recognize deterioration was identified as the most common reason for harm in a study of 2010 hospitalized patient deaths in the United Kingdom between 2010 and 2012 [15].

Aggregate VS scoring systems such as the early warning score (EWS) have been developed to aid in the identification and risk stratification of patients at risk of or experiencing clinical deterioration. Once identified, clinical response teams, often termed "rapid response teams" (RRTs), may intervene to provide stabilization or transfer to a higher level of care. This identification and response have been described as the afferent and efferent arms, respectively, of rapid response [16]. The afferent response is contingent upon appropriate and timely recognition of clinical deterioration, which is accomplished primarily through the detection of abnormal VS. The use of intermittent VS monitoring may fail to detect clinical deterioration, thereby precluding or delaying this process.

The advent of wearable and wireless devices capable of continuous VS monitoring integrated into the clinical workflow offers a solution to the failure-to-detect paradigm associated with intermittent VS monitoring; however, clinical outcome data are needed. Evidence regarding outcomes with continuous VS monitoring relies almost exclusively on before-and-after comparison studies, and the research has also focused primarily on surgical patients [17]. Two systematic reviews of continuous VS monitoring concluded that existing study quality is low-to-moderate and does not show benefit of continuous compared with intermittent VS monitoring [18,19]. However, these reviews were limited by the heterogeneity of devices included in the studies and narrow scope of the patient populations. That is, the analyses included over 15 different device types making cross comparison and generalization challenging. Additionally, the analyses included almost entirely surgical populations, with individual studies including niche surgical areas such as gastrointestinal cancer, again limiting the generalizability of the analyses.

The granular detection capabilities of continuous and wireless VS monitoring mitigate the variability that is inevitable in today's complex health care systems, allowing capture and intervention of clinical deterioration to improve quality of care.

At Atrium Health Wake Forest Baptist Medical Center, continuous VS monitoring using wearable and portable monitoring device technology on surgical and medical wards has been in place since 2015 and is coupled with VS threshold–based alarms and interventions based on best practices. An earlier report from our institution demonstrated a significant decrease in RRT calls after implementation [20,21]. We have also reported substantial changes in heart rate (HR) and blood pressure (BP) detected by these monitoring devices that would have gone undetected with traditional intermittent VS monitoring. Furthermore, we recently reported a propensity-matched analysis of 36,000 surgical ward patients, where 12,345 intermittently monitored patients were compared with 7955 continuously monitored patients, and a nearly 2 times increased odds of intensive care unit (ICU) admission or in-hospital mortality was seen in the intermittently monitored group [22]. The inherent differences between a primary surgical population, where nearly all continuous postprocedure monitoring research has been conducted, and a primary medical population is paramount to the significance of this work. Primary medical admissions are inherently different from surgical ones. Medical patients often have multiple acute problems related to single or multiple intersected disease processes. Often, patients admitted to a medical service are deemed too sick or high risk to undergo surgery.

Therefore, we sought to evaluate and compare clinical outcomes in a large propensity-matched medical ward population admitted to a single institution who received either continuous or, as a contemporaneous control, intermittent VS monitoring as the standard of care every 4 hours to 8 hours. We hypothesized that earlier detection of VS aberrations through continuous VS monitoring would reduce ICU transfer and in-hospital mortality. Secondary outcomes included heart failure (HF), myocardial infarction (MI), acute kidney injury (AKI), and RRT activations.

Methods

Population and Setting

We first identified adult patients (aged ≥18 years) admitted to a tertiary care center (Atrium Health Wake Forest Baptist Medical Center main campus) over 2 years (between January 1, 2018, and December 31, 2019) under a primary medical service.

Primary medical services included hospitalist, general internal medicine, and family medicine. Provider staffing varied by service but included physician attendings, advanced practice providers, and medical residents. Primary medical services represented the typical breadth of patients admitted to hospital medicine services. Admission diagnoses were not included in propensity matching. Patients having any surgery during admission were excluded from analysis. Race and ethnicity were self-described by patients on admission then retrospectively collected with other demographics from the electronic health record (EHR).

Ethical Considerations

Regarding human subject research ethics review, our study was a secondary analysis and did not actively involve nor enroll human subjects. Our study and a priori defined statistical analysis plan were approved by the Wake Forest University Health Sciences Institutional Review Board (IRB; approval number IRB00083520). Informed consent from human subjects was not obtained for this secondary analysis. Primary consent for data collection was allowed by the IRB without additional consent. Privacy and confidentiality protection were maintained using de-identified data for analysis and using only data needed for the analysis. Data were stored in a secure location per IRB requirements.

Monitoring Protocols

Patients admitted to the medical wards either received (1) VS monitoring with a continuous monitoring device, ViSi Mobile, (Sotera Wireless Inc), or (2) standard intermittent VS monitoring (every 4-8 hours). Briefly, the ViSi Mobile system is a portable wrist-mounted system that received clearance from the Food and Drug Administration in 2012. These ViSi devices were purchased and implemented by the Wake Forest Baptist Hospital system in 2015. Today, ViSi monitors are on several different medical and surgical units; however, these devices are not available on all units. If units do not have ViSi monitors or patients decline to wear the monitor, then intermittent monitoring is used.

Hospital units with ViSi devices are staffed by the same number of personnel as those not doing this monitoring. Nurse-to-patient ratios on our floors range from 1:3 to 1:6. For this analysis, patients were not randomized into continuous or intermittent VS monitoring. The type of monitoring was dependent upon the floor a patient was admitted to, which was dependent on bed availability and not patient clinical status. Based on clinical experience, there would not have been a significant crossover between groups; that is, once a patient arrived on the floor and was allocated to either continuous or intermittent VS monitoring, they would then most likely continue that strategy until discharge—unless, for example, a patient was transferred to a different unit and received a different type of monitoring strategy there.

The ViSi device records oxygen saturation (SpO_2), HR, respiratory rate (RR), continuous noninvasive BP, and either 3-lead or 5-lead electrocardiogram. Continuous BP measurements are estimated from pulse arrival time, specifically the time that elapses between the R wave being detected and the arrival of the resulting pulse at the SpO_2 finger sensor. According to the manufacturer, the estimated maximal mean error for BP measurements is 5 mm Hg with a standard deviation ≤8 mm Hg [23].

ViSi monitors were calibrated daily with the oscillometric brachial cuff method and connected to the hospital's wireless network, and measurements were distributed to the central nurse's station for that unit and continuously displayed. The ViSi monitoring system measures VS nearly continuously, and these data are transmitted to the central nurse's station for each respective unit; however, these data are not transmitted nor recorded directly in the EHR. That is, nurses or nursing assistants must still see the patient and collect VS from the device or the monitoring station remotely and then manually document (chart) these vitals in the EHR. No matter what, the VS assessment includes direct patient visualization to measure and record patient alertness. The VS data not recorded in the EHR are temporarily stored on the ViSi manufacturer's cloud for a set period of time and are then destroyed. Unfortunately, we were *only* able to acquire and evaluate the EHR data.

VS abnormalities exceeding established thresholds for the local hospital system generated alerts at the floor's central nursing station and to the nurses' hospital-supplied phones (ASCOM). Alarms not addressed by the primary nurses were escalated to other floor nurses, then to the unit manager. Time to escalation depended on the VS and the relative degree of abnormality. For example, SpO_2 abnormality alerts, if not acknowledged, were quickly escalated over minutes.

EWS at our institution are based on the patient's weighted VS of HR, RR, SpO_2, temperature, BP, rate and percentage of inspired oxygen, and level of awareness determined by the patient's nurse [24]. EWS are calculated by the EHR every 4 hours based on data input from ViSi monitors, which can be collected from the central display or at the bedside, or those collected by intermittent monitoring. Patients, regardless of monitoring strategy, must be observed at bedside to determine level of awareness for EWS calculation. Total scores range from 0 to 20. Ad hoc EWS may be generated by the clinical team in response to changes in a patient's clinical status through either monitoring strategy. For example, if abnormal VS are detected by ViSi monitoring and an alarm is generated at the central nurse's station, the clinical team may assess the patient and generate an updated EWS. An RRT activation is triggered if the EWS is ≥8.

Outcomes

Our primary outcome was the risk of a composite of in-hospital mortality or ICU admission during the hospital encounter. Secondary outcomes were the individual components of the primary outcome (in-hospital mortality and ICU admission), as well as HF, MI, AKI, and RRT activations throughout the hospitalization. Exploratory outcomes included hospital length of stay (LOS), ICU LOS, and median EWS values for the entire LOS. Diagnoses of HF, MI, and AKI were identified using International Classification of Diseases, Tenth Revision billing codes available in the EHR.

Statistical Analysis

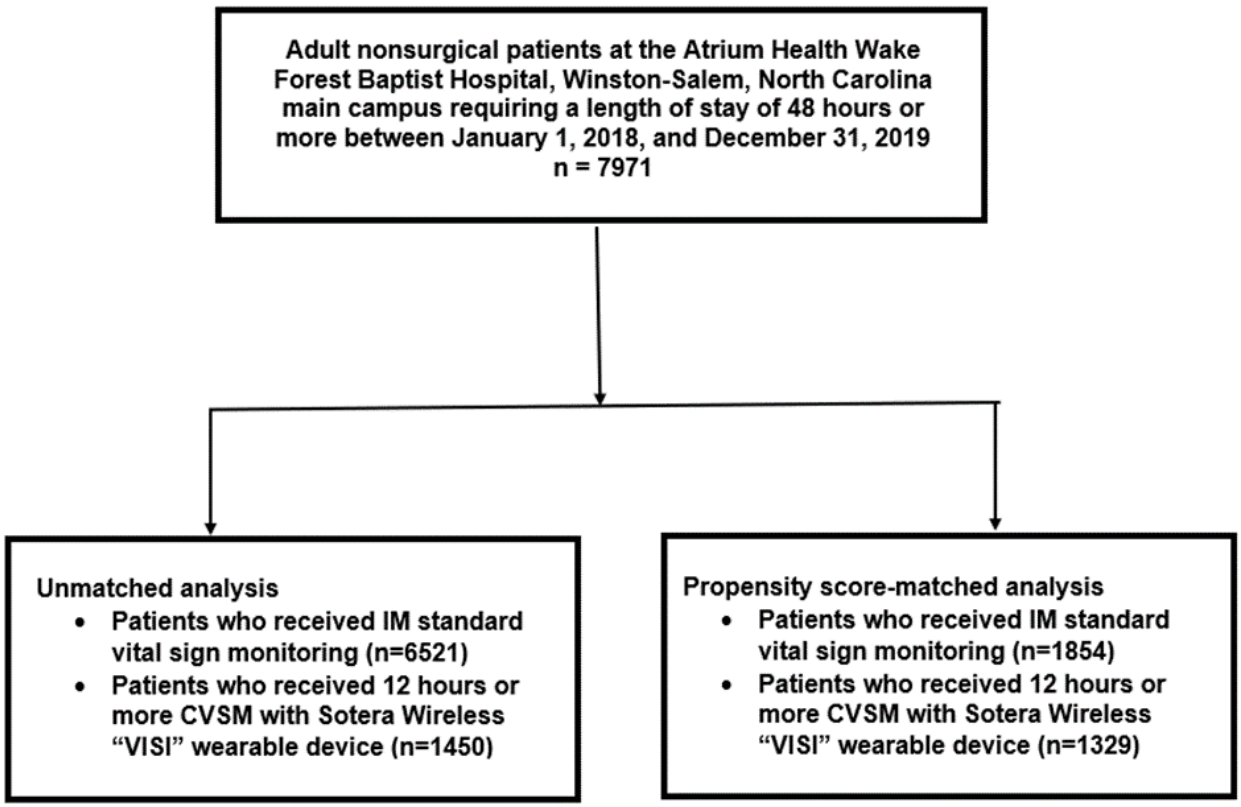
Statistical analysis was performed in R v3.6.1 (R Foundation for Statistical Computing) using RStudio environment v1.1.456. The participants were first stratified into continuous VS monitoring and contemporaneous controls as intermittent VS monitoring groups. Sequential random nearest neighbor matching with a propensity score ratio of 1:3 and with a caliper of 0.25 [25,26] was used to balance the potential factors affecting the outcome including selection bias. To create propensity score–matched pairs, we performed random 1-to-3 matching using the MatchIt package in R, in which the control variables in our study were race, gender, ethnicity, age,

XSL•FO
RenderX

quarter-year of admission, BMI, Charlson Comorbidity Index (CCI), patient's primary insurance type, and source of admission [27]. The variable selection for propensity score matching was based on feedback from clinical expertise. To adjust for the effect of time and variability of the continuous wireless monitoring device use, the quarter-year of admission was used as a covariate in the model. Standardized differences were used as indicators of intergroup balance. If the standardized differences were <10%, the covariates between the 2 groups were considered well-balanced.

For summary statistics, categorical variables were described as numbers and percentages, and non-normally distributed continuous variables were described as median and IQRs.

Primary, secondary, and exploratory outcomes were compared between groups and subgroups. Multivariable logistic regression analysis was performed to detect differences in outcomes between groups. Initially, restricted cubic splines were included with age and CCI to relax the linearity assumptions of the multivariable logistic regression model. As the nonlinear components of age and CCI were not statistically significant, the splines were removed from the variables. The multivariable logistic regression adjusted model was controlled for race, gender, ethnicity, age, BMI, patient's primary insurance type, source of admission, and CCI. The *P* value for significance level within the primary and secondary outcome analyses was set at .004 for each group of analyses after Bonferroni correction for multiple comparisons.



To test the influence of unobserved confounding, we used an E-value analysis to quantify the potential implications of unmeasured confounders. E-value is defined as the minimum strength of an association on the risk ratio scale that an unmeasured confounder would need to have with both the exposure and the outcome, conditional on the measured covariates, to fully explain away a specific exposure-outcome association.

We further performed multivariate logistic regression analysis for the composite outcome on the whole study cohort (n=7971) to assess the effect of continuous monitoring sensitivity after controlling for race, gender, ethnicity, age, BMI, and CCI as a sensitivity analysis.

Results

We identified 7971 patients who met inclusion criteria (Figure 1). Over the study period, 1450 patients received 12 hours or more of continuous VS monitoring, compared with 6521 contemporaneous controls who received intermittent VS monitoring (Table 1).

For propensity matching, 1329 (1329/1450, 91.7%) patients receiving continuous wireless VS monitoring were matched with 1854 (1854/6521, 28.4%) contemporaneous patients receiving intermittent VS monitoring. When propensity matching was not possible, they were excluded from propensity score–matched analysis. Multimedia Appendix 1 shows the patient demographics and clinical characteristics of patients not matched.

Before propensity matching, 365 (365/6521, 5.6%) of intermittent VS monitoring patients had in-hospital mortality or ICU admission compared with 29 (29/1450, 2%) in the continuous wireless VS monitoring group (Multimedia Appendix 2).

After propensity matching, patients who had intermittent VS monitoring had greater odds of the primary composite outcome, compared with patients who were on continuous VS monitoring (odds ratio 2.79, 95% CI 1.89-4.25; *P*<.001; Table 2, Figure 2).

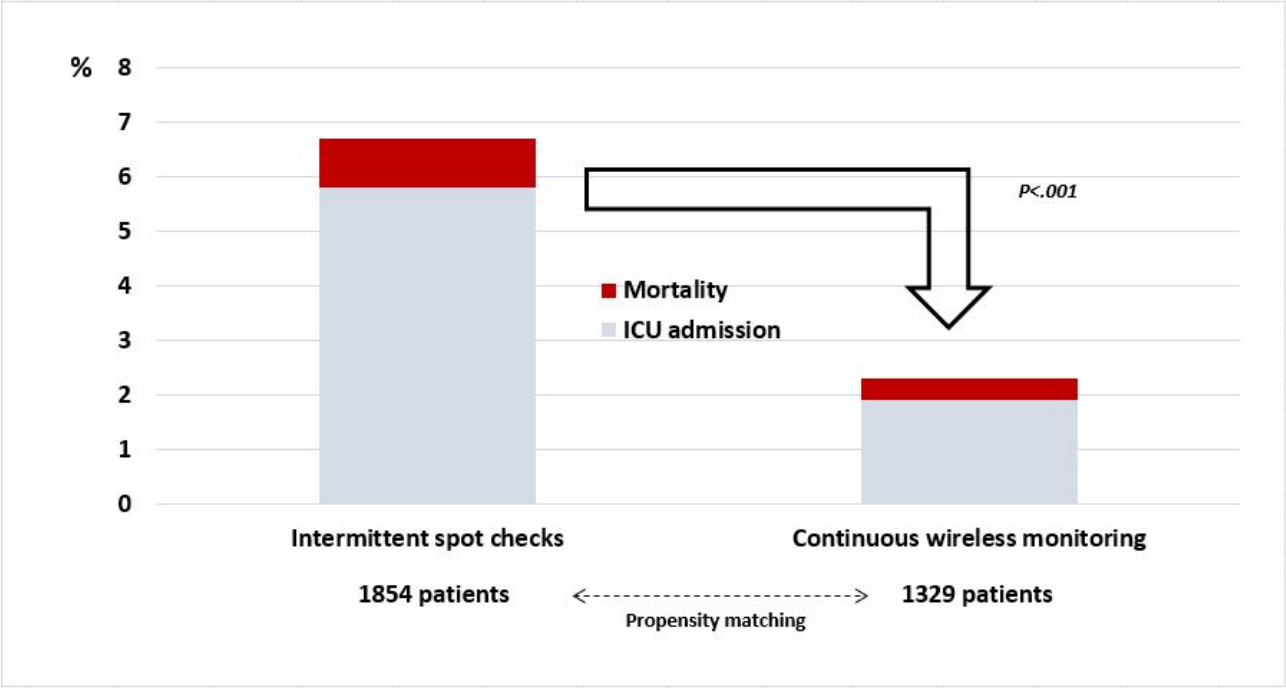

Table 2. Primary and secondary outcomes in the unmatched and matched models from the retrospective propensity-matched analysis of continuous versus intermittent vital sign monitoring in primary medical patients at an academic tertiary medical center from January 1, 2018, to December 31, 2019.

Outcomes	Unmatched model		Propensity-matched model		E value
	Odds ratio (95% CI)	*P* value	Odds ratio (95% CI)	*P* value	
Composite of in-hospital mortality or ICU[a] admission	2.79 (1.96-4.15)	<.001	2.79 (1.89-4.25)	<.001	2.73
In-hospital mortality	2.11 (0.99-4.47)	.08	1.91 (0.79-4.31)	.18	2.11
ICU admission	3.02 (2.06-4.63)	<.001	3.07 (2.03-4.82)	<.001	2.91
Heart failure	0.96 (0.81-1.14)	.63	1.03 (0.83-1.28)	.77	1.14
Myocardial infarction	1.22 (0.69-2.38)	.52	1.58 (0.77-3.47)	.23	1.83

monitoring. Hospital LOS, ICU LOS, and median EWS during the LOS are shown in Table 3.

Figure 3. Forest plot of odds ratios (95% CIs) of primary and secondary outcomes for patients receiving intermittent monitoring vs continuous wireless vital sign monitoring from the retrospective propensity-matched analysis in primary medical patients at an academic tertiary medical center from January 1, 2018, to December 31, 2019. ICU: intensive care unit; RRT: rapid response team.

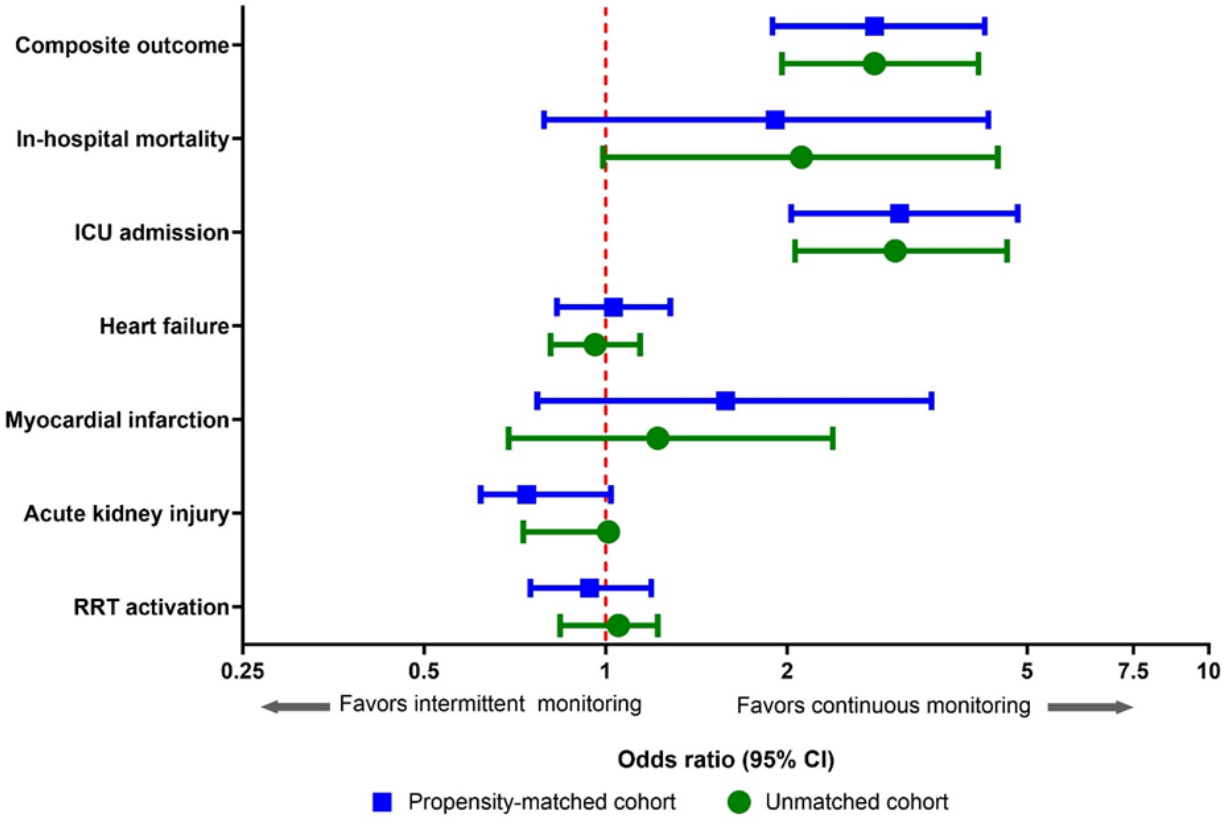

Table 3. Table 3. Exploratory outcomes for propensity-matched cohorts from the retrospective propensity-matched analysis of continuous versus intermittent vital sign monitoring in primary medical patients at an academic tertiary medical center from January 1, 2018, to December 31, 2019.

Outcomes	Continuous vital sign monitoring (n=1329)	Intermittent vital sign monitoring (n=1854)	*P* value
Hospital LOS[a] (days), median (IQR)	3.12 (2.07-5.25)	3.21 (2.09-5.30)	.80
ICU[b] LOS (days), median (IQR)	3.32 (2.01-4.75)	2.45 (1.73-4.00)	.10
EWS[c] during LOS, median (minimum-maximum)	2.00 (1.00-9.00)	1.00 (0.00-9.00)	<.001

[a]LOS: length of stay.

[b]ICU: intensive care unit.

[c]EWS: early warning score.

Multimedia Appendix 3 shows the covariate balance plot before and after propensity score matching between the continuous monitoring cohort and intermittent monitoring cohort. A caliper width of 0.25 was used for the propensity match.

Discussion

Principal Findings

In this retrospective propensity-matched analysis, the standard of care intermittent VS monitoring of adult medical ward patients was associated with nearly 3-fold greater odds of ICU admission or in-hospital mortality as compared with continuous VS monitoring. Our work is novel in that this is, to the best of our knowledge, the first propensity-matched study of continuous VS monitoring in the medical ward. Primary medical admissions are inherently different from surgical ones. Medical patients often have multiple acute problems related to single or multiple intersected disease processes.

Comparison With Prior Work

Our findings corroborate several before-and-after studies mainly conducted with surgical cohorts and are additionally supported by a recently published propensity-matched study by our group in a primary surgical population [28-30]. We hypothesized that, through earlier detection with continuous VS monitoring, patients were able to receive clinical attention sooner, thereby precluding severe clinical deterioration requiring ICU admission.

XSL•FO
RenderX

This hypothesis is supported by similar RRT activation rates but greater odds of ICU admission of patients receiving intermittent VS monitoring.

We report a significant difference in favor of continuous monitoring for the primary composite outcome; however, this composite is only from ICU admissions. When compared with a recently published national database study of unplanned ICU admissions of patients who received standard of care intermittent monitoring, we had a greater percentage of patients in our intermittent monitoring arm transfer to the ICU (2.5% vs 5.8%) [31]. Baseline characteristics, including median CCI, were similar; however, the national study included patients with COVID-19 (2021), while our study examined a prepandemic cohort (2018-2019). Moreover, hospitals in the national database varied significantly from ours in terms of size, teaching status, and regional location, which could have influenced outcomes.

Limitations

Our study was limited primarily by its retrospective approach. First, although propensity matching allowed us to match patients on baseline covariates, we were unable to match based on admission diagnosis or ongoing changes in a patient's hospital course. We were unable to match on admission diagnosis due to limitations in our EHR data (eg, admission diagnosis missing, inaccurate, or incorrect). Changes over the hospital course occurred after receiving the intervention (continuous versus intermittent monitoring); therefore, the changes were not used to match patients. The inability to match admission diagnosis is a major limitation, but we feel this is offset by our hospital's triage system by bed availability, which is agnostic to monitoring strategy. The use of continuous wireless VS monitoring or intermittent VS monitoring was not based on patient condition, but it is possible that, over time, patients admitted to continuous VS monitoring units may have represented a subset of clinically different patients from their intermittent VS monitoring counterparts. That is, patients receiving intermittent VS monitoring may have initially been sicker, or more continuous wireless VS monitoring use may have been deployed over a time course to a healthier group. To account for these differences, cohorts were matched on a combination of baseline covariates present on admission along with every quarter-year of admission to adjust for time variance of continuous wireless VS monitoring use throughout our large hospital system. The difference between the number of patients receiving continuous VS monitoring in 2018 compared with 2019 is related to an issue that occurred with the continuous VS monitoring server. Our approach with propensity matching was set at a caliper of 0.25, and the drop-off for continuously monitored patients does demonstrate that patient groups may be different at baseline within the defined caliper. Most of the imbalance was due to the time of year of admission and CCI, which was matched adequately. An increase in the caliper from 0.25 to 0.35 did not show any significant change in the matched cohort number. Second, we relied on reported rates of conditions from discharge summaries and administrative codes, which have their inherent flaws.

Third, our large administrative data set does not have granular information that would allow a deeper understanding of the mechanisms of favorable outcomes with continuous VS monitoring. This includes the number of and reasons for alarms and false alarms as well as the VS captured by the continuous devices. Similarly, we had limited information on EWS values at the time of RRT activation but did include median, minimum, and maximum EWS and absolute numbers of RRT activations for the entire LOS for both groups. A smaller pilot from the same institution and devices showed a rate of 2.3 alarms per patient per day and a significant decrease in RRT calls, from 189 to 158 per 1000 discharges after implementation using a before-and-after study design [21].

Future Directions

Interesting future outcome research could include whether continuous VS monitoring was associated with changes in medical management, including the timing of antibiotics, discontinuation of supplemental oxygen, and antihypertensive prescriptions. Future work should consider the limitations of this study in order to strengthen the approach, including admission diagnosis matching, granular VS capture, and comparisons between monitoring strategies.

Conclusion

The ability to continuously monitor patient VS outside of the critical care unit or emergency department using a wearable and wireless device represents a significant technological advancement. However, the quality of evidence for the benefit of continuous VS monitoring is low to moderate, and most studies have been performed in the postoperative setting with before-and-after comparisons. This is the first propensity-matched study using a large data set with contemporaneous controls and a focus on patients with primary medical problems. The inherent differences between a primary surgical population, where nearly all continuous postprocedure monitoring research has been conducted, and a primary medical population is paramount to the significance of this work.

In conclusion, patients receiving intermittent VS monitoring had nearly a factor-of-3 increase in the odds of ICU transfer and in-hospital mortality compared with those receiving continuous VS monitoring. Prospective interventional studies are necessary to confirm the impact of continuous VS monitoring on morbidity and mortality.

Abstract

Background: Antimicrobial resistance is a global threat. Australia has high antibiotic prescribing rates with the majority of antibiotics prescribed by general practitioners (GPs) for self-limiting acute respiratory tract infection (ARTIs). Australian GP trainees' (registrars') prescribing for ARTIs may have been affected by the introduction of remunerated telehealth consultations in 2020. Understanding of the impact of telehealth on antibiotic stewardship may inform registrar educational programs.

Objective: This study aimed to compare the prevalence of antibiotic prescribing by GP registrars in telehealth versus face-to-face (F2F) consultations for common cold (upper respiratory tract infection [URTI]), bronchitis, sore throat, acute otitis media, and sinusitis.

Methods: A cross-sectional analysis of data from the Registrar Clinical Encounters in Training (ReCEnT) study, a multicenter inception cohort study of registrars' in-consultation clinical and educational experiences. Analysis used univariable and multivariable logistic regression using 2020-2023 ReCEnT data. The outcome variable was "antibiotic prescribed" for new presentations of URTI, acute sore throat, acute bronchitis, acute sinusitis, and acute otitis media. The study factor was consultation type (telehealth or F2F).

Results: A total of 2392 registrars participated (response rate=93.4%). The proportions of diagnoses that were managed via telehealth were 25% (5283/21384) overall, 19% (641/3327) for acute sore throat, 29% (3733/12773) for URTI, 21% (364/1772), for acute bronchitis, 4.1% (72/1758) for acute otitis media, and 27% (473/1754) for acute sinusitis. Antibiotics were prescribed for 51% (1685/3327) of sore throat diagnoses, 6.9% (880/12773) of URTI diagnoses, 64% (1140/1772) of bronchitis diagnoses, 61% (1067/1754) of sinusitis diagnoses, and 73% (1278/1758) of otitis media diagnoses. On multivariable analysis, antibiotics were less often prescribed in telehealth than F2F consultations for sore throat (adjusted odds ratio [OR] 0.69, 95% CI 0.55-0.86; *P*=.001), URTI (adjusted OR 0.64, 95% CI 0.51-0.81; *P*<.001), and otitis media (adjusted OR 0.47, 95% CI 0.26-0.84; *P*=.01).

XSL•FO
RenderX

There were no significant differences for acute bronchitis (adjusted OR 1.07, 95% CI 0.79-1.45; *P*=.66) or acute sinusitis (adjusted OR 1, 95% CI 0.76-1.32; *P*=.99).

Conclusions: GP registrars are less likely to prescribe antibiotics for sore throat, URTI, and otitis media when seeing patients by telehealth versus F2F. Understanding the reason for this difference is essential to help guide educational efforts aimed at decreasing antibiotic prescribing by GPs for conditions such as ARTIs where they are of little to no benefit. There was no evidence in this study that telehealth consultations were associated with greater registrar antibiotic prescribing for ARTIs. Therefore, there is no deleterious effect on antibiotic stewardship.

Introduction

Antimicrobial resistance is a major threat to global health [1]. Australia's antibiotic prescribing rates are much higher than countries of similar socioeconomic status. In 2021, the rate of Australian community antimicrobial use was 17.5 defined daily doses (DDD) per 1000 inhabitants per day, compared with England (15.9 DDD), Canada (11.4 DDD), and the Netherlands (7.9 DDD) [2]. The majority of antibiotics in Australia are prescribed in general practice (family practice). Inappropriate prescribing of antibiotics in outpatient settings, especially in primary care or general practice, is a major driver of antimicrobial resistance [3]. Therefore, antibiotic stewardship in general practice is vital.

In 2022, overall 36.6% of Australians were prescribed at least one antibiotic in the community [2]. The most common reason for prescription of antibiotics in general practice is nonpneumonia, self-limiting acute respiratory tract infections (ARTIs) [4]. ARTIs (common cold [upper respiratory tract infection {URTI}], acute bronchitis, acute sore throat, acute otitis media, and acute sinusitis) are not generally recommended to be treated with antibiotics, irrespective of symptom severity (in the case of URTI and bronchitis) [2,5-7]. Established Australian general practitioners (GPs) have been found to prescribe antibiotics for ARTIs at a higher rate than European GPs [2,8].

Vocational trainees in general practice are a group of particular interest regarding antibiotic stewardship. Trainees are developing and establishing patterns of practice that may be stable over time [9-11], including antibiotic prescribing [12]. In Australia, GP trainees ("GP registrars") comprised 16% of the GP workforce by headcount in 2022-2023 [13]. They have lower antibiotic prescribing rates for ARTIs compared with established Australian GPs [14]. In 2019, established GPs prescribed antibiotics in 36% of acute URTI and 82% of bronchitis cases, whereas registrars prescribed antibiotics in 12% of acute URTI and 72% of bronchitis cases. A similar trend exists for Australian GPs and registrars' prescribing for sore throat, otitis media, and sinusitis [15,16].

Furthermore, in longitudinal analyses between 2010 and 2019, registrars' prescribing for URTI, acute bronchitis, sore throat, sinusitis, and otitis media reduced significantly [16,17]. URTI prescribing decreased from 24% of presentations in 2010 to 12% in 2019, acute bronchitis or bronchiolitis prescribing from 84% to 72%, sore throat from 76% to 60%, otitis media from 88% to 77%, and sinusitis from 84% to 66% [16,17]. While these temporal trends are mirrored in both established GP and registrar populations [15-17] and despite lower prescribing rates than established GPs, registrars' antibiotic prescribing for most ARTIs still exceeds international benchmarks [5,8].

Due to community lockdown and implementation of strict infection prevention during the COVID-19 pandemic, remuneration for Australian GP telehealth consultations was introduced (via the Medicare Benefits Schedule of medical services subsidized by the Australian Government [18]). In the second quarter of 2020, overall 36% of GP consultations in Australia were conducted via telehealth and it is now an established mode of consultation in Australian general practice [19].

Antibiotic prescribing may be affected by consultation modality, that is, remote telehealth consultations as compared with face-to-face (F2F) consultations. It is plausible that clinical uncertainty related to reduced diagnostic confidence consequent upon limited ability to examine patients might drive inappropriate antibiotic prescribing [20,21]. This has implications for antibiotic stewardship. A systemic review and meta-analysis reported that antibiotics were more highly prescribed in telehealth consultations for otitis media and pharyngitis. However, no difference was found in prescribing between modalities for sinusitis, upper respiratory infections, or urinary tract infections [22]. In another systematic review and meta-analysis of 13 studies, antibiotic prescribing for respiratory, urinary, or skin and soft tissue infections in telehealth compared with F2F consultations varied depending on infection type [23]. When the 10 observational studies were pooled, there was significantly less prescribing for sinusitis in telehealth consultations and significantly more prescribing for otitis media in telehealth consultations. Pharyngitis, conjunctivitis, and urinary tract infections had nonsignificantly higher antibiotic prescribing rates in telehealth consultations. There was also no significant difference in prescribing for bronchitis between the 2 modalities [23]. However, the methodological quality of these studies indicates that more research is needed into the effect of consultation modality on antibiotic prescribing rates.

XSL•FO
RenderX

A further systematic review found that studies (published before February 2020) of remote prescribing (telephone, video, internet-based, and text-based consultations) of antibiotics for respiratory tract disease, compared with F2F consultations, had similarly conflicting results [24].

A qualitative study of Australian GP registrars and their clinical supervisors found concerns regarding impaired diagnostic capacity for ARTIs during telehealth consultations and suggested that this could lead to organizing further in-person assessment (arrangement of a F2F follow-up appointment to confirm the diagnosis) or to overprescribing of antibiotics [21]. Overall, there remains a large evidence gap relating to the effects of consultation modality on antibiotic prescribing and the potential reasons for this effect.

The context of, and impetus for, the introduction remunerated telehealth in Australia was the COVID-19 pandemic. An interrupted time-series analysis in England found the overall volume of prescribing of antibiotics primarily used for ARTIs increased between national lockdown in March 2020 and May 2022 [25]. Some Australian studies have found that there was a substantial decrease in dispensing of antimicrobials in Australia in 2020 [2], especially for antibiotics commonly prescribed for ARTIs [26]. A retrospective study also found that the proportion of respiratory tract infections (not further defined) for which antibiotics were prescribed via telehealth was lower than that of F2F consultations at an early stage of the pandemic. However, this percentage progressively increased over time, and by the end of 2021 was almost equivalent to that of F2F consultations [27].

Therefore, there is still some uncertainty regarding whether consultation modality affects antibiotic prescribing rates in primary care settings. GP registrars are a physician demographic of singular interest in this aspect of antibiotic stewardship. They are in a formative stage of their careers when practice patterns are being formed, and once established, GPs may continue to prescribe antibiotics [11,12]. A particular cause for concern related to telehealth during this formative practice period is that clinical uncertainty may drive registrars' inappropriate antibiotic prescribing [20,21]. Given constraints on important diagnostic components (physical examination) during telehealth, it is plausible that widespread uptake of telehealth may be problematic for registrars' antibiotic stewardship.

To the best of our knowledge, no studies have been conducted on the prevalence of GP registrars' or trainees' antibiotic prescribing for respiratory tract infections through telehealth. Understanding antibiotic prescribing patterns in telehealth versus F2F consultations will help inform GP registrar education and training in antimicrobial stewardship.

This study aimed to address this evidence gap by estimating the prevalence of antibiotic prescribing by GP registrars for URTI, bronchitis, sore throat, acute otitis media, and sinusitis during telehealth as compared with F2F consultations. We hypothesized that registrars would prescribe antibiotics in a greater proportion of telehealth consultations for URTI, bronchitis, sore throat, acute otitis media, and sinusitis than prescribed in F2F consultations.

Methods

Study Design

This was a cross-sectional analysis nested within the Registrar Clinical Encounters in Training (ReCEnT) study.

ReCEnT Setting and Participants

ReCEnT is a multicenter inception cohort study of Australian GP registrars' in-consultation clinical and educational experience. The detailed methodology is published elsewhere [28]. ReCEnT is a routine part of the educational program of registrars in participating training regions. Registrars may also elect to provide informed consent for the data to be used for research purposes. During the period reported here, all registrars training in New South Wales, Tasmania, and eastern Victoria (approximately 43% of Australian GP registrars) [29] were eligible for participation.

ReCEnT Data Collection

In ReCEnT, each registrar electronically records details of 60 consecutive consultations, once in each of their first 3 general practice training terms [28]. At the beginning of each collection period, registrars provide demographics and practice data via a questionnaire. In each of the 60 individual consecutive consultations, patient demographics, diagnosis formulations, and clinical and educational actions are recorded. Data are recorded via a dedicated internet-based portal.

For the analyses reported here, data from 7 six-monthly data collection rounds between 2020 and 2023 (following the onset of COVID-19 pandemic with consequent expanded telehealth remuneration for GPs) were used.

Outcome and Study Factor

The outcome factor was "antibiotics prescribed" (yes or no). This was determined using the Anatomical Therapeutic Chemical Classification J01 [30]. The study factor (independent variable of interest) was "consultation modality" (F2F or telehealth). "Telehealth" included both telephone and videoconference consultations.

Independent Variables

Analyses were adjusted for a large range of independent covariates. These included registrar, patient, practice, and consultation variables. The registrar variables were age, gender, training term, full-time, or part-time training status, if qualified as doctor in Australia, and if the registrar had worked at the practice previously.

Patient variables were age group specific to the ARTI problem type (refer to Table S1 in Multimedia Appendix 1), gender, Aboriginal and/or Torres Strait Islander status, and whether the patient was new to the practice or to the registrar.

Practice variables were training region, rurality determined by the Australian Standard Geographical Classification [31], practice size (practices with <6 full-time equivalent doctors are considered "small practices"), socioeconomic status of the practice location (Socioeconomic Index for Areas-Index of Relative Social Disadvantage) [32], and billing policy (whether

XSL•FO
RenderX

the practice routinely bulk bills all patients, ie, accepts the government-provided rebate as payment in full).

Consultation content variables were consultation duration, number of diagnoses managed, and whether registrars sought assistance or information during the consultation (no information source used, supervisor called, and another source used).

Consultation action variables included whether pathology was ordered, whether imaging was ordered, whether referrals were made, whether follow-ups were arranged, and whether learning goals were generated.

Analysis Level

Analyses were conducted at the level of individual diagnosis (rather than at the registrar or consultation level). The diagnoses were restricted to initial presentations of several self-limited and nonpneumonia ARTIs: acute bronchitis, URTI, acute otitis media, acute sore throat, and acute sinusitis. Refer to Table S1 in Multimedia Appendix 1 for the International Classification of Primary Care 2 plus codes used for these diagnoses [33].

Statistical Methods

Participant Characteristics

Overall characteristics of the registrars who participated in this study were calculated at either the registrar level or registrar-round level (each individual registrar contributes up to 3 rounds of data) and reported as n (%) or mean (SD).

Descriptive Analyses

Total diagnoses of the conditions of interest and the proportions of these diagnoses managed by telehealth were calculated. The proportion of telehealth consultations that were undertaken via video compared with phone was calculated.

The proportion of antibiotics prescribed for all new ARTI diagnoses, and individually for new URTIs, acute bronchitis, acute sore throat, acute otitis media, and acute sinusitis, was calculated for telehealth consultations and for F2F consultations. The proportion of types of antibiotics by ARTI diagnoses and consultation modality was also calculated.

Main Analyses

To estimate the association between consultation modality and antibiotic prescription, univariable and multivariable logistic regression models were estimated with the outcome “antibiotic prescribed” for new cases of each of the following: URTI, acute bronchitis, acute sore throat, acute otitis media, and acute sinusitis. Models were estimated within the generalized estimating equations framework to account for repeated measures within registrars. An exchangeable working correlation structure was assumed. An augmented backward selection process was followed to select explanatory variables for inclusion in the final multivariable model for each diagnosis. Variables in the model with *P* values of >.20 were tested for removal. A variable was removed if the resulting model did not have substantively different effect sizes than the previous model (more than 10% different from its value in the previous model). Model fit was assessed using the Hosmer-Lemeshow goodness of fit test. The logistic model assumption of linearity in the log-odds for continuous variables was also checked.

Regressions modeled the log-odds that antibiotics were prescribed for a given presentation. Effects are expressed as odds ratios (ORs) with 95% CIs. Significance was declared at the conventional .05 level, with the magnitude and precision of effect estimates also used to interpret results. Analyses were programmed using STATA (version 16.0; StataCorp) and SAS (version 9.4; SAS Institute).

Post Hoc Analysis

In post hoc analyses, the proportion of registrars’ arrangement of follow-up appointments (with themselves or another GP at the practice) following the index consultation for each ARTI, separately for telehealth and F2F index consultations, was calculated. Differences for telehealth compared with F2F index consultations were tested with chi-square tests.

Missing data were handled using complete case analysis. No imputation was performed to address the missing data (Tables S2-S6 in Multimedia Appendix 2).

Ethical Considerations

Ethics approval was by the University of Newcastle Human Research Ethics Committee (Reference H-2009-0323) and the RACGP National Research and Evaluation Ethics Committee (NREEC-23-0000000161). Registrars provided written informed consent for data routinely collected as part of the educational program to also be used for research purposes. All data were deidentified. No compensation was provided to participants as ReCEnT is a routine part of training.

Results

Participant Characteristics

A total of 2392 registrars (response rate: 93.4%) contributed data from 301,403 consultations, entailing in 425,059 diagnoses. Table 1 provides details of the characteristics of participating registrars.

[b]ACRRM: Australian College of Rural and Remote Medicine.

[c]FTE: full-time equivalent.

[d]GP: general practitioner.

[e]SEIFA-IRSD: Socioeconomic Indexes for Areas-Index of Relative Social Disadvantage [32].

Descriptive Findings

Overall, there were 21,384 new diagnoses of our 5 nominated conditions available for analysis. These included 3327, 12,773, 1772, 1754, and 1758 new diagnoses of sore throat, URTI, bronchitis, sinusitis, and otitis media representing 0.7%, 3%, 0.4%, 0.4%, and 0.4%, of all diagnoses, respectively.

The proportions of diagnoses managed via telehealth were as follows: ARTI, 25% (5283/21384); acute sore throat, 19% (641/3327); URTI, 29% (3733/12773); acute bronchitis, 21% (364/1772); acute otitis media; 4.1% (72/1758) and acute sinusitis; and 27% (473/1754). Of the total ARTI consultations managed via telehealth (n=5283), most were managed over the phone (video consult rate: 3.8% [201/5283]). Patient and consultation factors are given in Table 2 for telehealth versus F2F consultations.

For all ARTIs, overall, antibiotics were prescribed in 20% (1035/5283) of telehealth diagnoses compared with 31% (5015/16101) of F2F diagnoses. Refer to Table S7 in Multimedia Appendix 3 for the most commonly prescribed antibiotics for each condition. Refer to Tables S8-S12 in Multimedia Appendix 4 for the characteristics associated with prescribing antibiotics for each ARTI condition.

[a]ARTI: acute respiratory tract infection.

Main Analyses

Examining each of the 5 individual ARTI conditions: the proportions for which antibiotics were prescribed, and the unadjusted and adjusted ORs (from the univariable and multivariable logistic models) for prescribing antibiotics in telehealth, as compared with F2F consultations, are given in Table 3 (refer to Tables S13-S17 in Multimedia Appendix 5 for the full models). The univariable analyses showed reduced odds of prescribing antibiotics via telehealth (compared with F2F) for sore throat (OR 0.62, 95% CI 0.52-0.74; *P*<.001), and URTI (OR 0.62, 95% CI 0.52-0.75; *P*<.001) but greater odds of prescribing for acute bronchitis (OR 1.40, 95% CI 1.11-1.76; *P*=.005), whilst in multivariable analyses, there were statistically significant differences for sore throat (adjusted OR 0.69, 95% CI 0.55-0.86; *P*=.001), URTI (adjusted OR 0.64, 95% CI 0.51-0.81; *P*<.001), and otitis media (adjusted OR 0.47, 95% CI 0.26-0.84; *P*=.01).

[a]OR: odds ratio.

[b]URTI: upper respiratory tract infection.

Post Hoc Analysis

The percentages of registrars' new ARTI diagnoses with follow-up GP appointments organized are presented in Table 4. There were no statistically significant changes in follow-up, but there was some evidence for more follow-ups following F2F for new otitis media problems (*P*=.06) with clinically significant effect size n/N (11.5%).

[a]URTI: upper respiratory tract infection.

Discussion

Principal Findings

On multivariable analysis, antibiotics were (statistically and clinically) significantly more likely to be prescribed in F2F consultations than in telehealth consultations for sore throat, URTI, and otitis media problems. For sinusitis and bronchitis, there were no significant differences in prescribing. There were no significant differences in rates of follow-up consultations organized for ARTIs between the initial consultation modalities, though there was some evidence (*P*=.06) for follow-up appointments to be made more frequently following F2F appointments when the diagnosis was acute otitis media.

Comparison to Previous Work

A context for our findings (which are specific to antibiotic prescribing for ARTIs) is that previous studies have reported significantly higher rates of prescribing of medicines in general in F2F consultations compared with telehealth consultations, both by Australian GP registrars [34] and in the wider Australian general practice context [35]. In line with this trend, a recent international publication which compared antibiotic prescribing rates for infections (including but not limited to ARTIs) reported higher prescribing rates in F2F consultations [36].

Our results similarly suggest that antibiotics were more likely to be prescribed in F2F consultations for URTI, otitis media, and sore throat. However, these findings differ from results from 2 systematic reviews and meta-analyses [22,23]. Bakhit et al [23] reported greater antibiotic prescribing for otitis media in telehealth consultations, but no difference between consultation modalities in antibiotic prescribing for pharyngitis. Suzuki et al [22] similarly reported that antibiotics were more frequently prescribed via telehealth for otitis media and pharyngitis. This may be partially due to differences in disease classifications. For example, our classification of sore throat includes, but is not limited to, pharyngitis, whereas both of these systematic reviews examine pharyngitis alone, or group all ARTIs together [22,23]. Furthermore, our study was restricted to a GP registrar population, compared with a wider GP population in these systematic reviews.

Regarding sinusitis and bronchitis, our results are consistent with previous studies that reported no significant difference in antibiotic prescribing rates between consultation modalities for sinusitis [22] or bronchitis [23]. In contrast, some studies have reported that fewer antibiotics were prescribed in telehealth vs F2F consultations for sinusitis [23,37,38]. Previous studies reported that the overall antibiotic prescription rates were lower in telehealth consultations for respiratory tract infections [27], especially in early stages of the COVID-19 pandemic (between 2020 2021), both in Australia [26] and internationally [39,40]. Therefore, it is possible that some of these discrepancies may relate to changes in antibiotic prescribing by modality over time, given that our data are from 2020 to 2023.

One possible explanation for our finding of fewer antibiotic prescribing in telehealth consultations is that registrars organized prompt review appointments (eg, to be able to adequately examine the patient) and deferred antibiotic prescription to the F2F review. In a previous qualitative study, some Australian GPs indicated they were not likely to prescribe antibiotics for acute infections without physically examining the patient (in a follow-up consultation) [21]. However, in our post hoc univariate analyses, we found no significant evidence to support this contention. Similarly, a study looking at the management of sinusitis reported no difference in the follow-up rate between e-visits and F2F consultations [38].

XSL•FO
RenderX

Managing patient expectations may be easier in a telehealth consultation compared with a F2F consultation. A recent qualitative study on the management of acute infections via telehealth reported that some GPs found it easier to deny antibiotics during a telehealth consultation, which could be justified by the lack of physical examination [21]. Conversely, other GPs found themselves prescribing more antibiotics in telehealth consultations as a way to mitigate diagnostic uncertainty [21]. Therefore, while it may be easier to manage patient demand via telehealth, the evidence remains mixed.

Strengths and Limitations

The ReCEnT study has a large sample size, a singularly high response rate for studies of GPs [41], and collects are large amount of registrar, patient and practice variables, which allows for fine-grained adjustment for potential confounding in relationships of factors (eg, consultation mode) with registrars' prescribing. A particular strength is the tight linkage of prescribed medicine with the diagnosis for which it was prescribed.

A further strength is that, in contrast to a number of other studies of this topic, we examined individual clinical presentations (sore throat, acute bronchitis, acute otitis media, URTI, and acute sinusitis) rather than a heterogeneous combination of conditions, such as "acute respiratory infections" [27].

The generalizability of our registrar population results to the wider, established GP population is potentially limited as vocational training is a singular period in GPs' professional lives. However, within the apprenticeship-like model of GP training in Australia, registrar prescribing behavior (including antibiotic prescribing) is strongly influenced by, and reflects, the prescribing of their supervisors and senior GP colleagues [20,42]. This is reflected in the temporal pattern of Australian registrars' antibiotic prescribing mirroring that of established GPs, though at slightly lower rates [15-17]. The generalizability of our findings to vocational training settings in countries beyond Australia is strong in countries with similar apprenticeship-like training structures (eg, the United Kingdom, New Zealand, Ireland, and several European countries). However, generalizability to countries with "residency" training programs, such as in North America [43], is less certain.

This study has several limitations. First, patients' past medical history and the severity of the index ARTI, which could affect patients and practices electing to schedule telehealth or F2F consultations, were not documented. However, antibiotics are not recommended by authoritative Australian evidence-based guidelines for URTI and acute bronchitis [6], irrespective of severity. For conditions such as acute otitis media, sore throat, and acute sinusitis, where antibiotics are indicated in some circumstances and symptom severity may influence both decision-making and the decisions to consult by F2F or telehealth, symptom severity is an unmeasured potential confounder in our analyses. However, it should be noted that symptom severity is not reliably recorded in primary care databases and is infrequently adjusted for in analyses of antibiotic prescribing [8,23,27,36,44].

Second, ReCEnT does not collect data on whether an antibiotic prescription was filled by the patient. However, this limitation is not of significant importance as the aim of the study was to establish registrars' prescribing behavior rather than patients' adherence.

Third, the cross-sectional study design does not allow for implications of causality. However, this study design was appropriate for the aim of estimating the prevalence of antibiotic prescribing by GP registrars for ARTIs during telehealth compared with F2F consultations.

Future Directions

It is possible that there is more clinical uncertainty in telehealth consultations due to the lack of physical examination, communication barriers, and potential miscommunication from poor internet connection or slow speeds [45]. However, concerns that diagnostic uncertainty (especially due to limitations to physical examination) may drive inappropriate antibiotic prescribing for ARTIs and compromise antimicrobial stewardship have not been supported by our findings, which may, in fact, suggest the contrary. Noting the heterogeneity in the literature on this topic, further research is indicated to establish if our findings are particular to registrars, during the COVID-19 and immediately after the COVID-19 period, or if there is unmeasured confounding in our findings.

Our findings also demonstrate the importance of considering individual respiratory tract infections rather than relying solely on analyses of grouped heterogeneous respiratory infections.

Registrars' antibiotic prescribing for sore throat, URTI, and otitis media diagnoses was significantly higher in F2F consultation than in telehealth consultations. However, there were no significant differences in antibiotic prescribing for bronchitis or sinusitis between the 2 consultation modalities. Therefore, we have no evidence from our work to discourage registrars from conducting telehealth consultations for ARTIs on the basis of concerns regarding antibiotic stewardship. Further research is needed to explore the reasons why registrars prescribe antibiotics more highly in F2F consultations than telehealth consultations for sore throat, URTI, and otitis media consultations.

Acknowledgments

We acknowledge the contribution of the GP registrars and the practices of the participating Regional Training Organizations, GP Synergy, Eastern Victoria GP Training, and General Practice Training Tasmania, and of the previous participating Regional Training Providers. In 2023, GP Synergy, Eastern Victoria GP Training, and General Practice Training Tasmania merged to deliver GP Training as part of the Royal Australian College of General Practitioners, funded by the Australian Department of Health. Alexandria Turner is funded through a postdoctoral fellowship from the National Health and Medical Research Council's (NHMRC) Centre for Research Excellence in Minimising Antibiotic Resistance in the Community (CRE-MARC).

Abstract

Background: Monitoring the emotional states of patients with psychiatric problems has always been challenging due to the noncontinuous nature of clinical assessments, the effect of the health care environment, and the inherent subjectivity of evaluation instruments. However, mental states in psychiatric disorders exhibit substantial variability over time, making real-time monitoring crucial for preventing risky situations and ensuring appropriate treatment.

Objective: This study aimed to leverage new technologies and deep learning techniques to enable more objective, real-time monitoring of patients. This was achieved by passively monitoring variables such as step count, patient location, and sleep patterns using mobile devices. We aimed to predict patient self-reports and detect sudden variations in their emotional valence, identifying situations that may require clinical intervention.

Methods: Data for this project were collected using the Evidence-Based Behavior (eB2) app, which records both passive and self-reported variables daily. Passive data refer to behavioral information gathered via the eB2 app through sensors embedded in mobile devices and wearables. These data were obtained from studies conducted in collaboration with hospitals and clinics that used eB2. We used hidden Markov models (HMMs) to address missing data and transformer deep neural networks for time-series forecasting. Finally, classification algorithms were applied to predict several variables, including emotional state and responses to the Patient Health Questionnaire-9.

Results: Through real-time patient monitoring, we demonstrated the ability to accurately predict patients' emotional states and anticipate changes over time. Specifically, our approach achieved high accuracy (0.93) and a receiver operating characteristic (ROC) area under the curve (AUC) of 0.98 for emotional valence classification. For predicting emotional state changes 1 day in advance, we obtained an ROC AUC of 0.87. Furthermore, we demonstrated the feasibility of forecasting responses to the Patient Health Questionnaire-9, with particularly strong performance for certain questions. For example, in question 9, related to suicidal ideation, our model achieved an accuracy of 0.9 and an ROC AUC of 0.77 for predicting the next day's response. Moreover, we illustrated the enhanced stability of multivariate time-series forecasting when HMM preprocessing was combined with a transformer model, as opposed to other time-series forecasting methods, such as recurrent neural networks or long short-term memory cells.

Conclusions: The stability of multivariate time-series forecasting improved when HMM preprocessing was combined with a transformer model, as opposed to other time-series forecasting methods (eg, recurrent neural network and long short-term memory), leveraging the attention mechanisms to capture longer time dependencies and gain interpretability. We showed the potential to assess the emotional state of a patient and the scores of psychiatric questionnaires from passive variables in advance. This allows real-time monitoring of patients and hence better risk detection and treatment adjustment.

Introduction

Background

The presence of a specific mood status is a necessary criterion for many psychiatric diagnoses, as outlined in the *Diagnostic and Statistical Manual of Mental Disorders* [1], and self-perceived mood is a fundamental component of assessing mental states in psychiatry [2,3]. Therefore, precise monitoring and following of mood conditions play a vital role in mental health care. For instance, both positive and negative mood states, as well as their fluctuations, have demonstrated their predictive value for significant outcomes, such as compulsive overeating episodes in bulimia nervosa, adherence to treatment in bipolar disorder, and opioid use disorders [4,5]. In recent years, technological advancements have facilitated the real-time tracking of individuals' self-reported mood status. One notable advancement is the use of smartphone-delivered ecological momentary assessment (EMA), which allows for the analysis of an individual's experiences, behavior, and emotions as they unfold in their natural environments [6]. However, the effectiveness of this method of mood state evaluation largely depends on the individual's level of self-awareness and ability to interact with the EMA platform. In many cases, psychiatric disorders can cause behavioral changes that decrease the likelihood of individuals engaging with an EMA tool, resulting in missing data. Consequently, a crucial research priority is the development of objective behavioral biomarkers for mood states that can be passively sensed without requiring active involvement from individuals.

By harnessing the power of patients' mobile phones and wearable devices, it has become feasible to gather continuous sensor data in a noninvasive manner, providing valuable insights into their daily activity patterns [7]. These models hold the potential to forecast mental health crises and detect abnormal behavioral patterns, facilitating early intervention [8].

In this study, we examined daily summaries of passively collected behavioral data, treating them as multivariate time series. Passively collected data refer to behavioral information recorded through sensors embedded in devices such as wearables and mobile phones, where patient interaction is not required for data capture. This passive data collection is supplemented by actively provided inputs from patients, such as self-reported emotions or responses to questionnaires tailored to the study context. The dataset used in this research was obtained using the Evidence-Based Behavior (eB2) app, a platform developed by our research group and implemented across multiple studies. These studies encompass a variety of patient cohorts, providing extensive behavioral data complemented by responses to psychological, quality-of-life, and nutrition-related questionnaires, depending on the specific objectives of each study.

For time-series analysis, we used transformer models, which are particularly well suited for capturing long-range dependencies within sequential data [9]. Leveraging the advantages offered by transformer models for time-series analysis, we aimed to uncover underlying patterns in the data collected over time. The attention mechanism in transformers is a fundamental feature that enables the model to prioritize relevant temporal dependencies within the input sequence. By assigning varying weights to different time samples in the sequence, transformers can effectively capture and integrate the most pertinent information for accurate forecasting [10,11]. Furthermore, transformer models exhibit the ability to handle sequences of variable lengths. This flexibility renders transformers scalable to datasets containing many time points, accommodating diverse time-series lengths without sacrificing performance [12]. These attributes position transformers as a promising option for time-series forecasting, as they facilitate the modeling of complex temporal patterns and enhance forecasting accuracy.

Related Work

Overview

This section covers different aspects related to depression diagnosis and tracking, including research in patient emotional state monitoring and the reliability of the Patient Health Questionnaire-9 (PHQ-9) for diagnosis. Moreover, it explores how researchers are using passive observations to obtain standardized and objective insights into patients' self-reported states. Following this, we introduce works that apply machine learning and deep learning methods to analyze such data for enhanced diagnosis accuracy and longitudinal patient tracking. Finally, we provide some background on transformer-type attention models for time-series forecasting.

Depression Diagnosis and Tracking

As numerous studies have shown [13-15], depression remains the worldwide leading cause of disability. However, conventional diagnosis and tracking approaches primarily rely on self-reported depressive symptoms in clinical settings—methodologies that were established over half a century ago. These methods typically entail survey completion or face-to-face interviews, offering limited accuracy, ecological validity, and reliability while imposing significant costs for monitoring and scalability [16]. Moreover, the subjective nature of patient and clinician evaluations, combined with the fluctuating nature of mental health conditions over time, emphasizes the need for ongoing, longitudinal assessments to accurately capture these nuances effectively. In terms of assessing depression, the PHQ-9 has shown to be reliable for the criteria-based diagnosis of this disorder, alongside giving a valid measure of depression severity. These characteristics, plus its brevity, make the PHQ-9 a useful clinical and research tool [17].

XSL•FO
RenderX

A set of studies focused on the relationship between mood variability and some psychiatric disorders. In this work, we used mood in the sense of the subjective variation of the patient's emotional state, as expressed by the patient [18]. Research indicates that mood variability including hypomania, cyclothymia, and hyperthymia has been described in 40% to 50% of patients with depression and that such variability could also characterize anxiety disorders [19,20]. Over the past 2 decades, there has been a surge in research linking various patterns of short-term emotional change to adaptive or abnormal psychological functioning, often with conflicting results [21]. Psychiatric decompensations are characterized by specific patterns of emotional fluctuations across time and provide insight into what constitutes optimal and suboptimal emotional functioning.

Advances in EMA and Passive Monitoring

To prevent bias and capture changes in behavior over time and across different contexts, several researchers proposed a shift from relying solely on global retrospective self-reports collected during research or clinic visits in clinical psychology assessment [22]. In EMA, data are repeatedly collected on an individual's current behaviors and experiences as they happen in their everyday environments [6,23]. EMA helps reduce memory bias, provides more accurate insights into daily life, and allows for the study of small-scale influences on behavior in real-world settings. Technologies used for EMA range from traditional written diaries and phone calls to electronic diaries and physiological sensors [22]. In this case, an EMA-style monitoring is conducted to rely solely on passively collected variables through mobile phone sensors and wearables, excluding all the patient-reported data.

Several studies that reviewed the passive follow-up of patients with different conditions, including bipolar disorder, schizophrenia, and depression, highlighted the potential of passive biomarkers for the monitoring of different types of disorders. Particularly, variables such as accelerometry, location, audio, and use data showed a high general performance [24]. Other studies explored the detection of daily-life behavioral markers through mobile phone GPS and use sensors. They showed that features extracted from these sensors provided markers strongly related to depressive symptom severity [21]. In this line, one of the variables that has shown a correlation with the individual's mental state is daily activity [25,26]. A study focused on detecting emotional state instabilities through passive data found that 3 weeks of continuous, passive recordings were enough to reliably predict mood changes, obtaining average and median errors of mood instability scores within a margin of 5% [27].

Machine Learning and Deep Learning Approaches for Behavioral Data Analysis

Due to the potential demonstrated by these variables in predicting emotional states and their variability in patients, previous works have focused on the application of machine learning and deep learning algorithms to analyze these data [28]. A study by Ghandeharioun et al [13] applied machine learning methods to data on sleep behavior, motion, phone-based communication, location changes, and phone use patterns to impute missing clinical scores from self-reported measures and predict depression severity from these continuous sensor measurements. Similarly, other studies evaluated the performance of random forest and support vector machine classifiers for binary classification of the PHQ-9 score, resulting in 60.1% and 59.1% accuracy, respectively, demonstrating a proof of concept for the detection of depression from passive features [29]. Following this approach, diagnostic meta-analyses have demonstrated the effectiveness of the PHQ-9 for depression screening using mobile devices through various machine learning techniques [30].

Recent studies [30,31] have emphasized the importance of continuous follow-up and the analysis of temporal behavioral patterns in the longitudinal monitoring of patients. Aiming to address the lack of clarity on the temporal scale, specificity, and person-specific nature of the associations between smartphone data and affective symptoms, a study was conducted on smartphone-based passive sensing to identify within- and between-person digital markers of depression and anxiety symptoms over time [31]. Here, hierarchical linear regression models and temporal windows were used to understand the timescale at which sensed features relate to mental health symptoms and explore the predictions in the distal, medial, and proximal times. In line with this, other studies used multilevel modeling to examine the relationships between daily mood and mood variability with symptoms of depression, generalized anxiety, and social anxiety to confirm the empirical evidence linking EMA of mood variability with psychiatric disorders [32]. The findings showed both common and specific emotional dynamics that defined the severity of affective symptoms.

Our research aligned with previous studies by aiming to predict self-reported emotional states and their fluctuations as well as the PHQ-9 scores [33]. However, our methodology differs from conventional approaches by integrating into patients' natural daily routines rather than relying on an experimental setup. Besides, our sample included patients with a variety of disorders who were expected, but not compelled, to actively report data via the app. This setup introduced challenges, notably the substantial presence of missing data, which we addressed using a hidden Markov model (HMM), as documented in previous literature [34]. We build upon this paper, which predicted emotional valence from passive variables, using HMM to handle missing values and classification methods. With the proposed model, we enhanced the emotional valence prediction achieved in this paper and obtained a more reliable prediction as the time horizon expanded. In addition, we included the prediction of the scores of the PHQ-9 questions.

To leverage the continuous acquisition of passive variables and work with these temporal data sequences, this study adopted a transformer-based approach. Transformer models, based on attention mechanisms, offer several advantages for time-series forecasting. The transformer architecture, as introduced by Vaswani et al [10], excels at capturing long-range dependencies, making it well suited for time-series data where distant historical information can be crucial. Attention mechanisms within transformers enable contextual understanding, allowing the model to weigh the significance of past elements, thereby improving forecasting accuracy [10,12].

XSL•FO
RenderX

In addition to the previously mentioned studies, several publications delved into the application of transformers to multivariate time-series data [12,35,36], showcasing the flexibility and adaptability of the transformer architecture in capturing complex temporal relationships. Initially developed for natural language processing tasks, transformers have demonstrated a seamless transition to time-series forecasting due to their inherent capability to model temporal data. This shift underscores the versatility and robustness of transformer-based models in addressing diverse sequential data tasks beyond language processing. Furthermore, pretrained transformer models can be fine-tuned for specific forecasting tasks, leveraging insights from diverse datasets, as demonstrated in various transfer learning applications. Finally, attention weights also contribute to their utility in analyzing and forecasting time-series data in a more interpretable way [37].

To the best of our knowledge, no previous studies have used transformer models specifically for emotion recognition relying solely on behavioral (passive) data from mobile devices. This represents a novel direction in leveraging behavioral data for emotion classification and change detection, particularly in real-world, noninvasive contexts.

In other domains, emotion recognition has been explored using transformer models applied to various data modalities. For text-based emotion recognition, transformer models such as Bidirectional Encoder Representations from Transformers (BERT) and GPT proved to be effective in capturing emotional nuances in textual data. For instance, Xie et al. [38] used GPT (developed by OpenAI) to encode dialogue features, while Li et al. [39] combined Robustly Optimized BERT Pretraining Approach (RoBERTa, developed by Facebook AI) embeddings with wav2vec (version 2.0, developed by Facebook AI) for cross-modal emotion recognition.

For audio-based emotion recognition, speech data have been modeled using architectures such as wav2vec (version 2.0). Chen and Rudnicky [40] fine-tuned wav2vec (version 2.0) for detailed speech emotion analysis, while Sun et al [41] combined it with BERT for multimodal integration.

Transformers have also been used for visual-based emotion recognition, where facial expressions and gestures were analyzed. Praveen et al [42] used the multihead attention mechanism to fuse visual and audio features, effectively capturing both spatial and temporal dynamics.

Multimodal emotion recognition, which combines text, audio, and visual data, has been a common approach. Xie et al [38] proposed a Crossmodality Fusion Transformer, and Zhao et al [43] introduced MEmoBERT for cross-modal emotion classification tasks.

In the field of physiological emotion recognition, transformer-based models such as modality-agnostic transformer based self-supervised learning [44] and conformer [45] have demonstrated high accuracy in analyzing electroencephalogram and electrocardiogram signals for emotion classification.

In contrast to these approaches, our work focused exclusively on behavioral data collected passively through smartphones and wearable devices, without relying on more invasive techniques such as video, voice, or physiological signals such as electroencephalogram. This distinction offered significant advantages. By aligning with natural patient behavior and environments, our method reduced intrusiveness, ensured scalability, and facilitated seamless integration into daily life, making it particularly suitable for real-world applications.

Objectives

The general goal was to acquire objective indicators of patients' conditions and fluctuations in their emotional well-being from passive biomarkers. For this, we focused on predicting the emotional valence of patients as well as the PHQ-9 score. This approach aimed to address the challenge of subjectivity and the absence of continuous monitoring in psychiatry, ultimately aiding in the identification of potentially risky situations. This would facilitate timely intervention and treatment adaptation, thus improving the quality of life of the patients and their environment. We strived to achieve this prediction several days in advance of the actual event. Moreover, the incorporation of attention mechanisms served the additional purpose of advancing our understanding of behavioral patterns.

Methods

Recruitment: Patient Inclusion and Exclusion Criteria and Indications

Participants were eligible for inclusion in the study if they were aged ≥18 years and were diagnosed as clinical outpatients with mental disorders by specialists or if they were attending therapy groups. Among these groups, there were 3 main categories: high suicidal risk, eating disorder, and common mental disorder (CMD). CMD encompasses a group of distress states manifesting with anxiety, depression, and unexplained somatic symptoms that are typically encountered in community and primary care settings [46]. Furthermore, patients from other studies, including cohorts of patients affected by cancer, HIV, obstructive sleep apnea, and cardiac conditions, as well as control patients, were included.

Participants were required to own a smartphone running on Android or iOS operating systems, which they connected to a Wi-Fi network at least once per week. Only participants who provided written informed consent for the eB2 study were included.

Patients received instructions from the clinicians at the beginning of follow-up. For most cohorts, only information regarding the app's functionality was provided. However, 2 groups received specific guidance: patients with eating disorders were required to compulsorily complete meal entries, while patients with CMD were encouraged to regularly log their emotions and periodically complete the PHQ-9. There was no obligation or a set number of required responses for these tasks.

Passive data sources included both mobile and wearable devices. In some studies involving patients with HIV, cancer, or obstructive sleep apnea, patients were provided with wearables. For the remaining studies, if patients had their own wearable, information was extracted from the most reliable data source.

XSL•FO
RenderX

Data

This study was conducted on a sample of 4403 patients from 8 distinct cohorts, each characterized by a different pathology or condition. Out of the 4358 patients, the patient cohorts included individuals with CMD (n=1785, 40.54%), eating disorder (n=1477, 33.54%), high suicidal risk (n=413, 9.38%), cancer (n=84, 1.91%), obstructive sleep apnea (n=48, 1.09%), HIV (n=24, 0.54%), cardiology-related conditions (n=20, 0.45%), as well as control participants (n=507, 11.51%).

The data for this study were derived from secondary analyses of multiple clinical studies conducted in collaboration with various hospitals. All studies were designed to monitor patients with distinct health conditions using the eB2 platform. Despite differences in data sources, standardized protocols for data collection were applied across all studies to ensure consistency in data quality. All users were Spanish or French. Among them, 57.48% (2531/4403) were female, 40.93% (1802/4403) were male, and sex information was missing for the remaining 1.59% (70/4403) of the users. All age groups were well represented, with a mean age of 46 (SD 14.8; range 18-77) years at the start of the measurement period.

Patient monitoring was conducted using the eB2 MindCare app [47,48]. The eB2 app operates by harnessing information from diverse sources within the patient's ecosystem. Using phone sensors, Google Fit (Google LLC), and wearable devices, it acquires data at varying intervals, facilitating a nuanced understanding of the patient's daily activities. In parallel with this passive monitoring, patients had the option to input subjective experiences, sleep patterns, and emotional states throughout the day. Emotional states were cataloged within the app, offering 20 options in a spectrum from anger to delight [49,50].

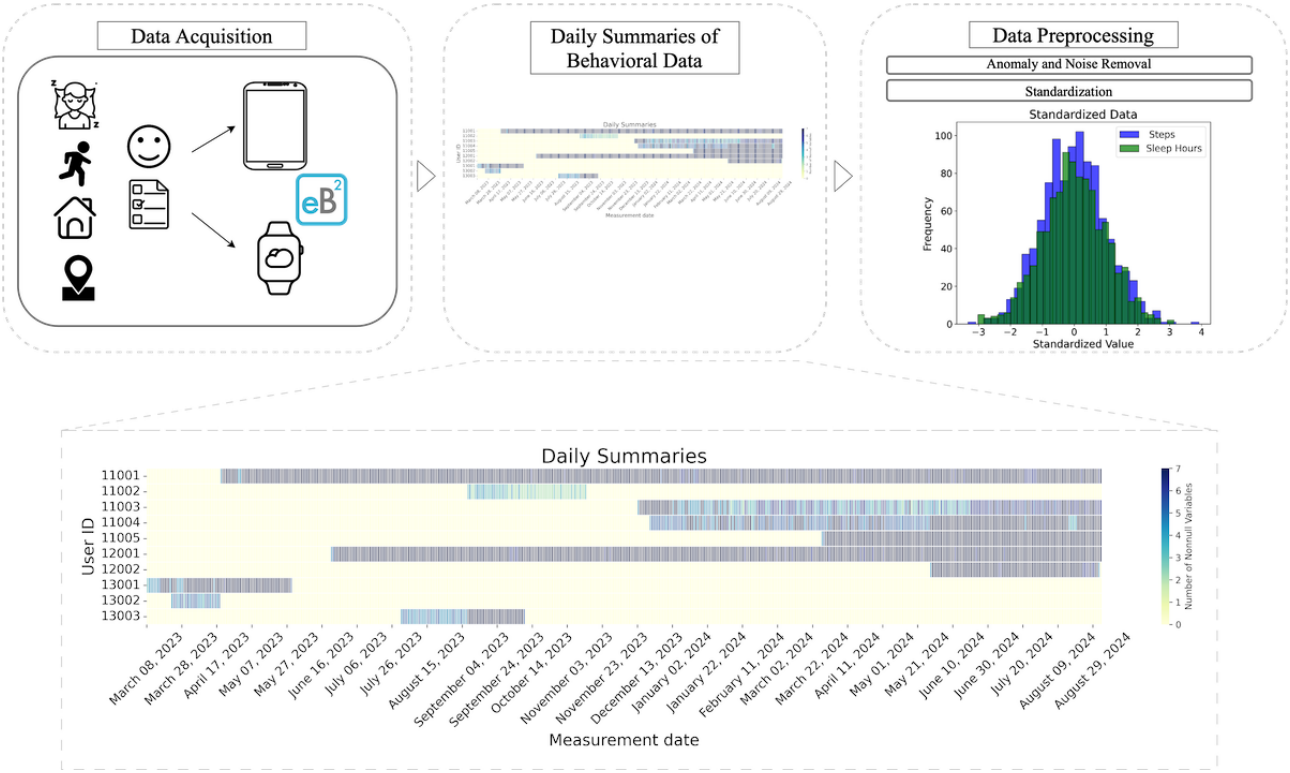
Daily summaries of these data were the primary focus, although alternative granularities were also considered (such as hours and minutes). Therefore, when predicting sequences or emotions at the next temporal moment, this temporal interval was in days. The data collection period for this study spanned 8 years, from 2016 to 2023, and the average duration of passive activity sequences for patients was 224 days, with an SD of 200 days.

The data used as inputs for training the models were daily summaries of the following passive variables: step count, covered distance, sleep hours, app use, time at home, number of visited places, and practiced sport (a binary variable indicating whether the patient practiced sports during the day). The targets we aimed to predict from these passive data were patients' emotional valence and PHQ-9 scores. The ground truth values for these targets were derived from self-reported emotions and questionnaire answers that patients completed through the app. A more detailed description of the different cohorts is included in Multimedia Appendix 1.

Preprocessing

To ensure the variables were sampled at the same frequency, daily summaries were created for each variable. These daily summaries were derived by aggregating the data according to the specific variable.

Sleep hours, distance, steps, and app use were calculated using passive data collection methods from various sources. Sleep hours were determined based on a prioritization hierarchy: user-entered data were the most prioritized, followed by wearable devices; mobile data; and finally, a sleep estimation model. Daily distance was calculated using GPS signals from mobile devices, collected every 5 minutes. Step counts were gathered at intervals of 1 to 5 minutes, depending on the manufacturers of the smartwatch devices. To calculate daily totals, step data from each slot were merged by priority (wearables over mobile). App use was recorded every 5 minutes, capturing which apps were used and the duration of their use. For these 4 variables, once the data were collected and selected from the priority sources, the data were summed to obtain the daily summary of each variable.



To identify home and work locations, the DenStream algorithm was used. Location data were collected over a 15-day period to form clusters. Once the clusters were established, incoming location data were tagged in real time as either home, work, or other. The cluster definitions were updated every 30 days following the initial 15-day period. On the basis of this clustering process, the time a user spent at home was calculated. Data were collected every 5 minutes and tagged upon entry to indicate the cluster corresponding to home. The total time at home was measured in seconds and aggregated for daily summaries.

The variable practiced sport was a Boolean value indicating whether a user engaged in physical activity lasting at least 15 minutes during the day. This variable was updated whenever new physical activity data were received. Physical activity detection was based on three primary sources: (1) activities automatically labeled by devices (eg, mobile phones and wearables), (2) manually logged activities by users through the provider's app, and (3) activities logged directly into the eB2 MindCare platform.

To address the variations between sensors and data formats, which resulted in anomalies and noise in the information, a preprocessing stage was implemented. This included removing negative values, thresholding the time-related variables to 24 hours, the time step count to 30,000 per day, and the distance to 500 km. Finally, data were standardized over all the patients' sequences (mean 0, SD 1 for input features). Standardization was performed to ensure all variables had a uniform scale, which improved the efficiency and performance of machine learning algorithms. This was particularly important for models sensitive to differences in feature scales, such as neural networks or distance-based methods. Figure 1 shows the sequence of data preprocessing.

XSL•FO
RenderX

Figure 1. The data preprocessing pipeline: data acquisition, obtention of the daily summaries, and standardization of behavioral data. The sequence shown in the daily summaries displays the temporal sequence of passive data for 5 different patients. The intensity of the lines indicates the amount of nonmissing behavioral data the patient has for that day.

Regarding passive data, the mean percentage of missing data was approximately 60.23% (594,699/986,909), with step count (519,168/986,909, 52.61% of total missing) having the fewest missing values and time at home being the least complete (685,614/986,909, 69.47% total missing). Table 1 shows the percentage of missing values per passive variable grouped by year.

Regarding targets, Table 1 shows the percentage of missing emotion ratio and PHQ-9 answers in comparison with the passive data. It can be observed that the variables reflecting the patients' mood (self-reported emotions and PHQ-9 answers), which they must enter actively, had the lowest percentage of registered data. This is why we aimed to predict these 2 variables using passive data, as they were more complete and allowed for continuous monitoring of the patient's condition without relying on the patients to input the data.

In this study, we handled emotions following the classification scheme by Russell [51], which characterizes emotions in a 2D space. The circumplex model by Russell [52] proposed that emotions could be understood along 2 independent and bipolar dimensions: valence (pleasantness or unpleasantness) and activation (high arousal or low arousal). Independence implied that valence and activation were uncorrelated, while bipolarity suggested that opposite emotions lied at opposite poles of each dimension. For example, happiness and sadness represented opposite ends of the pleasantness spectrum, whereas emotions such as tension and sleepiness were at opposite extremes of the activation dimension.

Using this framework, emotions reported by patients were assigned a level of valence as positive (pleasant), negative (unpleasant), or neutral. For instance, positive valence emotions included happiness, enthusiasm, or satisfaction, while negative valence emotions included sadness, anger, or frustration. Neutral valence emotions fell in the center of the pleasantness spectrum, representing a lack of strong affective polarity [53]. Related studies [54] similarly relied on the model proposed by Russell [52] to categorize emotions, either in 1D using valence or in 2D with both valence and arousal. From this scheme, we focused on emotional valence, which was the first prediction target.

The daily valence was determined by the difference between the counts of positive and negative emotions and can take values between 0 and 2 (negative, neutral, and positive valence).

In addition, the PHQ-9, comprising the 9-item depression module extracted from the full Patient Health Questionnaire, was examined as another target variable. According to this questionnaire, diagnosis of major depression was established if "more than half the days" over the past 2 weeks exhibited the presence of ≥5 depressive symptom criteria, with one of these symptoms being either depressed mood or anhedonia [17]. The responses to the questionnaire were derived from the cohort of patients with CMD, comprising a total of 597 completed surveys. In the context of this investigation, each of the 9 questionnaire items was treated independently. This approach was adopted due to the diverse nature of the questions, which collectively encompassed various facets of the patients' daily experiences. The simultaneous prediction of all scores posed a considerable methodological challenge in this initial endeavor.

2022	239,773	119,631 (49.89)	189,051 (78.85)	128,221 (53.48)	139,454 (58.16)	192,852 (80.43)	191,660 (79.93)	—	—
2023	125,455	58,778 (46.85)	96,824 (77.18)	65,042 (51.84)	69,014 (55.01)	98,919 (78.85)	98,449 (78.47)	—	—
Total	986,909	519,168 (52.60)	626,037 (63.43)	635,705 (64.41)	667,705 (67.66)	685,614 (69.47)	672,537 (68.15)	950,833 (96.34)	967,171 (98.00)

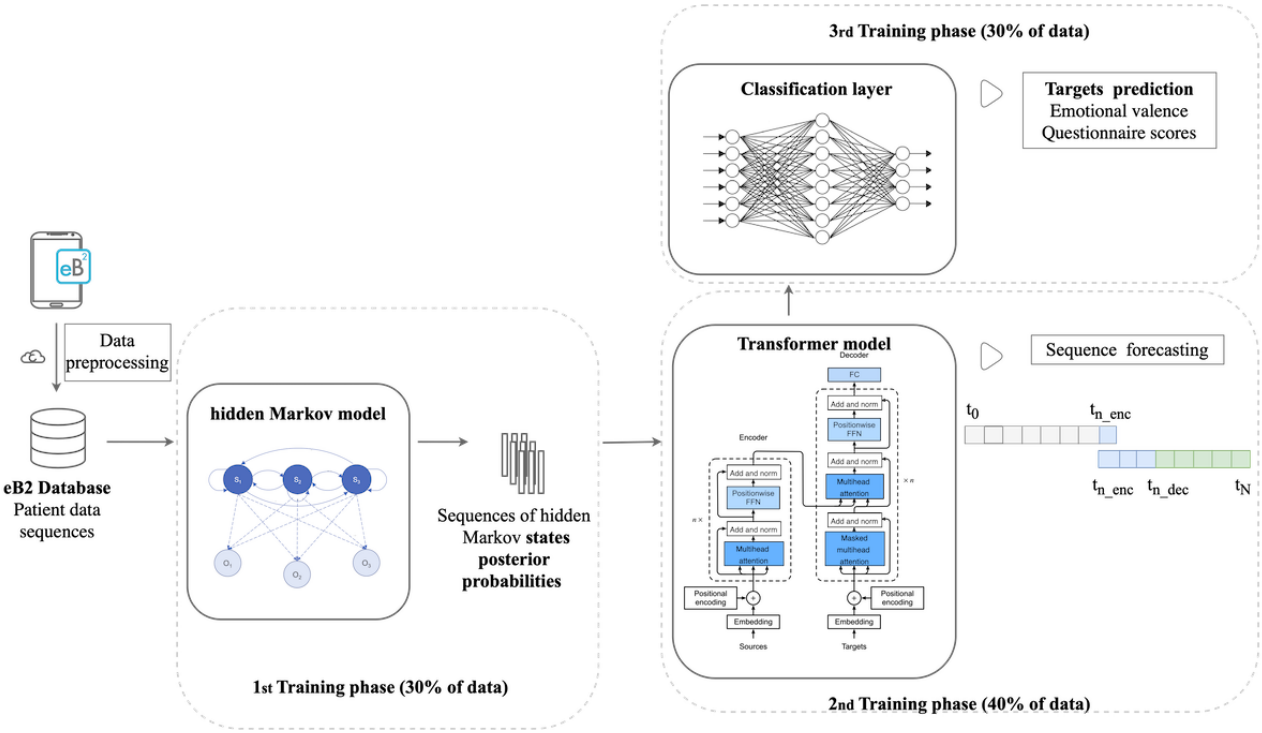
[a]Passive variables include steps, distance, sleep, app use, time at home, location clusters, emotions ratio, and PHQ-9.

[b]PHQ-9: Patient Health Questionnaire-9.

[c]Not available.

Originally, this score comprised 4 classes. However, due to the insufficient number of answers for each type and the frequency-based nature of the responses (ranging from “not at all” to “nearly every day”), the intermediate classes sometimes merged with the 2 extreme groups. Consequently, we decided to classify the answers into 2 broader classes: 0 (representing “not at all” and “several days” as low frequency) and 1 (representing “more than half of the days” and “nearly every day” as high frequency).

Models



Overview

Our global model, illustrated in Figure 2, consisted of 3 main submodels that were trained separately. Hence, we considered that the global model was trained in three stages: (1) training of the HMM to deal with missing fields, (2) the autoregressive transformer to pretrain the model to capture the temporal structure of the data, and (3) the classification model itself.

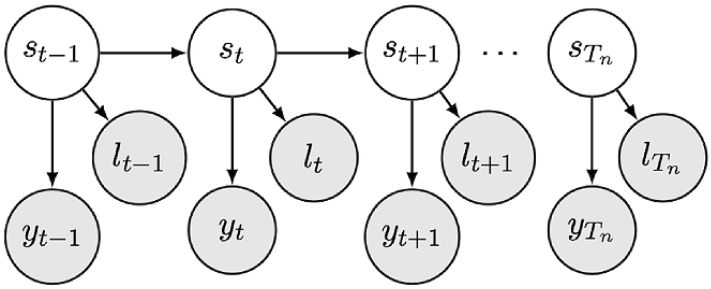
Initially, the raw data underwent the preprocessing and quality control mentioned previously. To prevent data leakage between the different training phases and biases, the original dataset was divided into 3 subsets for training and validation purposes, with 30% (296,072/986,909), 40% (394,765/986,909), and 30% (296,072/986,909) of the data allocated to the HMM, transformer, and classification layers, respectively, as shown in Figure 2. The partitions were made by assigning equitable percentages of each cohort to each subset to mitigate biases, assigning unique different users to each of them. The following sections describe the 3 main stages in detail.

XSL•FO
RenderX

Figure 2. A graphical abstract of the proposed scheme illustrating the underlying architecture, comprising 3 primary blocks. The first block involves the use of hidden Markov models (HMMs) to address missing data and extract posterior state probabilities. The second block uses a transformer model equipped with an attention mechanism to facilitate pattern recognition and time-series forecasting. Finally, the scheme incorporates a classification layer responsible for patient-reported variables, namely, emotional valence or Patient Health Questionnaire-9 score. eB2: Evidence-Based Behavior; FFN: feed-forward network; t : initial time of the sequence; t _enc: length of the sequence of observed data used as input for the encoder; the encoder is fed with observed data from t to t _enc, in this case, 30 days; t _dec: length of the sequence of observed data used as input for the decoder; the decoder is fed with data from t _enc to t _dec, in this case, for training purposes, the observed sequence consisted of 20 days; tN: forecasting horizon in days, it does not have a fixed value, for example, in this study, N is either 1 or 3, depending on the prediction horizon.

Probabilistic Generative Model for Dealing With Missing Data: HMMs

Our objective was to evaluate the efficacy of transformer models in enhancing time-series forecasting. However, transformer models do not inherently accommodate missing data, presenting a challenge for our analysis. To address this limitation, we used HMMs. In addition, we leveraged the latent space representation provided by HMMs, using the posterior probabilities of the hidden states for training the transformer model.



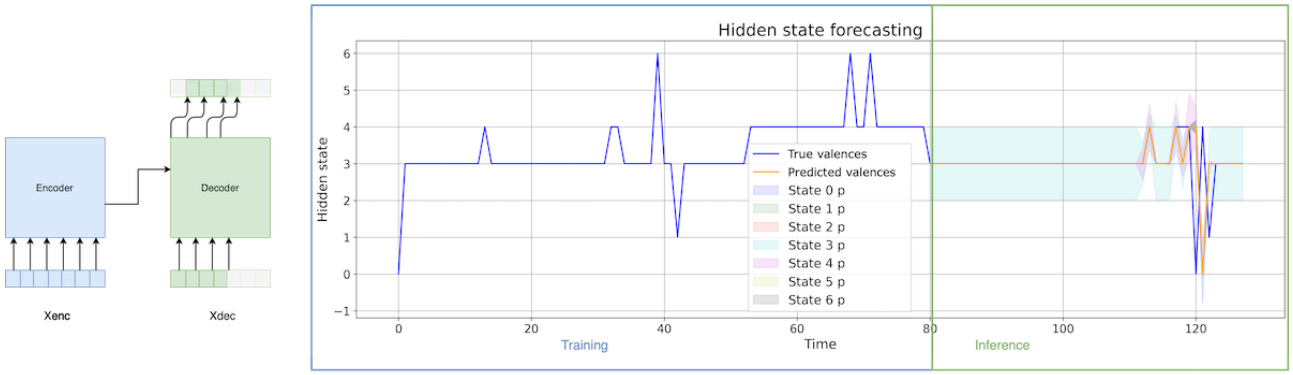
HMMs, commonly used in time-series analysis, represent a temporal variant of Markov models [55,56]. These generative models are characterized by a collection of observable variables, and a notable advantage lies in their ability to manage missing data without necessitating prior imputation, achieved through marginalization. In the HMM, a sequence of observable variables O is generated by a corresponding sequence of internal hidden states S. However, these hidden states are not observed directly. Instead, transitions between hidden states follow the assumption of a first-order Markov chain. This transition process is defined by a start probability vector π and a transition probability matrix A. In addition, each observable emission is associated with a probability distribution, conditioned on the current hidden state. These emission probabilities are specified by parameter B. Together, these parameters $\lambda=(\pi, A, B)$ fully define the HMM.

The dataset used in this study exhibited heterogeneity, encompassing both categorical variables such as practiced sports as well as continuous variables presumed to take real values (Table 1). For this purpose, we used the heterogenous-HMMs implementation from the HMMs in Python (PyHMM) library, which facilitates the use of various distributions to manage the emission probabilities of each feature type, as depicted in Figure 3 [34,55,57].

In this initial phase, the HMM was trained using 30% (296,072/986,909) of the available data. Once trained, the model was used to infer the state posterior probabilities. At each time step, the set of passive data for a given day and patient was represented by a hidden state posterior probability vector, with a total of 7 hidden states in this instance. Previous studies [34] tested different hidden state configurations, and 7 hidden components were found to effectively capture the underlying patterns in the data. The optimal number of hidden states was determined using the Bayesian Information Criterion and Akaike Information Criterion on a randomly selected subset of sequences with varying levels of missingness [58]. This number of hidden states also led to the best results when a classifier was applied to predict emotions.

XSL•FO
RenderX

Figure 3. Architecture of the heterogeneous hidden Markov model. The model is described by their hidden states sequence (s0:Tn), continuous observations sequence (y0:Tn), and discrete observations sequence (l0:Tn). In our case, (l0:Tn) corresponded to the sequence of discrete observation: practiced sport and (y0:Tn) was the sequence of continuous observations: steps, location distances, sleep time, app use, time at home, and location clusters count.



The hidden states' posterior probabilities refer to the probabilities of the hidden states given the observed data. These probabilities are calculated using the observations and the model parameters. The sequence of hidden states probability vectors served as the embedding of the daily information for each patient, enabling the training of subsequent models.

Sequence Forecasting With the Transformer Model

Due to the limited data on emotions and PHQ-9 responses, to obtain a more informative representation of the time series, we first performed a phase of self-supervised training, following a forecasting approach. To achieve this, we used a transformer model for time-series forecasting, leveraging its strengths in handling sequential data. Transformers have shown promising results in capturing long-range dependencies and can provide interpretability regarding the most relevant parts of the sequence for each specific task. Our transformer followed the basic encoder-decoder structure, as depicted in Figure 4 [10], incorporating elements from the encoder of the Informer model [12].

The encoder within the transformer architecture comprised a series of 3 layers. Each layer incorporated 2 distinct sublayers: a multihead self-attention mechanism and a position-wise fully connected feedforward network. Following each sublayer was a residual connection and layer normalization. Likewise, the decoder consisted of 3 layers. In addition to the 2 sublayers present in each encoder layer, the decoder incorporated a third sublayer responsible for performing cross-attention over the output generated by the encoder stack. Residual connections and layer normalization were similarly applied around each sublayer to the encoder. To prevent the decoder from attending to subsequent positions, modifications were made to the self-attention sublayer within the decoder stack, implementing causal (masked) self-attention.

Figure 4. (A) Simplified encoder-decoder architecture of the transformer model. (B) Example of model training and inference. During training, the model learns the parameters to forecast the future state, using the real data as a reference. During inference, the transformer's decoder is responsible for forecasting the future state value in an autoregressive manner. The blue line shows the true states, and the orange line shows those predicted by the model. During inference, the possible future states have associated probabilities, which are illustrated in the graph with different-colored margins around the orange line. Xenc: input sequence for the encoder; Xdec: input sequence for the decoder.

Through the encoder, we obtained contextual information, and with the decoder, we performed the prediction of future observations, considering both the contextual information and the current observations. To incorporate information about the relative or absolute position of tokens in the time series, we combined a positional encoding with the input embeddings at the beginning of both the encoder and decoder stacks [10].

The transformer model was trained from scratch in a forecasting paradigm, wherein the transformer's output was compared to the actual output shifted 1 day ahead. This approach enabled the model to predict future time points with precision. As our dataset consisted of real-world data, it was uncommon for the patients to have extensive sequences of data. Because of this limitation, for model training, we experimented with different sequence lengths, aiming to strike a balance between model performance and sequence duration. Through experimentation with various sequence lengths for both the encoder and decoder, we determined that a sufficiently large sequence (between 25

XSL•FO
RenderX

and 30 days) was required to adequately capture relationships and facilitate accurate forecasting.

For training, we used diverse training schedules, integrating early stopping and dropout techniques to mitigate data overfitting. The loss functions we tested included both mean squared error and mean absolute error, computed between the predicted and actual future sequences. Optimization was carried out using the Adam optimizer across 80 epochs.

A hyperparameter grid was defined, including values for embedding dimensions (32, 64, 128), which represent the dimension of the embedding vector for each data point; number of attention heads (4, 8, 16), indicating the number of heads in each attention layer; number of encoder and decoder layers (2, 3, 4, 6), referring to the attention blocks that include the attention, add and normalization, feedforward, and add and normalization layers; feedforward dimensions (128, 256, 512), which correspond to the dimension of the feedforward layers; dropout rate (0.3, 0.5); and learning rate (0.01, 0.001, 0.0005).

The best-performing model, which we presented in our results, was trained using sequences spanning 50 days of passive data, with 30 days allocated for the encoder and 20 days for the decoder. During inference, using the preceding 30 days of collected data was sufficient for forecasting, as the model could then predict further into the future autoregressively. The optimal model configuration was achieved with an embedding dimension of 32, 4 attention heads, 3 layers, a feedforward dimension of 128, a dropout rate of 0.3, and a learning rate of 0.001. The results obtained for the different combinations of hyperparameters, as well as a more detailed explanation of the used architecture, are included in Multimedia Appendix 2 [10,12,34,57].

Emotional State and PHQ-9 Score Classification

For this section, we used the output of the transformer model to train the subsequent classification layers, aimed at predicting specific targets. The objective was to predict emotional valence and the PHQ-9 scores for the following day.

For the prediction of emotional states, the HMM was first applied to the data sequences to obtain the posterior probabilities of the hidden states of the Markov model, which represented the embeddings of the passive data sequences. Subsequently, forecasting for the following days was conducted using the transformer, which was trained in the previous phase. These outputs were then used to train a model for emotional valence classification.

Several classification models were experimented with, including multilayer perceptron, ensemble models, support vector classifier, and extreme gradient boosting (XGB). Among these, random forest classifiers, as part of the ensemble models, and XGB demonstrated superior performance. This constituted the third training phase, which we evaluated through the F_1-score, accuracy, precision-recall curves, and receiver operating characteristic (ROC) curves, along with their respective area under the curves (AUCs). For each input day, these models provided a probability distribution of the predicted emotional valence for the following day, which in this case was a probability distribution among 3 possible outcomes (0, 1, and 2). In this regard, we analyzed both the probability distributions of the valence predicted by the model and the concrete valence estimated for the following day (the one with the highest probability).

To predict the binary PHQ-9 score for each question, we compared several classifiers by training them with temporal windows of 15, 7, and 3 days using the transformer output (the contextual embeddings), the emotions predicted by the classifier, or a combination of the hidden states' posterior probabilities and the predicted emotions.

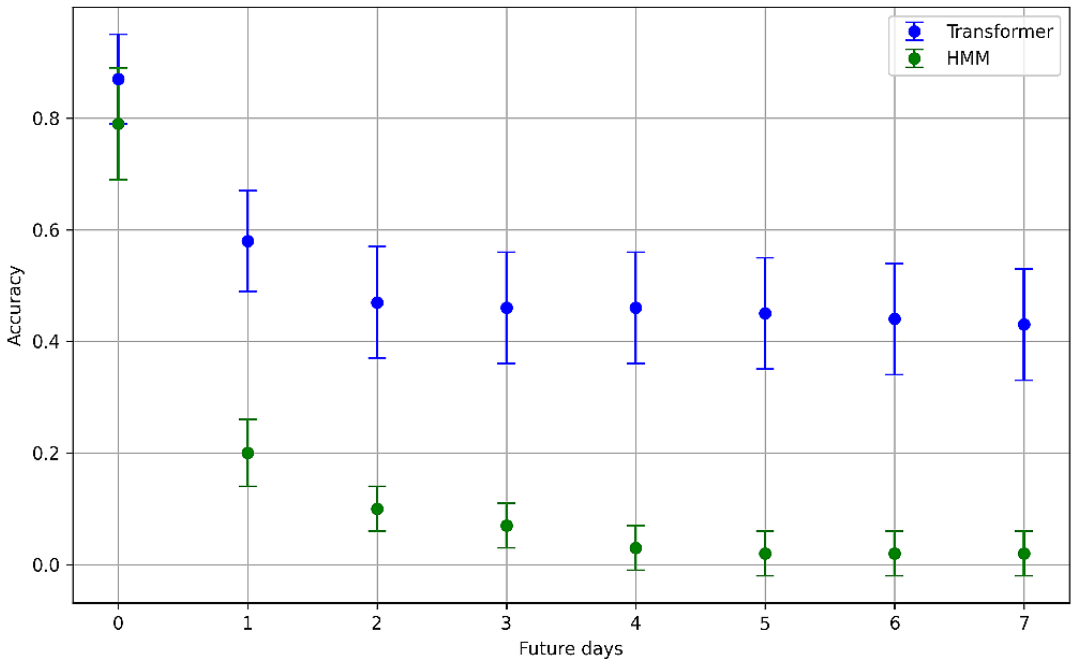
Ethical Considerations

Each clinical study received approval from the relevant institutional review board in compliance with ethical standards and the Declaration of Helsinki. Institutional review board approval numbers are indicated in brackets and correspond to the center where approval was obtained for each project and country. Patients at high risk of suicide were identified through collaborations with the Jiménez Díaz Foundation (FJD, EC005-21), Montpellier University Hospital (CPP Ouest IV 20/18_2), and Clínica Nuestra Señora de la Paz. Patients with CMDs were recruited from FJD (PIC148-22), while those with eating disorders were monitored at specialized mental health centers, including Adalmed and Ita mental health clinics. The study also includes patients with cancer monitored in partnership with Gregorio Marañón Hospital (EB2COLON2023), Centro Nacional de Investigaciones Oncológicas, and Fuenlabrada Hospital; patients with HIV/AIDS from Gregorio Marañón (MICRO.HGUGM.2022-002); patients with heart problems from Clínico San Carlos Hospital (19/239-O_P); and patients with obstructive sleep apnea monitored at FJD (PIC163-22). Informed consent was obtained from every participant at the time of inclusion, ensuring adherence to ethical guidelines and participant rights.

Results

Time-Series Forecasting

In this section, we first compare the time-series forecasting capabilities of the transformer and the HMM, without considering specific target predictions, solely as a comparison of their ability to capture the temporal structure and prediction performance of both models.



For the forecasting of the sequences of the posterior probabilities of the hidden states, which represent the information of the passive observations, our results demonstrated enhanced stability over time when comparing the transformer model to the HMM. Specifically, when both models performed autoregressive forecasting, predictions made by the transformer model exhibited greater similarity to the true values as we project further into the future beyond the last observed day.

Figure 5 presents the accuracy of state forecasting, measured as the rate of correctly predicted states for 0 to 7 days into the future. While both models performed similarly for immediate next-day predictions, the transformer's predictions decayed more gradually than those of the HMM as the forecasting horizon extended. The chosen configuration for the transformer

XSL•FO
RenderX

model involved training with sequences of 50 days—30 days for the encoder and 20 days for the decoder—during the initial training phase, encompassing all potential patient sequences. Training with shorter sequences yielded inferior forecasting performance.

Figure 5. Comparison of models in state match forecasting. HMM: hidden Markov model.

Emotional Valence Forecasting

Regarding emotional valence forecasting, our results focused on predicting emotional state 1 day ahead. The most effective approach involved using the XGB algorithm with a 7-day window of the transformer model decoder as input for the classification layers.

Alternative approaches were explored for the classification. One included incorporating model-embedded vectors of the hidden states, not the final output of the decoder, to potentially enhance informativeness; however, this yielded comparable results to only using the transformer's decoder output. Another strategy involved retraining the entire model (including the transformer and classifier) or some of the layers via fine-tuning, as opposed to solely training the classifier while keeping the transformer parameters frozen to improve task performance. However, the results were similar, and given the time and resource requirements for complete retraining, we opted to train the classification layers for the specific task.

Results across different models used for classification exhibited minor variations, potentially attributed to the embedded vectors effectively capturing necessary information for forecasting, irrespective of the classification model's complexity.

Table 2 shows the results for valence classification. Notably, the XGB model performed best with a ROC AUC of 0.982 and an accuracy of 0.93. Of particular interest was the discrimination of class number 2 (representing a neutral state), which is challenging to classify due to its scarcity. Despite a slight bias toward negative valence, models achieved robust discrimination for negative and positive states and notably good results for the neutral state, accurately predicting events 1 day in advance.

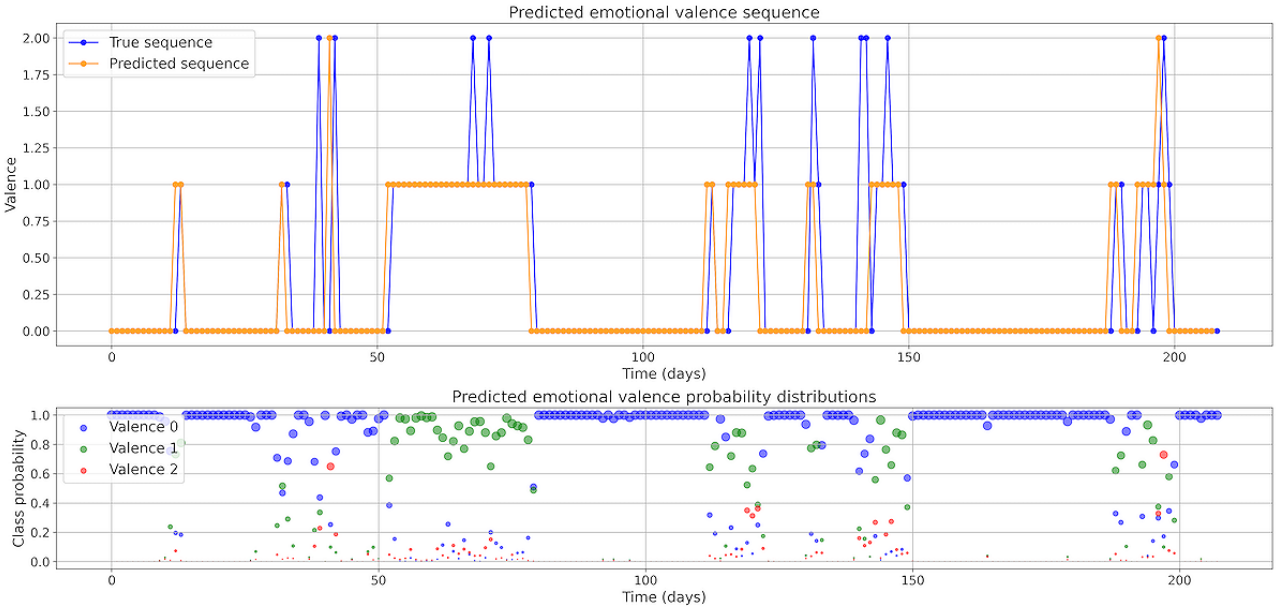
Table 2. Metrics for emotion classification models[a].

Metric	MLP[b]	RF[c]	XGB[d]	XGB retrained	XGB embedding
Precision	0.86	0.87	0.89	*0.89*	0.84
Recall	0.82	*0.86*	*0.86*	0.85	0.8
F_1-score	0.84	*0.87*	*0.87*	0.86	0.8
Accuracy	0.91	0.93	0.93	*0.94*	0.9
AUC[e]	0.97	0.98	*0.98*	0.98	0.92
PR[f]	0.89	0.92	*0.93*	0.9	0.88

[a]For each metric, the results obtained with the best model are italicized.

[b]MLP: multilayer perceptron.

[c]RF: random forest classifier.



[d]XGB: extreme gradient boosting.

[e]AUC: area under the curve.

[f]PR: precision-recall.

Figure 6 illustrates individual patients' emotional series, where the blue line represents the actual emotion for the current day, the orange line represents the forecasted emotion for the following day, and the circles represent the probabilities predicted by the classification model for each emotional valence for the next day. The position and size of the circles correspond to their probability values, with higher probabilities resulting in larger circles. Purple indicates valence 0 (negative), green indicates valence 1 (neutral), and red indicates valence 2 (positive).

Figure 6. Sequences of real emotions (blue) and those predicted by the model (orange) for the following day. The colored circles denote the probability distribution of the emotional state. Purple indicates state 0 (negative valence), green indicates state 1 (neutral), and red indicates state 2 (positive valence). This figure pertains to a patient (ID: 218) selected from a set of patients with high variability of emotion in their temporal sequence.

Regarding emotional valence change detection, analyzing the emotional valence distributions revealed a pattern. During stable periods, the distributions were skewed, meaning that most of the probability mass was concentrated around a single valence outcome. However, near a change, the distributions become closer to a uniform distribution. That is, the probability mass was distributed more evenly among the possible outcomes.

To detect the change, we considered calculating the entropy and the Jensen-Shannon (JS) divergence within a temporal window of the sequence. We calculated the entropy of the valences' probability distributions (equation 1) for a 3-day window, including the previous 3 days to each event. The JS divergence (equation 2) was computed between the present-day distribution and an average distribution over a temporal window to determine which approach could better determine the shift in emotional state: whether an increment in disorder within the window or a comparison between the actual and previous distribution.

$$H(x) = -\Sigma\, p_i \log_2 p_i \quad \textbf{(1)}$$

$$D_{JS}(P||Q) = \tfrac{1}{2}\Sigma\,(p_i \log_2 p_i/q_i + q_i \log_2 q_i/p_i) \quad \textbf{(2)}$$

XSL•FO
RenderX

In Figure 7, we display the real changes in emotional valence alongside the JS divergence, and in Figure 8, we display real changes and change detection through entropy. An increase in entropy within a 3-day temporal window, as seen in this case, is associated with a shift in emotional state. Similarly, divergence remains low, close to 0, during stable periods, with most peaks corresponding to real shifts in emotion.

Figure 9 shows the ROC AUC for emotional change detection with entropy and JS divergence. The results of change detection are shown for patients with mental disorders, for patients who have not been diagnosed with mental disorders, and for all study participants to compare detection across different scenarios. For the global case, lower thresholds for both metrics yielded better results, with JS divergence outperforming entropy by 0.13 ROC AUC for change detection.

Figure 7. The Jensen-Shannon (JS) divergence calculated in a temporal window (blue curve) and the true emotion changes (gray vertical lines) for 2 patient sequences.

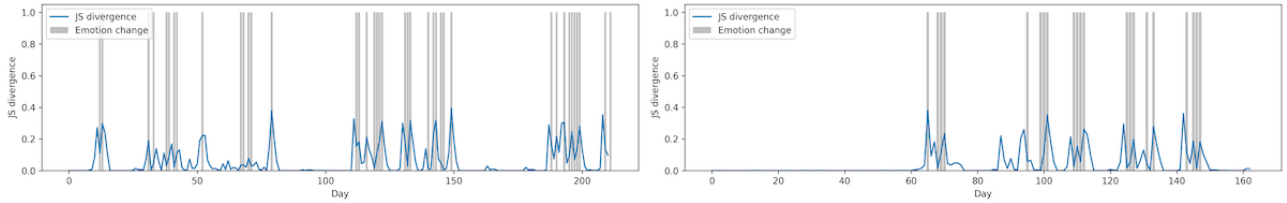


Figure 8. Entropy calculated in a temporal window (blue curve) and the true emotion changes (gray vertical lines) for 2 patient sequences.

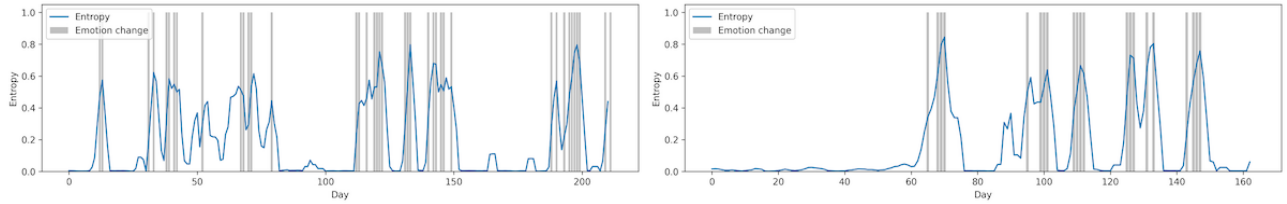

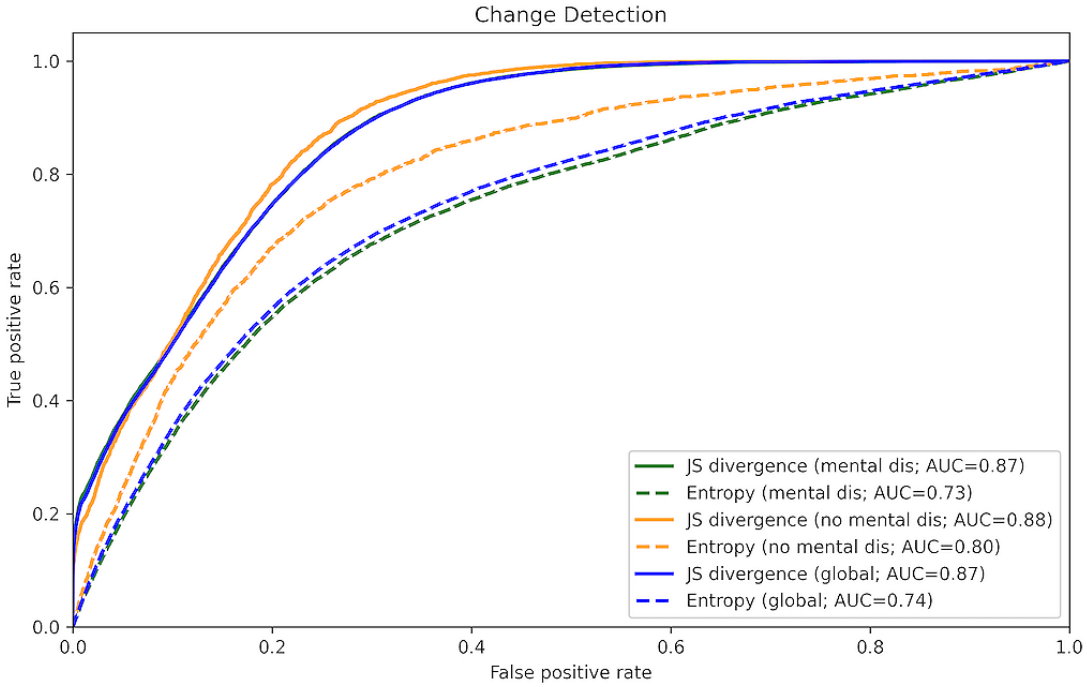

Figure 9. The receiver operating characteristic (ROC) curves for change detection with Jensen-Shannon (JS) divergence and entropy. The curves are obtained for change detection in patients with mental disorders, in patients without any diagnosed mental disorders, and for the entire study cohort (global). AUC: area under the curve; Mental dis.: patients with mental disorders; no mental dis.: patients without any diagnosed mental disorders.

PHQ-9 Score Forecasting

Table 3 presents the accuracy and AUC results for the questionnaire score forecasting, delineated by the classification into 2 classes over a temporal window of 7 days using the decoder transformer outputs. The predictions were obtained using both a random forest classifier and an XGB classifier, both of which demonstrated similar results. Among the results presented in Table 3, the difference lies in the input provided to the classifier: either solely the transformer output (hidden states), the transformer output combined with the corresponding emotional state forecasting, or solely the emotional state. Notably, the results across all 3 configurations were similar,

XSL•FO
RenderX

with slight improvements when using either the hidden states alone or solely the emotion distribution sequence as input.

When comparing different questions, certain inquiries demonstrated higher predictability than others. Notably, question 9 consistently yielded the most accurate predictions across all configurations. This question pertained to whether patients have experienced thoughts of being better off dead or hurting themselves. In addition, question 8, which addresses difficulties in movement or speech that others may notice, exhibited relatively accurate predictions, along with question 5, which was related to appetite, and question 7, which was related to concentration problems.

Table 3. Patient Health Questionnaire-9 (PHQ-9) score forecasting results for questions 1 to 9[a].

PHQ-9 question	Transformer embeddings[b]		Transformer embeddings and emotion[c]		Emotion sequence (3 days)[d]		Emotion sequence (15 days)[d]	
	Accuracy	ROC[e] AUC[f]	Accuracy	ROC AUC	Accuracy	ROC AUC	Accuracy	ROC AUC
1	0.57	0.62	0.57	0.60	*0.59* [g]	*0.63*	0.57	0.61
2	0.6	0.60	0.57	0.59	*0.63*	*0.64*	0.63	0.63
3	0.55	0.51	0.55	0.50	0.55	0.55	*0.58*	*0.62*
4	*0.62*	*0.61*	0.53	0.49	0.53	0.54	0.57	0.57

7	0.52	0.54	0.55	0.54	0.61	0.62	*0.67*	*0.64*
8	0.64	0.52	0.61	0.53	0.68	0.50	*0.72*	*0.56*
9	*0.91*	*0.77*	0.91	0.74	0.91	0.60	0.91	0.74

[a]Results correspond to the classifier performance with different input sets. All the inputs correspond to sequences of different data types (as specified in the columns) before the day with a PHQ-9 record.

[b]Classifier inputs: sequence of embeddings obtained from the transformer.

[c]Classifier inputs: sequence of embeddings obtained from the transformer along with emotion valence prediction obtained from the emotion classifier.

[d]Classifier inputs: the inputs consist exclusively of the emotion predictions obtained from the emotion classifier. Therefore, these columns correspond to sequences of valence predictions of 3 and 15 days before the day with a PHQ-9 entry that is being predicted.

[e]ROC: receiver operating characteristic.

[f]AUC: area under the curve.

[g]For each question, the results obtained with the best model are italicized.

Discussion

Principal Findings

Regarding time-series forecasting, our findings indicated that the transformer model surpassed the HMM in predicting future time steps, resulting in more stable predictions. This suggests that attention mechanisms within the transformer model are effective in capturing longer temporal dependencies, leading to improved prediction stability. Such capabilities are particularly beneficial for assessing a patient's state several days in advance, providing valuable insights into their potential behavior and enabling the early detection of high-risk situations.

The findings concerning emotional changes were generally positive, encompassing both global emotion detection results and change detection 1 day in advance. The variance in outcomes across different machine learning classification algorithms was minimal, highlighting the robustness of the variables and their latent representation. This indicated that accurately predicting a patient's emotional state could be achieved solely through passive variables, with the representation of these variables in the posterior probabilities of the hidden states (obtained with generative models) proving to be informative.

When examining individual patient sequences, it became apparent that in many instances, we could correctly anticipate mood shifts in advance. As for change detection using measures such as entropy or divergence, there appeared to be a correlation between the disorder in emotional valence probability distribution within a specific temporal window and the subsequent emotional state change. Furthermore, global findings indicated that divergence yielded superior results for change detection, suggesting that identifying relative disorder between the current prediction distribution and the past-window distribution holds greater significance than overall disorder within the window, although both contribute to change detection. Similar results were obtained when comparing change detection in patients without any mental disorders and patients with mental disorders. This indicated that the detection was accurate in both cases, with slightly better results for the patients without mental disorders. This can be expected, as the literature suggests that these patients exhibit less fluctuation in their emotions compared to patients with mental disorders.

XSL•FO
RenderX

Regarding the PHQ-9 answers, our model aimed to predict responses with considerable accuracy across both high- and low-frequency classes, allowing for a comprehensive overview of the PHQ-9 outcomes. Upon analyzing differences between answers, those better predicted were typically the ones where patients found it easier to detect their emotions regarding the topic and the frequency of their thoughts. For instance, question 9, corresponding to "Thoughts that you would be better off dead, or of hurting yourself," exhibited the highest classification AUC and accuracy. Conversely, answers such as "Trouble falling or staying asleep, or sleeping too much" and "Feeling bad about yourself or that you are a failure or have let yourself or your family down" yielded poorer results.

Having an approximate score on this questionnaire proved to be a valuable tool, facilitating the monitoring of changes in depressive symptoms over time and guiding treatment decisions. Consequently, it can be used for screening purposes to identify individuals who may require further evaluation for depression.

Limitations

There was a high percentage of missing data in the passive variables, with the minimum percentage of missing data being 52.6% (519,168/986,909) for the number of steps and the maximum percentage being 69.47% (685,614/986,909) for time at home. In addition, there was a very high rate of missing data in the active variables we aimed to predict, such as emotional valence, which had 96.34% (950,833/986,909) missing data.

The recording of emotions was slightly imbalanced, with a higher rate of negative emotions recorded (negative: 16,536/36,076, 45.83%; positive: 10,972/36,076, 30.41%; and neutral: 8568/36,076, 23.74%). Consequently, there was greater sensitivity for detecting negative valence compared to neutral and positive states.

We had limited responses (n=549) for the PHQ-9, and they were sporadic for most of the patients. The mean interval between 2 responses was 25.27 days, with a mode of 14.5 days. On average, each patient responded 4.65 times. Thus, predicting the global score based on passive data was challenging.

Conclusions

Our study yielded several key findings. First, the use of passive variables led to favorable outcomes in both emotion valence detection and change analysis. This underscores the potential of leveraging passive data sources for monitoring and understanding emotional states. Moreover, using temporal methods enabled accurate prediction of emotional states up to a day in advance, with stable results for subsequent days. This temporal stability in prediction highlights the robustness of our approach and suggests its potential applicability in real-world settings where timely intervention is crucial. Further exploration may elucidate the potential for extending prediction horizons beyond a single day, thereby enhancing the utility of our method in long-term monitoring scenarios. Furthermore, our model demonstrates promising performance in predicting PHQ-9 scores, providing an approximate understanding derived solely from passive data. This highlights the utility of this approach as a screening tool for identifying individuals at higher risk of having a crisis or whose depressive symptoms are changing, thereby enabling timely intervention or adjustment in treatment.

Future work should focus on the interpretability of the data. This includes exploring the impact of each variable to assess the patient's condition as well as the effects of removing or adding new variables (such as heart rate and oxygen saturation). In addition, delving deeper into the understanding and extraction of information from the time series could help identify behavioral patterns that determine patient progression as well as pinpoint specific moments that are most relevant for changes in a patient's emotional state, ultimately aiding in adapting the treatment.

While there is room for improvement, particularly in refining the predictive accuracy and expanding the scope of our analysis, our findings represent a significant step forward in the development of in situ support and unobtrusive monitoring strategies for mental health disorders.

Abstract

Background: Ulcerative colitis (UC) is a chronic disease characterized by frequent relapses, requiring long-term management and consuming substantial medical and social resources. Effective management of UC remains challenging due to the need for sustainable remission strategies, continuity of care, and access to medical services. Intelligent diagnosis refers to the use of artificial intelligence–driven algorithms to analyze patient-reported symptoms, generate diagnostic probabilities, and provide treatment recommendations through interactive tools. This approach could potentially function as a method for UC management.

Objective: This study aimed to analyze the diagnosis and treatment data of UC from both physical hospitals and internet hospitals, highlighting the potential benefits of the intelligent diagnosis and treatment service model offered by internet hospitals.

Methods: We collected data on the visits of patients with UC to the Department of Gastroenterology at Tianjin Medical University General Hospital. A total of 852 patients with UC were included between July 1, 2020, and June 31, 2023. Statistical methods, including chi-square tests for categorical variables, *t* tests for continuous variables, and rank-sum tests for visit numbers, were used to evaluate the medical preferences and expenses of patients with UC.

Results: We found that internet hospitals and physical hospitals presented different medical service models due to the different distribution of medical needs and patient groups. Patients who chose internet hospitals focused on disease consultation and prescription medication (3295/3528, 93.40%). Patients' medical preferences gradually shifted to web-based services provided by internet hospitals. Over time, 58.57% (270/461) of patients chose either web-based services or a combination of web-based and offline services for UC diagnosis and treatment. The number of visits in the combination of web-based and offline service modes was the highest (mean 13.83, SD 11.07), and younger patients were inclined to visit internet hospitals (49.66%>34.71%). In addition, compared with physical hospitals, there was no difference in testing fees and examination fees for patients with UC in internet hospitals, but medicine fees were lower.

Conclusions: The intelligent diagnosis and treatment model provided by internet hospitals demonstrates the potential benefits in managing UC, including feasibility, accessibility, convenience, and economics.

Introduction

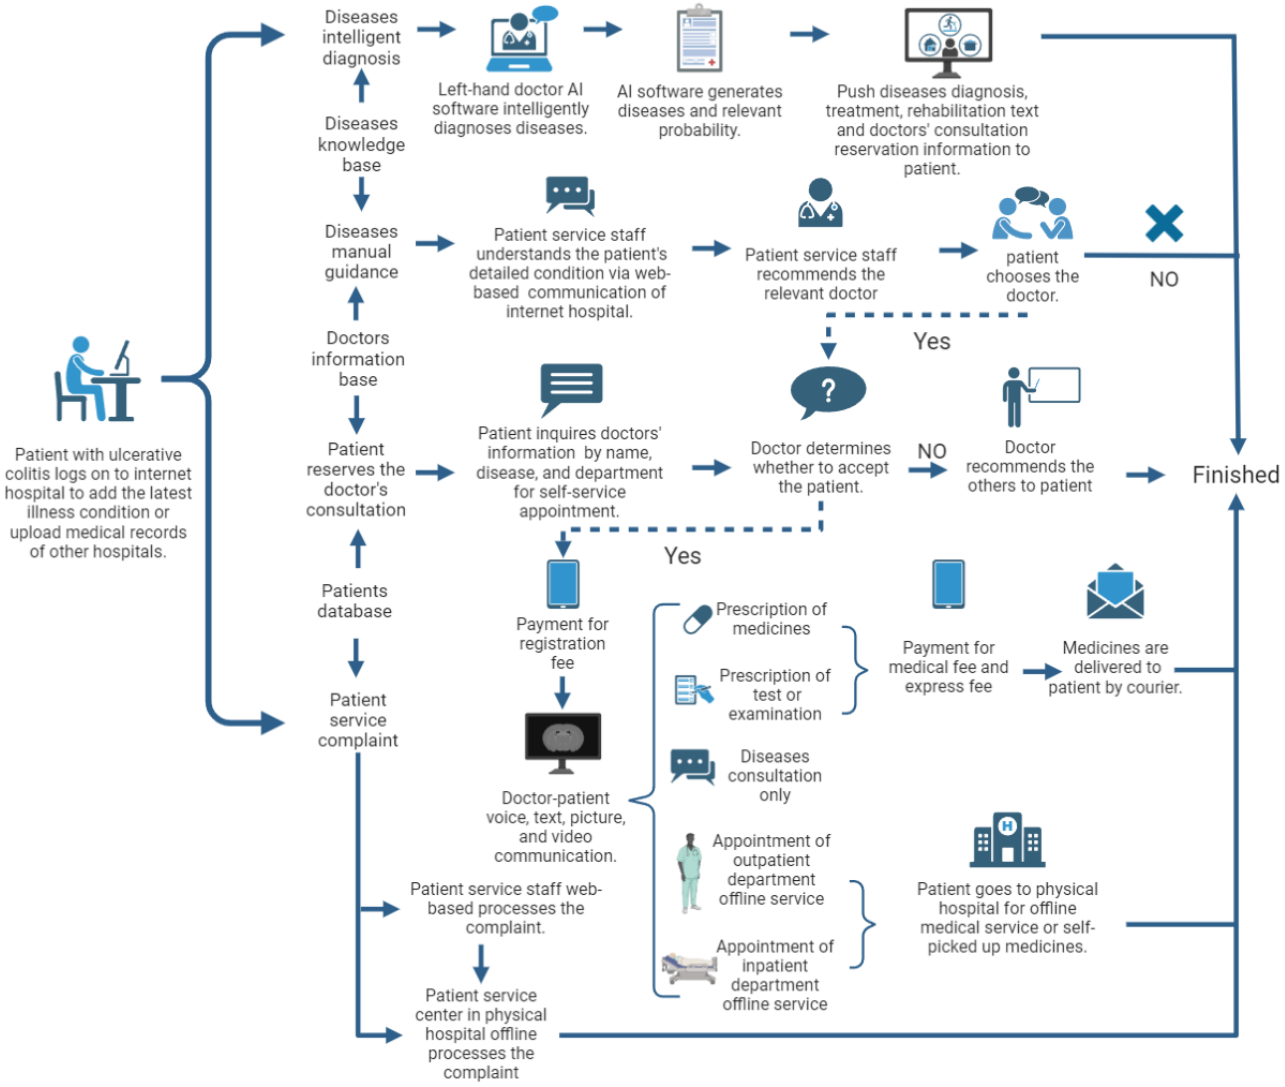
Ulcerative colitis (UC) is a chronic inflammatory bowel disease (IBD) affecting the rectum and colon, characterized by a relapsing and remitting course. As of 2023, UC affects an estimated 5 million individuals globally, with a rapidly increasing incidence [1]. This growing prevalence imposes a substantial economic burden on both health care systems and patients.

Uncontrolled UC can lead to severe complications, including malnutrition [2], intestinal infections [3,4], colon cancer [5], anemia, perforation, toxic megacolon [6], and sepsis. These complications not only decrease the quality of life but also increase the risk of mortality. Effective management strategies are essential to reduce these risks.

Traditionally, patients with UC have required frequent clinic visits and hospitalizations due to the complexity of the disease. To overcome these challenges, several telehealth models have been developed to monitor disease activity and facilitate management, reducing the number of outpatient visits and hospital admissions while improving medication adherence [7,8]. Recent advancements in artificial intelligence (AI), particularly large language models such as ChatGPT, show promise in supporting chronic disease management [9,10]. Studies have highlighted their potential for interpreting medical information and generating responses to common patient queries, thereby enhancing patient education and engagement. Despite these advancements, limitations remain, including short follow-up periods, restricted generalizability to broader UC populations, lack of common-sense judgment, and delays in information updates. In addition, existing telehealth models often rely heavily on pharmacists for medication management [11-13], but greater clinician involvement is essential to ensure comprehensive care for patients with UC.

The internet hospital, as a digital expansion of traditional medical services, uses advanced information and communication technologies to offer consultation, prescription, and follow-up services [14]. Internet hospitals established by physical hospitals can connect web-based and offline medical services, ensuring the continuity of care and adequately meeting the medical needs of patients. The COVID-19 pandemic significantly accelerated their development, as government initiatives promoted the use of internet-based health care platforms to enhance access and continuity of care [15-17]. By early 2023, over 3000 internet hospitals were operating across China, demonstrating the growing importance of this model in managing chronic diseases such as UC. Since internet hospitals are not constrained by geographical limitations, patients can conveniently download the client software for internet hospital services on their mobile phones and schedule appointments for various medical services. Consequently, internet hospitals enhance the accessibility and convenience of health care delivery, particularly in addressing the challenges faced by chronic patients who frequently visit hospitals and experience prolonged waiting times for medical treatment.

Based on the current situation and the development trends in health care, we propose 4 hypotheses regarding internet hospitals in the context of UC management. First, internet hospitals can comprehensively meet the medical service needs of patients with UC by leveraging intelligent tools for diagnosis, treatment, and follow-up. Second, more patients with UC will opt for internet hospital services in the future, drawn by the convenience of digital health care. Third, the accessibility of internet hospitals will lead to an increase in the frequency of visits by patients with UC. Finally, internet hospital services are more economical, reducing costs such as transportation and medicine fees.



Methods

Data Sources

The data for this study were obtained from Tianjin Medical University General Hospital, a Grade-A tertiary general hospital located in Tianjin. In response to the COVID-19 epidemic and the need for effective prevention and control measures, Tianjin Medical University General Hospital established an internet hospital, which officially commenced operations in March 2020. The intelligent diagnosis system in the internet hospital uses AI-based tools, such as the Left-Hand Doctor software, as an auxiliary diagnosis and treatment tool., This system uses deep learning algorithms and big data processing to evaluate symptoms and generate diagnostic probabilities. It also integrates interactive dialogue systems to guide patients through their treatment journey [18,19]. The flowchart of the internet hospital's web-based service is shown in Figure 1.

Data Collection and Inclusion Criteria

We retrieved 15,248 medical records using keywords related to IBD and UC, including *ICD* (*International Classification of Diseases*) codes K52.915 and K51.900, from the database of Tianjin Medical University General Hospital. After excluding 21 incomplete records, 1999 cases with no more than 4 consultations were excluded, as UC is a chronic disease requiring regular follow-up. We believe that if patients visit fewer than 4 times in 3 years, their data may be incomplete, and new patients may not have developed medical habits. In addition, infrequent visits do not accurately reflect preferences for offline or web-based services. We also excluded 126 cases involving only COVID-19 nucleic acid testing and 3285 Crohn disease records. Ultimately, 852 patients were included, with a total of 9817 UC-related visits over 3 years. Of these, 445 (52.2%) were male patients, 407 (47.8%) were female patients, and 649 (76.2%) patients had basic health insurance. This data collection flowchart is shown in Figure 2.

Study Design

In this study, we extracted the diagnosis and treatment data of patients with UC from the Department of Gastroenterology between July 1, 2020, and June 31, 2023. The dataset includes data from in-person consultations at the physical hospital outpatient department and web-based consultations through the internet hospital over the same period. The data also includes information about patients with UC, such as their gender, age, disease diagnosis, treatment time, treatment method, medical expenses, and medical insurance. Our research team tracked the associated patients' visits to UC over 3 years, using their identification card numbers as unique identifiers. Starting in July 2020, the data were divided into 6-month periods to discover the changing trends in the medical services sought by patients with UC, as the promotion and application of internet hospitals continued to grow.

Measures

Medical preferences refer to the types of medical modalities that patients with UC select based on their individual needs, experiences, and the advantages of each modality. From an empirical perspective, we analyze the number of patients using different medical service modes over time to illustrate trends.

The economy of internet hospitals specifically pertains to the comparison of web-based medical fees with those charged in offline settings, including testing fees, examination fees, and medicine fees. Furthermore, patients who opt for internet hospital services can save time and transportation costs for themselves and their companions.

Statistical Analysis

We used chi-square tests to analyze differences in medical preferences and service demands between patients with UC using physical or internet hospitals. We used *t* tests to compare medical expenses across the 2 service modes, while rank-sum tests were used to evaluate differences in the number of patient visits among different medical modes. Frequency and percentages were used to characterize noncontinuous variables, including gender, age group, patient needs, and the number of patients. In contrast, mean and SD values were used to describe continuous variables such as the number of visits and medical fees. All data analysis was performed using IBM SPSS Statistics (version 25).

Ethical Considerations

This study was reviewed and approved by the Ethics Committee of the Tianjin Medical University General Hospital (approval number IRB2024-YX-066-01). The study involved analyzing patient data from the hospital database and did not involve human experimentation or compensation. The data used for this research were extracted from the hospital's information system with previous approval from the Tianjin Medical University General Hospital. To ensure patient privacy and confidentiality, identifying information such as names, addresses, and contact details were removed during data extraction. As a result, the datasets used in the study were anonymized, and no personally identifiable information was accessible to the research team. All patient-related datasets met ethical and legal requirements for data protection. The study adhered to the principles of informed consent, and participants were fully informed of the study's purpose and procedures. In addition, the research team complied with all relevant local, national, and international laws and regulations regarding the protection of personal information, privacy, and human rights. The Ethics Committee of the Tianjin Medical University General Hospital granted approval for this study following a thorough review of the research protocol.

Results

Characteristics of Web-Based and Offline Service Demand

The web-based service mode of the internet hospital can provide equal diagnosis and treatment as a physical hospital. However, web-based consultations (n=3528) were fewer than offline consultations (n=6289), with a significant difference in service demands (P<.001, Table 1). The primary web-based service was prescribing medication (2071/3528, 58.70%), followed by

XSL•FO
RenderX

disease consultations (1224/3528, 34.70%). These findings indicated that web-based services played an important role in the diagnosis and treatment needs of patients with UC, meeting their basic needs, and facilitating follow-up and disease management for chronic diseases. These findings highlight the role of web-based platforms in addressing the basic needs of patients with UC and supporting follow-up care and disease management.

Table 1. Patients' service needs and numbers of visits across different age cohorts over 3 years (N=9817; χ23=879.9, *P*<.001).

Patients' demands for diagnosis and treatment services	Web-based service, n/N (%)	Offline service, n/N (%)
Prescribe medicine	2071/3528 (58.70)	4634/6289 (73.69)
Prescribe testing and examination	125/3528 (3.54)	553/6289 (8.79)
Prescribe drugs, testing, and examination	108/3528 (3.06)	419/6289 (6.66)
Disease consultation only	1224/3528 (34.70)	683/6289 (10.86)

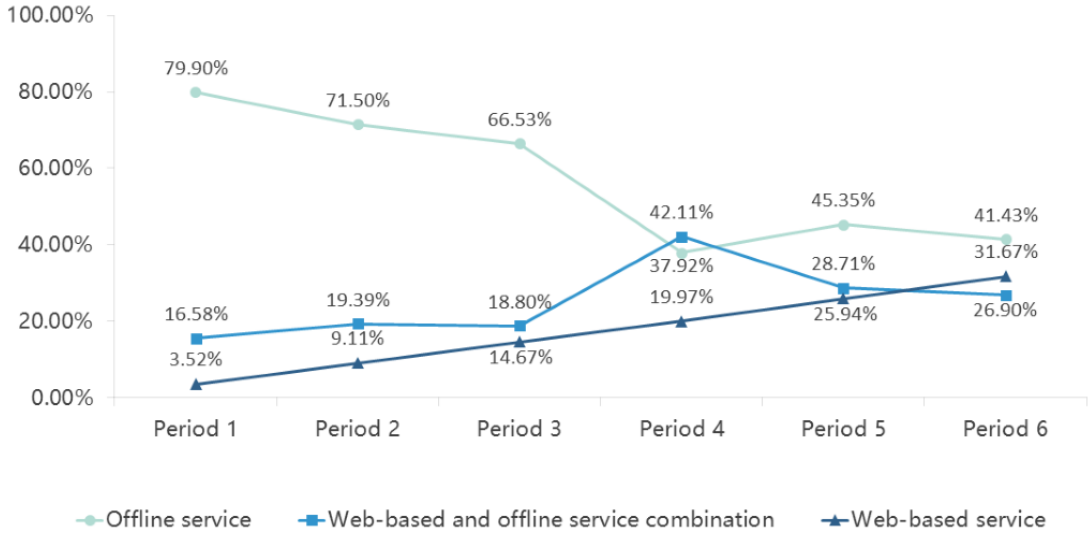
Preference of Different Ages for Medical Treatment Modes

Patients with UC in the age groups of younger than 30 years and between 30 and 40 years demonstrated a greater preference for web-based consultations, with rates of 49.66% and 34.71%, respectively. In contrast, patients aged 50 years and older predominantly opted for in-person consultations at physical hospitals, as indicated by their preference rates of 43.09% compared with 28.03% in Table 2.

Table 2. Patients' visit numbers for different age cohorts across different diagnosis and service modes over 3 years (N=9817; χ24=278.7, *P*<.001).

Patients' visit numbers of different age cohorts	Web-based service, n/N (%)	Offline service, n/N (%)
Age≤30 years	621/3528 (17.60)	712/6289 (11.32)
30<Age≤40 years	1131/3528 (32.06)	1471/6289 (23.39)
40<Age≤50 years	787/3528 (22.31)	1396/6289 (22.20)
50<Age≤60 years	493/3528 (13.97)	1156/6289 (18.38)
Age>60 years	496/3528 (14.06)	1554/6289 (24.71)

Changing Trend of Diagnosis and Treatment Service Modes



During period 1, only 3.52% of patients opted for completely web-based services, while the majority (n=318, 79.90%) preferred entirely offline services, as given in Table 3. By period 6, there was a significant increase in the percentage of patients choosing either completely web-based services (n=146, 31.67%) or a combination of web-based and offline services (n=124, 26.90%), together comprising a total of 58.57%. In contrast, the proportion of patients selecting exclusively offline services decreased from 79.90% in Period 1 to just 41.43% by period 6. The trend of patients selecting various diagnosis and treatment service modes over the 6 periods is given in Figure 3. This trend reflects the growing acceptance and use of web-based diagnosis and treatment options among patients with UC.

Table 3. Number (percentage, %) of patients choosing different diagnosis and treatment service modes across 6 periods (χ210=368.9, *P*<.001).

Periods	Offline service, n (%)	Web-based and offline service combination, n (%)	Web-based service, n (%)
Period 1	318 (79.90)	66 (16.58)	14 (3.52)
Period 2	306 (71.50)	83 (19.39)	39 (9.11)
Period 3	322 (66.53)	91 (18.80)	71 (14.67)
Period 4	262 (37.92)	291 (42.11)	138 (19.97)
Period 5	229 (45.35)	145 (28.71)	131 (25.94)
Period 6	191 (41.43)	124 (26.90)	146 (31.67)

XSL•FO
RenderX

Figure 3. Percentage of patients choosing different diagnosis and treatment service modes across 6 periods.

Preference of Medical Treatment Modes

The number of patients (n=498, 58.45%) who opted for a combination of web-based and offline services, as well as completely web-based consultations, exceeded that of those choosing physical hospitals (354/852, 41.55%) in Table 4. However, patients who chose the combination of web-based and offline care had the highest number of visits (mean 13.83, SD 11.07).

Table 4. Number of patient visits for consultations with different medical service modes over 3 years (N=852; Kruskal-Wallis H=51.39, *P*<.001).

Service modes	Number of patients, n (%)	Number of visits, mean (SD)
Offline service	354 (41.55)	9.33 (6.78)
Web-based and offline service combination	424 (49.77)	13.83 (11.07)
Web-based service	74 (8.68)	8.80 (6.81)

Difference in the Fee of Web-Based and Offline Treatment

The testing fees and examination fees for patients with UC in different age groups showed no statistical difference. However, there was a significant disparity in medicine fees for web-based and offline services among patients with UC of all age groups, with web-based drug fees being lower than offline ones, as given in Table 5.

Table 5. Web-based and offline service expenses (yuan) for different age cohorts (N=9817).

Service expenses	Age≤30 years	30<Age≤40 years	40<Age≤50 years	50<Age≤60 years	Age>60 years
Testing fee					
Web-based service, mean (SD)	289.19 (24.79)	293.49 (23.74)	288.75 (25.32)	325.23 (41.22)	264.90 (46.69)
Offline service, mean (SD)	322.26 (29.99)	325.18 (23.76)	307.42 (37.13)	328.38 (25.38)	266.10 (19.10)

Discussion

Principal Findings

The findings indicate that internet hospitals can effectively address the needs of patients with UC. An increasing number of patients with UC, particularly younger individuals, are opting for internet hospitals for their treatment and follow-up care. This trend not only facilitates better management of UC but also contributes to a reduction in health care costs associated with the disease.

The Tianjin Medical University internet hospital platform features the Left Hand Doctor AI software, which provides relevant information on disease diagnosis, treatment, rehabilitation, and available specialists. Consequently, the AI-driven model enhances patients' ability to choose the appropriate clinical departments and health care providers. In contrast to certain internet hospitals that lack support from physical facilities, medications prescribed by this platform can be obtained either through self-pickup at a physical location or via express delivery. In addition, examination and testing procedures can be conducted at a physical hospital. Patients unable to receive a diagnosis through web-based consultations may be referred to a physical hospital's outpatient department for further treatment. Those needing inpatient care can schedule hospitalization appointments directly via the internet hospital platform. In addition, medical disputes can be mediated at the reception service center of the physical hospital. This indicates that the internet hospital effectively facilitates continuity between web-based and offline medical services.

The COVID-19 pandemic has significantly accelerated the adoption of internet hospitals, with video consultations increasingly replacing many in-person visits [20]. Our findings demonstrate that web-based platforms, such as internet hospitals, play a pivotal role in addressing the long-term management needs of patients with UC. The majority of patients using web-based services sought medication prescriptions (58.70%) and disease consultations (34.70%), indicating the practicality of these platforms for chronic disease management and effectively reducing the burden on offline medical resources. Furthermore, our discoveries reveal a significant increase over time in the number of patients choosing fully web-based services or a combination of web-based and offline services. This trend suggests that internet hospitals will become increasingly accessible in the future. Together, these findings highlight the value of integrating web-based and offline services to ensure comprehensive care, especially in resource-constrained settings.

Age-based preferences indicated that younger patients (younger than 40 years) were more likely to use web-based consultations (49.66%), while older patients (50 years and older) predominantly chose offline services (43.09%). This suggests that emerging digital health methods, such as internet hospitals, are more easily accepted by younger people. The flexibility and convenience of web-based platforms appeal to younger demographics, whereas older patients may favor the familiarity and perceived reliability of in-person care. These trends highlight the need for a hybrid model to accommodate diverse patient preferences. Furthermore, web-based services significantly reduced medicine costs compared with offline services (P<.001), with consultation fees also being lower under the unified internet hospital policy in Tianjin. These cost advantages make web-based platforms a more economical option for the long-term management of UC, alleviating the financial burden on patients.

Our findings align with previous studies that demonstrated the growing role of telemedicine in managing chronic diseases. For example, de Jong et al [21] showed that telemedicine systems, such as myIBDcoach, significantly reduced hospital admissions and improved medication adherence in patients with IBD [21]. Similarly, 2 other studies highlighted the effectiveness of telehealth models in improving patient outcomes [22,23]. While these studies focused on specific telehealth tools, our research provides a broader analysis of internet hospital services, demonstrating their capacity to integrate web-based and offline care while maintaining cost-effectiveness and accessibility. However, unlike earlier studies that relied on short follow-up periods [24], our analysis spans 3 years, offering a more comprehensive view of the long-term impact of internet hospitals. A recent study by Al-Sheikh et al [25] emphasized the efficacy of telehealth models in reducing health care costs in IBD management [25]. However, it was unable to eliminate the cost variance resulting from the disparity in hospital registration techniques, as the research participants were from different hospitals. The participants of our study are all from the General Hospital of Tianjin Medical University, thereby effectively avoiding the interference of hospital technical factors.

Strengths and Limitations

Our study has several strengths. First, this retrospective study provides insights into the use of internet and physical hospitals for UC management over 3 years, with a representative sample from a Grade-A tertiary hospital. Second, it is the first to investigate how internet hospitals can facilitate standardized care for patients with UC outside traditional settings. However, this study has limitations. The internet hospital system lacks data on the quality of care and patient satisfaction, which limits the evaluation of service outcomes. A service quality model, a satisfaction degree questionnaire, and even a comprehensive satisfaction degree index measured by a 5-point Likert scale are proposed to be designed based on the conditions of the internet hospitals and then integrated into the hospital information system. Therefore, quality and satisfaction data can be automatically obtained from the hospital database. Furthermore, long-term studies are needed to assess the sustained effects of internet hospitals on patient outcomes, as well as the accuracy and precision of AI diagnosis tools such as the Left-Hand Doctor mentioned in the paper.

Conclusion

Internet hospitals represent an innovative approach to UC management, offering a series of web-based intelligent diagnosis and treatment services. Through seamless integration of web-based and offline care, they ensure continuity of care. Compared with the traditional medical model, this approach highlights the potential benefits in terms of feasibility, accessibility, convenience, and economy. This intelligent mode

XSL•FO

can also be applied to the medical service and disease management of other chronic diseases.

Abstract

Background: Virtual consultations represent a notable change in health care delivery following the COVID-19 pandemic. Understanding the dynamics of virtual consultations is critical in assessing health care system resilience and adaptability in times of crisis.

Objective: This study aimed to describe the availability and hours of use of telephone, video, and human chat consultations before and during the COVID-19 pandemic period, and identify factors associated with their availability.

XSL•FO
RenderX

Methods: Primary care physicians (PCPs) from 20 upper-middle– and high-income countries completed a cross-sectional web-based survey in 2020. Factors associated with availability were investigated using chi-square tests and effect size (ES) estimates calculated using Cramer V.

Results: A total of 1370 PCPs were included in this study (85.4% of the total sample of 1605). Telephone consultations were the most frequently available type of virtual consultations before and during the pandemic (73.1% and 90.4%, respectively). Significant increases in availability and use were observed during the pandemic for all the types of virtual consultations. The largest absolute increase in availability was observed for video consultations (39.5%), followed by telephone (17.3%) and chat (8.6%; all $P<.001$). The largest increase in use was observed for telephone consultations (+11 hours per week, $P<.001$). Digital maturity of the practice was weakly associated with availability of video consultations both before (ES 0.2) and during (ES 0.2) the pandemic ($P<.001$ for both), and with chat consultations before the pandemic only (ES 0.1, $P=.001$). Greater availability of video and chat consultations was found in PCPs who had completed digital health training, both before and during the pandemic ($P<.001$ for all). There was significant country-level variation in the use and availabilities of the technologies between both time periods. The association between country and the availability of telephone consultations changed from strong (ES 0.5, $P<.001$) to weak (ES 0.2, $P=.03$), while the relationship between country and video consultations changed from moderate (ES 0.3, $P<.001$) to strong (ES 0.5, $P<.001$).

Conclusions: Our study demonstrates the transformative impact of the COVID-19 pandemic on the availability of virtual consultations globally, and how practice-level factors, predominantly digital maturity, digital health training, and country, were associated with the availability of virtual consultations. Further exploration of drivers of availability, particularly at the national level, is needed to ensure sustained and effective implementation of virtual consultations.

Introduction

The emergence of virtual consultations, defined as remote health care interactions facilitated by digital technologies, is a significant evolution in health care delivery. Telephone, video, and chat consultations may be more accessible than in-person appointments, as they offer rapid real-time communications with providers without a need to travel [1,2]. Despite these potential benefits, before the COVID-19 pandemic, these technologies, particularly telephone consultations, were steadily gaining traction, but had not reached widespread integration into most mainstream primary health care systems [3,4].

During the COVID-19 pandemic, virtual care became vital to the safe and efficient continuation of primary care delivery, when minimizing in-person encounters was essential to protect both health care staff and patients from the risk of infection [5,6]. Many health systems adopted some form of “virtual first” approach to primary health care provision [4]. The initial virtual encounter aimed to manage patients’ needs without in-person contact wherever possible while reserving “higher risk” face-to-face visits for those at greatest need, and where physical examination was deemed to be essential.

Throughout the pandemic, primary care physicians (PCPs) faced barriers in adopting and implementing virtual consultations, with potential consequences impacting the quality of care delivered to patients [2]. The ability of PCPs to effectively transition to virtual service delivery depends on multiple factors, including organizational and policy incentives, digital health infrastructure capacity and investment, cultural norms and attitudes, and the digital health literacy and skills of PCPs and patient populations [3,4,7-9]. These factors would act as barriers or drivers to differing degrees depending on the specific consultation technology, with likely fewer infrastructural or skill barriers for telephone consultations compared to video or chat consultations [10]. These factors may have resulted in variation in adoption and use of different virtual consulting technologies between PCPs and providers from different settings [2,4].

With growing demand for rapid and convenient access to primary care, alongside financial constraints requiring efficiency gains, virtual care appeared as an attractive solution to enhance patient accessibility [2]. Consequently, virtual consultations continue as a core component of health care delivery in many upper-middle– and high-income countries beyond the pandemic [4].

Examining the landscape of virtual health care technologies before and during the pandemic can help us better understand the magnitude of the transition to these new models of care. This transition highlights the investments made into the digital health capacity of primary care systems, carrying significant long-term implications for how care is delivered. However, how the availability and uptake of virtual consultations varied across PCPs from different settings, including different countries, is uncertain [11].

The aim of this study was to analyze access and use of virtual consultations before and during the pandemic, and factors

XSL•FO
RenderX

associated with availability of virtual consulting technologies between PCPs from different settings. Specific aims include to analyze the availability and hours of use of telephone, video and chat consultations before and during the COVID-19 pandemic, and to identify factors associated with their availability.

Methods

Study Design

This study used data from a cross-sectional web-based questionnaire completed by PCPs of 20 upper-middle- and high-income countries (Australia, Brazil, Canada, Chile, Colombia, Croatia, Finland, France, Germany, Ireland, Israel, Italy, Poland, Portugal, Spain, Slovenia, Sweden, Türkiye, the United Kingdom, and the United States). The questionnaire was designed and administered by the inSIGHT Research Group, a consortium of academic primary care researchers from the 20 countries previously listed. The study adheres to the STROBE (STrengthening the Reporting of OBservational studies in Epidemiology) guidelines for reporting observational studies [12].

Data Collection

Participants were eligible if they were practicing PCPs in 1 of the 20 countries listed above, between March and September 2020. The study was conducted between June and September 2020. National leads in each country invited PCPs through their formal organizations or personal networks through email or social media (ie, Facebook and Twitter [subsequently rebranded X]). The questionnaire was hosted on Qualtrics (Silver Lake) and was available in English, French, German, Italian, Spanish, and Portuguese. A complete description of the study protocol, including the full questionnaire and power analyses, has been previously published [13]. Sections of the questionnaire relevant to this study are included in pages 2-5 in Multimedia Appendix 1.

Study Variables

Participants were asked to answer whether chat (ie, using a text-based messaging system), telephone or video consultations were available in their practice before or during the COVID-19 pandemic (from March 11, 2020). Respondents ticked a box for each period considered (ie, before or during the COVID-19 pandemic) to indicate a technology was available in that period.

Respondents were subsequently asked how many hours they spent per week on each type of consultation in each time period. Before analysis, hours per week spent on each of the 3 virtual consultation technologies were cleaned to remove answers of ≥100 hours per week. A response of >0 hours spent on a technology was considered evidence for the technology being available. This study includes PCPs who responded to at least 1 question on the availability or hours of use of virtual consultation technologies.

Predictor variables included country, urbanicity (rural, mixed, and urban), and practice digital maturity. Practice digital maturity was assessed using the digital maturity framework developed by Flott et al [14], which considers the 6 dimensions of usage, resources, and abilities (organizational and individual), interoperability, general evaluation methodology, and impact. PCPs could agree or disagree with 6 statements about their practice's digital maturity, corresponding with the 6 dimensions. A digital maturity score was calculated for each PCP by granting 1 point for each statement with which the PCP indicated agreement, giving a possible range of 0 to 6 where a score of 6 indicates high digital maturity. PCPs were also asked whether they have completed training on digital technologies before or during the COVID-19 pandemic.

Statistical Analysis

The total number of hours spent per week before and during the pandemic on virtual consultation technologies was calculated for PCPs who reported availability of at least one of the technologies in the period. For PCPs who reported the technology as available in both time periods, the number of hours spent by PCPs on each technology before and during the COVID-19 pandemic were compared using paired Wilcoxon signed rank tests, and the relationship between the predictors and change in hours of use of each technology was investigated using univariable linear regression models.

McNemar tests were conducted to compare availability of each technology before and during the COVID-19 pandemic period. Absolute differences in the percentage of PCPs with each technology available in each time period were described. Plots were created to visualize changes in technology availability and hours of use by country of PCP employment.

Cramer V was calculated to estimate the effect size (ES) of practice factors upon the variation in the availability of digital technologies before and during the COVID-19 pandemic. Cramer V estimates of ES to describe the strength of association between the predictors and outcomes were categorized as weak (0-0.29), moderate (0.3-0.49), or strong (≥0.5). The change in percentage of PCPs with each technology available was visualized by country. *P* values for statistical tests were adjusted for multiple comparisons using the Holm-Bonferroni method [15]. All analyses were performed in R (version 4.3; R Foundation for Statistical Computing) [16], and a significance level of .05 was used throughout.

Ethical Considerations

Ethical approval was granted by the UK Imperial College Research Ethics Committee (reference 20IC5956), which oversees health-related research with human participants. Survey participants gave their written informed consent to participate in the study. Data collected were anonymous and no compensation was given for participation in the survey.

Results

Overview

This study includes responses from 1370 PCPs who responded to at least 1 question on the availability and/or hours of use of virtual consultation technologies, representing 85.4% of the total sample of 1605 (Table 1).

[a]PCP: primary care physician.

The majority (827/1370, 60.4%) of the respondents were female and 57.6% (790/1370) were aged between 30-49 years. Almost a third (444/1370, 32.4%) of the respondents had clinical experience of more than 20 years. PCPs spent a median of 36 (IQR 28-40) hours on clinical work per week. The highest proportion of the respondents (852/1370, 62.2%) worked in practices based in urban areas. The median digital maturity score of their practices as reported by PCPs was 4 (IQR 2-5). Training on digital-first technologies was undertaken by (312/1370, 22.8%) PCPs before the pandemic and by (375/1370, 27.4%) PCPs during the pandemic period. A breakdown of PCP characteristics by country is available in Tables S1 and S2 in Multimedia Appendix 1.

Use of Digital Technologies

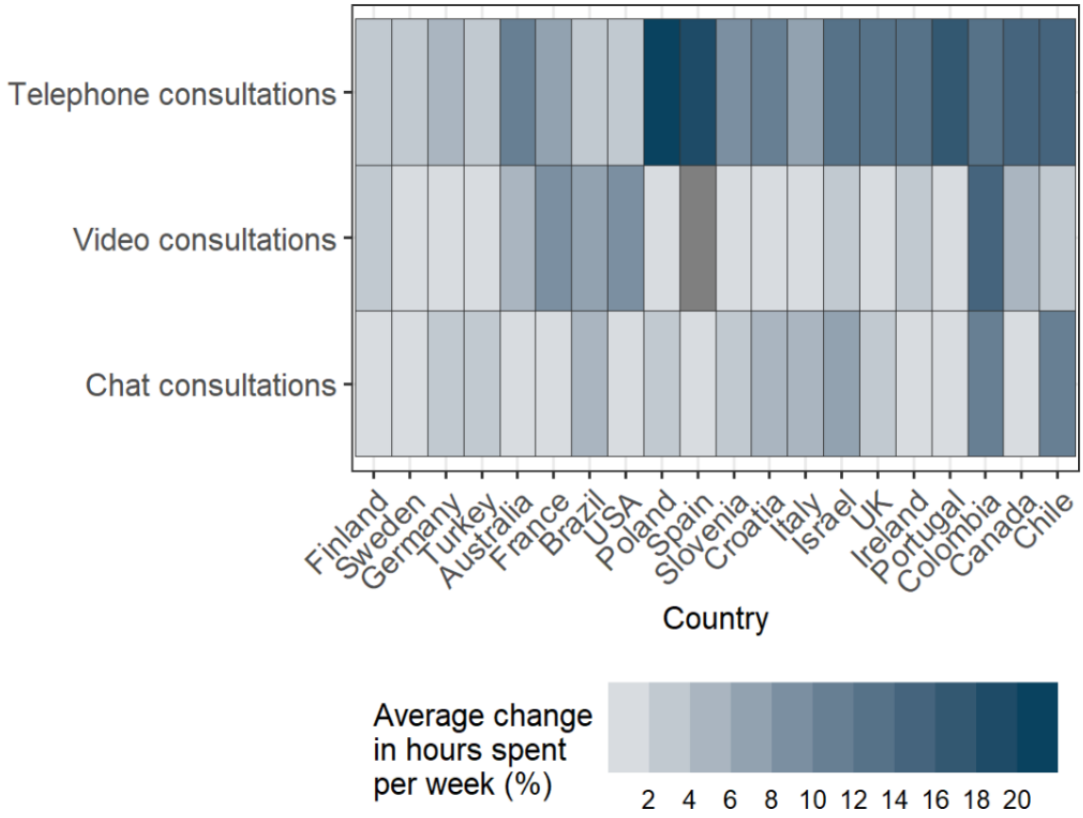
PCPs reported spending a median of 3 hours per week using these tools (IQR 1-5), increasing to 15 (IQR 8-25) during the pandemic period (P<.001). Hours spent per week on specific technologies are shown in Table 2.

The average number of hours per week spent on each type of virtual consultation increased during the pandemic (Table 2). The greatest change was observed for time spent on telephone consultations (+11.0 hours/week, P<.001), on which 91.8% of PCPs reported spending increased time.

Country of PCP employment was associated with changes in hours spent per week on telephone (R^2=0.2, P<.001) and chat consultations (R^2=0.1, P=.001), but not with changes in hours spent on video consultations (R^2=0.1, P=.73). The increase in hours spent per week on telephone consultations was largely driven by PCPs from Poland, Spain, Canada, Chile, and Portugal, who spent more than 15 additional hours per week on telephone consultations during the COVID-19 pandemic compared with before (Figure 1).

No association was found between changes in hours of use of any of the 3 virtual consultation technologies and any of practice digital maturity score, training, or urbanicity (Figure S1 in Multimedia Appendix 1).

Table 2. Average change in hours spent on virtual consultations by primary care physicians before and during the COVID-19 pandemic period, amongst primary care physicians who had the technology available in both time periods. The COVID-19 pandemic period was defined as the period from March 11, 2020 onwards to the date of survey completion by the primary care physicians (between June and September 2020).



Technology	Denominator	Mean hours spent per week before the pandemic	Mean hours spent per week during the pandemic	Mean difference in hours, mean (SD)[a]	P values[b]
Telephone consultations	883	3.8	14.2	+11 (10.7)	<.0001
Video consultations	127	1.3	4.3	+4.5 (7.3)	<.0001
Chat consultations (ie, using a messaging system)	365	2.4	5.3	+3.4 (6.7)	<.0001

[a]The mean difference describes the mean of the change in hours spent by each primary care physician on the technology.

[b]P values correspond to 2-sample Wilcoxon tests.

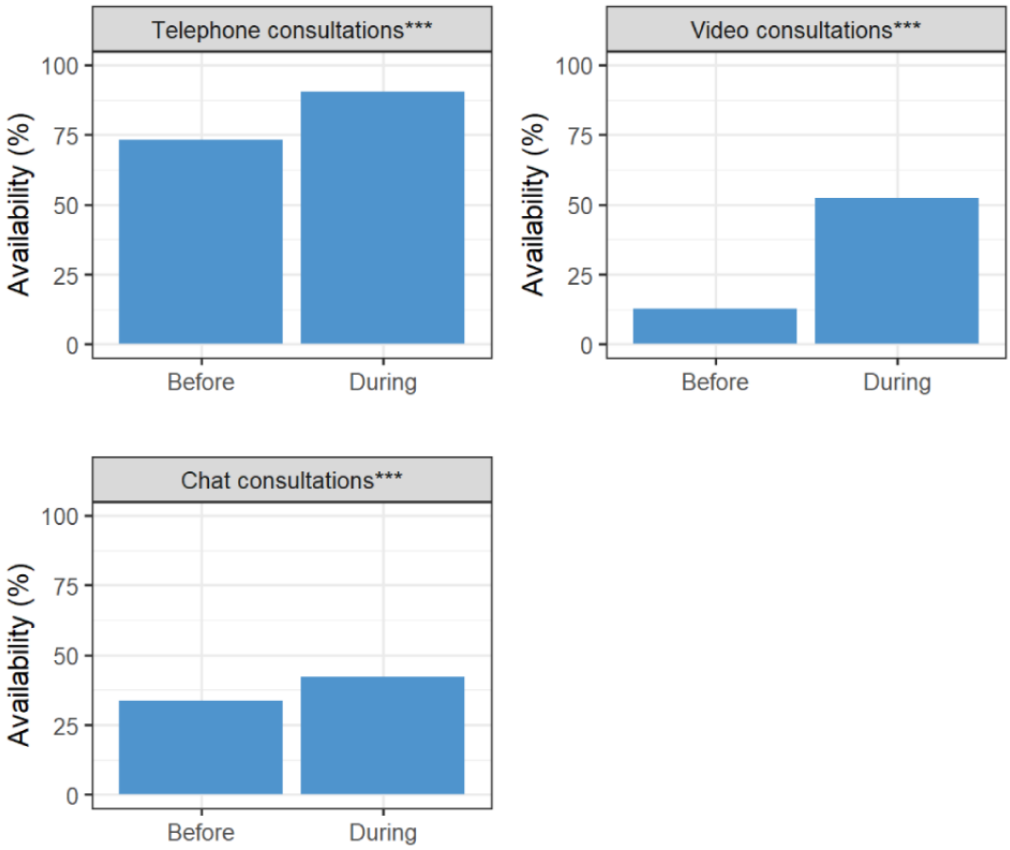
Figure 1. Mean change in hours spent per week on virtual consultation technologies by primary care physicians during versus before the COVID-19 pandemic period, by country of primary care physician employment. The COVID-19 pandemic period was defined as the period from March 11, 2020, onwards to the date of survey completion by the primary care physician (between June and September 2020). Grey cells indicate where no data was available for change in hours of use.

Availability of Virtual Consultations Before and During the COVID-19 Pandemic



Before the pandemic, telephone consultations were the most frequently available virtual consultation technology (73.1%, 1002), followed by chat consultations (33.7%, 462) and video consultations (12.8%, 176). During the pandemic, telephone consultations remained the most frequently available solution (90.3%, 1238), followed by video consultations (52.3%, 717) and chat consultations (42.3%, 580).

Statistically significant increases were observed for all types of virtual consultation during the pandemic. During the pandemic, telephone consultations remained the most commonly available technology (90.4%, 1238; Figure 2). The largest absolute increase in availability was observed for video consultations (+39.5%, $P<.001$; Figure 2; Table S3 in Multimedia Appendix 1).

Of the 365 PCPs who lacked access to telephone consultations before the COVID-19 pandemic, 87.7% gained availability to this type of virtual consultation during the crisis. Correspondingly, 49.3% (n=584), and 21.8% (n=196) of PCPs who previously did not have access to video consultations, or chat consultations, respectively, reported gaining access to these technologies during the COVID-19 pandemic period.

XSL•FO
RenderX

Figure 2. Percentages of primary care physicians who reported virtual consultation technologies as available to them before versus during the COVID-19 pandemic period. The COVID-19 pandemic period was defined as the period from March 11, 2020, to the date of survey completion by the PCP (between June and September 2020). ***: adjusted *P* values <.001.

Factors Associated With Availability

Before the COVID-19 pandemic, practice urbanicity was weakly associated with availability of telephone consultations (ES 0.1, *P*<.001). Digital health training was weakly associated with availability of video (*P*<.001) and chat consultations (*P*=.04). Digital maturity score was weakly associated with increased availability of video consultations (*P*<.001) and chat consultations (*P*=.001). There was moderate to strong association between the country and availability of each of the technologies (Figure 2; ES range: 0.3-0.5, *P*<.001 for all).

During the pandemic, significant associations remained between availability and country, digital health training, and digital maturity score (Figure 2). Country persisted as significantly associated with the availability of chat consultations (*P*<.001), video consultations (*P*<.001), and telephone consultations (*P*=.03). Digital maturity score remained only weakly associated with the availability of video consultations (*P*<.001), but not with telephone or chat consultations. Digital health training was weakly associated with the availability of video (as observed before the pandemic), but also with chat consultations (*P*<.001 for both). Practice digital maturity score was no longer associated with chat consultations during the pandemic.

The strength of univariable associations between the availability of the technologies and the predictors differed before and during the COVID-19 pandemic. The strength of the associations between the country and telephone consultations decreased from strong to weak between the 2 time periods. In contrast, the strength of association between video consultations and country increased from moderate to strong.

A detailed overview of the nature of such associations is provided below.

Country Variations

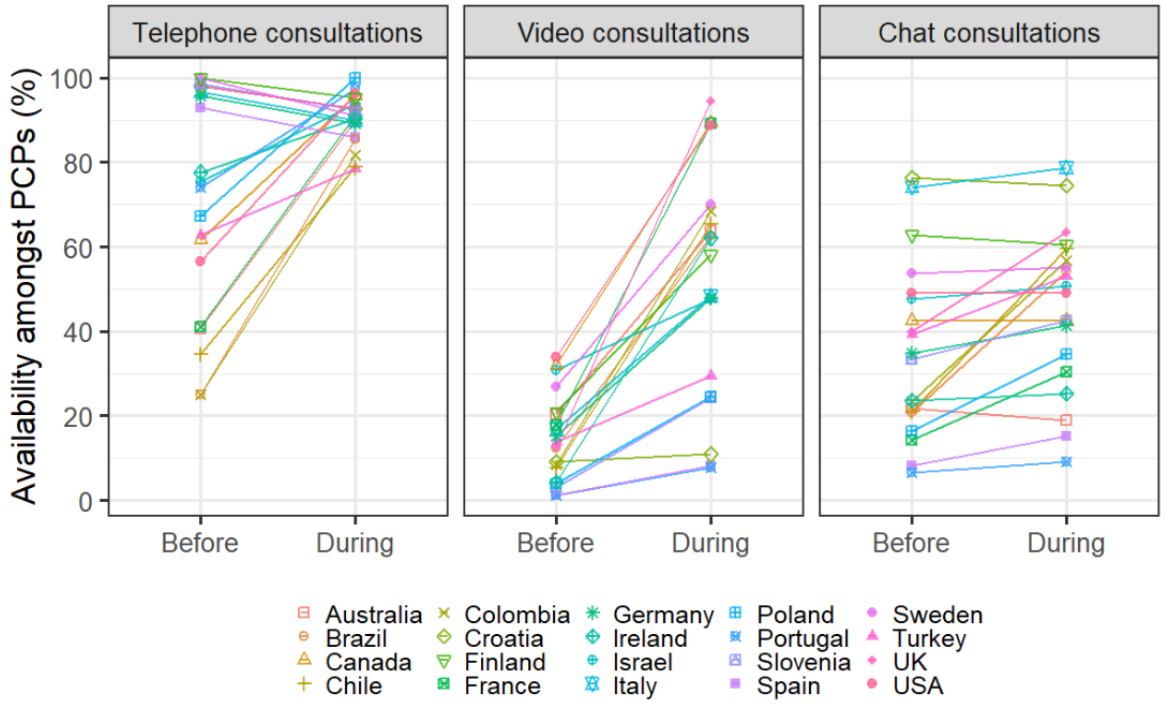
Availability of chat consultations varied greatly by country for both time periods, ranging from 9% to 78.7% for before the COVID-19 pandemic, and 6.5%-75.4% during the COVID-19 pandemic. Most countries showed only small changes in availability of chat consultations from before to during the COVID-19 pandemic (Figure 3). The largest changes in availability were observed for PCPs from Chile (+38.5%), Colombia (+33.3%), Brazil (+33.3%), and the United Kingdom (+23.6%). Changes in availability of <10% were observed for PCPs from 13 of the 20 countries surveyed.

There was less variation in availability of telephone consultations between countries during than before the COVID-19 pandemic period (Figure 4). Before the pandemic, availability of telephone consultations across countries ranged from 25% to 100%, while during the pandemic, availability ranged from 78.4% to 100%. There were distinct differences in change in telephone consultation availability by country. Average availability of telephone consultations decreased amongst PCPs from countries, which reported >90% availability of telephone consultations before the COVID-19 pandemic while increases in availability were observed for all other countries.

XSL•FO
RenderX

Availability of video consultations was low across all countries before the COVID-19 pandemic period, with less than 35% of PCPs from each country having them available (range 1.1%-33.4%). Availability of video consultations increased on average for PCPs from all countries, to differing degrees by country (Figure 4). The largest increases were observed for PCPs from the United Kingdom (+81.8%), followed by PCPs from France (+71.4%), Colombia (+60.0%), and Ireland (+57.8%).

Figure 3. Absolute difference in percentage of primary care physicians from each country reporting the technology as available to them before versus during the COVID-19 pandemic. The COVID-19 pandemic period was defined as the period from March 11, 2020, to the date of survey completion by the primary care physician (between June and September 2020). PCP: primary care physician.



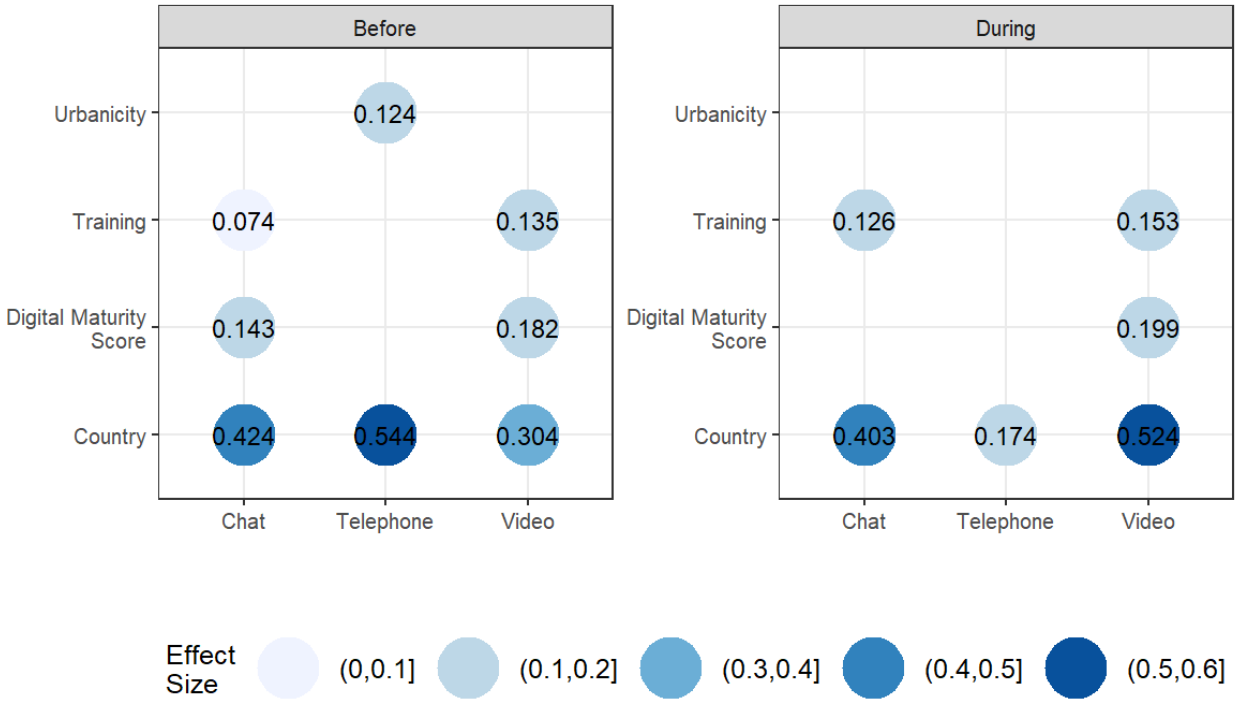


Figure 4. Effect size of primary care physician and practice factors on the reported availability of digital consultation technologies before and during the COVID-19 pandemic. The COVID-19 pandemic period was defined as the period from March 11, 2020, to the date of survey completion by the primary care physician (between June and September 2020). Effect sizes correspond to Cramer V measures of association; larger effect sizes indicate a stronger relationship between the predictor and availability. Estimates for nonsignificant relationships are not shown.

XSL•FO
RenderX

Urbanicity

Before the pandemic, the percentage of PCPs with telephone consultations available was highest amongst those from rural practices (83.4%), compared with mixed (77.5%) or urban settings (69%). This difference by practice urbanicity did not persist into the pandemic period. Availabilities of video and chat consultations were similar across PCPs from urban, mixed, and rural settings in both time periods.

Digital Health Training

Higher availability of video consultations was reported amongst PCPs who had completed, versus never completed, training in digital-first technologies, both before (18% vs 9%, $P<.001$) and during (61.1% vs 45.8%, $P<.001$) the pandemic. PCPs who had completed training reported greater availability of chat consultations before (37.8% vs 30.7%, $P=.04$) and during (49.5% vs 37%, $P<.001$) the pandemic period.

Digital Maturity

Availability of video consultations before and during the pandemic was greater amongst PCPs from more digitally mature practices. Availability of chat consultations before the pandemic was highest in PCPs from practices with a digital maturity score of 6 (42.7%), followed by 4 (39.6%) and 1 (35.7%). After adjustment for multiple testing, there was no association detected between digital maturity and availability of chat consultations during the pandemic.

Discussion

Principal Findings

Telephone consultations were the most frequently available type of virtual consultations both before and during the pandemic (73.1% and 90.4%, respectively). Significant increases in availability during the pandemic were observed for all the types of virtual consultations, alongside significant increases in hours spent on every type of virtual consultation. The largest increase in availability was observed for video consultations, whereas, although a minority of countries did display large increases in availability of chat consultations (Figure 3), a smaller change emerged in availability of chat consultations overall.

Regarding the factors associated with availability, PCPs from rural practices reported greater availability of telephone consultations before the COVID-19 pandemic but this association did not persist in the pandemic. Practice digital maturity was significantly (although weakly) associated with the availability of video consultations both before and during the pandemic, and with chat consultations before the pandemic only. Digital health training was weakly associated with the availability of both video and chat consultations, both before and during the pandemic.

There was significant country-level variation in the hours of use and availabilities of the technologies between both time periods (Figures 1 and 3). The association between country and the availability of telephone consultations changed from strong to weak, while the relationship between country and video consultations changed from moderate to strong. There was similarly strong country-level variation in availability of chat consultations in both periods.

Comparison With Previous Work

Telephone consultations were the most frequently available and used virtual consultation modality, increasing during the pandemic compared with before. Their higher use and uptake were likely driven by their lower resource requirements and maintenance costs compared with video and chat consultations [7,10]. In addition, telephones are readily available to most patients and telephone consultations were already widely used in primary care in many places (Figure 3) [4], reducing the need for additional infrastructure or training. Supporting this, telephone consultation availability was independent of practicing digital maturity level or training in digital-first technologies, unlike video or chat technologies (Figure 2).

Before the pandemic, rural PCPs reported greater availability of telephone consultations compared with PCPs from urban or mixed settings. This is unsurprising, given the benefits of virtual consultations where geographic isolation can limit health care accessibility [17]. However, during the pandemic, availability of telephone consultations became similarly high amongst PCPs from rural, mixed, and urban settings, likely attributable to the need for social distancing and consequent adoption of telephone consultations in urban areas. Future research should address whether these changes persisted in the postpandemic period.

Smaller increases were apparent in the availability and use of chat consultations during the pandemic, compared with video. This may reflect specific implementation barriers for this type of virtual consultation, alongside their perception as an adjunct to, rather than as a replacement for, other consultation methods [18]. Previous UK research found that most online consultations required in-person or telephone follow-up [19,20]. There are safety considerations with chat consultations, including the challenges of identifying patient cues solely from written communication [21]. The proportionately greater increase in availability of video is likely explained by the ability to see the patient, which contributes substantially to the confidence of professionals in making a clinical assessment [22].

Adherence to data privacy regulations poses a particular challenge for implementing chat consultations, potentially discouraging uptake. Fulfilment of the legal obligation to record and store patient information can be difficult for chat consultations, necessitating PCPs to keep separate clinical records [23-25]. Most commonly used commercial messaging systems (eg, Telegram, iMessage, and WhatsApp) do not comply with health data privacy and security regulations [23,25]. Despite potential nonadherence to ethical or data privacy guidelines, commercial instant-messaging providers are widely used for clinical purposes by patients and health care staff [24,26-28].

Among the factors examined, the country had the strongest association with availability of virtual consultation technologies and was the only significant predictor of change in hours of use. The varied ability to transition to virtual service delivery between countries is likely attributable to various governance and infrastructural factors. Some countries have national

XSL•FO
RenderX

long-term digitization goals for primary care, including strategies for virtual consultation adoption [29-31]. Coupled with guidelines on their effective and safe use [32,33], these would have facilitated greater adoption by PCPs. Countries also varied in their organizational and IT readiness to incorporate new consultation technologies into existing operations [9]. In the case of video and chat, regional variation in the availability of suitable platforms, internet coverage, and smart devices may have affected the feasibility of these consultations, contributing to a digital divide [10,31,34]. Implementation of video consultations in some countries was impeded by the need to update national health data regulations [3] and reimbursement policies [4,7,17,33]. It would be a valuable area of future work to map systems-level characteristics and explore associations between them and availability and use of virtual consultations.

Country-level variation in telephone consultation availability reduced during the pandemic compared with before, while the variation for video consultations increased (Figures 2 and 4). This indicates that the COVID-19 pandemic amplified discrepancies in barriers and facilitators of video consultation implementation between countries. Before the COVID-19 pandemic, video consultations were in the earlier stages of adoption in many countries, whereas telephone consultations were already widely available (Figure 3) and easier to scale up, for reasons previously stated [4]. Many countries continue to lack strategies for interoperability or digital education [29], likely contributing to the low adoption of video consultations post the pandemic [9]. Future research should investigate whether there have been sustained country-level differences in video consultation implementation beyond the pandemic.

Strengths and Limitations

A primary strength of our study is the large number of PCPs surveyed from 20 countries, which included a mix of urban and rural settings, during a critical transition period for primary care service delivery. However, the findings must be interpreted in light of some accompanying weaknesses. The generalizability of the study's findings may be limited by the reduced representativeness introduced by use of convenience sampling. Convenience sampling may introduce some self-selection bias for PCPs who hold stronger views about the research topic and are more vocal in sharing their experiences. Use of an anonymous web-based survey, disseminated by email and social media, prevented the identification of whether multiple respondents were employed at the same organization. In addition, due to the cross-sectional nature of the survey, we cannot establish directionality in the associations detected and causality should not be inferred. Nonetheless, these limitations are inherent to most survey-based studies and should not detract from the value of our findings.

In addition, the survey was not available in all the languages spoken by the countries surveyed which possibly excluded some PCPs from participating or affected their interpretation of questions. The study did not consider the type or size of health care organizations. Smaller practices may have incurred greater difficulties in transitioning to virtual service delivery models, particularly those in lower income areas, due to facing higher operating costs [7,10]. Another limitation is that PCPs were surveyed exclusively from upper-middle and high-income countries, restricting the generalizability of the findings to health care systems of similar economic contexts.

Finally, there have likely been significant changes in the implementation and perceptions of digital health technologies since the survey administration in 2020. An examination of availability and use of these virtual consultation technologies in more recent years, including in postpandemic contexts, would be a valuable area of future work. Nevertheless, these findings reflect a critical period for understanding the adaptability of health care systems in times of crisis.

Implications for Policy and Practice

Understanding the variations in the availability of virtual consultation technologies within and between countries is essential to ensure that their continued use does not impose additional barriers [35]. While the pandemic reduced country-level discrepancies in the availability of telephone consultations, a widening gap emerged with the availability of video consultations. Further investigation is needed to determine if these disparities reflect variations in patient, clinician, or health care organization preferences, or if they stem from digital capacity limitations.

To fully harness the potential of digital health innovations, health care providers must possess a robust understanding of their capabilities, limitations, and ethical implications. However, despite the finding of a positive relationship between training in digital first technologies and availability of chat and video consultations, less than a third (27.4%) of PCPs had completed such training. There is therefore a need for comprehensive digital health training for physicians, ensuring that they are equipped with the digital health literacy essential for delivering optimal patient care in the modern health care landscape [11].

As video consultations experienced the most significant rise, it is crucial to establish through further research whether this pattern persists in current practice, and whether this consultation modality offers substantial advantages beyond simply reducing in-person interactions. It is possible that video consultations served primarily as a tool for clinical risk mitigation during the pandemic; as restrictions on in-person appointments have stopped, the high use of video consultations may have declined [9]. This underlines the need for further studies to understand the postpandemic landscape.

Conclusions

This study highlights the significant role the COVID-19 pandemic played in driving the global adoption of virtual consultations in primary care. The increased use of virtual consultation technologies during the COVID-19 pandemic underscores the flexibility of primary care systems to adapt rapidly to the constraints imposed by the pandemic. This shift enabled continued service delivery while minimizing exposure risks for both patients and health care staff.

This research identified practice-level factors, particularly the country of practice and practice digital maturity, and digital health training, as key factors associated with the availability of these technologies. Although the COVID-19 pandemic

XSL•FO
RenderX

motivated increased usage of virtual consultations overall, it also revealed widened discrepancies between countries in their ability to implement video consultations. Systems-level research is necessary to identify the country-level facilitators and barriers toward implementation of video consultations, to ensure their continued use.

Acknowledgments

ALN, G Greenfield, GK, BH, and AM are supported by the National Institute for Health and Care Research (NIHR) Applied Research Collaboration Northwest London. ALN is also funded by the NIHR Patient Safety Research Collaboration, with infrastructure support from Imperial NIHR Biomedical Research Centre. The views expressed in this publication are those of the authors and not necessarily those of NIHR or the Department of Health and Social Care. Generative artificial intelligence was not used in any aspect of the manuscript preparation.

Data Availability

The datasets generated and/or analyzed in this study are available upon reasonable request from the corresponding author.

Authors' Contributions

ALN and the inSIGHT group (comprising JC, AC, CC, G Gusso, RDH, GJ, THK, LL, HL, EM, KN, DP, and RT) contributed to the conception and design of the study. GK contributed to data preparation and analysis. GK, ALN, TB, G Greenfield, and BWJH contributed to interpretation of results and drafting the manuscript. AC, CC, DP, EL, G Gusso, GJ, HL, JC, KN, LL, RDH, RT, AM, ALN, and THK revised the manuscript. All authors provided critical review and approved the final version of the manuscript.

Conflicts of Interest

BWJH also works for eConsult Health, provider of a platform for online consultations for primary, secondary and urgent or emergency care in the National Health Service.

Abstract

Background: Heart failure (HF) is a complex, life-threatening condition marked by high morbidity, mortality, reduced functional capacity, poor quality of life, and substantial health care costs. HF with reduced ejection fraction (HFrEF) represents the subgroup of HF with the highest risks of mortality and hospitalization, necessitating the prioritization of care and management models to optimize treatment outcomes in these patients. Currently, data on the effectiveness of telemedicine models in resource-limited settings, such as low- and middle-income countries, are scarce.

Objective: This study aimed to evaluate the impact of telemedicine on improving prognosis in patients with HFrEF in Vietnam.

Methods: In this prospective cohort study, we recruited patients who received either remote monitoring and management (telemedicine) or standard monitoring and management (usual care) in the outpatient department of the Vietnam National Heart Institute, Bach Mai Hospital, Hanoi, Vietnam. Eligible patients were ≥18 years old, had a diagnosis of HFrEF defined as left ventricular ejection fraction (LVEF) ≤40%, had a history of HF hospitalization within the past 12 months, and presented with clinical symptoms classified as New York Heart Association (NYHA) II or III. The primary composite outcome was defined as the time to the first unplanned HF hospitalization or all-cause mortality. The follow-up period for all outcomes extended to 12 months.

Results: In total, 426 patients (298/426, 70% male; 128/426, 30% female) with a mean age of 61.3 (SD 14.6) years and a mean LVEF of 32.1% (SD 6.0%) were included in our study. Of these patients, 121 received telemedicine care, while 305 received usual care. The primary outcome occurred in 23 (23/121, 19%) patients in the telemedicine group and 82 (82/305, 26.9%) patients

XSL•FO
RenderX

in the usual care group during the follow-up period, indicating a significant reduction in risk (adjusted hazard ratio [aHR] 0.57, 95% CI 0.35-0.94; *P*=.03). However, this effect was primarily driven by a significant reduction in unplanned HF hospital admissions (aHR 0.57, 95% CI 0.33-0.98; *P*=.04) rather than in all-cause mortality (aHR 0.77, 95% CI 0.36-1.63; *P*=.49).

Conclusions: This study demonstrates that a simplified telemedicine model, even in resource-limited settings such as Vietnam, can effectively facilitate the remote monitoring and management of patients with HFrEF, resulting in significant reductions in HF-related hospitalizations and all-cause mortality.

Introduction

The universal definition of heart failure (HF) describes it as a clinical syndrome characterized by symptoms or signs caused by structural or functional cardiac abnormalities, corroborated by elevated natriuretic peptide levels or objective evidence of pulmonary or systemic congestion [1,2]. HF has long been regarded as a global pandemic, with an estimated 64 million individuals worldwide with this condition, and this number continues to rise [3]. The economic burden of HF on global health care systems is substantial and continuously increasing due to the growing incidence of HF [3]. In the United States alone, the total cost of HF is projected to reach approximately US $70 billion by 2030 [4].

Despite significant advances in HF treatment over the past decades, mortality rates remain high, with 1-year mortality rates ranging from 14% to 30% and 5-year rates ranging from 50% to 75% [3,5]. Additionally, patients with HF frequently require hospitalization due to acute exacerbations of the disease, making HF the leading cause of hospitalization for individuals older than 65 years in Europe [2,5-7]. The frequency of hospitalizations is strongly associated with disease progression and increases the mortality risk in this patient population [2,5,7,8]. HF is classified based on left ventricular ejection fraction (LVEF) into 3 categories: HF with reduced LVEF (HFrEF), HF with mildly reduced LVEF, and HF with preserved LVEF, with LVEF values of ≤40%, 41% to 49%, and ≥50%, respectively [2,8]. HFrEF accounts for approximately one-half of all patients with HF and has the highest mortality and hospitalization rates among the 3 groups [2,5]. Furthermore, guided by abundant evidence synthesized from landmark trials, the management of HFrEF based on guideline-directed medical therapy recommended by leading cardiovascular societies promises significant benefits for this patient group [2,6]. In contrast, most clinical trials have failed to identify truly effective therapies for patients with HF with mildly reduced LVEF and HF with preserved LVEF, resulting in relatively limited and low-grade evidence in the treatment recommendations for these HF subtypes. Given this context, in resource-limited settings such as Vietnam, it is essential to prioritize the development of strategies, such as telemedicine models, to optimize the care and management of high-risk patients, particularly those with HFrEF, who are more likely to derive substantial benefits from proper monitoring and care. This approach represents a more resource-efficient strategy than focusing on the other 2 HF subtypes.

Over the past decade, remote monitoring and telemedicine solutions have emerged as promising strategies to enhance HF care and management by enabling closer patient monitoring and facilitating timely, personalized clinical decision-making by health care providers [7,9,10]. Numerous clinical trials have demonstrated the benefits of telemedicine for patients with HF, particularly for reducing the risk of HF-related hospitalizations [9-12]. However, most of these studies have been conducted in high-income countries using advanced patient monitoring technologies in telemedicine models. Conversely, data on the benefits of telemedicine in low- and middle-income countries (LMIC) like Vietnam, where HF is rapidly becoming a significant health care burden, remain limited [13].

Against this backdrop, we conducted this study to evaluate the effectiveness of a simplified telemedicine model designed to accommodate the limited resources available in LMIC at improving the prognosis of patients with HFrEF in Vietnam.

Methods

Study Design, Setting, and Participants

This prospective cohort study was conducted at the Vietnam National Heart Institute (VNHI), Bach Mai Hospital, Hanoi, Vietnam. Between January 2023 and October 2023, the study recruited 2 cohorts of patients managed and monitored in the outpatient department at VNHI. One cohort consisted of patients who received remote monitoring and management (telemedicine model), while the second cohort received standard monitoring and management (usual care model). This study was registered with the National Agency for Science and Technology Information, Vietnam (registration number: CT07/01-2022-3). As the first study to evaluate the effectiveness of a telemedicine model for patients with HF in Vietnam, the findings and experiences obtained during the implementation of this telemedicine program will provide a foundation for refining the model and expanding its application to other health care facilities across the country. Bach Mai Hospital was selected as the sole study site because it is the only center classified as the highest

XSL•FO
RenderX

level in northern Vietnam's hierarchical health care system. Geographically, its location in Hanoi, the capital city and central hub of northern Vietnam, facilitates access to patients from diverse regions across the north. Furthermore, with a team of highly experienced physicians and nurses specializing in HF management and medical education, the implementation of the telemedicine model at Bach Mai Hospital was expected to not only ensure the highest quality of care for patients enrolled in this study but also enhance the potential for successful knowledge and technique transfer to lower-level health care facilities in the future.

Participants were eligible if they (1) were aged 18 years or older, (2) were diagnosed with HF according to European Society of Cardiology criteria with an LVEF ≤40% [2], (3) had been admitted to the hospital for acute HF within 12 months prior to starting the study, and (4) had a clinical presentation of NYHA classification of II or III. Patients were excluded from the study if they had severe mental or physical disorders (eg, major depression), were undergoing hemodialysis, or had been admitted to the hospital for any reason within the previous week. Additionally, the exclusion criteria included patients with a left ventricular assist device or those who had experienced a pulmonary embolism, acute stroke, cardiogenic shock, cardiac surgery, coronary revascularization, or cardiac resynchronization therapy implantation within 1 month prior to the study. Patients scheduled for coronary revascularization, transcatheter aortic valve implantation, transcatheter mitral valve repair, or cardiac resynchronization therapy implantation within the next 3 months were also excluded. Furthermore, patients with severe pulmonary diseases, including chronic obstructive pulmonary disease (stage C/D), uncontrolled asthma, or pulmonary hypertension (World Health Organization [WHO] class III-IV), as well as pregnant women, were not eligible for inclusion. In our study, the necessary costs (for patient management and provision of measurement devices) for patients in the telemedicine group were significantly higher than the costs for patients in the usual care group (where care and management continue as usual, with coverage by insurance or out-of-pocket payment by patients). To optimize the research resources, we chose a ratio of 1:2.5 rather than a balanced patient ratio of 1:1 between the 2 groups. This approach helped reduce the number of patients required in the telemedicine group, thus lowering the total costs while still ensuring sufficient statistical power. Using a sample size calculation for a time-to-event end point with a maximum follow-up period of 12 months and assuming median survival times of 17 months for the usual care group and 29 months for the treatment group, with a significance level of .05 and patient ratio of 1:2.5 between the telemedicine and usual care groups, the minimum required sample size was calculated to be 120 patients for the telemedicine group and 298 patients for the usual care group to achieve 80% power [9,14]. To account for potential withdrawals, an additional 3.5% was added, resulting in a final estimated sample size of 433 patients.

Study Procedures

The remote monitoring and management program for outpatients, referred to as the telemedicine model, was approved and implemented in the outpatient department at VNHI, Bach Mai Hospital, beginning in January 2023. Due to the unavailability of advanced specialized monitoring devices in Vietnam, our center developed a telemedicine model using simple monitoring devices that patients and caregivers can easily operate at home, such as automatic electronic blood pressure monitors and weighing scales. Throughout the study period, all potential patients seen and managed in the outpatient department were assessed by their primary treating physicians and invited to participate in the telemedicine program.

Our recruitment process consisted of 2 phases. In Phase 1, all patients meeting the inclusion criteria and consenting to participate in the study were assigned to the telemedicine group. Patients who declined participation in the telemedicine group were assigned to the usual care group. This process continued until the target number of patients for the telemedicine group (n=123) was reached. In Phase 2, all patients meeting the inclusion criteria and consenting to participate in the study were allocated to the usual care group. This phase continued until the target number of patients for the usual care group (n=310) was achieved.

Upon enrollment in the telemedicine program, patients were required to report their health status to the telemedicine center daily. The information provided included blood pressure, heart rate, and body weight measurements taken at home using validated devices (either by the patients themselves or their caregivers), as well as any new or unusual symptoms such as dyspnea, fatigue, chest pain, palpitations, swelling, cough, or fever. This reporting followed the Self-Check Plan for HF management recommended by the American Heart Association [6]. Reporting of information was encouraged to be conducted via a specialized app developed for our telemedicine program, accessible on smartphones, either by the patients themselves or their caregivers. Symptoms were entered as a checklist, while measurement results were input into designated fields, and any specific signs were reported as free-text entries. The app was designed to validate the completeness of the entered information and display warnings if essential data were missing. Additionally, the app issued daily reminders at 8 PM or a time selected by the patient, alerting them to submit their health information to the telemedicine center if they had not already done so. Information collected through this method was automatically stored in the patient's profile within the telemedicine system database. For patients without access to smartphones or those experiencing difficulties using the app, alternative reporting methods were available. Patients or caregivers could report information via SMS text messaging (including photos of measurement results displayed on devices) or through direct video or phone calls to telemedicine center nurses. In such cases, the nurses manually entered the reported information into the system database. At 8 PM daily, or at the patient's chosen time, if no health updates had been received, the system sent alerts to the telemedicine center staff, prompting them to proactively contact the patient to collect the necessary information. Patient data were securely stored in the telemedicine center's online database, accessible at any time by cardiologists on our clinical team.

Based on the daily information provided by patients and the health history recorded in the database, nurses at the

XSL•FO
RenderX

telemedicine center assessed whether a more detailed evaluation by a specialist was necessary. The following signs or symptoms (either newly developed or pre-existing but worsening during this episode) were considered indicative of an unstable condition with a high risk of acute decompensated HF, thereby necessitating a review of the patient's health status by a cardiologist: frequent cough, shortness of breath at rest, inability to lie flat due to dyspnea, confusion, dizziness, loss of appetite, greater difficulty sleeping, sadness or depression, increased swelling in the lower extremities, sudden weight gain of more than 1 kg within 24 hours or 2 kg in a week, systolic blood pressure (SBP) <90 mm Hg, diastolic blood pressure (DBP) <60 mm Hg, heart rate >100 bpm, blood pressure >180/110 mm Hg, or SBP or DBP increase or decrease >20 mm Hg compared with the average SBP or DBP of the previous day. In certain cases, an additional real-time interview with patients was arranged to collect further information. After gathering all necessary information from the patient's online medical records and direct interviews, physicians were granted autonomy to make decisions based on their clinical judgment and the European Society of Cardiology guidelines for the diagnosis and management of acute HF [2]. We did not propose a rigid protocol for physicians within this telemedicine model, as flexibility was deemed essential given the variability in patients' clinical conditions, geographic differences, and the availability of health care services in their respective areas. Physicians' decisions may include advising the patient to visit the emergency department, seek hospitalization at a cardiology center, or consult a local clinic for further evaluation (eg, electrocardiography, chest X-ray, echocardiography, laboratory tests). Other options may involve adjusting medication (limited to oral drugs), recommending lifestyle changes or home exercises, or determining that no further action is required. In more complex cases, a multidisciplinary team at the telemedicine center would discuss the situation to reach a final decision. In addition to nurse-initiated evaluations, each patient's health records were reviewed biweekly by telemedicine center physicians based on the online database.

The usual care group comprised patients who were monitored and managed through the standard process in the outpatient department at the VNHI. Throughout the study, these patients remained under the supervision of cardiologists and other physicians in the outpatient department. Treatment adjustments or prescriptions were based solely on the independent decisions of their primary treating doctors and were not influenced by the patient's participation in the study. Follow-up visits were typically scheduled every 3 months but could vary depending on the patient's condition, as assessed by the primary treating doctors.

Baseline data (including demographics; anthropometrics; clinical history; signs and symptoms; medication lists; and data from electrocardiograms, echocardiograms, and lab tests) were collected at the time of patient enrollment. BMI was classified according to the WHO diagnostic criteria for Asian adults: A BMI of 18.5-22.9 kg/m² was considered as normal weight, <18.5 kg/m² as underweight, 23-24.9 kg/m² as overweight, and ≥25 kg/m² as obese [15]. We did not use medication adherence of patients as an outcome of interest due to concerns that missing data from patients who died or were lost to follow-up could introduce significant bias.

Study Outcomes

The primary outcome of the study was defined as a composite end point consisting of the first unplanned hospitalization due to HF or all-cause mortality, evaluated over a follow-up period of up to 12 months after patient enrollment. Secondary outcomes included (1) all-cause mortality and (2) the first unplanned hospitalization specifically due to HF.

Statistical Analysis

Baseline characteristics were summarized as mean (SD) or median (IQR), as appropriate, for continuous variables and as numbers (percentages) for categorical variables. The between-group differences in continuous variables were tested using either the independent Student *t* test or the Wilcoxon rank-sum test, depending on their distribution. Categorical variables were compared using Pearson chi-square tests or Fisher exact tests, as appropriate.

All survival analyses of outcomes were conducted on a time-to-first-event basis. Cumulative incidence curves for all-cause mortality were generated using the Kaplan-Meier method to visually represent survival probabilities over time. Differences between the survival curves of the 2 groups were evaluated using the log-rank test to determine statistical significance. To assess the impact of telemedicine on the primary and secondary outcomes, multivariable Cox-proportional hazards regression models were applied, estimating hazard ratios (HRs) and the corresponding 95% CIs while adjusting for potential confounders. The confounding variables incorporated into the multivariable analysis were determined by a panel of HF experts from the Vietnam Heart Association. These variables were selected based on well-documented predictors of mortality and HF hospitalization in patients with HFrEF, as outlined in clinical guidelines and supported by previous studies [1,2,6,8,13,16]. Specifically, the variables included baseline demographic characteristics (age, sex), BMI classification, comorbidities, LVEF, the use of guideline-directed medical therapy for HFrEF, and N-terminal pro-B-type natriuretic peptide (NT-proBNP) levels. In addition, these variables, as well as the analyses of the primary composite end point and secondary end points (mortality and HF hospitalization), were prespecified before the commencement of the study. Furthermore, we conducted a sensitivity analysis, incorporating additional variables (cardiac comorbidities, relevant medications, socioeconomic status, and health literacy–related factors) into the multivariable Cox regression models to validate the robustness of the results from the primary analyses. Event rates were reported as the number of events per 100 patient-years of follow-up, accounting for any censored data due to loss to follow-up or the end of the study period.

All statistical analyses were performed using Stata SE version 18.0. All comparisons were 2-tailed, and *P* values <.05 were considered statistically significant.

Ethical Considerations

The study was conducted in accordance with the principles of the Declaration of Helsinki. The study protocol was reviewed and approved by the Institutional Review Board of Bach Mai Hospital, Hanoi, Vietnam (number: 1973/BM-HĐĐĐ). All participants provided written informed consent prior to enrollment, after receiving a comprehensive explanation of the study's purpose, procedures, and potential risks and benefits. To protect participant privacy, all personal identifiers were removed from the data set.

Results

Participants

A total of 426 patients with HFrEF (298/426, 70% male; mean age 61.3, SD 14.6 years), including 121 patients in the telemedicine group (81/121, 66.9% male; mean age 60.6, SD 15.4 years) and 305 patients in the usual care group (217/305, 71.2% male; mean age 61.6, SD 14.4 years), were involved in this study (Multimedia Appendix 1). Of the 273 eligible patients who initially declined participation in the study, 187 declined because they did not plan to continue HF management at Bach Mai Hospital, 41 declined due to concerns about the safety of their health during participation, 29 declined due to concerns about the additional time or costs associated with participation, and 16 declined due to concerns regarding the security of their privacy and personal information. At the end of Phase 1 of the recruitment process, a total of 123 patients were recruited into the telemedicine group, while 15 patients were assigned to the usual care group. A survey identified 2 primary reasons for patients agreeing to participate in the study but refusing to join the telemedicine group: (1) concerns about the treatment efficacy of the telemedicine model, as it was a new approach not previously implemented in Vietnam (13/15, 87%), and (2) concerns about potential additional costs associated with participation in the telemedicine model (2/15, 13%). In Phase 2, an additional 295 patients were recruited into the usual care group to reach the target number of 310. Notably, among the 15 participants who opted out of the telemedicine intervention, 11 (73%) resided within a 5-km radius of our hospital, whereas only 42 (34%) of the 123 participants included in the telemedicine group lived within this proximity. This proximity, which facilitates regular follow-up visits at the hospital, may have contributed to the participants' reluctance to choose telemedicine, a recently implemented health care model in Vietnam. The majority of patients were married (401/426, 94.1%) and resided in rural areas (259/426, 60.8%). Most reported a monthly income of US $300 to US $450 (275/426, 64.6%), slightly above the national average of US $300. Notably, all patients had health insurance (426/426, 100%), largely attributable to Vietnam's universal health care coverage policy. In Table 1, we present the detailed baseline characteristics of the participants in the 2 groups. The mean LVEF of the overall population was 32.1% (SD 6.0%) and comparable between the telemedicine group (32.1%, SD 6.0%) and the usual care group (32.1%, SD 6.0%; P=.56).

The most common comorbidities among the study participants were hypertension (128/426, 30.1%), coronary artery disease (109/426, 25.6%), chronic kidney disease (93/426, 21.8%), and diabetes (91/426, 21.4%). The mean BMI of the study population was 22.1 (SD 2.9) kg/m^2, with an obesity rate of 15.3% (65/426), based on the WHO classification for Asians, and an underweight rate of 10.6% (45/426). At the start of the study, 52.4% (223/426) of patients were being treated with an angiotensin-neprilysin inhibitor, 22.3% (95/426) with an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker, 80.8% (344/426) with a sodium-glucose cotransporter-2 inhibitor, 70% (209/426) with beta-blockers, 68.5% (292/426) with a mineralocorticoid receptor antagonist (only spironolactone), 61.7% (263/426) with loop diuretics, and 7% (30/426) with thiazide-like diuretics (no patients were prescribed thiazide diuretics). Analysis results indicated no statistically significant differences in demographic characteristics, BMI, echocardiographic findings, laboratory measurements, comorbidities, socioeconomic status, health literacy, or therapeutic regimens between the telemedicine and usual care groups.

During the follow-up period, data from our telemedicine database indicated that, among the 121 patients in the telemedicine group, 75 patients (62%) reported a complete set of daily measurements on at least 90% of the total days enrolled in the telemedicine program. Additionally, 30 patients (30/121, 25.6%) provided complete measurements on 70% to 90% of the days, 13 patients (13/121, 9.9%) on 50% to 70% of the days, and only 3 patients (3/121, 2.5%) on fewer than 50% of the days.

Primary Outcome

During the 12-month follow-up period, the primary end point occurred in 23 of 121 patients (19%) in the telemedicine group and in 82 of 305 patients (26.9%) in the usual care group. Specifically, there were 10 deaths (10/121, 8.3%) and 19 first unplanned HF hospitalizations (19/121, 15.7%) in the telemedicine group, compared with 29 deaths (29/305, 9.5%) and 71 first unplanned HF hospitalizations (71/305, 23.3%) in the usual care group. This indicates a significant reduction in the risk of the composite end point (first unplanned HF hospitalization or all-cause mortality) over the 12-month follow-up in the telemedicine group (adjusted HR 0.57, 95% CI 0.35-0.94; *P*=.03; Figure 1 and Table 2).

Secondary Outcomes

Regarding the secondary end points, after adjusting for covariables, telemedicine continued to demonstrate a significant reduction in the risk of HF hospitalization (adjusted HR 0.57, 95% CI 0.33-0.98; *P*=.04; Figure 2 and Table 2). Conversely, although there was a trend suggesting a slight reduction in mortality risk in the telemedicine group, the difference was not statistically significant (adjusted HR 0.77, 95% CI 0.36-1.63; *P*=.49; Figure 2 and Table 2).

Figure 2. Kaplan-Meier cumulative event curve for the secondary outcomes: (A) first unplanned heart failure hospitalization, (B) all-cause mortality.

Sensitivity Analysis

The sensitivity analysis, incorporating additional variables (documented ventricular tachycardia, diagnosed valvular heart disease, diagnosed cardiomyopathy, thiazide-like use, ivabradine use, locality, marital status, education, monthly income, monthly treatment affordability) into the multivariable Cox regression models (Multimedia Appendix 2) for the outcomes of interest, demonstrated that the efficacy of telemedicine remained consistent with the primary analysis (Table 2), suggesting the robustness of the results.

Discussion

Principal Findings

To the best of our knowledge, this is the first study to evaluate the efficacy of telemedicine for reducing mortality and HF hospitalization among patients with HFrEF in Vietnam. In this prospective cohort study, we demonstrated that a resource-limited telemedicine model, which does not require the support of advanced specialized devices, could still provide significant prognostic benefits for HFrEF patients. Specifically, patients monitored and managed through telemedicine had a 43% lower risk of experiencing the primary outcome compared with those receiving usual care (adjusted HR 0.57, 95% CI 0.35-0.94; *P*=.03). However, this composite primary outcome was primarily driven by a significant reduction in unplanned HF hospital admissions (adjusted HR 0.57, 95% CI 0.33-0.98; *P*=.04) rather than in all-cause mortality (adjusted HR 0.77, 95% CI 0.36-1.63; *P*=.49).

Comparison With Prior Work

Patients with HFrEF exhibit the highest rates of hospitalization and mortality among patients with HF [5,17,18]. Furthermore, there is a well-documented pattern of gradually increasing cardiac filling pressures, even during the “stable” phase following hospital discharge [19,20]. This progressive rise in congestion ultimately leads to the recurrence of symptoms and, consequently, the need for rehospitalization [16,21]. As a result, this population requires close monitoring and management to prevent and address exacerbations while simultaneously promoting patient self-management and empowerment. Remote monitoring and telemedicine have emerged as critical components in the management of HF, offering significant

XSL•FO
RenderX

improvements in patient outcomes while optimizing health care resource allocation [7,22]. A primary benefit is the increased accessibility to care, facilitating real-time monitoring of physiological parameters and symptoms from patients' homes [7,22]. This approach minimizes the necessity for frequent in-person clinic visits and promotes patient engagement in self-management, thereby reducing the logistical burden of travel [7]. Furthermore, evidence suggests that remote monitoring allows for the early detection of HF deterioration, enabling timely therapeutic adjustments and decreasing the risk of hospitalizations [23,24]. A meta-analysis of 29 randomized controlled trials (RCTs) published in 2019 demonstrated that telemedicine significantly improves quality of life and reduces the risk of HF-related hospitalization in patients with HF [25]. One notable RCT is the TIM-HF2 study conducted in Germany, which included 1571 patients with NYHA class II or III HF with an LVEF ≤45%, with a maximum follow-up duration of 393 days [9]. The telemedicine model used in this trial was a structured remote patient management intervention in which patients were monitored daily via a telemonitoring system that included a 3-channel electrocardiogram device, a device to measure blood pressure, a device to measure SpO_2, and weighing scales. This telemonitoring system also facilitated the transmission of data from the patient's home to the telemedical center, where specialized software classified patient risk based on preprogrammed algorithms. The subsequent actions taken by the telemedical center's physicians were informed by the patient's risk level and health data within the system. The results of the TIM-HF2 trial revealed that the remote patient management group had a significantly lower all-cause mortality rate compared with the usual care group (HR 0.70, 95% CI 0.50-0.96; *P*=.03), although there was no significant difference observed in cardiovascular mortality (HR 0.67, 95% CI 0.45-1.01; *P*=.056) [9]. More recently, the multicenter AMULET trial conducted in Poland with 605 patients with HF and an LVEF ≤49% was published in 2021 [10]. Patients in the intervention group (telecare) were monitored and managed under the AMULET model, which included regular consultations with nurses at ambulatory care points. Information collected after each visit, including HF signs and symptoms and measurements of vital parameters, showed that, after 12 months of follow-up, patients in the telecare group experienced a 31% lower rate of composite events (unplanned HF hospitalizations or cardiovascular deaths) compared with those receiving standard care (HR 0.69, 95% CI 0.48-0.99; *P*=.04) [10]. Notably, the implementation of AMULET telecare primarily reduced the risk of first hospitalizations due to HF (HR 0.64, 95% CI 0.41-0.99; *P*=.04) but did not significantly impact the risks of cardiovascular mortality (HR 1.03, 95% CI 0.54-1.98; *P*=.93) or all-cause mortality (HR 0.99, 95% CI 0.59-1.67; *P*=.98) [10].

Although direct comparisons between our study and others using different telemedicine models may be limited due to variations in research methodologies, study populations, and telemedicine processes (eg, monitoring technologies, interventions, and communication methods), the comparable benefits observed in our research underscore the viability of remote health care models adapted to resource-limited settings, such as Vietnam and other LMIC [10,22]. Despite the absence of advanced monitoring devices, our telemedicine model demonstrated good efficacy, likely due to 3 main factors. First, the model ensures that physicians can regularly monitor patients' weight, cardiovascular symptoms, and vital signs, which are the most critical information needed for early assessment and timely advice [7]. This helps to improve the prevention of congestion and reduce the risk of HF-related hospitalizations. Second, our protocol allows for direct communication between physicians and patients when necessary. This ensures the accuracy and clarity of information exchanged and enhances patient trust and adherence to treatment [7]. Finally, our study population consisted of high-risk HF patients (mean age >60 years, mean LVEF approximately 30%, with a history of HF hospitalization in the past 12 months), which may explain the significant benefit observed from the telemedicine model [7,9,23].

In high-income countries, health care systems are typically well-developed and uniformly distributed, with both urban and rural areas having well-resourced health care centers capable of providing high-quality care for a wide range of diseases. In contrast, Vietnam and most LMIC operate under a hierarchical health care model due to limited resources. In this model, only a few medical centers and hospitals in major cities receive prioritized investments, allowing them to employ highly skilled medical staff and use advanced technologies to provide high-quality care and optimize outcomes for complex medical conditions. Health care centers in rural and remote areas often receive minimal resources and lack specialists due to lower income and limited career development opportunities in these regions [26]. Consequently, these facilities can only provide basic health care services and lack the capacity to manage complex conditions like HF effectively. The implementation of telemedicine in Vietnam and other developing countries holds significant potential to overcome these limitations [26,27]. For patients in remote or underserved areas or those who face challenges in accessing specialized centers, telemedicine provides an opportunity for regular management, monitoring, and consultation with experienced physicians. This approach could improve health care quality, reduce costs and travel time, and enhance convenience for patients [22]. However, widespread adoption of telemedicine for HF management in resource-limited settings faces challenges due to the high costs of advanced monitoring devices commonly used in developed countries. Given the resource constraints in Vietnam and other developing countries, we propose a cost-effective, scalable telemedicine model that uses phone-based monitoring and affordable devices to measure essential parameters for HF management, such as blood pressure, heart rate, and body weight. The findings of this study demonstrate that this low-cost telemedicine model can provide significant benefits for patients with HFrEF in Vietnam compared with usual care. This approach may represent a viable strategy for enhancing HF care in resource-limited settings.

Strengths and Limitations

Although this study represents the first evaluation of telemedicine's efficacy in managing patients with HF in Vietnam using a simplified model designed for resource-limited settings, several limitations warrant consideration. First, as this

XSL•FO
RenderX

was not an RCT, residual confounding variables may persist despite multivariable adjustments. This limitation could introduce bias, emphasizing the need for a well-designed trial to validate our findings in the future. Second, the single-center design limits the generalizability of the findings. The results may not be applicable to other health care settings or populations, particularly in regions or countries with differing health care infrastructures. Additionally, the cohort's sociodemographic and clinical characteristics likely reflect the specific health care context in Vietnam, including unique patterns of comorbidities, health care access, and cultural factors. This may reduce the external validity of the findings when applied to different settings.

Conclusions

Our study demonstrates that a simplified telemedicine model, without the inclusion of advanced monitoring devices in resource-limited settings such as Vietnam, can still effectively monitor and manage patients with HFrEF remotely, yielding significant benefits for reducing the risk of composite outcomes. However, this effect is primarily attributed to the reduction in unplanned HF hospitalizations rather than mortality. Future studies with more robust designs conducted across diverse regions and populations are necessary to validate these findings.

Abstract

Background: The COVID-19 public health emergency catalyzed widespread adoption of both video- and audio-only telemedicine visits. This proliferation highlighted inequities in use by age, race and ethnicity, and preferred language. Few studies have investigated how differences in health system telemedicine implementation affected these inequities.

Objective: This study aims to describe patients who used telemedicine during the public health emergency and identify predictors of telemedicine use across 2 health systems with different telemedicine implementations.

Methods: This retrospective cohort study included adults with diabetes receiving primary care between July 2020 and March 2021 at 2 independent health systems in San Francisco, California. Participant sociodemographic characteristics, health information, and telemedicine utilization were acquired from electronic health records. The primary outcome was visit type (any audio or video telemedicine vs in-person only) during the study period. We used multivariable logistic regression to assess the association between visit type and key predictors associated with digital exclusion (age, race and ethnicity, preferred language, and neighborhood socioeconomic status), adjusting for baseline health. We included an interaction term to evaluate health system impact on each predictor and then stratified by health system (academic, which prioritized video-enabled visits, vs safety net, which prioritized audio-only visits).

Results: Among 10,201 patients, we found higher odds of telemedicine use in the safety net system compared with the academic system (adjusted odds ratio [aOR] 2.94, 95% CI 2.48-3.48). Patients with younger age (18-34 years: aOR 2.55, 95% CI 1.63-3.97; 35-49 years: aOR 1.39, 95% CI 1.12-1.73 vs 75+ years) and Chinese-language preference (aOR 2.04, 95% CI 1.66-2.5 vs English) had higher odds of having a telemedicine visit. Non-Hispanic Asian (aOR 0.67, 95% CI 0.56-0.79), non-Hispanic Black (aOR

XSL•FO
RenderX

0.83, 95% CI 0.68-1), and Hispanic or Latine (aOR 0.76, 95% CI 0.61-0.95) patients had lower odds of having a telemedicine visit than non-Hispanic White patients. We found significant interactions between health system and age, race and ethnicity, and preferred language (P<.05). After stratifying by health system, several differences persisted in the academic system: non-Hispanic Asian (aOR 0.57, 95% CI 0.46-0.70) and Latine (aOR 0.67, 95% CI 0.50-0.91) patients had lower odds of a telemedicine visit, and younger age groups had higher odds (18-34 years: aOR 3.97, 95% CI 1.99-7.93; 35-49 years: aOR 1.86, 95% CI 1.36-2.56). In the safety net system, Chinese-speaking patients had higher odds of having a telemedicine visit (aOR 2.52, 95% CI 1.85-3.42).

Conclusions: We found disparities in telemedicine utilization by age, race and ethnicity, and preferred language, primarily in the health system that used more video visits. While telemedicine expanded rapidly recently, certain populations remain at risk for digital exclusion. These findings suggest that system-level factors influence telemedicine adoption and implementation decisions impact accessibility for populations at risk for digital exclusion.

Introduction

Prior to the COVID-19 public health emergency (PHE), the adoption of telemedicine (defined here as real-time virtual visits between patients and clinicians) in the United States was limited due to both policy and implementation challenges [1,2]. The PHE served as a catalyst for widespread adoption: telemedicine policies expanded coverage to include reimbursement parity for both video- and audio-only visits, with notably high adoption of audio-only visits in safety net settings [3-5]. The proliferation of telemedicine, however, also introduced important concerns about equity [6]. Persistent inequities in utilization and access have been documented, with studies indicating that older adults, racial and ethnic minority groups, individuals with limited English proficiency, and those with lower income are less likely to adopt telemedicine, particularly video-enabled services [7-12]. These patterns of underutilization highlight the broader issues of digital exclusion, driven by challenges such as limited digital literacy and lack of access to technology and web-based service [6,12].

However, an understudied aspect in these studies is how health system factors and their implementation of telemedicine impact these disparities. Audio visits, provided more frequently by community health centers and safety net systems, are predominantly used by low-income, older, or racially and ethnically minoritized patients [3]. It remains unclear whether these patterns in telemedicine utilization are a result of patient characteristics or reflective of health systems being underresourced. Understanding the drivers of these patterns of telemedicine utilization is crucial, as it informs the development of interventions that address disparities and enhance equitable distribution of telehealth services.

To address this gap in the literature, we evaluated telemedicine use in 2 distinct health systems in San Francisco, California: University of California, San Francisco (UCSF), an academic medical system, and San Francisco Health Network (SFHN), a safety net system. Telemedicine implementation during the PHE differed across the systems. UCSF started implementing video visits and training prior to the PHE and encouraged video as the predominant modality during the PHE, resulting in 50% of all visits (including in-person and telemedicine) being video visits [13]. In contrast, SFHN encountered delays in video implementation and did not prioritize video visits, resulting in telemedicine visits being primarily delivered as audio-only encounters (>95%) [14]. In this study, we aimed to (1) describe characteristics of patients with and without a telemedicine visit during the PHE in each health system, and (2) evaluate associations between key sociodemographic factors—age, race and ethnicity, preferred language, and neighborhood socioeconomic status (nSES)—and telemedicine use, including health system interaction effects. We sought to identify whether disparities in telemedicine use were driven by patient characteristics and by variations in the implementation of telemedicine across systems.

Methods

Study Setting and Data Source

This retrospective cohort study included patients with diabetes receiving primary care between July 1, 2020, and March 31, 2021, at 1 of 2 independent health care systems in San Francisco: UCSF and SFHN. UCSF is an academic tertiary care medical care center with 4 primary care practices. SFHN is a safety net health system for San Francisco County with 14 primary care practices.

Study Sample

The study cohort was identified using electronic health records (EHRs) and included adult patients (aged 18 years and older) with diabetes mellitus who had at least 1 primary care or endocrinology encounter between July 1, 2020, and March 31, 2021 (hereafter referred to as the study period). Participants were required to have a diagnosis of diabetes prior to the beginning of the study period. In addition, participants must have been empaneled in primary care as of April 1, 2019 (approximately 1 year before start of the PHE), defined as having assigned a primary care provider and at least 1 primary care encounter within the 3 years prior to April 1, 2019. Details on this cohort are provided in a prior publication [14].

Ethical Considerations

Data were deidentified for analysis and reporting. This study was approved by the UCSF institutional review board (#20-31253) with waiver of informed consent.

Variables

Participants' sociodemographic characteristics, health information (eg, comorbidities, vitals, and laboratory results), and telemedicine utilization were derived from EHRs. The primary outcome was defined as whether participants had any telemedicine visit (audio- or video-only visit vs in-person visit only) with their diabetes care team (primary care or endocrinology) during the study period. Key predictor variables were as follows: age (18-34, 35-49, 50-64, 65-74, and ≥75 years); race and ethnicity (non-Hispanic Asian, non-Hispanic Black, Hispanic or Latine, non-Hispanic White, and non-Hispanic other race); preferred language (English, Spanish, Chinese, and other); and nSES quintile at the census tract level based on geocoded residential address [14]. nSES is a validated composite SES measure that incorporates 5-year census tract level data from the 2013-2017 American Community Survey on income, education, poverty, employment, occupation, housing, and rent values [15]. nSES quintiles are based on the distribution of nSES across US Census tracts from Bay Area counties, with the first quintile (Q1) reflecting lowest nSES and the fifth quintile (Q5) reflecting highest nSES.

Covariates included average baseline hemoglobin A_{1c} control, baseline blood pressure (BP) control (≤120/80, 121/81-140/90, and >140/90 mm Hg), patient sex (male or female), insurance type (Medicare, Medicaid, commercial, Healthy Workers [county administered], or uninsured), patient portal enrollment (yes or no, as a proxy for digital access), and Charlson Comorbidity Index (CCI) score category (0-2 or 3+). Hemoglobin A_{1c} control, BP control, and CCI were used to adjust for differences in utilization based on medical need.

Statistical Analysis

We described patient-level differences in telemedicine use associated with each predictor, overall and by health care system, using chi-square tests for categorical predictors and 2-tailed *t* tests for continuous predictors. Our regression analyses included a multivariable logistic regression model using the combined health system data to determine the adjusted effects of key predictors on telemedicine utilization and a second model using an interaction term to estimate the effect of health system on each of our key predictors (age, race and ethnicity, preferred language, and nSES). We calculated predicted margins for the significant key predictors. Next, we stratified models by health system. Each logistic regression model controlled for our listed covariates. Missing data for hemoglobin A_{1c} values and BP measurements were imputed using multiple imputation by chained equations [16]. Results were presented as adjusted odds ratios (aORs) with 95% CIs. Two-tailed significance was determined with α value of .05. All analyses were performed using Stata 17 [17].

Results

Included Participants

The final study cohort included a total of 10,201 adult patients with diabetes across the 2 health systems (Table 1 and Multimedia Appendix 1). As shown in Multimedia Appendix 1, there was different racial and ethnic, linguistic, and nSES distribution in the 2 health systems. The academic health system had mostly non-Hispanic White and non-Hispanic Asian patients (929/3623, 26%, and 1430/3623, 39%, respectively), while the safety net system had more non-Hispanic Asian and Hispanic or Latine patients (2302/6578, 35%, and 2244/6578, 34%, respectively). Most of the patients in the academic health system had an English-language preference (2935/3623, 81%); however, less than half of the patients at the safety net system preferred the English language (2847/6578, 43%). Furthermore, the safety net system mostly took care of patients living in the lowest nSES quintile (2551/6578, 39%), whereas the academic health system had about 20% (Q1: 640/3623, 17.7%; Q2: 682/3623, 188.%; Q3: 716/3623, 198.%; Q4: 883/3623, 24.4%; and Q5: 702/3623, 19.4%) of patients in each nSES quintile.

Of the 10,201 patients in the cohort, 81% (n=8305) had at least 1 telemedicine visit during the study period. Patients in the safety net system were more likely to use telemedicine than patients in the academic health system (5655/6578, 86% vs 2650/3623, 73%; *P*<.001). Among the combined health systems, there were significant differences in telemedicine use by age (*P*<.001), language preference (*P*<.001), and nSES quintile (*P*<.001). Within the academic health system, there were only significant differences in telemedicine use by age group, with younger patients showing higher adoption (*P*<.001), and by racial or ethnic groups, with lower adoption by non-Hispanic Asian patients (*P*<.001). The safety net system showed significant differences in telemedicine use by racial and ethnic groups, with highest adoption by non-Hispanic Asian patients and lowest by non-Hispanic Black patients (*P*<.001), and by language preferences, with highest adoption by Chinese speakers (*P*<.001).

Adjusted Analyses

Combined Health System Data

After adjusting for key predictors (age, race and ethnicity, language, and nSES) and covariates (baseline hemoglobin A_{1c}, baseline BP, sex, insurance type, patient portal enrollment status, and CCI), safety net patients had higher odds of having a telemedicine visit compared with academic health system patients (aOR 2.94, 95% CI 2.48-3.48; Table 2). Patients aged 18-34 and 35-49 years also had higher odds of having a telemedicine visit than patients older than 75 years (aOR 2.55, 95% CI 1.63-3.97; aOR 1.39, 95% CI 1.12-1.73). Non-Hispanic Asian, non-Hispanic Black or African American, and Hispanic or Latine patients had lower odds of using telemedicine than non-Hispanic White patients (aOR 0.67, 95% CI 0.56-0.79; aOR 0.83, 95% CI 0.68-1.00; aOR 0.76, 95% CI 0.61-0.95, respectively), whereas patients with Chinese as their preferred language had higher odds of using telemedicine than those with an English-language preference (aOR 2.04, 95% CI 1.66-2.50). No significant differences were found among nSES. Results are displayed in Table 2. There was a significant interaction between health care system and each individual-level key predictor ($P<.05$; Multimedia Appendix 2). Health system significantly modified the effect of telemedicine use across age, racial and ethnic, and language preference groups, which is shown in Figure 1A-C, respectively. Estimated predicted probabilities for significant key predictors after applying the health system interaction term are provided in Multimedia Appendix 3. The interaction between health system and nSES was not statistically significant.

Stratified Data by Health System

Given the significant interactions by health system, we analyzed each system independently. At the academic health system, participants in the younger age groups (aged 18-34 years and 35-49 years) had higher odds of having a telemedicine visit than those aged 75 years and older (aOR 3.97, 95% CI 1.99-7.93; and aOR 1.86, 95% CI 1.36-2.56, respectively; Table 2). In the academic health system, non-Hispanic Asian (aOR 0.57, 95% CI 0.46-0.70) and Hispanic or Latine (aOR 0.67, 95% CI 0.50-0.91) participants were less likely to have a telemedicine visit than non-Hispanic White participants. There were no significant differences in telemedicine utilization based on language preference or nSES in the academic health system.

On the other hand, in the safety net system, patients with a Chinese language preference had higher odds of having a telemedicine visit (aOR 2.52, 95% CI 1.85-3.42; Table 2). In the safety net system, there were no significant differences in telemedicine utilization based on age, race and ethnicity, or nSES. These findings were consistent with the interaction analysis (Figure 1).

Discussion

Principal Results

Our study explored differences in telemedicine uptake among a cohort of primary care patients with diabetes across 2 large, unaffiliated health systems in San Francisco, California, during the COVID-19 PHE. Our final adjusted results highlight that health system is a significant predictor of telemedicine use and that disparities in telemedicine utilization may arise from differing implementation strategies by health systems, such as prioritization of audio-only versus video visits. Potential inequities could arise if audio-only visits are not widely implemented or perceived as inferior, despite payor policies that are meant to increase their implementation. Health systems may need to tailor and evaluate telemedicine implementation strategies to address disparities in utilization and ensure equitable access to services, especially for populations at greatest risk for digital exclusion.

Comparison With Prior Work

Our findings using the combined health system data are consistent with prior studies and indicated that groups traditionally vulnerable to digital exclusion (older and minoritized racial and ethnic groups) have lower odds of digital health uptake. These disparities in the context of telemedicine utilization have been well documented since the early stages of the PHE and have also been noted in the post-PHE era [6,11,18-22]. Novel to other studies, we found that these disparities differed across health systems with different telehealth implementation, even after adjustment for patient characteristics. When stratifying our models by health system, more disparities were found within the academic health system, where older, Asian, and Hispanic or Latine patients had lower odds of having a telemedicine visit than younger and non-Hispanic White patients, respectively; these disparities were not significant in the safety net system. In contrast, within the safety net system, Chinese-speaking patients had higher odds of having a telemedicine visit than other language preference groups.

Offering Audio-Only Visits May Increase Telemedicine Accessibility

The safety net system evaluated in our study serves a diverse group of patients who are at an increased risk for digital exclusion [14]. Despite this challenge, its adoption of a telemedicine infrastructure that primarily uses audio-only visits may have mitigated potential disparities in telemedicine access. While in-person visits remain the gold standard for primary care, robust audio-only options can augment the accessibility of care to patients reliant on telemedicine [23]. Studies have suggested that patients are more satisfied with telehealth modalities overall compared with in-person visits in terms of access and care provided, with no preference between video and audio-only visits [24,25]. Audio-only visits may be more accessible than video visits due to increased ease of use and lower technological requirements such as high-speed web access, smartphones, and laptops. Excluding or limiting these audio-only options may disproportionately impair access for minoritized racial and ethnicity groups, older adult patients, and non–English-speaking patients.

Our findings may have implications for patients in rural areas. Like urban safety net systems, patient served by rural health care systems are often at risk for digital exclusion, including having limited broadband access, lower rates of device ownership, and lower rates of digital literacy, suggesting that audio-only telemedicine may be necessary to prevent exacerbating health access disparities in these regions [26].

Considerations for Policy Makers and Health Care System Leaders to Ensure Telemedicine Equity

Our findings raise important considerations for future telemedicine policy, especially when considering the disparities observed within the academic health system. These disparities may partly be a consequence of the delayed and temporary approval for reimbursement of audio-only visits at a level similar to in-person visits by the Centers for Medicare & Medicaid Services [4]. The safety net system primarily served uninsured patients or those with public insurance (Medi-Cal) and Healthy Workers, where reimbursement rates were similar across audio-only and in-person visits. In contrast, the academic health system serves patients with private insurance or Medicare, both of which reimbursed video visits at lower rates than in-person or audio-only visits and thus had different incentives for telemedicine implementation. Inconsistent reimbursement across different telemedicine modalities can disproportionately impact populations at risk of digital exclusion and exacerbate existing health inequities. While video-enabled telemedicine care has been perceived in the United States to be more equivalent to in-person care and, therefore, reimbursed at a similar level for a longer period, audio-only telemedicine care has been perceived as providing lower quality and inadequate care, and therefore is reimbursed often at a much lower rate. This has resulted in limited motivation from many health care systems to provide audio-only encounters, which are more accessible to the populations that have experienced barriers to accessing

XSL•FO
RenderX

traditional face-to-face health care and have limited digital literacy or access to digital tools [27].

Policy makers should assess the impact of reimbursement policies across different telemedicine modalities and payors to ensure equitable adoption and appropriate utilization among all patient groups, especially patients who may forgo care otherwise without accessible telemedicine modalities. While most payor are concerned that increased accessibility may lead to higher utilization and costs, payors should also recognize the value of this opportunity to improve health care access for historically excluded populations.

Policies for encouraging delivery of more accessible telemedicine services should be implemented in conjunction with policies that address the barriers to accessing video-based telemedicine care. This may include policies that increase affordability of web access and devices as well as targeted investments in digital literacy programs [28]. Community-based initiatives, such as mobile technology training program and device distribution efforts, may reduce barriers to telehealth adoption [29]. These programs can be scaled to address the needs of populations with low digital literacy or limited access to digital tools [29].

Health systems leaders need to evaluate both the technologic needs and the health care requirements of their populations when developing telemedicine strategies, ensuring accessibility and equity while adapting to evolving policies and regulations. Incorporating multiple telemedicine options into care models can improve accessibility for older adults, patients with language barriers, and those in areas with limited broadband connectivity.

Both policy makers and health care leaders must evaluate the impact of policies on health equity over time. Consistent, systematic data collection and reporting on telemedicine utilization and its impact on clinical outcomes by sociodemographic characteristic such as race and ethnicity, language preference, and insurance coverage can help identify persistent gaps and guide future policy. When policies and implementation methods are aligned with real-world patient needs, particularly for populations at high risk of digital exclusion, telemedicine can serve as a tool to effectively reduce health disparities.

Limitations

Our sample included data from 2 urban health systems through March 2021, limiting generalizability to other systems and to later periods of the PHE. Future research evaluating the impact of telemedicine implementation in rural settings and examining trends in later post-PHE periods could further validate and broaden the applicability of these findings. However, more than 80% of the US population resides in urban areas, so our findings still have great relevance to many individuals [30]. In addition, differences in patient populations and institutional practices may be contributed to our findings. The safety net system may have had fewer disparities in telehealth use due to greater experience serving patients with limited digital access and stronger support for digital health literacy. However, our findings align with prior studies suggesting that telephone-based telehealth may improve accessibility and adoption among patient facing barriers to video-based services. We did not have access to the EHRs from outside systems, so we could not account for external encounters, although we limited our cohort to patients actively receiving primary care at UCSF or SFHN to mitigate this. Baseline measures of diabetes and BP control relied on single time points and may not perfectly reflect control through the study period. Incorporating longitudinal data in future analyses may help provide a more nuanced understanding of how disease control may be associated with telemedicine use.

Conclusions

This retrospective study examined a cohort of 10,201 primary care patients with diabetes during the PHE and found that inequities in telemedicine utilization varied across health systems with differing telemedicine implementation. Notably, disparities related to patient age and racial and ethnic identity underscore potential barriers to health care access. Compared with the safety net system with widespread adoption of audio-only visits, patients in the academic health system were less likely to have any telemedicine visit. Furthermore, lower telemedicine utilization was observed among older patients and minoritized racial and ethnic groups in the academic health system—disparities that were not present in the safety net system, which serves a more diverse population. Ultimately, our findings suggest that rapid, widespread telemedicine implementation prioritizing video telemedicine may exacerbate disparities in telemedicine utilization. Providing both audio-only and video appointments may enhance accessibility to care for populations historically at risk for digital exclusion.

Abstract

Background: The purpose of digital remote monitoring (DRM) is improving cancer care management. However, its effectiveness largely depends on the role of nurse navigators (NNs) within these systems to process data and lead action.

Objective: This study aims to fill gaps in our understanding of the role of NNs within a specific system, drawing on the Cancérologie parcours région Ile-de-France (CAPRI) DRM program applied to oncology patients.

Methods: The CAPRI DRM, targeting patients taking oral anticancer agents, combines digital interfaces with NN interventions. A phase 3 randomized controlled trial involving 559 patients assessed its safety and efficacy, with the primary end point being the relative dose intensity. This report focuses on patients in the CAPRI arm, evaluating the impact of NN interventions on outcomes such as toxicity, hospitalization, and emergency visits. Data on patient characteristics, NN interventions, and patient satisfaction surveys were analyzed using structural equation modeling.

Results: The study included 187 patients. Patient characteristics were significantly correlated with outcomes. Across all the models we used, the quality of NN interventions was consistently associated with higher patient satisfaction, with correlation coefficients ranging from 0.332 (95% CI 0.154-0.510; $P<.001$) to 0.366 (95% CI 0.182-0.550; $P<.001$). The number of grade ≥3 toxicity events correlated positively with NN referrals to oncologists. Hospitalization length was positively related to NN referral (coefficient 0.102, 95% CI 0.051-0.153; $P<.001$) and inversely to NN advice (coefficient –0.045, 95% CI –0.096 to 0.006; $P=.08$). Emergency visits showed a negative correlation with NN actions (coefficient –0.478, 95% CI –0.923 to 0.033; $P=.04$) and a positive correlation with NN calls and referrals (coefficient 0.516, 95% CI 0.069-0.963; $P=.02$).

Conclusions: This study shows the central role of NNs in making DRM effective. Despite the study's limitations, these results support the design of DRM as a hybrid model of automated digital tools and human support. Future research should explore the applicability of such a DRM model in various clinical settings to clarify the optimal association between automated systems and NN expertise.

KEYWORDS

digital remote monitoring; nurse navigators; patient care; oncology; toxicity; patient satisfaction; hospitalization

Introduction

Background

The tremendous uptake of digital care (mobile apps and web portals) has paved the way for improving the use of remote patient monitoring (ie, the digitally remote collection of patient-generated data that is automatically sent to health care providers), and it has created opportunities to further integrate digital remote monitoring (DRM) into the delivery of various health services. Several clinical trials implementing DRM tools showed that their use may improve the quality of care compared to standard care, reduce costs, supplement (or replace) in-hospital care, and improve management of clinical events in different chronic conditions [1,2], including cancer [3-7].

However, implementing supportive digital remote monitoring interventions remains challenging, with concerns about potential overuse and exacerbation of health inequalities due to the digital divide [8-11]. Successful DRM implementation relies on several factors, combining patient-reported outcomes, carefully designed technology, and specialist health care professionals' expertise [7-12].

What Role Is Played by Nurse Navigators?

Considering the importance of professional expertise, the actions of nurse navigators (NNs) may become crucial. Their expertise lies in clinical care and patient navigation, meaning that NNs can enhance the usability and safety of DRM technologies [12]. They can be a critical link between patients and the health care system, ensuring digital tools are effectively integrated into patient care. NNs can interpret data from digital tools, provide timely interventions, and guide patients through their treatment journey [12-14].

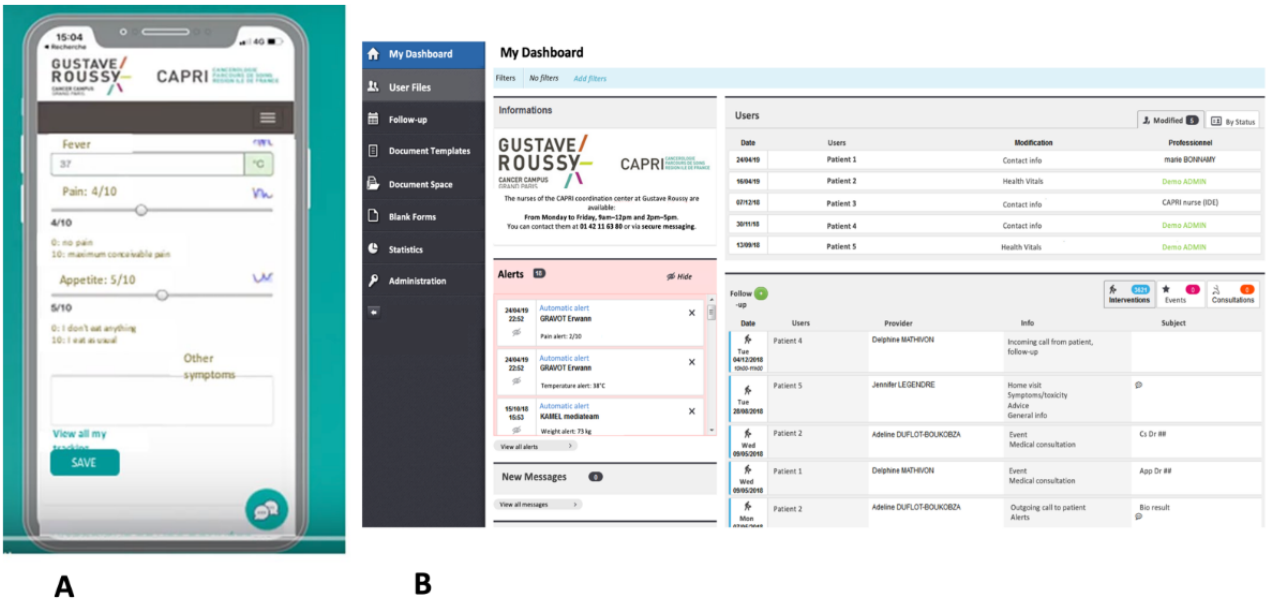
Despite the postulated importance of NNs in DRM, more research is needed to explore the extent to which they contribute to the effectiveness of these systems, especially in oncology. This study aims to fill this gap by examining the impact of NNs in the Cancérologie parcours région Ile-de-France (CAPRI) DRM program, considering factors such as toxicity management and care use.

Methods

An Example of DRM: CAPRI

CAPRI is an application of DRM in oncology. It specifically targets patients receiving oral anticancer agents, focusing on improving adherence, managing toxicities, and enhancing overall patient care. The core of CAPRI lies in its dual components: a digital interface (including a smartphone app and a web portal) and the active involvement of NNs in patient monitoring and intervention [14]. NNs involved in the CAPRI study received in-house training during two 2-hour sessions on how to use the application.

The safety and efficacy of CAPRI were assessed in a phase 3 randomized controlled trial (RCT) comparing the CAPRI DRM intervention against the standard of care. The trial included 559 randomized patients followed for 6 months. The study's primary end point was the relative dose intensity (RDI), defined as the ratio of the dose delivered over time to the prescribed dose intensity. Secondary end points included treatment adherence, toxicity management, patient-reported outcomes, and overall quality of life. The trial's design and results have been published elsewhere [15]. The main results showed that the CAPRI group (n=272) showed a significant improvement in RDI (93.4% vs 89.4%; *P*=.04), an enhanced patient experience (Patient Assessment of Chronic Illness Care score 2.94 vs 2.67; *P*=.01), reduced hospitalization length (2.82 vs 4.44 days; *P*=.02), and decreased grade ≥3 toxicities (27.6% vs 36.9%; *P*=.02).



This study is an ancillary analysis of the 272 patients included in the CAPRI intervention arm. Its objective is to detail the mechanisms of the NN interventions' effects on patient outcomes in the intervention arm.

Data Collection

Three distinct types of data collected during the RCT were used: patient characteristics and outcomes, including demographics and outcomes that have been previously published [15]; NN interventions, extracted from the NN dashboard used during the trial (Figure 1); and patient perceptions and satisfaction, based on a dedicated patient questionnaire administered at the end of the RCT to assess patients' use, perceived utility, and satisfaction with the program. Data were available for 69% of patients (n=187).

XSL•FO
RenderX

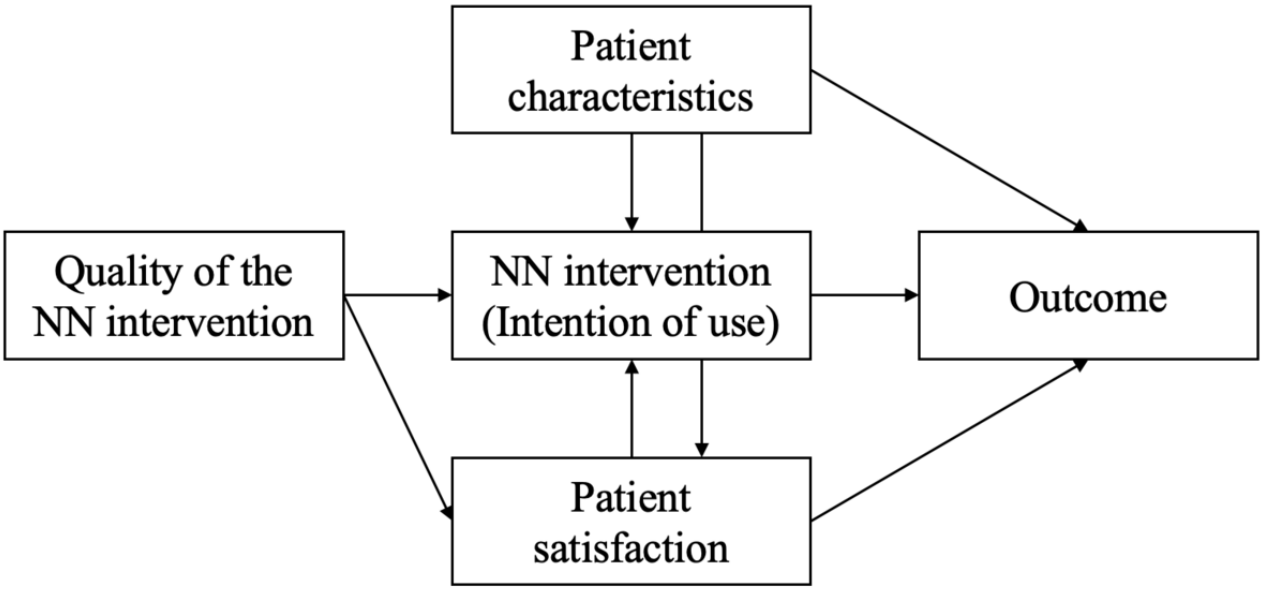


Figure 1. Screenshots of the patient smartphone app (A) and nurse navigators' dashboard (B).

Data Analysis

The role of NN interventions in outcomes, including toxicity, hospitalization length, and emergency service visits, was explored using a structural equation modeling approach. As shown in Figure 2, the framework used draws inspiration from the DeLone and McLean [16] model, which explains the success of information systems like DRM based on the roles of system quality, user satisfaction, and use.

Figure 2. Structural modeling framework used to explore the effects of nurse navigator (NN) interventions on outcomes.

The structure used considers that differences in outcomes are mediated through the NN interventions after adjusting to individual patient's characteristics. The quality of the NN interventions and patients' satisfaction were assessed using the patient questionnaire. Through factor analysis, it was verified that the associated questionnaire items corresponded to shared underlying dimensions, thereby allowing the reduction of these items to the unified latent variables used in the structural model.

CAPRI use was based on the number and frequency of NN interventions throughout the RCT, separated into (1) the number of inbound or outbound calls, (2) actions taken (appointment management, electronic health record management, information about administrative issues), (3) referrals (external health care providers, internal oncologists), (4) advice to patients, and (5) coordination actions. Patient characteristics included sociodemographic data, fitness (World Health Organization score) and metastatic cancer status. Before introduction into the model, variables were standardized to account for different measurement scales, while missing data were imputed using a complete information maximum likelihood approach.

Final models were selected using an iterative process based on the model's fit, which was evaluated using several global

XSL•FO
RenderX

indicators, including the standardized root mean square residual, adjusted goodness of fit, Tucker-Lewis index, comparative fit index, and root mean squared error of approximation. Our sample size (n=187) refers to general rules adopted for structural equation models with a small numbers of variables (4 to 7, depending on the model) [17]. A complete model and methodological description are available in Multimedia Appendix 1.

Ethical Considerations

This study was a secondary analysis based on the results of the CAPRI study, which was conducted according to applicable laws and regulations and the Declaration of Helsinki and was approved by an ethics committee (CPP Paris-Ile-de-France IV [2016/20SC] and US Department of Health and Human Services (00003835). The study was registered on ClinicalTrials.gov (NCT02828462). All patients included in the study provided informed consent to participate in the study. The informed consent form clarified that the collected data were part of the CAPRI study and would be used for primary and secondary analyses. To protect participants' privacy, all data were anonymized. No compensation was offered to participants.

Results

Patient Characteristics

Overall, 187 patients from the intervention arm of the CAPRI trial were included. The characteristics of the respondents were similar to those of the complete set of patients, except for a longer follow-up period, as shown in Table 1.

Table 1. Patient characteristics.

Characteristics	Participants in this study (n=187)	Participants in the CAPRI[a] study intervention arm (n=272)	*P* value
Age (years), mean (SD)	59.8 (14.2)	59.1 (14.0)	.59
Female participants, n (%)	103 (55.8)	156 (57.3)	.63
Performance status[b], n (%)			.24
WHO[c] 0	92 (49.2)	121 (44.5)	
WHO 1	82 (43.9)	120 (44.1)	
Metastatic cancer, n (%)	147 (78.6)	222 (81.6)	.42
Follow-up duration (weeks), mean (SD)	148.7 (48.3)	133.0 (54.2)	.02

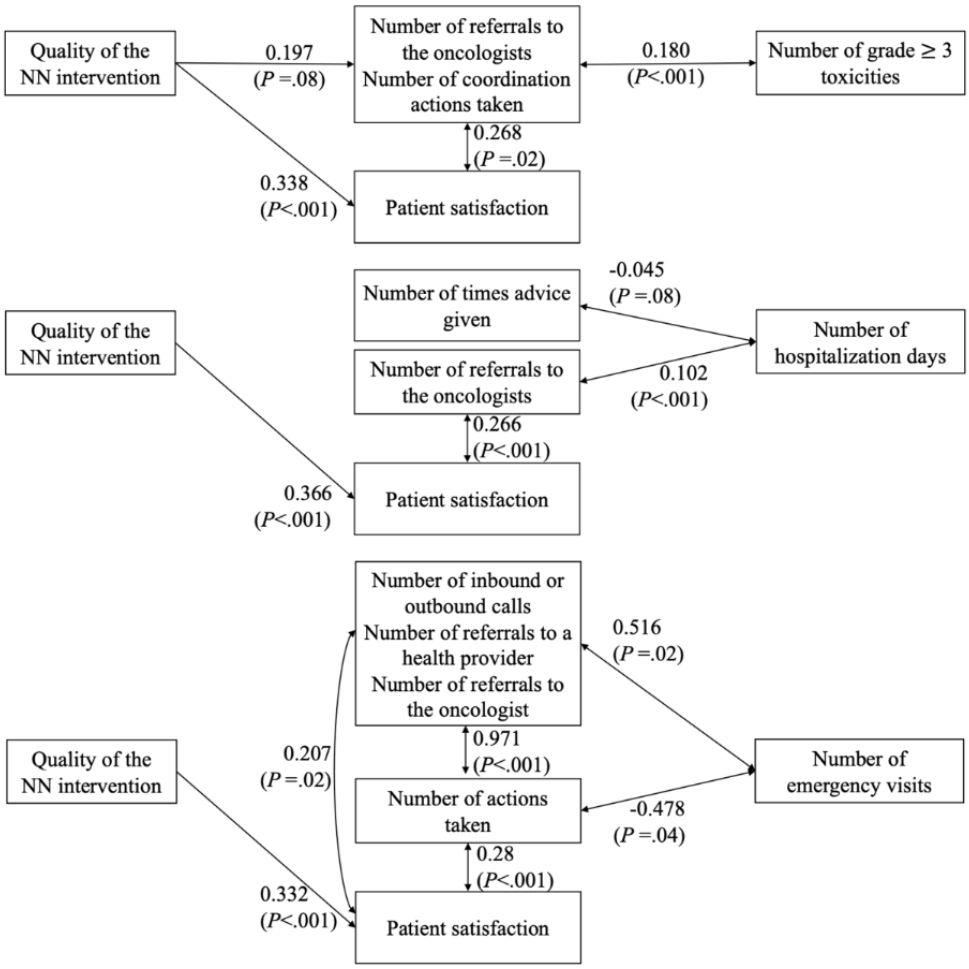
[a]CAPRI: Cancérologie parcours région Ile-de-France.

[b]Performance status reflects cancer patients' functional ability, ranging from normal activity (0) to completely bedridden (4).

[c]World Health Organization.

As expected, patients' characteristics, including age, performance status, and metastatic stage, were significantly associated with the selected outcomes (Multimedia Appendix 1, Figures S3 to S5).

The Role of NN Interventions



Structural model results, which do not show patients' characteristics, are presented in Figure 3.

Across all the models we used, the quality of NN interventions was consistently associated with higher patient satisfaction, with correlation coefficients ranging from 0.332 (95% CI 0.154-0.510; SE 0.091; z=3.64; P<.001) to 0.366 (95% CI 0.182-0.550; SE 0.094; z=3.90; P<.001). Likewise, patient satisfaction was consistently and positively associated with NN interventions, with similarly strong correlation coefficients ranging from 0.207 (SE 0.088, 95% CI 0.035-0.380; z=2.341; P=.02) to 0.283 (SE 0.079, 95% CI 0.128-0.438; z=3.598; P<.001).

The number of grade ≥ 3 toxicity events was positively associated with the number of referrals to oncologists and coordination actions. Hospitalization length was positively correlated with the number of referrals to oncologists (coefficient 0.102, 95% CI 0.051-0.153; SE 0.026; z=3.90; P<.001) and negatively associated with the number of times advice was given (coefficient –0.045, 95% CI –0.096 to 0.006; SE 0.026; z=–1.73; P=.08). Emergency visits were negatively related to the number of actions taken (coefficient –0.478, 95% CI –0.923 to –0.033; SE 0.227; z=–2.10; P=.04) and positively associated with the number of calls and the number of referrals (coefficient 0.516, 95% CI 0.069-0.963; SE 0.228; z=2.26; P=.02).

Discussion

This study corroborates past findings that nurse-led interventions in a DRM program for cancer patients can impact health outcomes [9-11]. The actions taken by NNs within CAPRI were associated with reduced emergency service use and hospitalization length. This suggests that NNs are critical in providing appropriate advice and avoiding unnecessary emergency service use and hospital interventions. The positive associations between emergency service use, hospitalization length, and grade ≥ 3 toxicity events and NN interventions, such as coordination or referrals, likely reflect a prioritization in monitoring and treating severe cases. This also highlights the versatility of NNs in managing most patient interaction and orientation without direct oncologist referrals, confirming their potential in delegating certain oncologist tasks [18].

These findings emphasize the importance of considering DRM as a hybrid model that combines digital tools with human support, especially in complex cases. Additionally, patients' preferences for different platforms (phone or web based) or reluctance to use digital platforms highlights the need for flexibility and human availability in DRM implementation [19].

Despite its contributions, this study had limitations, including its single-center nature, which might affect the external validity of the findings. This hybrid model's application to other cancer conditions and its generalizability requires further investigation.

In conclusion, the study illuminates the role of skilled nurses in DRM implementation, suggesting the need for future research to explore the division of tasks between automated alert systems and human expertise, particularly in managing complex cases and cancer pathways. The potential managerial implications underline the importance of clearly defining the role of NNs and considering their activity in payment models for digital remote monitoring systems [20].

Acknowledgments

The authors thank the Gustave Roussy clinical and research teams, as well as the patients and their families. The study was funded by the French National Research Agency, the Agence Régionale de Santé Ile-de-France, Philanthropia Lombard Odier Foundation, Novartis, and AstraZeneca. The funding bodies were not involved in the study design.

Abstract

Background: Emerging infectious disease disasters receive extensive media coverage and public attention. Nurse burnout and attrition peak during health crises such as pandemics. However, there is limited research on nursing issues related to repeated emerging infectious disease crises over time.

Objective: The purpose of this study was to analyze and draw implications from changes in key nursing issues reported by the news media during the outbreaks of severe acute respiratory syndrome (SARS; 2003), influenza A (2009), Middle East respiratory syndrome (MERS; 2015), and COVID-19 (2020) in Korea using topic modeling.

Methods: A total of 51,489 news articles were extracted by searching for the keywords “nursing” or “nurse” in the title or body of articles published from April 2003 to May 2021 (during new infectious disease outbreaks) in the open integrated database. The selected news articles were preprocessed then analyzed for text and structure using a 3-step keyword analysis method, latent Dirichlet allocation topic modeling, and keyword network analysis.

Results: Among the 51,489 news articles collected with the search terms “nursing” and “nurse,” 17,285 (33.6%) were selected based on the eligibility criteria and used in the final analysis. Using topic modeling, we derived 5 topics each for SARS, influenza A, and MERS and 6 topics for COVID-19. The themes commonly identified through topic modeling and keyword network analysis across the 4 epidemics were “response to emerging infectious diseases in Korea,” “demand for nurses,” “vulnerability in the work environment,” and “roles and responsibilities of nurses.” Although the topic names were the same, the meanings implied by the comprehensive keywords for each epidemic varied depending on the epidemic and the times.

Conclusions: Analysis of the identified themes and associated keyword network revealed that issues related to nurse shortages, working conditions, and poor treatment were not unique to the COVID-19 pandemic but rather recurring themes from previous epidemics. Our findings can be used to inform strategies to improve the professional roles, work environment, and treatment of nurses during health crises. Suggestions for future nursing-related policy impact and change research are also provided.

Introduction

An emerging infectious disease (EID) is a newly recognized or previously known disease characterized by new virulence or spread in previously unaffected areas [1]. Since the 2000s, South Korea has had 4 EIDs: severe acute respiratory syndrome (SARS) in 2003, novel swine-origin influenza A (H1N1) in 2009, Middle East respiratory syndrome (MERS) in 2015, and COVID-19 in 2020. Among them, influenza A and COVID-19

XSL•FO
RenderX

were declared as pandemics by the World Health Organization (WHO). Antiviral treatments were provided free of charge in Korea starting in August 2009 during the SARS outbreak, after which the number of infections and deaths were no longer regularly recorded. Before then, 270 deaths and 2417 infections were recorded, and at the time of manuscript submission, SARS had resulted in an additional 0 deaths and 4 infections according to official reports. Although the exact number of infections has not been counted since August 2009, more than 700,000 cases had been prescribed antiviral drugs from August 2009 to December 2009. During the MERS period, there were 39 deaths and 186 infections. Regarding COVID-19, 34,572,552 confirmed cases and 35,605 deaths were reported from January 20, 2020, to August 30, 2023, the period involving full monitoring [2].

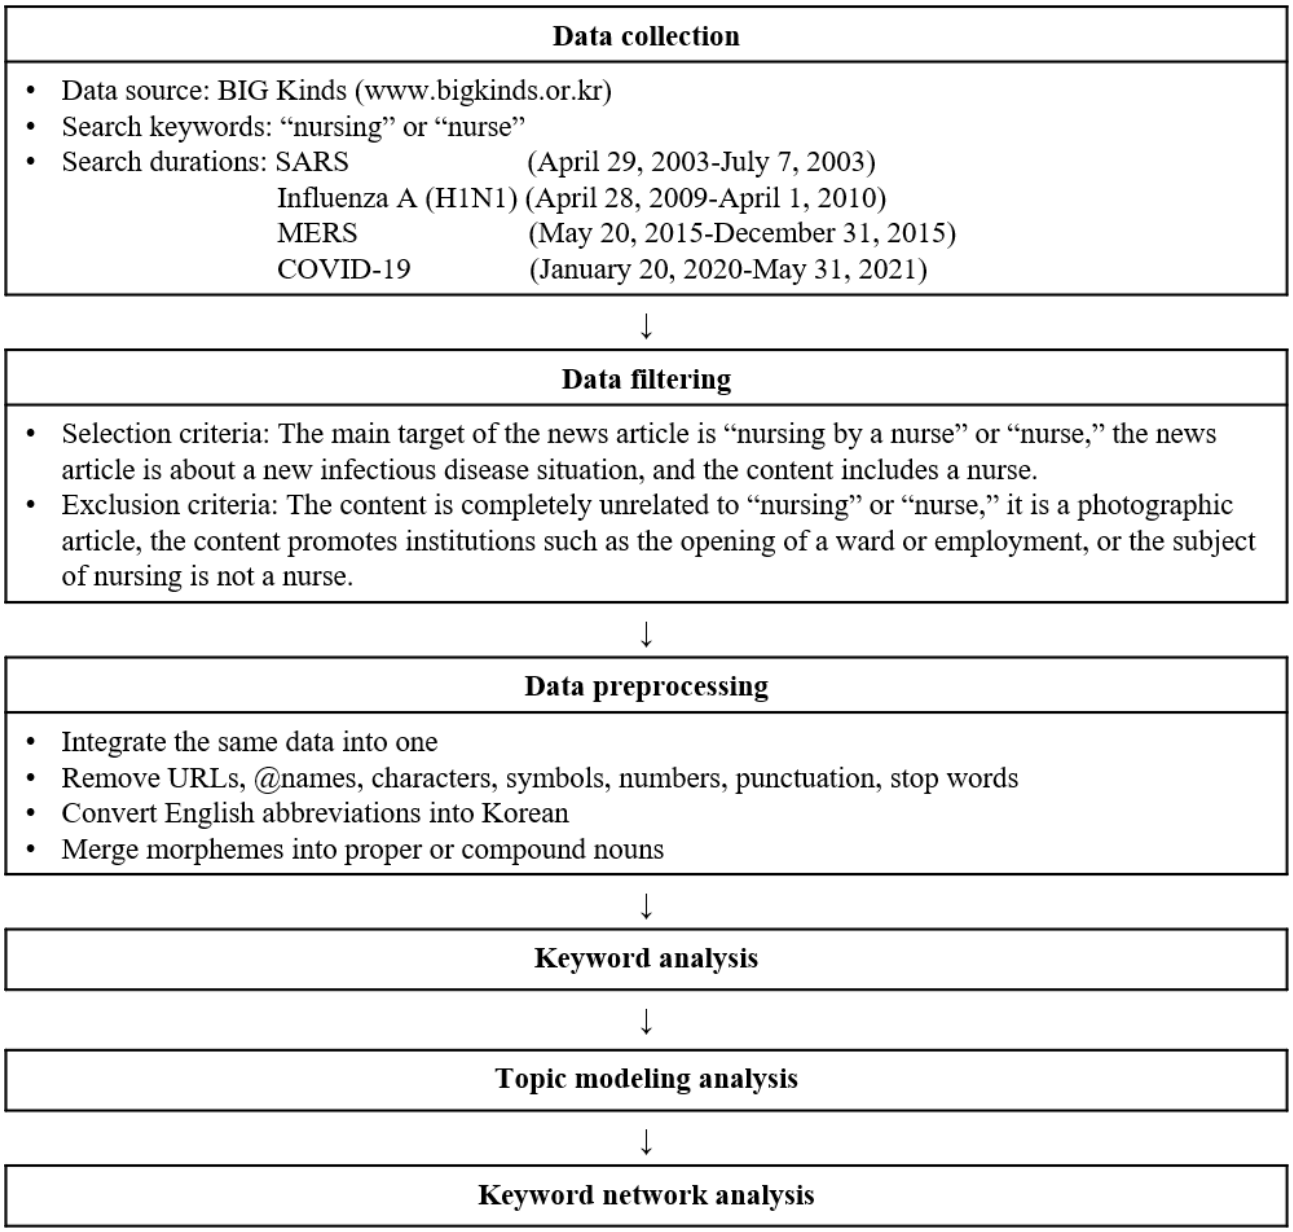
EID catastrophes receive extensive media coverage and public attention. Indeed, public interest in nurses peaks during health crises, such as infectious disease epidemics [3]. EID outbreaks increase public recognition of and attention to the dedication of nurses working on the front lines of the disaster response [4]. Meanwhile, nurses experience physical and psychological burnout as well as professional ethical conflicts owing to the risk of infection, heavy workloads, patient violence, and the stigma of being a carrier of infection [5-8]. Rising rates of nurse burnout and resignation during inadequate infectious disease crisis responses have become global concerns [9,10]. The loss of skilled nurses may lead to a decline in the quality of nursing care and organizational nursing capacity, which may pose a risk to national health crisis responses and public health.

Although infectious disease outbreaks can be traumatic for individuals and communities, they can also lay the groundwork for health system transitions after the outbreak ends, through institutional and policy improvements that identify and address health system weaknesses revealed during the response. With respect to issues in the nursing workforce, scholars have suggested that societal consensus for improvements in working conditions and institutional arrangements for health resources and protection are needed to minimize nurse burnout and attrition in special situations, such as infectious disease outbreaks [6,8,11,12]. At the national level, discussions about appropriate investments and compensation systems for the training and deployment of infectious disease professionals and collaboration with the medical community are needed, whereas at the societal level, increasing public awareness of health workers and building public consensus through media coverage have been emphasized as obligations [7,13,14]. Media's reports of issues in the field of infectious diseases play an important role in forming society's perceptions of an infectious disease response, nursing, and nurses. Problems that are not resolved over a long period of time, occur repeatedly, and increase public interest become social issues, which become part of a public agenda that the general public recognizes as appropriate for the government to solve. This public agenda is then developed and set as a specific policy agenda.

Previous studies analyzing media coverage of infectious disease outbreaks focused on public perceptions of nursing portrayals and issues [3,4,15,16] and were mostly limited to specific epidemic periods. However, these studies did not track how nursing issues were portrayed during recurrent outbreaks since the 2000s, the unique characteristics of each period, and how characteristics have changed. In the context of COVID-19, which was declared as an endemic by the WHO, policies that address the underlying issues and promote a better future urgently need to be developed. Prior studies using content analysis techniques to analyze data collected through standardized questionnaires or media inevitably had limited data to reflect public perceptions and trends. To compensate for this, it is necessary to grasp the meaning inherent in big data such as online news and social media, and topic modeling and keyword network analysis methods, which have been widely used recently to analyze unstructured text in big data, overcome the limitations of manual analysis by humans [17-19].

Therefore, this study aimed to analyze the changes in major nursing issues reported by the news media when 4 new infectious diseases occurred in the 2000s using topic modeling and keyword network analysis methods and derive the implications. Specifically, we aimed to identify the issues that should be considered to effectively respond to new infectious disease crises that may occur in the future and ensure public safety. Our findings could provide the basis for the development of desirable infectious disease response strategies.

Methods



Data Extraction

We collected data from the Korea Press Foundation's article information website [20], an open-access database containing news articles from 54 media organizations. We collected data published between April 2003 and May 2021 corresponding to the periods of EID epidemics. Specifically, we analyzed news articles published during the SARS, influenza A, MERS, and COVID-19 outbreaks.

A total of 51,489 news articles were extracted by searching for "nursing" or "nurse" as the keyword in the title or text of the article during the outbreak of each new infectious disease. Although the terms "nursing" and "nurse" appeared in the text of these articles, irrelevant content, such as promotional material, was excluded using the selection and removal criteria detailed in Figure 1. These criteria were informed by advice from experts in the field of nursing research and clinical experience. A total of 17,285 news articles were selected using these criteria and used for the final analysis. Figure 1 details the data extraction process used in this study.

XSL•FO
RenderX

Figure 1. Study process. MERS: Middle Eastern respiratory syndrome; SARS: severe acute respiratory syndrome.

Data Preprocessing

We preprocessed the metadata of the selected news articles using the *KoNLP* and *tm* packages for natural language processing in R version 4.1.0. Specifically, we removed terms, including symbols, special characters, names of private individuals, and media company names. English terms, such as "SARS" and "OECD," were occasionally removed during terminology preprocessing; these terms were converted into their Korean equivalents to maintain consistency. During morpheme analysis, complex nouns like "living treatment center" were segmented into "living," "treatment," and "center," causing loss of meaning. To address this, these terms were reconstituted as proper or compound nouns based on N-gram analysis and the context of the original article. Abbreviated Korean terms were replaced with their official names to ensure terminological consistency.

Keyword Analysis

We used the *tm* package in R version 4.1.0 to calculate word frequencies and determine the importance of specific terms using the term frequency-inverse document frequency metric value. Statistical weights were calculated to assess the significance of specific terms within the corpus for keyword analysis of the news articles.

Topic Modeling

Topic modeling classifies and integrates topics in extensive document sets using probabilistic statistical methods to identify latent high-level concepts, extract the topics implicit in the documents, and derive common high-level concepts latent in the topics [21]. We used the latent Dirichlet allocation (LDA) algorithm of the *topicmodels* package of R version 4.1.0 to analyze the topics embedded in the documents. The coding of the analysis was based on the work of Grün and Hornik [16] and open-source code on the GitHub site.

XSL•FO
RenderX

We configured the LDA algorithm by setting the document extraction parameter (α) to 50/k, and the previous parameter delta (or eta) of the word distribution constituting the topic was set to 0.1. Gibbs sampling was used to estimate the topic distribution for the document, with 1000 repetitions used for Gibbs sampling [16,22].

We also conducted a quantitative analysis to select the appropriate number of topics. We calculated perplexity values ranging from 2 to 20 using the *topic models* and *LDAvis* packages of the R program. The topic modeling analysis was repeated by applying different numbers of topics based on the perplexity values. For the analysis, we repeated the adjustment of the λ value of the LDA visualization and reviewed the original text of the news articles to extract a list of the 30 most representative keywords for each topic.

Keyword Network Analysis

Keyword network analysis visualizes keyword relationships by calculating co-occurrence frequencies and metrics such as connection centrality, proximity centrality, and mediation centrality [23]. We performed keyword network analysis using the *Network*, *sna*, and *ggplot2* packages in the R program to improve the specific content and structure of the topics and the words constituting the topics derived from thematic modeling. Considering the visibility of the network around thematic keywords, the correlation coefficient was established, and the relationship between the simultaneous appearance of words was analyzed.

The top 15 keywords were selected as the main keywords for each topic through quantitative analyses including topic modeling analysis, keyword network analysis, and verification by nursing experts, and the topic names reflected the same higher-level concept to examine the trends of the topics and keywords that make up the topic by period of the new infectious disease based on the main keywords. In this study, 15 keywords for the new infectious disease topic and topic are presented.

Ethical Considerations

All news article data analyzed in this study were publicly available and not subject to copyright restrictions. The Institutional Review Board of Kyung Hee University approved this study (IRB number KHSIRB-21-334(EA)).

Results

News and Keyword Counts

After preprocessing the data from a total of 17,285 news articles, we extracted 1974 words for the SARS epidemic, 9520 words for influenza A, 15,639 words for MERS, and 24,888 words for COVID-19, resulting in a total of 52,021 words. The numbers of news articles and keyword types analyzed increased progressively across successive infectious disease outbreaks, and the average daily number of news articles was the highest during the MERS period.

Top Topics and Keywords During Epidemics

Table 1 presents the keywords and topic names identified for each epidemic period. We selected 5 topics each for SARS (perplexity=1599.241, λ=0.7), influenza A (perplexity=977.101, λ = 0.8), and MERS (perplexity=1717.432, λ=0.7) and 6 topics for COVID-19 (perplexity=2515.911, λ=0.6). We sorted the topics in the order of the largest percentage of word clusters that make up the topic and identified them as themes.

[a]SARS: severe acute respiratory syndrome.

[b]MERS: Middle East respiratory syndrome.

[c]Abbreviations for specific hospital names.

[d]OECD: Organisation for Economic Co-operation and Development.

[e]WHO: World Health Organization.

Trends in Nursing-Related Topics in Media Coverage

According to the topic modeling analysis, we classified a total of 7 topics from all news articles, and the topics commonly derived from the 4 infectious disease periods were "response to emerging infectious diseases in Korea," "demand for nurses," "vulnerability in the working environment," and "roles and responsibilities of nursing professionals." Although the overarching concepts remained consistent, the keywords comprising each topic varied across the duration of infectious diseases. Notably, the keywords that comprised the topics for each epidemic period differed. We observed that the topic "vaccination for emerging infectious diseases" appeared only in the influenza A and COVID-19 pandemics, and "government response and public opinion" appeared only in the MERS and COVID-19 periods. Moreover, the topic "response to emerging infectious diseases in other countries" appeared only during SARS (Table 2). Table 1 shows the topics and word clusters identified by our model.

Table 2. Trends in nursing-related topics in media coverage, reported as tokens for each outbreak.

Trends	SARS[a], %	Influenza A (H1N1), %	MERS[b], %	COVID-19, %
Response to emerging infectious diseases in Korea	18.2	21.7	21.5	20.8
Demand for nurses	31.2	26.3	23.6	17.7
Vulnerability in the working environment	19.7	18.7	16	17.5
Roles and responsibilities of nursing professionals	15.4	21.1	21.8	23.9
Government response and public opinion	—[c]	—	17.1	13
Vaccination for emerging infectious diseases	—	12.2	—	7.1
Response to emerging infectious diseases in other countries	15.5	—	—	—

[a]SARS: severe acute respiratory syndrome.

[b]MERS: Middle East respiratory syndrome.

[c]Not applicable.

Theme 1. Response to Emerging Infectious Diseases in Korea

During the 4 periods, the "response to emerging infectious diseases in Korea" topic accounted for approximately 20%, ranking third during the SARS and MERS outbreaks and second during the influenza A and COVID-19 outbreaks. The keyword patterns were similar between SARS and MERS and between influenza A and COVID-19, reflecting trends observed in the keyword frequency analysis.

Keywords for each period include the name of the respective virus and terms describing the outbreak situation, such as "infection," "suspected patient," "outbreak," and "presumed patient" during the SARS period; "infection," "spread," "outbreak," "confirmed patient," and "deaths" during the influenza A period; "confirmed case," "infection," "additional," "quarantine," and "closure" during the MERS period; and

XSL•FO
RenderX

"China," "pandemic," "outbreak," "situation," "world," and "the dead" during the COVID-19 period, indicating the evolving scale and severity of infectious disease outbreaks in Korea over time.

In addition, keywords related to infectious disease response and preparedness such as "isolation," "disinfection," "designation," "National Institute of Health," "constitute," and "dedication" during SARS changed to "hub-hospital," "prevention," "treatment," "mask," "countermeasure," "test," and "Tamiflu" during the influenza A and MERS periods and keywords related to preparation such as specific hospital names and "hospital," "emergency room," "Central MERS Control Countermeasure Headquarters," "treatment," "isolation," and "closed" during the COVID-19 period. Keywords related to preparation, such as "mask," "protective clothing," "treatment," and "hospitalization" diminished in number, with response-focused keywords emerging in their place.

Theme 2. Demand for Nurses

The topic "demand for nurses" ranked first and represented the largest proportion during the SARS to MERS periods; during COVID-19, the topics of "roles and responsibilities of nursing professionals" and "response to emerging infectious diseases in Korea" represented higher proportions, with "demand for nurses" dropping to third place. When examining the keyword flow of topics by period, the keywords "system," "policy," "countermeasure," and "response" were associated with "the aged," "society," "facility," "psychiatric," "dementia," "the disabled," and "welfare" during the SARS period; "service," "the aged," and "the disabled" during the influenza A period; "comprehensive nursing service," "hospital," and "infection disease" during the MERS period; and "Daegu," "living treatment center," and "dedicated hospital" during the COVID-19 period, showing that the areas in which nurses were needed and the reasons for a nursing demand changed as a result of health and welfare systems and policies for infectious disease responses.

In addition, "nursing care," "family," "profession," and "role" during the SARS period; "manpower" during the influenza A period; "nursing staff," "caregiving," and "nurse's aide" during the MERS period; and "treatment," "medical worker," and "critical patient" during the COVID-19 period represent keywords related to the perception of the role of nurses. The keywords "nursing college," "nursing department," "expansion," and "quota" during the influenza A period; "nurse's aide" during the MERS period; and "support," "deploy," "dispatch," "allowance," and "recruitment" during the COVID-19 period represented changes in ways to meet the nursing demand by period.

Theme 3. Vulnerability in the Working Environment

The topic "vulnerability of the working environment" had the second highest weight during the SARS period, but its weight decreased during the influenza A and MERS periods. Its weight increased to 4th place during the COVID-19 period. During the SARS period, keywords such as "son and daughter," "woman," "parent," "workplace," "thought," "risk," "exercise," "night duty," "health," and "prevention" were topics about women's conflicts between work and childcare and health risks related to work, while during the influenza A period, keywords such as "patient," "hospital bed," "OECD," "level," "facility," "insufficiency," "intensive care unit," and "region" showed a quantitative shortage of nurses and medical facilities. During the MERS period, news reports focused on topics such as "contact," "infection," "addition," "duty," and "emergency room" regarding nurse infections, while during the COVID-19 period, news reports focused on topics such as "group infection," "duty," "contact," "working environment," "site," and "rest."

Theme 4. Roles and Responsibilities of Nursing Professionals

The topic "roles and responsibilities of nursing professionals," which was the lowest during the SARS period, showed an upward trend from the influenza A period to the COVID-19 period, and during the COVID-19 period, it had the largest change among the 6 derived topics.

The keywords of the "roles and responsibilities of nursing professionals" topic changed mainly based on specific incidents reflecting the situation at the time. During the SARS period, specific incidents related to keywords such as "blood," "drunk driving," "hospital," and "sexual harassment" included a case in which a nurse switched the blood of a drunk driving colleague with her own blood and submitted it, a case in which a doctor sexually harassed a nurse, and an illegal medical practice by a nurse or nursing assistant. During the influenza A period, keywords related to the incidents and accidents at the time, such as a case in which a newborn was switched due to a nurse's mistake, included "adjudge" and "obstetrics and gynecology" and related to bioethics, such as euthanasia, included "grandmother" and "death with dignity." During the MERS period, keywords such as "family," "thought," "heart," "gratitude," and "cheer" showed support for doctors and nurses who were infected during the MERS response process, which occurred mainly in specific hospitals. During the COVID-19 period, keywords such as "medical school quota," "expansion," "Korean Medical Association," and "Korean Nurses Association" mainly focused on issues such as doctors' strikes and nurses who stayed by patients' sides during the infectious disease outbreak.

Theme 5-7. Topics Derived Only During a Particular Infectious Disease Period

The fifth topic "government response and public opinion" was derived during the MERS and COVID-19 periods, and it had the second lowest proportion in both periods. During the MERS period, from the keywords "virus," "the public," "outbreak," "anxiety," "information," "fear," and "open," we could infer that the public experienced anxiety due to a lack of information on new infectious diseases from the government's disclosure of information. During the COVID-19 period, keywords such as "nurse," "president," "gratitude," "encouragement," "controversy," and "criticism" emphasized the controversy over the president's thank you message to nurses during the doctors' strike and the public's support for the struggles of medical staff, such as the "Thanks to Challenge," as social issues.

XSL•FO
RenderX

"Vaccination for emerging infectious diseases" was derived only during the influenza A and COVID-19 periods, and this topic had the lowest proportion of all topics in both periods. During the influenza A period, the keywords "student," "school," and "school parent" indicate that children and adolescents were the main targets of vaccination, while during the COVID-19 period, the keywords "nursing facility," "targets," and "worker" show that the targets of vaccination changed to older adults and health care workers. "AstraZeneca," "side effects," "Pfizer," and "effect," which appeared only during the COVID-19 period, indicate the situation of and public interest in the development of COVID-19 vaccines, which were not available at the beginning of the outbreak, and vaccination.

The main keywords of the "response to emerging infectious diseases in other countries" topic, which was derived only during the SARS period, consisted of the names of countries that experienced significant damage from new infectious diseases, such as "China," "Taiwan," and "Hong Kong," and keywords about the situation of the outbreak, such as "death," "outbreak," "addition," and "transmission."

Discussion

Principal Findings

This study was based on the basic premise that, in public health crises such as new infectious diseases, media reports related to the field, including nursing and nurses, become more active, reflecting high social interest in major issues. This study attempted to explore the problems that were highlighted during 4 new infectious diseases that occurred in Korea and considerations regarding social awareness and improvement to policies in relation to major nursing issues. Therefore, this study compared and analyzed the main agenda and potential meaning of news articles on nursing and nurses for each new infectious disease period using the big data analysis techniques of topic modeling and keyword network analysis. In addition, we discussed the understanding of current nursing phenomena and the trends and implications of public opinion surrounding nursing based on the results.

As a result of topic modeling analysis, 7 topics were classified from all news articles. The commonly derived topics from the 4 infectious disease periods included "demand for nurses," "response to emerging infectious diseases in Korea," "vulnerability in the working environment," and "roles and responsibilities of nursing professionals." Topics with the same higher concept had changes in the associated keywords according to the infectious disease period. The following sections discuss the potential meaning in each topic by referring to the visualization results of the related keyword network map, focusing on the topics commonly derived during the new infectious disease periods.

Response to Emerging Infectious Diseases in Korea

First, the keywords for the topics during the SARS, MERS, influenza A, and COVID-19 periods showed similar patterns when analyzing the relevance of the topic by period. Depending on the duration of the infectious disease, the keywords "outbreak," "spread," "addition," and "pandemic" were used to express the seriousness of the domestic infectious disease situation. The potential meaning of the words related to the keywords "National Institute of Health," "dedication," and "designation" during SARS and "hub-hospital" during influenza A was the government's practical policy proposal to prepare for new infectious diseases. These policies included the designation of regional hub hospitals and securing state-designated inpatient treatment beds that were proposed during SARS and influenza A and were implemented and partially improved after the end of those infectious disease periods. However, the number of public medical resources, such as treatment beds and health professionals, that could be practically used was significantly insufficient for the number of infected patients during the MERS and COVID-19 periods [24].

In addition, keywords such as "medical staff," "infection," "closed," "hospital room," and "hospitalization" during MERS and COVID-19 highlighted vulnerabilities in emergency room environments, including inadequate infection control measures and gaps in infection control in nursing hospitals and nursing facilities where older adult patients, who are vulnerable to infection, are mainly hospitalized. The emergency room is where infected patients primarily access the hospital. Problems including the lack of facilities such as separate isolation zones and negative pressure isolation rooms for the treatment of infected patients revealed during the MERS period, the lack of education on infection control, and the response of emergency medical workers increase the risk of medical staff becoming infected and are viciously linked to patient infection and the lack of response personnel [25]. In addition, in emergency rooms, there is a greater need for systematic infection control by professional personnel such as nurses because older adult patients in nursing hospitals and facilities are more likely to contract infectious diseases due to low immunity and group living and the risk of death from infection is high [26,27]. This is a matter to be considered first in terms of policy for infection control in environments where patients and medical personnel are at a high risk of infection. After MERS, the enforcement regulations outlined in the Emergency Medical Service Act were revised to improve emergency room facilities and manpower standards [28], and through the revision of the enforcement regulations of the Medical Act during the COVID-19 period, the standards and fees for mandatory infection control rooms for infection control were expanded [29]. However, the effectiveness of the policy is still limited because it does not resolve gaps in infection control outside the scope of the policy, such as the lack of infection control experts and nursing hospitals and facilities with fewer than 100 beds. Although policies such as the revision of the Emergency Medical Service Act aimed to address these gaps, their effectiveness remains limited due to insufficient implementation and resource allocation. Similar challenges in emergency room preparedness were noted in countries such as Italy and the United States during the COVID-19 pandemic, underscoring the global nature of these vulnerabilities.

Demand for Nurses

In the "demand for nurses" topic, the need to increase the number of nurses has been steadily highlighted over the past

XSL•FO
RenderX

20 years, and the keyword "insufficiency," which appeared only during the influenza A and COVID-19 periods shows that the shortage of nurses during the COVID-19 period was also a problem that was raised during the influenza A period. In the topic analysis results, the focus on nursing demand changed from health and welfare services to responding to infectious diseases, and in the change of keywords over time, the area of public interest also changed according to the reason for the demand in nurses and the field of activity. The areas where nurses' activities are performed are diverse and include medical institutions, communities, schools, and businesses; nurses are also recognized as particularly indispensable for the national welfare service, especially in a society where the number of older adult and single-person households is increasing [30,31]. Among the government's systems related to the demand for nurses, the comprehensive nursing service (currently, the integrated nursing care service), which was introduced in 2013 to reduce the burden of care and expenses for people in a nuclear family and an aging society, accelerated the expansion of the service, as domestic nursing and door-to-door cultural issues were raised in terms of hospital infection control during the MERS period in 2015. Nurses with specialized knowledge and skills were recognized as a major element of the service, which proceeded to actively use nurses [32,33]. Many previous studies on integrated nursing care services have shown positive effects of these services for improving patient safety, reducing hospital infections, and increasing patient satisfaction with medical services [32,34,35]. Accordingly, there seems to be no difference in public opinion on the need for a change in the demographic and social structure, the response to infectious disasters at the health care level, a quantitative increase in nurse demand and quantity, and policies to increase the number nurses.

In terms of meeting the demand for nursing during periods of new infectious diseases, the focus was on recruiting nurses and distributing manpower to prevent the infection of the vulnerable, such as older adults, and school quarantine during the SARS and influenza A periods. Changes for the issue of nursing supply were mainly made to comprehensive nursing services as a preventive measure against hospital infections. During the COVID-19 period, there was a shortage of nursing personnel who could be immediately placed in response to infectious diseases in medical institutions in nonmetropolitan areas such as Daegu, life treatment centers, and hospitals dedicated to infectious diseases. The government filled the demand for nurses with temporary measures through the dispatch of nursing personnel recruited through the input of nursing officers and allowances. However, the urgent recruitment of the personnel needed in the field of infectious diseases was ineffective due to insufficient nursing experience, education, and training [36,37]. It is believed that the gap in the nursing field continues because there is a real need for nurses with the experience and capacity to care for infectious disease patients and intensive care patients, while the government's policies for and public opinion about increasing the nursing supply focused purely on the number of nurses rather than the quality and capacity of nursing.

The fact that the policy to increase the number of nurses recognized nursing as a job that not only resolves the imbalance of local medical personnel or meets medical needs but also resolves employment difficulties and guarantees employment after graduation is similar to the ideas expressed in the original news article [38] titled "Graduation is Employment, Nursing and Explosion of Popularity" and research showing that high school students who are about to pursue careers perceive nursing as an economically stable and good job compared with other occupations [39]. In addition, in research analyzing the meaning of work for new nurses in 2021, more than 50% of the nurses had family and relatives who recommended they pursue nursing, or they applied to the nursing department because they were able to easily get a job after graduation [40].

Since 2008, the year just before the influenza A outbreak, Korea implemented a policy to establish a nursing department and increase the number of admissions. As a result of this policy, during the swine flu period, there were 414,000 licensed nurses in 2019, and 20,000 new nurses entered the workforce every year [30]. However, there are only 215,000 nurses working in medical and health institutions, which represents about one-half of the licensed nurses [41]. According to data from a survey on the status of hospital nursing staff placements every year since 2010, the turnover of new nurses increased from 30.5% in 2011 to 47.7% in 2020, and the number one reason for resignation within a year after the announcement was "work maladjustment" [42,43]. The burden of work on new nurses was correlated with the reality shock caused by the conflict between the hospital organizational culture and nursing professionals [44]. Nurses are aware of the risk of infection at infectious disease sites, but they have a sense of calling and must perform patient care at the forefront [45,46]. In patient care, the experience of a conflict between infection risk situations and professional beliefs increased nurses' intentions to leave more than the general situation of care [10,47]. Based on these preceding studies, there is likely a difference between the actual clinical field and the public's perception of nursing in terms of the purpose of employment identified in the results of this study. Although economic feasibility cannot be excluded from policies to resolve employment difficulties, it is necessary to consider nursing professionals in policy and media in order to prevent the departure of new nurses, increase the number of experienced nurses, and change the public's perception of nurses.

Vulnerability in the Working Environment

In the "demand for nurses" topic during the influenza A and COVID-19 outbreaks, a critical issue was the shortage of skilled nurses—particularly in nonmetropolitan areas—in addition to skills to handle special equipment such as ventilators and extracorporeal membrane oxygen supply required for intensive care nursing as well as clinical experience [36]. Given the strong link between nursing demand, supply, and working conditions, the topics "demand for nurses" and "vulnerability in the working environment" are closely interconnected [37] and can be interpreted together. In this study, hot topics included conflicts between women's work-family balance during the SARS period, health risks due to night work, domestic medical facilities and manpower at a lower level than in OECD countries during the influenza A period, and the shortage of nurses in nonmetropolitan areas. The changes in keywords such as high secondary infections of nurses related to new infections, emergency rooms, and nursing hospitals; work weighting; and

XSL•FO
RenderX

society's expectations for sacrifice and commitment should be considered as major variables to resolve the shortage of nurses.

According to a survey by the Hospital Nurses Association, the average resignation rate of domestic nurses over the past decade has been over 13%. When the reasons for resignation in 2010 and 2020 were compared, the second highest reason of "marriage, childbirth, and childcare" in 2010 fell significantly from 14.8% of responses in 2010 to 6.3% of responses in 2020. "Work maladjustment," which was ranked third (13.1%) in 2010, was ranked first (17.1%) in 2020, and "transition to other jobs," which was ranked second (5.9%) in 2010, increased to 12.2% in 2020 [42,43]. This is likely the result of government policy and efforts to improve the conflict that comes from the balance between work and family for female nurses, which appeared in the topic during SARS. However, high-risk working environments for infection and the lack of experienced nurses during MERS and COVID-19, during which there was a focus on the quantitative increase of nurses following the influenza period; the policy to increase the number of nurses; and the poor treatment suggest that more active interventions and improvement are needed at the organizational level.

Inadequate facilities in which to rest and the social stigma of being perceived as infection carriers—both personally and for family members—accelerate burnout and increase turnover intentions among nurses, and secondary infections among nurses create a vicious cycle of labor shortages and increased patient infections [48,49]. The government expanded the admission quota for nursing colleges starting in 2008 in an effort to increase the absolute total number of nurses, but it did not have a significant impact on resolving the shortage of nurses in local small and medium-sized hospitals [50]. In addition, in March 2018, the Ministry of Health and Welfare announced policies aimed at improving nurses' working conditions, addressing human rights violations such as workplace bullying and sexual harassment, expanding nursing personnel, strengthening professionalism, improving the quality of nursing services, and creating a policy foundation for nursing personnel [51]. In this regard, the system for calculating inpatient nursing management fees was revised to base payments on patient-to-nurse ratios according to the actual situation in local hospitals in April 2018. The system was improved so that additional profits from hospitalization fees generated by changes based on the number of patients were used to improve the treatment of nurses. In addition, the night-only nurse management fee and the night-care fee for general wards established in October 2019 were applied to general hospitals and hospitals outside of Seoul so that additional allowances for night work could be paid. However, since both systems are merely recommendations, there were practical limitations for nurses to feel that their treatment was improved [52]. In February 2019, a Task Force Team was promoted to oversee nursing policies such as managing the supply and demand of nursing personnel and improving the working environment. In May 2021, a nursing policy department was established in the Ministry of Health and Welfare with social consensus on the need for a dedicated department during the COVID-19 period [42]. As such, the government has continuously implemented policies to address the shortage of nurses, and evaluation of the effectiveness of some policies is expected to take some time. This is an opportune time to reconsider whether fragmented and temporary approaches to nursing challenges have exacerbated systemic issues, such as the revision of the medical law that tried to reorganize nursing assistants from the "demand for nurses" topic during the MERS period or the "vulnerability in the working environment" topic, which is related to a high risk of infectious diseases and the need for high-intensity work. In addition, active monitoring is needed to determine how closely a series of policies has approached the practical problems of the nursing field, and feedback mechanisms during a changing infectious disease situation are needed. Although these policies mark progress, their voluntary nature limits their effectiveness in achieving widespread improvements.

Roles and Responsibilities of Nursing Professionals

The keyword changes in the topic of "roles and responsibilities of nursing professionals" mainly included incidents and accidents related to the morality of nurses, such as drunk driving and illegal medical practices during the SARS and influenza A periods. Given the focus on keywords related to infectious diseases during the MERS and COVID-19 periods, the conflict over work ethics in the nursing of infected patients versus the nurse's own safety and social expectations was considered a major agenda.

Since the image of nurses formed in the media has been considered to influence potential future nurses' career choices and intentions and some stories about nurses can negatively influence not only nursing supply but also potential improvements in the working environment and treatment of nurses, many previous studies have proposed monitoring of the images of nursing expressed in the media and internal management of the nursing community [3,53].

The analysis of correlations between keywords during the MERS period highlighted social expectations for nurses in special situations such as public health disasters as well as conflicts between nurses' protective instincts and work ethics and their families and colleagues. In this regard, the original news articles reviewed in this study described the critical condition of medical personnel who had secondary MERS infections and experiences with social isolation, such as nurses' children being ostracized by their neighbors due to the stigma of working with MERS-infected patients [54]. The ambivalence of social expectations for nurses responding to infectious diseases is reflected by the description of medical personnel as heroes through the "Thanks to the Challenge" campaign and the praise for volunteer nurses in Daegu and Gyeongbuk. The precedent of the government's legal response to the collective resignation of Taiwanese medical staff due to the infection and death of medical personnel is another example and was captured in the topic "response to emerging infectious diseases in other countries" during SARS. The ambivalence was also present in an overseas example [3] that described a nurse volunteering at an infectious disease site during the Ebola outbreak as a virus eradication hero versus an infection spreader and villain. Since social stigma and isolation during an infectious disease outbreak add to the mental and social stress of nurses and influence nursing and turnover intentions, the following are needed:

XSL•FO
RenderX

accurate information delivery by the media, a stable medical system, and an organizational protection and support system [48,49].

Meanwhile, in the context of the COVID-19 period, the government attempted to implement a policy to expand the number of medical schools to respond to infectious diseases, and the related medical strike led to the aggravation of nurses' work [55]. Previous studies have highlighted the 2-sided phenomenon of social expectations, which consists of systemic problems such as poor hospital infection control, inadequate government response, and increased public fear through negative media reports rather than the attitude of medical personnel, including nurses, when responding to infectious diseases [6,48]. This is similar to the relationships between the topics of "government response and public opinion" and "roles and responsibilities of nursing professionals," which include indiscriminate disclosure of information about infectious diseases in the media during the MERS period and the controversy over the president's thank you message to nurses during a doctor strike during the COVID-19 period. This suggests that active interest and the adoption of a leading role by the government are needed to avoid delays in policy and social consensus as a result of insufficient government responses and issue-oriented media reports.

Limitations

In this study, limitations were related to the search used to identify issues in the nursing field as well as the data collection period, which was restricted to the periods around outbreaks of new infectious diseases and limited the ability to compare the situation before and after an outbreak. Therefore, future research should adopt a multifaceted approach that incorporates time series analysis, dynamic topic modeling, and expanded data collection periods to capture broader trends. In addition, as this study started during the COVID-19 outbreak and we were unable to predict when the outbreak would end, we collected data only until May 31, 2021, due to limited time available for data analysis. Therefore, any changes in the situation after that data were not reflected in the research results, and we recommend collecting and analyzing data after that date.

Conclusion

This study analyzed the relevance of nursing-related agendas in news articles during 4 major EID outbreaks. Our analysis revealed that nurse shortages, poor working conditions, and inadequate treatment of nurses were recurring issues across the epidemics and were not unique to the COVID-19 pandemic. Although society and nursing professionals agree on the essential role of nurses in the health sector, significant differences persist in perceptions of their roles and responsibilities. The results suggest that retaining experienced nurses to strengthen crisis response capabilities should be closely linked to the working environment. Addressing nurse shortages requires not only increasing their numbers but also implementing substantial policy support to ensure safe working environments, better treatment conditions, and heightened societal recognition of their roles. Medical organizations, professional associations, governments, and the media should develop policies that incorporate nurses' perspectives. These efforts can foster positive social consensus on nursing and support a stable health care system during health crises. Our findings are expected to be used as a basis for establishing strategies to improve the professional role, environment, and treatment of nurses during health crisis situations. Finally, these findings emphasize the need for holistic reforms to strengthen nursing's role in mitigating future health crises. We recommend further research on the effects and changes of nursing-related policies.

Acknowledgments

This research was supported by the Government-wide R&D Fund for Infectious Disease Research (GFID), Republic of Korea (grant number RS-2022-KH125928 [HG22C0051]).

Authors' Contributions

EKY and JO collaboratively developed the study design and co-authored the initial manuscript draft. EKY supervised the study and validated the findings, while JO collected and preprocessed the data and conducted the analysis. Both authors interpreted the results and contributed to the writing and revision of the final manuscript.

Abstract

Background: Artificial intelligence–driven clinical decision support systems (AI-CDSSs) are pivotal tools for doctors to improve diagnostic and treatment processes, as well as improve the efficiency and quality of health care services. However, not all doctors trust artificial intelligence (AI) technology, and many remain skeptical and unwilling to adopt these systems.

Objective: This study aimed to explore in depth the factors influencing doctors' willingness to adopt AI-CDSSs and assess the causal relationships among these factors to gain a better understanding for promoting the clinical application and widespread implementation of these systems.

Methods: Based on the unified theory of acceptance and use of technology (UTAUT) and the technology-organization-environment (TOE) framework, we have proposed and designed a framework for doctors' willingness to adopt AI-CDSSs. We conducted a nationwide questionnaire survey in China and performed fuzzy set qualitative comparative analysis to explore the willingness of doctors to adopt AI-CDSSs in different types of medical institutions and assess the factors influencing their willingness.

Results: The survey was administered to doctors working in tertiary hospitals and primary/secondary hospitals across China. We received 450 valid responses out of 578 questionnaires distributed, indicating a robust response rate of 77.9%. Our analysis of the influencing factors and adoption pathways revealed that doctors in tertiary hospitals exhibited 6 distinct pathways for AI-CDSS adoption, which were centered on technology-driven pathways, individual-driven pathways, and technology-individual dual-driven pathways. Doctors in primary/secondary hospitals demonstrated 3 adoption pathways, which were centered on technology-individual and organization-individual dual-driven pathways. There were commonalities in the factors influencing adoption across different medical institutions, such as the positive perception of AI technology's utility and individual readiness to try new technologies. There were also variations in the influence of facilitating conditions among doctors at different medical institutions, especially primary/secondary hospitals.

XSL•FO
RenderX

Conclusions: From the perspective of the 6 pathways for doctors at tertiary hospitals and the 3 pathways for doctors at primary/secondary hospitals, performance expectancy and personal innovativeness were 2 indispensable and core conditions in the pathways to achieving favorable willingness to adopt AI-CDSSs.

Introduction

Background

Artificial intelligence–driven clinical decision support systems (AI-CDSSs), aimed at enhancing medical decision-making, have been in use since the 1980s [1]. These systems leverage clinical knowledge, patient information, and health data to improve health care services by allowing intelligent detection, management, and improvement of patient health conditions [2,3]. According to statistics, the total number of outpatient visits to medical and health institutions in China reached 5.5 billion in 2023, with doctors at public hospitals averaging 7.1 outpatient visits and 2.3 hospital visits per day and with the burden on primary health care institutional doctors being even greater [4]. According to "World Health Statistics 2023: Monitoring Health for the SDGs, sustainable development goals" released by the World Health Organization (WHO), China has a low doctor density and uneven distribution of health care resources [5]. To relieve the pressure on doctors and improve the efficiency of medical services, China has actively explored the application of AI-CDSSs, with the National Health Commission of China issuing a national policy on the promotion of clinical decision support systems (CDSSs) in 2023.

With the evolution of artificial intelligence (AI) technology, current AI-CDSSs can generate specific assessments and recommendations through logical reasoning, analyze patient data from electronic medical records, and offer decision support to health care providers [6]. AI-CDSSs are widely used in clinical diagnoses, drug treatments, preventive measures, and patient management, and are recognized for their roles in enhancing health care decision-making and doctor performance [7]. For instance, scholars, such as Hanson et al [8], have conducted research from the perspective of patient management, evaluating the application of AI-CDSSs in the nursing field, and have confirmed that certain systems are able to improve the accuracy and comprehensiveness of nursing treatment. Alsharqi et al [9], among others, have evaluated the application effects of AI-CDSSs in the automatic image selection field of echocardiography. They found that AI-CDSSs can effectively identify, distinguish, and explain images through machine learning models. Islam et al [10] studied how AI-CDSSs could help patients continuously observe different parameters for controlling insulin levels, automatically analyzing the personal data of diabetic patients. The application of AI-CDSSs in the field of anesthesiology is also extensive. According to existing research, AI-CDSSs can improve the preoperative use of antibiotics and beta-blockers, reduce the use of inhaled anesthetics, and assist in completing anesthesia records and billing work [11-13].

AI-CDSSs are primarily targeted at physicians, whose acceptance is pivotal for their implementation. Sambasivan et al [14] extended the unified theory of acceptance and use of technology (UTAUT) model and explored the factors influencing doctors' willingness to adopt new CDSSs in a developing country context, considering user involvement in decision-making, perceived threat to autonomy, effort expectancy, and performance expectancy. Their study involved doctors from 12 hospitals representing 10 different specialty areas. However, physicians' attitudes toward these systems varied, with some exhibiting favorable inclinations and others exhibiting reluctance, primarily attributed to apprehensions about technological readiness, data confidentiality, absence of personalized interaction, and skepticism toward emerging technologies.

Thus, although some doctors have expressed positive attitudes toward adopting AI-CDSSs, others still harbor reservations, citing concerns over technology immaturity, data privacy and security, absence of human touch, and a distrust of new technologies. For instance, Wagner et al [15] found that only 54.9% of family doctors were willing to use AI for medical diagnosis, while O'Leary et al [16] reported that 82% of health care professionals saw the usefulness of AI in diagnosing rare diseases. In their 2020 study, Park et al [17] discovered that over 75% of American radiology students believed AI would play a crucial role in future medicine, while almost half of them expressed decreased enthusiasm for radiology due to AI adoption. Scheetz et al [18] found that 71% of the health care professionals surveyed in Australia and New Zealand believed AI would improve medicine, while 85.7% felt it would impact health care manpower. In a South Korean study, only 5.9% of doctors were very familiar with AI [19]. Similarly, in a UK study, medical students indicated they were not adequately prepared for AI. Scholars have also expressed concerns about humans being replaced by AI in health care [20].

Thus, despite the potential benefits, skepticism persists among scholars and doctors regarding the integration of AI in health care, citing concerns about technology replacing human roles. For instance, Poon and Sung [21] highlighted doctors' skepticism toward AI technology in clinical practice that impeded the progress of AI applications owing to a lack of trust.

Investigating doctors' willingness to adopt AI-CDSSs and understanding the factors influencing their acceptance can have a significant impact on the comprehensive integration of AI-CDSSs into clinical applications. Sambasivan et al [14]

XSL•FO
RenderX

employed structural equation modeling to explore doctors' willingness to use AI-CDSSs in developing countries, revealing that concerns about potential threats to professional autonomy could dampen doctors' willingness to embrace these systems. Conversely, active involvement in the planning, design, and implementation of AI-CDSSs was associated with increased acceptance and readiness to use these technologies. Similarly, Laka et al [22] utilized logistic regression analysis to explore the adoption willingness of AI-CDSSs, finding that doctors in local primary care facilities, as opposed to those in larger hospitals, identified factors, such as time constraints, perceived threats to professional autonomy, and considerations of patient preferences, as significant barriers to adopting AI-CDSSs.

Current research has focused mainly on examining the impact of individual factors or certain factors affecting the allocation of medical resources. Thus, the literature lacks in-depth analysis of the interactive mechanisms and synergistic effects of factors influencing doctors' intentions to adopt AI-CDSSs. There is also a lack of comprehensive analysis that combines the multiple factors influencing doctors' intentions to adopt AI-CDSSs for assessing their causal relationships. To explore the driving mechanisms of multiple conditional linkages on doctors' adoption willingness, our study focuses on doctors at different medical institutions in China, not only providing important assistance for the application of AI-CDSSs in hospitals at all levels in China, but also offering experiential references for other developing countries in the use and adoption of AI-CDSSs. Using fuzzy set qualitative comparative analysis (fsQCA), we clarify the synergistic effects of multiple factors influencing doctors' intentions to adopt AI-CDSSs, thereby providing theoretical support for promoting their application in the medical field.

Framework for AI-CDSS Adoption Willingness

The integration of the UTAUT was proposed in 2003 by Venkatesh et al [23] to explain the relevant factors influencing an individual's willingness to accept or use new technology. The UTAUT consists of 4 key factors: performance expectancy, effort expectancy, social influence, and facilitating conditions, which influence behavior through willingness [24]. The UTAUT also considers the moderating effects of sex, age, experience, and voluntary use. The theory was established in the context of the organizational implementation of new technology, with the influencing factors having clear utilitarian characteristics. With the emergence of AI technology, an increasing number of scholars are using the UTAUT to study individual AI technology adoption issues. The technology-organization-environment (TOE) framework proposed by Tornatzky et al [25] suggests that technological, organizational, and external environmental factors also have a certain impact on an organization's adoption and implementation of new technology.

There is an interactive relationship between medical institutions and doctors. An organization's attitude toward innovation will affect employees' acceptance of new technology [26]. In addition, the adoption willingness and behavior of AI technology in an organization may be affected by the adoption willingness of employees [27]. Therefore, based on the UTAUT model and TOE framework, this study constructed a multi-layer dynamic impact model for AI technology adoption among physicians.

Technical Factors Influencing the Adoption of AI-CDSSs by Doctors

Performance expectancy is one of the key constructs in the UTAUT model used to explain and predict individual technology acceptance behavior [28]. In a hospital setting, it can capture the extent that doctors believe that using new technology will help improve their job performance [29]. Previous studies have shown that performance expectancy is crucial for doctors' adoption and acceptance of AI-CDSSs [30], similar to the perceived usefulness in the technology acceptance model (TAM). Compared with other technology application scenarios, doctors place more emphasis on the impact of technology on their job performance when adopting new technology. Currently, AI technology has the ability to assist in eliminating redundant work steps, providing decision support, and improving job performance [31,32]. However, there are also issues, such as communication barriers between doctors and AI technology, which can impact work efficiency. The effectiveness of AI technology in the workplace is yet to be widely validated [33]. Therefore, performance expectancy still plays an important role in doctors' willingness to adopt AI technology.

Perceived risk refers to the degree of insecurity that doctors perceive when they are using technology to execute tasks and exchange data [34]. AI technology requires big data to achieve powerful learning, which means that AI technology may involve the input of data from various parties, such as individuals and vendors. When there is a risk of information leakage, doctors using AI technology may face legal, moral, and ethical issues. This can have a significant impact on their willingness to adopt AI technology.

Organizational Factors Influencing the Adoption of AI-CDSSs by Doctors

Social influence refers to the influence doctors feel from their social environment regarding a specific behavior. It is a key factor in the UTAUT model that affects an individual's willingness to adopt new technology [30]. In an organizational context, doctors are frequently influenced by colleagues and leaders, and they enhance their sense of belonging by conforming to these groups. When faced with emerging technologies, such as AI, there may not be enough information for an informed decision, making doctors more susceptible to peer influence. However, leaders also influence doctors' willingness to adopt AI technology [35] and have the power to authorize subordinates, determine job promotions, provide rewards, and administer punishments. Thus, doctors align with leaders to receive recognition.

The UTAUT construct "facilitating conditions" refers to the extent that doctors perceive that the necessary infrastructure and resources in the organization support their use of new technology [30]. Thus, this would also influence a doctor's willingness to adopt AI technology. The promotion of new technology requires organizations to provide various resources such as knowledge, funds, and technology. Simpler and more

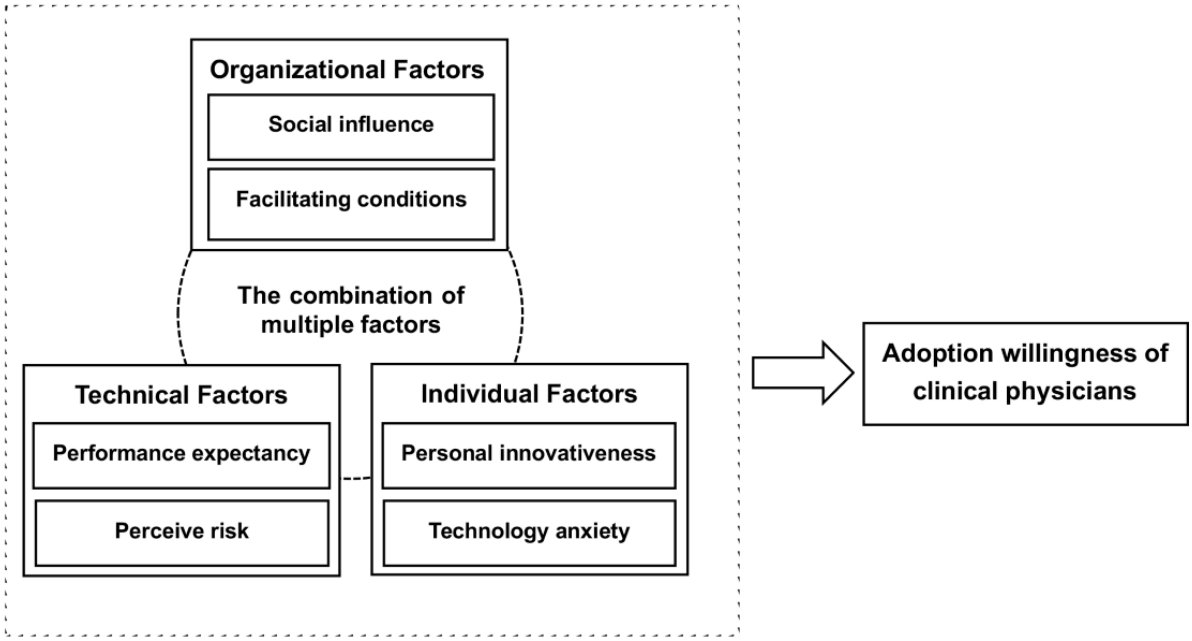
XSL•FO
RenderX

convenient external support conditions are associated with a greater likelihood of doctors adopting AI technology. Research has shown that facilitating conditions positively influence an individual's willingness to adopt AI technology [36,37].

Individual Factors Influencing the Adoption of AI-CDSSs by Doctors

Technology anxiety refers to an individual's emotional anxiety or fear of the performance of new technology. For example, when individuals believe that the technology may threaten their sense of self, they may experience technology anxiety, which reduces their willingness to adopt it [28]. The existing and potential capabilities of AI technology to replace human abilities are constantly increasing, causing individuals to experience stronger feelings of anxiety compared with other technologies. Therefore, our study included technology anxiety as a factor in our framework.

Personal innovativeness reflects an individual's willingness to try something new. Innovation diffusion theory suggests that owing to differences in innovation capabilities, individuals' willingness and behaviors vary in this respect. Some scholars have proven that in consumer scenarios, personal innovativeness positively influences individuals' willingness to adopt self-service technologies [38]. As AI technology is a revolutionary innovation, personal innovativeness is needed to drive doctors toward a greater willingness to adopt it. Therefore, we assume that personal innovativeness significantly impacts doctors' willingness to adopt AI technology.



Study Model

Our study applies the UTAUT model for the basis of our research framework to analyze the factors influencing doctors' adoption of AI-CDSSs, adding other factors as well. Our model considers 3 perspectives: technology, organizations, and individuals. The technical factors included are performance expectancy and perceived risk, the organizational factors are social influence and facilitating conditions, and the individual factors are technology anxiety and personal innovativeness. We have incorporated performance expectancy, social influence, and facilitating conditions from the UTAUT model, and based on the research by Chen et al [37], personal innovativeness and perceived risk have been introduced into the model and confirmed, along with key factors in the UTAUT model that significantly influence doctors' acceptance of AI technology. Huang et al [39] demonstrated how technology anxiety reflected an individual's emotional anxiety or fear regarding the performance of AI technology. When individuals perceived the technology as threatening their sense of self, they experienced technology anxiety, which reduced their willingness to adopt the technology. Therefore, we have included technology anxiety in the model. Considering that AI technology often does not require users to learn how to operate it, as it possesses anthropomorphic characteristics that are different from nonintelligent technologies [8], we did not include effort expectancy. The factors ultimately in our analysis framework are performance expectancy, perceived risk, facilitating conditions, social influence, technology anxiety, and personal innovativeness.

Thus, we assume that doctors' willingness to adopt AI technology will be influenced by these various factors. Although some studies have investigated the individual effects of these elements on doctors' AI adoption willingness, providing a foundation for our understanding of the factors influencing the willingness to adopt AI technology, research struggles to answer how these factors interact to influence the willingness to adopt AI technology under multiple situational conditions. Additionally, research has not identified the deep-rooted causal relationships that are affecting doctors' willingness to adopt AI technology. To fill this gap in the literature, based on the UTAUT model and incorporating the TOE framework, we have explored the complex causal mechanisms of how environmental, technological, and individual factors influence doctors' willingness to adopt AI technology from a configurational perspective, proposing a theoretical model (Figure 1).

Figure 1. Analysis framework of the factors influencing Chinese doctors' willingness to adopt artificial intelligence–driven clinical decision support systems.

Methods

Method Selection

We used fsQCA to explore the complex causal mechanisms influencing clinical doctors' willingness to adopt AI-CDSSs, primarily for the following reasons. First, using this method uncovers the nonlinear relationships between various influencing factors and the doctors' willingness to adopt AI-CDSSs. The fsQCA method also explores combinations of influencing factors instead of individual factors [40]. Second, as our research question was "Which factors can lead clinical doctors to have a higher willingness to adopt AI-CDSSs?", the use of this method can reveal multiple equivalent paths that influence doctors' willingness to adopt AI-CDSSs. Third, compared with other qualitative comparative analysis methods, fsQCA is more suitable for handling continuous variables. Fourth, fsQCA can be applied to different sample sizes ranging from very small (<50 cases) to very large (thousands of cases) [41].

Data Collection

An online questionnaire was developed and shared with doctors in China who met specific criteria related to their work experience. We distributed 578 questionnaires through the Wenjuanxing platform [42]. After eliminating any invalid submissions, we had 450 valid responses, resulting in a questionnaire response rate of 77.9%. Detailed demographic information on the participants is presented in Table 1.

According to "Hospital Classification Management Measures" issued by the National Health Department, hospitals in China are classified into 3 levels. Tertiary hospitals provide medical and health services across regions, provinces, and cities, and nationwide. Secondary hospitals provide comprehensive medical and health services to multiple communities and undertake teaching and research tasks in regional hospitals. Primary hospitals are grassroot hospitals and health centers that provide preventive, medical, health, and rehabilitation services to their local communities [43]. In this study, we divided hospitals into only 2 categories for simplicity: tertiary hospitals and primary/secondary hospitals. Among the respondents, there were 332 responses from clinical doctors working in tertiary medical institutions and 118 responses from clinical doctors in primary/secondary medical institutions, as mentioned above.

Variable Measurement and Calibration

To ensure the reliability and validity of our scales, we based them on mature scales developed by scholars in the field of technology adoption and appropriately adjusted them for our research question to create measurement items for our main variables [23]. The main variables were performance expectancy, perceived risk, facilitating conditions, social influence, technology anxiety, personal innovativeness, and adoption willingness. Participant responses were on a 5-point Likert scale assessing the extent that they agreed with the content described in the items. We calculated the average score of the corresponding items within each scale to measure the variable. We use SPSS (version 25.0) to analyze the reliability and validity of the scales. All variables had a Cronbach α greater than .8, composite reliability greater than 0.8, Kaiser-Meyer-Olkin (KMO) values greater than 0.7, and average variance extracted values greater than 0.5, indicating that the scales had good reliability and validity. To ensure the overall reliability of our results, we removed items with factor loadings less than 0.6, and the conditions were still met after these items were deleted (Table 2).

To meet the Boolean logic requirements for qualitative comparative analysis, variables need to be transformed into sets and cases need to be assigned to the sets before conducting fsQCA, a process known as data calibration. In this process, we need to establish calibration points for "full membership," "crossing point," and "full nonmembership." We adopted a scholar's calibration method for the Likert scale questionnaire data, coding "completely agrees (5)" as "full membership," "neutral (3)" as "crossing point," and "completely disagrees (1)" as "full nonmembership." By setting these 3 thresholds, we converted the original data into fuzzy scores ranging from 0 to 1, using the calibrate (x, n1, n2, n3) function in the fsQCA software.

Ethical Considerations

This study was approved by the Clinical Research Ethics Committee of China-Japan Friendship Hospital (number: 2024-KY-254). All participants provided informed consent before the investigation began. Furthermore, information on

XSL•FO
RenderX

the research participants was kept confidential, and personal private information was not disclosed.

Results

Necessary Condition

According to the fsQCA method, before conducting the configuration analysis, the first step is to perform a necessity analysis on the individual condition variables, with the results reflected through consistency and coverage. Consistency represents the degree that the condition variables are a subset of the outcome variables. Identifying a necessary condition generally requires a consistency score higher than 0.9. Coverage represents the extent that the condition variables explain the outcome. This is only meaningful for conditions that pass the consistency test, with no acceptable threshold. The results of the necessity test for the individual conditions are shown in Table 3.

In Table 3, we can see that the consistency of personal innovativeness in influencing doctors' willingness to adopt AI-CDSSs at primary/secondary hospitals was higher than 0.9 and coverage was as high as 0.933. This indicates that personal innovativeness is a necessary condition influencing doctors' willingness to adopt AI-CDSSs in these hospitals. The consistency of the other variables was less than 0.9, indicating that they are not sufficient to constitute the necessary conditions affecting doctors' willingness to adopt AI-CDSSs, with these variables having relatively weak independent explanatory powers. Thus, we need to further analyze the combining effects of these condition variables and their impacts on our outcome variable.

Table 3. Necessary condition analysis.

[a]"~" indicates the negation of the condition.

[b]Consistency exceeds 0.8.

Adequacy Analysis of Configuration

As mentioned, we conducted fsQCA separately for tertiary and primary/secondary hospitals. According to the principles of fsQCA, we included 6 condition variables. We retained 85% of the case numbers to set the frequency threshold, with case number thresholds of 5 and 2 for tertiary hospitals and primary/secondary hospitals, respectively. The consistency threshold for each configuration was higher than 0.8, and the proportional reduction in inconsistency threshold was greater than 0.75. A configuration with consistency below the threshold was assigned a value of 0 (Tables 4 and 5).

After standard analysis of the improved truth table, we found 3 types of solutions: complex, intermediate, and parsimonious. Among them, we obtained the intermediate solution through a counterfactual analysis, assuming that the emergence of personal innovativeness may increase doctors' willingness to adopt AI-CDSSs, whereas the other individual conditions may contribute to doctors' willingness to adopt AI-CDSSs. We identified the core conditions for each configuration by comparing the nested relationships between the intermediate and parsimonious solutions. The conditions appearing in both the parsimonious and intermediate solutions were considered core conditions for that configuration, whereas those appearing only in the intermediate solution were considered marginal conditions (Table 6).

In Table 6, we can see that there are 3 pathways leading to positive doctors' willingness to adopt AI-CDSSs in tertiary hospitals, which have been presented below.

Configuration for Doctors at Tertiary Hospitals

Technology Driven

The core condition for both pathways S1a and S1b was performance expectancy, which played a dominant role in the pathways. The findings indicate that these doctors believe that AI-CDSSs are helpful in clinical work, can improve work efficiency, and can enhance work quality. Pathway S1a indicated that under high performance expectancy, even without perceived technical risks for AI-CDSSs and without organizational factors, such as convenience of AI use and social influence, doctors have favorable adoption willingness for AI-CDSSs. Pathway S1b indicated that under high performance expectancy, without technology anxiety and perceived risk but with social influence, such as influence from surrounding groups, doctors still have favorable adoption willingness for AI-CDSSs.

Individual Driven

The core condition for pathways S2a and S2b was personal innovativeness, which played a primary role in these pathways. The findings indicate that these doctors are willing to try new AI technology, as they typically favor innovativeness that enables continuous learning of new medical technologies and treatment methods. Pathway S2a showed that when doctors reflect strong personal innovativeness, without perceived risks, convenience factors, and social influence, they have positive adoption willingness for AI-CDSSs. Pathway S2b indicated that when doctors have personal innovativeness without perceived risks and technology anxiety for AI-CDSSs, but with a certain degree of social influence, they still tend to have positive adoption willingness for AI-CDSSs.

Technology-Individual Dual Driven

The core conditions for pathways S3a and S3b were performance expectancy and personal innovativeness, indicating that doctors with both high performance expectancy and high personal innovativeness develop strong adoption willingness. Pathway S3a demonstrated that doctors with high performance expectancy and high personal innovativeness need support from certain convenience factors as well as a certain degree of social influence to engender strong adoption willingness for AI-CDSSs. Pathway S3b showed that when doctors have high performance expectancy, high personal innovativeness, and some degree of technology anxiety and social influence, they still tend to have high adoption willingness for AI-CDSSs.

Configuration for Doctors at Primary and Secondary Hospitals

Technology-Individual Dual Driven

The core conditions for pathways N1 and N2a were performance expectancy and personal innovativeness, indicating that doctors with both high performance expectancy and high personal innovativeness have strong adoption willingness for AI-CDSSs. Pathway N1 showed that doctors with high performance expectancy and high personal innovativeness have strong adoption willingness when influenced by leaders, colleagues, and other people regarding the use of AI. Pathway N2a demonstrated that doctors with high performance expectancy, high personal innovativeness, and no perceived risks or technology anxiety for AI technology have strong adoption willingness.

Organization-Individual Dual Driven

The core conditions for pathway N2b were convenience factors and personal innovativeness, indicating that doctors who receive support from their workplace and from technology and have high personal innovativeness develop strong adoption willingness. In other words, with high convenience factors, personal innovativeness, and low social influence, even without perceived risks and technology anxiety, doctors have strong adoption willingness for AI-CDSSs.

Comparative Analysis

Comparing doctors at tertiary hospitals with those at primary/secondary hospitals, we can point out the similarities and differences. The pathways reflect what drives the doctors at these different medical institutions to stronger adoption willingness for AI-CDSSs.

Similarities

AI technology and personal factors play dominant roles in influencing the adoption of AI-CDSSs by doctors at all the hospitals analyzed. There are not only single-dimensional factors that affect doctors' adoption willingness, but also combinations of factors, as in the technology-individual dual model, that have an impact on adoption. At the technological level, doctors believed that the application of AI-CDSSs in clinical diagnosis and treatment processes can provide efficient diagnostic support and improve the quality of clinical services. Although issues, such as overdiagnosis, may exist with AI-CDSSs, doctors considered the overall technology of AI-CDSSs to be safe and reliable. At the individual level, doctors demonstrated strong acceptance and openness to AI technology, showing no anxiety regarding the emergence of new technologies. In particular, they appeared willing to try new AI technologies.

Differences

Convenience factors had a greater impact on the adoption willingness of doctors at primary/secondary hospitals than on the adoption willingness of doctors at tertiary hospitals. According to pathways S1a and S2a, a lack of convenience factors did not affect the strong adoption willingness of doctors at tertiary hospitals. This finding indicates that even when the marginal condition of the convenience factor is missing, these doctors still have a positive adoption willingness for AI-CDSSs. In contrast, looking at pathway N2b, convenience factors are a necessary condition for doctors at primary/secondary hospitals, and these doctors will only favor adoption of AI-CDSSs when convenience factors are present. Thus, convenience factors are the objective material factors influencing the willingness of these doctors to adopt AI-CDSSs. As tertiary hospitals are generally regional hospitals that have comprehensive hospital facilities and advanced information systems, such convenience factors are present; thus, they do not significantly influence the adoption of AI-CDSSs among doctors at these facilities. Unlike tertiary hospitals, primary/secondary hospitals are often county hospitals or primary health care institutions, with some located in remote rural areas and having fewer hardware and software resources to support their doctors. Therefore, the impact of

XSL•FO
RenderX

convenience factors on the adoption willingness of doctors at these medical institutions is greater. The survey results imply that only when there is sufficient external support for doctors at these primary and secondary institutions will they actively adopt AI-CDSSs.

Robustness Test

To test the robustness of our results, we adjusted the consistency threshold from 0.8 to 0.85 and 0.72 [44]. There were no substantial changes observed in the configuration of the pathways or parameters. The results indicated that the adjusted structure remained consistent with the original structure and the pathways were the same as those before the adjustment. Therefore, the results remained robust.

Discussion

Principal Findings

We constructed a theoretical framework based on the UTAUT and TOE framework using configurational thinking and fsQCA to configure 6 conditional elements. We explored the multiple concurrent factors and causal complex mechanisms that influence the willingness to adopt AI-CDSSs among clinical doctors at different medical institutions in China from technological, organizational, and individual perspectives. Our results provide a theoretical basis for the further integration of AI-CDSSs into clinical applications. The following are our key results.

We found that the paths driving high AI-CDSS adoption willingness among clinical doctors in tertiary hospitals fell into 6 categories, which were summarized in 3 configurations: technology driven, individual driven, and technology-individual dual driven. The paths driving high AI-CDSS adoption willingness among clinical doctors at primary/secondary medical institutions fell into 3 categories, which were summarized in 2 configurations: technology-individual and organization-individual dual driven.

Comparing tertiary hospitals with primary/secondary medical institutions, we observed some commonalities and some differences in the paths driving doctors to a positive willingness to adopt AI-CDSSs. In terms of commonalities, AI technology and individual factors play dominant roles in doctors' adoption willingness. The doctors indicated their beliefs that AI-CDSSs can provide efficient diagnostic support and improve the quality of medical services. Moreover, they indicated that they are willing to try new technologies. In terms of differences, convenience factors had a greater impact on doctors at primary/secondary medical institutions. These doctors would actively adopt AI-CDSSs only with sufficient external support.

By studying doctors from different levels of medical institutions in China and their adoption paths of AI-CDSSs, we found that resource availability may be an important factor influencing the adoption willingness of doctors at different medical institutions. For example, tertiary hospitals have greater access to resources, such as funding and technical support, compared with primary/secondary hospitals. Additionally, differences in organizational culture and management styles and values may impact doctors' attitudes toward AI-CDSSs. The characteristics of patient populations served by different levels of medical institutions may also influence doctors' perceptions of AI-CDSSs, as patient needs and complexities can vary across hospital settings.

Finally, our research results can serve as a reference for other developing countries for promoting the application of AI-CDSSs or AI technologies in clinical treatment, contributing to enhancing the medical service capabilities of medical institutions.

Theoretical Contributions

Our study contributes to the literature in several ways. First, we built a comprehensive analytical framework for doctors' willingness to adopt AI technology. This is based on the UTAUT and TOE framework combined with specific characteristics and application scenarios for AI technology, with a focus on technical, organizational, and individual factors. Previous studies have focused mainly on the causal relationships between individual variables and the willingness to adopt AI technology. However, our study introduces multiple factors that can influence doctors' willingness to adopt AI technology, namely, performance expectancy, perceived risks, convenience factors, social influence, technology anxiety, and personal innovativeness. Building on the UTAUT model, we incorporated additional factors, specifically personal innovativeness, technology anxiety, and perceived risks, into the analytical framework. As such, we were able to enrich the theoretical research regarding the factors influencing doctors' willingness to adopt AI technology.

Second, we explored the synergistic effects influencing doctors' willingness to adopt AI-CDSSs from a configuration perspective, expanding the application of the UTAUT model in explaining causal complexity. Although the UTAUT model is widely used to explain individual adoption of new technologies within organizations, existing studies on AI adoption have largely overlooked the complexity of causal relationships. Owing to limitations in research methods, existing technology adoption models have been unable to test and explain the impact of multiple conditions on doctors' willingness to adopt AI-CDSSs. In our study, we empirically investigated the synergistic effects of 6 specific factors related to technology, organization, and individual aspects on doctors' willingness to adopt AI-CDSSs from a configuration perspective. By addressing the aforementioned issues, we expand the application of the UTAUT model in explaining causal complexity.

Finally, we used the fsQCA method to analyze the configurations of doctors' willingness to adopt AI-CDSSs at different medical institutions. Our results indicate that across different medical institutions, performance expectancy and personal innovativeness are the 2 important conditions for doctors to engender strong adoption willingness for AI-CDSSs, whereas perceived risks hinder adoption. Social influence can either promote or hinder doctors' willingness to adopt AI-CDSSs, and convenience factors have a greater impact on doctors' adoption willingness at primary/secondary medical institutions. In summary, our research extends the literature on doctors' willingness to adopt AI-CDSSs and provides theoretical support for future practical applications.

XSL•FO
RenderX

Practical Implications

From the perspective of the 6 configurations among the doctors at tertiary hospitals and the 3 configurations among the doctors at primary/secondary medical institutions, performance expectancy and personal innovativeness were the 2 indispensable and core conditions in the pathways to achieving strong willingness to adopt AI-CDSSs. Thus, AI product providers and health care managers should look closely at these factors when designing and implementing such systems. The organizational factor of facilitating conditions for doctors at primary/secondary medical institutions also appeared to be a necessary condition influencing the adoption willingness of doctors at these institutions. As such, we recommend the following measures for the AI-CDSS process.

Importance of Performance Expectancy in Adoption

For AI product providers, improvements in the quality and applicability of AI products can be achieved by focusing on the designing of AI-CDSSs that meet the specific needs of different clinical doctors. This means involving these doctors in the design and development process of AI-CDSSs to ensure that these systems address practical needs. In addition, to ensure that AI-CDSSs comply with data privacy and security standards, security measures should be included to increase doctors' trust in the systems. The systems should also be evaluated regularly for effectiveness and impact, and should be continuously improved based on feedback to ensure they are meeting user needs and expectations.

Importance of Personal Innovativeness

Health care institution managers should provide the appropriate training and support for doctors before introducing AI-CDSSs. This can be done through various activities, such as videos and practical exercises, among others. Such training can help doctors become comfortable with using AI-CDSSs and increase their effectiveness, boosting doctors' confidence in the systems and their willingness to adopt the systems. In addition, doctors should be actively encouraged to be innovative, cultivate innovation awareness, and improve their acceptance of new technologies.

Importance of Addressing Technology Anxiety

Individual doctors need to actively participate in training to understand the basic functions and uses of AI-CDSSs. Some doctors may be skeptical of AI-CDSSs, fearing that these systems will replace their work or reduce work quality. Appropriate training can help change this negative mindset, encouraging doctors to recognize that these systems are meant to assist and enhance the efficiency and accuracy of clinical work, and not to replace doctors.

Limitations

This study has some limitations that can serve as starting points for future research. First, our research scope was limited to medical institutions in mainland China, thereby lacking comparisons with doctors in foreign medical institutions regarding the adoption paths of AI-CDSSs. Second, differences between medical institutions at different levels, such as funding, staffing, and equipment configuration, may influence doctors' perceptions, acceptance, and experience with AI-CDSSs, leading to variations in questionnaire responses. In addition, we used fsQCA to explore the driving mechanism underlying doctors' adoption willingness based on the interactive matching of multiple conditions, which does not verify the impact of individual variables or a few factors on adoption willingness. To address the limitations of the fsQCA method, future research could consider including the use of structural equation modeling (SEM) to design a more complex model structure by considering the relationships between latent variables and the correlations between multiple observed indicators, thus providing a more comprehensive data analysis and explanation. Finally, the sample size of the questionnaire in primary/secondary hospitals was less than that in tertiary hospitals, but the hospitals included in this study were representative. Because AI has more value in areas with weak medical resources, our future research will focus on the willingness of primary hospitals to use AI. We will refine research plans, expand the sample size of the survey, and improve the compliance of the hospitals included.

Conclusion

Our study built a comprehensive analytical framework for doctors' willingness to adopt AI-CDSSs, considering specific characteristics and application scenarios for AI technology, with a focus on technical, organizational, and individual factors. We used fsQCA to explore doctors' willingness to adopt AI-CDSSs in different types of medical institutions in China along with the factors influencing their willingness. From the perspectives of the 6 pathways of the doctors at tertiary hospitals and the 3 pathways of the doctors at primary/secondary hospitals, performance expectancy and personal innovativeness were 2 indispensable and core conditions in the pathways to achieving favorable willingness to adopt AI-CDSSs. The comparative analysis revealed both similarities and differences between doctors at tertiary hospitals and those at primary/secondary hospitals in terms of their adoption of AI-CDSSs. While technical and individual factors were found to be influential in driving adoption willingness across all hospitals, the impact of facilitating conditions differed between the different levels of medical institutions. Facilitating conditions were identified as a significant driver for adoption among doctors at primary/secondary hospitals, underscoring the importance of external support and resources in facilitating the adoption of AI-CDSSs in these settings.

In conclusion, the results of our research provide valuable insights into the factors influencing doctors' willingness to adopt AI-CDSSs in different health care settings. By addressing performance expectancy, personal innovativeness, and organizational support, health care organizations can promote a more favorable environment for the implementation and utilization of AI technologies, ultimately enhancing clinical decision-making systems and improving patient care outcomes. Continued research and implementation of these strategies can further advance the integration of AI-CDSSs in health care and pave the way for the widespread application of AI technology in clinical practice.

By exploring the positive practice and policy promotion of AI-CDSS application in China, our research can provide a

XSL•FO
RenderX

positive reference for the governments of developing countries with similar conditions and uneven distribution of medical resources. At the technical level, the effectiveness and safety of AI technology should be ensured, so that AI can meet the needs of clinical practice. At the organizational level, medical institutions should organize technical training, so that doctors can understand and learn the combination of AI technology and clinical practice, and build a new model of human-machine collaboration. For areas with relatively weak medical resources, the government and medical institutions should increase the infrastructure construction required for AI applications and provide adequate technical support to help doctors solve technical problems.

Acknowledgments

We would like to thank the interviewees who participated in the study. This work was supported by the National Natural Science Fund for Young Scholars of China (72104255) and Chinese Academy of Medical Sciences (CAMS) Innovation Fund for Medical Sciences (2021-I2M-1-046).

Abstract

Background: The literature is equivocal as to whether the predicted negative mental health impact of the COVID-19 pandemic came to fruition. Some quantitative studies report increased emotional problems and depression; others report improved mental health and well-being. Qualitative explorations reveal heterogeneity, with themes ranging from feelings of loss to growth and development.

Objective: This study aims to analyze free-text responses from children and young people participating in the Children and Young People With Long COVID study to get a clearer understanding of how young people were feeling during the pandemic.

Methods: A total of 8224 free-text responses from children and young people were analyzed using InfraNodus, an artificial intelligence–powered text network analysis tool, to determine the most prevalent topics. A random subsample of 411 (5%) of the 8224 responses underwent a manual sentiment analysis; this was reweighted to represent the general population of children and young people in England.

Results: Experiences fell into 6 main overlapping topical clusters: *school*, *examination stress*, *mental health*, *emotional impact of the pandemic*, *social and family support*, and *physical health (including COVID-19 symptoms)*. Sentiment analysis showed that statements were largely negative (314/411, 76.4%), with a small proportion being positive (57/411, 13.9%). Those reporting negative sentiment were mostly female (227/314, 72.3%), while those reporting positive sentiment were mostly older (170/314, 54.1%). There were significant observed associations between sentiment and COVID-19 status as well as sex (P=.001 and P<.001, respectively) such that the majority of the responses, regardless of COVID-19 status or sex, were negative; for example, 84.1% (227/270) of the responses from female individuals and 61.7% (87/141) of those from male individuals were negative. There were no observed associations between sentiment and all other examined demographics. The results were broadly similar when

XSL•FO
RenderX

reweighted to the general population of children and young people in England: 78.52% (negative), 13.23% (positive), and 8.24% (neutral).

Conclusions: We used InfraNodus to analyze free-text responses from a large sample of children and young people. The majority of responses (314/411, 76.4%) were negative, and many of the children and young people reported experiencing distress across a range of domains related to school, social situations, and mental health. Our findings add to the literature, highlighting the importance of specific considerations for children and young people when responding to national emergencies.

Introduction

Background

The emergence and rapid spread of SARS-CoV-2 thoroughly disrupted day-to-day life globally, whether through the direct effects of infection or the implementation of preventive control measures [1]. Adolescence is a sensitive period when friendships and social interactions are important for mental health, brain development, and self-concept construction [2]. Thus, the COVID-19 pandemic was a fertile ground for the development and exacerbation of concerns related to children and young people and their mental health, with experts anticipating that it would lead to a higher prevalence of mental health conditions and increased demand on services [3].

In England, COVID-19 preventive measures comprised school closures (with a transition to web-based learning), lockdowns, and restrictions on leisure activities. These restrictions encompassed limits on time spent outdoors, as well as regulations on whom individuals could interact with and how they did so (ie, social distancing). The implementation of such measures was feared to be detrimental to the mental health of children and young people [4]; for example, the effects of school closures and social distancing, including their resultant loneliness, can be long-lasting, with evidence from previous pandemics suggesting that associations with poorer mental health can persist for nearly a decade [5]. Indeed, pandemics can exert a broad negative impact on children and young people, causing stress and feelings of helplessness, as well as behavioral, sleep, and eating problems, with higher rates of depression and anxiety likely during and after a pandemic [6].

Regarding the COVID-19 pandemic specifically, the literature is equivocal as to whether the predicted deterioration in mental health came to fruition. Some quantitative studies report more children and young people reaching thresholds for mental health conditions [7] and increased emotional problems and depression [4,8]. However, other studies report improved mental health and well-being, including sleep hygiene [9] and fewer externalizing and internalizing problems [10-12]. Therefore, it is unsurprising that a systematic review of 51 studies revealed heterogeneity regarding the impact of COVID-19 on the mental health of children and young people [12]. Similarly, qualitative explorations of the experiences of children and young people during the pandemic revealed heterogeneity, with prominent themes ranging from feelings of loss to growth and development [13]; for example, while most children and young people adapted well to school closures and web-based learning, experiences ranged from a lack of motivation to complete work to improved productivity [14]. Equally, while some children and young people from Black and ethnic minority backgrounds reported a negative mental health impact, others reported improved well-being and better coping strategies after lockdown [15]. More broadly, many children and young people aged 13 to 24 years across the United Kingdom reported worse mental health, school-related concerns, and socializing concerns, while a minority viewed pandemic experiences and the resultant changes as helpful (eg, strengthened familial relationships) [16]. Reasons for the observed heterogeneity are multifactorial and could include a research focus on specific subpopulations of children and young people (eg, those with special educational needs [17], specific ethnic groups [15], or groups considered vulnerable and high risk [7,11]) rather than the general population of children and young people; alternatively, experiences of children and young people could vary by pandemic stage [18]. Indeed, a lack of generalizability was a limitation highlighted in previous studies with small samples (eg, N=168 [4] and N=37 [16]) recruited from specific regions [4,8-11,14,15,19]. Similarly, qualitative research draws on the experiences and beliefs of small, selective samples and can rarely be considered to provide generalizable conclusions (although generalizability is not the primary aim of such research) [20].

Objectives

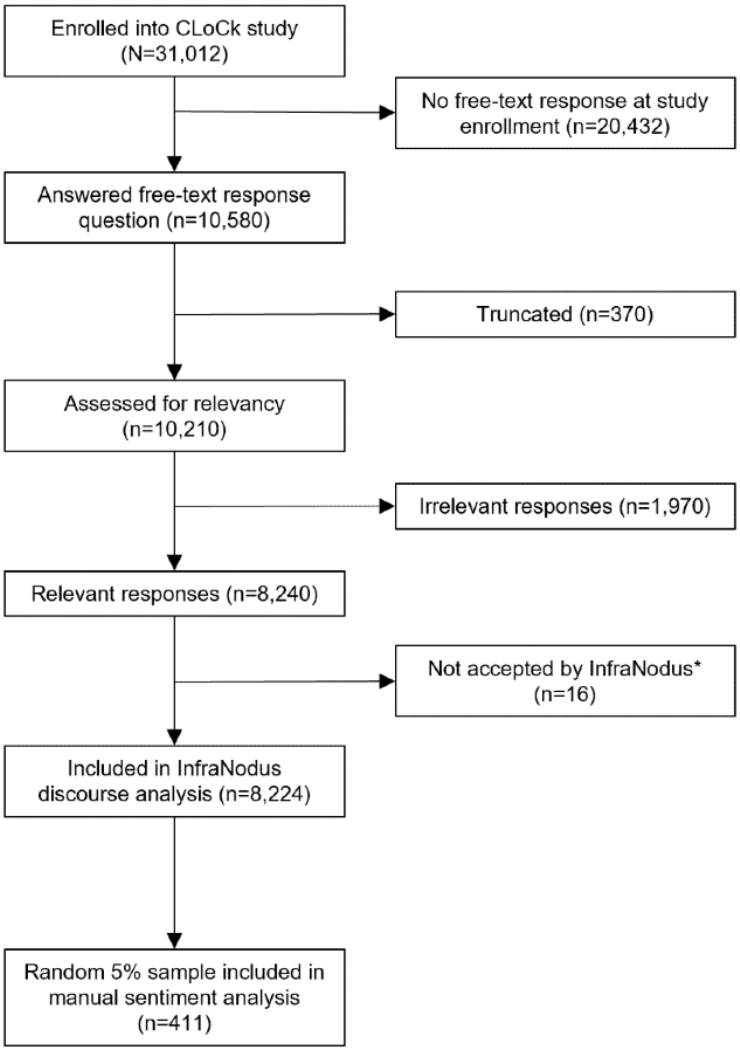
To overcome this limitation, we analyzed 8224 self-reported free-text responses from children and young people. Specifically, we used free-text responses from the Children and Young People With Long COVID (CLoCk) study, which recruited >30,000 children and young people aged 11 to 17 years when they underwent polymerase chain reaction (PCR) testing for SARS-CoV-2 between September 2020 and March 2021 [21]. At recruitment, children and young people were asked “to tell us about [their] health or how the pandemic or lockdown affected [them].” We aimed to analyze these responses to determine the most important topics and the main “sentiment” to understand the impact of the pandemic. To ensure that our findings were representative of the broader population of children and young people in England, we applied survey weights [22] to the sentiment analysis.

XSL•FO
RenderX

Methods

Study Design and Setting

In this study, we focus on the free-text responses of children and young people (aged 11 to 17 y at index PCR test) collected at study enrollment, which was 3, 6, or 12 months after their index PCR test (ie, April 2021-December 2021). During this period, most pandemic-related restrictions were gradually lifted (April-July 2021), until the beginning of December 2021 when measures were reimplemented to slow the spread of the SARS-CoV-2 Omicron variant [23].



The UK Health Security Agency's Second Generation Surveillance System, which is a dataset containing results of all SARS-CoV-2 PCR tests conducted by hospital and public health laboratories as part of national mandatory testing, was used to identify 219,175 children and young people (n=91,014, 41.53% tested positive, while n=128,161, 58.47% tested negative) who underwent PCR testing between September 2020 and March 2021 [21,24]. Children and young people who tested positive were matched, at CLoCk study invitation, to those who tested negative based on age, sex, region of residence, and month of test. Index of Multiple Deprivation (a proxy for socioeconomic status, grouped into quintiles) was determined via the lower super output area (ie, small local area level–based geographic hierarchy) in which the children and young people resided [25]. Consenting children and young people completed web-based questionnaires 3, 6, 12, and 24 months after their index PCR test, although the sweeps of data collection varied by month of test [21,24]; for example, children and young people who tested in January to March 2021 were able to provide data 3, 6, 12, and 24 months after the test compared to those who tested in October to December 2020 who were only able to do this at 6, 12, and 24 months. The questionnaire included demographics, elements of the International Severe Acute Respiratory and Emerging Infection Consortium pediatric COVID-19 questionnaire, and several validated scales (eg, the Strengths and Difficulties Questionnaire [26]). The questionnaire ended with a final, optional, free-text response question prompting children and young people to "Please use this space if there is anything else you would like to tell us about your health or how the pandemic or lockdown have affected you." This was the final question before survey submission. This study focused solely on the free-text responses provided at study enrollment.

Participants and Sample Size

In total, 31,012 children and young people enrolled into the CLoCk study [21] (ie, 31,012 children and young people submitted their enrollment questionnaire). Of these 31,012 respondents, 10,580 (34.12%) completed the free-text response question (Figure 1). The web-based questionnaire platform truncated free-text responses at 621 characters; to ensure that the experiences of the children and young people were not misrepresented, we excluded from analysis all responses exceeding 619 characters (370/10,580, 3.5%). Thus, 10,210 (96.5%) of the 10,580 responses were subject to data cleaning and relevancy assessment as described in the next subsection.

XSL•FO
RenderX

Figure 1. Participant selection flowchart. CLoCk: Children and Young People With Long COVID.

Data Cleaning and Relevancy Assessment

Free-text responses were fully anonymized—any potentially identifiable information (eg, child's or young person's name, email addresses, and hospital names) was redacted; for example, an anonymized response was as follows:

> *[T]he only thing that affected me is the move from [city name] to [city name] but regarding covid my mental health is ok although during the lockdown it was often low.*

All 10,210 responses were assessed for relevancy (refer to Textbox 1; of note, statements regarding COVID-19 vaccination, its immediate symptoms, timing with regard to SARS-CoV-2 infection or both were excluded because we are interested in the effects of SARS-CoV-2 itself and the associated COVID-19 preventive measures, eg, lockdowns, rather than vaccination side effects; moreover, the exclusion criteria are not mutually exclusive: a response may have been excluded for multiple reasons). One author (NKR) screened all responses. Any uncertainties were discussed with another author (SMPP) to reduce subjectivity and potential bias. Of the 10,210 responses assessed for relevancy, 1528 (15%) were discussed. Certain words or phrases were standardized across responses for consistency; for example, all variations of "COVID-19" (eg, "covid-19," "COVID 19," and "covid19") were revised to read "COVID." The final stage of data cleaning involved the checking and correction of spelling mistakes by 3 authors (NKR, LFS, and AD), with any uncertainties on how to rectify a spelling mistake (33/8240, 0.4%) discussed to achieve consensus.

XSL•FO
RenderX

Textbox 1. Relevancy assessment criteria and selected examples of free-text responses (included and excluded) provided by children and young people and not truncated at study enrollment (n=10,210).

Inclusion criteria (included: n=8240)

- Statements about the respondents' health related to SARS-CoV-2 infection, their health during the COVID-19 pandemic more generally or both.
- Statements about the respondents' experience of the pandemic, lockdown or both.
- Examples
  - "During the pandemic, I did lose quite a few friends and my mental health got worse"
  - "I enjoyed online learning as it gave me the opportunity to self teach something I found I am good at and I feel it is a useful skill for development. I was fitter during lockdown as I had more time to exercise and many good traits I picked up in lockdown I have kept"
  - "The first lockdown triggered phobias and anxiety. This worsened after grandad was in hospital with COVID"

Exclusion criteria (excluded: n=1970)

- Null responses (eg, "No," "N/A," or equivalent)
- Statements unrelated to the respondents' health or experiences of the pandemic or lockdown
- Nonsensical responses
- Statements revealing diagnoses before the pandemic (eg, autism)
- Statements discussing medication, health, or experiences before the pandemic with no comparison to medication, health, or experiences during the pandemic
- Statements about COVID-19 vaccination: its immediate symptoms and timing with regard to SARS-CoV-2 infection
- Responses related to whether the respondents tested positive for SARS-CoV-2 and its immediate impact (eg, on cough or smell within the first few weeks after infection)
- Statements on health guidance (eg, opinions on vaccination strategy) with no reference to their impact on the respondents personally
- Current colds, coughs, influenza, hay fever, seasonal allergies, and so on
- Correcting or clarifying previous questionnaire entries and expressing dissatisfaction with survey
- Examples
  - "TEST"
  - "are we going to go into another lockdown?"
  - "icciycih"
  - "I called [footballer] for my birthday, it was a small party. Suddenly, he arrived at the restaurant with a box of chocolates, all ashamed. He apologised for the gift and said he didn't know what to get because he had never been invited to a birthday party before"
  - "Have chronic fatigue syndrome (ME) since before COVID 19"
  - "I am allergic to aspirin"
  - "I have had glandular fever so most of these problems are and can be linked to it"
  - "I have had two Pfizer vaccinations, with an achy arm for a day or two as my only symptoms"
  - "China made covid Please tell boris that I want to go to him next party"
  - "Boris Johnson is rude"
  - "Help the NHS!! No more pandemic and vaccine effort until they have sufficient support in my opinion"

Quantitative Text Analysis

InfraNodus, an artificial intelligence (AI)–powered tool that processes and visualizes text-based data [27], was used. The tool follows these steps [28]:

1. Text normalization: words are converted into their lemmas (ie, the dictionary form) to reduce redundancy (eg, "families" becomes "family"), and syntax elements (eg, commas) are removed.
2. Stop word removal: words without significant semantic meaning (eg, "is" and "are") are filtered out. InfraNodus generates a default stop word list based on the uploaded text, which can be customized (see InfraNodus Discourse Analysis section).
3. Network graph visualization: words are displayed as a network graph that highlights the most influential words, with the option to detect topical clusters (ie, groups of words that tend to co-occur). The network graph is interactive,

XSL•FO
RenderX

allowing users to read through the text by relevant concepts (vs reading in a linear fashion).

InfraNodus Discourse Analysis

The terms "health," "COVID," "pandemic," and "lockdown" were part of the question wording. Therefore, before analysis, these words were included as stop words because they could potentially conceal other important topics. InfraNodus was then used to determine the most influential words and measure patterns occurring within the relevant 8224 free-text responses examining the experiences and health during the pandemic of children and young people. This was achieved using "betweenness centrality" scores [28]. This is a numerical measure of a word's influence over information flow and its ability to link different parts of the text network graph [28]. Words with the highest betweenness centrality scores were represented as larger nodes on the graph. Subsequently, topic modeling was undertaken. To achieve this, InfraNodus applied a community detection algorithm that identified groups of words more densely connected to each other than to the rest of the network, yielding an output of topical clusters [28].

Sentiment Analysis

Sentiment analysis measured the positive, negative, or neutral feelings reported by children and young people in the free-text responses. Initially, we set out to use InfraNodus for the sentiment analysis of all eligible responses; however, there were major discrepancies between researcher-assigned and InfraNodus-assigned sentiment (refer to Table S1 in Multimedia Appendix 1 for examples). Thus, to assess the main "sentiment" of children and young people during the COVID-19 pandemic, sentiment analysis was undertaken manually using the sentiment framework outlined in Textbox 2. A random sample was chosen for the sentiment analysis for pragmatic reasons, given the time available. This sample size represented 5% (411/8224) of the available data. The random selection aimed to mitigate potential biases inherent in other selection approaches, such as sequential sampling, which may have resulted in selection of responses predominantly from a specific time point. NKR and a second rater (LFS) met to discuss in depth the sentiment framework presented in Textbox 2, going through examples of positive, negative, and neutral statements. Subsequently, NKR's rater reliability was assessed by LFS who assigned a sentiment to a random subsample of 206 (50.1%) of the 411 responses. Agreement between the raters was 94.7% (195/206). Chi-square tests were used to examine associations between free-text sentiments and demographics.

XSL•FO
RenderX

Textbox 2. Sentiment framework for classification of free-text responses provided by children and young people at study enrollment.

Positive sentiment

- Largely communicating relatively high or high levels of well-being during the pandemic
- Largely communicating satisfaction with health guidelines and COVID-19 preventive measures (eg, school closures and lockdowns) and associated outcomes
- Largely communicating good health during the pandemic
- Examples
  - "I think the pandemic and lockdown has motivated me to be healthier and I am in overall better mental and physical health than before the pandemic"
  - "I liked being at home and doing schoolwork at home. But I missed seeing people"
  - "I loved the lie ins"

Neutral sentiment

- No positive or negative expressions
- General, factual statements
- Examples
  - "Made me be more independent- online learning and having to study the curriculum for my GCSE exams in 2021"
  - "Gained some weight"
  - "I live in an SGO I have not been able to see my mum as she lives in a hostel for over a year"

Negative sentiment

- Largely communicating poor well-being during the pandemic, including concerns about family members' health
- Largely communicating upset, frustration, or concern with health guidelines or COVID-19 preventive measures (eg, school closures and lockdowns) and associated outcomes
- Largely communicating poor health
- Examples
  - "I have not been able to see my friends and feel lonely. It scares me and makes me anxious, I have trouble concentrating"
  - "Found it very hard to stay on top of schoolwork so it has affected my mental health as I am quite stressed"
  - "I feel that my education has suffered because of lockdowns and within lockdowns I have gained problems with eating."

Reweighting: Sentiment Analysis

Sentiment analysis reweighting was conducted using Stata 17 (StataCorp LLC) [29]. Multimedia Appendix 1 provides detailed information on survey weight development and application, which is briefly summarized herein. Survey weights were developed to account for (1) not all children and young people invited to participate enrolling into the study, (2) not all children and young people enrolling providing a free text response, (3) not all free text respondents having done so relevantly (including within the character limit), and (4) not all those responding relevantly being randomly sampled for manual sentiment analysis. These 4 developed survey weights were combined to obtain a fifth survey weight that was used to reweight the analytic sample (n=411) to the target population (ie, all those invited to enroll; N=219,145). As the target population may not be representative of children and young people in England [22], we recalibrated our sentiment analysis to the general population of children and young people in England using census data from 2021 [30].

Ethical Considerations

Research ethics approval was granted by the Yorkshire and The Humber—South Yorkshire Research Ethics Committee (21/YH/0060; Integrated Research Application System project ID: 293495). Web-based informed consent was obtained from parents or carers of children and young people aged ≤15 years, with these children and young people also providing web-based assent. Those aged 16 to 17 years provided web-based informed consent, but their parents or carers did not, as per UK Health Research Authority–recommended processes [31]. Data privacy and confidentiality were maintained by redacting any potentially identifiable information in the free text (eg, child's or young person's name, email addresses, and hospital names) before analysis to achieve full anonymization. Those who completed and submitted questionnaires were compensated with a £10 (US $12.23) voucher for each completed questionnaire.

RenderX

Results

Participant Demographics

Compared to those invited to participate in the CLoCk study, those included in the InfraNodus and sentiment analyses were broadly similar, with, for example, participants more likely to be female individuals (Table 1). There were some demographic differences in those excluded due to truncation and irrelevancy; for example, while more female individuals (279/370, 75.4%) and older children and young people (253/370, 68.4%) were excluded due to truncation, younger children and young people (1088/1970, 55.2%) were more likely excluded due to irrelevancy (Table S2 in Multimedia Appendix 1).

[a]Ethnicity data were not available for children and young people at study invitation; this was self-reported at study enrollment.

[b]IMD: Index of Multiple Deprivation.

InfraNodus Discourse Analysis

The InfraNodus discourse analysis revealed 6 main topical clusters related to *school*, *examination stress*, *mental health*, *emotional impact of the pandemic*, *COVID-19 symptoms*, and *social and family support*. Each cluster is described in detail in the following subsections (of note, the majority of statements fell into multiple clusters).

School

Children and young people reported struggling academically, with participants stating that the pandemic "affected my school

XSL•FO
RenderX

learning a lot" (PID 8126), and that absence due to restrictions caused much stress, upset, and worry due to finding it "difficult to catch up with work I have missed" (PID 7995). Concentration was commonly reported as an issue, with a respondent reporting having found "it harder to concentrate in class, harder to complete homework without being distracted and more stressful to complete tests" (PID 6851). However, there were some children and young people who enjoyed web-based classes during COVID-19 restrictions, even going as far as to say, "I liked online school" (PID 8161) and "I prefer home schooling" (PID 8196). Nevertheless, others struggled, commenting as follows: "I...hated having to do my work on a laptop" (PID 8076) and "I cannot concentrate as well as in the classroom" (PID 8051). Moreover, social skills seem to have been affected by school closures, with a participant stating that they "find it difficult to communicate with people and [I] get uncomfortable when people approach [me]" (PID 8146), while another shared as follows:

> *I feel it negatively affected my social skills slightly, making it harder for me to talk to acquaintances.* [PID 8046]

Examination Stress

In this cluster, children and young people reported high levels of stress due to COVID-19 restrictions and their impact on examinations. One young person reported as follows:

> *[S]chool is way more stressful, there's so many changes to how exams are going or if we don't have any etc. such as what subjects are being dropped or topics we don't need etc.* [PID 7531]

Another person berated the government, noting that "the way the government dealt with my GCSEs was very stressful" (PID 6101). A common complaint was the government's handling of examinations, with this varying depending on pandemic stage; for example, some had qualms with the sudden news of an exam:

> *[D]on't tell people they are not going to have exams and then give them exams with less than a month's warning. It's honestly a joke.* [PID 5386]

Others struggled with the consequences of GCSEs being cancelled:

> *As my GCSEs were obviously cancelled I have been sitting up to 5 exams every day for weeks.* [PID 5996]

Some expressed frustration at "all that study [being] wasted" (PID 4891) and even attributed the physical symptoms felt (eg, tiredness and weakness) to the "uncertainty around my exams" (PID 5996).

Mental Health

Children and young people became more aware of their mental health during the pandemic, with a respondent stating, "I think I have some mental illnesses" (PID 8221) and another sharing that "the lockdowns have severely affected my mental health" (PID 8176). Many children and young people reported having ≥1 mental health conditions (eg, oppositional defiant disorder, obsessive-compulsive disorder, eating disorders, and depression) and commented on the impact that COVID-19 preventive measures had on them:

> *What affected me the most was having to be in and out of school when there was a case of coronavirus as I find it hard to go to school and this made my anxiety disorder worse as I had to restart going back after two weeks of isolation.* [PID 8096]

Nevertheless, some children and young people reported that their "mental health got better" (PID 5629), while one respondent commented as follows:

> *[T]he pandemic helped me to focus on my mental health and forced me to better look after myself so, in a way, it was positive for me.* [PID 7716]

Emotional Impact of the Pandemic

Anxiety was a common complaint:

> *I have felt very anxious about COVID. It has made me not want to leave my house or parents in case they die.* [PID 51]
>
> *[T]he pandemic makes me more worried in general about the small things in everyday life.* [PID 31]

Similarly, a respondent expressed being "a bit more worried about the future and also what may happen as a direct impact of the pandemic" (PID 346). Many children and young people reported experiencing frustration, feeling unhappy, and being more prone to worrying during the pandemic. Moreover, loneliness was also a common complaint, with a respondent reporting as follows:

> *[T]he lockdown and the pandemic have made me feel a lot more isolated than I previously did.* [PID 291]

Physical Health (Including COVID-19 Symptoms)

Within this topical cluster, the children and young people mainly reported the long-lasting impact of testing positive for COVID-19 infection, with changes to smell and taste being prominent:

> *The fact that food tastes and smells bad in some cases (smells bad in many cases) has impacted how much I eat and my diet, for instance I can't eat eggs anymore as they taste rotten. My diet has changed as a result.* [PID 46]
>
> *I have not been able to taste very well for about the past 3 months ever since I got COVID. This includes foods tasting very weird, not eating food I used to like, not being able to smell clear things other people can.* [PID 196]

The impact of changes to smell and taste seemed to be long-lasting; for example, a respondent stated they got their "taste partially back 11 months after I was positive for coronavirus" (PID 2451). Some children and young people made a reference to the term "long COVID":

> *I have long COVID...where I have distorted/lost my smell and taste.* [PID 1621]

Sleep disturbances were also commonly reported:

XSL•FO
RenderX

> *"[M]y sleeping pattern started to go downhill. I was awake all night and sleeping through the day.* [PID 861]

However, there were some who did not report such difficulties, stating they "only had minor symptoms which went away within a week" (PID 1851) or that they "don't feel I have had any long term issues as a result of having COVID" (PID 2786).

Social and Family Support

There was marked heterogeneity in terms of the impact of COVID-19 on social and family support. Some children and young people reported feeling distanced:

> *During COVID I didn't have as much contact with friends or family so I became a bit distant.* [PID 736]

> *It affected me as I couldn't hang out with my friends and I feel like I've lost a connection between them.* [PID 2251]

Others shared the opposite experience:

> *COVID has been devastating for everyone. It's a very difficult and challenging time. However, it has helped me become closer with my family and friends.* [PID 756]

Some made use of web-based platforms to engage with their friends (eg, game consoles and Microsoft Teams), which helped mitigate the impact of the COVID-19 preventive measures. A respondent reported having "been able to spend a lot of time with my friends virtually using my games console so haven't felt bored or lonely" (PID 1016). Though children and young people acknowledged the impact of the lockdown in relation to loss of support:

> *[M]y support system of friends were suddenly cut off and couldn't be there physically for me anymore.* [PID 1026]

However, some also described how it expanded social circles:

> *[O]ver the course of the pandemic I will say that I have made more friends than I would have otherwise because people would add me and my friends into group chats. Some of my closest friends have come from this.* [PID 1026]

Familial problems were reported by some children and young people, with a respondent stating that they "argued with my parents because I spend all my time with them" (PID 3676). Another stated as follows:

> *I think the pandemic has affected me badly. Being confined in a space with my mum and sister and not having a personal space to debrief has been difficult. I have realised a lot about myself and my family and they're not good things but I am grateful that I know this information otherwise I would have gone living my life like I was wrong all the time.* [PID 3271]

Sentiment Analysis: Original and Reweighted

Manual sentiment analysis of the 411 randomly sampled free-text responses yielded 314 (76.4%) negative, 57 (13.87%) positive, and 40 (9.73%) neutral statements. There were observed associations between the free-text sentiment and COVID-19 status as well as sex (P=.001 and P<.001, respectively; Table S3 in Multimedia Appendix 1) such that most of the responses, regardless of COVID-19 status or sex, were negative; for example, 84.1% (227/270) of the responses from female individuals and 61.7% (87/141) of those from male individuals were negative (Table S3 in Multimedia Appendix 1). There were no observed associations between the free-text sentiment and all other examined demographics (ie, age, ethnicity, region of residence, and Index of Multiple Deprivation quintile). When reweighted to the general population of children and young people in England, sentiment proportions remained largely consistent: 78.52% (negative), 13.23% (positive), and 8.24% (neutral). Most of those with negative sentiment were female (227/314, 72.3%), while those with positive sentiment were mostly older (35/57, 61%; Table 2).

Discussion

Principal Findings

Using an innovative AI method and self-reported data from 8224 children and young people during the COVID-19 pandemic, we found that the experiences of the children and young people fell into 6 main topical clusters related to *school*, *examination stress*, *mental health*, *emotional impact of the pandemic*, *physical health (including COVID-19 symptoms)*, and *social and family support*. Importantly, there was substantial overlap between the topical clusters, such that, for example, *examination stress* and *school* could be collapsed into 1 cluster. Similarly, *mental health* and *emotional impact of the pandemic*

XSL•FO
RenderX

could be classified together under *well-being*. Manual sentiment analysis showed that the majority of statements made by children and young people were largely negative (314/411, 76.4%), with only a small proportion (57/411, 13.9%) classified as positive. When reweighted to the general population of children and young people in England, the overriding sentiment prevalences were largely unchanged.

Our findings are in line with previous literature using different methods that saw COVID-19–related school closure as a contributing factor to the increased stress, frustration, anxiety, and loneliness experienced by children and young people [32]. Repeated cross-sectional comparisons (before and after the pandemic) of children and young people referred to specialist Child and Adolescent Mental Health Services found an increase in emotional problems and depression as well as the number of children and young people reaching thresholds for mental health conditions in those recruited at the time of schools reopening [7]. The authors suggest that this may be due to stresses involved in adjusting to the return to school. Qualitative descriptions paint a similar picture, with a minority benefiting from school closures (eg, because of reduced stress due to the lack of examinations), while the majority wanted to return for the social aspect and reported concentration difficulties, fears of falling behind, and frustration at their seemingly fruitless efforts [33]. Likewise, the examination by Scott et al [34] of the diary entries of children and young people over a 6-week period between July and October 2020 revealed that the pandemic had a negative impact on the mental health of children and young people, with many reporting anxiety, loss, stress, and loneliness, which is in line with the mental health and emotional impact of the pandemic clusters found in this study. Similar to our findings, while concerns surrounding school-related matters were prevalent (eg, long-term consequences of school closures and cancelled examinations), a minority of children and young people viewed school closures positively [34]. Sleep disturbances and loss of taste and smell commonly reported within the topical cluster of COVID-19 symptoms were in line with previous findings, with sleep hygiene negatively affected [11]. In terms of social and family support, the loneliness reported by some children and young people within this cluster is in line with quantitative data from the CLoCk study [23,35]. More broadly, previous literature indicates that 27% and 8% of children and young people reported “slightly more” and “much more” loneliness, respectively, during the first UK national lockdown [19].

The heterogeneity highlighted in this study brings together seemingly opposing findings in the literature; for example, some previous studies reported improved familial and peer relationships [9], whereas others reported tensions at home [36]. An explanation for previous discrepant findings and our current heterogeneous results may be explained by noting that variation in health and well-being by pandemic stage is possible; for example, in the Co-SPACE study, trends in emotional, conduct, and hyperactivity problems followed changes in COVID-19 preventive measures, that is, most problems increased after lockdown announcements and decreased as restrictions eased and schools reopened [18]. Notably, studies reporting improved mental health were typically conducted during the first UK national lockdown (March 2020-June 2020), which was novel because it was children’s and young people’s first experience of a lockdown and may have been qualitatively different from subsequent lockdowns [9]. Using data that largely come from children and young people themselves allows for their voices to be heard both in terms of the content of their written expressions and also the sentiment of the words used. Although previous studies have indicated the heterogeneity of experiences [37], this is the first study that used sentiment analysis to quantify the heterogeneity of experiences and health of children and young people during the pandemic. We found that more than three-quarters of the written expressions of children and young people were negative (314/411, 76.4%), and most of these negative statements were written by female individuals (227/314, 72.3%). By contrast, <15% (57/411) of the statements were positive, and these were mostly written by older children and young people (35/57, 61%). Understanding the basis for the heterogeneity of experiences and health during the pandemic is important because it helps identify factors that may contribute to resilience in the face of adversity as in the case of the pandemic. Notwithstanding these findings, it has also been highlighted that psychological distress during the COVID-19 pandemic varied across countries [38], with, for example, a quarter of the children and young people surveyed in Malaysia reporting depressive symptoms during lockdown and amid rising cases and fatalities [39], while 37% of children and young people aged 18 to 24 years in Southeast and South Asia reported positive attitudes toward the pandemic [40]. Thus, our findings might be restricted to children and young people in England.

Our study’s large sample size is a strength, taking into account the responses of >8000 children and young people regarding their experiences during the pandemic. Nonetheless, study limitations are acknowledged; for example, InfraNodus topical clusters were not entirely distinct: *examination stress* and *school* were similar, as were *mental health* and *emotional impact of the pandemic*. While the AI tool we used considered these as discrete clusters, we acknowledge that children and young people are complex beings, and the thoughts and emotions expressed in their written responses could straddle multiple clusters. While manual examination of the responses did not yield substantive differences between some clusters, the AI software did not allow for the identified clusters to be collapsed. Software limitations were further highlighted in the sentiment analysis. We intended to use the AI software to run the sentiment analysis on all 8224 free-text responses. However, our analysis highlighted several notable discrepancies between InfraNodus-assigned and human-assigned sentiment, especially in complex, nuanced statements. Examples of these discrepancies are provided in Table S1 in Multimedia Appendix 1. This issue reflects a limitation in the AI tool’s capacity to capture the full emotional range in the responses, particularly in contexts involving children’s expressions, which may convey implicit distress or complex emotional states not adequately interpreted by keyword-based algorithms. InfraNodus was not specifically trained on data from children and young people, which likely contributed to its misinterpretations. Sentiment analysis tools developed for general audiences often lack the contextual sensitivity needed for younger populations, whose expressions may differ significantly in language complexity,

XSL•FO
RenderX

structure, and sentiment cues. This highlights the need for AI sentiment tools to be trained specifically on data from children and young people to improve their interpretive accuracy. Furthermore, while we considered applying a natural language processing approach to extend the themes generated from our sentiment analysis and to predict themes across the full sample, this was not feasible within our current resources. Developing a contextual sentiment analysis framework for this purpose, which would allow for predictive insights and the potential identification of overlooked themes, would have required substantial computational support and additional funding. As such, this remains a limitation of our study. We recommend that future research consider integrating natural language processing methods such as topic modeling to analyze the remaining 95% (7813/8224) of the free-text responses, thereby enhancing theme coverage and providing a more comprehensive understanding of the thematic patterns across all data. In addition, reweighting the discourse analysis would have helped ensure representativeness, although this was not possible with the software used. These limitations highlight the importance of not relying exclusively on AI-generated interpretations of text and the need for specialist, substantive knowledge of the topics and data examined.

A small percentage of responses (370/10,580, 3.5%) were truncated and excluded from analysis. However, as the prevalence of truncation was low, it is unlikely that this exclusion introduced bias into our analysis. More generally, although the children and young people invited to take part in the CLoCk study were a nationally representative sample, they are a specific population (children and young people aged 11-17 y who underwent PCR testing). Therefore, children and young people who are invisible to the public health system may be excluded. In addition, there is further potential for selection bias because only 34.12% (10,580/31,012) of those completing the questionnaire answered the free-text response question. However, there seem to be no major demographic differences between those enrolling and those who answered the free-text question. To mitigate this bias, future research might consider making the free-text response question compulsory. The underrepresentation of positive sentiments may reflect a tendency for those more negatively impacted by the pandemic to respond to both the questionnaire and provide a relevant free-text response. To mitigate these selection issues, the sentiment analysis was reweighted to the general population of children and young people in England using census data from 2021 [30]. Although the questionnaire was designed to be completed by children and young people themselves, there was no way to check that responses were written by the children and young people as opposed to a parent or carer. Moreover, parental influence may have affected responses among those children and young people who completed it with parental assistance. Future studies would benefit from distinguishing between the input of children and young people and parental input by, for example, including a question asking whether the questionnaire was completed solely by the child or young person, solely by a parent or carer, or primarily by the child or young person with assistance from a parent or carer.

As in any manual qualitative data analysis, unconscious rater bias had the potential to affect the results. Thus, measures were taken to minimize its impact: for the manual sentiment analysis, a second rater assessed the sentiment of half the responses (206/411, 50.1%), yielding excellent agreement (195/206, 94.7%) between the raters. We acknowledge that the relevancy assessment of all 10,580 free-text responses by a second rater would have been beneficial; however, this was not possible due to limited capacity. Nevertheless, subjectivity in determining the relevance of statements during the relevancy assessment was mitigated by discussing all uncertainties with another researcher and by adopting a collaborative approach to developing the relevancy criteria. Finally, we acknowledge that temporal variation in health and experiences is possible and remains a literature gap that needs addressing. However, this was beyond the scope of this study. Ongoing work is examining how the health and experiences of children and young people evolved throughout the pandemic to provide a more comprehensive understanding of how the pandemic impacted their physical, mental, and emotional well-being, as well as their access to health care, education, and social support systems.

Conclusions

In conclusion, the study used InfraNodus to analyze >8000 free-text responses from children and young people during the COVID-19 pandemic. What emerged was that the majority of the text responses (314/411, 76.4%) indicated negative experiences, and many of the respondents reported experiencing distress across a range of domains related to school, social situations, and mental health. In terms of practical implications for policy makers, educators, and health care providers, this analysis highlights the importance of specific considerations for children and young people when responding to national emergencies; for example, the insights gained show that consistency in relation to education guidance, mitigations for social isolation and loneliness, and increased support on return to education would have reduced much stress; therefore, the application of these measures during and after national emergencies should be considered.

Acknowledgments

This work is independent research jointly funded by the National Institute for Health and Care Research (NIHR) and UK Research and Innovation (UKRI; Children and Young People With Long COVID study; COV-LT-0022). All research at Great Ormond Street Hospital NHS Foundation Trust and UCL Great Ormond Street Institute of Child Health is made possible by the NIHR Great Ormond Street Hospital Biomedical Research Centre. SMPP was supported by a UK Medical Research Council Career Development Award (MR/P020372/1) and a Senior Nonclinical Fellowship (MR/Y009398/1). The views expressed are those of the authors and not necessarily those of the National Health Service, the NIHR, UKRI, or the Department of Health and Social Care. The Department of Health and Social Care, as the NIHR and UKRI awarded grant COVLT0022, but was not involved in

study design, data collection, analysis, interpretation, or manuscript writing. Michael Lattimore, UK Health Security Agency, is acknowledged as project officer for the Children and Young People With Long COVID study.

Data Availability

Children and Young People With Long COVID study data are publicly available in the UK Data Service repository [41].

Authors' Contributions

NKR conducted the analysis for the study, accessed and verified the data, and drafted the manuscript. SM assisted with the analysis, including its design, and contributed to the drafting of the manuscript. MC-B assisted with the analysis, including its design, and reviewed the manuscript. RS contributed to the design of the Children and Young People With Long COVID (CLoCk) study, submitted the ethics and research and development applications, and reviewed the manuscript. LF-S contributed to data cleaning and analysis and reviewed the manuscript. BCFC reviewed the manuscript. AdO contributed to data cleaning and reviewed the manuscript. TN assisted with the analysis, including its design, and reviewed the manuscript. YX assisted with the literature review and reviewed the manuscript. KM adapted the questionnaire for the online Snap Surveys platform and reviewed the manuscript. ED, IH, TF, and TC contributed to the design of the CLoCk study and reviewed the manuscript. RS accessed and verified the data and designed the participant sampling and dataflow for the CLoCk study. TS conceived the idea for the CLoCk study, submitted the successful grant application, and reviewed the manuscript. SMPP conceived the idea for this study, assisted with the statistical analyses, accessed and verified the data, and drafted the manuscript. All members of the CLoCk Consortium made contributions to the conception or design of the work, were involved in drafting both the funding application and the manuscript, approved the version to be published, and agree to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved. Members of the CLoCk Consortium: Dougal Hargreaves, Shamez Ladhani, Marta Buszewicz, Esther Crawley, Bianca De Stavola, Shruti Garg, Anthony Harnden, Michael Levin, Vanessa Poustie, Kishan Sharma (sadly deceased), Olivia Swann, Roz Shafran, Terence Stephenson, Isobel Heyman, Tamsin Ford, Trudie Chalder, Emma Dalrymple, Terry Segal, Malcolm Semple, and Elizabeth Whittaker.

Conflicts of Interest

TS is chair of the UK Health Research Authority and therefore recused himself from the research ethics application. TC is part-funded by the National Institute for Health Research (NIHR) Biomedical Research Centre at South London and Maudsley NHS Foundation Trust, King's College London. She has grants from Guy’s St Thomas Charity Grants, NIHR, and UKRI for post–COVID-19 syndromes. TC is a member of the National Institute for Health and Care Excellence committee for post–COVID-19 condition. She has received travel expenses, accommodation costs, and honorarium for several lectures in Europe and has received travel expenses and accommodation costs for attending the American Thoracic Society Conference. She was on the Expert Advisory Panel for COVID-19 Rapid Guidelines. She has written self-help books on chronic fatigue and has conducted workshops on chronic fatigue and postinfectious syndromes. TF’s research group receives payment for research consultancy to Place2Be, a third-sector organization providing mental health training and interventions in UK schools. All other authors declare no other conflicts of interest.

Abstract

Background: The ubiquitous use of mobile phones among medical students has been linked to potential health consequences, including poor sleep quality.

Objective: This study investigates the prevalence of mobile phone addiction and its association with sleep quality among medical students across 6 Latin American countries.

Methods: A descriptive, cross-sectional, multicenter study was conducted between December 2023 and March 2024 using a self-administered online survey. The survey incorporated the Mobile Phone Addiction Scale and the Pittsburgh Sleep Quality Index to evaluate mobile phone addiction and sleep quality among 1677 medical students. A multiple regression model was applied to analyze the relationship between mobile phone addiction and poor sleep quality, adjusting for sex, age, and educational level to ensure robust results.

Results: Mobile phone addiction was identified in 32.5% (545/1677) of participants, with significant differences across countries. The overall mean Pittsburgh Sleep Quality Index score was 7.26, indicating poor sleep quality. Multiple regression analysis revealed a strong association between mobile phone addiction and poor sleep, controlled for demographic variables (β=1.4, 95% CI 1.05-1.74).

Conclusions: This study underscores a significant prevalence of mobile phone addiction among medical students and its detrimental association with sleep quality in Latin America. The findings advocate for the need to address mobile phone usage to mitigate its negative implications on student health and academic performance. Strategies to enhance digital literacy and promote healthier usage habits could benefit medical education and student well-being.

mobile phone; addiction behavior; sleep quality; medical students; Latin America

Introduction

By 2024, approximately 17.8 billion mobile phones are projected to be in use globally, according to Statista [1]. Initially designed for voice communication, mobile phones have evolved into essential tools for text messaging, complex communication, and daily activities [2]. The advent of smartphones with advanced computational capabilities has further integrated these devices into modern life [3]. While they offer substantial benefits, such as enhanced access to educational and informational resources, excessive use also poses significant risks [4]. Acute or chronic overuse of mobile phones has been associated with physical issues like headaches, carpal tunnel syndrome, tendinitis, and accidents caused by distraction [5]. In addition, excessive use can result in less overt but impactful effects, including reduced motivation, impaired memory and concentration, sleep disturbances, and learning difficulties [6].

One of the most well-documented negative consequences of mobile phone usage is its disruption of sleep patterns and quality. Prolonged screen exposure and late-night cellphone use adversely affect both the quantity and quality of sleep [7,8]. Poor sleep has been linked to a range of health problems, including cardiovascular diseases, mental health disorders, neurodegenerative conditions, musculoskeletal issues, and a reduced overall quality of life [9,10]. University students, particularly those belonging to Generation Z (Gen Z), also known as iGen or postmillennials, face compounded risks. Born between 1996 and 2015, Gen Z is the first generation to grow up with the internet and portable digital technology. These “digital natives” excel in mobile phone use and social media interaction but have less experience with traditional communication methods, such as print media. For medical students, the demands of their academic schedules, combined with excessive mobile phone usage, pose risks to mental health, sleep quality, and academic performance [11].

In recent years, mobile phones have become indispensable tools in the academic training of medical students [12]. Originally designed for personal communication, these devices have evolved into essential academic resources, facilitating learning and collaboration. However, this transition has also been associated with dependency and excessive use, raising concerns about potential addiction [13]. Constant internet connectivity provided by smartphones fosters engagement not only with educational resources but also with addictive behaviors and content [3]. These include compulsive information seeking, excessive use of online games and shopping platforms, and problematic online interactions such as cybersexuality and cybercontacts [14]. For medical students, in particular, problematic smartphone use, nomophobia (a fear of not having mobile phone connectivity), and general dependency not only negatively impacts academic performance but also poses significant health risks [15-18].

Recent studies in the United States and Turkey have identified a correlation between increased mobile phone use and poor sleep quality among university and medical students [19,20]. A meta-analysis further highlighted that sleep quality is closely linked to academic performance in medical students, emphasizing the need for interventions to address this issue [14]. Despite this growing body of evidence, research on the impact of mobile phone addiction on sleep quality among medical students in Latin America remains limited.

Medical students in Latin America face unique challenges, including demanding schedules, irregular sleep patterns, and high stress levels, which may make them particularly vulnerable to mobile phone addiction. In addition, the reliance on mobile phones for communication and education in resource-limited health care education systems could exacerbate these issues.

This study aims to investigate the prevalence of mobile phone addiction and its association with sleep quality among medical students in 6 Latin American countries. By addressing this gap, we hope to provide insights that can inform targeted interventions to improve the well-being and academic success of medical students in the region.

Methods

Study Design

A descriptive, cross-sectional, multicenter study was conducted from December 2023 to March 2024.

Setting and Participants

This study used a self-administered online survey targeting medical students enrolled at universities across 6 Latin American countries: Bolivia, Colombia, Ecuador, Panama, Paraguay, and Peru. Participants included undergraduate students from the first to the final years (sixth or seventh) of their medical degree. Participants were selected using a nonprobability convenience sampling method through the online survey platform SurveyMonkey. Participation was voluntary.

Survey Development and Measures

The research team designed a 49-item anonymous online survey to collect data on demographic characteristics, mobile phone usage, and sleep quality among the Latin American medical student population. An initial version of the questionnaire was reviewed by a public health expert to ensure its relevance, accuracy, and to preempt potential errors. It was then pilot tested with 20 medical students from Ecuador to fine tune comprehension and design; data from this phase were excluded from the final analysis. Revisions after pilot test produced the final version of the survey, which was drafted in Spanish. The report on the online survey used in this research, prepared following the CHERRIES (Checklist for Reporting Results of Internet E-Surveys), is provided in Table S1 in Multimedia Appendix 1.

Questionnaire and Variables

The final version of the questionnaire was structured into 3 sections to meet the research objectives.

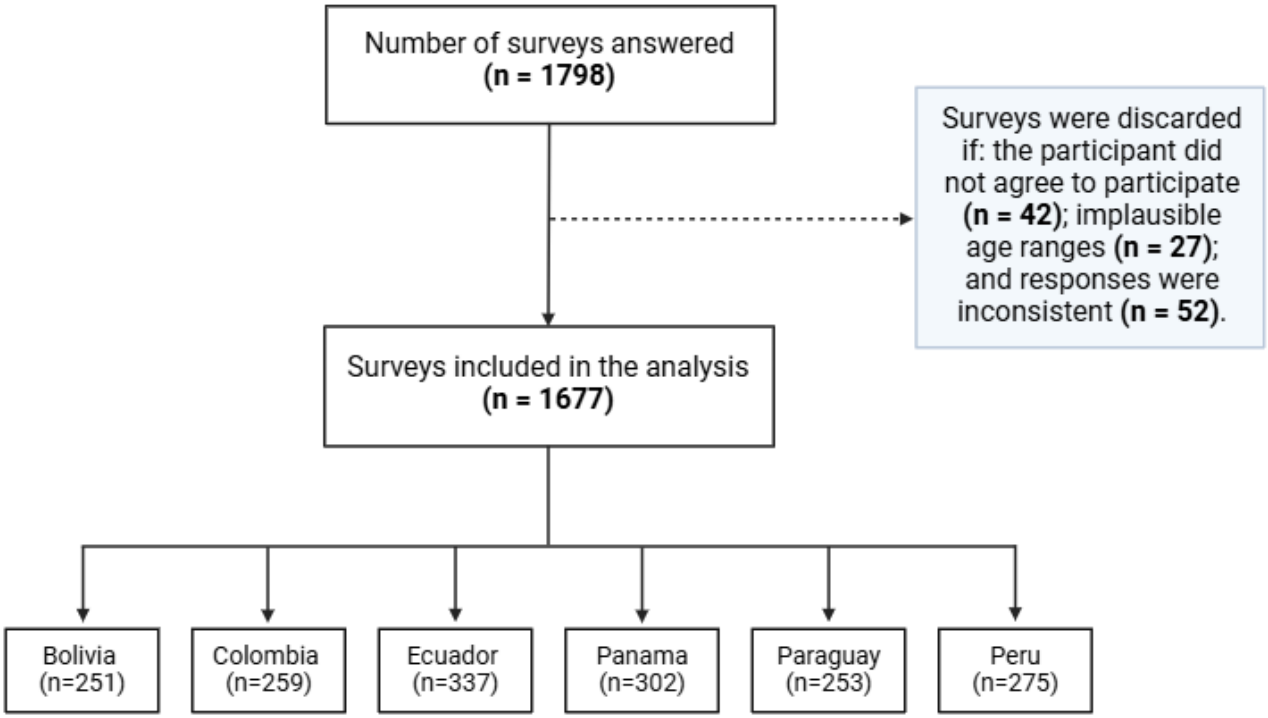
XSL•FO
RenderX

Demographic Data

The first section collected demographic information such as sex, age, country of residence, year of study, and type of university, categorized by funding source (public or private). It also included an additional year category (7th year) to account for students in countries such as Colombia and Panama, where medical training can extend up to 13 semesters.

Mobile Phone Addiction

The second section used the Mobile Phone Addiction Scale, designed and validated by Basu et al [21], which adheres to *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*) criteria for substance dependence syndrome. It comprised 20 questions rated on a 6-point Likert scale (from 1-completely disagree to 6-completely agree). The questionnaire evaluated 6 addiction components: intense desire, poor control, abstinence, tolerance, diminished interest in alternative pleasures, and harmful use. Addiction presence was defined if half or more of the questions in each component were affirmed; global addiction was noted when three or more components were present.



Sleep Quality

The third section used the standardized Pittsburgh Sleep Quality Index (PSQI) [22,23], designed to evaluate sleep quality through 19 questions covering 7 components: subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleep medication, and daytime dysfunction. Scores ranged from 0 (no difficulty) to 3 (very severe difficulty), with a total score from 0 to 21. A score of 5 or less indicated normal rest, while scores greater than 5 indicated poor rest, categorizing the overall sleep quality level.

Data Collection and Management

The online platform SurveyMonkey was used to facilitate data collection. Participants accessed the survey through a unique link shared across social media channels, including Facebook and WhatsApp (Meta). The preamble of the survey outlined the study's aims, assured confidentiality, and sought informed consent. Participants were required to agree to the informed consent and accept the participation agreement to proceed, reinforcing the survey's anonymity. To ensure high data integrity, all responses were meticulously reviewed for potential errors or inconsistencies, such as implausible age ranges or respondents selecting all available answers. This scrutiny led to the exclusion of questionnaires from an original sample of 1798 survey responses before filtering to a final total of 1677 responses which were considered valid and included in the study (Figure 1).

Figure 1. Flowchart of the Strengthening the Reporting of Observational Studies in Epidemiology–based sample selection process for this study.

Bias

To mitigate potential bias during data collection and management, several strategies were used. For example, IP addresses were used to eliminate duplicate submissions by configuring the SurveyMonkey platform to limit 1 response per IP address. To ensure anonymity the questionnaire was carefully curated to avoid collecting any identifiable information, including IP addresses, beyond what was necessary for filtering duplicates. In the analysis phase, additional steps were taken to minimize bias. One of the researchers meticulously reviewed the results, and any discrepancies identified were collaboratively resolved. This rigorous approach ensured that only valid and genuine responses were included in the final analysis, substantially enhancing the reliability and credibility of the study's findings. The use of a nonprobability convenience

XSL•FO
RenderX

sampling method was justified in this study of medical students across 6 Latin American countries due to logistical, resource, and time constraints. This method enabled the inclusion of participants from multiple universities, making the study feasible and cost-effective while capturing valuable insights into issues such as mobile phone addiction and sleep quality. Although convenience sampling introduces potential biases, including selection bias and limited generalizability, it was the most practical option given the difficulty of accessing a more representative sample across diverse regions. Despite these limitations, the approach allowed for timely data collection and provided exploratory insights into the specific challenges faced by medical students.

Statistical Analysis

The current study used descriptive statistical tests to analyze the responses for each categorical variable, including the calculation of frequencies and percentages. For quantitative variables, measures of central tendency (mean) and dispersion (SD) were evaluated.

To evaluate the relationships between the variables studied, inferential statistical tests were used. Chi-square tests were conducted to assess the influence of participant characteristics on the presence of mobile phone addiction. *t* tests and one-way ANOVA were used to examine the influence of characteristics on sleep quality as determined by mean PSQI scores.

Ordinary least squares (OLS) regression was conducted as part of a multiple regression model adjusted for sex, age, and educational level was used to estimate the association between mobile phone addiction and poor sleep quality, expressed by β and 95% CI. In all statistical analyses, a *P* value of <.05 was considered statistically significant. All the analysis was conducted using R (R Foundation for Statistical Computing).

Ethical Considerations

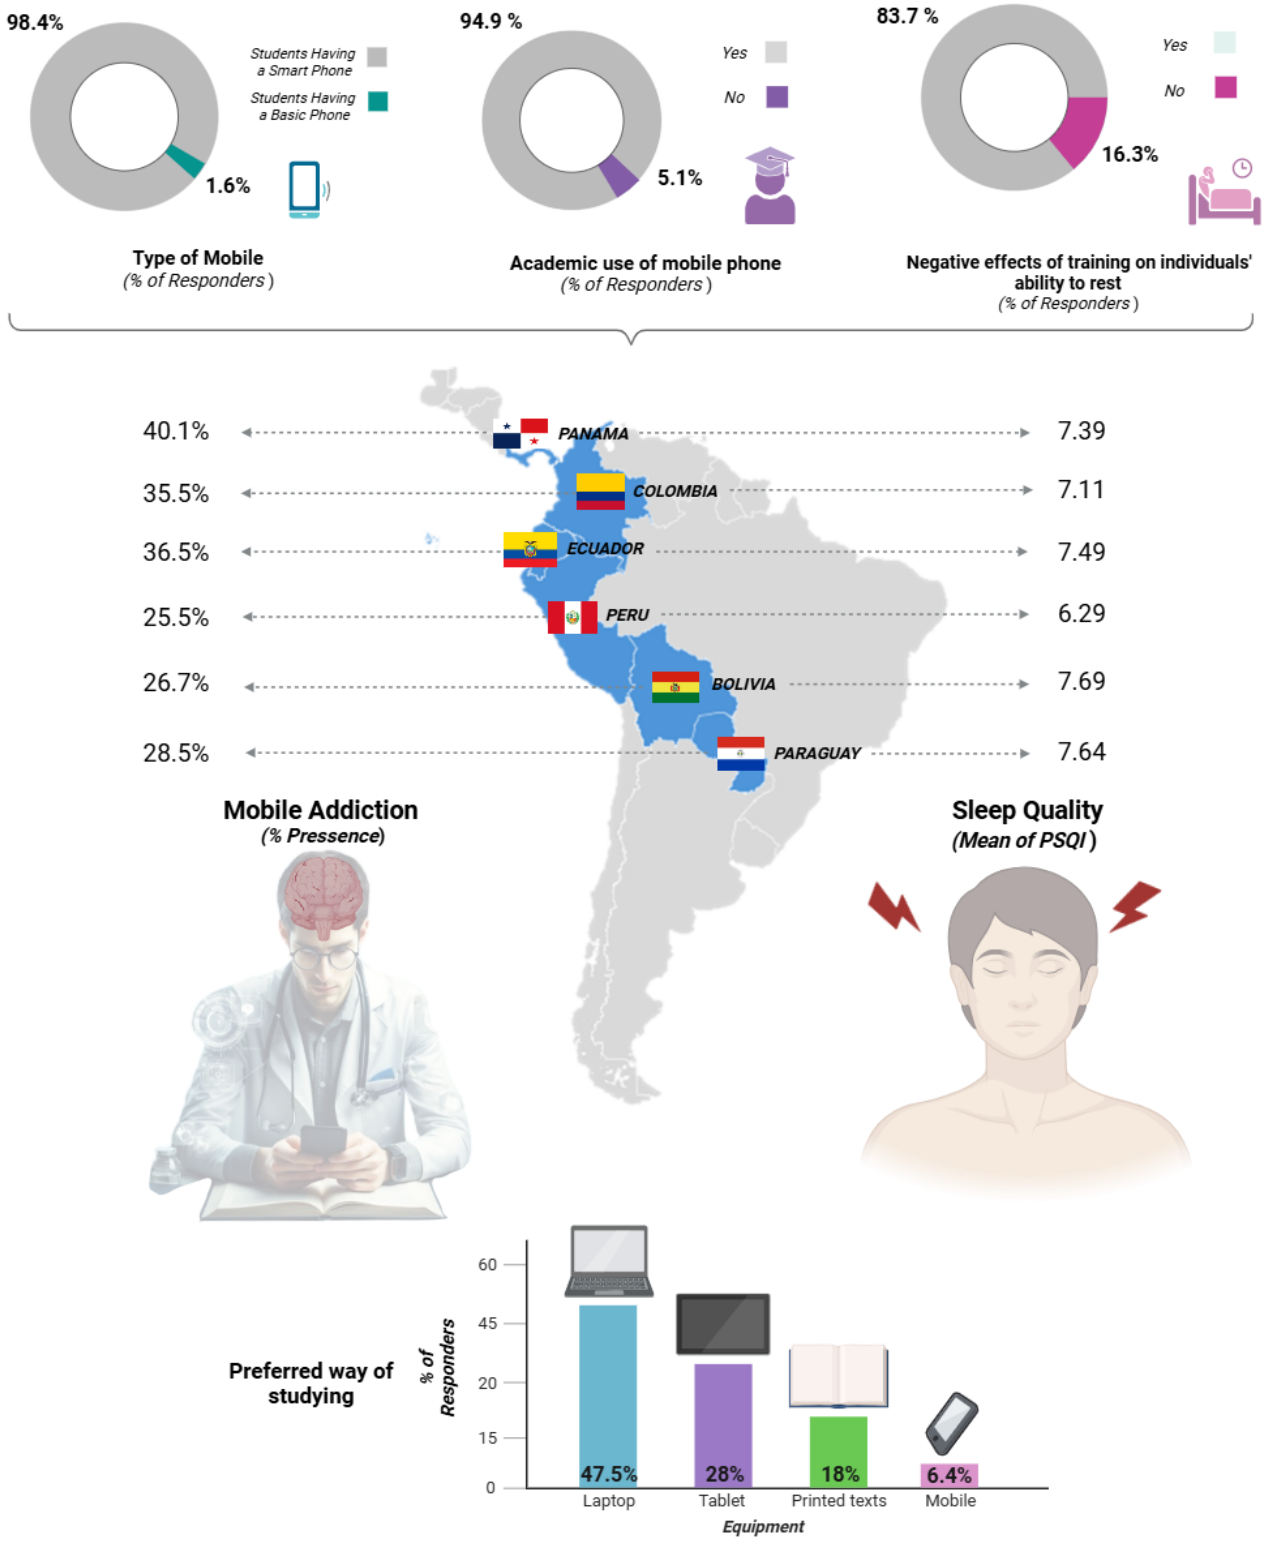
This study was conducted in strict adherence to the ethical standards set forth in the Declaration of Helsinki. It also followed the ethical protocols approved by the Ethics Committee of Universidad de Las Américas, under code 2023-EXC-004. The research team was trained to ensure that all aspects of the study upheld the principles of participant anonymity and voluntary participation. No personally identifiable or sensitive information was solicited or included in the research data.

Results

Demographic Characteristics

A total of 1677 medical students from 6 Latin American countries participated in this study. Ecuador and Panama had the highest representations at 20.1% and 18.0%, respectively. The majority of participants were female (1083/1677, 64.4%), and over half (973/1677, 58%) were in their initial years of undergraduate study (1st to 3rd year). The majority (967/1677, 57.7%) were enrolled in private universities (Table 1).

Table 1. Demographic characteristics of medical students from 6 Latin American countries.



Characteristics	Bolivia (n=251	Colombia (n=259)	Ecuador (n=337)	Panama (n=302)	Paraguay (n=253)	Peru (n=275)	Overall (n=1677)

Public university	3 (1.2)	170 (65.6)	81 (24%)	261 (86.4%)	24 (9.5)	171 (62.2)	710 (42.3)

XSL•FO
RenderX

Smartphone Usage

Smartphones were used by nearly the entire study population (1651/1677, 98.4%), with 94.9% (1591/1677) reporting using mobile phones for academic purposes. However, computers or laptops were preferred for studies (797/1677, 47.5%), while mobile phones were the least preferred option for studying (108/1677, 6.4%; Figure 2).

Figure 2. Characteristics of cell phone use, academic preparation, and distribution of cell phone addiction and sleep quality by country of residence among Latin American medical students.

Mobile Phone Addiction

According to the Mobile Phone Addiction Scale, 32.5% (545/1677) of participants exhibited mobile phone addiction. The domain most affected was tolerance to use (974/1677, 58.1%), followed by an intense desire to use the phone (708/1677, 42.2%). A decrease in pleasure was the least

XSL•FO
RenderX

common symptom, noted in only 9.8% (165/1677) of the sample (Table S2 in Multimedia Appendix 1).

According to the distribution among the participating countries, the highest prevalence of mobile phone addiction was observed in medical students from Panama (121/302, 40.1%), while the lowest was in Peru (70/253, 25.5%; *P*<.001; Figure 2). Furthermore, the presence of mobile phone addiction was associated with certain participant characteristics, being significantly higher (38/86, 44.2%) among medical students who stated they did not use their phones for academic purposes (*P*=.02), as well as among those who reported that their undergraduate preparation negatively affected their rest (448/1251, 35.8%; *P*<.001). In addition, medical students who preferred printed texts had the lowest percentage of mobile phone addiction (81/302, 22.8%) when compared with those participants using screen devices (mobile phone, computer, and tablet; *P*=.002; Table 2).

Table 2. Relationship between the characteristics of the participants with mobile phone addiction and sleep quality.

Characteristics	Mobile addiction			PSQI[a]	
	Absence, n (%)	Presence, n (%)	*P* value	Mean (SD)	*P* value
Sex			.92		.02

[a]PSQI: Pittsburgh Sleep Quality Index.

Sleep Quality

As measured by the PSQI, a general mean of poor sleep quality of 7.26 (SD 3.45) was found among medical students from the 6 study countries. The components with the highest scores (indicating the worst sleep quality) were subjective sleep quality (1.33, SD 0.77) and daytime dysfunction (1.31, SD 0.84), while the lowest scores were found in the use of sleep medication (0.27, SD 0.70) and habitual sleep efficiency (0.89, SD 1.12; Table 3).

XSL•FO
RenderX

Table 3. Characteristics of the components of sleep quality in medical students in Latin America.

PSQI[a] values	Bolivia (n=251), mean (SD)	Colombia (n=259), mean (SD)	Ecuador (n=337), mean (SD)	Panama (n=302), mean (SD)	Paraguay (n=253), mean (SD)	Peru (n=275), mean (SD)	Overall (n=1677), mean (SD)
PSQI	7.69 (3.61)	7.11 (3.43)	7.47 (3.31)	7.39 (3.49)	7.64 (3.52)	6.29 (3.22)	7.26 (3.45)
Sleep quality components							
Subjective sleep quality	1.40 (0.87)	1.31 (0.75)	1.31 (0.69)	1.42 (0.74)	1.38 (0.8)	1.13 (0.75)	1.33 (0.77)
Sleep latency	1.15 (0.91)	1.20 (0.97)	1.11 (0.86)	1.08 (0.97)	1.39 (0.97)	0.996 (0.88)	1.15 (0.93)
Sleep duration	1.33 (1.13)	1.09 (1.05)	1.23 (1.04)	1.23 (1.09)	1.01 (1.07)	0.924 (1.01)	1.14 (1.07)

Daytime dysfunction	1.29 (0.9)	1.28 (0.78)	1.41 (0.84)	1.43 (0.86)	1.28 (0.79)	1.11 (0.81)	1.31 (0.84)

[a]PSQI: Pittsburgh Sleep Quality Index.

Differences in sleep quality by country showed the highest scores for Bolivian (7.69, SD 3.61) and Paraguayan (7.64, SD 3.52) students, while Peru had the lowest score (6.29, SD 3.22; *P*<.001). Complementary post hoc analyses revealed that Peruvian medical students had significantly lower PSQI scores (better sleep quality) compared with their counterparts from Bolivia (*P*<.001), Ecuador (*P*<.001), Panama (*P*=.001), and Paraguay (*P*<.001; Figure 2).

Furthermore, characteristics associated with higher PSQI scores (worse sleep quality) were found in female medical students (7.39, SD 3.5; *P*=.02), those from private universities (7.57, SD 3.48; *P*=.001), those who preferentially use mobile phones for studying (8.21, 3.71; *P*=.02), and those who consider that academic preparation affects their sleep quality (7.49, SD 3.37; *P*<.001; Table 2).

Effect of Mobile Phone Addiction on Sleep Quality

The negative influence of mobile phone addiction on sleep quality was statistically significant across all seven components of the PSQI, showing higher mean scores (worse quality) in the group of medical students with mobile phone addiction, including in the dimensions of habitual sleep efficiency and use of sleeping medication (Table 4).

Table 4. Effect of mobile phone addiction on the components of sleep quality of medical students in Latin America.

Components	Mobile addiction		*P* value
	Absence (n=1132), mean (SD)	Presence (n=545), mean (SD)	
Subjective sleep quality	1.27 (0.76)	1.44 (0.76)	<.001
Sleep latency	1.08 (0.9)	1.28 (0.97)	<.001
Sleep duration	1.06 (1.05)	1.29 (1.09)	<.001
Habitual sleep efficiency	0.83 (1.09)	1 (1.17)	.003
Sleep disturbance	1.15 (0.54)	1.29 (0.59)	<.001
Use of sleeping medication	0.23 (0.67)	0.33 (0.77)	.01
Daytime dysfunction	1.19 (0.81)	1.56 (0.84)	<.001

A multiple regression was testes to demonstrated that mobile phone addiction is a factor associated with poor sleep quality as measured by mean PSQI scores even after adjusting for sex, age, and level of studies. The model largely met the assumptions of OLS regression, including linearity, independence, and homoscedasticity. However, the normality test of the residuals did not fully satisfy the assumption of normality. Despite this, we chose to retain the OLS model for several reasons. First, OLS is robust to deviations from normality, particularly when the sample size is large, as was the case in this study. Second, the central limit theorem suggested that the distribution of the residuals would approximate normality with a sufficiently large sample, even if the data were not perfectly normally distributed. Finally, the main goal of this model was to estimate the relationships between variables, and OLS provided unbiased, consistent, and efficient estimates under the assumption of homoscedasticity and linearity, which the model satisfied. Therefore, despite the minor concern regarding normality, the OLS model remained appropriate for the analysis. The model demonstrated the relationship between mobile phone usage and sleep quality among medical students in the study (β=1.4, 95% CI 1.05-1.74; Table 5).

Discussion

Principal Findings

By the third decade of the 21st century, access to and use of mobile phones has become nearly universal, a reality that includes medical students in Latin America [24]. This research aimed to explore mobile phone addiction among medical students across 6 Latin American countries, as well as to evaluate their sleep quality and the potential impact of excessive and unhealthy mobile phone use on sleep.

This multicenter study included 1677 undergraduate medical students, revealing a notable predominance of female participants. This finding aligns with recent research indicating that a majority of medical students in Latin America are female [25,26]. Nearly 100% of participants reported using a smartphone, a rate comparable with those reported among medical students in other regions [27]. In addition, 94.9% of participants used their devices for academic purposes, a figure higher than in other regions but consistent with global trends favoring the academic use of mobile phones among undergraduate medical students [12,28,29].

Although smartphones are primarily associated with barrier-free communication through social networks, they also possess numerous tools that are increasingly integrated into academic training, particularly among medical students. However, prolonged and uncontrolled use of these devices can have significant health effects on users [30-32]. Medical students are uniquely affected by mobile phone addiction and poor sleep quality due to the combination of demanding academic schedules, high stress levels, and the pervasive nature of digital technology. The rigorous nature of medical training often necessitates extensive study hours, leading students to rely heavily on smartphones for quick access to educational materials. This reliance, coupled with the need for social interaction and recreation through the same devices, often results in prolonged and uncontrolled usage.

Despite being regarded as a tool for academic enhancement, approximately one-third (32.5%) of the study population exhibited mobile phone addiction, with rates ranging from 25.5% among Peruvian students to 40.1% among Panamanian students. Comparing addiction rates globally is challenging due to variations in the questionnaires used to assess mobile phone use, addiction, or overuse, such as the Smartphone Addiction Scale (SAS-SV) or the Cell Phone Overuse Scale (COS) [33]. For example, Kamal et al [34] reported a 48% addiction rate among Pakistani medical and dental students using a similar instrument, while other studies found addiction rates ranging from 10.7% among Iranian medical students [35] to 34.4% among first and second-year medical students in Srinagar, India [36]. The questionnaire used in the present study [21] found that addiction was most commonly characterized by tolerance (using the phone more than expected and considering the usage excessive) and a strong desire to use the phone, particularly for immediate interaction on social networks or phone use even when others are nearby, traits typical of addictive behaviors [37]. Despite the heterogeneity in assessment tools, the body of research underscores the pervasive nature of mobile phone addiction among medical students worldwide, including in Latin America.

Interestingly, this study found no significant demographic variables related to overuse or addiction to mobile phones, such as gender [38,39]. However, there was a concerning relationship between students who did not use mobile phones for academic purposes and higher rates of addiction, potentially due to a preference for leisure activities such as social networking, gaming, or streaming platforms [40]. In addition, students who reported that their studies negatively affected their rest exhibited higher rates of addiction, suggesting an indirect relationship between mobile phone addiction and poor sleep. This notion is supported by findings showing that students who preferred printed texts for studying had lower addiction rates.

Sleep quality studies have become more standardized with the widespread acceptance of the PSQI. The average PSQI score

XSL•FO
RenderX

among students in this study (7.26, SD 3.45) indicated poor sleep quality, considerably higher than scores reported in similar studies, including military medical students (PSQI score=5.78, SD 2.26) [41], Indian medical students (PSQI score=4.43, SD 2.62) [39], and Iranian medical students (PSQI score=5.38, SD 2.31). Systematic reviews report meta-mean PSQI scores between 5.95 and 6.1 [33,42]. Poor sleep quality among medical students is well-documented and has been attributed to heavy study loads, irregular schedules, and a preference for study over sleep [43,44]. In this study, students from private universities and women exhibited worse sleep quality, a trend previously observed in other research [41].

There was a significant and consistent association between mobile phone addiction and poor sleep quality, with addicted students scoring higher across all PSQI dimensions (subjective sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleep medication, and daytime dysfunction) compared with those without addiction (P<.05). Regression analyses revealed a global association between mobile phone addiction and diminished sleep quality, even after adjusting for sex, age, and educational level (β=1.4; 95% CI 1.05-1.74; P<.001). This association has been widely evidenced in previous studies of medical students across different countries and academic levels [33,35,38,39,41,45].

The findings of this study offer several plausible explanations for the observed association between mobile phone addiction and poor sleep quality. Smartphones facilitate a wide range of activities, including gaming, streaming, and social media use, all of which compete for users' limited time and attention, often displacing sleep. Social media platforms, in particular, are deliberately designed to capture and retain user engagement through features such as "infinite scroll," notifications, direct messaging (DMs), and interaction metrics like likes, follows, and shares [46,47]. These features create an attention-driven ecosystem where users are incentivized to remain active, with their engagement monetized for advertising purposes [46].

In addition, the blue light emitted by smartphones has been widely recognized as a disruptor of circadian rhythms [48-50]. Artificial light exposure, particularly at night, delays the release of melatonin, the hormone responsible for regulating sleep-wake cycles, exacerbating sleep disturbances. Among medical students, this effect is particularly concerning due to their already irregular schedules and high stress levels [51-53]. The combination of attention-capturing smartphone apps and blue light exposure likely contributes to prioritizing phone use oversleep, providing a compelling explanation for the current study's findings.

This study highlights a critical issue, emphasizing the dual impact of mobile phones on the present and future of academic medical training [54]. While these devices provide significant benefits, including portable and digital access to textbooks, scientific articles, and practical tools such as video content, infographics, and podcasts [24,55-57], heir use also presents risks. These resources can enhance knowledge acquisition, even in resource-limited settings like Latin America. However, decision-makers, including university institutions and educators, must be cognizant of the potential negative consequences of mobile phone use in academic environments. These include cross-device addiction, indirect effects on sleep quality, and other physical and mental health challenges.

The broader implications of these findings extend beyond sleep disturbances. Poor sleep quality and mobile phone addiction can significantly impair cognitive function, emotional regulation, and physical health, which are vital for medical students' academic success and future professional practice. Sleep deprivation and distractions caused by addiction may hinder students' ability to learn effectively, retain critical information, and perform competently in clinical settings, ultimately impacting patient care.

Addressing these challenges requires urgent intervention. Institutions should integrate sleep education into medical curricula, emphasizing its importance for cognitive performance and overall well-being. Behavioral strategies, such as implementing "digital detox" periods or encouraging the use of apps that monitor and limit screen time, can help students manage their smartphone use. Furthermore, counseling and support services tailored to stress management and time optimization can address the underlying causes of overuse and improve sleep hygiene.

Limitations

This study has several limitations that should be acknowledged. First, the survey was conducted online, which may have introduced a sampling bias, favoring medical students with easier access to technology or greater familiarity with online platforms. In addition, the reliance on self-reported data poses the risk of social desirability bias, where participants may exaggerate their academic use of smartphones or provide responses they perceive as socially acceptable.

The subjective sleep assessments used in this study, specifically the PSQI, are practical, cost-effective, and widely used in population-based research due to their ease of administration and scalability. However, subjective measures are inherently limited by recall bias and participants' ability to accurately evaluate their sleep habits. In contrast, objective sleep assessment methods, such as actigraphy and polysomnography, provide direct and measurable data on sleep parameters and are considered more precise. These objective tools often reveal discrepancies compared with subjective assessments, as personal perceptions may lead to overestimation or underestimation of sleep duration or quality. Nevertheless, objective methods may fail to account for psychological factors influencing perceived sleep quality, which subjective tools can capture.

In this study, the reliance solely on subjective measures, such as the PSQI, represents a limitation. This approach may not fully reflect the complexity of sleep patterns or detect potential clinical sleep disturbances. Future research should consider integrating objective assessments to complement and validate self-reported sleep data, providing a more comprehensive understanding of sleep behaviors. Furthermore, the cross-sectional design of this study precludes the establishment of causality between mobile phone addiction and poor sleep quality. It remains unclear whether academic mobile phone use contributes to addiction and reduced sleep quality, or if

XSL•FO
RenderX

academically successful students inherently use smartphones more frequently and experience shorter sleep durations.

Finally, while the study included participants from 6 Latin American countries, the findings may not be universally generalizable across the entire region due to cultural, economic, and educational differences. Future studies should aim to include more diverse populations to enhance the external validity of the results.

Conclusions

In conclusion, this study reveals a substantial prevalence of mobile phone addiction among medical students from 6 Latin American countries, affecting approximately one-third of the sample. In addition, the overall sleep quality of student participants was found to be poor, as indicated by a mean PSQI score higher than previously reported. Findings suggest that using mobile phones for studying can indirectly contribute to poorer sleep quality by diverting attention to other activities during study sessions. This underscores the dual nature of mobile technology, which can serve both educational and recreational purposes, each with differing impacts on the lives and health of students. Importantly, we identified a significant association between mobile phone addiction and poor sleep quality. Overall, this study confirms the widespread academic integration of mobile phones among medical students in Latin America and highlights the significant need for strategies to address the use of these devices in academia and their potential impact on health and academic success.

Abstract

Background: The emergence of disease-modifying treatment options for Alzheimer disease is creating a paradigm shift in strategies to identify patients with mild symptoms in primary care settings. Systematic reviews on digital cognitive tests reported that most showed diagnostic performance comparable with that of paper-and-pencil tests for mild cognitive impairment and dementia. However, most studies have small sample sizes, with fewer than 100 individuals, and are based on case-control or cross-sectional designs.

Objective: This study aimed to examine the predictive validity of the Japanese Cognitive Function Test (J-Cog), a new computerized cognitive battery test, for dementia development.

Methods: We randomly assigned 2520 older adults (average age 72.7, SD 6.7 years) to derivation and validation groups to determine and validate cutoff points for the onset of dementia. The Mini-Mental State Examination (MMSE) was used for comparison purposes. The J-Cog consists of 12 tasks that assess orientation, designation, attention and calculation, mental rotation, verbal fluency, sentence completion, working memory, logical reasoning, attention, common knowledge, word memory recall, and episodic memory recall. The onset of dementia was monitored for 60 months. In the derivation group, receiver operating characteristic curves were plotted to determine the MMSE and J-Cog cutoff points that best discriminated between the groups with and without dementia. In the validation group, Cox proportional regression models were developed to predict the associations of the group classified using the cutoff points of the J-Cog or MMSE with dementia incidence. Harrell C-statistic was estimated to summarize how well a predicted risk score described an observed sequence of events. The Akaike information criterion was calculated for relative goodness of fit, where lower absolute values indicate a better model fit.

Results: Significant hazard ratios (HRs) for dementia incidence were found using the MMSE cutoff between 23 and 24 point (HR 1.93, 95% CI 1.13-3.27) and the J-Cog cutoff between 43 and 44 points (HR 2.42, 95% CI 1.50-3.93). In the total validation group, the C-statistic was above 0.8 for all cutoff points. Akaike information criterion with MMSE cutoff between 23 and 24 points as a reference showed a poor fit for MMSE cutoff between 28 and 29 points, and a good fit for the J-Cog cutoff between 43 and 44 points.

Conclusions: The J-Cog has higher accuracy in predicting the development of dementia than the MMSE and has advantages for use in the community as a test of cognitive function, which can be administered by nonprofessionals.

Introduction

Dementia is a syndrome associated with neurodegenerative diseases, characterized by a general decline in cognitive abilities, which affects daily activities. It ultimately has a significant impact on patients and their careers and social relationships. The most common symptoms of dementia include problems with memory, thinking, behavior, emotions, language, and reduced motivation [1]. The population of Japan is aging more rapidly than that of any other country. As of 2020, the number of Japanese people older than 65 years of age has reached a record high of 36 million, or 29% of the total population of 125 million. The number of people with dementia in Japan is projected to reach 7 million by 2025. To address this issue, the Basic Act for Dementia to Promote an Inclusive Society was approved on June 14, 2023, and took effect on January 1, 2024. This law requires national and local governments to ensure the social participation of people with dementia, develop a consultation system, and promote research for the development of a symbiotic society so that people with dementia can live with peace of mind and protect their human rights [2].

The Basic Act for Dementia to Promote an Inclusive Society includes measures to promote early detection, diagnosis, and response to dementia regarding prevention strategies. Early identification through screening would also allow patients and their families to receive care at an earlier stage in the disease process, potentially facilitating discussions regarding decision-making (eg, health care, financial, and legal), while the patient still has decision-making capacity [3]. Several progressive local governments have already initiated screening programs for the early detection of dementia risk. However, the cognitive function tests used as screening methods are Mini-Mental State Examination (MMSE) or similar conventional paper-and-pencil tests. The delay in digitizing cognitive tests might limit the number of older adults who are eligible for primary screening. A meta-analysis reported a high rate of undetected dementia, particularly in populations with low socioeconomic status [4]. This is likely due to the lack of widespread implementation of appropriate cognitive screening tests. Furthermore, the meta-analysis results suggested that studies that used the *Diagnostic and Statistical Manual of Mental Disorders, Third andFourth Editions* criteria to identify dementia had a higher rate of underdetection than those that used the MMSE [4].

Lecanemab (Leqembi), a treatment agent for early Alzheimer disease (AD), can significantly alter the disease course for patients in the early stages [5]. Among participants with early symptomatic AD and amyloid and tau pathology, donanemab significantly slowed clinical progression in those with low or medium tau and in the combined low or medium and high tau pathology population [6]. The World Health Organization guidelines on risk reduction for cognitive decline and dementia provide evidence-based recommendations regarding lifestyle behaviors and interventions to delay or prevent cognitive decline and dementia [7]. These preventive paradigms create the need to identify patients with mild symptoms, typically in primary care settings, and refer them to AD specialists for formal diagnosis and to determine treatment or prevention eligibility.

Primary screening of cognitive function in the community is required to facilitate early hospital visits for early diagnosis of AD. The involvement of psychologists and other professionals in administering specialized neuropsychological assessments in the community is limited, and a screening test for cognitive function that can be administered by nonprofessionals would improve primary screening. To address these issues, cognitive testing as a digital biomarker that is reliable and self-administered and can detect cognitive dysfunction at an early stage is required. A review and recommendation on routine screening for cognitive impairment in adults aged 65 years and older by the US Preventive Services Task Force asks that clinicians remain alert to early signs of cognitive impairment for individual evaluation [3].

A systematic review on digital cognitive tests reported that most of these tests showed diagnostic performance comparable with that of paper-and-pencil tests for mild cognitive impairment (MCI) and dementia [8]. Furthermore, digital biomarkers related to memory and executive function might be more sensitive than those related to other cognitive domains [9]. These findings suggest that digital cognitive battery tests are promising sensitive clinical tools for detecting MCI and early dementia. However, most studies have small sample sizes, with fewer than 100 individuals, and are based on case-control or cross-sectional designs [9]. Further studies may require the use of digital cognitive biomarkers in long-term follow-up to monitor the conversion from normal cognition to dementia.

We developed a digital cognitive test, the Japanese Cognitive Function Test (J-Cog), which assesses orientation, verbal ability, attention, visuospatial performance, reasoning, and memory, to identify older adults with cognitive impairment in primary settings. The purpose of this study was to evaluate the effectiveness of the J-Cog in predicting the development of dementia and compare the accuracy of the J-Cog with that of the MMSE [10], one of the most widely used tests of cognitive function. If the detective validity of the J-Cog is confirmed, it can be widely used in the community as a cognitive screening tool.

Methods

Participants

In total, 4167 community-dwelling older adults who were recruited from Takahama City, Japan, for the National Center for Geriatric and Gerontology-Study of Geriatric Syndromes (NCGG-SGS) [11], which is a Japanese national cohort study, were enrolled in this study. The inclusion criteria were residence in Takahama and age ≥60 years at the time of the examination (September 2015 to February 2017). The exclusion criteria were

XSL•FO
RenderX

(1) availing the Japanese certified public long-term care insurance system, which requires support or care (n=76); (2) not availing the certified public long-term care insurance system but having the inability to perform basic activities of daily living (such as eating, dressing, bathing, climbing stairs) and maintain functional mobility, personal hygiene, grooming, and toilet hygiene (n=9); (3) history of dementia (n=7) and the following conditions or symptoms suspected of causing dementia: Parkinson disease (n=16), stroke (n=219), or depression (n=97), and a score of <21 on the MMSE [12] (n=67); and (4) missing data for cognitive assessments and other measurements (n=1156). Of the initial 4167 participants, 1647 were excluded, and data from 2520 older adults were analyzed (1017 men and 1503 women). The mean age was 72.7 (SD 6.7; range 60-96) years. Analyses with dementia incidence as an outcome were conducted on 2292 participants who were available for follow-up.

Measurements of Cognitive Function

Overview

Cognitive tests included the J-Cog and MMSE, administered once on the same day by well-trained assessors. The MMSE is commonly used to assess cognitive problems and is often a component of dementia diagnosis (range 0-30, higher scores indicating better functioning) [10].

Japanese Cognitive Function Test

Overview

The J-Cog was developed by neuropsychological researchers at the National Center for Geriatrics and Gerontology as a cognitive test for measuring the domains of cognitive impairment that are generally recognized in MCI. The initial version comprised 15 tasks, which were evaluated in terms of their simplicity, importance, and feasibility. Based on these assessments, the final version, comprising 12 tasks, was developed.

The J-Cog was presented on an iPad (Apple Inc) with a 9.7-inch touch display. The task instructions and questions were presented on the display with a letter size of at least 1.0 cm^2. This battery consists of 12 tasks—orientation, designation, attention and calculation, mental rotation, verbal fluency, sentence completion, working memory, logical reasoning, attention, common knowledge, word memory recall, and episodic memory recall [13]—that assess cognitive functions that tend to decline with age. The participants were given 20-30 minutes to complete the battery (described further in this study). Higher J-Cog scores indicate better cognitive ability (range 0-72). An operator supported each participant in setting up the iPad, understanding the task protocols, and recording their data. The participants only needed to touch the display to complete the tasks using a digital pen. Because the J-Cog is a mixture of examinations in which the display of the screen is made invisible to the participant and examinations in which the display of the screen is shown to the participant, the examinations were conducted by well-trained operators.

Task 1: Orientation

The participants indicated the month, day, and weekday of the test date. The participants also indicated the prefecture and city of their current location. All 5 questions in each task were shown, and we calculated the total number of correct answers (0-5 points).

Task 2: Designation

The participants looked at pictures of eyeglasses, keys, wallets, watches, and cell phones and responded with the name of the object. One point was awarded for each item (0-5).

After naming the objects, they had 15 seconds to memorize the 5 objects they named. The participants then chose 1 of 5 items and answered where it would be stored, that is, under the television, on the dresser, on the shoebox, under the table, or in the dresser. These encoding tasks were scored during memory recall.

Task 3: Attention and Calculation

The participants responded to additions and subtractions of up to 2 digits by rote calculations. There were 6 questions, each presented only once (0-6 points). If there was obvious noise, the questions were presented again.

Task 4: Mental Rotation

The participants saw a completed figure with 3×3 and 4×4 squares showing kana (Japanese alphabet) and completed an incomplete figure with rotated kana missing (0-5 points). First, the participants were asked to answer example questions. If the answer to the example question was incorrect, the correct answer was taught, and the test was conducted after the participants understood the rules. The time limit was 20 seconds for the 3×3 task and 30 seconds for the 4×4 task.

Task 5: Verbal Fluency

The participants were asked to say as many words as possible to fit the category (eg, for vegetables, answer carrots, onions, and lettuce). They had 15 seconds to respond to as many categories as possible (0-20 points).

Task 6: Sentence Completion

The participants responded to the words that applied to the blanks in the sentence from 5 choices (0-2 points). They read a sentence with a missing word and selected the word that fits the blank based on the context of the sentence; 2 types of sentences were presented, each containing 5 choices.

The participants were asked to read the question silently and provide the correct answer. If they did not know the answer, they were asked to select “don’t know.” After each question, the participants were asked to press the next button to complete their full response.

Task 7: Working Memory

Participants were shown images of blue dots. After a while, some of the dots changed to white, then returned to blue. They were then asked to indicate which dots had changed to white. In addition, 2 questions were asked: one with 3×3 dots, and the other with 4×4 dots (0-7 points).

XSL•FO
RenderX

Task 8: Logical Reasoning

The participants responded to a logical reasoning text task and 4 fill-in-the-blank questions (0-4 points). Participants were asked to read the instructional text and question silently and select the correct response according to the instructions.

Task 9: Attention

The participants were shown 2 similar pictures and had 30 seconds to find the 1 shape present in only 1 of the pictures (0-1 points).

Task 10: Common Knowledge

The participants looked at pictures of national flags and were asked to choose the corresponding country from 8 options. There were 8 questions (0-8 points).

Task 11: Word Memory Recall

The participants responded to the 5 objects memorized in task 2 (0-5 points).

Task 12: Episodic Memory Recall

The participants responded with the object and location of the object that they stored away in task 2. If the participant were unable to answer, they listened to the options and selected the correct answer (0-4 points).

Measurement of Incidence of Dementia

Participants who did not have dementia at baseline and were diagnosed with dementia during the 60-month, follow-up period were considered to have new-onset dementia. Data were collected from the Japanese National Health Insurance System and the Japanese long-term care insurance system. In Japan, all adults aged ≥65 years have public health insurance, which includes one of the following: health insurance for employed individuals (Employees' Health Insurance), national health insurance for unemployed and self-employed individuals aged <75 years (Japanese National Health Insurance), or health care for individuals aged ≥75 years (Later-Stage Medical Care). In this study, participants were followed up monthly for new-onset dementia (AD, vascular dementia, frontotemporal dementia, or other dementia subtypes), as recorded by the Japanese National Health Insurance System and Later-Stage Medical Care. Participants were considered to have dementia based on a diagnosis made by a physician according to the *International Classification of Diseases, Tenth Revision*. We identified cases of dementia from the NCGG-SGS data according to the corresponding *International Classification of Diseases, Tenth Revision* codes (Multimedia Appendix 1). The diagnosis of dementia from the UK Biobank inpatient data, which have criteria similar to those of the NCGG-SGS (Multimedia Appendix 1), was previously validated and showed a positive predictive value of 87.3% for any dementia compared with the clinical expert adjudication of full-text medical records [14].

The long-term care insurance system is a mandatory form of social insurance that supports the daily lives of older adults with disabilities [15,16]. In Japan, all individuals aged ≥65 years are eligible for institutional or community-based services depending on their disability level, and those aged ≥40 years with disabilities related to aging, such as cerebrovascular disease, are also eligible to access benefits. The disability certification process consists of two parts: (1) the degree of disability based on a questionnaire developed by the Ministry of Health, Labor, and Welfare of Japan, and (2) a physician's written opinion prepared by the attending physician [17]. We identified dementia based on the level of independence in the daily living of older adults with dementia in the disability certification process. The level of independence was classified into 5 ranks, from mild to severe (I, II, III, IV, and M); individuals with moderate dementia-related behavioral disturbances and cognitive impairment with slight dependence were classified as rank II. We defined dementia as symptoms of rank II or higher, as derived from a primary care physician's written opinion. These criteria were the same as those used in previous studies in Japan [18-21].

Analysis of Potential Confounding Factors

Dementia results from a combination of factors that occur over time, including demographics and chronic conditions. All multivariate-adjusted models reported included the following covariates unless otherwise noted: age at enrollment, sex, educational level, drinking, smoking, presence of chronic conditions, BMI, and regular exercise. The self-reported chronic conditions included in the model were hypertension, diabetes, cancer, and osteoarthritis [22,23].

Ethical Considerations

This study was approved by the ethics committee of the Institutional Review Board of the National Center for Geriatrics and Gerontology (approval 770). All the participants were informed of the study and provided their written consent before their participation in this study, agreeing to the anonymous use of their data for publication. Data were deidentified before analysis and stored securely in a password-protected file on a password-protected computer. No compensation was provided to the study participants.

Statistical Analysis

First, those who participated at baseline and could follow the development of dementia during the follow-up period were randomly divided into the derivation and validation groups (1:1). Data homogeneity analysis regarding the control variables and J-Cog scores was tested using independent sample 2-tailed *t* tests or chi-square tests for contingency tests, depending on the variable structure. Incident dementia diagnoses per 1000 person-years were calculated for all participants and for participants classified by the cutoff point. Chi-square tests were used to compare the groups for incident dementia.

In the derivation group, receiver operating characteristic curves were plotted to determine the MMSE and J-Cog cutoff points that best discriminated between groups with and without dementia (the cutoff points are denoted with the 2 points on either side of the cutoff separated by a "/"). The area under the receiver operating characteristic curve was calculated, and the cutoff points for maximizing the sensitivity and specificity of each test were determined using the Youden index [24]. Based on these cutoff points, participants were categorized as having either high or low cognitive ability. We compared the accuracy of predicting the development of dementia by classifying

XSL•FO
RenderX

participants using the MMSE cutoff point 23/24, which is used to determine the risk of dementia [10].

In the validation group, 3 Cox proportional regression models were developed to predict the associations of the group (lower or higher cognitive ability) classified using the J-Cog or MMSE with dementia incidence. Specifically, the first and second models used MMSE score cutoffs of 23/24 and 28/29, respectively, and the third model used a J-Cog score cutoff of 43/44. All the models were adjusted for the potential confounding factors mentioned above. The adjusted hazard ratio (HR) and 95% CIs were obtained from the respective models. Harrell C-statistic was estimated to summarize how well a predicted risk score described an observed sequence of events. Generally, a C-statistic value greater than 0.7 indicates a good match [25,26]. The Akaike information criterion (AIC) was calculated for relative goodness of fit, where lower absolute values indicate a better model fit. Differences in Akaike information criterion (ΔAIC) of 3 or more were considered meaningful [27]. Harrell C-statistic and AIC were calculated using the *dynpred* (version 0.1.2) and *survival* (version 3.5.7) R package [28,29]. As sensitivity analyses, Cox proportional regression models were used, stratified by age group (65-74 years vs 75 years or more) and educational history (less than 9 years vs 10 years or more). These are variables that have a robust relationship with cognitive decline and dementia [30,31], and we felt that the stratified analyses would show the benefits of population-specific cognitive testing.

All statistical tests were considered significant at $P<.05$, and statistical analyses were performed using IBM SPSS Statistics (version 24.0) and R version 4.3.2 (R Core Team).

Results

Of the 2520 participants, 181 (7.2%) were diagnosed with dementia, 29 (1.2%) moved away from Takahama City, 138 (5.5%) died during the follow-up period, and 61 (2.4%) terminated the study for other reasons (Figure 1). Incident dementia diagnosis per 1000 person-years (95% CI) for total participants was 15.7 (13.6-18.1).

We examined whether the possible confounders of dementia incidence and cognitive tests differed at baseline between the derivation and validation groups (Table 1). No significant differences were observed in any of the measurements between the 2 groups (all $P>.05$). Table 2 presents the possible confounding factors for dementia incidence and cognitive test results for participants grouped according to the presence or absence of dementia. In the derivation group, significant differences were found for age ($P<.001$), educational level ($P<.001$), drinking ($P=.02$), diabetes ($P=.002$), cancer ($P=.04$), MMSE ($P<.001$), all subscores in the J-Cog (all $P<.05$), and total J-Cog score ($P<.001$) between participants with and without dementia (Table 2). In the validation group, significant differences were found for age ($P<.001$), sex ($P=.02$), education level ($P<.001$), hypertension ($P=.05$), osteoarthritis ($P<.001$), MMSE, and all subscores in the J-Cog (all $P<.05$) except for orientation and designation, and total J-Cog score ($P<.001$) between the participants with and without dementia incidence (Table 2).

The Youden index was used to determine the cutoff points for future dementia incidence during a 60-month period, which were 28/29 and 43/44 points on the MMSE and J-Cog, respectively. Incident dementia diagnoses per 1000 person-years with 95% CI for the low and high cognitive ability groups were 21.0 (17.9-24.6) and 7.1 (5.1-10.0) according to the MMSE 28/29 cutoff, 35.0 (29.5-41.4) and 6.0 (4.5-8.0) according to the J-Cog 43/44 cutoff, and 42.5 (31.1-58.0) and 13.2 (11.2-15.5) according to the MMSE 23/24 cutoff. The low cognitive ability groups, which were divided according to the 3 cutoff points, included significantly more participants with incident dementia than those with high cognitive ability ($P<.001$).

The predictive performances of all 3 risk cutoff points for dementia are presented in Table 3. In the total validation group participants, significant HRs for dementia incidence were found using the MMSE 23/24 and J-Cog 43/44 cutoffs (MMSE 23/24: HR 1.93, 95% CI 1.13-3.27; J-Cog 434/44: HR 2.42, 95% CI 1.50-3.93; Figure 2). The C-statistic was above 0.7 for all cutoff points. The ΔAIC with the MMSE 23/24 cutoff as a reference indicated that the MMSE 28/29 cutoff had poor discrimination, and the J-Cog 43/44 cutoff had good discrimination.

A subgroup analysis of participants aged 65-74 years showed no significant HRs (HR 1.31, 95% CI 0.53-3.22) at the MMSE 28/29 cutoff and a poor fit (ΔAIC=5.6). Participants aged 75 years and older showed a good fit at the J-Cog 43/44 cutoff (ΔAIC=–23.2), with significant HRs (HR 2.71, 95% CI 1.84-4.00) and good discrimination (C-statistics=0.714). In participants with less than 9 years of education, significant HRs for dementia incidence were found at the MMSE 23/24 and J-Cog 43/44 cutoff points (MMSE 23/24: HR 1.83, 95% CI 1.18-2.83; and J-Cog 43/44: HR 2.26, 95% CI 1.38-3.69). The ΔAIC using the MMSE 23/24 cutoff as a reference showed a poor fit at the MMSE 28/29 cutoff (ΔAIC=4.9) and a good fit at the J-Cog 43/44 cutoff (ΔAIC=–5.3). In participants with more than 10 years of education, significant HRs for dementia incidence were found at the MMSE 28/29 and J-Cog 43/44 cutoff points (MMSE 28/29: HR 1.84, 95% CI 1.06-3.22; and J-Cog 43/44: HR 3.53, 95% CI 2.10-5.93). The ΔAIC using the MMSE 23/24 cutoff as a reference showed good fit at the MMSE 28/29 (ΔAIC=–3.5) and J-Cog 43/44 cutoff points (ΔAIC=–22.7).

Figure 2. Cox survival estimates for dementia incidence according to cognitive ability: (A) hazard estimates of dementia incidence with MMSE cutoff point 23/24; (B) hazard estimates of dementia incidence with MMSE cutoff point 28/29; and (C) hazard estimates of dementia incidence with J-Cog cutoff point 43/44. The cutoff points are denoted by the 2 points on either side of the cutoff separated by a "/". J-Cog: Japanese Cognitive Function Test; MMSE: Mini-Mental State Examination.

Discussion

Principal Findings

In this study, we developed and validated the J-Cog to establish a digital cognitive marker with a low economic and human burden to serve a large number of older adults. The J-Cog is a promising free tool for use in community centers and primary care clinics so that at-risk older adults can receive timely cognitive screening in the community. This study showed that the J-Cog has good criteria and predictive validity for identifying older adults who have developed dementia. Automated administration and scoring algorithms can reduce the workload of professionals and health care staff.

In this prospective study, dementia risk was significantly associated with the MMSE 23/24 and J-Cog 43/44 cutoff points, and a good fit at the J-Cog 43/44 cutoff point. The advantages of the MMSE include rapid administration and high acceptance as a diagnostic tool among health professionals and researchers [32]. Traditionally, a 23/24 cutoff has been used to select patients with suspected cognitive impairment or dementia [33]. However, sociocultural variables, such as age and education, among others, may affect individual scores [34,35]. A review to determine the accuracy of MMSE for the early detection of dementia reported no evidence supporting the substantial role of the MMSE as a stand-alone, single-administration test in the identification of participants who could develop dementia [36].

The optimal cutoff point for the development of dementia in this study was a high MMSE score of 28/29. The mean MMSE score was 27 (SD 2), and the median score was 28 (IQR 25-29). Only 211 (8.4%) of 2520 participants had MMSE scores below 23, which is traditionally considered a high-risk factor for dementia [10]. The reason for the higher cutoff point in this study may be the high distribution of MMSE scores.

The MMSE cutoff point of 23/24 showed better accuracy than 28/29 for participants in the total validation group, those aged 65-74 years, and those with less than 9 years of education. These results suggest that the MMSE 23/24 cutoff is a robust indicator of the development of dementia. However, the MMSE 28/29 cutoff point of showed a better fit than that of 23/24 for participants with more than 10 years of education. This result is in line with that of a previous study that reported the need for a higher MMSE cutoff for diagnosing dementia for patients with high educational levels [37].

The J-Cog showed a better fit for detecting the onset of dementia than the MMSE 23/24 cutoff points. The findings were similar in analyses in which participants were stratified by age and educational level, indicating the superiority of the J-Cog over MMSE in predicting incident dementia. In addition to predictive validity, the J-Cog has certain advantages over pen-and-paper cognitive function tests, such as the fact that (1) it does not require a professional to administer the test, (2) it can be administered free of charge, and (3) scoring and judgment are automated. These benefits are important for covering a large number of participants in a community setting for cognitive testing.

Comparison With Previous Work

The emergence of disease-modifying treatment options for AD has led to a paradigm shift in treatment strategies. Amyloid-targeted therapies are ideally used in the early stages of the disease, at the stage of MCI, and no later than mild dementia, because they slow disease progression but cannot reverse decline [38]. This preventive paradigm creates the need to identify patients with mild symptoms, typically in primary care settings, and many digital biomarkers have been developed. Systematic reviews on digital cognitive tests reported that most showed diagnostic performance comparable with that of paper-and-pencil tests for MCI and dementia. However, most studies have small sample sizes of fewer than 100 individuals and are based on case-control or cross-sectional designs [8,9]. In this study, a large population was followed for 60 months after implementation of the J-Cog to determine the predictive validity of the development of dementia in community-dwelling older adults. A recent systematic review reported the evaluation of digital cognitive testing applications, with a particular focus on the older people [39]. The review included an analysis of 20 articles. The number of cognitive tasks included in the accepted digital cognitive tests ranged from 1 to 10, with only 2 (10%)

XSL•FO
RenderX

tests including more than 8 tasks. The cognitive domains included executive functions, memory, visuospatial, attention, language, orientation, processing speed, learning, praxis or gnosis, abstractions, and calculations [39]. Many of these domains were included in the J-Cog. Previous studies have not found any validation of predictive validity with dementia onset as an outcome. This study provides the first evidence that digital cognitive tests are a tool that can predict the future onset of dementia.

Limitations

Although the J-Cog has some advantages over pen-and-paper cognitive function tests, there are some limitations to interpreting the results of this study. First, the participants were not randomly recruited, which may have resulted in an underrepresentation of cognitive impairment, because the participants were sufficiently healthy to undergo health examinations. Second, data on dementia subtypes were not collected (eg, AD, vascular dementia, dementia with Lewy bodies, and frontotemporal dementia). Thus, the data do not allow inferences regarding the correlation between the J-Cog and dementia pathology. Third, we were unable to contact an informant (eg, a family member) to verify the medical records, lifestyle information, or asymptomatic aberrant behavior. In addition, this study only identified dementia using specific *International Classification of Diseases, Tenth Revision* codes and information from the long-term care insurance system, so it was not possible to identify the onset of dementia in people who had dementia due to other factors or who had no record. These may have led to an underestimation of early-onset dementia in particular. Finally, information about the participants' medical conditions and comorbidities was collected through self-reports, and because we did not have access to medical records, we were unable to confirm these reports.

Conclusions

In this study, the J-Cog, a computerized cognitive battery test, was shown to be valid for detecting dementia development. The J-Cog is a cognitive function test that can be widely used in the community, and its social implementation should be promoted in the future so that AD treatment can be implemented in a timely and appropriate manner. A future extension of this study would be to improve the usability of the J-Cog so that it could be administered remotely and to remove the need for an operator to improve efficiency compared with paper-and-pencil tasks.

Acknowledgments

The study was supported by Japan Society for the Promotion of Science (Grant-in-Aid for Scientific Research (A), 26242059); Ministry of Health, Labour and Welfare (Research project on health and welfare promotion for the elderly); the National Center for Geriatrics and Gerontology (Research Funding for Longevity Sciences 27-22); Japan Agency for Medical Research and Development (15dk0107003h0003, 15dk0207004h0203); Research Institute of Science and Technology for Society (RISTEX); and Japan Science and Technology Agency (JST) (Japan and Solution-Driven Co-creative R&D Program for SDGs [SOLVE for SDGs]: Preventing Social Isolation & Loneliness and Creating Diversified Social Networks: 22-221037254). The funders had no role in the design and conduct of the study; the collection, management, analysis, and interpretation of the data; the preparation, review, or approval of the manuscript; or the decision to submit the manuscript for publication. The authors acknowledge the substantial contributions of the dedicated and skilled staff at the National Center for Geriatric and Gerontology-Study of Geriatric Syndromes (NCGG-SGS). The authors are also grateful to the NCGG-SGS who volunteered to participate in this study.

Authors' Contributions

HS had full access to all data in the study and took responsibility for the integrity of the data and accuracy of the data analysis. Concept and design were contributed by HS and HM. Acquisition, analysis, and interpretation of data were contributed by TD, K Tsutsumimoto, KM, KH, K Tomida, and MM. Drafting of the manuscript was handled by HS. Critical revision of the manuscript for important intellectual content was contributed by all authors. Statistical analysis was contributed by HS and MM. Funding was handled by HS.

Conflicts of Interest

None declared.

Abstract

Background: It is unclear how exposure to different types of screen content is associated with early development among preschool children.

Objective: This study aims to precisely evaluate the screen exposure time across different content types and to explore the associations with the Ages and Stages Questionnaire, Third Edition (ASQ-3) score and 5 capacity domains in children aged 34.5-66 months.

Methods: This monitoring study used intelligent technology to collect data on the 7-day screen time and the time spent viewing each content type. The participants were 2 groups of Shanghai kindergarten kids. The data were collected between March 2023 and July 2023. Screen exposure data (total daily time and time for each type of content) were collected from children aged between 34.5 and 66 months. A self-designed questionnaire and the Healthy Screen Viewing for Children intelligent technology app were used to assess screen exposure to all media and tablets. The ASQ-3 was used to assess early development in children aged 34.5-66 months.

Results: In the 535-child sample, the results of linear regression analysis indicated that both screen time of more than 60 minutes and exposure to smartphones and tablets were negatively associated with ASQ-3 score. Among 365 participants with data collected by the Healthy Screen Viewing for Children app, median regression showed that the median total ASQ-3 score was negatively associated with screen time for noneducational content (β=–.055; 95% CI –0.148 to –0.006; *P*=.03), screen time for both educational and noneducational content (β=–.042; 95% CI –0.081 to –0.007; *P*=.001), and fast-paced content (β=–.034; 95% CI –0.062 to –0.011; *P*=.049). The median gross motor score was negatively associated with screen time for parental guidance-13–rated content (β=–.015; 95% CI –0.022 to 0.009; *P*=.03), educational and noneducational content (β=–.018, 95% CI –0.038 to –0.001; *P*=.02), static content (β=–.022; 95% CI –0.050 to 0.007; *P*=.02). This study also revealed that the median fine motor score was negatively associated with screen time for guidance–rated content (β=–.032, 95% CI –0.057 to –0.003; *P*=.006), parental guidance (PG) rated content (β=–.020; 95% CI –0.036 to –0.007; *P*=.004), noneducational content (β=–.026; 95% CI –0.067 to –0.003; *P*=.01), both educational and noneducational content (β=–.020; 95% CI –0.034 to –0.001; *P*<.001), fast-paced content (β=–.022; 95% CI –0.033 to –0.014; *P*<.001), static content (β=–.034; 95% CI –0.050 to 0.018; *P*<.001), animated content (β=–.038; 95% CI –0.069 to –0.001; *P*=.004), and screen use during the daytime (β=–.026; 95% CI –0.043 to 0.005; *P*=.005).

XSL•FO
RenderX

Conclusions: The results indicated that the time spent viewing noneducational, static, fast-paced, and animated content was negatively associated with early development among preschool children. Limiting screen time in relevant aspects is recommended.

KEYWORDS

types of screen content; screen time; intelligent technology; early development; preschool

Introduction

Since iPads and similar touch-enabled media technological devices are becoming increasingly popular worldwide, the increasingly younger trend of screen exposure may threaten the early development of toddlers and preschool children [1]. Although the World Health Organization [2] and pediatric societies worldwide (eg, Australian [3] and Canadian [4] 24-Hour Movement Guidelines) have recommended no more than 1-2 hours per day for children aged 2 to 5 years, the global prevalence of children who meet the screen time guidelines (1 hour/day) is only 35.6% (95% CI 30.6%-40.9%) [5]. Excessive screen time is associated with child language skills [6]; development [7]; mental health symptoms, including irritability, inattention, and hyperactivity [8]; obesity [9,10]; and physical inactivity [11,12].

The most active and most vulnerable period for brain and neural development is from the ages of 2 to 5 years [13] because children are able to generalize an action learned based on 2D screen images to a real 3D situation beginning at 2 years of age [14]. In addition to excessive screen time, there is still controversy about whether and how exposure to screen content during early life could influence children's physical, psychological, and social development. Previous studies have shown that early exposure to violent entertainment programs is associated with aggressive behavior in childhood [13], and watching entertainment programs has adverse effects on cognitive development [15]; moreover, a cohort study showed that viewing entertainment programs was associated with greater expressive word skills [16]. Several intervention experiments have shown that watching cartoons with a fast screen-switching rate reduces executive function in children, but exposure to content with a slow screen-switching rate has no significant effect on executive function in children [17,18]. Several studies have suggested that playing games can improve children's cognitive abilities, such as attention, visual processing, and spatial imagination, in the short term [19], but the long-term learning and educational benefits are not obvious [20].

In general, there is an urgent need for greater awareness about the complexities of the impact of exposure to screen content on children's development, especially regarding touch-enabled media technology [21]. The most recent umbrella review of screen time studies, also calls for more objective measurements [22]. However, previous research seems simple and unable to match the pace of technological advances because the majority of screen exposure measurements are based on parent-reported screen viewing time and content, which might be susceptible to recall bias [1,23]. Conversely, the World Health Organization recommends that toddlers view high-quality content but fails to specify what defines such quality or offers representative examples [2]. Therefore, the primary aim of this study was to collect real-time screen exposure data through intelligent monitoring technology and then examine the association between screen viewing content and time and children's early development. These results may be beneficial for defining high-quality evidence for direct future recommendations.

Methods

Study Design and Population

This monitoring study was conducted in 2 districts of Shanghai, Xuhui District (urban), and Pudong New Area (suburban), from March 2023 to July 2023. A random sampling method was used to select a kindergarten from each of the 2 districts. For each kindergarten, a cluster sampling method was used to select 5 classes, in which the average number of children in each class was 30, from the junior, middle, and senior grades. A total of 535 preschool children were included in this study, and they were required to use the Huawei iPad for 1 week. During the recruitment process, we repeatedly emphasized that children should use tablets according to their daily habits at home and that parents should neither indulge in children's use which may lead to an overestimation of screen exposure duration nor overly regulate it which may result in an underestimation of screen exposure duration. All the children were provided with intelligent monitoring technology and completed a developmental screening questionnaire. The minimum sample size was calculated to be 462 by using the following formula: , where the reported prevalence of abnormal development among nationwide Chinese preschool children was approximately 10.8% to 26.2% [24]. In this study, the prevalence (p) was 10.8%, the type I error (α) was .05, the $z_{1-/2}$ was 1.96, the precision (d) was 0.04, and the design effect (deff) was 2 [25]. The inclusion criteria for participant enrollment were as follows: (1) children aged between 2 and 6 years; (2) children whose parents or other caregivers allowed them to use screen devices, such as televisions, smartphones, iPads, and computers; and (3) children whose parents or other caregivers understood the questionnaire.

Measures

Screen Exposure Monitoring Technology

The "Healthy Screen Viewing for Children (HSVC)" mobile app, developed by the Department of Preresearch of Huawei Corporations and installed on the Huawei iPad, was used to automatically collect data on screen time and screen content while running in the background. The screen time was calculated by obtaining the start time point and end time point as well as the sum of the duration of use for every app. Correspondingly, app name labels, namely, screen content information, were also

XSL•FO
RenderX

collected simultaneously (the specific data collection and storage procedures are shown in Figure S1 in Multimedia Appendix 1). Considering that video applications (eg, YouTube and Netflix) cannot reflect the viewing program according to the application name, the HSVC application takes screenshots every 60 seconds to obtain images of the screen as an important source of data on-screen content. All the abovementioned screen exposure data were uploaded in real-time to the cloud server of Huawei Corp and can be downloaded from the Huawei Research Platform. Based on the data of 268 preschool children from the accuracy survey, the accuracy between the screen-time category from the HSVC records and the 24-hour diary according to the Bayesian classification of the testing set and training set were 0.96 and 0.93, respectively; moreover, the κ value of representativeness was 0.61.

Classification of Screen Content

The 7-day monitoring study ultimately collected 138.98 thousand screen records and 41,812 screenshot images. Based on previous studies and the Delphi method, screen content type was classified into the following six regulations.

- App function direction: entertainment videos, video games, tools, educational videos, and short videos.
- Suggested audience: General audience, parental guidance suggested (PG), parents strongly cautioned (PG-13), and restricted according to the film rating system formulated by the Motion Picture Association of America [26].
- Educational direction: Educational and noneducational content.
- Screen pace direction: The pace of content was defined as 2 episodes viewed for the number of times a complete change occurred (eg, from the living room to the stadium) according to a previous standard [18], and we categorized pace into fast-paced, medium-paced, and slow-paced content (switched more than 6 times per minute, 2 to 6 times per minute, and less than 2 times per minute, respectively).
- Screen interaction direction: Static, touch-enabled, and interactive for children and caregivers.
- Realistic or animated direction: The content corresponded to the program or game, which mainly included realistic content, animated content, and both realistic and animated content.

The specific classification procedures and standards are shown in Table S1 in Multimedia Appendix 1.

Developmental Screening

The Chinese version of the Ages and Stages Questionnaire, Third Edition (ASQ-3), which is a widely used, parent-reported screening tool, was used for developmental screening. The ASQ-3 comprises the following 5 domains and includes 30 items: communication (6 items), gross motor (6 items), fine motor (6 items), problem-solving (6 items), and personal-social (6 items) [27]. Each item is scored on a 3-point scale ranging from 10=yes to 5=sometimes to 0=not yet. The total ASQ-3 score is obtained by summing the corresponding item scores, with a higher ASQ-3 score indicating a preferable development level [28,29]. After validation via standardized testing of developmental (Bayley Scales of Infant Development) and intellectual (Stanford-Binet Intelligence Test–4th Edition) skills, the ASQ-3 was found to have moderate to high sensitivity (0.70-0.90) and specificity (0.76-0.91), as well as strong concurrent validity (r=0.85) and internal consistency (α=.51-.87) [30,31]. The ASQ-3 was released web-based through the Wenjuanxing platform. It included the filling instructions for ASQ-3. Parents were required to conduct evaluations on children in a quiet environment and then fill in the questionnaires themselves. We also provided contact information so that parents could give feedback in a timely manner and solve problems when encountering difficulties in filling out the questionnaires.

Covariates

Based on the results of univariate analysis of demographic characteristics, lifestyles, Ages and Stages Questionnaire (ASQ) scores, and each dimension (Table S2 in Multimedia Appendix 1), we respectively selected the indicators that had statistically significant associations with ASQ and its 5 dimensions as covariates and incorporated them into the regression models of ASQ and each dimension respectively, in order to evaluate the associations between screen exposure content and ASQ more accurately. In addition, we investigated children's screen exposure in kindergartens. The results of 70 questionnaires showed that the screen exposure in schools was background screen exposure (such as playing videos and music in the classroom during recess gymnastics time while children were doing sports outdoors). The median duration of background screen exposure was P_{50}=30 (20-30) minutes, and children rarely actively obtained information from background exposure. Therefore, this study did not include background screen exposure as a covariate in the analysis.

Caregiver-Reported Questionnaire

Based on the literature, the covariates in this study included child age, child gender, caregiver, maternal educational attainment, paternal educational attainment, monthly income, single child status, and health-related behaviors, including day sleep time, night sleep time, indoor physical activity level, outdoor physical activity level and screen control by caregivers.

A screen exposure questionnaire was used to measure screen time on all media to compensate for the inability of the HSVC to collect data from television, computers, and other nontablet media. The screen times for televisions, personal computers, smartphones, and tablets were derived from graded responses (0 minute, 1-29 minutes, 30-59 minutes, 60-120 minutes, or >120 minutes) to the question "How long does your child spend using TVs/PCs/cell phones/tablets on an average day?" The age at first screen exposure was derived from frequency responses (under the age of 1 year, 1-2 years, 2-3 years, or older than 3 years). The types of on-screen content were derived from ranked responses (eg, mainly educational or mainly entertainment or both educational and entertainment) to the question "What types of on-screen content is your child exposed to?" The response methods used for the type of on-screen content, namely, age restriction, animated direction, fast-paced, and touch-enabled, were similar to those used for educational direction. Caregivers' interactions with children when viewing programs and playing games are related to early development; thus, the use of co-viewing programs and co-playing games was derived from

XSL•FO
RenderX

frequency responses, which included seldom, sometimes, and often.

Statistical Analysis

Participant characteristics are presented as frequencies with percentages and as the means with SDs. First, we used descriptive analysis to show the demographic characteristics of the participants in the whole sample with questionnaire data and in the subsample with HSVC device records. Second, a 2-tailed Student *t* test and ANOVA were performed to explore the distribution of the total ASQ-3 score for the whole sample and the scores on the 5 domains according to demographic characteristics, lifestyle, screen time category of the 4 media types, screen use styles, and type of screen exposure content, as shown in Tables S2 and S3 in Multimedia Appendix 1. Then, 6 multiple linear regression analyses were performed to examine the associations between the total ASQ score and the scores on the 5 domains (dependent variable), screen time category of the 4 media types, screen use styles, and type of screen exposure content (independent variables) adjusted for age, gender, parental educational attainment, and monthly income (control variable; Table S4 in Multimedia Appendix 1). Furthermore, Spearman correlation analysis was performed to examine the univariate association between the total ASQ score and the scores on the 5 domains and between screen viewing time and exposure to different types of content according to the HSVC application, as shown in Table S5 in Multimedia Appendix 1. Finally, median regressions were used to examine the nonlinear correlation trend between the median score on the ASQ and median time of exposure to content according to the HSVC sample application, as shown in Table S6 in Multimedia Appendix 1. The estimates of the independent variables for the total ASQ score and the domain scores were summarized using regression coefficients (β) and 95% CIs. Statistical analyses were performed using R software (version 4.3.2; R Foundation for Statistical Computing).

Ethical Considerations

Before the participants underwent screen exposure monitoring and questionnaire surveys, we informed their parents (legal guardians) of the whole process of participation in the surveys as well as the benefits and risks involved, and the legal guardians signed the informed consent. This study conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Ethics Committee for Medical Research at the School of Public Health, Fudan University (IRB#2023-11-1088). When extracting data from the Huawei Research Platform and the web-based questionnaire library for analysis, all the data were deidentified, and an anonymous study ID was used as an identifier for each participant. In this study, we provided a gift of a paintbrush set, worth approximately US $15, to each child participating in the research.

Results

Participant Characteristics

As shown in Table 1, among a total of 535 children and 365 preschool children with tablet use, 298 (55.7%) and 205 (56.2%) were boys, and more than half of the participants' caregivers were their mothers (n=297, 55.5% and n=205, 55.6%, respectively). The majority of participants' parents had a bachelor degree (mothers: n=290, 54.2% and n=196, 53.7%; fathers: n=286, 53.5% and n=194, 53.2%). Most of the participants' monthly incomes were over US$ 1750 (n=309, 57.8% and n=202, 55.4%). Nearly half of the participants were only children (n=272, 50.8% and n=185, 50.7%). Only 50 (9.3%) and 33 (9.1%) of participants had insufficient sleep during the day, while 412 (77%) and 280 (76.7%) of participants had insufficient sleep during the night (less than 10 hours). Less than half of the participants reported insufficient indoor physical activity (209, 39.1% and 138, 37.8%) or insufficient outdoor physical activity (183, 34.2% and 120, 32.9%).

The daily median screen time on all media was 98.6 (60-65.5) minutes, and the screen time on tablets was 41.1 (0-107.2) minutes. The mean total score and score for each domain of the ASQ for the total sample and tablet sample were 269.3 (SD 33.33) and 269.89 (SD 30.75); 55.05 (SD 7.47) and 54.86 (SD 5.51) for communication); 51.54 (SD 10.39) and 51.61 (SD 10.12) for gross motor; 50.38 (SD 11.26) and 50.45 (SD 10.86) for fine motor; 56.61 (SD 6.92) and 56.82 (SD 6.01) for problem-solving; and 55.73 (SD 7.11) and 56.14 (SD 6.45) for personal-social, respectively. The participant characteristics and total ASQ and domain scores did not significantly differ between the 2 sample populations (P>.05).

[b]ASQ: Ages and Stages Questionnaire.

Associations Between Screen Exposure Type and ASQ-3 Scores

The univariate associations between demographic characteristics and lifestyle variables and ASQ-3 scores are shown in Table S2 in Multimedia Appendix 1. Age, gender, maternal and paternal educational attainment, and monthly income were associated with the total ASQ score and domain scores (*P*<.05). The results of the univariate association between screen exposure types and ASQ-3 scores are shown in Table S3 in Multimedia Appendix 1. Smartphone screen time, iPad screen time, education content category, animated or realistic content, co-viewing programs, and co-playing games were associated with the total ASQ score and the domain scores (*P*<.05).

Furthermore, as shown in Table S4 in Multimedia Appendix 1, the results of the fully adjusted linear regression model suggested that older age, compared with an age of approximately 34 months 16 days to 50 months 30 days, was more strongly associated with the personal-social score (β=2.29; 95% CI 0.02-4.56; *P*=.048 and β=2.79; 95% CI 0.75-4.83; *P*=.008). Male gender was negatively associated with the total ASQ score (β=–8.92; 95% CI –14.41 to –3.43; *P*=.002), fine motor score (β=–4.16, 95% CI –6.04 to –2.28; *P*<.001), and personal-social score (β=–2.52; 95% CI –3.71 to –1.33; *P*<.001). Comparing with no exposure to smartphones, the total ASQ-3 score, gross motor scores were negatively associated with the use of smartphones for less than 30 minutes (β=–8.62; 95% CI –15.58 to –1.67; *P*=.01 and β=–3.16, 95% CI –5.4 to –0.92; *P*=.01), from 30-60 minutes (β=–13.28; 95% CI –21.98 to –4.58, *P*=.003 and β=–4.52; 95% CI –7.32 to –1.71; *P*=.002) and for more than 60 minutes (β=–12.89; 95% CI –24.75 to –1.02; *P*=.03 and β=–4.71; 95% CI –8.54 to –0.88; *P*=.02). The duration of iPad screen time exceeding 1 hour (β=2.45; 95% CI 0.39-4.51; *P*=.02) had a more negative association with the fine motor score than did never using iPads. Engagement in co-playing games with caregivers was positively associated with the total ASQ-3 score (β=11.64; 95% CI 2.66-20.62; *P*=.01), communication (β=2.19; 95% CI 0.1-4.27; *P*=.04), and fine motor scores (β=4.76; 95% CI 1.68-7.84; *P*=.003), respectively.

Associations Between Screen Content and ASQ-3 Score

The Spearman correlation coefficients between the screen content and ASQ-3 scores based on the HSVC data are shown in Table S5 in Multimedia Appendix 1. The results showed that education content, pace, screen interaction, animated and realistic content, date, and screen time duration were associated with the total ASQ-3 score, fine motor score, problem-solving score, and personal-social score (*P*<.05).

Furthermore, the results of the median regression between screen content and the ASQ-3 score after adjusting for age, gender, monthly income, co-viewing programs, and co-playing games are shown in Table S6 in Multimedia Appendix 1. This study showed that the median total score on the ASQ-3 was negatively associated with screen time for noneducational content (β=–.055; 95% CI –0.148 to –0.006; *P*=.03), educational and noneducational content (β=–.042, 95% CI –0.081 to –0.007; *P*=.001), and fast-paced content (β=–.034; 95% CI –0.062 to –0.011; *P*=.049). The median gross motor score was negatively associated with screen time for PG-13 rated content (β=–.015; 95%CI –0.022 to 0.009; *P*=.03), educational and noneducational content (β=–.018, 95% CI –0.038 to –0.001; *P*=.02), static content (β=–.022, 95% CI –0.050 to 0.007; *P*=.02). This study also found that the median fine motor score was negatively associated with the time spent viewing G rated content (β=–.032; 95% CI –0.057 to –0.003; *P*=.006), PG rated content (β=–.020; 95% CI –0.036 to –0.007; *P*=.004), noneducational content (β=–.026; 95% CI –0.067 to –0.003; *P*=.01), both educational and noneducational content (β=–.020; 95% CI –0.034 to –0.0010; *P*<.001), fast-paced content (β=–.022; 95% CI –0.033 to –0.014; *P*<.001), static content (β=–.034; 95% CI –0.050 to 0.018; *P*<.001), animated content (β=–.038; 95% CI –0.069 to –0.001; *P*=.004), and screen use during the daytime (β=–.026; 95% CI –0.043 to 0.005; *P*=.005). This study suggested that screen time during the daytime and the time spent viewing touch-based content were negatively associated with the median

XSL•FO
RenderX

problem-solving (β=–.017; 95% CI –0.050 to –0.007; *P*=.03) and personal-social scores (β=–.016; 95% CI –0.033 to 0.003; *P*=.006), respectively.

Discussion

Principal Findings

Based on 7 days of monitoring data collected by the HSVC application from 2 representative samples of kindergarten children aged 34.5 to 66 months, we analyzed the association of different screen content types and the ASQ-3 score. We found that greater exposure to noneducational programs, fast-paced content, static, animated content, and screens during the daytime was associated with a lower median gross motor score and median fine motor score after controlling for covariates; moreover, greater exposure to noneducational programs and fast speed programs was also associated with lower total ASQ-3 scores.

The results showed that the mean (SD) total screen time and tablet screen time was 111.6 (140.9) minutes and 31.1 (42.5) minutes per day for children aged 34 months 16 days to 50 months 30 days, 172.7 (286.5) minutes and 41.2 (45.5) minutes per day for children aged 51 months 0 days to 56 months 30 days, and 159.3 (191.5) minutes and 42.4 (52.3) minutes per day for children aged 57 months 0 days to 66 months 0 days; these findings are similar to previous studies [32-34]. Whether educational programs are beneficial for early development in toddlers and preschool children is still controversial. This study also did not observe a positive or negative association; however, a significant finding was revealed that exposure to noneducational content was negatively associated with early development (total score on the ASQ-3) or fine motor in preschool children included in this monitoring study. Although there is little direct evidence of a relationship between the ASQ score and its domain scores, several longitudinal studies have shown that exposure to noneducational content before 3 years of age is negatively related to executive functioning and cognitive development at older ages, which are fundamental to the development of fine motor [35-37]. Another longitudinal study confirmed that screen use time was negatively correlated with fine motor skills 1 year after birth among children aged 3-6 years by cross-lagged path analysis [38]. The earlier cross-lagged conclusion may be explained by the results of this study, in which screen time in relation to categories containing both educational and noneducational content was still negatively associated with fine motor skills because it is inevitable to avoid noneducational content for preschoolers.

This study also revealed that exposure to fast-paced content (more than 6 times per minute) was negatively associated with the total ASQ score and fine motor score, while these relationships were not found for low-paced (less than 2 times per minute) or medium-paced (2 to 6 times per minute) content. Furthermore, the daily tablet screen time via tablet for fast-paced content (76.4 minutes) was far greater than that for medium- (8 minutes) and slow-paced content (9.1 minutes); namely, the predominant pace of the screen content for children aged 2-6 years was fast, which is consistent with the findings of previous studies showing that preschool children often view fast-paced content, with rapid screenshots and angle changes [18]. Several controlled experimental studies have shown that watching fast-paced television significantly impairs executive function immediately in children aged 4-6 years [17,18], and these test programs could appropriately reflect fine motor, problem-solving, communication, and personal-social skills.

Touch-enabled media technological devices (tablets and smartphones) play an important role not only because of their growing popularity among children but also because of their influence on early development; the use of tablets and smartphones was associated with decreased scores on the ASQ and its domains in this study, while other media did not show this relationship. Although exposure to touch-enabled content was not associated with the ASQ score, exposure to static content was negatively associated with gross motor and fine motor scores. There is some experimental evidence that toddlers can more readily learn from touchscreen devices than from televisions [39], possibly because the use of tablets is beneficial for motor development in preschoolers [40].

Animated content is widespread in children's media, and even realistic programs incorporate unrealistic elements. This study revealed that exposure to fantastic and both fantastic and realistic content was negatively associated with the fine motor score; these results are consistent with previous experimental studies [17]. In the working memory system, the content of screen stimuli is encoded, processed, and stored, while animated content is difficult to process because there is no stored schematic to use for interpreting animated content, especially for children's immature brains [17,41]. Engagement in such activities could lead to a decrease in local neurotransmitters in the lateral prefrontal cortex, subsequently resulting in a reduced availability of these neurotransmitters [42].

This study also revealed that general audience and PG content were associated with lower fine motor scores, while PG-13 content was associated with lower gross motor scores. A plausible explanation regarding this result may be that regardless of what the suggested audience of the screen content is, screen use can replace the time spent on physical activity [12,43]. A previous study revealed that the viewing of PG-13 and restricted content was associated with higher hyperactivity and aggression scores and a lower social skills rating. However, this association was not found in early childhood [44].

Limitations and Strengths

To our knowledge, this study was the first to examine preschool children's tablet screen time for different content types via 7-day intelligent monitoring records. By analyzing a sample of representative kindergarteners, we analyzed the associations between screen time and exposure to content types and early development. Several limitations of this study, however, should be mentioned.

First, because of the 7-day monitoring design, we could not calculate the causal relationship between screen exposure and early development. Longitudinal prospective studies and randomized clinical trials are needed to determine causal and cause-and-effect relationships regarding genetic and environmental factors. Second, this monitoring study could

XSL•FO
RenderX

accurately measure tablet screen exposure, while other media, such as televisions and smartphones, were measured via questionnaires on the frequency of different types of screen use; thus, the HSVC application should be appropriately used in other devices, such as smartphones or game machines. Third, although the participants were from developed provinces in China, we recruited kindergarteners from urban and suburban areas, which might influence the generalizability of the results to lower-income districts because all areas in Shanghai have relatively high incomes compared with the national average income level. Fourth, in the screen time assessment collected by questionnaires, a limitation was that no distinction was made between weekends and weekdays in the screen time question asked to families and the real-time screen time calculation, which may result in the existence of deviations in the estimation of the screen time. Fifth, although we informed parents to let children use tablets according to their usual habits at home, this process might still increase or change children's screen exposure behaviors to some extent. In future studies, we will explore ways to make parents accept the installation of intelligent monitoring technology on their own tablets and smartphones so as to restore children's screen exposure behaviors to the greatest extent possible. Finally, although this survey investigated the age intervals of children according to the age versions of ASQ-3, this study failed to investigate the specific dates of birth of children. Therefore, it may affect the rigor of statistical analysis to some extent.

Conclusions

This monitoring study showed that screen time associated with exposure to different content types was significantly associated with early development among preschool children, especially for noneducational, static, fast-paced, and animated content, which were associated not only with the total ASQ score but with gross motor and fine motor scores. The highest priority should be placed on limiting the aggregated screen time of noneducational, static, fast-paced, and animated content programs or games, which provide insight into defining high-quality screen content in guidelines.

Acknowledgments

The authors are grateful to Huawei for developing intelligent software for children's screen exposure. The authors also thank the excellent work of all kindergarten teachers from the Pudong New District and Xuhui District and all study participants. This work was supported by the National Natural Science Foundation of China (grant 82304260); China Postdoctoral Science Foundation (grant 2023M730626); and Shanghai Municipal Health Commission (grant GWV-10.2-YQ23). The 6th Round Three-Year Initiative Plan for Strengthening Public Health System Construction in Shanghai (project GWVI-6).

Abstract

Background: The pursuit of sleep quality has become an important aspect of people's global quest for overall health. However, the objective neurobiological features corresponding to subjective perceptions of sleep quality remain poorly understood. Although previous studies have investigated the relationship between electroencephalogram (EEG) and sleep, the lack of longitudinal follow-up studies raises doubts about the reproducibility of their findings.

Objective: Currently, there is a gap in research regarding the stable associations between EEG data and sleep quality assessed through multiple data collection sessions, which could help identify potential neurobiological targets related to sleep quality.

Methods: In this study, we used a portable EEG device to collect resting-state prefrontal cortex EEG data over a 3-month follow-up period from 42 participants (27 in the first month, 25 in the second month, and 40 in the third month). Each month, participants' sleep quality was assessed using the Pittsburgh Sleep Quality Index (PSQI) to estimate their recent sleep quality.

Results: We found that there is a significant and consistent positive correlation between low α band activity in the prefrontal cortex and PSQI scores (r=0.45, P<.001). More importantly, this correlation remained consistent across all 3-month follow-up recordings (P<.05), regardless of whether we considered the same cohort or expanded the sample size. Furthermore, we discovered that the periodic component of the low α band primarily contributed to this significant association with PSQI.

Conclusions: These findings represent the first identification of a stable and reliable neurobiological target related to sleep quality through multiple follow-up sessions. Our results provide a solid foundation for future applications of portable EEG devices in monitoring sleep quality and screening for sleep disorders in a broad population.

EEG; electroencephalogram; alpha oscillation; prefrontal cortex; sleep; portable device

Introduction

Sleep is a fundamental behavior closely related to daily life, and sleep quality plays a crucial role in human health [1-4]. Poor sleep quality often leads to various types of physical ailments [5-7]. Previous studies have conducted systematic research across different species (flies [8], rodents [9-14], cats [15,16], nonhuman primates [17], and humans [18-21]) to characterize the neural mechanisms across multiple stages of sleep. However, there are still many challenges in translating findings from animal experiments to humans, and sleep remains a complex concept. Our understanding of the relationship between sleep quality and the brain is still incomplete.

Electroencephalogram (EEG) is widely used in human studies to investigate sleep-related issues [22-24]. Different types of neural oscillations typically represent different stages of sleep [10] and are applied in various research areas. However, sleep quality is a subjective experience, and we hypothesize that this subjective perception stems from the brain's (eg, prefrontal cortex) daily neural responses. If this hypothesis holds, then under resting-state conditions, we should be able to identify certain neurobiological characteristics in the brain that are significantly associated with subjective sleep quality. Neural oscillations [25,26] are prominent biological features in EEG [27-31], such as α oscillations (8-13 Hz). Previous studies have explored the association between various types of neural oscillations and sleep quality [32-37]. However, much of the current research progress relies on single-session data collection, and there is a lack of follow-up studies. Hence, the stability of these associations remains unclear.

Therefore, in this study, to test the above hypothesis, we used a portable EEG device to collect resting-state EEG data (both open-eye and closed-eye conditions) from participants while also assessing their sleep quality (Pittsburgh Sleep Quality Index [PSQI]). The study involved a 3-month follow-up, with a total of 42 participants. In the first month, 27 people participated, followed by 25 people in the second month, and 40 people in the third month. A total of 22 participants completed all 3 sessions. We performed spectral analysis and correlation analysis on the data and further explored the periodic and aperiodic components of the spectra.

Methods

Participants

A total of 42 right-handed healthy individuals (19 females and 23 males; age: 34.9, SD 8.0 years) were recruited for this study, who were mainly from nearby communities through posters posted on the publicity walls. The sample size was calculated by G*Power software (Heinrich-Heine-Universität Düsseldorf), the sample size is calculated with 28 (given effect size of 0.65, α of 0.05, and β of 0.05 in the difference between means [matched pairs in eyes-open and eyes-closed state]). Hence, on average, we recruited around 30 participants each month. In the first month, 27 people participated, followed by 25 people in the second month, and 40 people in the third month. A total of 22 participants participated in all 3 months, 24 people participated in months 1 and 2, 25 people participated in months 1 and 3, and 23 people participated in months 2 and 3.

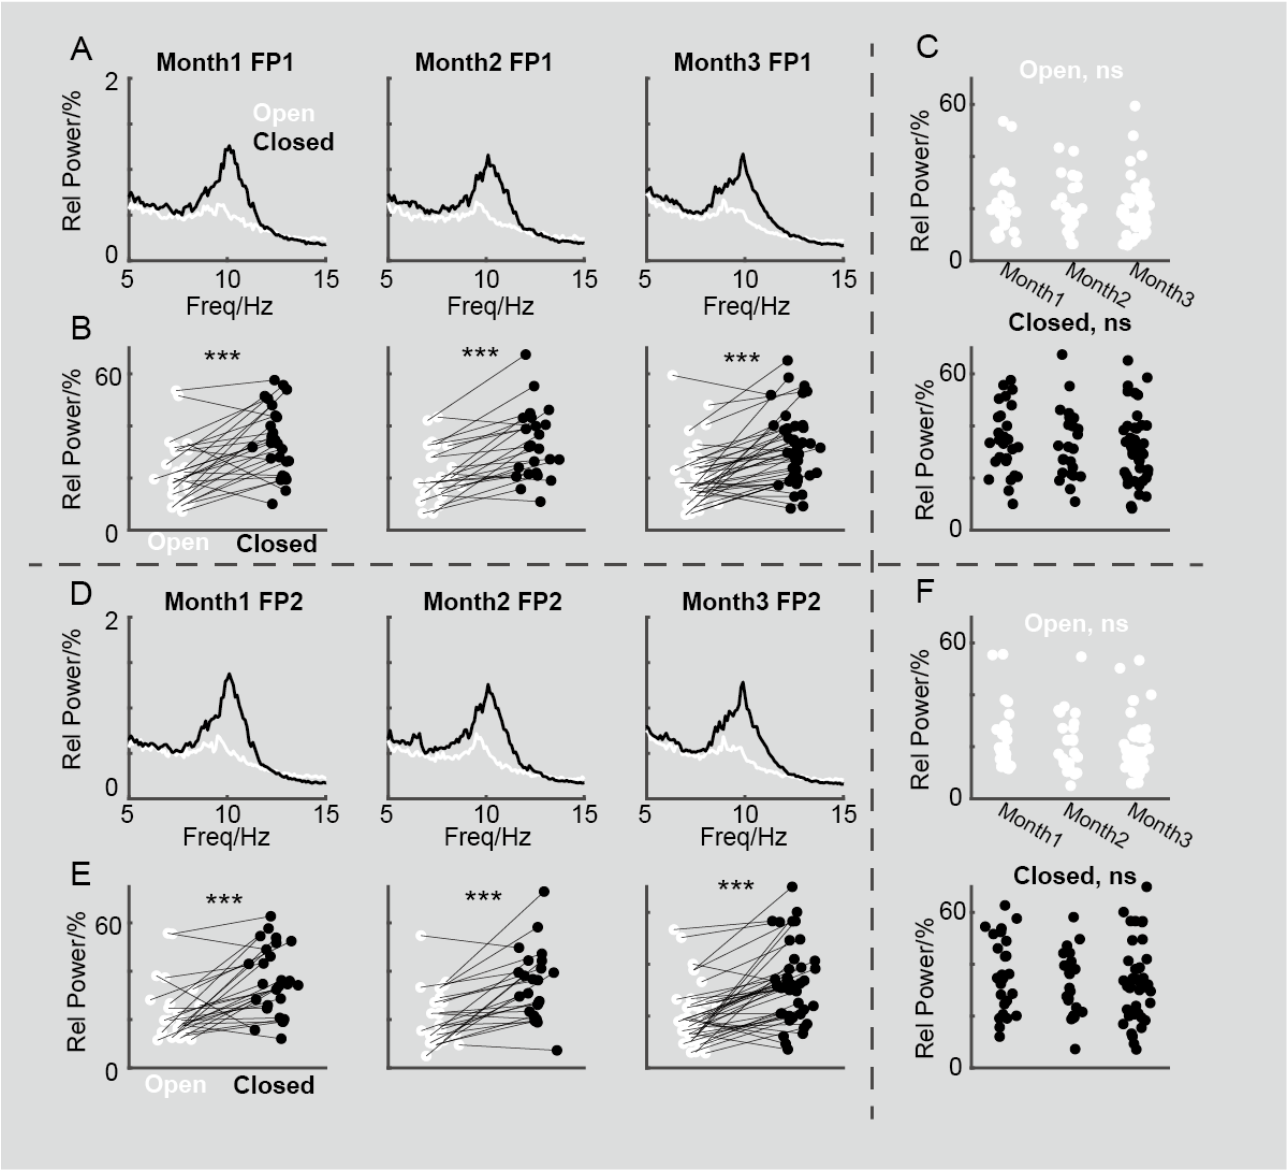
Ethical Considerations

Informed consent was obtained from all participants. All procedures were performed according to the National Institutes of Health Guidelines, and the research protocol was approved by the Shenzhen Institute of Advanced Science and Technology, Chinese Academy of Science (SIAT-IRB-240915-H0913). The study data are anonymous. The participant compensation is calculated based on the duration of the experiment (US $14.1 per hour) each month. The timer starts when the participant begins preparation for the experiment and stops when the experiment ends (after EEG data collection and completion of the PSQI questionnaire). The total duration of each experiment is typically 15-20 minutes.

Neurophysiological Recording

Each month, resting-state EEG in both open-eye and closed-eye states (counterbalanced order) was recorded (3 minutes each) using a 2-electrode (FP1 and FP2) setup (Brain Pro, Shenzhen Shuimu AI Technology Co Ltd, China). During the recording, the reference electrode was set at the earlobe, and real-time filtering was implemented with a bandpass filter with cutoff frequencies of 0.5 and 30 Hz. EEG data are wirelessly transmitted to a computer via Bluetooth. Each participant collected data in the morning, usually 2-3 hours after waking up. The sampling rate was 512 Hz and the scalp impedance was maintained below 10 kΩ for the electrode. Eye-blink artifacts were removed with unsupervised machine-learning algorithms [38].

Estimation of Sleep Quality



The PSQI [39] was used to evaluate the participants' sleep quality after monthly EEG recordings. The evaluation included several indicators: sleep quality, time to fall asleep, sleep duration, sleep disorders, daytime dysfunction, and total sleep score. Each factor is scored in 4 levels based on a score of 0-3. The cumulative score for each factor was summed to yield the PSQI total score (0-21 points), with a higher total score indicating poorer sleep quality.

Power Spectrum Analysis

The power spectrum of the EEG response was estimated using the multitaper method [40,41] (time-bandwidth product, 3; tapers, 5; Chronux toolbox, which was implemented using custom software written in MATLAB. Similar methods have been used in several studies in the field of biomedical science (eg, biological science [42-45], medical science [28,30], and public health [46-50]). Relative power can be defined as Equation 1 (Figure 1C).

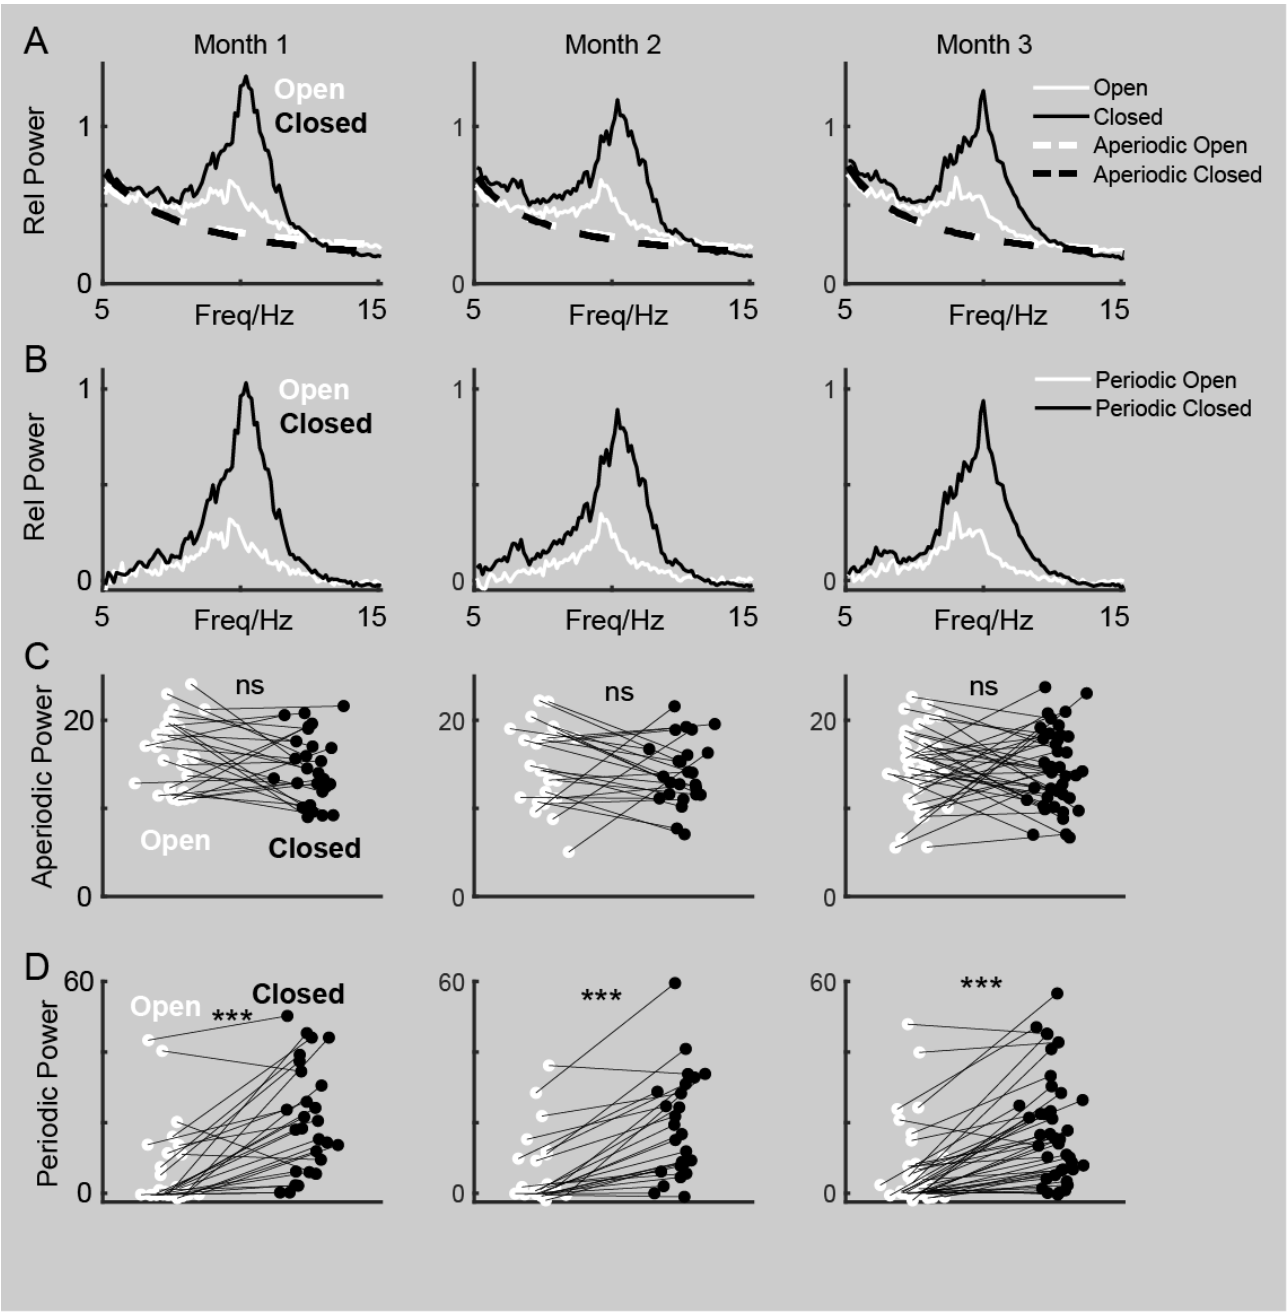
(1)

Descriptive Model for Dissecting Aperiodic and Periodic Activity

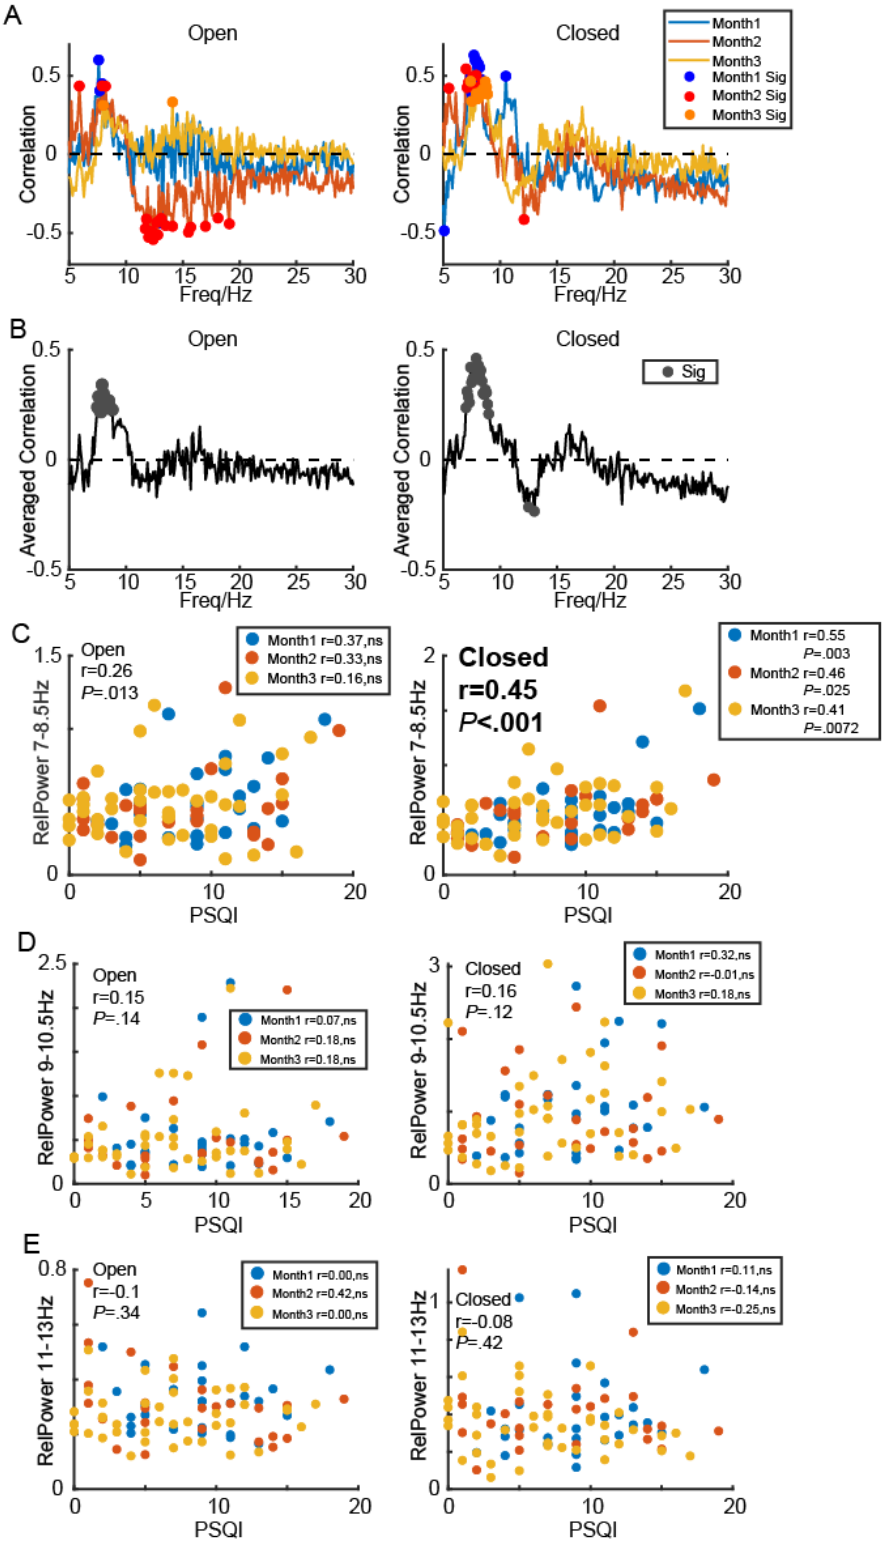
The power spectrum was considered as the sum of 2 components: aperiodic and periodic components. Aperiodic activity in the power spectrum refers to the frequency components of brain activity that do not follow a regular periodic or oscillatory pattern. It does not have a clear, repeating waveform or regular frequency. This activity is typically more broadband and can be described by a continuous distribution of power across a range of frequencies. Periodic activity in the power spectrum refers to frequency components of brain signals that exhibit a regular, repetitive oscillatory pattern over time. These oscillations have specific, identifiable peaks in the power spectrum at distinct frequencies. The aperiodic component of the power spectrum was extracted using a 1/f-like function (Equation 2), where a, b, c, and d represent the model parameters to be estimated. The periodic component was defined as the residual obtained by subtracting the aperiodic component from the raw power spectrum. This method has been used in the characterization of γ-band and α-band activities [51-53].



Statistical Analysis

In Figures 1B and 1E, a pairwise *t* test was examined to test the differences in relative α power between open-eye and closed-eye states in 3 months respectively. Similarly, in Figure 2C, a pairwise *t* test was used to test the differences in relative α

XSL•FO
RenderX



power associated with aperiodic activity between these states over the same time period. In Figure 2D, a pairwise *t* test was used to evaluate the differences in relative α power related to periodic activity between open-eye and closed-eye states in 3 months respectively. In Figures 1C and 1F, a *t* test with Bonferroni correction was used to compare the differences in relative α power among 3 months for both open-eye and closed-eye states. Additionally, in Figures 3A and 3B and Figures 4A and 4B, Pearson correlation analysis was conducted to measure the relationship between relative power at each frequency and the PSQI. Figures 3C-E and 4C-E display Pearson correlations between PSQI and relative power in low α (LA, 7-8.5 Hz), medium α (MA, 9-10.5 Hz), and high α (HA, 11-13 Hz) bands, respectively. Figures 5 and 6 illustrate the Pearson correlation between PSQI and relative power in aperiodic and periodic activity across the LA, MA, and HA bands, respectively.

Results

Overview

In this study, we aimed to explore the relationship between different frequency components of portable EEG and sleep quality, and whether a stable neurobiological feature strongly associated with sleep quality can be found through portable EEG. First, we collected a batch of portable EEG data from participants in the first month and identified some features as potential targets that are significantly correlated with sleep quality. However, it cannot be determined whether this result can be repeated and stable. Therefore, we collected 2 additional batches of data in the second and third months, with 22 participants from the 2 follow-up periods also participating in the first data collection. Through this, we verified that the significant relationship between the target feature and sleep quality can be repeated and stable. During these 3 months of data collection, other participants also participated in the data collection.

Stable Neural Recording Using Portable EEG Device in 3 Months

Our data collection lasted for 3 months, with EEG data collected once each month and the PSQI scale used to assess sleep quality. Before conducting the correlation analysis, we needed to verify the signal quality of the portable EEG device, which had 2 recording electrodes in the prefrontal region (FP1 and FP2). We performed frequency analysis on the EEG data collected each month (in both open-eye and closed-eye conditions), and after averaging at the group level, we observed an obvious peak around 10 Hz (FP1, Figure 1A; FP2, Figure 1D), representing α oscillations. The spectral shapes were similar, and the α oscillation intensity in the closed-eye condition was significantly stronger than in the open-eye condition across all 3 months (P<.001; FP1, Figure 1B; FP2, Figure 1E), which is consistent with previous research [54-57]. The relative power in the α band (8-13 Hz) showed no significant differences (P>.05) between open-eye and closed-eye conditions over the 3 months (FP1, Figure 1C; FP2, Figure 1F). Therefore, in subsequent analyses, we will average the spectra of the 2 prefrontal electrodes to represent the neural oscillatory activity in the prefrontal region.

Low α-Band Activity Significant Correlated With Sleep Quality

After ensuring the stability of the portable EEG signal recordings, we first performed a correlation analysis between relative power across different frequency bands (5-30 Hz) and PSQI (Figure 3A, with the first month represented in blue, the second in orange, and the third in yellow). Although significant correlations appeared in multiple frequency bands each month (as indicated by the solid-colored dots), one band consistently showed a significant positive correlation across all 3 months, specifically the LA band (around 7-8.5 Hz), both in open-eye (Figure 3A left) and closed-eye (Figure 3A right) conditions. When we averaged the correlation coefficients across the 3 months, this phenomenon became even more pronounced (Figure 3B).

Based on previous studies [54,58,59], the traditional α band (8-13 Hz) may contain several suboscillations, such as LA, MA, and HA. In the subsequent analysis, we fixed 3 frequency bands to correspond to LA (Figure 3C), MA (Figure 3D), and HA (Figure 3E) to explore the relationship between the relative energy of these α subbands and sleep quality. We found a significant positive correlation between the relative power in the LA band and PSQI, a result that did not appear in the MA and HA bands. This significance was stronger in the closed-eye condition (r=0.45, P<.001) than in the open-eye condition (r=0.26, P=.01).

Since the number of participants varied each month, Figure 4 presents a generalized group-level result across a broad population. However, 22 participants in our data set completed all 3 experiments, allowing us to examine whether this LA biomarker remains consistent within the same group. The results from this consistent group (Figure 4) were also aligned with those of the broader population. Our findings suggest that the increase in the relative power within the LA band is significantly correlated with a decline in sleep quality, a result that remained consistent across multiple follow-ups in a broad population.

Periodic Activity in LA Band Contributes to the Relationship Between

Furthermore, to more precisely characterize the different components in the spectrum, we used a classic descriptive mathematical model to decompose each participant's spectral data for each recording into periodic activity (Figure 2A) and aperiodic activity (Figure 2B). After decomposition, we found no significant differences in aperiodic activity between open-eye and closed-eye conditions (Figure 2C); the differences were primarily observed in the periodic activity (Figure 2D). These comparisons remained consistent across the 3 months of recordings (Figure 2A-D).

The next question we addressed was whether the significant correlation between sleep quality and LA intensity shown in the previous results was mainly contributed by the periodic or aperiodic components (Figure 5). After the decomposition, we plotted scatterplots to show the correlations between PSQI and both periodic and aperiodic activities in the LA, MA, and HA bands. We found that, in the LA band, periodic activity was significantly correlated with PSQI (P<.01) in both open-eye and closed-eye conditions, while aperiodic activity was not. In the MA and HA bands, neither periodic nor aperiodic activities were significantly correlated with PSQI (P>.05).

Additionally, the results from the consistent group of participants (Figure 6) were aligned with those from the broader population (Figure 5). Our findings suggest that the increase in periodic activity in the LA band is significantly associated with a decline in sleep quality, a result that remained consistent across multiple follow-ups in a broad population.

Discussion

Principal Results

Rapid screening for cognitive functions, such as sleep quality, requires identifying stable and reliable neurobiological targets.

XSL•FO
RenderX

Additionally, for convenience, portable EEG devices are essential for quick data collection. In this study, we explored the relationship between the neurobiological characteristics of portable EEG and sleep quality through multiple follow-ups for the first time. We found that, at the group level, the relative power in the LA band of the prefrontal region was significantly positively correlated with recent sleep quality. More importantly, this correlation remained consistent after several months of continuous follow-up, regardless of whether we considered the same population or an expanded cohort. Furthermore, through detailed decomposition of the spectrum, we discovered that the periodic components of the LA band primarily contributed to this significant correlation. Our research lays a solid foundation for using portable EEG for rapid screening of sleep-related issues, bringing this technology into households everywhere in the future.

Comparison With Prior Work

Sleep is a classic issue in the field of neuroscience [60-64]. During sleep, the EEG signals show specific patterns in different stages. In the beginning, high-frequency (β, γ, and α), low-voltage waves will gradually switch to higher voltage, slower waves (θ and δ), which are the feature patterns of nonrapid eye movement (NREM) sleep [18,20,65]. During NREM sleep, stages 1, 2, and 3 are classified depending on the EEG frequency and specific pattern. Spindles or bursting firing of neurons were found shortly after falling asleep. During rapid eye movement sleep, the EEG patterns were similar to those during awake [18]. In rodent studies, compared with humans, rats exhibit a more fragmented sleep pattern, with most research primarily focusing on rapid eye movement and NREM sleep stages [9,24]. During deep sleep, δ band activity often predominates, while during light sleep, θ oscillations are more prevalent. α activity typically appears in the resting state with eyes closed before sleep or during drowsiness with eyes open [66,67], which suggests that α oscillations themselves are a prelude to the sleep phase. If there is an abnormal α oscillation in the brain, it is likely to affect sleep [68,69], particularly during the process of falling asleep. However, it remains unclear how different sub-α oscillations are related to sleep quality, and this is the basis of our research. Therefore, our study does not focus on changes in neural oscillations during sleep but instead examines whether resting-state EEG has oscillatory characteristics that are significantly and consistently associated with subjective sleep quality. One possible intervention for improving sleep is yoga or meditation training, which has been shown in previous studies to significantly enhance sleep quality [70,71] and is also closely related to α oscillations [72]. Our research further refines this relationship by finding that, among various sub-α oscillations, LA band activity is significantly negatively correlated with sleep quality at the group level, while no such correlation was found with medium or HA band activity. This result could also be applied to the field of neuromodulation in the future. Improving sleep quality is a concern for many people, and previous studies have found that techniques like TACS can enhance sleep quality [65,73-75]. However, a fundamental question is how to select the appropriate frequency band for stimulation. Our research will provide important insights in this regard.

Mechanisms of Suboscillations in α Band Activity

Our study focused primarily on the α frequency band, as it is widely recognized in EEG research as a prominent biomarker with strong underlying neurobiological mechanisms [76-79]. However, our analysis also included other frequency bands, such as θ and β (Figures 3A and 4A). These bands, however, did not show stable and consistent significant correlations with sleep quality. Although the 8-13 Hz α oscillation band is narrow, it includes various suboscillations. Some studies suggest that these α suboscillations may have different origins [58,59] and are associated with different cognitive functions [80,81], but the finer neural mechanisms underlying these suboscillations remain unclear. From a dynamical systems perspective [82], the generation of different α suboscillations could be related to the differing time constants of excitatory and inhibitory neurons within the system, directly leading to frequency changes. This implies that different α suboscillations may have hierarchical relationships. It may also explain the discrepancies in previous studies regarding the mechanisms of α oscillations. For instance, some believe they originate subcortically (such as the pulvinar thalamus [83-86]), while others argue for a cortical origin (such as layer 5 of the cortex [87,88]). Our study used electrodes to record from the prefrontal cortex, but due to the relatively low spatial resolution of EEG, we cannot guarantee that the signal originates solely from the prefrontal cortex. It could also come from other brain regions or nuclei. Future studies will need to design more experiments to verify the relationship between different α suboscillations and various brain regions.

Potential Applications on Large-Scale Screening of Sleep Disorders in the Population

Currently, compared with other methods for capturing brain neural responses (functional magnetic resonance imaging, functional near-infrared spectroscopy, magnetoencephalography, and various invasive recording methods), functional magnetic resonance imaging and magnetoencephalography are expensive and have strict use conditions, while functional near-infrared spectroscopy lacks good spatial and temporal resolution. The most likely method to be widely applied in human communities is portable EEG. Although it does not have good spatial resolution, its temporal resolution and ability to reliably capture electrical signals make it particularly effective. This is especially true for the precise detection of α oscillations, which can be correlated with cellular-level or local circuit level of α oscillation mechanisms observed in animal experiments [89,90]. Just as we hoped for a rapid screening method to detect COVID-19 infections during the pandemic [48,91], today, we also desire a rapid screening tool for detecting cognitive function abnormalities in large populations. The results from current portable EEG research happen to meet this need, and our study provides strong support for this approach. In the future, we will design more experiments related to cognitive functions to fully leverage the advantages of portable EEG.

Limitations

One limitation of this study is that it only explored the relationship between the prefrontal region and sleep quality. However, other brain regions may also be associated with sleep quality. Due to the limited number of electrodes in the portable

XSL•FO
RenderX

EEG system, we were unable to address this question in this study. Therefore, in future experiments, we plan to develop portable EEG systems with more electrodes to further investigate this issue. Another issue is that there are various types of artifacts in EEG data. Since we are using a portable EEG device, efforts have been made to make it as portable as possible, which resulted in a reduction in the number of electrodes used. The device only has 2 electrodes, and therefore, the EEG data from this device is not suitable for traditional artifact removal methods, such as principal component analysis or independent component analysis [92,93]. We acknowledge that there may be potential muscle artifacts in the FP1 and FP2 channels, but these artifacts primarily affect the β or γ frequency bands. Our study, however, specifically avoids these controversial frequency bands and focuses solely on the α band, which is safe and uncontroversial. One more issue is that the source of EEG signals has always been a topic of debate [94,95]. While we observed this phenomenon in the prefrontal cortex, we cannot currently determine whether it originates solely from the prefrontal region without the involvement of other brain areas, this question could potentially be addressed by combining intracranial EEG with surface EEG for source localization. Last, this study does not argue that abbreviated analyses should replace more detailed methods universally, but rather that they offer a viable alternative for certain types of studies, especially those that prioritize efficiency. A deeper, more comprehensive analysis of EEG data can yield valuable insights as well, the trade-offs study between abbreviated and more comprehensive EEG analysis methods should be further compared in the future.

Conclusions

These findings mark the first identification of a stable and reliable neurobiological target—relative power in the LA band during the closed-eye state—associated with sleep quality across multiple follow-up sessions. Our results lay a robust foundation for future applications of portable EEG devices in monitoring sleep quality and screening for sleep disorders across diverse populations.

Acknowledgments

This work was funded by the National Natural Science Foundation of China (82201701) and the Beijing Municipal Hospital Research and Development Project (PX2021068), and we gratefully acknowledge the financial support and technical resources provided by Shenzhen Shuimu AI Technology Co Ltd.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to the policy of the institution but are available from the corresponding author on reasonable request.

Authors' Contributions

CH, XZ, and Y Lin conceived and designed the study. WX, JM, SH, Y Lia, WC, and FW contributed to data collection. CH and ZZ contributed to the literature search, data analysis, and interpretation of results. All authors contributed to writing the paper.

Conflicts of Interest

SH, JM, WX, FW, Y Lia, and WC are employees of Shenzhen Shuimu AI Technology Co Ltd. The authors declare that no other competing interests exist. The other authors declare no competing financial conflicts of interest to disclose.

Abstract

Background: The onset of the COVID-19 pandemic in early 2020 introduced unprecedented disruptions impacting the emotional well-being and daily routines of US youths. However, the patterns and persistence of these impacts over the pandemic's multiyear course remain less well understood.

Objective: This study examined longitudinal changes in affect and daily mobility patterns observed in adolescence and young adulthood from June 2016 to April 2022. The study aimed to quantify changes in youths' mood and daily routines following the pandemic's onset and in response to local COVID-19 case rates as well as the persistence of these effects over the pandemic's multiyear course.

Methods: Colorado-based adolescent and young adult twins (N=887; n=479, 54% female; $mean_{age}$ 19.2, SD_{age} 1.5 years on January 01, 2020) participating in the CoTwins study between June 2016 and April 2022 were followed via a smartphone app, which recorded persistent GPS location data and, beginning in February 2019, administered an abbreviated Positive and Negative Affect Schedule every 2 weeks. Nonlinear trajectories in affect and daily mobility over time and in response to local COVID-19 counts were modeled via generalized additive mixed models, while the magnitude and persistence of pandemic-related changes were quantified via linear mixed effects regressions.

Results: Between January and April 2020, participants experienced a 28.6% decline in daily locations visited (from 3.5 to 2.5; SD 0.9) and a 60% reduction in daily travel distance (from 20.0 to 8.0 km; SD 9.4). Mean positive affect similarly declined by 0.3 SD (from 3.0 to 2.79; SD 0.6), while, correspondingly, mean negative affect increased by 0.3 SD (from 1.85 to 2.10; SD 0.6). Though mobility levels partially recovered beginning in the summer of 2020, daily locations visited remained slightly below 2019 levels through the study's conclusion in April 2022 (standardized β=–0.10; P<.001). Average positive affect similarly remained slightly below (standardized β=–0.20; P<.001) and negative affect slightly above (standardized β=0.14; P=.04) 2019 levels through April 2022. Weekly county-level COVID-19 transmission rates were negatively associated with mobility and positive affect and positively with negative affect, though these effects were greatly weakened later in the pandemic (eg, early 2022) or when transmission rates were high (eg, >200 new cases per 100,000 people per week).

XSL•FO
RenderX

Conclusions: Findings demonstrate large initial declines in daily mobility, a moderate decline in positive affect, and a moderate increase in negative affect following the pandemic's onset in 2020. Though most effects attenuated over time, affect and mobility levels had not recovered to prepandemic levels by April 2022. Findings support theories of hedonic adaptation and resiliency while also identifying lingering emotional and behavioral consequences. The study highlights both youth's resiliency in adapting to major stressors while also underscoring the need for continued support for youth mental health and psychosocial functioning in the pandemic's aftermath.

Introduction

Individuals throughout the world faced widespread disruptions and uncertainty during the COVID-19 pandemic. From January 2020 to March 2023, the United States confirmed more than 100,000,000 cases and 1,100,000 deaths from COVID-19 [1]. Beginning in March 2020, many states closed schools and nonessential businesses and encouraged residents to minimize trips away from home [2]. Youths (ie, late adolescents and emerging adults) in particular faced unique stressors during the pandemic, most notably disruptions to developmental milestones, such as transitioning into college or the workforce, peer group formation, and parental separation [3-5], often with significant impacts on their mental health, including increases in rates of self-reported anxiety and depression symptoms [6-8].

Consistent with these mental health impacts, modest declines in positive emotional experiences and increases in negative emotional experiences following the pandemic's onset are widely reported, though stronger impacts have been reported for adolescents and younger adults, especially in response to stressful pandemic-related experiences [9-14]. While such findings have been widely replicated, studies of the pandemic's psychological impacts are frequently limited by measurement and study design concerns. Most lack pre–COVID-19 data, and report perceived changes in emotional well-being, which may be especially prone to recall biases in the context of traumatic events like the pandemic [15,16] rather than actual changes in emotional experiences before and after the pandemic's onset. Furthermore, such studies were generally collected at only a few time points, often during the first few months of 2020, limiting their ability to observe changes in well-being over the multiyear course of the pandemic.

Psychological theories of adaptation to stressful experiences offer different predictions on the persistence of pandemic-related distress. Hedonic adaptation theory [17] predicts that, following stressful life events, emotional well-being may initially be substantially impacted but will recover to a pre-existing "set point" over the subsequent months or weeks [18,19]. This theory predicts that pandemic-related impacts on emotional experiences gradually attenuated over subsequent weeks and months as individuals adjusted to the event. Contrastingly, theories regarding the psychological impact of traumatic experiences assert that sufficiently distressing events may have lasting emotional consequences, suggesting many individuals may have faced lasting distress in the pandemic's aftermath [20,21].

One response to the challenge of validly capturing pandemic-related impacts via retrospective self-report was the use of behavioral "proxy" measures, like smartphone-based GPS location data, for which prospective data were available and which did not use self-report [22]. Such data can capture features of daily routine mobility patterns, including their frequency, distance, duration, and regularity [23-26]. This research has identified widespread changes in mobility patterns following the pandemic's onset and the implementation of lockdown policies, including fewer locations visited and shorter travel distance, and frequently a gradual recovery toward prepandemic mobility patterns following the first few months of the pandemic [27-33]. Several studies found that mobility changes were moderated by factors like local pandemic severity and sociodemographic characteristics like age, race or ethnicity, and income levels [28,29,32,34-36].

Pandemic-related mobility disruptions are widely studied among adults, though little research has investigated effects on youth mobility. Youths are less risk averse than adults [37,38], experienced lower risk of severe illness from COVID-19 [39], and were likely differentially impacted by pandemic-related policies (eg, school closures). Hence, youths and adults likely experienced a different set of salient restrictions and motivations impacting their daily routines.

GPS location data are useful for identifying changes in daily routines, though they cannot capture the pandemic's psychological impacts. Such impacts are predominantly studied via self-report instruments. However, as previously discussed, the rapid onset of the pandemic precluded prospective data collection for many studies, leading much of the literature on COVID-19–related psychological impacts especially prone to recall biases. Ongoing longitudinal studies with prospectively measured psychological surveys, especially those conducted over multiple years before and during the pandemic, are key sources of such prospective data. Such studies are well suited to improve and expand upon the COVID-19 literature, allowing for the measurement of the pandemic's impact on psychological outcomes with greater robustness to self-reporting biases and greater information on the persistence of pandemic-related effects.

XSL•FO
RenderX

This study investigated the magnitude and persistence of changes in youth affect and daily mobility patterns following the COVID-19 pandemic, using GPS mobility data and biweekly affect surveys collected for up to 70 months between June 2016 and April 2022 from a sample of Colorado-based adolescent and young adult twins. These data are unique in that they pair multiple years of continuously collected intensive longitudinal behavioral surveys and persistent GPS location data, with data collection beginning years before and concluding years after the COVID-19 pandemic's onset, allowing for fine-grained analyses of changes in mood and daily routine both prior to and during the pandemic's multiyear course. Investigating initial pandemic-related impacts on youth affect and mobility and the persistence of these changes over subsequent years, this study aimed to inform ongoing efforts to both understand and mitigate the lasting consequences of pandemic-related experiences on youth mental health and psychosocial functioning.

We had 2 primary aims. First, to investigate the magnitude of COVID-19–related disruptions to youth daily routines, measured via GPS-based mobility measures, and emotional experiences, measured by biweekly surveys measuring positive and negative affect, and the persistence of these effects over the pandemic's multiyear course. Second, we estimated the effect of local pandemic severity (measured by the weekly incidence of county-level COVID-19 cases) on daily routine and affect as well as whether case count effects differed over the course of the pandemic.

Consistent with similar work in adults [32], we predicted sharp declines in measures of daily mobility in March 2020, following the implementation of COVID-19 mitigation policies in many US states, and a gradual return to prepandemic mobility patterns over the following months, as COVID-19–related restrictions eased, vaccines became available, and attitudes toward social gatherings grew more permissive. Similarly, we predicted moderate to large declines in positive affect and increases in negative affect in early 2020, with a return to baseline over the following months due to hedonic adaptation and increasing opportunities for enjoyment and social engagement with the loosening of pandemic-related restrictions. Finally, we predicted reduced mobility and poorer emotional well-being in areas with greater COVID-19 transmission rates and that this relationship would be strongest during the initial months of the pandemic, reflecting greater fear and uncertainty about the pandemic's impacts.

Methods

Participants

Potential CoTwins participants were identified from birth records maintained by the Colorado Department of Health and Human Services as twins between the ages of 14 and 17 years upon recruitment. Recruitment procedures included both English and Spanish language digital and physical advertising as well as phone-based recruitment by study research assistants. Participants in this study were 887 twins who, at the time of their initial intake visit, were between the ages of 14 and 17 years, enrolled in a Colorado high school, and owned their own Android or iOS smartphone device (see Table 1 for participant demographics).

Parents and children both provided informed consent and assent prior to participation, and the study was approved by institutional review boards at both the University of Minnesota and the University of Colorado, Boulder. Intake visits for the first 670 participants were conducted between April 2015 and October 2016 on the University of Colorado, Boulder campus. These participants were initially recruited to participate for 1 year with the opportunity to continue for an additional year. Participating youths and their parents provided demographic information and baseline youth or parent-report data during an initial in-person assessment visit, which included cognitive testing, interviews, and both youth and parent-report questionnaires [40]. Youth participants then completed routine surveys and provided GPS data via a smartphone app for the duration of their participation in the study. A second wave of recruitment occurred between October 2018 and July 2021, with participants agreeing to participate for an additional 3 years. Of the original 670 twins, 76.1% (n=510) participated in this wave, and 217 new participants were recruited. Due to COVID-19 university-mandated lockdowns, no intake visits occurred between February 2020 and February 2021, though new participants were still recruited at this time, completing both baseline and follow-up surveys remotely via the CoTwins smartphone app (Vrieze lab). Data collection was completed in April 2022.

Greater than $150,000	225 (25.4)
Declined to provide	164 (18.5)
Highest attained parent education, n (%)	
Less than high school	4 (0.1)
High school diploma or graduate equivalency degree	42 (4.7)
Some college or associate degree	230 (25.9)
Bachelor degree	310 (34.9)
Master degree or higher	249 (28.1)
Declined to provide	52 (5.9)
Age (years), mean (SD)	
Age on January 1, 2020	19.18 (1.54)

[a]Participants were 887 adolescent and young adult twins initially recruited as high school students in the state of Colorado who provided affect surveys and persistent GPS location data over multiple years between June 2016 and April 2022. Participant demographic information was collected via parent report during an initial in-person intake assessment.

Procedure

The CoTwins study's primary aim was to investigate the development of substance use and executive functions in adolescence and emerging adulthood. The study used a twin design to allow genetic and environmental influences on these behaviors to be quantified. Upon enrolling in the study, CoTwins participants completed an in-person intake visit on the University of Colorado, Boulder campus that included baseline assessments and the installation of the CoTwins smartphone app. This app was then used to administer regular self-report assessments and collect time-stamped GPS location data for the duration of the study. Study staff regularly reviewed questionnaire completion rates and GPS data collection and contacted twins to assist with technical issues as needed. Additional information on the CoTwins study procedure is available in both Alexander et al [23] and Freis et al [40].

Measures

Positive and Negative Affect

Positive and negative affect surveys were deployed to participants' smartphones once every 2 weeks via an abbreviated form of the Positive and Negative Affect Schedule (PANAS) [41,42]. The abbreviated PANAS consisted of 5 items assessing

XSL•FO
RenderX

negative affect and 5 items assessing positive affect. Example items include “indicate to what extent you have felt afraid over the past few days” (negative affect) and “indicate to what extent you have felt inspired over the past few days” (positive affect). Each PANAS item was answered on a 5-point scale from 1=very slightly to 5=extremely. The average past week positive and negative affect were both computed by taking the mean score of all the positive or negative items.

Daily Mobility Measures

Participant location was collected via the CoTwins smartphone app, installed on each twin’s personal phone. To limit battery drain, the “significant change” location application programming interface was used on iOS devices, such that a participant location was recorded each time the device registered a “significant” change in location (eg, a movement greater than roughly 100-200 m). On Android devices, the app was designed to record the participant’s location once every 5 minutes.

After visual inspection and data cleaning steps, which included removing duplicated, incomplete, inaccurately measured, or highly improbable locations (such as those implying participant movement speeds greater than 600 km per hour), locations were aggregated into points of interest, also called “staypoints,” which were locations where participants were estimated to have spent at least 30 minutes within a 200 m radius [43]. This was done to help standardize the number and meaning of GPS locations observed each day between Android and iOS participants or between participants living in urban or rural areas. All locations recorded outside the United States were removed from analyses. This allowed for harmonization with COVID-19 case count data, ensured consistent data quality and availability, and reduced possible confounding effects due to heterogenous policies, cultural environments, and atypical travel experiences. From an initial sample of 42.0 million unique GPS locations, data cleaning and aggregation procedures yielded a dataset of 2.1 million staypoints from 598,966 participant days.

Two daily mobility measures were computed from these staypoints: daily locations visited, defined as the number of staypoints recorded by a participant on a given day, and daily travel distance, the straight-line distance (in kilometers) between a day’s consecutively recorded staypoints. Travel days, in which the daily travel distance exceeded 500 km, were excluded from analyses to reduce the effect of outlying values. Additional information on the computation and measurement properties of these measures is available in Alexander et al [23].

COVID-19 Case Count

The Johns Hopkins Coronavirus Research Center provided daily data on the number of new COVID-19 cases recorded in each US county between January 20, 2020, and March 10, 2023 [1]. These were mapped to participants’ modal county each day (defined as the county where a participant recorded the greatest number of staypoints) to measure the degree of COVID-19 transmission in a participant’s environs. To help account for reporting artifacts (eg, counties reporting weekend cases on the following Monday), daily county-level case count was aggregated by week and standardized by the county’s population as weekly county-level case count per 100,000 people.

Date

A date term was used to model changes in affect and mobility over time both before and during the pandemic. This was included in statistical models as the number of days since January 20, 2020, the date of the first US COVID-19 case. Data collected prior to pandemic onset were assigned negative date values. Several follow-up analyses included a categorical effect of date to compare affect and mobility levels between January and April (corresponding to the first 4 months of the COVID-19 pandemic) in 2019-2022. Categorical date effects were restricted to data from January to April each year. This was done to account for seasonality effects, to isolate the especially large effect of the first months of the pandemic in early 2020, and to account for the lack of available data after April 18, 2022. This categorical date variable had 4 levels: indicating whether an observation was recorded from January 20 to April 30, 2019, from January 20 to April 30, 2020, from January 20 to April 30, 2021, or from January 20 to April 18, 2022 (the final day with available affect or mobility data in the study).

Model Covariates

Participant sex was coded as male (0) or female (1). Participant age on January 20, 2020 (included as a constant to reduce collinearity with date effects) was recorded in years. Weekday or weekend status was coded as weekday (0) or weekend (1). The operating system was recorded as either Apple iOS (0) or Android OS (1).

Missing Data

To help account for any systematic missingness in either the affect or mobility measures, a common challenge in intensive longitudinal research [44], we included the proportion of missing days of location data and the proportion of missed PANAS responses as model covariates. The proportion of missing days of location data was defined as the proportion of days between a participant’s first and last recorded location with no recorded staypoints. The proportion of missed PANAS surveys was computed as 1 minus the number of recorded affect surveys divided by a “theoretical maximum” number of affect surveys a person could have recorded, defined as the number of surveys a participant would have completed if they had completed 1 affect survey every 2 weeks between the date of their first and last survey response (rounded upward to the nearest integer to prevent fractional values).

Ethical Considerations

All study protocols were reviewed and approved by institutional review boards at both the University of Minnesota (STUDY00000748) and the University of Colorado, Boulder (14-0433), to ensure compliance with ethical standards for the treatment of research participants. Participants’ parents provided written consent, and participants provided verbal assent during the study recruitment and prior to their initial baseline visit. Data were securely stored on both local encrypted devices at the Universities of Minnesota and Colorado, Boulder, and on the remote encrypted data storage platform, Box. Data identifiers, including participants’ names, birthdates, and home addresses, were stored separately from their behavioral and GPS data, which were assigned anonymized individual and family

XSL•FO
RenderX

ID codes (to retain twin pair relationships in the data). Raw GPS data, which potentially allow for the inference of participant addresses and other significant locations, were deemed inherently identifying and were thus subject to additional privacy protections, including a separate participant ID, which could only be reconciled with participants' behavioral data using a securely stored ID mapping available only to the study investigators. Only location metadata, which were not inherently identifying, including the number of daily locations visited and daily travel distance, were considered in this investigation or paired with participants' behavioral data. Participants were compensated US $100 for their first baseline visit (plus reimbursement for any travel costs), up to US $150 (for completion of all surveys and complete GPS location data) per year of participation, and an additional US $100 after offboarding from the study.

Analyses

All models reported in the Results section are presented in Table 2 along with their corresponding interpretation. A variety of statistical approaches were considered to model changes in affect and mobility patterns following the onset of the COVID-19 pandemic and in response to local COVID-19 cases, including linear mixed effects models, structural equation–based latent growth curve models, and generalized additive mixed models ("GAMMs"). Mobility and affect data were correlated at the individual and family level, were collected frequently at unevenly spaced intervals, and were expected to exhibit highly nonlinear trajectories both over time and in response to local COVID-19 cases. We therefore determined that GAMMs were best suited to accommodate these correlated, time unstructured data and expected nonlinear relationships [45,46].

GAMMs were fit using the *gamm4* package in R (R Foundation for Statistical Computing) [46]. Models are presented in Table 2. Linear fixed effects included sex, age, smartphone operating system, and the proportion of missing location and survey data. Random intercepts of individuals nested within families and nonlinear "smooth" terms (fit via penalized regression splines) of either date or case count were also included. Models of daily mobility further included a covariate, indicating whether the observation was recorded on a weekday or a weekend. Fixed effects covariates of both month and season were considered to correct for possible seasonality in affect and mobility patterns, though these were ultimately excluded due to a lack of sufficient prepandemic affect data to infer typical seasonal trends (particularly for affect data, which were first available in February 2019), as well as collinearity between season, COVID-19 onset, and COVID-19 case counts. Smooth effects for date were fit using thin plate regression splines with k=35 basis functions, while smooth effects for case counts were fit with k=10 basis functions. Selection of the number of basis functions was supported via the k-basis dimension test to prevent model underidentification [46,47]. To assess whether mobility and affect were significantly increasing or decreasing at a given date or case count level, we computed first derivatives and 99% CIs of the smooth date and case count terms at 10,000 equally spaced points on the smooth's curve using the R package *gratia* [48,49].

Such GAMMs are useful for visualizing complex mean trajectories, but they consequently do not provide readily interpretable fixed effects coefficients for date or case count effects. Hence, complementary to these generalized additive models, we further fit linear mixed effects models, via the R package *lme4* [50], which included all fixed effects covariates included in the GAMMs, nested random intercepts for individuals nested within families, and both fixed and random effects of the year (see the Measures section) or local COVID-19 transmission rates. Similarly, to assess whether affect or mobility differed in their responsiveness to the local case count over time, we also fit mixed effects models with these same covariates along with a linear case count effect, year effect (where year indicated whether an observation was recorded in 2020, 2021, or 2022), and a case count×year interaction effect (see Table 2 for formal and text-based descriptions of each model). In an attempt to control for seasonal effects, only data collected from January through April in 2019-2022 (coinciding with the largest pandemic-related impacts in 2020) were included in these linear mixed effects models.

We considered several different strategies to reduce the impact of missing surveys and location data. The proportion of missing affect surveys and missing days of GPS location data for each participant were recorded as model covariates. Relationships between missingness, participant demographics, and affect and mobility measures were explored to identify possible attrition effects on outcomes. Additional strategies were considered, such as running analyses in a latent growth curve modeling framework with full information maximum likelihood estimation [51] or multiple imputation of missing data. However, given that predictor variables were only rarely missing, measurement occasions were irregularly spaced, and affect and mobility trajectories were highly nonlinear, we concluded that GAMMs remained better suited to modeling these relationships [45,46]. Similarly, multiple imputation was ultimately not used due to computational constraints and to the large number of missing days of data, implying a large fraction of missing information impacting the accuracy of imputation results [52]. Finally, additional biometric "ACE" decomposition models [53] were devised to investigate the extent to which COVID-19 experiences and corresponding affect and mobility changes were subject to genetic influences, though these models were ultimately not used after initial efforts demonstrated inadequate statistical power (eg, heritability estimates for local COVID-19 case counts that ranged from 0% to 100%) when estimating monthly and quarterly biometric variance parameters (identifying changes in genetic and environmental contributions over time, a significant difference between 2 or more variances, was further underpowered and typically requires thousands of twin pairs, rather than the hundreds available in CoTwins).

Table 2. Description of models, terms included, and related research aims[a].

Research aim	Model	Terms
Quantify mean changes in affect or mobility over time or across COVID-19 transmission levels.	$Y_{ij}=f_1(u_{1ij})+X_{1ij}\beta_1+Z_{1ij}b_1+\varepsilon_{ij}$ (1)	• Y_{ij}: Vector of participant *i* in family *j*'s affect or mobility • $f_1(u_{1ij})$: Smoothing function representing the nonlinear effect of date or local case counts on affect or mobility • $X_{1ij}\beta_1$: Linear effect β_1 of covariates X_{1ij} • $Z_{1ij}b_1$: Random effects (intercept) b_1 for individual *j* nested in family *j* • ε_{ij}: Random error term
Obtain parameter estimates for affect and mobility changes by year and across COVID-19 transmission levels.	$Y_{ij}=X_{2ij}\beta_2+Z_{2ij}b_2+\varepsilon_{ij}$ (2)	• Y_{ij}: Vector of participant *i* in family *j*'s affect or mobility • $X_{2ij}\beta_2$: Linear effect β_2 of covariates X_{2ij}, including an effect of year or local case count • $Z_{2ij}b_2$: Nested random effects b_2 of individual i within family *j*, including a random slope of year or local case count • ε_{ij}: Random error term
Test whether the effect of local COVID-19 case counts on affect or mobility is moderated by year.	$Y_{ij}=X_{3ij}\beta_3+Z_{3ij}b_3+\varepsilon_{ij}$ (3)	• Y_{ij}: Vector of participant *i* in family *j*'s affect or mobility • $X_{3ij}\beta_3$: Linear effect β_3 of covariates X_{3ij}, including an effect of year, local case count, and a year by local case count interaction term • $Z_{3ij}b_3$: Nested random effects b_3 of individual *i* within family *j*, including random slopes of year and case count • ε_{ij}: Random error term

[a]Description of each specific research aim, the corresponding statistical model, and definitions for each term within each model. Models were run using data provided by 887 adolescent and young adult twins initially recruited as high school students in the state of Colorado, who provided biweekly affect surveys and persistent GPS location data over multiple years via smartphone between June 2016 and April 2022.

Results

Descriptive Statistics

Descriptive statistics for affect and mobility measures are provided in Table 3. To assess the extent of reliability of the remote affect surveys over the multiyear duration of the study, Cronbach αs were computed at each assessment for participants' first 70 remote affect surveys. These αs ranged from 0.67 to 0.91 for positive affect (mean α=0.78) and from 0.75 to 0.89 (mean α=0.83) for negative affect, indicating that affect surveys were adequately reliable for the duration of the study. Intraclass correlation coefficients (single random raters) for the affect surveys over time were 0.52 for average positive affect and 0.55 for average negative affect, indicating that individuals' self-reported positive and negative affect varied between assessments but was moderately highly correlated with affect measurements at other time points. Mobility measure intraclass correlation coefficients were 0.14 for daily locations visited and 0.04 for daily travel distance, suggesting highly variable mobility patterns over the multiyear duration of the study. A greater percentage of both location data and affect surveys were missing for younger participants (β=–0.40 to –1.12; all *P*<.001) and Android users (β=0.97-44.05; all *P*<.001). Missing location data were significantly more prevalent in female participants (β=0.22; *P*<.001), while missing affect surveys were more common among participants (β=2.88; *P*<.001).

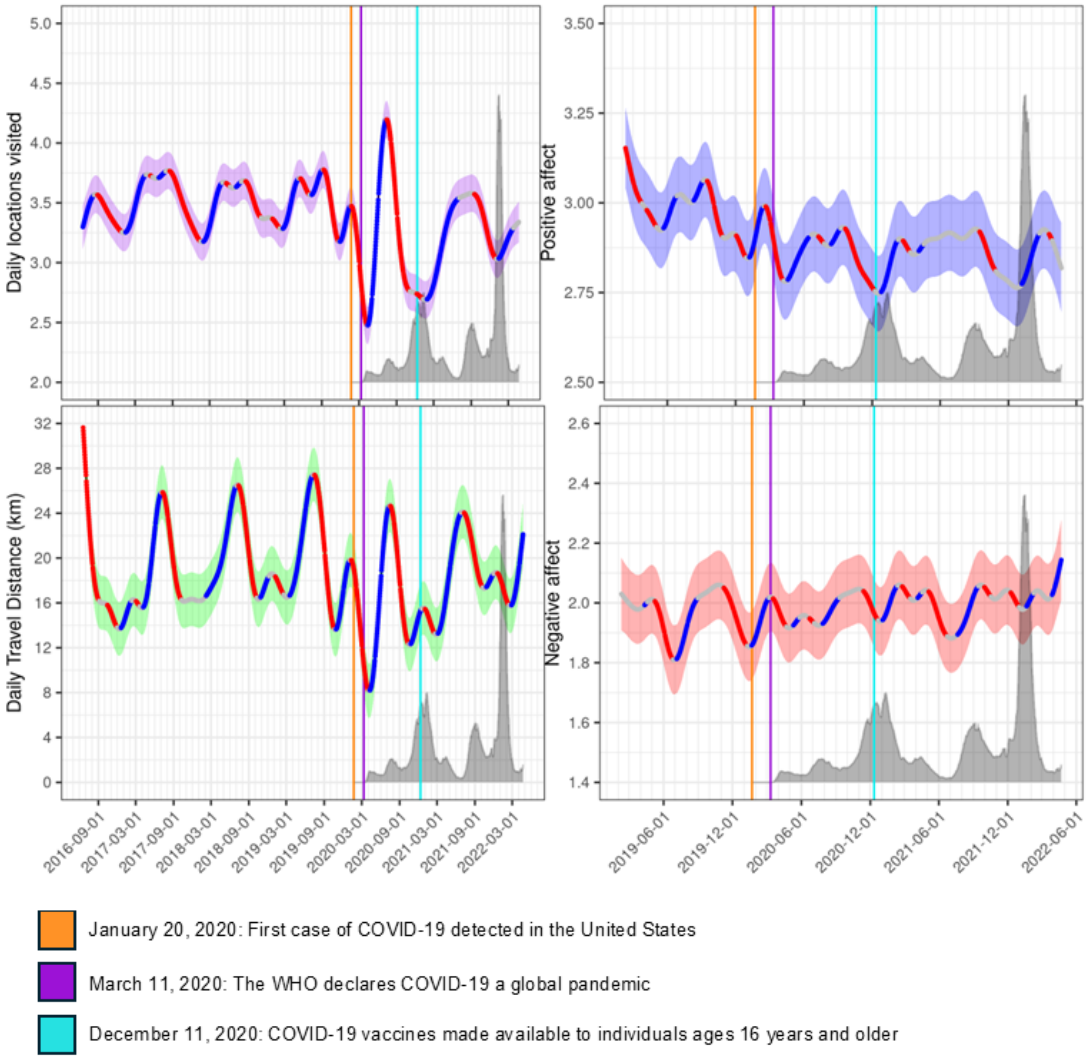
[f]The mean participant's portion of missing days of location data or completed affect surveys (see the Missing Data section for additional information on missingness).

Change Over Time and Pandemic Onset Effects on Affect and Mobility

Table S1 in Multimedia Appendix 1 reports the results of GAMMs of daily locations visited, daily travel distance, positive affect, and negative affect conditioned on a smooth date term, fixed effects covariates, and random intercepts of individuals nested in families. Significant fixed effects of covariates are reported in Table S1 in Multimedia Appendix 1 and included male sex (positive affect and negative affect), age on January 20, 2020 (locations visited and travel distance), weekend day (locations visited and travel distance), Android OS (locations visited, positive affect, and negative affect), percent missing location data (locations visited and travel distance), and percent missing affect surveys (locations visited and travel distance). Effective degrees of freedom tests of nonlinearity [47] indicated that date smooths were significantly nonlinear for all outcome variables ($F_{31.2,33.8}$=29.0-400.7; all P<.001), while k-basis dimension tests [47] suggested that basis dimensions were sufficient to prevent underfitting (k=0.98-1.01; P=.14-.81).

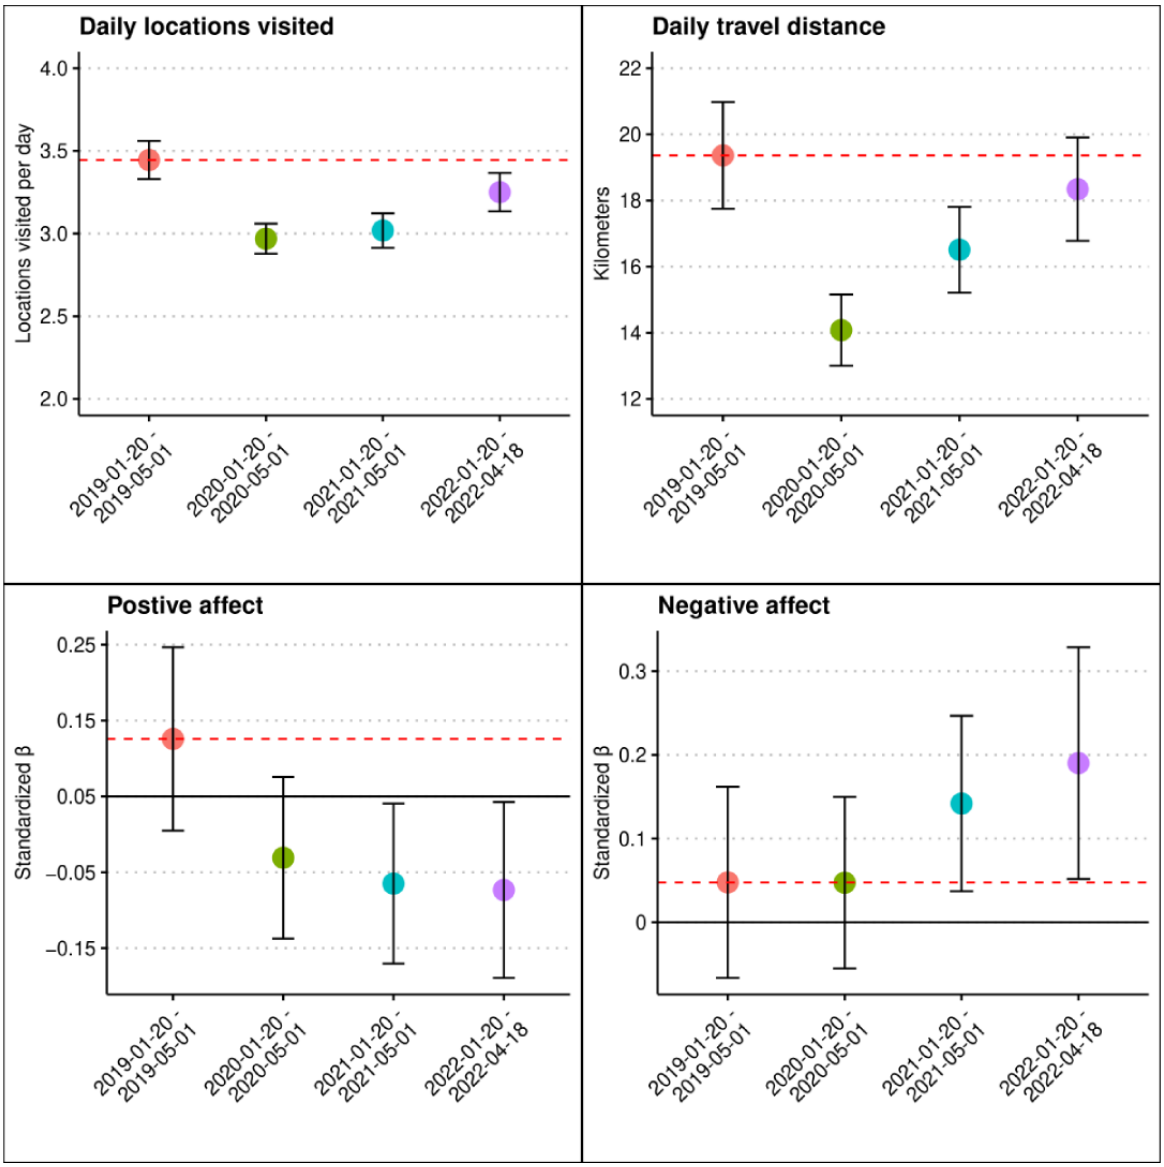
Smooth date effects (adjusted for fixed effects covariates), characterizing the change in mean affect and mobility levels over time, are presented in Figure 1. Prior to the onset of the pandemic in January 2020, mobility measures were largely stable over time, though with seasonal fluctuations of higher mobility in the summer months and lower mobility during the winter. During the first several months of the COVID-19 pandemic, from January to May 2020, both daily locations visited and daily travel distance fell sharply to their lowest levels observed during the study, falling by 29%, from 3.5 to 2.5 locations per day, and by 60%, from 20 to 8 km per day, respectively. Both mobility measures sharply rebounded during the summer of 2020, with daily locations visited increasing by 68% and daily travel distance increasing by 200%. They then plummeted between September and December, with mean daily locations visited falling from a high of 4.2 locations per day to a low of 2.8 locations per day and mean daily travel distance falling from a high of 24 km per day to a low of 12 km per day, coincident with a large outbreak of COVID-19 cases. Beginning in December 2020 and January 2021, roughly coincident with when COVID-19 vaccines were first made broadly available to adults older than 16 years of age, daily mobility measures steadily increased for much of 2021 and 2022, though with significant decreases of ~0.6 locations per day and ~8 km per day between September 2021 and January 2022, possibly reflecting the return of seasonal declines in mobility during the winter observed prior to the pandemic's onset. By mid-April 2022, participants visited an average of 3.3 locations per day with a daily travel distance of 28 km, both of which were similar to levels observed in the spring of 2019.



During 2019, positive affect significantly increased during the summer months and significantly decreased during the fall and winter months (all P<.01). In contrast, negative affect significantly decreased during the summer of 2019, significantly increased in the late summer and fall, and significantly declined in the late fall and winter (all P<.01). Average positive affect saw modest changes following the pandemic's onset in early 2020, initially increasing from a mean of 2.85 in January to 3.0 in February 2020 before declining to 2.79 by April 2020 (a decline of 0.3 SDs), its lowest observed level during the study period. Contrastingly, mean negative affect initially increased from 1.85 to 2.10 between January and March 2020 (an increase of 0.3 SDs) before declining slightly to 1.91 in April and May 2020, concurrent with the implementation of COVID-19 lockdown policies. Over the subsequent 2 years, positive affect remained consistently below prepandemic levels, though with significant fluctuations: declining significantly during 2 large COVID-19 outbreaks in the fall and winter of 2020 and 2021

XSL•FO
RenderX

and increasing significantly in late 2020 or early 2021 (coincident with the rollout of the COVID-19 vaccine) and in early 2022. In contrast, mean negative affect levels continued to modestly fluctuate over the subsequent months and years of the pandemic, though generally remaining slightly above levels observed prior to the pandemic's onset.



The results of mixed effects models quantifying differences in average affect or mobility from January to April in 2019-2022 are presented in Table S2 in Multimedia Appendix 1 as well as in Figure 2. Fixed effects covariate estimates were largely consistent with those obtained via GAMMs (Table S1 in Multimedia Appendix 1). Daily locations visited between January and April 2020, 2021, and 2022 were all significantly below mean levels observed between January and April 2019 (standardized β=–0.24 to –0.10; all P<.001). Similarly, mean daily distance traveled remained below January-April 2019 levels in January-April 2020 and 2021 (standardized β=–0.13 to 0.07; all P<.001), though they were not significantly different from 2019 levels in January-April 2022 (standardized β=–0.03; P=.29). Mean positive affect remained significantly below early 2019 levels in January-April 2020, 2021, and 2022 (standardized β=–0.20 to –0.16; all P<.001). Relative to early 2019 levels, the mean negative affect was not significantly different in January-April 2020 or 2021 (standardized β=0.00-0.09; P=.99-.07) but was significantly higher in January-April 2022 (standardized β=0.14; P=.04).

Figure 1. Pandemic onset effects on affect and mobility measures over time. Affect and mobility measures regressed onto a smooth date term (fit via penalized spline regression). Participants were 887 adolescent and young adult twins initially recruited as high school students in the state of Colorado who provided biweekly affect surveys and persistent GPS location data over multiple years via smartphone between June 2016 and April 2022. Colored bands indicated 95% CIs. Blue segments of the curve indicate areas where the derivative of the curve is significantly greater than 0 (P<.01), while red segments indicate areas where the derivative is significantly less than 0 (P<.01). For reference, the number of daily national COVID-19 cases is presented in dark gray behind each curve. WHO: World Health Organization.

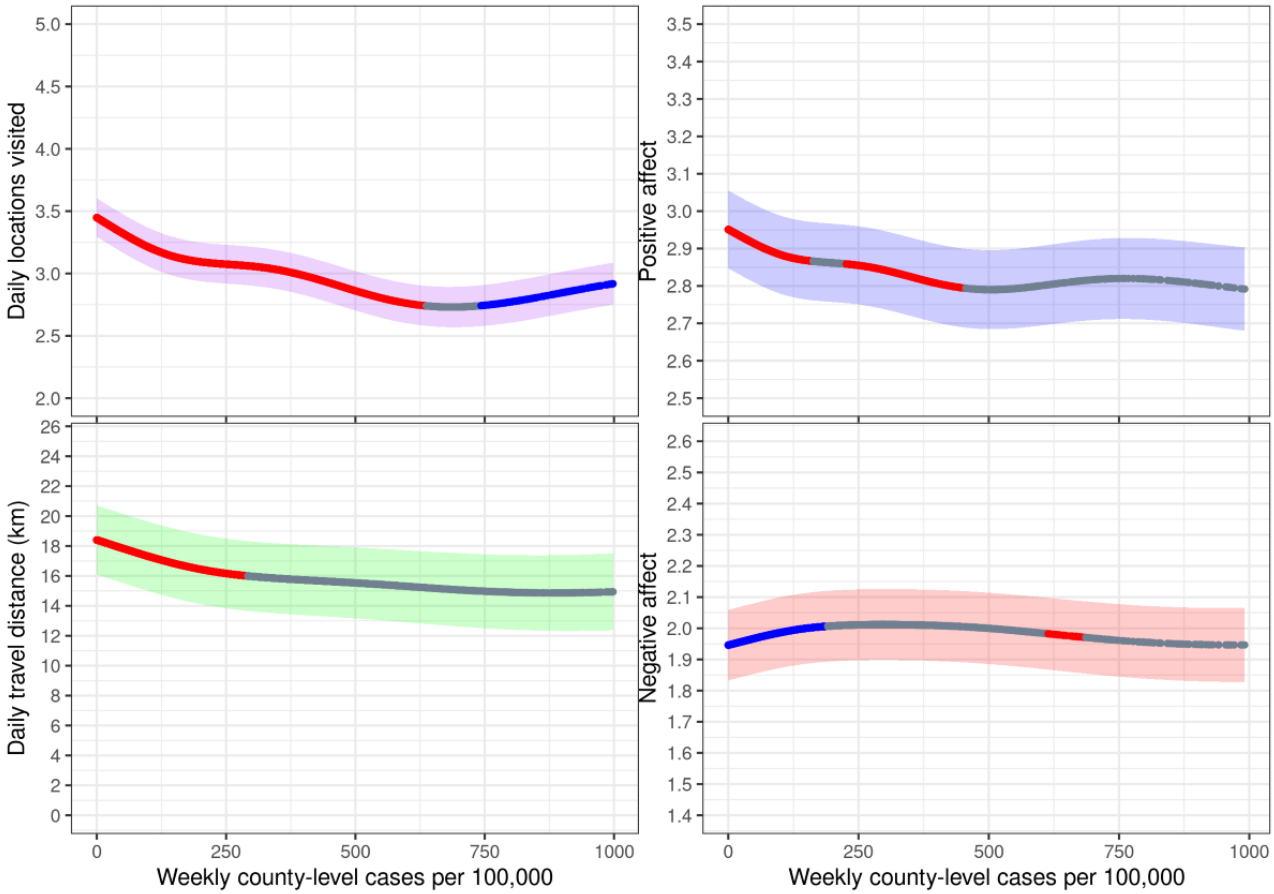
RenderX

Figure 2. Differences in average affect and mobility: January-April 2019-2022. Predicted affect and mobility values from January 20 to May 1, 2019-2022, according to linear mixed effects models. Estimates are derived from 887 adolescent and young adult twins initially recruited as high school students in the state of Colorado who provided affect surveys and persistent GPS location data via smartphone over multiple years between June 2016 and April 2022. Affect values are represented in SD units for interpretability. Red dashed lines denote the estimated level of each outcome in 2019. Error bars represent 95% CIs.

Local Case Count Effects on Affect and Mobility

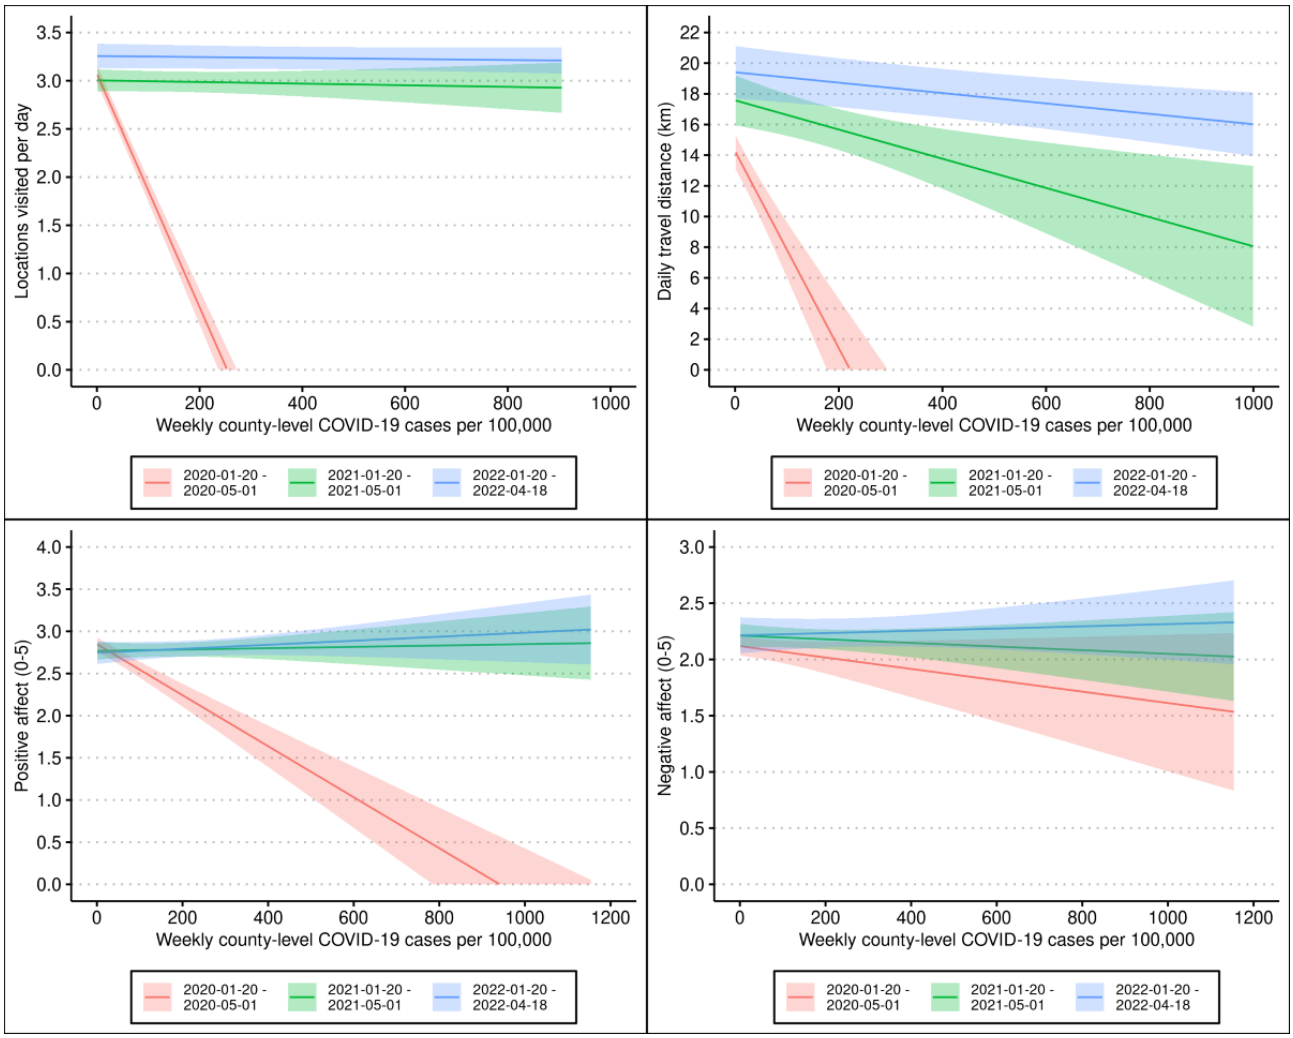
Results of GAMMs of affect and mobility measures regressed on a smooth effect of local past-week COVID-19 cases per 100,000, fixed effects covariates, and random intercepts of individuals nested in families are presented in Table S3 in Multimedia Appendix 1. Fixed effects covariates showed largely the same relationships to affect and mobility measures as in the smooth date GAMMs (Table S1 in Multimedia Appendix 1). Case count smooths were significantly nonlinear for all outcome variables ($F_{5.77,8.55}$=23.04-338.9; *P*s<.001). *k*-Basis tests were significant for negative affect (*k*-index=0.93; *P*<.001) and daily travel distance (*k*-index=0.97; *P*=.03), suggesting possible underfitting, though these models' effective degrees of freedom, 6.54 and 5.77, respectively, were deemed sufficiently different from *k*, 9.00, that it was not necessary to refit these models with additional basis dimensions [47].



The effects of local case count smooths, corrected for fixed effects covariates, on affect and mobility measures are presented in Figure 3. Increased county-level COVID-19 transmission was associated with small or moderate declines in positive affect and both measures of mobility, though increases above several hundred past-week county-level cases per 100,000 were generally not significantly related to either positive affect or mobility, with the exception of a modest but significant increase in daily locations visited at very high levels of transmission above 750 cases per participant. Correspondingly, negative affect exhibited a small but statistically significant increase of 0.06 SDs, as local COVID-19 incidence increased from 0 to 190 past-week local cases per 100,000, though further increases in local COVID-19 transmission generally exhibited nonsignificant relationships with negative affect.

Mixed effects models testing for interactions between local case count and the year in which the observation was reported are

XSL•FO
RenderX



presented in Table S4 in Multimedia Appendix 1 and visualized in Figure 4. Covariate effects were largely consistent with those observed in previous models. An increase of 100 additional weekly cases per 100,000 was associated with significantly greater reductions in daily locations visited, daily travel distance, and positive affect during 2020 than during 2021 or 2022 (standardized β=0.096-1.527; all P<.001) and with significantly attenuated reductions in negative affect during 2022 than during 2020 (standardized β=0.184; P<.001).

Figure 3. Local case count effects on affect and mobility measures. Affect and mobility measures regressed onto smooth past-week county-level COVID-19 cases per 100,000 people. Trajectories were estimated from biweekly affect surveys and persistent GPS location data provided by 887 adolescent and young adult twins initially recruited as high school students in the state of Colorado, who provided data via smartphone over multiple years between June 2016 and April 2022. Colored bands indicated 95% CIs. Blue segments of the curve indicate areas where the derivative of the curve is significantly greater than 0 (P<.01), while red segments indicate areas where the derivative is significantly less than 0 (P<.01).

XSL•FO
RenderX

Figure 4. Effects of local case count on affect and mobility measures moderated by date. The linear effect of COVID-19 case counts on affect and mobility between January 20 and May 01 in 2020 (the initial phase of the COVID-19 pandemic), 2021, and 2022 obtained via linear mixed effects models. Estimates are derived from linear mixed effects models of biweekly affect surveys and persistent GPS location data collected from 887 adolescent and young adult twins, who provided data over multiple years via smartphone between June 2016 and April 2022. Shaded regions indicate 95% CIs.

Discussion

Principal Findings and Comparison to Prior Work

This study investigated changes in affect and mobility patterns in American youths throughout the COVID-19 pandemic. As a nearly 6-year intensive longitudinal design, this study represents a lengthy and longitudinally rich investigation into the pandemic's psychological impact on youths.

Consistent with expectations, during the first pandemic months in 2020, we observed large decreases in participants' average locations visited per day and daily travel distance, a moderate decrease in mean positive affect, and a modest increase in mean negative affect. These changes are consistent with prior research conducted in adults [10,14,29,32,34,54], suggesting that youths exhibited behavioral and emotional changes similar to adults. However, we found that mean changes in affect during the first months of the pandemic were quite small; the average positive and negative affect between January 20 and May 1, 2020, differed by less than 0.2 SDs from average levels over the same period in 2019. These youths were, on average, resilient in the face of the pandemic's dramatic uncertainties.

Other studies have noted small or null changes in young adults' positive and negative affect following the pandemic's onset across varying national contexts, including in samples of college students in the northeastern United States [12], Germany [55], and China [56] and in a national web-based survey of British youths [57]. Taken together, both our results and the broader literature suggest that, across a wide range of cultural contexts, policy environments, and COVID-19–related experiences, average impacts on youth affect were likely small in magnitude even at the pandemic's onset. However, these small average impacts do not negate the possibility that youths exposed to particularly stressful life events during the pandemic remained vulnerable, as is suggested by several papers that find youths exhibited greater emotional lability in response to pandemic-related stressors relative to middle-aged and older adults [54,58,59].

Contrary to expectation, daily locations visited and positive affect remained significantly below and negative affect significantly above early 2019 levels through at least April 2022. This incomplete return to mean prepandemic levels more than 2 years after the pandemic's onset is more consistent with trauma-based theories on the psychology of disasters [20,21],

XSL•FO
RenderX

which predict lasting emotional impacts following traumatic experiences like natural disasters. Prior research has noted postpandemic increases in youth anxiety and depression symptoms [6-8] as well as broader secular trends of increasing youth mental health problems both before and during the pandemic [60,61]. Persistent postpandemic affective changes may be a further contributor to increasing youth mental health problems. That said, effect sizes are minimal if significant, and the lasting scar of the pandemic is of uncertain significance in the lives of these youths, at least on average.

These persistent differences—years after the pandemic onset—may reflect psychological scarring or may represent the ongoing spread of COVID-19 in April 2022. Yet, we found that the relationship between affect and case count greatly attenuated with time, showing almost no relationship with affect by 2022. Another explanation is that these differences represent developmental effects associated with participants transitioning from adolescence to early adulthood. However, existing research indicates that the transition from adolescence to emerging adulthood is associated with an increase in positive affect [5] and daily mobility [23] and a decrease in negative affect [5,62], opposite of our findings. Identifying the causes of these persistent affect and mobility differences 2 years after the pandemic's onset is likely beyond the scope of any single study; yet, speculatively, a combination of sociocultural changes, ongoing pandemic-related stressors, and lasting psychological impacts in the aftermath of the pandemic represents reasonable initial hypotheses for contributing factors.

Our hypothesis that local case count would be associated with reduced mobility and positive affect and increased negative affect was partially supported. These effects were strong earlier in the pandemic and decayed later that year and in the months surrounding the availability of vaccines. The reasons for this change could be myriad, including vaccine availability, the loosening of COVID-19 restrictions, a better understanding of the limited effects of infection on youths, or more simply changing attitudes toward the pandemic.

Limitations

Some limitations of this study are of note. Though we find clear changes in affect and mobility upon the pandemic's onset and extending over multiple years because of the complexity of the relationships between COVID-19–related policies, COVID-19 spread, and participant responses (as well as a lack of comprehensive data on COVID-19–related policy implementation), it was not possible in this study to disambiguate the specific features of the pandemic driving these changes, which likely included both individuals' reactions to the spread of COVID-19 and to state and local policies enacted to reduce the pandemic's severity (eg, school and business closures). Participants were adolescents or young adults and tended to be wealthy, educated, and White, albeit 15.6% (n=138) of Hispanic ethnicity, largely consistent with the ethnic diversity of Colorado. Generalization to other socioeconomic or ethnic contexts may not be straightforward. Indeed, generalizability may be particularly challenging for studies of pandemic-related behavior, as experiences of the pandemic varied considerably across geographic and sociodemographic contexts [31,34,35]. Twin participants are necessarily more similar to one another in their behaviors, personalities, and life circumstances than unrelated individuals. Hence, the effective sample size of the study is likely smaller than suggested by the study (N=887). While twin samples can be used to facilitate biometric analyses, such as the extent to which behavioral phenotypes and their relationships are subject to genetic influences, this sample lacked adequate statistical power to undertake these analyses in this study, at least as they pertained to the study's objectives to examine pandemic-related changes.

Missingness remains a particularly important challenge to the collection and interpretation of intensive longitudinal data, especially over multiple years. As expected in lengthy intensive longitudinal studies, both affect surveys and mobility data were subject to substantial missing data [63,64]. Efforts to characterize and limit this impact included covarying for the proportion of missing data in all models and reporting and investigating relationships between attrition, demographics, and model outcomes and covariates. We identified several significant relationships between attrition and demographics, affect, and mobility, suggesting that, though we partially account for missingness via a fixed effects covariate, this strategy may not have fully accounted for missingness effects, especially if missingness was influenced by unanticipated and unmeasured confounds [65].

Conclusions

In summary, we found substantial reductions in daily mobility and modest changes in positive and negative affect following the onset of the COVID-19 pandemic in early 2020, with reductions in daily locations visited and positive affect and increases in negative affect relative to early 2019 levels persisting through at least mid-2022. We further found that increases in local COVID-19 case counts were associated with reduced mobility and positive affect as well as increased negative affect, though with diminishing effects above several hundred cases per 100,000 and weaker effects in 2021 or 2022 relative to 2020. Lasting changes in affect and mobility do not appear to be well explained by the ongoing spread of COVID-19 during mid-2022 and instead may reflect numerous other factors, possibly including lasting pandemic-related harms, sociocultural changes, or disruptions to normative trajectories in social, emotional, professional, or educational development.

Abstract

Background: During the COVID-19 pandemic, information and communication technology (ICT) became crucial for staying connected with loved ones and accessing health services. In this scenario, disparities in ICT use may have exacerbated other forms of inequality, especially among older adults who were less familiar with technology and more vulnerable to severe COVID-19 health consequences.

Objective: This study investigated changes in ICT use, psychological and physical health, and social capital before and after the pandemic among the oldest old population (aged 80 years or older after the pandemic) and explored how internet use influenced these changes.

Methods: We leveraged data from the InveCe.Ab study, a population-based longitudinal cohort of people born between 1935 and 1939 and living in Abbiategrasso, a municipality on the outskirts of Milan, Italy. Participants underwent multidimensional assessment at baseline (2010) and after 2, 4, 8, and 12 years. We restricted our analysis to cohort members who participated in the last wave (ie, 2022) and who did not have a diagnosis of dementia (n=391). We used linear mixed models to assess the impact of COVID-19 and time on changes in social capital, physical and psychological health, and ICT use in a discontinuity regression design while controlling for age, sex, education, and income satisfaction. Then, we assessed the influence of internet use and its interaction with COVID-19 on these changes.

Results: COVID-19 had a significant impact on social relationships (β=–4.35, 95% CI 6.38 to –2.32; *P*<.001), cultural activities (β=–.55, 95% CI –0.75 to –0.35; *P*<.001), cognitive functioning (β=–1.00, 95% CI –1.28 to –0.72; *P*<.001), depressive symptoms (β=.42, 95% CI 0.10-0.74; *P*=.009), physical health (β=.07, 95% CI 0.04-0.10; *P*<.001), and ICT use (β=–.11, 95% CI –0.18 to –0.03; *P*=.008). Internet use predicts reduced depressive symptoms (β=–.56, 95% CI –1.07 to –0.06; *P*=.03) over time. The interaction between internet use and COVID-19 was significant for cultural activities (β=–.73, 95% CI –1.22 to –0.24; *P*=.003) and cognitive functioning (β=1.36, 95% CI 0.67-2.05; *P*<.001).

Conclusions: The pandemic had adverse effects on older adults' health and social capital. Contrary to expectations, even ICT use dropped significantly after the pandemic. Internet users maintained higher psychological health regardless of time and

XSL•FO

COVID-19 status. However, COVID-19 was associated with a steeper decline in cognitive functioning among internet nonusers. Policy makers may develop initiatives to encourage ICT adoption among older adults or strengthen their digital skills.

Introduction

Information and Communication Technology Use Among Older Adults in Italy

In the last few decades, the use of information and communication technology (ICT) has become pervasive and consistently more frequent at all ages [1,2]. The digitalization of public services has made it necessary for citizens to develop a certain degree of confidence in using digital devices [3]. In addition to population aging and contextual factors, this situation has contributed to an increase in the number of older adults who use ICT [4].

Indeed, the most recent Eurostat data shows that in 2023, the prevalence of internet use among the Italian population in the age group of 75 years or older has reached 25.7%, up from 13.1% in 2019. However, this strong increase in internet use among the oldest old segments of the population does not even remotely bridge the grey digital divide, that is, differences in technology adoption among the younger and oldest segments of the population. Indeed, internet use among individuals of all ages in Italy is 60 percentage points higher, reaching 87.7% in 2023 [5].

A growing number of studies have focused on different aspects of older individuals' use of ICT, including social media [6], smartphones [7], and computers [8]. Concurrently, the concept of the "digital divide," that is, the difference between those who have access to and use (effectively) digital media and those who do not [9], has become highly relevant in the literature on ICT use among older adults [10,11].

One key area of investigation is the relationship between digital inequalities, access to health services, and social capital formation and maintenance, which is often fueled by digital interactions. Given recent research [12] that has advocated for the adoption of a multidimensional perspective in the study of inequalities, this study focuses on the interrelation between digital inequalities and inequalities in health and social capital in the context of the COVID-19 pandemic using longitudinal data on the oldest old segments of the population (older than 80 years) living in the area of Abbiategrasso (Italy).

This study's context is particularly interesting in the context of research on older adults' habits and health, as well as the impact of COVID-19 on these dimensions. Indeed, Italy has one of the oldest populations in the world. Abbiategrasso is in Lombardy, a region that was among the first to be affected by the COVID-19 pandemic in the West, with dramatic consequences on the mortality rate, health, and social life of older adults.

Social Capital and ICT Use Among Older Adults

One of the main motives behind ICT use is the desire to stay connected with others. As a matter of fact, several existing studies on the issue have focused on the effects of ICT use on social capital, as Warburton et al [13] highlighted in their review. In this respect, one key challenge in this literature is the lack of consensus on the operationalization of social capital [14]. A pioneering work by Putnam et al [15] defined social capital as a set of networks, rules, and trust that yields mutual benefits. An alternative interpretation is the one by Bourdieu [16] who viewed social capital as the sum of potential resources that people can use when they are members of a group. Alternatively, Coleman [17] interpreted social capital as the construct that facilitates collective action within a social structure and distinguishes social capital within and outside the family.

Notwithstanding the aforementioned different interpretations of social capital, its relationship with ICT use is bidirectional. On the one hand, the possibility of staying connected with others is one of the main motives for the use of ICT among the general population and in old age. On the other hand, building and maintaining social relationships, especially intergenerational relationships, is crucial to helping older adults improve their digital skills. However, the vast literature on the relationship between ICT use and social capital in old age (for a review, see [13]) has numerous limitations due to a lack of consensus in the operationalization of social capital, lack of identification of mechanisms that drive the formation and maintenance of social capital in old age, and limited focus on the oldest old people (those aged older than 80 years).

An additional level of difficulty is related to the role of ICT in the formation and maintenance of social capital among older adults. With the increasingly widespread use of digital media, the very concept of social capital may change [18] to include forms of socialization other than physical meetings and in-person participation in groups. Accordingly, research on this topic has considered the role of ICT use in these new forms of social capital [19]. The influence of ICT in stimulating face-to-face interactions (and other forms of social capital in its "traditional" sense, as presented above) has been widely investigated [20,21]. In addition, research has explored the effects of ICT use on dimensions of social capital, such as social participation, social exclusion, and loneliness [22]. Nonetheless, additional research is needed not only to validate and replicate prior research results but also to reflect on how, in the postpandemic context, continuously evolving digital technologies and new forms of digital interactions may foster social capital.

Health and ICT Use Among Older Adults

The relationship between ICT use and health in older individuals seems complex. This is due not only to the multifaceted nature of health but also to the diverse ways ICT can be used in the context of health care, ranging from telehealth to the e-booking of medical appointments to web-based searches for health-related information.

Research on cognitive function shows that nondaily users of digital tools have overall lower cognitive performance than daily users [23], highlighting the beneficial effects of the use of digital tools on memory processes [24]. With respect to psychological health, research shows that people who use ICT experience fewer depressive symptoms and greater well-being [25-28].

The effects of ICT use on physical health in older adults have been studied less extensively. The literature mostly focuses on rehabilitation protocols using digital tools such as mobile apps. In this respect, the use of digital devices has proven to be effective in improving older people's autonomy in daily activities [29] and recovery from falls [30], which are likely to occur in old age [31].

Since multimorbidity is a relatively frequent condition in old age [32], studying the impact of ICT use on the management of related symptoms is a particularly interesting endeavor. Research has shown that the use of digital technologies by older people with two or more long-term health conditions can help them face day-to-day issues related to symptom management and self-reported perceptions of health conditions [33]. Overall, it seems that the use of digital technologies has positive effects on managing symptoms of coexisting pathologies and their perceived severity in old age.

The Impact of the COVID-19 Pandemic on Older Adults' Social Capital, Health, and ICT Use

The COVID-19 pandemic had a remarkable impact on all the dimensions of interest in this research: social capital, health, and ICT use. First, social distancing measures limited older people's ability to meet with family members and friends and hindered the possibility of participating in face-to-face volunteer work, associations, and activities within the local community [34].

Several activities have been moved to the digital sphere. Older people seem to have shifted traditional face-to-face relationships to nonphysical contact through video calls, social messaging, and social media [35]. In this respect, the pandemic seems to have accelerated the digitalization of society, and in fact, the importance of access to and the ability to proficiently use digital technologies in day-to-day activities from socializing to accessing health services. Indeed, recent research has documented a large amount of ICT adoption among the older people population during the pandemic. It seems that the shift from in-person to web-based activities during the most acute phase of the pandemic encouraged older adults to start or continue using digital technologies [36].

With respect to health, the COVID-19 pandemic clearly had important direct and indirect effects on the physical and mental health of older people. First, as widely documented, the severity of symptoms and the COVID-19–related mortality rate increase with age [37]. However, the pandemic may also have had a strong indirect impact on the health and well-being of older people [38,39]. In particular, the congestion of several nations' health services due to the unprecedented demand for health care resulted in delays in diagnostic and therapeutic medical visits for health conditions other than those strictly related to COVID-19. This circumstance may have led to medical conditions that required attention to be overlooked.

Other studies have examined the role of ICT use in recovery from the SARS-CoV-2 infection. On this matter, existing protocols, which are regularly under evaluation [40], show that the use of digital devices to recover from COVID-19 is favored by patients [41] and allows more personalized treatment plans [42]. While limited evidence exists to date, it is reasonable to anticipate a growing body of research in this area in the future.

Research Questions and Hypotheses

The evidence discussed above shows a multifaceted state of the art. While the number of studies investigating this topic has recently increased, existing research still has numerous potential shortcomings that this study aims to address.

First, limited research has been conducted on the effects of ICT use on health and social capital in adults aged 80 years and older, a rapidly growing portion of the population with unique health and social care needs. However, this topic has rarely been studied by researchers. We believe that this methodological choice might lead to an incomplete understanding of the issue. This research aims to fill this gap by studying the effects of ICT use with data from a sample of people around and older than 80 years.

Second, most existing studies were cross-sectional [43,44]. This type of research design is suitable for studying the associations between different dimensions, but it is not optimal for drawing conclusions on the direction of these associations. One limitation that affects the literature on the relationship between ICT use and health is a lack of assessment of the direction of the association between these two dimensions. While some of the aforementioned studies seem to suggest that ICT use drives better health outcomes, good health could be seen as a prerequisite (and a driver) for the acquisition of digital skills and digital technology adoption. Accordingly, longitudinal studies provide a favorable environment to establish the order of events (whether ICT adoption is associated with subsequent health outcomes), aiding in the assessment of causation [45].

Furthermore, analyzing prospective longitudinal cohort data is appropriate for capturing changes over time, which is crucial for studying a rapidly growing and dynamic phenomenon such as ICT use in older individuals.

Third, many studies on this topic have been conducted using qualitative research designs [46,47]. The advantages of these designs include a deeper investigation of subjective experiences and the possibility of investigating complex concepts without being bound to a predefined set of possible responses. However, qualitative studies lack standardized measurement, which is

XSL•FO
RenderX

crucial for tracking evolution over time and assessing the magnitude of effects.

Furthermore, most existing studies have focused on only some of the dimensions considered in this study, namely, the effects of ICT use on cognitive functioning [48] and social relationships [43]. However, to our knowledge, no study to date has explored the evolution of ICT use, cognitive functions, and social relationships concurrently over time while adopting a multidimensional and multidisciplinary approach.

Considering the above, this research's objective is 2-fold. First, this study assesses the effects of the COVID-19 pandemic on changes in the ICT use, social capital, and physical and psychological health of the oldest old population. Second, this study aims to investigate whether ICT use plays a role in mitigating the impact of the COVID-19 pandemic on the aforementioned dimensions.

Specifically, two research questions (RQs) guided the investigation presented in this work.

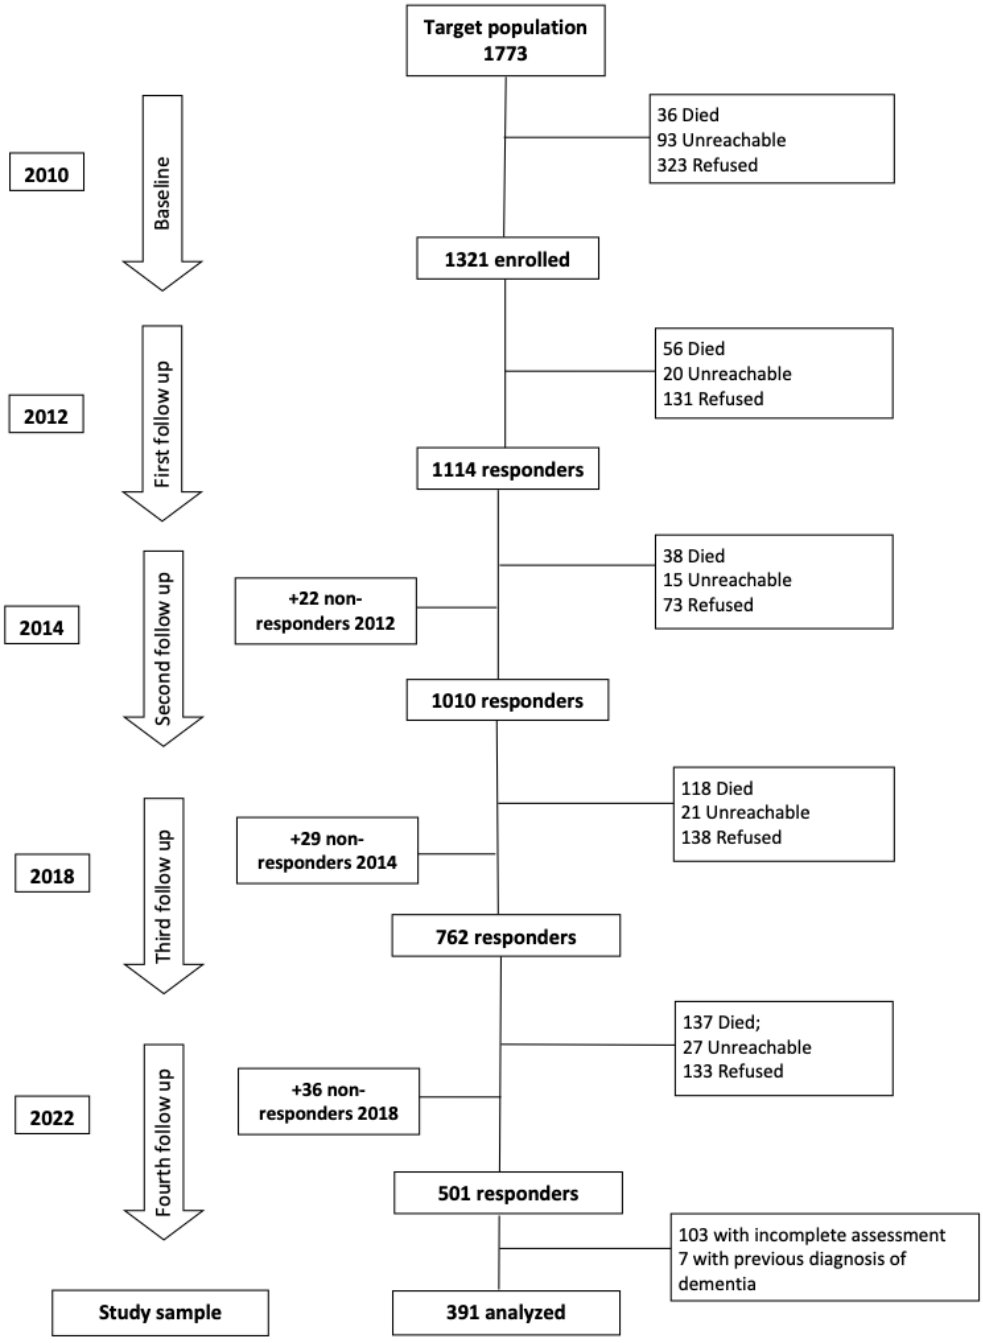
RQ1: Is there any change in ICT use, psychological and physical health, and social capital before and after the pandemic among the oldest old population?

RQ2: Do higher levels of ICT use have an impact on psychological and physical health and social capital over time in the context of the COVID-19 pandemic?

In light of current knowledge on this topic, we hypothesized that during the COVID-19 pandemic, health and social capital deteriorated while ICT increased. We also hypothesized that prepandemic ICT use is positively associated with social capital and health as it facilitates interpersonal communication, promotes social gatherings, and facilitates recovery from health issues.

Methods

Study Context



The data used in this research were collected as part of the study InveCe.Ab [49], a population-based cohort study conducted in Abbiategrasso, a municipality on the outskirts of the Metropolitan City of Milan (Italy). This study aimed to analyze the effects of aging on cerebral functions and the biological, social, clinical, and neuropsychological factors related to the onset of dementia. The data were collected at baseline (2010) and at follow-ups (2012, 2014, 2018, and 2022). The target population included older adults born between 1935 and 1939 who resided in Abbiategrasso on the prevalence day (November 1, 2009). Data in each wave were collected through a multidimensional assessment that included a social and lifestyle questionnaire, a medical visit, a neuropsychological evaluation, and the collection of anthropometric measures and blood samples.

Participants

The baseline sample of the InveCe.Ab study included 1321 people. Figure 1 shows the flowchart of study participation throughout the observation period (12 years, from 2010 to 2022). In this work, we analyzed data from a subsample composed of people who participated in the 2022 wave (after the COVID-19 outbreak), who were not previously diagnosed with any form of dementia, and who completed the full version of the questionnaire on social and lifestyle variables in the postpandemic wave in 2022 (n=391). We excluded sample members diagnosed with dementia from the analysis because we assumed that cognitive impairment could lead to measurement errors in self-reported health and social relationships, as well as endogeneity. Moreover, we excluded data collected through a shortened version of the social and lifestyle questionnaire since it did not include some of the variables considered in this study. We compared the main sociodemographic features at baseline between the study sample (n=391) and the InveCe.Ab participants who were not included, excluding 156 cases with incident dementia (from 2010 to 2018) and 8 with incomplete baseline assessment (n=766). They were comparable for sex (study sample=57% female, n=223; unselected=53%, n=404 female; P=.17), while the study sample was slightly younger (study sample mean 72.0, SD 1.3; unselected mean 72.2, SD 1.3; P=.02) and highly educated (study sample mean 7.4, SD 3.3; unselected mean 6.6, SD 3.3; P<.001).

XSL•FO
RenderX

Figure 1. Flowchart of the InveCe.Ab study and participants selection for the present investigation. At baseline, we enrolled 1,321 individuals from the target population (recruitment rate: 80.35%). At each follow-up, all alive InveCe.Ab participants still residing in Abbiategrasso were recontacted. Reasons for non-participation at each wave are detailed on the right side of the flow chart, while, on the left side, we reported the number of participants enrolled among those who did not participate in the previous follow-up.

Measures

In the following, we describe the measures used in the analysis.

ICT Use

ICT use was measured with the following three questions: "Do you use a mobile phone?" "Do you use a computer?" and "Do you use the internet?" The answer options were "yes," "no," and "I don't know." A derived variable was computed as the sum of the 3 questions.

Social Capital

To capture the multidimensional nature of social capital as much as possible, we computed two variables, namely, "Social

XSL•FO
RenderX

relationships" and "Cultural activities." The former was the product of the monthly frequency of in-person contact with family, friends, and colleagues, ranging from 0 (there are none or not living together) to 2 (we meet frequently [four or more times a month]), and self-reported satisfaction with these contacts, ranging from 0 (not at all satisfied) to 4 (very satisfied).

The "Cultural activities" variable was computed as the sum of cultural activities (in the last year) that entailed contact with other people. These included going to the cinema or the theatre, attending courses, volunteering, participating in associations or groups, and playing cards. Responses ranged from 0 (no involvement) to 2 (frequent involvement).

Physical Health

This dimension was quantified with the Cumulative Illness Rating Scale (CIRS) [50], a 14-category measure of clinical and functional acuteness. The first 13 elements of the CIRS scale were averaged to form the CIRS severity index.

Psychological Health

The assessment of psychological health comprised 2 dimensions: cognitive functioning and mood. The former was explored with the administration of the Mini-Mental State Examination, which is a screening test used to detect cognitive impairment [51]. The latter was assessed with the Geriatric Depression Scale, a self-reported measure of depressive symptoms in old age [52].

Time

The passing of time was measured with a variable that could take five values (2010, 2012, 2014, 2018, and 2022) corresponding to the years the InveCe.Ab waves took place.

COVID-19

The presence or absence of the COVID-19 pandemic in a specific wave was operationalized with a dichotomous variable that took a value of 1 in 2022 and 0 in all other years.

Sociodemographic Variables

Age at baseline, sex, education, and the perception of the adequacy of one's income were considered relevant confounding factors due to their established association with ICT adoption and use.

Statistical Analysis

Power

To determine the minimum sample size required for the analyses, we conducted a power analysis with G*Power (version 3.1.9.7) [53]. Under the linear multiple regression-random model group, we set the effect size at $\rho 2=0.05$, the significance criterion at $\alpha=0.05$, and the power at 0.80. Our sample size was sufficiently large to conduct the analyses, as it exceeded 309, which is the sample size required for conducting this study, based on the aforementioned calculations.

Data Analysis

Inferential analysis was conducted using R [54] and RStudio [55].

To investigate the effects of the pandemic on changes in the dimensions of interest (RQ1), we ran a series of linear mixed models (LMMs) with social capital, physical and psychological health, and ICT use as the outcomes and time and COVID-19 as the predictors in a discontinuity regression design [56]. Age, sex, education, and the perception of the adequacy of one's income were included as controls. Since we leveraged longitudinal data with repeated measures over the waves, we computed these models with random intercepts for the participants. To further assess the impact of the COVID-19 pandemic in a discontinuity regression framework, we compared the predicted values (PVs) of the postpandemic wave (2022) based on the prespecified models considering the first four waves (2010-2018) and compared them with the observed values (OVs) measured in 2022 with 2-tailed paired-sample *t* tests.

To address RQ2, we used the same approach but included: internet use and the interactions between internet use and time, and between internet use and COVID-19, as predictors, and time, COVID-19, age, sex, education, and the perception of the adequacy of one's income as covariates. The COVID-19 variable was conceived as a dichotomous variable that took a value of 1 in 2022 and 0 in all other years, while time was calculated as years from baseline. We adopted internet use as a predictor (rather than the abovementioned ICT use-derived variable) because web-based activities are likely to have a greater impact on the variables of interest than other forms of ICT use. Thus, this model included a time-varying predictor (internet use) and time-varying covariates.

Ethical Considerations

The study procedures were in accordance with the principles outlined in the Declaration of Helsinki of 1964 and the subsequent amendments. The InveCe.Ab study protocol was approved by the Ethics Committee of the University of Pavia on October 6, 2009 (Committee report 3/2009).

Results

Sample Features

Descriptive statistics are reported in Table 1. On average, the participants were 72 (SD 1.3) years old when the InveCe.Ab study started (2010) and had an average education level of 7.4 (SD 3.3) years. The majority of the sample was composed of female participants (n=223, 57%). Most people perceived their income as adequate or just enough. In the prepandemic wave conducted in 2018, approximately 7% (n=30) of the participants reported that they did not use any ICT devices, while approximately 22% (n=87) were internet users.

Table 1. Descriptive statistics of the sample at baseline (2010).

Variables	Study sample (N=391)
Sociodemographic characteristics	
Age at baseline (years), mean (SD)	72.0 (1.3)
Sex (female), n (%)	223 (57)
Education, mean (SD)	7.4 (3.3)
Perceived adequacy of one's income, n (%)	
Not adequate	30 (7)
Just enough	171 (43.7)
Adequate	190 (48.6)
Variables of interest, mean (SD)	
Social relationships	51.5 (16.8)
Cultural activities	6.6 (1.9)
Physical health (CIRS[a] severity index)	1.5 (0.3)
Cognitive functioning (MMSE[b])	27.8 (2.3)
Depressive symptoms (GDS[c])	2.3 (2.6)
Internet use, n (%)	51 (13)
Computer use, n (%)	72 (18)
Mobile phone use, n (%)	350 (89.5)

[a]CIRS: Cumulative Illness Rating Scale.

[b]MMSE: Mini-Mental State Examination.

[c]GDS: Geriatric Depression Scale.

Over the years, our sample has shown a steady increase in the percentage of internet users, rising from 13% (n=51) in 2010 to 16% (n=64) in 2012, 17% (n=67) in 2014, and eventually reaching 27% (n=106) by 2022. Meanwhile, the proportion of sample members who do not use ICTs has remained relatively stable, fluctuating slightly around 9% throughout the period, with specific figures of 8% (n=34) in 2010, 9% (n=38) in both 2012 and 2014 (n=36), and 10% (n=42) in 2022.

The Impact of the COVID-19 Pandemic

Table 2 shows the results of the LMM models used to evaluate the effect of COVID-19 on the longitudinal changes in the measures of interest.

COVID-19 appears to have reduced social relationships (β=–4.35; conditional R^2=0.58), cultural activities (β=–.55; conditional R^2=0.67), cognitive functioning (β=–1.00; conditional R^2=0.57), and ICT use (β=–.11; conditional R^2=0.77), and increased depressive symptoms (β=.42; conditional R^2=0.58) and multimorbidity (β=.07; conditional R^2=0.57). These effects were independent of time, sex, age, education, and perception of the adequacy of one's income.

These results were further supported by 2-tailed paired-sample *t* tests that tested the differences between the mean PVs on the basis of waves 1 through 4 and the mean OVs in wave 5. Such *t* tests showed that the participants' social relationships (mean difference=–4.37; *P*<.001; PV=48.66; OV=44.39), cultural activities (mean difference=–0.56; *P*<.001; PV=6.36; OV=5.80), cognitive functioning (mean difference=–1.01; *P*<.001; PV=27.49; OV=26.51), and ICT use (mean difference=–0.10; *P*<.001; PV=1.42; OV=1.32) after the spread of the COVID-19 pandemic were significantly lower than expected. Concurrently, multimorbidity (mean difference=0.07; *P*<.001; PV=1.62; OV=1.68) and depression (mean difference=0.43; *P*<.001; PV=2.97; OV=3.42) were significantly greater than expected.

[d]*P* values <.05.

The Role of Internet Use

Table 3 shows the results of the LMM models assessing the effect of internet use on the longitudinal changes in the measures of interest. Figure 2 shows the changes in the measures of interest across the assessment wave stratified by internet use.

We found that internet use had a significant effect on depressive symptoms (β=–.56; conditional R^2=0.58) while only a marginally significant effect (*P*<.10) was found for social relationships (β=2.91; conditional R^2=0.58) and cultural activities (β=0.28; conditional R^2=0.68). The interaction term between internet use and time was not significant, indicating that the effects of internet use on the measures of interest were stable across waves. However, the interaction between internet use and COVID-19 was significant for cultural activities (β=–0.73; conditional R^2=0.68) and cognitive functioning (β=1.36; conditional R^2=0.58), thus indicating that the effect of internet use on the measures of interest was modified by the pandemic, resulting in a steeper decline for internet users in cultural activities and a steeper decline in cognitive functioning for internet nonusers. A trend toward the significance of the interaction term was further found for physical health (β=–.07; conditional R^2=0.58). These effects were independent of time, COVID-19 status, sex, age, education, and the perception of the adequacy of one's income.

Table 3. Linear mixed models estimating the effect of internet use on social relationships, cultural activities, cognitive functioning, depressive symptoms, and physical health during the COVID-19 pandemic.

	Social relationships	Cultural activities	Cognitive functioning	Depressive symptoms	Physical health
Internet use					
Estimates (SE)	2.91 (1.67)	0.28 (0.17)	0.16 (0.22)	–0.56 (0.26)	0.03 (0.03)

Discussion

Principal Results

This study explored the impact of the COVID-19 pandemic on social capital, health, and ICT use among older adults (RQ1) and investigated the effects of internet use on older adults' social capital and health throughout time and in the context of the COVID-19 pandemic (RQ2).

With regard to RQ1, our results largely confirmed our hypotheses. In particular, the COVID-19 pandemic predicted reduced social capital in terms of social relationships and cultural activities that entail contact with other people. In addition, the results indicated that the pandemic was predictive of worsened physical condition. Consistently, we found that the pandemic predicted lower levels of psychological health, which was assessed through the Mini-Mental State Examination and Geriatric Depression Scale to capture different aspects of this dimension, namely, cognitive functioning and depression. With respect to ICT use, we expected that the COVID-19 pandemic would predict heightened ICT use. This hypothesis has roots in the body of knowledge showing that the pandemic yielded higher levels of use of digital technologies among older adults to stay connected with family and friends as a result of restrictions on in-person contact imposed by authorities. However, this hypothesis was not confirmed by the study results. In contrast, we found that the pandemic predicted a lower level of ICT use.

XSL•FO
RenderX

With respect to RQ2, the results partially confirmed the hypotheses. More specifically, internet use was found to be positively associated with older adults' psychological health. Our results confirmed this hypothesis. Internet use was inversely related to depressive symptoms over time. Additionally, we found that COVID-19 modified the relationship between internet use and cognitive functioning, with nonusers showing a steeper decline in cognitive functioning during the pandemic.

We also expected internet use to be predictive of higher social capital levels. However, internet use did not predict the number of cultural activities that involve contact with other people, such as attending courses and participating in associations. This may be because training and associateship still follow channels other than digital channels. Interestingly, the relationship between internet use and cultural activities was modified by the pandemic and showed a greater reduction in cultural activities related to internet use. During the COVID-19 pandemic, cultural activities that entailed contact with other people were significantly limited and not recommended, especially for older adults. We, therefore, speculate that the impact was greater for those who were habitually more involved in these kinds of activities. Although the participants' sociodemographic characteristics were accounted for in our models, we cannot rule out the possibility that internet users might have a sociodemographic profile that entails greater involvement in cultural activities that imply contact with other people. This is confirmed by internet users' higher levels in this dimension at the baseline, as Figure 2 suggests.

Moreover, internet use is not significantly correlated (at standard significance levels, ie, $P<.05$) with the level of social relationships, which is the other variable considered in this study for the assessment of social capital. This lack of association could be attributed to the fact that our measure of social relationships measures the frequency of in-person interactions with family, friends, and colleagues. Instead, internet use may have primarily facilitated increased communication through digital channels rather than face-to-face contact.

It should be noted, however, that the cut-off for statistical significance may be relaxed in our analysis in light of the relatively small sample size. As such, we consider marginally statistically significant the association between internet use and social relationship ($P=.08$) and cultural activities dimensions ($P=.09$).

Finally, internet use did not affect physical health. A possible explanation for this result is that the oldest-old segments of the population might use the internet mainly for communicating and may lack the skills required for digital access to health care services.

Comparisons With Previous Work

With regard to RQ1, our results align with the findings of previous studies on the negative effects of the COVID-19 pandemic on social activities [57,58]. In relation to physical health, our results are in line with those of other studies showing that older adults are more vulnerable than other age groups to COVID-19 symptoms [59]. This outcome is consistent with existing evidence regarding older people's health susceptibility to unfavorable consequences of viral infections [60]. Regarding the adverse impact of the pandemic on psychological health, our results reflect existing knowledge on the topic that highlights the adverse impact of the pandemic on older adults' health, such as lower cognitive functioning [61] and higher levels of depression [62]. With respect to the negative effect on ICT use, this finding might be explained by the return to in-person contact after the pandemic (in 2022, when our postpandemic data were collected) and the resulting lower levels of digital technology use by older adults. Another aspect should be considered when interpreting these results: given the unexpected and extraordinary nature of the pandemic, older people may have faced these challenging times with the skills and tools that they had already mastered, which did not necessarily include ICT devices. Indeed, in our sample, only 13% (n=51) of older adults used the internet at baseline, and 22% (n=87) used it in the last wave before the pandemic (ie, 2018). Rather than increasing ICT take-up, this age group may have turned to alternative sources of support. Such interpretation may be confirmed by the percentage of people who reported no use of ICT at all (around 10%, n=42) versus the percentage of ICT nonusers in 2018 (around 7%, n=30). Additionally, a possible decline in participants' physical and cognitive conditions may have led to a lower level of ICT use.

Moving to RQ2, the lack of statistically significant predictive effect of internet use on greater social capital is consistent with the groundbreaking study conducted by Kraut et al [63], showing that greater internet use in older age was associated with lower levels of communication with relatives in the household and reduction in the social circle size. This result was partially corroborated by the study by Zhao [64], which showed that people who use the internet for nonsocial purposes do not differ from internet nonusers when it comes to network size.

In relation to the effects of internet use on psychological health, our results are consistent with existing studies that show an overall positive effect of ICT use on older adults' psychological health [65]. The effects of internet use on cognitive functioning may have different interpretations. Several studies have shown that the use of technology fosters cognitive function since it requires several cognitive skills. For instance, Choi and Hart [66] reported that greater ICT use is associated with better performance in tasks related to episodic memory and executive functions. Similarly, Yeung et al [67] demonstrated that higher levels of ICT use are associated with increased working memory and visuospatial ability. On the other hand, we cannot exclude reverse causality, with increased cognitive decline due to COVID-19 explaining a reduction in internet use.

The lack of effects of internet use on physical health is consistent with prior research that highlighted the sense of helplessness and insecurity of older adults in accessing digitally led health care [68]. Such concerns are greater in rural areas, where older adults show even lower levels of digital literacy and technology acceptance associated with health care [69]; hence, these findings may also apply to the suburban context of Abbiategrasso. Further research should explore different types of internet use among the oldest old people.

RenderX

In summary, our results integrated the current understanding of the topic and added new layers of knowledge. The longitudinal research design allowed us to explore the medium- to long-term effects of the dimensions considered herein, namely, older adults' ICT use, social capital, and health. In addition, we studied the impact of the COVID-19 pandemic on these dimensions. Overall, the pandemic seemed to have a widespread negative impact on all of these aspects. Nonetheless, internet use seemed to predict better psychological health levels over time. Thus, internet use is a protective factor as people age, independent of sociodemographic characteristics and the effect of COVID-19. We also found that COVID-19 modulated the relationships between internet use and several cultural activities and cognitive functioning, although in opposite directions.

This work has several strengths. First, to our knowledge, this is the first work that analyses ICT use, social capital, and health in the oldest old population (aged older than 80 years) and is based on probability-based longitudinal data and multidimensional assessments collected over a 12-year period. In particular, medical and neuropsychological evaluations were combined with a self-reported appraisal of social activities and lifestyles to provide detailed information on each dimension.

Second, participants from a limited geographical area were included in this study, which limited the potential biases that might arise when the sample comprises individuals from different communities. Moreover, the fact that the data collection waves were conducted before and after the most acute phase of the COVID-19 pandemic allowed us to compare the impact of this event on the dimensions of interest.

Finally, by adopting a longitudinal design, we could observe ICT use at baseline and outcomes of interest at later time points. This allowed us to overcome one key methodological limitation of the literature, which has adopted cross-sectional designs and failed to identify the direction of associations between the use of technologies, health, and social capital.

Limitations

This research has several limitations. First, since this was an observational study and did not entail the experimental manipulation of the variables of interest, the exploration of the direction of causal inferences has a certain degree of ambiguity. Additionally, ICT was measured as a dichotomous variable that assessed only use or nonuse. A more refined approach would capture nuances in the frequency of ICT use. Furthermore, the longitudinal data were limited to one wave after the most acute phase of the pandemic. Future research may replicate this analysis should additional survey waves become available. Finally, the generalizability of our results to populations with different sociodemographic characteristics is limited. Future studies may address this issue by conducting similar research in different contexts and among populations with more heterogeneous characteristics.

Conclusions

This study assessed the impact of the pandemic on older adults' health and social capital and explored the role of inequalities in ICT access by leveraging a population-based sample of older adults followed by a multidimensional assessment over a 12-year period.

We believe our results will be of interest not only to the scientific community but also to policy makers by assisting them in assessing the importance of fostering ICT use in old age and drafting policy measures accordingly. First, the pandemic significantly affected multiple dimensions of older adults' lives. Measures aimed at aiding older people are particularly necessary in areas most significantly affected by the pandemic. As internet use seems to have beneficial effects on psychological health in older adults, policy makers may develop initiatives that encourage the adoption of digital devices among older adults or strengthen their digital skills. Such initiatives may include but are not limited to, intergenerational educational programs through which young adults act as "cyber tutors" for older people [70,71] and courses to improve digital literacy in old age [72].

This work seeks to enrich the current body of knowledge on the effects of ICT use on older adults' social capital and health. This study provides direct evidence on the longitudinal trajectory of these relevant dimensions in a population-based sample of older adults residing in a specific context during the COVID-19 pandemic. Future research may address the limitations of this study and further develop a thorough understanding of these rapidly changing topics.

Acknowledgments

We are grateful to Fondazione Serpero which supported data acquisition for the InveCe.Ab fifth wave. We thank Prof Valentina Pacetti for her insightful contributions to the operationalization of social capital. This work has been supported by Fondazione Cariplo (grant 2022-1686).

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

AGaia conceived the study and acquired funding for the present work. LGV had a key role in data management, performed the analysis, and drafted the manuscript. ER contributed to the study design, and coordinated and supervised research activities. MR contributed to the study design and planned and supervised data analysis. AGuaita provided resources for data acquisition and

Abstract

Background: Health inequalities among older adults become increasingly pronounced as aging progresses. In the digital era, some researchers argue that access to and use of digital technologies may contribute to or exacerbate these existing health inequalities. Conversely, other researchers believe that digital technologies can help mitigate these disparities.

Objective: This study aimed to investigate the relationship between the digital divide and health inequality among older adults and to offer recommendations for promoting health equity.

Methods: Data were obtained from the 2018 and 2020 waves of the China Health and Retirement Longitudinal Study. Physical, mental, and subjective health were assessed using the Activities of Daily Living (ADL) scale, the Instrumental Activities of Daily Living scale, the Mini-Mental State Examination scale, and a 5-point self-rated health scale, respectively. The chi-square and rank sum tests were used to explore whether internet use and access were associated with health inequality status. After controlling for confounders, multiple linear regression models were used to further determine this association. Sensitivity analysis was conducted using propensity score matching, and heterogeneity was analyzed for different influencing factors.

Results: The 2018 analysis highlighted widening health disparities among older adults due to internet access and use, with statistically significant increases in inequalities in self-rated health (3.9%), ADL score (5.8%), and cognition (7.5%). Similarly, internet use widened gaps in self-rated health (7.5%) and cognition (7.6%). Conversely, the 2020 analysis demonstrated that internet access improved health disparities among older adults, reducing gaps in self-rated health (3.8%), ADL score (2.1%), instrumental ADL score (3.5%), and cognition (7.5%), with significant results, except for ADL. Internet use also narrowed disparities, with significant effects on self-rated health (4.8%) and cognition (12.8%). The robustness of the results was confirmed through propensity score–matching paired tests. In addition, the study found heterogeneity in the effects of internet access and use on health inequalities among older adults, depending on sex, age, education, and region.

Conclusions: The impact of internet access and use on health inequalities among older adults showed different trends in 2018 and 2020. These findings underscore the importance of addressing the challenges and barriers to internet use among older adults, particularly during the early stages of digital adoption. It is recommended to promote equitable access to the health benefits of the internet through policy interventions, social support, and technological advancements.

Introduction

Background

According to data from China's National Bureau of Statistics, by the end of 2023, the population aged ≥60 years in China had surpassed 290 million. This aging trend exceeds the world average and continues to rise. In response, China has introduced a national strategy to address population aging during the 14th Five-Year Plan (2021-2025) period. Health inequalities among older adults are widespread across various age groups and social structures [1]. These disparities are influenced by factors such as individual characteristics, the distribution of medical resources, regional economic development, and public policies [1]. They include differences based on socio-economic status [2,3], sex [4], education [5], and area of residence [6].

Meanwhile, the rise of information and communication technology has introduced digital health as a substantially factor in improving health outcomes. According to findings published by the China Internet Network Information Center [7] in 2020, only 24% of the older adult population in China has adopted internet use. Older adults face substantial challenges in accessing digital resources compared to other demographics, leading to a new form of social structural inequality known as the "digital divide" [8]. This divide is more pronounced among older adults due to limited internet access, the complexity of operating digital devices, and slower acceptance of new technologies [9].

Previous research presents differing views on the relationship between health inequity and the digital divide. One perspective holds that digital technology can enhance health, particularly in remote areas, through telemedicine, optimizing resource distribution, and promoting health equity [8]. Conversely, another perspective suggests that the digital divide may widen health disparities between older and middle-aged adults as well as among different groups of older adults. Digital health technologies, such as electronic medical records, telemedicine, disease surveillance, diagnostics, and drug discovery, are well established [10]. However, barriers to online health care modalities among older adults exacerbate health disparities, affecting equity in health care use [11]. For instance, some researchers have highlighted that inequality in access to and use of digital health is one of the key factors contributing to increased mortality rates among older adults during the COVID-19 pandemic [12].

Most previous studies have focused on the impact of internet use on health, yet it remains unclear whether such use has widened or narrowed health inequalities among different older adult populations. Given the varied effects of internet use across different demographics and the scarcity of research on its relationship with health inequalities, this paper uses cross-sectional data from China to construct a health inequality index. The aim is to explore the correlation between the digital divide and health inequality among older adults, thereby addressing gaps in existing research and providing strategies for improving health equity for older adults. This paper contributes by exploring how internet technology can be leveraged to improve the health status and equity of older adults, ultimately providing effective solutions to enhance social equity and reduce the digital divide.

Status of Health Inequalities Among Older Adults

Older adults bear a greater health burden as a group considered vulnerable, and health inequalities are more pronounced due to their living conditions and health-related behaviors. Health encompasses more than just the physical integrity of an individual [13]; it represents a comprehensive state of well-being requiring evaluation through various metrics. Health inequality indicators can be measured through subjective and objective measures. Subjective indicators are generally assessed by calculating the relative deprivation index using self-reported health status [14], while objective indicators encompass both physical and psychological levels. Physical health is commonly evaluated through one's ability to perform activities of daily living (ADL) [15] and instrumental ADL (iADL) [16]. Mental health in older adults, specifically depression and cognitive abilities, can be quantified using validated tools such as the Center for Epidemiologic Studies Depression Scale, the Symptom Checklist-90, the Montreal Cognitive Assessment, and the Mini-Mental State Examination (MMSE).

Various factors influence health inequalities among older adults, including residence area (urban or rural) [17,18], socioeconomic status [19], educational attainment [20], race [21], and early life experiences [22]. For instance, men from lower-income groups tend to have higher rates of smoking, leading to a higher prevalence of smoking-related illnesses, thereby contributing to health inequalities among different groups of older adults [23].

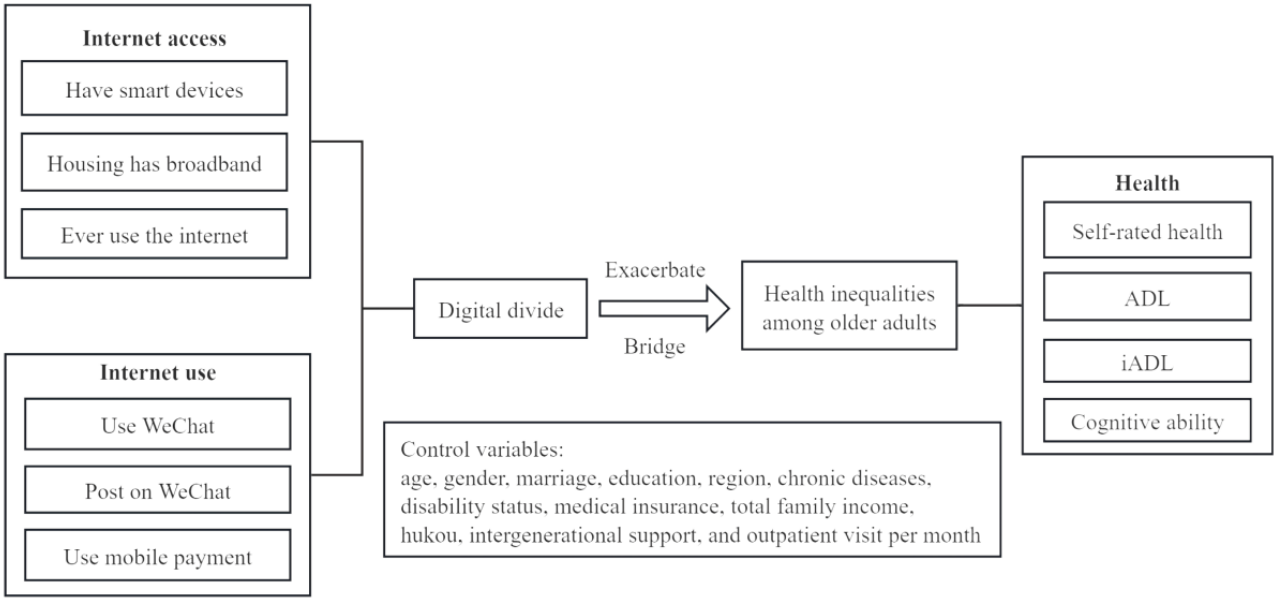
Dimensions of the Digital Divide

The digital divide refers to disparities in accessing, using, and benefiting from digital technologies among various groups. Within the framework of the 3-stage digital divide, this concept can be divided into 3 dimensions: the digital access divide, digital use divide, and digital outcome divide. The accessibility divide arises from limited internet connectivity; lack of computing devices, software, and accessories; and reduced interest in using the internet [24]. Internet access is typically assessed through household devices and network conditions [25,26]. With an increase in internet penetration, the access divide has narrowed, shifting focus toward diversified differences in use patterns and application depth, known as the "internet use divide." The use divide is related to technical expertise and effective use of digital technologies [27]. Scholars [28,29] have attempted to quantify these differences through use patterns and digital skills to measure individual use variations. The outcome divide dimension refers to differences in offline benefits derived from internet use [26,30]. The weak information acquisition and mastery abilities of older adults are proposed as key reasons for the emergence of the digital divide [31]. Thus, this study focuses on the impact of access and use divides on health inequalities.

Association Between Health Inequalities and Internet Use

The impact of the digital divide on health inequalities remains contested. Some scholars argue that the spread of the internet

XSL•FO
RenderX



has bridged the access divide to some extent, changing health information dissemination patterns and facilitating balanced information flow [32]. This can help reduce health inequalities among older adults, who are often disadvantaged in accessing information [33]. Services derived from digital technology, such as remote consultations, have the potential to alleviate imbalances in health care resource distribution, improving disparities between urban and rural health outcomes [34,35]. However, other studies suggest that while telemedicine can enhance health care access, it may not significantly impact health inequalities [36].

Conversely, it has been argued that the digital divide can exacerbate the inverse care law, potentially excluding those who would benefit most from digitally delivered health care [37]. Research has indicated that older adults may experience negative health effects due to the digital divide hindering their access to mobile health services [38]. A study in the Netherlands found that while older adults benefit from internet use, they do so to a lesser extent than younger people, which further exacerbates health disparities between age groups [39]. Research from Finland suggests that online health care services may intensify existing health disparities due to inequalities in access, skill, and use [40]. In addition, factors such as age [41], sex [42], socioeconomic status [43], and education level [44] influence digital health literacy [45] and telemedicine use, which in turn affect older adults' ability to understand and use digital health information and services. However, most previous studies exploring the relationship between the digital divide and health inequalities are review articles, with relatively few cross-sectional studies. Moreover, these studies often have limitations such as small sample sizes, unbalanced sex distributions, and higher educational attainment, which may introduce biases

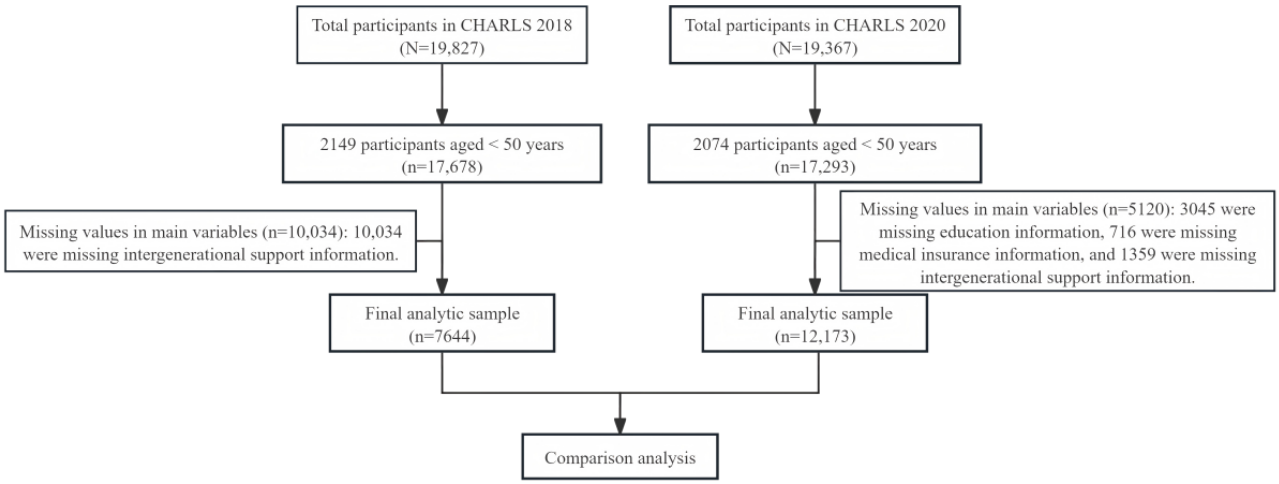
Objectives

On the basis of the 2018 and 2020 cross-sectional data from the China Health and Retirement Longitudinal Study (CHARLS), this study addresses the limitations of previous research by examining the impact of internet use on health inequality among older adults at a micro level. It focuses on the digital access divide and use divide to investigate their influence on older adults' health equity, including self-rated health, ADL, iADL [17], and MMSE scores. The theoretical framework is shown in Figure 1. This study is guided by the following research questions: (1) Does access to and use of the internet exacerbate or bridge health disparities among older adults? and (2) Does the impact of internet access and use on health inequality among older adults vary across different demographics?

Figure 1. Theoretical framework ("hukou" is a Chinese term for "household registration"). ADL: activity of daily living; iADL: instrumental activity of daily living.

Methods

Data Sources



This study conducted a secondary analysis using data from CHARLS, a nationally representative longitudinal survey conducted in China by Peking University. CHARLS aims to understand the conditions of adults aged ≥45 years, along with their spouses. CHARLS currently possesses 5 waves of data spanning from 2011 to 2020. For this study, data from 2018 and 2020 were used. According to the World Health Organization, older adults are defined as those aged ≥60 years. However, considering that individuals aged 50 to 60 years will soon transition into older adulthood, it is important to study the impact of digital technology on their intentions and behavior; therefore, the age range for this study was ≥50 years. CHARLS 2020 included 19,367 participants; after excluding 2074 (10.71%) participants aged <50 years and 5120 (26.44%) with missing key variable data, 12,173 (62.85%) participants were retained. CHARLS 2018 included 19,827 participants; after excluding 2149 (10.84%) participants aged <50 years and 10,034 (50.61%) with missing key variable data, 7644 (38.55%) participants were retained.

Ethical Considerations

Prior the survey, all participants provided written informed consent, and the survey protocols received approval from the Peking University Ethics Review Board (IRB00001052-11015; Figure 2) [46]. The survey was also anonymous, and answers were protected by privacy law.

Figure 2. Flowchart of sample selection. CHARLS: China Health and Retirement Longitudinal Study.

Variables and Measurements

Dependent Variable

This study used subjective and objective health indicators. Subjective indicators were measured through self-rated health, while objective indicators were divided into physical and psychological dimensions. Physical health was assessed based on the ability to perform ADL and iADL [17], and mental health was evaluated using cognitive function measured by the MMSE. Self-rated health consisted of five levels: (1) very unhealthy, (2) moderately unhealthy, (3) average, (4) moderately healthy, and (5) very healthy.

The ADL scale comprises 6 items: dressing, bathing or showering, self-feeding, getting into or out of bed, using the toilet (including getting up and down), and controlling urination and defecation (including catheter or pouch use). Responses were categorized into 4 levels: no difficulty, difficulty but able to perform, difficulty needing assistance, and unable to perform. Participants indicating *no difficulty* were scored as 1, while those indicating any level of difficulty were scored from 2 to 4 [47,48]. The total score ranges from 6 to 24 points.

The iADL scale includes 6 items: cooking, housework, shopping, managing money, making phone calls, and taking medication. Responses were assessed on a 4-point scale: 1=no difficulty, 2=difficulty but manageable, 3=difficulty needing assistance, and 4=inability to perform. Scores range from 6 to 24 points, with 6 indicating intact daily living skills and a higher score indicating greater impairment [47,48].

Cognitive function was evaluated using the MMSE [49], a concise assessment of adult cognitive status. The MMSE is used for screening cognitive impairment, gauging its severity, monitoring changes over time, and assessing treatment response. It consists of 30 items covering 7 cognitive domains: temporal orientation, spatial orientation, registration, attention and computation, recall, language, and praxis. Scores range from 0 to 30, with higher scores indicating better cognitive function.

According to the relative deprivation theory, older adults with poorer health status experience a greater sense of relative deprivation due to accumulating health disadvantages, leading to increased health inequality. We use the Kakwani relative deprivation index, which combines the results of self-rated health status, ADLs, iADLs, and cognitive function, to measure the degree of health inequality. The Kakwani index satisfies the problems of dimensionlessness, regularity, and transfer invariance. In addition, the Kakwani index can overcome the shortcomings of the Gini coefficient, which does not satisfy the additivity and decomposability. Therefore, this paper uses the Kakwani relative deprivation index to calculate the degree of health inequality of older adults. The measurement method is as follows: *Y* represents the sample size of older adults group of *n*, and arranged in order of the degree of health from smallest to the largest, the health distribution function for this group of older adults is as follows:

In equation 1, RD (y_j, y_i) denotes the relative deprivation index of health of the *j*-th older adult to the *i*-th older adult, and the relative deprivation index of health of the *i*-th older adult *n* is obtained by summing *j* and dividing it by the mean of the health level of all older adults in the group; hence, the degree of health inequality is as follows:

In equation 2, μ_Y represents the mean health level of all older adults in Y,  represents the mean health level of samples in Y with a health level of more than y_i, and  is the number of samples in Y with a health level of more than y_i as a proportion of the total sample.

XSL•FO
RenderX

Independent Variables

The digital divide is generally considered to have 3 dimensions: access divide, use divide, and outcome divide. This study focused on the first 2 dimensions. Three indicators were used to measure internet access level: the number of smart devices owned, broadband access at home, and the number of digital devices owned. The indicators were converted into a binary variable, where values 1 to 2 were assigned as 1. If any of the 3 indicators for internet access were 1, the individual was considered to have internet access.

To measure internet use level, 3 indicators were chosen: use of WeChat perform for socializing, posting on WeChat Moments, and using mobile payments [27]. WeChat, owned by the Chinese tech giant Tencent, is comparable to other social networking sites (SNSs) in western countries, such as Facebook and Twitter. The results of each question were denoted as 0 or 1, with higher values representing greater internet use capacity (ranging from 0 to 3).

Control Variables

Control variables were organized based on demographic characteristics: sex [50] (male=1 and female=0), age [51] (continuous variable), marital status [52] (married=1 and unmarried=0, where “unmarried” includes separation, divorce, widowhood, and never married), education [53] (no formal education=0, elementary school=1, and junior high school and above=2), chronic diseases [54] (yes=1 and no=0), disability status [55] (yes=1 and no=0), medical insurance [56] (urban employee medical insurance=1, urban and rural resident medical insurance=2, and other medical insurance=3), total family income [57] (log-transformed after bilateral trimming), *hukou* [58] (household registration; urban=0 and rural=1), intergenerational support [59] (determined by frequency of interactions with children; yes=1 and no=0), and outpatient visits [4] per month (range 0-30). Region of residence [60] (east, central, west, and northwest) was represented by 3 dummy variables.

Statistical Methods

Overview

Statistical analyses were conducted using Stata (version 15.0; StataCorp). Statistical significance was defined as 2-tailed *P* values <.05. Continuous data were presented as means and SDs, while categorical data were expressed as frequencies and percentages. The relationship between digital access (use) and health inequalities was examined using univariate analysis. Categorical variables were assessed using the chi-square test, continuous variables following a normal distribution were analyzed using the 2-tailed *t* test, and continuous variables not conforming to a normal distribution were evaluated using the Wilcoxon rank sum test.

Multiple Linear Regression

Multiple linear regression models were used to test the association between multiple dimensions of the digital divide and health inequalities. Subgroup analyses were conducted based on sex, age, *hukou* (household registration), educational level, and region. In addition to fully adjusted models, moderated effect analyses were conducted using interaction terms of internet access and use with other covariates to determine if the association between the digital divide and health inequality was moderated by these factors.

Propensity Score Matching Method

Sensitivity analyses were performed using propensity score matching (PSM). To analyze the impact of internet access and use on health inequality among older adults, the sample was divided into an experimental group (those who accessed or used the internet) and a control group (those who did not access or use the internet). Internet access (binary categorical variable) and internet use (converted into a binary variable using the median) were core variables for matching, and the nearest neighbor matching (1:1) principle was used to calculate the propensity score.

To further analyze the effects and mechanisms of internet access and use on health inequalities among older adults, the following model was constructed:

Where Y*i* denotes the degree of health inequality among older adults, D_i denotes the access or use of the Internet among older adults, X_i denotes other influences on the degree of health inequality among older adults, and ε is a random perturbation term. On the basis of the PSM model, internet access and internet use is set as a binary variable, and $D_i = \{0,1\}$ denotes whether the *i*-th older adult has access or use of the internet or not, that is, $D_i=1$ is access or use of the internet, and $D_i=0$ is no access or no use of the internet. There are 2 different scenarios of health inequality among older adults, one is the level of health inequality among older adults when accessing or using the internet (y_{1i}) and the other is the level of health inequality among older adults when not accessing or not using the internet (y_{0i}). The average treatment effect for the impact of the internet on health inequalities was calculated as:

In equation 5, average treatment effect denotes the difference between the level of health inequality among older adults with access and use of the internet $E(y_{1i}|Di=1)$ and the level of health inequality among older adults without access and use of the internet $E(y_{0i}|Di=1)$. Due to the unavailability of $E(y_{0i}|Di=1)$, $E(y_{0i}|Di=0)$ for the control group was used in the model as a proxy for the level of health inequality among older adults who use the internet.

Results

Characteristics of Study Participants

Table 1 presents the descriptive statistics of the sample, comprising 7644 observations from 2018 and 12,173 observations from 2020. In 2018, in total, 48.59% (3714/7644) of the participants were male, while 51.41% (3930/7644) were female. The average age of older adults was 65.11 (SD 10.02) years. In total, 73.31% (5604/7644) of the participants were

XSL•FO
RenderX

married at the time of the survey. Given that the average age of participants was approximately 65 years and education levels in China were generally low in the 1960s, this study classified participants with an education level of junior high school or above as “better educated.” The descriptive results indicate that only 30.65% (2343/7644) of the participants met this criterion. Most participants were rural residents (6449/7644, 84.37%). More than half of the respondents (4095/7644, 53.57%) had chronic diseases, and 14.21% (1086/7644) of the respondents had disabilities. Furthermore, 62.17% (4752/7644) of the respondents reported strong intergenerational support, indicating a tendency to contact and communicate with their children. Geographically, the distribution of older adults was fairly even across the eastern, central, and western regions, with the western region having the highest percentage (2642/7644, 34.56%) and the northeastern region having the fewest (491/7644, 6.43%).

[a]ADL: Activities Of Daily Living scale.

[b]iADL: Instrumental Activities of Daily Living scale.

In 2020, in total, 48.48% (5902/12,173) of the participants were male and 51.52% (6271/12,173) were female. The mean age of older adults was 63.97 (SD 9.20) years. More than 80% (9861/12,173) of the participants were married. For educational attainment, only 33.3% (4054/12,173) of the participants had a junior high school education or higher. Most older adults were rural residents (9456/12,173, 77.68%), and the primary health insurance was urban and rural residents' health insurance (10,209/12,173, 83.87%). More than half of the participants (7266/12,173, 59.69%) had chronic diseases, while 14.69% (1788/12,173) had disabilities. In addition, 43.46% (5290/12,173) of the participants reported strong intergenerational support. The regional distribution of older adults in 2020 was similar to that in 2018, with the Western region having the highest proportion (4007/12,173, 32.92%) and the Northeast having the lowest (713/12,173, 5.86%).

Regarding internet access and use among older adults, only 39.22% (2998/7644) of the households had broadband in 2018, whereas by 2020, more than half of the households (6974/12,173, 57.29%) had broadband. Smart device ownership also increased significantly, with only 8.52% (651/7644) of the older adults owning a smartphone in 2018 compared to 32.2% (3919/12,173) in 2020.

The health status of older adults was also analyzed descriptively. For subjective health evaluations, the largest proportion of participants in both 2018 and 2020 rated their health as "fair" (3431/7644, 44.89% and 5561/12,173, 45.68%, respectively). However, the proportion of participants rating their health as "very good" increased in 2020 compared to 2018, accounting for 10.01% (1218/12,173). In terms of objective health indicators, older adults had better ADL scores in 2018 compared to 2020, while iADL scores were worse in 2018 compared to 2020. Finally, older adults had higher cognitive ability scores in 2018, with an average score of 22.90 (SD 7.97), compared to 2020.

Results of Simple Regression

This section investigated the effects of internet access and use on health inequalities among older adults, using data from the CHARLS collected in 2018 and 2020. In CHARLS 2018, the findings indicated that internet access and use generally widened health inequalities among older adults. Specifically, internet access was found to have amplified disparities in subjective self-rated health, ADL, and cognitive ability, with effect sizes of 3.9%, 5.8%, and 7.5%, respectively, all of which were statistically significant. In contrast, internet access showed a significant narrowing effect on inequalities related to iADL, with an effect size of 5.1%. Similarly, internet use was associated with an increase in inequalities in subjective self-rated health and cognitive ability, with effect sizes of 7.5% and 7.6%, respectively, and these results were statistically significant.

XSL•FO
RenderX

However, internet use had a mitigating effect on iADL and ADL inequalities, with effect values of 5% and 0.8%, although these effects were not statistically significant (Tables 2 and 3).

[b]ADL: activity of daily living.

[c]iADL: instrumental activity of daily living.

Interestingly, the findings for CHARLS 2020 revealed a contrasting trend. In 2020, internet access was associated with a reduction in health inequalities in subjective self-rated health, ADL, iADL, and cognitive ability, with effect values of 3.8%, 2.1%, 3.5%, and 7.5%, respectively, all of which were statistically significant except for ADL. Likewise, internet use exhibited a narrowing effect on health inequalities, with respective effect sizes for subjective self-rated health, ADL, iADL, and cognition being 4.8%, 0.3%, 1.7%, and 12.8%. Except for ADL and iADL, these results were statistically significant. Notably, internet access and use demonstrated the largest impact on cognitive inequalities, highlighting cognition as a critical area affected by the digital divide (Tables 4 and 5).

Sensitivity Analysis: PSM

To assess the robustness of the results, PSM was performed to estimate the net effect of internet access and use on health inequalities among older adults. Before applying PSM, a balance test was conducted to ensure comparability between the treatment and control groups after matching, apart from the independent variables. The kernel density trend graphs for the 2 subsamples indicated improved convergence after matching across different submodels, with satisfactory results for sample support and equilibrium tests (Multimedia Appendix 1). In addition, standardized mean differences were used to measure the balance of covariates before and after matching. Table S1 in Multimedia Appendix 1 shows that the standardized mean differences for all key variables were reduced to <20% after matching, indicating adequate balance and supporting the robustness of the procedure.

The results of the PSM analysis were consistent with the regression analysis. In 2018, internet access significantly widened health inequalities, particularly in subjective self-rated health, ADL, and cognition, with effect sizes of 2%, 6.5%, and 2.2%, respectively. Internet use also widened disparities in subjective health and ADL, with effect sizes of 5.7% and 8.4%, respectively. However, in 2020, internet access and use showed a trend toward reducing health inequalities, with the greatest effect seen in narrowing cognitive disparities, at 4.6% and 5.2%, respectively. Overall, the consistency between the regression and PSM results affirms the robustness of the model (Tables 6 and 7).

Heterogeneity Analysis

To further explore the effect of internet access and use on health inequalities, a heterogeneity analysis was conducted using the 2020 CHARLS data, focusing on sex, age, education level, and urban and rural status. The subgroup analysis demonstrated that internet access had a stronger impact on reducing health inequalities among rural residents compared to urban residents. For rural populations, greater internet access significantly contributed to reducing health disparities (Table 8). Sex differences showed that internet use had a larger impact on reducing inequalities among males, with an effect value of 9.5% (*P*<.001). Regarding age, younger adults aged <60 years experienced greater benefits from internet access in reducing inequalities in self-assessed health and cognitive ability, with effect values of 5.6% (*P*<.01) and 14.8% (*P*<.001), respectively. Regarding education level, both internet access and use had a significant impact on reducing health inequalities among those with higher education, potentially due to their greater information literacy and ability to access health services online. Complete results are shown in Tables 8-15.

Discussion

Principal Findings

This study investigates the impact of internet access and use on health disparities among older adults in China, using multiple linear regression analysis and validating the findings with PSM methods. The results indicate that, in 2018, internet access and use tended to widen health inequalities among older adults, whereas in 2020, the effects were found to mitigate these inequalities. Factors such as urban or rural residence, sex, age, and education level also influenced the extent of these effects.

First, dual inequalities were observed in both the digital divide and health disparities among older adults. Significant improvements in internet access and use were noted between 2018 and 2020. In 2020, broadband coverage among older adults' households reached 57.29% (6974/12,173), the proportion of older adults owning smart devices was 35.5% (4321/12,173), and 3.3% (402/12,173) owned multiple digital devices. In contrast, these figures were 39.22% (2998/7644), 10.5% (803/7644), and 1.98% (152/7644), respectively, in 2018. Regarding health indicators, the proportion of older adults rating their health as "very good," along with ADL, iADL, and cognitive ability scores, all changed between 2018 and 2020, showing mixed trends. There was a slight improvement in self-rated health and ADL scores, whereas iADL and cognitive ability scores declined.

Second, results showed that internet access and use had differing impacts on health inequalities among older adults in 2018 and 2020. Our analysis of the 2018 data revealed that internet access and use generally exacerbated health inequalities for older adults. Specifically, internet access worsened disparities in subjective self-rated health, ADL, and cognition. However, it improved health inequalities in iADL. Through the internet, people could more conveniently handle daily affairs, reducing their reliance on physical services or facilities to a certain extent

XSL•FO
RenderX

and contributing to the enhancement of iADL levels. Particularly during the COVID-19 pandemic, services such as online shopping and telemedicine enabled individuals to complete many daily activities at home, minimizing outdoor activities and the risk of infection. This trend may have, to some degree, ameliorated health inequalities related to iADLs. Furthermore, iADLs may be more sensitive to changes in older adults' functional abilities, and even at lower levels of internet access, it could sensitively detect improvements in health equity. Furthermore, while the use of the internet appeared to have mitigated the disparity in iADL performance and cognitive abilities, it significantly intensified the imbalance between ADL performance and subjective health assessments. These findings remained robust after conducting a PSM test. This is consistent with previous research that used 2018 data from the Norwegian Diabetes Association to demonstrate that the digital divide can maintain and create health inequalities [61], which is basically consistent with our research results.

It was interesting to note that the results from 2020 showed that internet access and use actually contributed to improving health inequalities among older adults. Specifically, internet access had a mitigating effect on disparities in self-rated health, ADL, iADL, and cognitive inequality. In addition, internet use also narrowed inequalities in subjective self-rated health, ADL, iADL, and cognition. These findings remained robust following a PSM test. A 2020 study focusing on Chinese older adults found that digital participation played a mediating role in reducing depressive risks by indirectly improving mental health through the promotion of healthy lifestyles [62]. During the use of the internet, interaction and communication could stimulate thinking and broaden horizons, potentially mitigating differences in cognitive abilities to a certain extent. Meanwhile, given the severe aging issue in China, with many older individuals living alone, their children and friends could provide more timely care through mobile phones, which could reduce feelings of loneliness and benefit mental health among older adults.

During the COVID-19 pandemic in 2020, social distancing and travel restrictions prompted older adults to rely more heavily on the internet for socializing, shopping, and telemedical consultations, with the scale of China's mobile health care users reaching 661 million. This trend led to an increase in internet use. Furthermore, the COVID-19 pandemic itself could impact health inequalities among older adults. During this period, older adults faced greater psychological pressure and loneliness, adverse to cognitive function, while psychological panic might also introduce bias in self-assessments of health status. The inability to undergo physical examinations in person due to lockdowns and other restrictions negatively impacted their physical health. Older adults with lower ADL scores might encounter greater challenges in maintaining their daily living activities. However, internet use also provided conveniences for older adults, offering easier access to services and resources necessary for daily life, such as online shopping and remote household services. Older adults could better manage their daily lives using online calendars, reminder functions, and similar tools. In addition, they could access health information and participate in online health courses to support their health management.

Third, the difference in results between 2018 and 2020 can be attributed to the different stages of internet access, which had different effects on health equity. During the initial stages, as observed in 2018, the rate of internet access was low, potentially leading to widened health disparities among older adults due to their internet access and use. This was primarily because there was a learning curve associated with adopting new technologies, which was particularly challenging for older adults to master.

As internet technology became more widespread and society began to pay more attention to older adults' internet use, as seen in 2020, the gap in health inequalities started to diminish. The internet has been evolving with simpler and more intuitive designs, making it easier for older adults to navigate. Society has also been offering more internet education and training resources to help older adults improve their digital skills. For instance, in 2019, the Chinese government issued relevant policies to promote healthy aging. Furthermore, the range of health information and services available on the web has been expanding, including telemedicine and online health management. These services have become more accessible to older adults, regardless of their socioeconomic status [63]. These factors have all been working together to reduce the disparity in internet use among older adults, ultimately leading to a more equitable health landscape for this demographic.

Fourth, this study examines the heterogeneity of internet access and use on health inequalities in older adults concerning urban and rural areas, sex, age, and education level. In the older adult population, the influence of internet access on mitigating health inequalities is more pronounced among rural residents, although it also has a significant effect on urban dwellers. This could be explained by the fact that older adults in rural areas, through internet connectivity, gain access to health resources that were previously unavailable to them, whereas older adults in urban areas, who have had such access before, may experience less significant changes. However, older adults in urban areas tend to benefit more from acquiring and using the internet, as it facilitates improved health care information and services as well as living conditions. Conversely, older adults in rural areas may encounter greater life pressures and health challenges, coupled with a scarcity of resources and skills necessary for effective internet use. Consequently, these 2 groups exhibit varying degrees of impact on health outcomes. In terms of urban and rural areas, internet access has a more substantial impact on reducing health inequality among rural residents, who have limited access to health information. Accessing health information through the internet is crucial for improving the health of older adults in rural areas. Regarding sex, the effects of internet access on health inequalities are similar for men and women, whereas the effects of internet use are more prominent in men, possibly due to their greater aptitude for learning about electronics compared to women. In terms of age, the impact of internet access on reducing self-rated health inequalities and cognitive ability is more significant among younger adults aged <60 years, while the effect of internet use on both is essentially the same. Older adults approaching retirement tend to have stronger cognitive abilities and find it easier to learn how to use digital devices and online skills, resulting in a more significant

XSL•FO
RenderX

impact. Regarding education level, internet access has a greater impact on self-rated health among the highly educated population. Subjective self-assessment of health is an individual's personal evaluation, which is more influenced by the health knowledge they acquire. The application of science and technology promotes the popularization of health knowledge [64]. Highly educated individuals generally pay more attention to their health conditions and possess better information literacy [65,66]. Consequently, their subjective self-evaluation of health becomes more distinct from that of the unconnected population.

Finally, although the initial impact of internet access and use on health inequalities in older adults tends to increase before decreasing, this observation does not imply that we can neglect inequalities during the early stages. Instead, we should focus more on addressing the challenges and barriers that older adults face when initially using the internet. Through policy guidance, social support, and ongoing technological innovation, we can promote more equitable access for older adults to the health and well-being benefits that the internet provides. On the basis of this understanding, the following policy recommendations are proposed:

- Expand internet coverage to enable older adults to benefit more from digital resources.
- Promote active aging by enhancing older adults' information literacy, including training on digital skills through community programs and volunteerism.
- Strengthen internet coverage in rural areas to improve access to health information.
- Encourage collaboration between different sectors to address multiple social inequalities, such as interdepartmental cooperation to provide financial and technical support for the care of older adults.

There are several limitations to this paper. First, this study only used cross-sectional data from 2018 and 2020 to analyze the relationship between digital access and use and health outcomes among older adults, which limits our ability to establish causality and introduces the potential for reverse causality bias. Further longitudinal analysis is needed to assess the long-term effects and clarify the temporal sequence of these associations. Second, while this research attributes the difference in the impact of the internet on health inequality between 2018 and 2020 to varying levels of internet access, the specific impact mechanism and regulatory effects require additional verification in subsequent steps. Finally, although we conducted extensive stratified analyses across regions, education levels, urban and rural status, sex, and age, and included a wide range of control variables, we did not use survey weights. This choice was made to focus on associations rather than population-level inference, but it may affect the representativeness of our findings.

Conclusions

This study examined the relationship between internet access and use on health inequalities among older adults, finding that their impact initially widened and then narrowed these inequalities. As internet technology became more widespread and advanced, increased social attention and support for older adults' digital engagement contributed to this reduction. The internet is a powerful tool for improving health equity, but older adults often face barriers such as age and educational level, which make access to digital health benefits more challenging. Particularly, older adults in rural areas and with lower education levels have less access to information, making internet access even more crucial for improving health outcomes in these populations. Governments and society can promote equal, safe, and effective access to the health benefits of the internet for older adults through policy, social support, and technological innovation.

Abstract

Background: Exposure to food advertisements is a major driver of childhood obesity, and food companies disproportionately target Latinx youth with their least healthy products. This study assessed the effects of food and beverage advertisements featuring Latinx celebrities versus Latinx noncelebrities on Latinx and White adolescents.

Objective: This web-based within-subjects study aims to assess the effects of food and beverage advertisements featuring Latinx celebrities versus Latinx noncelebrities on Latinx and White adolescents' preferences for the advertisements and featured products.

Methods: Participants (N=903) were selected from a volunteer sample of adolescents, aged 13-17 years, who self-identified as Latinx or White, had daily internet access, and could read and write in English. They participated in a web-based Qualtrics study where each participant viewed 8 advertisements for novel foods and beverages, including 4 advertisements that featured Latinx celebrities and the same 4 advertisements that featured Latinx noncelebrities (matched on all other attributes), in addition to 2 neutral advertisements (featuring bland, nontargeted products and did not feature people). Primary outcomes were participants' ratings of 4 advertisements for food and beverage brands featuring a Latinx celebrity and the same 4 advertisements featuring a Latinx noncelebrity. Multilevel linear regression models compared the effects of celebrities and differences between Latinx and White participants on attitudes (advertisement likeability; positive affect; and brand perceptions) and behavioral intentions (consumption; social media engagement—"liking;" following; commenting; tagging a friend).

Results: Latinx (n=436; 48.3%) and White (n=467; 51.7%) participants rated advertisements featuring Latinx celebrities more positively than advertisements featuring noncelebrities on attitude measures except negative affect (*Ps*≤.002), whereas only negative affect differed between Latinx and White participants. Two of the 5 behavioral intention measures differed by celebrity advertisement status (*P*=.02*; P*<.001). Additionally, the interaction between celebrity and participant ethnicity was significant for 4 behavioral intentions; Latinx, but not White, participants reported higher willingness to consume the product (*P*<.001), follow brands (*P*<.001), and tag friends (*P*<.001). While White and Latinx adolescents both reported higher likelihoods of "liking" advertisements on social media endorsed by Latinx celebrities versus noncelebrities, the effect was significantly larger among Latinx adolescents (*P*<.01).

Conclusions: This study demonstrates the power of Latinx celebrities in appealing to both Latinx and White adolescents but may be particularly persuasive in shaping behavioral intentions among Latinx adolescents. These findings suggest an urgent need

XSL•FO
RenderX

to reduce celebrity endorsements in ethnically targeted advertisements that promote unhealthy food products to communities disproportionately affected by obesity and diabetes. The food industry limits food advertising to children ages 12 years and younger, but industry self-regulatory efforts and policies should expand to include adolescents and address disproportionate marketing of unhealthy food to Latinx youth and celebrity endorsements of unhealthy products.

Introduction

Developing obesity during adolescence increases future risk of diabetes, cardiovascular disease, and diet-related cancers during adulthood [1-7]. Youth of color experience higher rates of obesity relative to White youth [8-10]. More than 37% of Latinx adolescents are overweight or obese relative to 26.5% of White adolescents [1,11], indicating an urgent need to reduce rates of obesity among Latinx youth.

Food marketing is a major driver of adolescent and childhood obesity [12-16]. Food companies spend more than US $1.8 billion on youth-directed marketing [17,18], which primarily promotes products that are energy-dense and nutrient-poor [19-22]. Such exposure is concerning given the large body of evidence showing that viewing food advertising increases children's preferences for promoted foods and brands, caloric intake, purchases, and requests for advertised products [2,16,23-26].

Adolescents and youth of color represent key consumer groups to food marketers not only because of their spending power [27] and trendsetting abilities [28,29] but also because of their unique responsiveness to advertising [19]. Compared to children and adults, adolescents are more impulsive and have lower inhibitory control [30]. They use brands to help elevate their feelings of self-worth [30], fit in with their desired peer group [31], and distinguish themselves from their caregivers [32]. Food and beverage brands aim to appeal to Latinx youth through targeted or multiethnic marketing, which refers to identifying a community that shares some common needs or characteristics that an organization—in this case, marketers—uses to appeal to that group [33]. While multiethnic advertising aims to reach consumers of diverse ethnicities, monoethnic advertising reaches members of a single ethnic group [33]. A study by Shao et al [34] found that socially distinctive consumers (eg, Latinx minorities) are more likely to prefer same-race monoethnic advertisements because this exposure promotes a sense of shared identity and belonging [34]. Janssen et al [35] explored advertising on Instagram and found that celebrity influencers with a high number of followers have more "likes" and more followers with positive attitudes toward the products they endorse; this results in greater purchase intention [35]. While targeted marketing is not inherently problematic, monoethnic advertising coupled with celebrity or influencer sponsorships can potentially target Latinx adolescents and Generation Z teens with health-harming products that may exacerbate health disparities.

Adolescents are exposed to food marketing on social media [36-38], but few studies have examined how adolescents respond to such marketing. One cross-sectional study showed that among a nationally representative sample of adolescents, more than 70% of them self-reported that they "liked," shared, or followed food and beverage brand accounts [39]. The same study also found that Black and less acculturated Latinx adolescents were more likely to self-report that they engaged with brand accounts than White adolescents [39]. Recent experimental studies have revealed that adolescents rate social media advertisements highly when those advertisements have high numbers of "likes" [36]. One randomized trial examining the impact of influencer marketing—the promotion of products by popular web-based celebrities—showed that influencer marketing of unhealthy foods on social media significantly increased children's consumption of unhealthy snacks [40,41].

Exposure to unhealthy food advertisements that feature celebrity influencers is concerning as it can capture adolescents' attention through its appealing features. Viewing these advertisements can increase positive affect and feelings of connection to the celebrity or influencer because they are often seen as trustworthy and are already well-liked by the adolescent [42-44]. These positive feelings toward the celebrity or influencer then elicit positive feelings (greater positive affect, liking, and desire for the product) toward the unhealthy food and beverage they are promoting [45]. Previous studies have assessed participants' responses to advertisements using 3 attitudinal ratings, including how much they like the advertisement, brand, and product, which allows researchers to compare such ratings across experimental conditions [46]. Such attitudinal ratings are measured through self-report questions that ask how much the participant likes the advertisement, how much they like the brand, and how much they like the product featured in the advertisement. Consequently, the likelihood of the adolescent engaging with the advertisement posts (eg, through "likes," comments, and shares) increases, along with the likelihood that they will subsequently purchase or consume unhealthy food [42,47-51]. Purchase intentions are measured via a self-report question and defined as a participant's willingness to purchase the product in the near future. Previous studies have used purchase intention questions as an outcome when objective measurements of purchasing behavior are not possible [52-57]. Previous research has measured and experimentally compared this engagement by participants with brands and advertisements on social media. Further, Social Norms Theory proposes that adolescents in particular, may be especially vulnerable to many of the racially targeted marketing practices that companies use on social media [58,59] because adolescents are highly sensitive

XSL•FO
RenderX

to their peers [60,61], popularity cues, and conformity pressures [62,63].

Research has shown that these feelings of connection may be even stronger when the race of the person featured in the advertisement matches the race of the adolescent [42,64]. A number of theoretical frameworks in social psychology may inform an understanding of this effect. According to the social identity theory, individuals derive a significant portion of their self-concept from their group memberships, leading to the formation of social identities [65]. Emphasizing the importance of social categorization, social comparison, and group identification in shaping attitudes and behaviors, social identity theory suggests that Latinx adolescents' ethnic identity may play a crucial role in shaping their self-concept. Racially targeted marketing that features Latinx celebrities can tap into this social identity, thereby fostering a sense of belonging and positively influencing attitudes toward the advertised product. Relatedly, Distinctiveness Theory may help explain the heightened appeal and influence of food advertisements featuring Latinx celebrities. Distinctiveness Theory explains that individuals define themselves based on rare traits in their environment [42,66]. Ethnicity in particular is an attribute related to distinctiveness and has been shown to hold greater significance in self-definition than other social categories [66]. Because Latinx adolescents are part of a distinctive minority group, distinctiveness theory suggests that they may be acutely attuned to and influenced by ethnically targeted marketing.

Despite the pervasiveness of targeted marketing, no experimental studies have examined the effects of Latinx-targeted food marketing on Latinx and White adolescents. This study assessed the effects of food and beverage advertisements featuring a Latinx celebrity on the same advertisements featuring a Latinx noncelebrity (ie, an individual who is not famous), including differential effects on Latinx and White adolescents. Examining the influence of celebrity-endorsed food advertisements on the preferences of Latinx and White youth will enhance the field's theoretical understanding of how ethnically targeted marketing uniquely affects Latinx youth, which can help inform practical implications on how public policies can address unhealthy food marketing that targets youth of color. By harnessing a rigorous 2×2 mixed factorial design, this study is the first to objectively compare celebrities' and noncelebrities' food endorsements on Latinx and White youth. Our research questions, therefore, are as follows:

- To what extent does exposure to Latinx celebrities' food advertisements increase adolescents' preferences for the advertisement and the featured product, compared to Latinx-noncelebrities' food advertisements?
- To what extent does exposure to Latinx people in food advertisements increase preferences for the advertisements among Latinx adolescents compared to White adolescents?

We predicted that (1) both Latinx and White adolescents would report higher preferences, including more positive attitudes (advertisement likeability; positive affect; and brand perceptions) and behavioral intentions (product consumption and social media engagement) when advertisements featured Latinx celebrities versus Latinx noncelebrities; (2) Latinx adolescents would report higher preferences for all advertisements compared to White adolescents; and (3) Latinx adolescents would show a stronger positive response to Latinx celebrity advertisements than White adolescents.

Methods

Study Design

This web-based study used a rigorous 2×2 mixed-factorial experimental design with 2 independent variables: the ethnicity of the participant (Latinx or White) and whether the person in the advertisement was a celebrity or noncelebrity. Latinx and White adolescent participants (aged 13-17 years) each viewed 8 advertisements for novel foods and beverages, including 4 advertisements that featured Latinx celebrities and the same 4 advertisements that featured Latinx noncelebrities (matched on all other attributes), in addition to 2 neutral advertisements. Novel food advertisements feature brands that participants are likely to be unfamiliar with, either created by researchers or brands from other countries. Using novel brands minimizes the likelihood that participants' ratings will be driven by previous brand preferences and experiences. For example, using a well-known brand such as Coca Cola would drown out our ability to examine the effects of Latinx celebrities' endorsements due to preexisting attitudes and preferences by consumers. After viewing each advertisement, participants provided attitude measures (for someone like me, advertisement likeability, positive and negative affect, and brand perceptions) and behavioral intentions (consumption, "liking," following, commenting, and tagging a friend), before viewing the next advertisement. These outcome measures have been used in other food marketing research studies as primary and secondary outcomes [39,41,52].

Participant Recruitment

In January 2019, we recruited participants through Dynata, a survey firm that maintains panels of thousands of adolescents and adults in the United States who are interested in completing surveys in exchange for incentives such as cash, prize drawings, or donations to charity. Dynata's recruitment involves a rigorous process that uses multiple steps to recruit and screen potential participants. First, randomly selected participants from members of Dynata's panels are combined with a pool of potential participants who are joining Dynata for the first time after responding to web-based recruitment materials. Those recruitment materials include banner advertisements on social media platforms and other commonly visited websites where participants might notice and respond to the flyers. This combined group of potential participants then receives an invitation to "take a survey," but are not provided with additional details about surveys that might introduce selection bias (eg, "take a survey about food" might attract people with an interest in food). Second, to be eligible for a study, potential participants complete quality control questions and are randomly matched with surveys for which they likely qualify. Finally, among the randomly selected participants who expressed an interest in and have been randomly matched with a survey, a subset is

XSL•FO
RenderX

randomized to complete a specific survey and then receives a link to the survey.

Pretest (N=50) and study participants (N=903) were adolescents, aged 13-17 years, who self-identified as Latinx, or White, had daily internet access, and could read and write in English. Of the 1509 eligible participants who responded to the survey, 992 participants (65.7%) completed all questions. An additional 89 participants did not answer 8 of 10 attention-check questions correctly and were excluded from the analyses. These attention-check questions asked, "What does this advertisement say?" with 3 multiple-choice answers. The final sample included 903 adolescents (436 (48.3%) Latinx adolescents and 467 (51.7%) White adolescents).

Ethical Considerations

The Institutional Review Board for the New York University School of Medicine approved the study (protocol #115-0087), in accordance with all applicable regulations. Parents voluntarily provided consent and adolescent participants provided assent after reading general information about the study, explaining the nature and possible consequences of the study, and the length of the survey. Study data were deidentified to protect participants' privacy and confidentiality. Participants were compensated by our recruitment firm, Dynata, with incentives such as cash, prize drawings, or donations to charity.

Materials

To develop the 8 food and beverage advertisements, we first created pairs of advertisements for 8 novel foods and beverages using Photoshop (Adobe). Each pair included 1 advertisement that featured a Latinx celebrity and a matched advertisement with a Latinx noncelebrity. Because brand familiarity for well-known products (eg, Coca Cola) heavily influences advertisement ratings and the difficulty of changing preexisting attitudes about known brands [67], we selected brands that were only available in countries outside the United States. To increase the likelihood that the advertisements were perceived as Latinx-targeted and that participants would recognize the celebrities, the advertisements included a slogan with at least 1 Spanish word or the name of the celebrity in the slogan or as a signature.

The 16 advertisements (8 pairs) for pretesting included 4 male and 4 female celebrity or noncelebrity pairs and 4 foods and 4 beverages. We pretested these advertisements among 20 Latinx and White adolescents to match the advertisement pairs on the attractiveness of the person in the advertisement, perceived target audience, and celebrity recognition.

Pretest participants first rated the attractiveness of the person in the advertisement, indicated the perceived race or ethnicity of the person, and identified whether the person in the advertisement was a celebrity. They also indicated how much they thought the advertisement was intended for people like them and for people in their age group.

We excluded 1 pair of advertisements because only 10% of participants (n=2) perceived the celebrity to be Latinx and another pair because the majority did not recognize the celebrity. We excluded 2 additional pairs because they scored the lowest on both celebrity recognition and attractiveness measures. The final set of 4 advertisement pairs (Figure 1) included 3 advertisement pairs that featured Latina women alongside a sugar-sweetened beverage (n=2 pairs) or unhealthy food product (n=1 pair) and one that featured a Latinx male alongside a sugar-sweetened beverage. Similar to previous research, we blurred the faces and names of the celebrities in the advertisements in Figure 1. The participants saw unblurred images [35,68].

We also used Photoshop to create 2 additional advertisements to serve as neutral nontargeted stimuli. These 2 advertisements featured bland, unsavory products (ie, water and saltine crackers) and did not show people (Figure 2).

They were used to compare advertisement ratings by Latinx and White adolescents to enable us to control for overall differences in advertisement ratings in our final models.

RenderX

Figure 1. Final set of 4 pairs of advertising stimuli embedded into web-based survey. Each pair included (A) an advertisement featuring a Latinx noncelebrity and (B) an advertisement featuring a Latinx celebrity. Faces and names of the celebrities are blurred in the figure, but participants saw unblurred images.

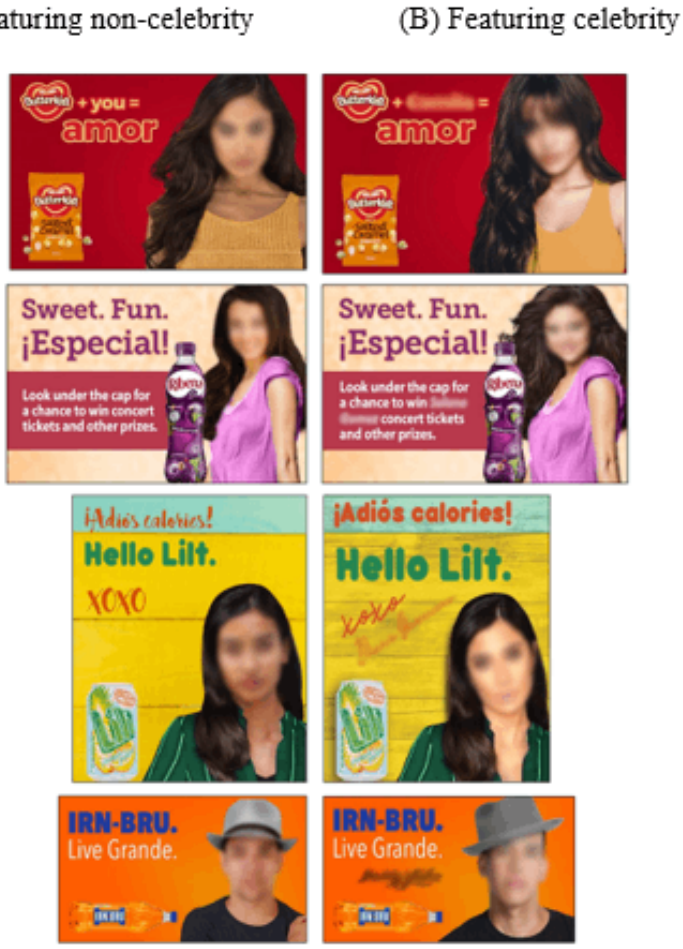

Figure 2. Final two 2 neutral, nontargeted advertising stimuli (control) embedded into web-based survey.

XSL•FO
RenderX

Survey Procedures

The web-based survey was designed using Silver Lake and CPP Investment's Qualtrics software, and the functionality of the survey was tested by the investigators before launching the study. Participants were required to complete the survey on a computer (instead of a mobile device) to ensure the visibility of advertisements. Participating on a mobile device might have made it more difficult to view the features of the advertisements in the survey due to the smaller screen size compared to desktops. Median survey completion time was 23 minutes. The study setting was anywhere a participant could access a computer to complete the experimental survey.

After providing assent and answering eligibility questions, participants were told the following cover story to conceal the true purpose of the study: "We are working with MTV to select commercials that their viewers might like and are interested in your attitudes and opinions on products featured in these advertisements. Participation in this study will involve viewing several different food and beverage advertisements and answering questions about them." All participants viewed and rated each of the 10 advertisements in a specific order as follows: they first viewed the neutral advertisement for water; then 2 celebrity advertisements and 2 noncelebrity advertisements for different brands presented in random order; then viewed the neutral advertisement for crackers; and finally, the remaining celebrity and noncelebrity advertisements presented in random order. This order ensured that participants did not see advertisements for 2 brands in the same group of 4 advertisements.

Primary Outcome Measures

The primary outcome measures and dependent variables are listed in Table 1.

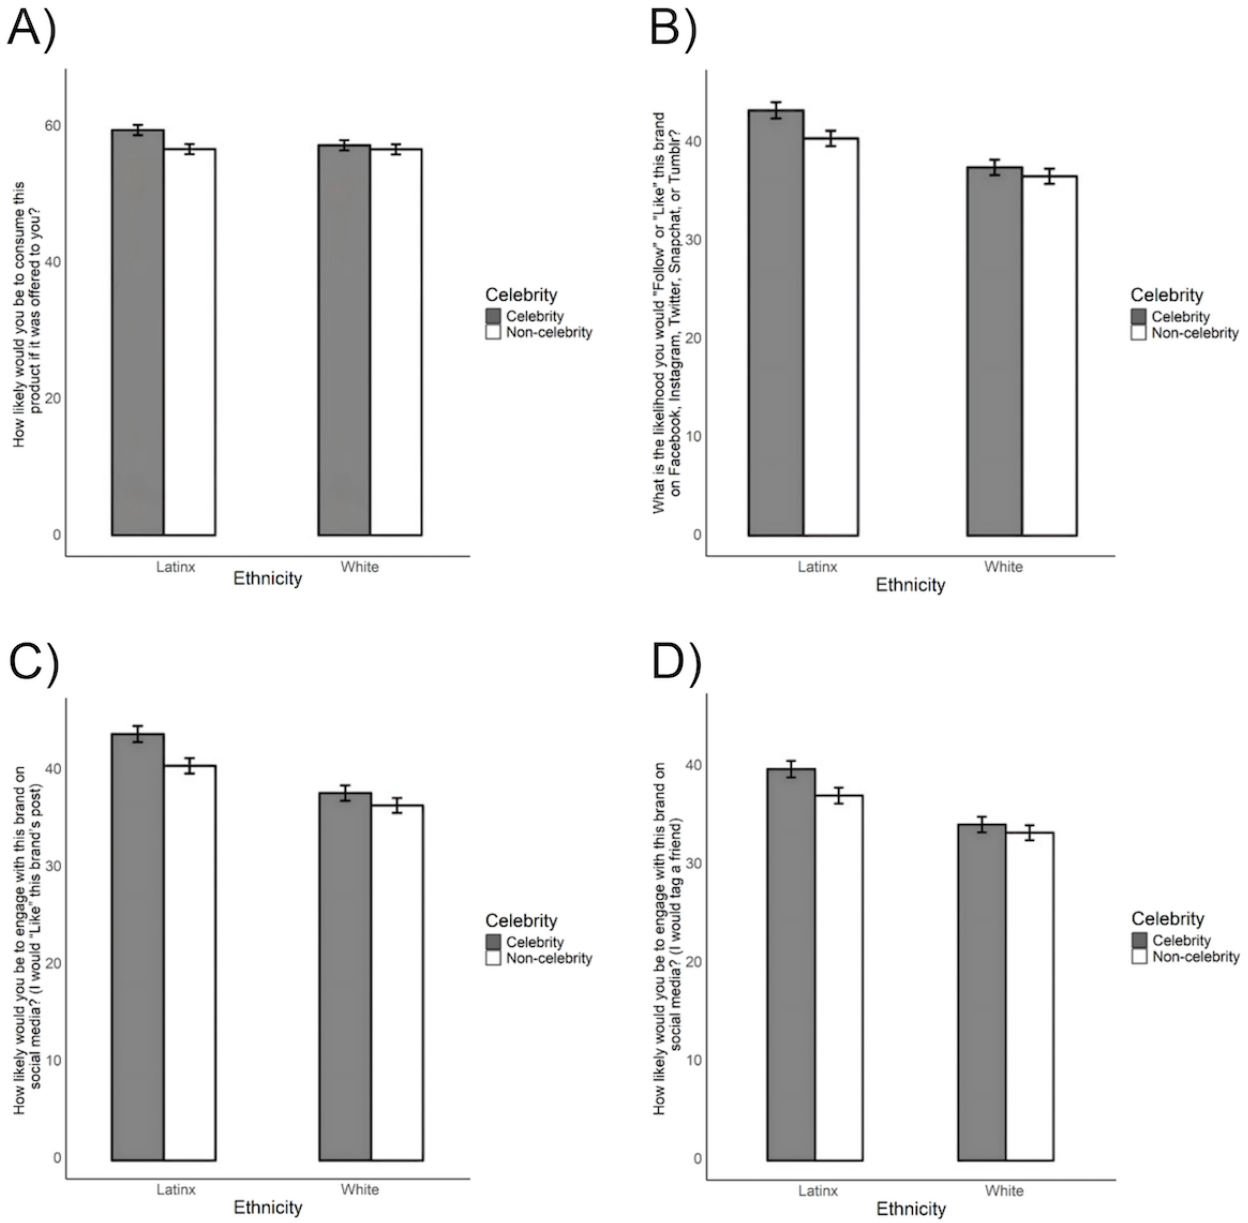
Table 1. Primary outcome measures for cognitive responses to advertisements, advertisement efficacy, and behavioral intentions after viewing advertisements.

Outcomes	Survey questions
Advertisement rating questions: Cognitive responses to advertisements and advertisement efficacy	
Likeability[a]	"How much did you like this ad?" (0="strongly disliked it" to 100="liked it a lot") [16,36]
Positive affect	"Did the ad for [Coke] make you feel: cheerful; good; pleased; stimulated; soothed?" (0="not at all" to 100="very much so". Scores were averaged into a composite positive affect score [69].
Negative affect	"Did the ad for [Coke] make you feel: insulted; irritated; repulsed?" (0="not at all" to 100="very much so". Scores were averaged into a composite negative affect score [69].
Taste preference	"How much do you think you would like the taste of this product" (0="Not at all" to 100="A lot") [53].
Advertisement efficacy[b]	"I like the brand in this ad," "I react favorably to the brand in this ad," "The brand in this ad is appealing," "The brand in this ad is good," and "The brand in this ad is pleasant," (0="disagree" to 100="agree") [70]. Brand liking statements were averaged for a combined brand perception rating.
Behavioral intention questions	
Likelihood to consume the advertised brand	"How likely would you be to consume this product if it was offered to you?" (0="very unlikely" to 100="very likely") [71]
Likelihood of following or liking the brand on social media[a]	"What is the likelihood you would Follow or Like this brand on Facebook, Instagram, Twitter, Snapchat, or Tumblr?" (0="very unlikely" to 100="very likely") [16,36]
Willingness to engage with the brand or advertisement on social media[a]	How likely would you be to engage with this brand on social media?: "I would comment on the brand's post" (0="very unlikely" to 100="very likely") ; "I would "Like" this brand's post" (0="very unlikely" to 100="very likely") ; "I would tag a friend" (0="very unlikely" to 100="very likely") [16,36]
Likelihood they were the intended audience for the post	"I feel the advertisement was intended for people like me" (0="disagree" to 100="agree"); "I do not believe the company was targeting consumers like me" (0="disagree" to 100="agree"); "The advertiser made this advertisement for people like me." (0="disagree" to 100="agree"). The inverse of question 2 was calculated and the scores of the 3 questions were averaged into a composite score [72].

[a]This item has not been validated but has been used before in previous research [16,36].

[b]This item is based on a published commonly used marketing scale study but was adapted [70].

Participants provided their attitudes about advertisements and brands immediately after viewing each advertisement, before viewing the next advertisement, using a sliding scale (0-100) for all questions (Table 1). We used 0-100 response scales to minimize bias and lack of reliability versus Likert scales [73], and, among some participant populations (eg, under-resourced communities), Likert scales contradict other response formats [74]. Other studies have shown that 0-100 scales offer stronger psychometric properties than Likert scales [75].



The question, "How much did you like this ad?" (0="strongly disliked it" to 100="liked it a lot") assessed advertisement likeability. A commonly used and validated marketing survey was used to evaluate affective advertisement responses [69]. Participants responded to the following 8 prompts: "Did the ad for [Coke] make you feel…cheerful; good; pleased; stimulated (positive affect); soothed; insulted; irritated; repulsed (negative affect)?" Affective advertisement responses included positive (cheerful, good, pleased, stimulated, and soothed) and negative

XSL•FO
RenderX

(insulted, irritated, and repulsed) attributes, rated as 0="not at all" to 100="very much so." Positive and negative attributes were averaged into separate composite positive and negative affect scores. Taste preference was measured with 1 question: "How much do you think you would like the taste of this product" (0="Not at all" to 100="A lot") [69]. Advertisement efficacy was measured with an adapted version of a commonly used marketing scale that asked participants the following 5 questions: "I like the brand in this ad," "I react favorably to the brand in this ad," "The brand in this ad is appealing," "The brand in this ad is good," and "The brand in this ad is pleasant," and rated from 0="disagree" to 100="agree" [71]. Brand liking statements were averaged for a combined brand perception rating [70].

Behavioral intention measures included the likelihood to consume the advertised brand [71] and willingness to engage with the brand or advertisement on social media, including the following questions: "What is the likelihood you would Follow or Like this brand on Facebook, Instagram, Twitter, Snapchat, or Tumblr?"; How likely would you be to engage with this brand on social media? ("I would comment on the brand's post" [0="very unlikely" to 100="very likely"]; "I would "Like" this brand's post" [0="very unlikely" to 100="very likely"]; "I would tag a friend" [0="very unlikely" to 100="very likely"]). The willingness to engage measures have not been validated but have been used before in previous research [16,36]. All responses were assessed on a sliding scale from 0="very unlikely" to 100="very likely" (Figure 3).

Figure 3. Latinx (n=436) and White (n=467) adolescents' ratings of likelihood of (A) consuming the product if it was offered to them; (B) following or liking the brand on Facebook, Instagram, Twitter, Snapchat, or Tumblr; (C) "Liking" the post on social media; and (D) tagging a friend on social media. Error bars indicate SDs.

XSL•FO
RenderX

Participants rated the likelihood they were the intended audience for the post across all 8 advertisements that featured people, using a scale developed by Aaker et al [72]. The scale asked three questions: (1) "I feel the advertisement was intended for people like me," (2) "I do not believe the company was targeting consumers like me," and 3) "The advertiser made this advertisement for people like me." We assessed these responses using a sliding scale from 0="disagree" to 100="agree." We reverse-coded question 2 and then averaged the scores.

Other Measures

Participants provided demographic characteristics, including age, race, ethnicity, grade level, parental education, and height and weight. They then indicated how often they checked social media if they had access to a smartphone, and which social media platforms they used. Participants who identified as Latinx also completed the Multigroup Ethnic Identity Measure-Revised, a 6-item measure that assesses exploration of and commitment to ethnic identity on a 5-point Likert scale: 1=strongly disagree to 5=strongly agree. The overall composite Multigroup Ethnic Identity Measure-Revised score is calculated by averaging the scores for each of the 6 items. The scale has been validated among adolescents to measure ethnic identity (among Latinx adolescents, α=.930) [76-78].

Statistical Analysis

We used 2-tailed *t* tests (continuous variables) and chi-square tests (categorical variables) to compare the demographic characteristics of Latinx and White participants. We also compared Latinx and White participants' ratings of the 2 neutral advertisements on all outcomes to determine whether the 2 groups systematically rated advertisements differently on any of the measures.

We used multilevel linear regression to account for multiple ratings by each participant. Dependent variables included all attitude and behavioral measures. Independent variables included binary terms for participant ethnicity and presence of a celebrity in the advertisement, an interaction term between participant ethnicity and celebrity, random effect of participant, and categorical brand indicator. There were no differences in Latinx and White adolescents' ratings of the neutral advertisements that did not feature people, so we did not control for that variable in the model. Across all the outcomes except targetedness, Latinx participants did not rate the neutral advertisements any differently than the White participants. They differed on targetedness—Latinx participants said they thought the neutral advertisements were more targeted to them. Due to differences in age by participant ethnicity (*P*=.04), we included a categorical indicator of age as a covariate in all models. All analyses were conducted in R (R Foundation for Statistical Computing) in February 2020.

Results

Overview

More than half of participants (n=540, 59.8%) were aged 13-15 years and 40.2% (n=363) were aged 16-17 years (Table 2). Approximately one-half identified as Latinx (n=436, 48.3%). There were no significant differences in parental education (*P*=.21) or participant sex (*P*=.13) between Latinx and White participants. The majority of participants (n=870, 96.3%) reported having one or more social media accounts, and 41.1% reported using a smartphone "almost constantly" to access social media.

Attitudes About the Advertisement and the Brand

On average, participants reported liking the 8 advertisements that featured people (mean 53.58, SD 28.70; Table 3).

Positive affective responses were rated neutrally (mean 49.44, SD 28.85), while participants reported overall low negative affective responses to advertisements (mean 18.77, SD 25.79). Participants rated their perception of the brand on average as 51.63 (SD 29.25) across all 8 advertisements that featured people.

For all attitude measures except negative affect, all participants rated advertisements significantly more positively for advertisements with celebrities than with noncelebrities; there were no main effects of participant ethnicity nor interactions between celebrity and participant ethnicity. However, Latinx participants reported significantly more negative affect toward all advertisements (*P*=.01).

For brand perception, we found a main effect of celebrity but did not find an interaction, indicating that Latinx and White adolescents rated the brands with celebrities significantly higher than the brands without celebrities.

XSL•FO
RenderX

Table 3. Latinx (n=436) and White (n=467) adolescents' ratings of attitudes toward food advertisements featuring Latinx celebrities and Latinx noncelebrities, and behavioral intentions postadvertisement exposure[a,b].

Outcome	Latinx participants (n=436)		White participants (n=467)		Main effect of celebrity in the advertisement	Main effect of participant ethnicity	Interaction (participant ethnicity and celebrity in advertisement)
	Celebrity, mean (SD)	Noncelebrity, mean (SD)	Celebrity, mean (SD)	Noncelebrity, mean (SD)	β (*P* value)	β (*P* value)	β (*P* value)

Behavioral intentions							
How likely would you be to consume this product if it was offered to you?	58.88 (0.73)	56.12 (0.73)	56.67 (0.75)	56.09 (0.73)	0.59 (.36)	0.13 (.94)	2.17 (.02)
What is the likelihood you would "Follow" or "Like" this brand on Facebook, Instagram, Twitter, Snapchat, or Tumblr?	43.23 (0.82)	40.38 (0.78)	37.44 (0.78)	36.53 (0.76)	0.92 (.08)	4.01 (.049)	1.94 (.01)
How likely would you be to engage with this brand on social media?							
I would comment on the brand's post	40.13 (0.81)	37.85 (0.79)	35.74 (0.78)	34.88 (0.76)	1.54 (.01)	3.79 (.06)	—
I would "Like" this brand's post	43.91 (0.82)	40.65 (0.79)	37.84 (0.80)	36.56 (0.77)	1.28 (.02)	4.27 (.04)	1.98 (.01)
I would tag a friend	39.28 (0.83)	36.63 (0.80)	33.71 (0.79)	32.90 (0.76)	0.81 (.12)	3.92 (.06)	1.85 (.01)

[a]All models included age as a covariate.

[b]All response items were on a scale ranging from 0 to 100.

[c]Not available.

Behavioral Intentions

Participants reported that they would likely consume the product (mean 56.92, SD 31.22), and there was no main effect of celebrity or participant ethnicity. However, we found a significant interaction between participant ethnicity and celebrity (Table 3). Only Latinx participants indicated significantly higher consumption intention when the advertisement featured a celebrity compared to advertisements featuring a noncelebrity (*P*<.001).

On measures of social media engagement, participants rated their likelihood of following the brand on average 39.31 (SD 33.51) across all 8 advertisements. They indicated a similar likelihood to comment on the social media post (mean 37.09; SD 33.34), "like" the post (mean 39.65, SD 33.81), and "tag" a friend in the post (mean 35.55, SD 33.88).

The main effect of celebrity was significant for two of the four social media engagement measures: (1) participants were more likely to comment on or "Like" posts that featured celebrities in their advertisements compared to posts that featured noncelebrities (Table 3); (2) Latinx participants were more likely to "Follow" or "Like" brands or posts than White participants. There was a main effect of celebrity on participant's likelihood of commenting on the post such that participants reported a higher likelihood of commenting on posts that featured

XSL•FO
RenderX

celebrities (mean 38.1, SE 1.04 compared to those without (mean 36.5, SE 1.04; β=1.54; t_{6320}=4.25; *P*<.001). We also found the main effects of celebrity (β=1.28; t_{6319}=2.38; *P*=.02) and participant ethnicity (β=4.27; t_{968}=2.09; *P*=.04) for willingness to "like" the brand. The main effects were qualified by an interaction (β=1.98; t_{6319}=2.57; *P*=.01). While White participants reported higher willingness to "like" advertisements with celebrities compared to noncelebrities (mean 36.7, SE 1.42 vs mean 38.0, SE 1.42; *z*=2.38; *P*=.02); the effect of celebrity was significantly greater among Latinx participants (mean 41.0, SE 1.49 vs mean 44.3, SE 1.49; *z*=5.87; *P*<.001).

For willingness to "tag" a brand, we found no main effects of celebrity (t_{6319}=1.55; *P*=.12) or participant ethnicity (t_{963}=1.91; *P*=.06). However, we did find a significant interaction (t_{6319}=2.46; *P*=.01). While White participants were equally likely to "tag" an advertisement with a celebrity (mean 33.9, SE 1.43) compared with an advertisement without a celebrity (mean 33.1, SE 1.43; *z*=1.55; *P*=.12), Latinx participants were more likely to "tag" an advertisement with a celebrity (mean 39.7, SE 1.50) compared to an advertisement without a celebrity (mean 37.0, SE 1.50; *z*=4.91; *P*<.001).

Finally, for willingness to follow a brand on social media, we found no main effect of celebrity (t_{6319}=1.76; *P*=.08), but did find evidence of a main effect of participant ethnicity (β=4.01; t_{964}=1.98; *P*=.05), as well as a significant interaction (β=1.94; t_{6319}=2.59; *P*=.01). White adolescents reported the same willingness to follow a brand on social media regardless of whether the advertisement featured a celebrity (mean 37.6, SE 1.42) or not (mean 36.7, SE 1.42; *P*=.08). However, Latinx participants reported higher likelihood of following the brand on social media when the advertisement featured a celebrity (mean 43.6, SE 1.48 vs mean 40.7, SE 1.48; *z*=5.30; *P*<.001).

Discussion

Principal Findings

Our hypothesis for research question 1, is that both Latinx and White adolescents would report higher preferences, including more positive attitudes (advertisement likeability; positive affect; and brand perceptions) and behavioral intentions (product consumption; social media engagement), when advertisements featured Latinx celebrities versus Latinx noncelebrities was mostly supported. Specifically, both Latinx and White participants in our sample reported significantly higher positive attitudes and brand perceptions for brands endorsed by Latinx celebrities compared to Latinx noncelebrities. However, we found significant main effects of celebrity advertisements for just 2 behavioral intentions: likelihood to comment and like brand posts. The findings that celebrities increased the appeal of the advertisements and products reinforces previous research that showed celebrity-endorsed products are more appealing to adolescents [41] and preadolescents [79] compared to products endorsed by noncelebrities.

Our hypothesis for research question 2, that Latinx participants would report more positive attitudes and behavioral intentions for both Latinx celebrity and Latinx noncelebrity advertisements compared to White participants was supported for just 2 outcomes: likelihood to follow brands on social media and like a brand post. We found no significant main effects of participant ethnicity on positive attitudes, brand perceptions, or intent to consume. However, we did find the hypothesized interaction between celebrity and participant ethnicity for most behavioral intentions. Relative to White adolescents, Latinx adolescents reported a higher willingness to "like" and follow brands that featured celebrities compared to brands that featured noncelebrities. In addition, Latinx adolescents reported higher consumption intentions and likelihood to tag a post when advertisements featured celebrities compared to noncelebrities.

These results reinforce other studies on the effects of celebrity endorsements and targeted food marketing. Our findings that both Latinx and White adolescents reported a higher likelihood to comment, "like," or tag a friend in the post on social media when the advertisements featured celebrities versus noncelebrities is similar to previous research showing that celebrity endorsements increase willingness to engage with brands [80]. Like other studies demonstrating that celebrity endorsements made adolescents more likely to choose the endorsed product [79], we identified a main effect of celebrity on adolescents' willingness to consume the product—but only for Latinx adolescents.

Latinx celebrities may disproportionately influence Latinx adolescents' behavioral intentions, including intent to consume and follow brands on social media, compared to White adolescents and noncelebrity advertisements. One potential explanation for the disproportionate influence of Latinx celebrities on Latinx youth is that Latinx communities are underrepresented in popular media, and positive portrayals in the media may heighten Latinx adolescents' responses to targeted advertisements. Future studies should examine the extent to which exposure to Latinx-targeted advertisements increases Latinx adolescents' actual food purchases and caloric consumption.

This study makes several contributions to the literature on the effects of food advertising and exposure to racially targeted food advertising. First, this is the first experimental study to examine the intersection of food advertising and celebrity endorsements among Latinx youth. The results indicate a direct causal effect of celebrities on willingness to consume the product and follow or "like" the brand on social media for both Latinx and White youth, even though—after controlling for other possible explanations—Latinx youth were more likely to believe that the advertisements with Latinx celebrities targeted them. These findings demonstrate the power of celebrity endorsements on adolescents' preferences. Second, this study demonstrates that the intersection between celebrity endorsements and Latinx ethnicity is complex and warrants further research to disentangle these effects. Celebrities influenced adolescents' attitudes about the advertisements, but it appears that Latinx celebrities may have a disproportionate influence on Latinx adolescents' behavioral intentions.

Limitations

This study has several limitations. First, although we only included brands from outside the United States to avoid brand

XSL•FO
RenderX

familiarity potentially influencing outcomes, our pretest did not assess brand familiarity among participants. Some adolescents may have been familiar with the international brands in our advertisements, thereby influencing their ratings. An additional limitation is that we only included Latinx celebrities and Latinx noncelebrities. The lack of White people in advertisements limits our ability to discern if our outcomes were shaped by ethnic congruity or some other factor. Another limitation is that in using Dynata for participant recruitment, our sample was not nationally representative. Participants in Dynata's sample are more likely to use the internet than the general US population, but since our research studies social media, this sample may better reflect our population of interest. Another limitation of opt-in panels is the risk of response bias (eg, providing socially desirable answers). However, we believe this risk is greatly reduced because the survey responses are anonymous, and research involving Dynata shows that adolescents express a variety of preferences (ie, they do not give socially desirable answers) [52-57]. Another limitation is that within-subjects study designs introduce possible "order effects" bias. Because our participants saw each advertisement (eg, the popcorn advertisement featuring a celebrity) and later saw its counterpart (eg, popcorn advertisement featuring a noncelebrity), order effects bias would suggest that the ratings of the second advertisement in a given pair could be affected by their reaction to the first advertisement in that pair. We aimed to reduce such bias, however, by (1) separating the presentation order of advertisements so that participants never saw two similar advertisements in a row; and (2) randomizing the order (eg, for each advertisement pair, some participants saw the celebrity advertisement first, whereas others saw the noncelebrity advertisement first). Although we would have preferred to avoid any possibility of order effects by using randomization via a between-subjects design, within-subjects is valuable when large sample sizes are not feasible—when designing the study, we knew we would not be able to recruit a large enough sample of Latinx adolescents to warrant a between-subjects design with multiple study conditions. Within-subjects' designs are commonly used in experimental research studies, including studies focused on food-related behaviors [81-83]. Finally, we did not assess participants' familiarity with the people featured in the advertisements, nor did we ask how much they liked the person in the advertisement. Both of those ratings should have been controlled in our analyses because they could have affected participants' ratings. Our study has major strengths, though, including the tightly controlled manipulation of images and the pretesting of those matched celebrities and noncelebrities on perceived attractiveness and target audience. Research on the effects of monoethnic and celebrity advertising effectiveness on the Generation Z cohort should also be explored.

Conclusions

Our data advance the theoretical understanding of targeting marketing by showing that viewing ethnicity-congruent food advertisements is particularly powerful for Latinx youth, which is concerning given Latinx communities experience high rates of diet-related diseases. These findings can help support policies that address unhealthy food marketing that targets communities of color, similar to how tobacco research on targeted marketing helped shed light on tobacco companies' targeted marketing practices [84-87]. Furthermore, in response to concerns about targeted marketing, Facebook now prohibits any advertisement from targeting users based on race [88]. New York State's proposed Predatory Marketing Prevention Act would aim to prevent advertisements from misleading consumers. These findings can be communicated to policymakers to consider including racial/ethnic-targeted marketing in such bills [89]. These findings suggest an urgent need to reduce celebrity endorsements in ethnically targeted advertisements that promote unhealthy food products to communities disproportionately affected by obesity and diabetes. Celebrities should consider choosing endorsements that support the health of their young fans, and powerful celebrities may be able to encourage companies to allow them to endorse healthier products. The food industry limits food advertising to children aged 12 years and younger, but our findings indicate that industry self-regulatory efforts should expand to include adolescents and address disproportionate advertising of unhealthy food to Latinx youth.

Acknowledgments

The authors would like to thank the following New York University Food Environment and Policy Research Coalition research assistants and staff who have no conflicts of interest to report: Alysa Miller, Yrvane Pageot, Margaret Eby, Tenay Greene, Joshua Arshonsky, Chelsea Mangold, Shirley Valerio, Robert Suss, Sana Husain, Natasha Pandit, Carolyn Fan, Anne Dumadag, Andrea Rodriguez Barrio, Ruchi Desai, Ingrid Wells, Jessica Osterman, and Jemar Bather. Generative artificial intelligence was not used in any portion of the manuscript writing. Data collection and analyses were supported by the National Institutes of Health (NIH) Early Independence Award (DP5OD021373-01; principal investigator: MAB) from the NIH Office of the Director. The NIH had no role in the design and conduct of the study.

Abstract

Background: Racial inequity in health outcomes, particularly in colorectal cancer (CRC), remains one of the most pressing issues in cancer communication and public health. Social media platforms like Twitter (now X) provide opportunities to disseminate health equity information widely, yet little is known about the availability, content, and reach of racial health equity information related to CRC on these platforms. Addressing this gap is essential to leveraging social media for equitable health communication.

Objective: This study aims to analyze the volume, content, and exposure of CRC racial health equity tweets from identified CRC equity disseminator accounts on Twitter. These accounts were defined as those actively sharing information related to racial equity in CRC outcomes. By examining the behavior and impact of these disseminators, this study provides insights into how health equity content is shared and received on social media.

Methods: We identified accounts that posted CRC-related content on Twitter between 2019 and 2021. Accounts were classified as CRC equity disseminators (n=798) if they followed at least 2 CRC racial equity organization accounts. We analyzed the volume and content of racial equity–related CRC tweets (n=1134) from these accounts and categorized them by account type (experts vs nonexperts). Additionally, we evaluated exposure by analyzing follower reach (n=6,266,269) and the role of broker accounts—accounts serving as unique sources of CRC racial equity information to their followers.

Results: Among 19,559 tweets posted by 798 CRC equity disseminators, only 5.8% (n=1134) mentioned racially and ethnically minoritized groups. Most of these tweets (641/1134, 57%) addressed disparities in outcomes, while fewer emphasized actionable content, such as symptoms (11/1134, 1%) or screening procedures (159/1134, 14%). Expert accounts (n=479; 716 tweets) were more likely to post CRC equity tweets compared with nonexpert accounts (n=319; 418 tweets). Broker accounts (n=500), or those with a substantial portion of followers relying on them for equity-related information, demonstrated the highest capacity for exposing followers to CRC equity content, thereby extending the reach of these critical messages to underserved communities.

Conclusions: This study emphasizes the critical roles played by expert and broker accounts in disseminating CRC racial equity information on social media. Despite the limited volume of equity-focused content, broker accounts were crucial in reaching

XSL•FO
RenderX

otherwise unexposed audiences. Public health practitioners should focus on encouraging equity disseminators to share more actionable information, such as symptoms and screening benefits, and implement measures to amplify the reach of such content on social media. Strengthening these efforts could help bridge disparities in cancer outcomes among racially minoritized groups.

KEYWORDS

racial equity information; information exposure; health disparities; colorectal cancer; cancer communication; Twitter; X

Introduction

Colorectal cancer (CRC) is among the most common and deadly cancers in the United States [1]. Although there have been advancements in CRC prevention and treatment, racial disparities in CRC morbidity and mortality persist, with Black Americans facing higher CRC risks [2]. Thus, promoting CRC awareness and screening behaviors among Black Americans for CRC prevention and early detection to reduce racial disparities has become an urgent task for CRC-related health communication and education [3-9]. Improving the quality of information about CRC prevention, detection, and advocacy is an important step in providing education and resources for improved decision-making to contribute to efforts to reduce CRC disparities among Black Americans [10-14].

Web-based sources—such as social media and related platforms—are an increasing source of health information for the general public, particularly for Black Americans. Black Americans are more likely than White Americans to rely on a wide variety of sources to acquire CRC screening-specific information—including web-based sources [15-20]. Research on CRC information has generally focused on the extent to which information presented is misleading, distracting, or inaccurate. For example, researchers found that medical professionals classified almost 40% of CRC YouTube content as "not useful," and such content was viewed and engaged with more frequently than higher-quality content [17]. TikTok content varied in its utility and accuracy, but researchers commonly identified inaccurate and misleading content [18]. On the other hand, other research on Twitter (now X) indicated that tweets about CRC were mostly accurate [19], while other studies noted that CRC received less Twitter attention than other (eg, breast and prostate) cancer sites [20].

For cancer topics where there are disparities by race, ethnicity, or other identities, misleading information is not the only way that members of the public can be underserved. Specifically, if specific information relevant to a particular community does not reach this audience [14,21-23], the information can be "misleading" in another sense. For example, since the rate of mortality from CRC among Black Americans is higher compared with other racial groups, misperceptions prevail as to the recommended screening age for this group, even more so after the official guideline changes from the recommended screening age of 50 to 45 years [16]. Thus, if Black Americans are only exposed to messages that describe overall population averages or recommendations, they may be inadvertently "misled" in the sense that they are not given access to important information to inform their decisions about prevention and screening [14,22].

This study focuses on an aspect of this problem of specialized/targeted information reaching populations that experience health inequities. Specifically, we examine the extent to which messages sent about and related to inequities regarding CRC by those motivated to address the issue are likely to reach historically marginalized populations or whether they tend to remain within the professional circles of the health experts themselves. The basic problem is that while in theory, social media can connect anyone to anyone, in practice, people tend to connect with similar others [24], resulting in clusters of tight-knit groups with overlapping, shared relationships [25]. These structures, sometimes referred to as "echo chambers," can create a particular problem for the dissemination of so-called "expert" information that, by definition, comes from specialized sources like medical journals and scholarly publications. For example, if a particular group is underrepresented in the scientific community, and the latest expert findings regarding the structural barriers to treatment and elevated CRC mortality faced by this underrepresented group are shared only among a cluster of experts, this important information may not reach and inform prevention, screening, and treatment decisions for people with historically minoritized identities.

Our study attempts to understand this distinction—between what is said about racial equity and CRC by accounts that are concerned with it and what is shared with populations facing these health outcome inequities—by analyzing both the volume and content of racial equity–related tweets from CRC equity disseminator accounts—an original concept that we introduced, defined as Twitter accounts that disseminate information related to racial equity concerning CRC outcomes.

Some individuals break out of communicating only within smaller, isolated clusters. Social network theory refers to these individuals as brokers [26,27]. Brokers are connected to different communities and are thus a key source of information transfer and diffusion [25,26]. They thus have an outsized influence on the information exposure for individuals and groups who are not connected to experts or other specialized communities. In essence, those who are disconnected do not hear everything that is said, but they hear what the brokers say. For this reason, this study also addresses a gap in the literature on CRC social media content and exposure by examining the influence of broker accounts—a special subset of CRC equity disseminator accounts that is more likely to reach unique audiences in disseminating racial equity content.

By addressing both aspects of content and dissemination, this study contributes to a more nuanced understanding of the public communication environment surrounding CRC racial equity, which will help inform future health communication and education efforts aimed at reducing CRC disparities.

Methods

Identifying CRC Equity Organization Accounts

We first identified a list of organizations whose primary focus is health equity or the health of racially and ethnically minoritized populations and the promotion of preventive health behaviors (including CRC screening; Figure 1). We used the US Department of Health and Human Services' National Minority Organizations list [28] to identify these health agencies (such as the National Institute on Minority Health and Health Disparities) and supplemented the list with organizations specifically dedicated to CRC prevention (such as the Association of Black Gastroenterologists and Hepatologists and the Colorectal Cancer Alliance). We then looked for the corresponding public Twitter accounts of these organizations and narrowed our pool from 18 to 7 accounts that had at least 1500 followers. The average number of followers was 9204, with the National Institute on Minority Health and Health Disparities being the most followed account (27,451 followers) and the Center for Black Health being the least followed (1594 followers). We retrieved the list of followers of these 7 organization accounts, resulting in a total of 59,669 unique followers (average number of organizations followed=1.08, SD 0.32). The majority of these users (n=55,725, 93.4%) only followed 1 of the 7 health equity organizations. A much smaller proportion, 3944 (6.6%) users followed at least 2 of the 7 organizations and were considered as having a potential interest in the topic of racial equity regarding CRC.

Figure 1. Workflow for mapping CRC equity networks and roles. CRC: colorectal cancer.

Identifying CRC Equity Disseminators

We collected public tweets about CRC from 2019 to 2021 using the keywords "coloncancer," "colorectalcancer," "colon cancer," and "colorectal cancer" and restricted the region to the United States (N=194,204 tweets) due to possible country-related differences about CRC advocacy and screening recommendations (eg, free screening services in some countries). Of the 3944 users identified as having a potential interest in racial equity about CRC, there were 798 accounts that produced tweets containing any of the terms above (n=25,093 CRC-related tweets; 19,559 of them are unique). We considered these 798 accounts as potential CRC equity disseminators; those who could play a crucial role in disseminating information about CRC racial equity to people who may not follow equity organizations. We note that only 0.7% of equity disseminators' followers also followed any CRC equity organization account, suggesting that these users' exposure to CRC racial equity content is less likely to come from equity organizations but more likely to come from equity disseminators themselves.

Identifying Expert and Nonexpert Accounts Among the CRC Equity Disseminators

To identify the identities of the 798 CRC equity disseminators, we categorized Twitter users based on their self-provided Twitter profiles. Following the inductive categorization framework introduced by Xu et al [29] and their typology for health knowledge sharing in a Twitter-based community of practice, in which users were grouped by their degree of health care involvement (ie, expert, those with experience, those interested in health topics, and the general public) and their health care roles (ie, providers, advocacy, engaged or average consumers, media, government, and non–health care–related organizations), we classified each of our 798 as either "expert" (including professional health service providers such as health care practitioners, health scientists, organizations, research laboratories, and medical centers) or "non-expert" (including advocacy groups, organizations, or individuals; average or engaged consumers; media; and government agencies; see Xu

XSL•FO
RenderX

et al [29] for details on each category and definition). This resulted in 479 experts versus 319 nonexperts.

Identifying Broker and Nonbroker Accounts Among the CRC Equity Disseminators

In addition to tagging each of the 798 accounts as either an expert or nonexpert account, we also determined whether each was a broker or nonbroker. To arrive at this categorization, we collected all the followers of the 798 accounts (N=6,266,269 unique followers) and calculated the number of expert and nonexpert accounts each of the followers followed. An account was classified as a broker account if more than half of its followers did not follow any experts (other than this one if the account in focus itself was an expert account). This resulted in 500 brokers and 298 nonbrokers.

Intersection of Expertise and Brokerage: The Role of Expert Brokers

Now that each of the 798 CRC equity disseminator accounts is tagged as either an expert or not and a broker or not, an account was considered an expert-broker account if it fell into both categories. Conceptually, an account is an expert-broker if it is an expert account, and more than half of its followers do not follow any other experts. Based on this definition, among the 479 experts, 254 (53%) were expert-brokers. These expert-brokers are especially important because they can uniquely connect people to content produced by experts. For example, a doctor who is followed by accounts that do not follow other doctors is more likely to be a crucial unique source of information for their followers who would not get important information (eg, about screening recommendations) elsewhere. Because our study is about access to medical information pertinent to minoritized populations, we are interested in the role of these expert-broker accounts as opposed to expert-nonbrokers (ie, whose followers tend to follow other experts as well, in this case, a doctor whose followers are mostly individuals who also follow many other doctors).

Coding of CRC Equity Tweets

We are interested in the specific CRC content about racial equity sent by the 798 CRC equity disseminators. We identified these tweets using a combination of (computational) dictionary tagging and manual (human) coding. We first tagged CRC-related tweets using a custom dictionary consisting of terms and phrases signaling historically minoritized racial groups (see full list of these terms and phrases in Table 1). Several specific terms were adapted from previous research such as [30,31].

Next, we analyzed the major themes in these CRC racial equity tweets and inductively identified 13 nonmutually exclusive categories for manual coding (Table 2). Two coders went through the codebook training process and reliably coded 10% of random tweets into 13 content subcategories (Krippendorf α ranged from 0.85 to 0.94). The subcategories are not mutually exclusive, so that a given tweet may fall into multiple categories. In Table 2, examples of tweets, in line with best practices of social media research [32], we have removed the names associated with certain hashtags and mentions to ensure the tweets are anonymized and cannot be traced back to their original authors.

Table 1. Keywords for retrieving potential racial equity content from colorectal cancer tweets.

Categories	Keywords
People of color	“people of color,” “community of color,” “communities of color,” “colored,” “poc,” “woc,” “woman of color,” “minority,” “minorities,” “racial disparity,” “racial disparities,” and “racism”
Black	“black*,” “african american*,” “af american,” “brown,” “blk,” “blm,” “brother,” “brotha,” “m4bl,” “sister,” and “sista”
Hispanic/Latino/a/x	“hispanic*,” “latino*,” “latinx*,” and “latina*”
Indigenous	“indigenous,” “american indian*,” and “native american*”
Asian	“asian*” and “asian american*”

Category	Definition	Examples of tweets	Krippendorf α
Incidence of CRC	Mention of the prevalence of CRC and statistics of its impact	#ColorectalCancer is more common in men than women and among those of African American descent. The rate of new cases of colorectal cancer was 38.2 per 100,000 men and women per year based on 2013-2017 cases, age adjusted. Learn more from our page on #CRC. [User] discusses the concerning trends of #ColorectalCancer rates in younger patients and the higher incidence and lower survival rates being seen in Black people. #[local cancer center] #local cancer center].	0.89
Screening prevalence	Mention of the general prevalence of CRC screening or statistics about screening rates	Fewer than half of Native Americans over 50 are up-to-date with #ColorectalCancer screening. Learn how CDC is working with @[government agency] and @[government agency] to help. Due to COVID-19, colonoscopy screening for colon cancer among minorities declined nearly 90%. We are going #BlueForCRC to raise awareness and encourage preventative screenings.	0.89
Screening information	Providing details about screening options, or screening logistics	NEW ACG Clinical Guidelines on CRC Screening! info: -screen @ 45 (avg-risk adults) -recs if family Hx -qual indicators (ADR & withdrawal) -recs on aspirin for risk -1 versus 2-step tests -interventions to increase screening, esp. among African Americans “Mailed stool blood tests; followup phone calls are examples of effective strategies that increased #colorectalcancer screening among African Americans” @FightCRC	0.87
Benefits of screening	Using reasons to appeal to why screening is necessary, worth the effort, and beneficial	Getting routine screenings is imperative, regardless of family history. It’s worth it to have peace of mind that you don’t have colorectal cancer. #blackcommunity Colorectal cancer screening can detect cancer early—when it is most curable. Learn more about your screening options! #Latinxin-Medicine	0.86

Volume of Exposure to CRC Equity Tweets

We then examined the extent to which the followers of the 798 accounts were exposed to CRC equity tweets. Different from the analysis of content, which deals with unique tweets or unique equity tweets only (n=1134), the analysis of exposure deals with nonunique equity tweets (n=1333) to adjust for the cumulative effect of exposure to both unique tweets and retweets. As the exact mechanisms behind Twitter’s algorithms to display specific content to a user at a given time are unknown, we relied on Twitter’s public documentation [33], assuming that by subscribing to an account, a user could be exposed to all posts and updates from that account. Based on this logic, for each of the 6,266,269 unique followers of the 798 CRC potential disseminator accounts, we calculated the number of the accounts they followed, as well as the number of (nonunique) general CRC tweets and CRC equity tweets they could have been exposed to (which is equal to the number of the general CRC tweets and CRC equity tweets posted by the accounts they followed). Finally, we estimated the volume of exposure to CRC equity tweets among these followers overall and by account types (ie, whether the followed account is an expert, or a broker).

Ethical Considerations

All analyses are based on publicly available data. To respect privacy, we do not disclose usernames and identifiable information in our paper and only report aggregate results.

Results

Volume and Content of CRC Racial Equity Tweets

We begin by analyzing the content produced by the 798 potential equity disseminator accounts. Of the 19,559 (unique) CRC tweets these accounts produced, only 5.8% (n=1134) mentioned a historically minoritized racial group and thus were deemed likely to be specifically about CRC racial equity, disparity, or racial identity–specific impact/information (although not all of them necessarily discussed racial information in ways that signaled fairness and justice).

Table 3 provides a summary of the tweet categories’ respective volumes and proportions. Notably, outcome disparity (ie, specifying disparities in CRC outcomes between racial and ethnic groups) was the most common type of content, appearing in 56.53% (641/1134) of unique CRC racial equity tweets. Other common content categories were a call to action (ie, encouraging CRC detection/prevention; (505/1134, 44.53%), CRC risks or risk factors (351/1134, 30.95%), and raising awareness of CRC

XSL•FO
RenderX

(ie, emphasizing the need to communicate more about CRC; 337/1134, 29.72%). In contrast, details about CRC screening logistics or options (159/1134, 14.02%), benefits (98/1134, 8.64%), prevalence of screening (66/1134, 5.82%), and CRC symptoms (11/1134, 0.97%) were less common, though still present.

We next investigated which types of accounts tended to post different kinds of messages. Experts were more likely than nonexperts to send tweets about CRC racial equity, (z=14.88, P<.001). Specifically, of the 8210 unique CRC tweets produced by experts, 8.7% (n=716) of them mentioned at least 1 racially minoritized group. Nonexpert accounts, by contrast, only mentioned a racially minoritized group in 3.7% (418/11,349) of unique tweets they produced. There were also differences between expert and nonexpert accounts in their proportions of tweets for specific content subcategories. However, the only statistically significant difference is that experts focused more on celebrities' stories than nonexperts (P=.04; Table 3).

Table 3. Volume and proportion of colorectal cancer (CRC) racial equity tweets by content and account type. Proportions of specific content subcategories are compared between expert versus nonexpert accounts, brokers versus nonbrokers, and expert-brokers versus expert-nonbrokers.

Content type	Number of unique racial equity tweets from CRC equity disseminators (n=1134 tweets), n (%)	Number of unique racial equity tweets from experts (n=716 tweets), n (%)	Number of unique racial equity tweets from nonexperts (n=418 tweets), n (%)	Number of unique racial equity tweets from brokers (n=518 tweets), n (%)	Number of unique racial equity tweets from nonbrokers (n=616 tweets), n (%)	Number of unique racial equity tweets from expert-nonbrokers (n=556 tweets), n (%)	Number of unique racial equity tweets from expert-brokers (n=160 tweets), n (%)
Outcome disparity	641 (56.53)	412 (57.54)	229 (54.78)	282 (54.44)	360 (58.44)	322 (57.91)	90 (56.25)

[a]Values different at P<.05 level.

We also compared brokers to nonbrokers. Recall the definition of brokers as a subset of CRC equity disseminator accounts where more than half of their followers did not follow any experts (or any experts other than itself, if the account in focus was an expert account). Overall, brokers were less likely to talk about equity (518 tweets) than nonbrokers (616 tweets).

Examining the volume of equity tweets by expert brokers versus expert nonbrokers, we found that expert brokers produced fewer equity tweets (160 tweets) compared with expert nonbrokers (556 tweets). An examination at the account level revealed that only 30% (77/254) of experts who are brokers tweeted at least once about equity, compared with 46% (103/225) of expert-nonbrokers who did so. This pattern indicates that those who talk about equity more frequently are those with less reach beyond the community and who would otherwise not learn about this topic.

Exposure to CRC Racial Equity Tweets

We now turn to the question of how different types of accounts impact the kind of information that their followers are exposed to. In other words, which of the 798 potential CRC equity disseminators do the "best" job of exposing their followers to equity content. Since both tweets and retweets (not just unique tweets) contribute to exposure, the outcome of interest is the estimated nonunique equity tweets to which the followers of the 798 accounts (n=6,266,269) can potentially be exposed (mean 0.99, SD 3.89). Linear regression results showed that the number of accounts followed was positively associated with the number of racial equity tweets potentially seen (β=0.06, SE 0.000; P<.001). However, since only 309 (38.7%) out of the 798 potential disseminators posted any equity-oriented content, the estimated exposure for more than half (3,490,864/6,266,269, 55.7%) of all followers would be zero CRC racial equity tweets.

XSL•FO
RenderX

To determine which potential disseminator account has the most unique reach into the communities who would otherwise not learn about the topic, we evaluated the portion (%) of each account's followers for whom they are the only source of racial equity content. In other words, for what portion of their followers does each account category tend to be the only source? The results showed that brokers were substantially more likely to serve that role. For brokers, the average proportion of followers for whom they were the only source of equity tweets is 30%, with the median being 27% (IQR 17%-39%). By contrast, for nonbrokers, the average percentage is 11%, with the median being 10% (IQR 7.4%-14.5%). A linear regression was run using the percentage of followers for whom the source is the unique source as the dependent variable. Brokers, compared with nonbrokers, had a significantly higher proportion of their followers subscribing to them as unique sources of equity content (β=18.9, *P*<.001). These figures do not differ substantially between expert versus nonexperts (β=–0.5, *P*=.90), and including expert as an interaction term does not produce a difference (β=1.1, *P*=.80). The results indicate that broker accounts (regardless of expert or nonexpert status) who tweeted about equity had a unique potential, since they were the only source of this information for a much larger portion of their followers compared with nonbrokers who did so.

Discussion

Principal Findings

This study examined CRC content in the context of Twitter, focusing on racial equity–related discussions from CRC equity disseminator accounts on the platform. We analyzed the volume of CRC racial equity tweets overall and by specific content categories (eg, outcome disparity, screening, and narratives) and account types (experts vs nonexperts, brokers vs nonbrokers), and we identified the kinds of accounts that were most likely to uniquely expose their followers to racial equity related information. Findings provide insights into promoting cancer equity through health communication focusing on the role of brokers on social media.

Regarding the volume of CRC racial equity tweets, race and ethnicity was infrequently discussed on Twitter even among potential disseminators (accounting for only 5.8% of the unique tweets). This finding is consistent with previous research on health news stories from newspapers and local TV programs, which also found scant mentions of race or ethnicity [8,9]. Without featuring race and ethnicity–specific health information, people may not pay attention to CRC-related racial inequities. A lack of content tailored to racially and ethnically minoritized groups is concerning in light of the fact that tailored communication could better motivate individual and collective action [14].

While race and ethnicity is not a frequent feature overall in tweets from potential equity disseminators, outcome disparity is the most common content type when race and ethnicity is depicted. Emphasizing the differences in CRC risks and outcomes between racial groups may increase people's awareness of the disparity gap. However, research also found that when racial health disparity information was presented alone, it might have an adverse impact on the group with higher disease risks (the disadvantaged group), reducing their intention to engage in health behaviors [11-13]. This concern is intensified as the least frequent types of content in racial equity tweets are about strategies that could address CRC outcomes, including screening procedures, prevalence, and benefits. Featuring comparatively high disease risks without also highlighting detailed information about what can be done, how to do it, and the effectiveness of the solutions (eg, CRC screening) could trigger message resistance and behavioral inhibition [12]. Screening prevalence among Black Americans emphasizing progress toward addressing inequities may better motivate screening behavior compared with disparity information in and of itself [13]. The benefits of screening content could also convey the effectiveness of screening, which may serve as behavioral evaluation and response efficacy information both of which are important behavioral antecedents [34,35]. In addition, past research has found that Black Americans were more likely to come across screening-specific information via the web compared with White Americans, which was positively associated with screening behavior [11]. Thus, CRC racial equity tweets may benefit from including more screening-specific information.

However, the overall impact of these tweets may be less than one might assume. Our analysis showed that in line with our concern about the potential for CRC equity messages to reach new audiences, the accounts that talked the most about equity—experts—were less likely to reach unique audiences who would otherwise not learn about this topic. Consistent with network theory, brokers who tweeted about equity were more likely to serve that role since they were the only source of such information for a major portion of their followers. In essence, while experts were more vocal, the more insular nature of their following and networks may make them less capable as disseminators. This suggests that experts or others concerned about the dissemination of equity content might consider allying with accounts that have a greater or unique reach, identifying messages that these far-reaching broker accounts are likely to retweet, rather than simply producing more messages themselves.

Limitations

The study has several limitations. We identified potential disseminator accounts based on the 7 major CRC racial equity organization accounts with the most followers on Twitter (1500 or more). However, they represent only a part of the many equity-oriented organizations in the United States, and future research may include other related equity organizations with fewer followers on Twitter. Similarly, we only focused on the tweets from these accounts even though other Twitter accounts that are were not in this sample may also post CRC racial equity content. Thus, a user may be exposed to racial equity content, despite not following any of our potential disseminator accounts. Moreover, by focusing on only account followers, our measure of exposure to racial equity tweets might be a more conservative one. Future research could consider other measures of diffusion beyond follower-following relationship, such as retweet networks, for more complex exposure estimation. This paper also did not examine the actual audiences (eg, demographics of

XSL•FO
RenderX

different followers) and the impact of racial equity information diffusion on the audiences of such tweets. If members of historically minoritized racial groups do not see the tweets, this can undoubtedly mitigate some of the impact of such communication. Exploring this important research question will be crucial in gaining a more comprehensive understanding of how sharing such messages can lead to desirable outcomes. Last but not least, the official change of Twitter to X in July 2023, despite being irrelevant to the period of this study, means that future research might not be able to study this topic or other health topics on Twitter in the same way due to issues such as limited data access, shifts in user demographics, and changes in technical affordances. With the increasing prominence of platforms featuring long- and short-form video formats such as YouTube or TikTok [36], more research is needed to understand the availability and exposure to racial equity information on these platforms.

Conclusions

To conclude, the findings from this study highlight the importance of social media accounts that are in a position to diffuse racial equity information produced by equity organizations to otherwise disconnected audiences. Public health officials should encourage these accounts to post more information that focuses on CRC racial equity–related content and tailor their information to the needs of specific racial groups. In doing so, they should emphasize CRC symptoms and details about the screening guidelines/procedures, prevalence, and benefits in their racial equity posts to center and amplify information about CRC detection and prevention.

Abstract

Background: Mobile health (mHealth) tools have the potential to reduce the burden of chronic conditions that disproportionately affect Hispanic and Latinx communities; however, digital divides in the access to and use of health technology suggest that mHealth has the potential to exacerbate, rather than reduce, these disparities.

Objective: A key step toward developing health technology that is accessible and usable is to understand community member perspectives and needs so that technology is culturally relevant and appropriately contextualized. In this study, we aimed to examine the perspectives of Hispanic and Latinx community members in Washington State about mHealth.

Methods: We recruited English- and Spanish-speaking Hispanic or Latinx adults to participate in web-based focus groups through existing community-based networks across rural and urban regions of Washington State. Focus groups included a presentation of narrative slideshow materials developed by the research team depicting mHealth use case examples of asthma in children and fall risk in older adults. Focus group questions asked participants to respond to the case examples and to further explore mHealth use preferences, benefits, barriers, and concerns. Focus group recordings were professionally transcribed, and Spanish transcripts were translated into English. We developed a qualitative codebook using deductive and inductive methods and then coded deidentified transcripts using the constant comparison method. The analysis team proposed themes based on review of coded data, which were validated through member checking with a community advisory board serving Latino individuals in the region and finalized through discussion with the entire research team.

Results: Between May and September 2023, we conducted 8 focus groups in English or Spanish with 48 participants. Focus groups were stratified by language and region and included the following: 3 (n=18, 38% participants) Spanish urban groups, 2 (n=14, 29% participants) Spanish rural groups, 1 (n=6, 13% participants) English urban group, and 2 (n=10, 21% participants) English rural groups. We identified the following seven themes: (1) mHealth is seen as beneficial for promoting health and peace of mind; (2) some are unaware of, unfamiliar with, or uncomfortable with technology and may benefit from individualized support; (3) financial barriers limit access to mHealth; (4) practical considerations create barriers to using mHealth in daily life; (5) mHealth raises concern for overreliance on technology; (6) automated mHealth features are perceived as valuable but fallible, requiring human input to ensure accuracy; and (7) data sharing is seen as valuable for limited uses but raises privacy concerns. These themes illustrate key barriers to the benefits of mHealth that communities may face, provide insights into the role of mHealth within families, and examine the appropriate balance of data sharing and privacy protections.

XSL•FO
RenderX

Conclusions: These findings offer important insights that can help advance the development of mHealth that responds to community values and priorities.

Introduction

Background

Mobile health (mHealth) tools, broadly defined to include patient-facing, health-related mobile or wireless devices, such as sensors, trackers, and wearables [1,2], offer the potential to improve health care access and encourage health-promoting behaviors through personal health monitoring. In particular, mHealth powered by artificial intelligence to make actionable, personalized predictions is a growing field that aims to advance broad-reaching, patient-driven preventive care [3]. For example, recent work has demonstrated the efficacy of an artificial intelligence–aided home stethoscope in detecting asthma exacerbations in children, which can facilitate time-sensitive decisions about management [4]. Others are using mHealth monitoring devices, such as smart inhalers and smartwatches, to collect personal and environmental data to facilitate the development of predictive models for asthma attacks [5,6]. Mobile data collection and device availability beyond clinical settings may be particularly valuable for overcoming geographic, financial, and other structural barriers to health care that disproportionately affect marginalized and minoritized groups, including Hispanic and Latinx communities [7].

mHealth tools have the potential to reduce disease burden and have been shown to be especially well suited for managing chronic health conditions, such as asthma, and particularly pediatric asthma [8-11], by facilitating continuous monitoring [12]. In the United States, pediatric asthma disproportionately affects Hispanic and Latinx children. An analysis of health record data from community health centers across 18 states showed Spanish-preferring Latinx children have a higher likelihood of clinic visits for asthma exacerbations [13], and overall, Hispanic children have a 40% higher death rate from asthma compared to non-Hispanic White children [14]. Existing mHealth tools for pediatric asthma monitor a wide range of factors, including air quality, lung function, physical activity, sleep, and cough [15]. Hispanic individuals in the United States own smartphones at similar rates to other racial and ethnic groups and are more likely than White individuals to use a smartphone as their primary means of internet access [16]. However, at least 1 recent cross-sectional study has shown that Hispanic and Latinx families are significantly less likely to have reliable, high-speed internet as compared to White families [17], illustrating the persistence of the digital divide that imposes disproportionate barriers to accessing digital technologies such as mHealth. For example, an evaluation of remote digital studies found that minoritized groups, including Hispanic and Latinx individuals, were overrepresented in clusters with lower app use, suggesting a need for improved engagement approaches [18]. The digital divide may be even greater among those living in rural areas [16]. These patterns suggest that digital technologies may replicate and exacerbate existing disparities if devices are not implemented in a manner that is culturally appropriate and responsive to individuals' social determinants and lived realities [19-22]. Cultural appropriateness is essential to ensure a tool is acceptable and effective for its target population and can work toward maximizing meaningful benefits and minimizing important risks [23,24]. Likewise, sensitivity to how social and economic structures differentially shape populations' access to and use of health technology is necessary to support fairness when implementing devices into real-world settings [24]. A 2018 systematic literature review found that SMS text message–based mHealth tools were consistently studied among marginalized populations; however, there were gaps in studies of other mHealth strategies as well as their real-world implementation [25].

This Study

As a step toward informing health technology that is responsive to individuals' sociocultural contexts, we conducted an in-depth focus group study to provide formative research on the values and lived experiences of Hispanic and Latinx community members in Washington State as they relate to mHealth. We used focus group methods, incorporating relevant mHealth case examples, to allow for group discussion and deliberation [26]. Our specific aim was to describe the perspectives of Hispanic and Latinx community members in rural and urban regions of Washington State about mHealth.

Methods

Participants

We recruited participants through community-based networks in urban western Washington and rural central Washington in several ways. First, we contacted people who had signed up to be contacted about research opportunities on the Community Voices registry, a longstanding partnership with Hispanic communities in central Washington led by a study team member (LKK). Second, we contacted previous participants in other studies who had agreed to be contacted for future research. Third, we shared recruitment flyers with networks serving local Hispanic and Latinx communities.

Individuals were eligible to participate if they were aged ≥18 years, spoke either English or Spanish, and identified as Hispanic, Latino, Latina, or Latinx. All study materials were offered in both English and Spanish, and bilingual study team members were available for all participant interactions [27]. Participants completed a brief demographic questionnaire.

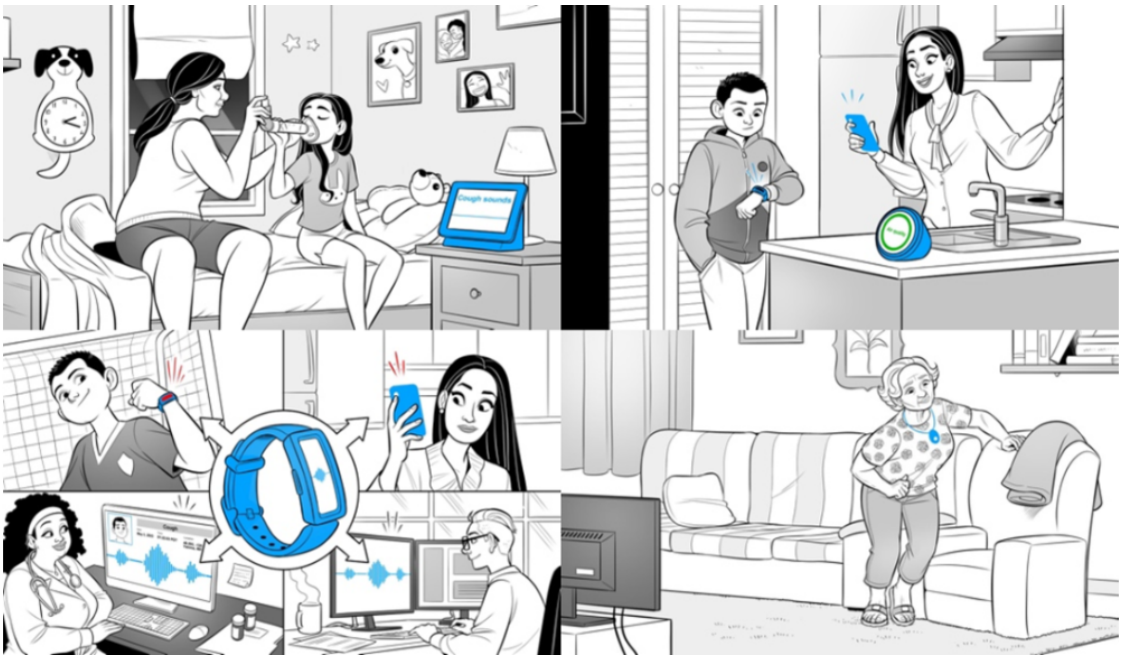
RenderX



Focus Groups

We developed a focus group guide (Multimedia Appendix 1) to explore key topics related to health technology use, including potential patient-level barriers and concerns as well as relevant mHealth design decisions, drawing on our multidisciplinary team's expertise in these topics. Our approach was also informed, in part, by the lived informatics model, which delineates a process through which people decide to use, experience using, and may ultimately abandon technology in real-world settings [28].

To ensure all participants had a shared understanding to foster robust deliberation [29], we created multimedia informational aids to present during the focus groups. We collaborated with Booster Shot Media, a private health-focused communication company comprised of a health communication expert and a pediatrician who is also a cartoonist with over a decade of experience developing multimedia tools for use in patient-centered research, to develop a series of illustrated narrative slideshows depicting Latinx families using mHealth devices. Our team first identified several clinical scenarios that would reflect realistic near-future uses of mHealth and would also be relevant to focus group participants' lived experiences. These scenarios were based on our collective knowledge of the communities where we planned to recruit and of mHealth development. Through iterative team discussion, we identified pediatric asthma as a paradigmatic example of a condition that disparately impacts Hispanic and Latinx populations in the United States, which is common in the region where we conducted our study and has several distinct opportunities for mHealth intervention. We also identified a second example case of fall risk in older adults as similarly amenable to mHealth intervention and relevant to this population. While we used these 2 example cases to provide tangible, relevant starting points for discussion, conversations were not limited to these clinical cases; instead, our discussion questions built on and expanded from these cases.

We developed the narratives of our slideshows by drawing on team members' personal and professional experiences with Latinx families as well as professional experiences with mHealth and pediatric asthma, and we worked with Booster Shot Media to finalize and illustrate the narratives. Booster Shot Media reviewed photos of Latinx individuals living in the regions where we recruited participants to create culturally relevant illustrations, which were refined through iterative review and feedback from team members with direct experience with the communities where we recruited. We also sought feedback on the slideshows from bilingual and bicultural colleagues outside of our study team. The final versions of the slideshows first presented concrete examples of how mHealth could be used to predict asthma exacerbations and manage asthma in children, how different devices might work, and how data might be shared. They described these examples through a family-based narrative showing parents and children working together to manage pediatric asthma. The second example showed an older adult, the family's "abuelita" (grandmother), using a wearable device to predict fall risk, which was a briefer narrative intended to explore potential differences in perspectives based on the individual using the device and the condition being tracked. These examples described how the depicted mHealth tools could make personalized predictions and improve those predictions based on collected data, but we did not explicitly use the term "artificial intelligence" to avoid raising potentially preconceived notions about artificial intelligence as depicted in the broader media. Example slideshow images are shown in Figure 1. The full slide decks and text are included in Multimedia Appendix 2 (English version) and Multimedia Appendix 3 (Spanish version).

Figure 1. Example narrative slideshow of families using mobile health to control pediatric asthma and monitor fall risk in an older adult. The slideshows were developed in collaboration with Booster Shot Media.

Focus groups were held on Zoom (Zoom Video Communications) and moderated by at least 2 members of the research team, with at least 1 additional team member present for note-taking and technology support. Native speakers in the research team facilitated the Spanish focus groups. Audio recordings were professionally transcribed verbatim, and Spanish focus groups were professionally translated into English. Transcripts were reviewed by the research team for accuracy of transcription and translation, deidentified, and uploaded to the cloud-based platform Dedoose (SocioCultural Research Consultants, LLC) [30] for qualitative analysis management.

We developed an initial codebook based on a deductive review of the focus group moderator guide topic areas. Two team members (MCD and SC) reviewed 2 focus group transcripts, revised the initial codebook using inductively derived codes from the transcripts, and coded those transcripts using the constant comparison method [31]. They continued this iterative process with additional transcripts until the codebook needed no further revision. A third coder (AB) was then trained. All transcripts were coded by the coding team and reviewed for consensus.

Coded excerpts were extracted for review and identification of themes [32,33]. We divided excerpts for review and summarization following the codebook structure, as our initial review suggested that themes aligned with the previously identified codes. This step allowed us to identify key themes and condense the data to facilitate reporting. Two team members (MCD and SC) summarized a portion of the excerpts and proposed themes, and to ensure credibility, a third member (SAK) independently summarized and proposed themes from all excerpts. Proposed themes were compared and discussed among the analysis team, which included a community-based researcher, a computer scientist, and a bioethicist. Our coding team additionally included a bioethics research assistant, and 2 of 3 coders were bilingual in English and Spanish. A summary of themes was shared with a community advisory board serving Latino individuals in central Washington for member checking, which validated and identified important nuances in our findings [34]. We then revised and finalized our themes through discussion with the entire research team.

Ethical Considerations

This study was approved as exempt by the institutional review boards at the University of Washington (STUDY00016183) and Seattle Children's Hospital (STUDY00004107). All participants reviewed an information sheet with a study team member in their preferred language and provided verbal consent. All transcripts were deidentified before analysis, and only deidentified quotes were reported. Participants received a US $50 gift card following the focus group.

Results

Participants

We conducted 8 focus groups: 5 in Spanish, 3 in English, and 4 each with rural and urban participants. These focus groups included 48 participants overall, with an average of 6 (SD 2) participants per focus group and a range of 3 to 9. Participants reported a mean age of 45 (SD 14) years, and most (43/48, 90%) were women. Most (38/48, 79%) indicated they were born outside the United States, including nearly all (31/32, 97%) participants in the Spanish focus groups and half (5/10, 50%) of participants in the rural English focus groups. Most (29/48, 60%) participants reported having either no health insurance or state-funded health insurance, and a majority (31/48, 65%) reported no formal post–high school education. Detailed participant characteristics, including self-reported experience with mHealth and asthma, are shown in Table 1.

Focus Group Themes

Overview

We identified seven overarching themes from our focus groups: (1) mHealth is seen as beneficial for promoting health and peace of mind; (2) some are unaware of, unfamiliar with, or uncomfortable with technology and may benefit from individualized support; (3) financial barriers limit access to mHealth; (4) practical considerations create significant barriers to using mHealth in daily life; (5) mHealth raises concern for overreliance on technology; (6) automated mHealth features are perceived as valuable but fallible, requiring human input to ensure accuracy; and (7) data sharing is seen as valuable for limited uses but raises privacy concerns.

We examined the data for differences in themes based on rural or urban location and English and Spanish language but did not identify distinct themes in any subgroups. Illustrative quotes for each theme are provided throughout.

Theme 1: mHealth Is Seen as Beneficial for Promoting Health and Peace of Mind

Most participants described mHealth as beneficial, discussing how this technology could help track chronic conditions and prevent serious health events through earlier intervention. For example, 1 participant noted the potential value of tracking their health conditions:

> *I would think it would be fantastic because I suffer from an autoimmune disease, I have no balance, so I have suffered several falls, and that would be a help for me, a help to be alert all the time. I would love to have that device.* [Urban; Spanish-speaking participant; translated; FG US3]

Another described how mHealth would have helped their family navigate interactions with their physician to improve their child's care:

> *I insisted a lot with the doctors. Because they all sent [my child with asthma] home, that his cough was normal, that his cough was temporary...I wish someone had given us that monitor, because we would go to the doctor and they would say: "And how is his cough? And how often is he coughing?" And I'd be like, "We've already had so many months without being able to sleep, like the least I pay attention to is the cough, what the cough sounds like." Yes, I would have liked to have had a device so it would have been easier for the doctor to know what his cough was like.* [Urban; Spanish-speaking participant; translated; FG US3]

One participant described the potential impact of earlier detection on their rural setting:

> *Here in [rural area], we only have one hospital, the emergency room is packed sometimes. We don't have enough beds on the floors. I feel it would really benefit in preventing people from going really bad to the hospital and flooding the hospital with people. Instead, they can use their devices and go to their doctor, take a little better care of their health or at least keep track of—especially with chronic issues. They can monitor if they're starting to notice some changes, then they can act on it earlier than later.* [Rural; English-speaking participant; FG RE2]

Many participants also discussed that these tools could promote peace of mind and feelings of safety. They linked the presented examples to their own experiences caring for children with asthma or supporting older family members in living independently, highlighting how technology could allow them to feel comfortable without needing to continuously monitor their family members. Several participants reflected on their fears as parents of children with asthma:

> *I used to take [my children] to my room so I can be watching them because it was scary. And especially at night, because during the day, they were fine. But at night, they usually had those asthma attacks when they were little. And we ended up in the hospital...As they get older, I mean, they tell you or they get out of*

XSL•FO
RenderX

> *their bedroom or whatever to tell you. But when they're little, they don't. So you have to be watching them.* [Rural; English-speaking participant; FG RE2]
>
> *I also think it's a very good idea because someone in my family has asthma, so, maybe that would have saved me a lot of sleepless nights.* [Urban; Spanish-speaking participant; translated; FG US2]

Others spoke about the value of mHealth monitoring for older people living independently:

> *This scenario made me think of my grandma who lives by herself, and she's very much a lot older. And she has a lot of health issues, right? So I think if her pressure is low or something and she falls, that could be—I think [an mHealth device] would be really helpful.* [Urban; English-speaking participant; FG UE1]
>
> *I have a neighbor who lives alone and is already old, and that makes me have all the access of her movements. Yes I would like that device to monitor...Because nobody is aware of her, she is left alone, and I think it would be very helpful.* [Rural; Spanish-speaking participant; translated; FG RS1]

In addition, some discussed the role of mHealth in allowing people to continue their regular activities, sometimes referencing our slideshow example of the boy using mHealth to manage his asthma while continuing to play soccer. A participant highlighted the importance of allowing a child to play sports without the added burden of fear about asthma:

> *I think it is good because the child would not abandon the games that he likes. And if that [mobile device to track asthma] did not exist, a mother would say, "You better not play." And if it did exist, she would say, "Yes, play. I am going keep an eye on you." Then, the child will no longer say, "If I do this, this will happen to me."* [Rural; Spanish-speaking participant; translated; FG RS2]

Theme 2: Some Are Unaware of, Unfamiliar With, or Uncomfortable With Technology and May Benefit From Individualized Support

Many participants noted that they had used mHealth apps for tracking things like physical activity or diet, but overall, most expressed a general unfamiliarity with mHealth technologies used to track and make predictions about risk for specific conditions. Several mentioned that no health professional had ever made them aware of such devices:

> *Well, I think [it would be good] for them to let us know that they have this kind of device, because I never heard that they have this device. They never told me.* [Rural; English-speaking participant; FG RE2]
>
> *[I would have questions about] the name of the devices, which company can provide them, if there is any support to be able to have those devices, if they are going to start providing them in the clinics, where one can get more information, or for example, in the clinic, who can one address specifically to say, "Hey, do you know if the device is already available".... In other words, how can one go about obtaining these aids.* [Rural; Spanish-speaking participant; FG RS2]

Participants further noted that some people might feel uncomfortable with using technology. They cited examples of older family members either avoiding technology in general or specifically avoiding wearable health devices. Some used these examples to highlight how the value of a device is contingent on an individual's comfort. For example, a participant provided an example of how their family supported their mother in getting comfortable with technology despite hesitancy about wearables and challenges with mobile devices:

> *So I know my mom wouldn't wear one, and we always worry about her also. She'll lose her phone and stuff, and we'll be trying to call her, and she won't find her phone, and so my best thing was to get her [a voice-activated device]. So I showed her how to use that, and she's pretty okay with it. So it's nothing she has to wear, but whenever she needs to make a phone call and she can't find her phone, that's what she uses.* [Rural; English-speaking participant; FG RE1]

Some participants expressed that most people could get used to new technology over time. One highlighted how quickly this could happen for children:

> *They just hop onto everything, whatever, and technology is not very difficult for them to get used to and learn it, and they pretty much get used to stuff real quick that has to do with—and especially if it has to do with their health is like you need to do it.* [Rural; English-speaking participant; FG RE1]

Others emphasized the need for practice over time:

> *Even if they want to, if it is not being used, they have the training, the direction—whatever they want to call it—to be able to use it and know what is going to happen, to know about the program or the equipment so they can help. If we don't know how to use something, it doesn't help us at all, on the contrary, it will give us more problems.* [Urban; Spanish-speaking participant; FG UE3]
>
> *I don't think it will be hard to learn. It would just take some time. To get used to anything, you get used to a new phone, you get used to anything you get new. So you get used to it. So it takes practice.* [Rural; English-speaking participant; FG RE2]

Some participants also identified a need for individualized support, such as developer-created tutorials or one-on-one support, to facilitate comfort with mHealth. One participant discussed the value of personal support:

> *I think, especially for Latino families, I think we need more person-to-person support. Like, "Take this, read it. If you have any questions, find me, call me." Because yes, sometimes we bring things into the house and we don't understand it and we don't know who to ask or how to use it. So, having that reinforcement, having that person who can guide you, help you and*

XSL•FO
RenderX

get you out of doubt when using new things. [Urban; Spanish-speaking participant; FG UE3]

Theme 3: Financial Barriers Limit Access to mHealth

The cost of devices was a concern for many participants, who raised questions about whether devices would be covered by insurance or what the cost would be for those without insurance coverage. Several called out the likely or actual cost of these devices as a barrier:

It'll probably come with a hefty price tag. [Urban; English-speaking participant; FG UE1]

I haven't used [mHealth], as the price is a bit high. [Rural; Spanish-speaking participant; translated; FG RS2]

I had one that was given to me as a gift, but it was one of the first ones that came out. Then, after that, well, I didn't—the truth is, financially I never put money to buy a new one for me, because they were more sophisticated, more expensive. [Urban; Spanish-speaking participant; translated; FG US2]

Some participants specifically noted the potential expense if multiple family members needed their own devices:

I would imagine for those who have more than one person in the family, it will cost a lot of money. [Rural; English-speaking participant; FG RE2]

If there are three, four, five children in the family, it is not enough to be buying—we are talking about the economic [impact], to be buying devices of all kinds and that [have] everything the child needs. [Rural; Spanish-speaking participant; translated; FG RS1]

Several participants highlighted the importance of insurance coverage for affordability, including how inconsistent insurance coverage could impact people's use of mHealth:

[MHealth devices] are expensive and all this. But if you have insurance and if it's within the insurance budget, they're not expensive. [Urban; Spanish-speaking participant; translated; FG US2]

The cost, that would be a problem that many people face, such as the costs of the products that provide us with these types of services. Like, for example, in my case I use a sensor, if it were not because I have an insurance, I couldn't afford it. [Urban; Spanish-speaking participant; translated; FG US1]

I think it also depends on cost or insurance, because a lot of us don't have access. An example. Right now, I no longer have access to insurance since I stopped working, because I have a temporary job, so in two months I run out of insurance. So, that's when the benefit comes or we no longer have benefit, for the drugs, the appointment, everything that comes with it is more expensive. So certain people who have or do not have health insurance, that's where I think the conflict really comes. But I think a lot of people would be willing to use it if they are cheap. [Rural; Spanish-speaking participant; translated; FG RS1]

One participant expressly noted that these resource limitations may disproportionately affect Latino individuals:

And of course, always the Latinos, right [laughs], we don't have the resources of those who speak English...Well, yes, the whites, they have them, we don't have them. [Urban; Spanish-speaking participant; translated; FG US2]

Theme 4: Practical Considerations Create Barriers to Using mHealth in Daily Life

Participants also discussed potential technical barriers, including inconsistent internet access, limited phone storage capacity, limited battery life, and technology crashing or simply not working. For example, a rural participant commented on the challenges of relying on inconsistent internet and cell service in their area:

How many times does our internet go away? How many times do the poles get knocked down or whatever, or there's lost connections? Something that we can have, like maybe going back to those dial tones. I don't know. Plugging them into the wall. I don't know, but trying to find something that's not going to crash on us, especially if your child is having one of these asthmatic attacks. [Rural; English-speaking participant; FG RE2]

Other participants also commented on inconsistencies in internet access:

Not everybody is going to have access to it. As they say now, "The Internet," but there are still places and there are still people who do not have access to it. [Urban; Spanish-speaking participant; translated; FG US3]

The only problem would be if, for example, how the device works; if it is with electricity, and if one day the power goes out; or if it is by means of wifi, even if the power goes out, it stops working. [Urban; Spanish-speaking participant; translated; FG US2]

Participants also described the breadth of challenges that people experience with their mobile devices:

Every device can fail at some point, or maybe it is low on battery or I don't know what it will have or—there is always a problem, but there is always—nothing is 100% safe. [Urban; Spanish-speaking participant; translated; FG US1]

The charge doesn't last long. So maybe having something that doesn't die so quickly. Again, mine could be because it's an older version or maybe it's time. Maybe it's a hint of having to go get a new one. I don't know. But the fact that it dies really, really fast because it's calculating everything. The more apps you have on it, the more battery it takes. [Rural; English-speaking participant; FG RE2]

It adds very quickly to your memory, it fills up very quickly. Well, make it less. Because can you imagine if we have a disease app? People who sometimes have so many diseases are going to fill up the phone and

XSL•FO
RenderX

> *sometimes the memory is not enough for them. Let it be less, please.* [Rural, Spanish-speaking participant; translated; FG RS2]

Participants further noted that the benefits of mHealth would be limited if not embedded within an environment that facilitated those benefits. For example, a child using a smartwatch to manage their asthma would need their school to allow them to use the device and coordinate with the family:

> *I wanted to ask you, to see if this device can be taken to school and the teacher can also have the information about the child, to be able to help him, because, just as the other family members can also help, they will have the information, the teacher can also help you.* [Urban; Spanish-speaking participant; translated; FG US1]

Similarly, another participant noted that not all work settings facilitate the use of mHealth devices:

> *Sometimes at work you can't even see the clock, much less the telephone. So, I think it would be a little difficult.* [Urban; Spanish-speaking participant; translated; FG US2]

Theme 5: mHealth Raises Concern for Overreliance on Technology

Some participants raised concerns about mHealth leading to overdependence on technology. For example, one participant described mHealth as a part of a broader societal move toward technology dependence:

> *Yes, we are advancing and we are advanced, but they are the things that leave us like a bad taste in our mouths: we are not up to date in the moment, in the second. Because I saw that suddenly, "Oh, three more hours on my phone. Leave me, I reinstall it, because it is not up to date."* [Rural; Spanish-speaking participant; translated; FG RS1]

Another participant discussed how technology could undermine one's self-reliance, especially for a child:

> *One of the challenges that I noticed even in the cartoon characters, that they showed Arturo's discouragement and feeling like he's trapped in all this technology causing him to not be the person that he wants to be because he wants to be a good soccer player, for sure. So that could interfere with his psyche and his confidence in himself.* [Rural; English-speaking participant; FG RE1]

Others spoke about the potential impact on family relationships. Some raised concerns about family members relying on devices and consequently neglecting to engage directly with their family members about their health:

> *I think there is a lot of elderly very, very alone, and this will make it worse, like, "Oh, okay. It will let me know. The little thing will send me a message if she falls." And I won't be able to like it. I'm kind of more old fashioned. I think maybe I can get more involved or ask a friend or ask more family to take care or be a company [] instead of just put a collar on it and just forget about it.* [Urban; English-speaking participant; FG UE1]
>
> *I have a teenager, and sometimes it's hard to make a conversation with them, right? So I think it will be more challenged to connect with them if you're just looking at the phone instead of asking him, "How you feel during the day?" or, "How was the challenge? How you feel when you run and jump?" And if I'm just worried about the app or what the phone said or the wrist coughing track, for me, it would be like I don't care how—it's going to be like stopping the communication. I would be more worried about the monitor and not asking my child. And maybe they will feel like, "Oh, she knows now that I've been coughing because she's been monitoring," instead of telling me, "How you feel with this and that?" And maybe the monitor is tracking just the coughing, but it didn't tell me what activities they were doing, and I think we'll be much better to stay with one-on-one communication with our kids.* [Urban; English-speaking participant; FG UE1]

Theme 6: Automated mHealth Features are Perceived as Valuable but Fallible, Requiring Human Input to Ensure Accuracy

Limitations of technology also came up in terms of data collection. Although automatic, continuous data collection was often seen as beneficial and easy, some participants noted that manual input would be more reliable in some cases, most notably in tracking mood and mental health. One participant suggested that manual input for a period would improve subsequent accuracy:

> *You wouldn't want or you wouldn't be able to just be with the child 24/7 all the time, which is why automatic kind of makes sense in this really busy world. But I guess in something like this where it's life or death and it's your child, you're willing to drop everything to be with them until this gets settled. So whether it's the day, the week, the weeks to then get it honed down to the accuracy and the level of punctuality that you need, it would make sense to do it manually as well. And then work automatically.* [Rural; English-speaking participant; FG RE1]

Another highlighted an example from their own experience of needing a human to step in when health technology fails:

> *I think we are going to realize if something is wrong with the device or with our child. I tell you this because my grandson uses a feeding pump and when the pump is failing, we can tell. So, then we call the technician and we have the possibility to feed him manually.* [Urban; Spanish-speaking participant; translated; FG US3]

Others discussed the importance of checking on data from the device to verify the information it provided, viewing the role of the device as providing them with a high level of information and then allowing them to make decisions. For example, one participant described the need to balance the ability to take

XSL•FO
RenderX

action when warranted with avoiding panic due to frequent alarms:

> *Imagine if [the device] is alarming every hour, then that can cause not only that the person gets scared or the child gets scared, but the others stay in panic, because they don't know if it is right, if it is correct. So it would be like, maybe, give them time to be able to verify all the symptoms and that yes, instead of sending and sending alerts.* [Urban; Spanish-speaking participant; translated; FG US3]

Another expressed skepticism that the information would provide clinical value:

> *For me, when my kids get sick or something, I never been asked by the pediatrician how many times it was coughing, never had to track that. It's just in general, how the kids are eating or playing or how they look, their appearance. Sometimes they look very tired, or you can tell when they couldn't breathe very well...So I think the monitor will be hard to track that, and I won't trust completely like, "Oh, you coughed 100 times. Let's go to the hospital."* [Urban; English-speaking participant; FG UE1]

Despite these concerns, participants generally indicated that they would prefer to receive false positive alerts rather than miss true positives:

> *I think, for me, it would be more stressful if I didn't detect a real asthma attack. Since it's about saving the child's life, what does it matter if it's a false alarm? Well, yes, I'm going to be a little stressed, but I'd rather have that than it not detect an asthma attack. I know that computers can't replace humans and they're not perfect either, but yes, I'd rather have the device be more sensitive and have a false alarm once in a while than not detect, not be sensitive enough to detect all asthma attacks.* [Urban; Spanish-speaking participant; translated; FG US2]

> *I would rather have a million false alarms than the one where they direly needed help and that one wasn't alerted.* [Rural; English-speaking participant; FG RE1]

Theme 7: Data Sharing Is Seen as Valuable for Limited Uses but Raises Privacy Concerns

Overall, participants endorsed the value of data sharing for uses such as providing emergency support or sharing clinical information with key family members or clinical team members. Participants also supported the use of data for improving the technology and making better predictions, at least on the level of the individual device. For example, one person described the importance of collecting location data as well as health data, both for emergency services and to improve accurate predictions:

> *I think it's very good, because it is giving the place where he is at. And let's say he is feeling very, very bad and can't even talk, then all that helps. And if someone is watching him, it would help, if he is in a place where no one else is around or close by, to find him, to alert the doctor, to know that the child is going to need help or that he is in difficulty...And maybe they can add more information, like "where you are, you're prone to have really bad air at this time of day." All of that could help them, the kids, make the best decisions for themselves.* [Urban; Spanish-speaking participant; translated; FG US3]

However, another participant described data sharing as a "double-edged sword" that would increase privacy concerns:

> *I know that it is to improve the service or the product, but it is also like a double-edged sword, because your information goes into more hands so, if it is no longer completely clear to you how your information is handled, when it is already in the hands of other people. So, in that aspect, I would like to have a little more privacy.* [Urban; Spanish-speaking participant; translated; FG US1]

Other participants also identified privacy concerns, highlighting the possibility of data breaches or data misuse:

> *So if somebody who isn't a professional hacks into his watch, that would be invasion of his privacy. If his friends, people at school, hack into his watch, he would probably be embarrassed. And again, it's just taking away his privacy, which the hacking is—could be an issue.* [Rural; English-speaking participant; FG RE1]

> *I would be afraid that, let's say, the medicine companies might say, "In this area there are many children with asthma or more attacks" and they might want to take advantage of that situation in some way. I don't know. And also, since all the information is virtual, and even if one is careful and cautious, there are many places where one's private information has been seen by many people who have nothing to do with it.* [Urban; Spanish-speaking participant; translated; FG US3]

These concerns were heightened for information they deemed sensitive, such as location data and information about sensitive or stigmatized health conditions. One participant identified mental health as an area that might raise particular concerns:

> *I think the disadvantage of using these technologies for more private things, as a mental health issue, is that there are times that they do like hacking, that they get into your phone and grab information that, obviously, you don't want other people to know or that is very sensitive. That's why I sometimes get nervous when I'm putting medical stuff on my phone.* [Rural; Spanish-speaking participant; translated; FG RS1]

Participants also suggested ways to find a balance between the value of data sharing in limited cases and the risks of privacy breaches. For example, one person proposed limits on the types of data to be shared:

> *Sometimes, everyone wants to keep [their information] private, and even more so when it comes*

XSL•FO
RenderX

> *to children, so maybe you are supposed to be sending the information to trusted people, but, for example, as a mother I would feel safer just having my daughter's location. So, or her father, as [another participant] mentioned. That is, the people as closer. But from then on, like, for example, the activity of coughing or anything else, obviously it does have to be shared, but for me, the location [should not be shared]*. [Urban; Spanish-speaking participant; translated; FG US1]

Another suggested that those accessing data enter into explicit agreements about data use:

> *The only ones that have access to the location would be his doctor or his doctor's office or the emergency room, the ambulance. I think that that would be—I know as a parent myself, I would be scared about people knowing where my kids' locations is at, right?...But giving access just to— even signing something saying that they're the only ones that are going to have access to their location in case of an emergency. Something written, not verbal. I would get something documented, written, that says, "I am only going to have access to their location in case of an emergency.*" [Rural; English-speaking participant; FG RE2]

Discussion

Principal Findings

Our focus group findings report important perspectives on mHealth from Hispanic and Latinx individuals across rural and urban regions of Washington State. Although the themes we report share similarities with perspectives of other communities, they highlight the importance of tailoring mHealth tools to the context in which they will be used, specifically among a community with high rates of underinsurance and limited financial resources, including many individuals in rural areas and many whose primary language is Spanish. Our results illustrate key barriers to the benefits of mHealth in these communities, provide insights into the role of mHealth within families, and examine the appropriate balance of data sharing and privacy protections.

Barriers to the Benefits of mHealth

Participants perceived mHealth as beneficial overall; however, our findings highlight several critical barriers to accessing those benefits. First, there was little awareness of the potential for mHealth to be used to manage chronic conditions. Participants with experience with asthma or other conditions expressed particular interest in having a health professional tell them about these types of tools. Second, many participants expressed that they or their family members might be uncomfortable using mHealth technologies, which could lead to them either never initiating or stopping the use of a device. Suggestions to provide time for practice, tutorials, or even personalized support arose in multiple focus groups as strategies to improve comfort and familiarity. Third, participants reported resource constraints and the lack of insurance coverage as significant barriers to accessing mHealth. Finally, participants identified both features of the device (eg, technical usability) and broader contextual features (eg, integration with school systems) as limiting the usability of mHealth tools if not adequately addressed. These findings, particularly related to resources and provision of support, are mirrored in qualitative work with other populations, including residents of rural areas [35] and English- and Spanish-speaking patients in a safety net setting (ie, care providers that serve patients regardless of their insurance status or ability to pay) [36]. Another pilot study that included interviews with 10 Latina women similarly identified limited access and underutilization of mHealth as limiting the technology's social value to the broader community [37]. The imbalance of high perceived benefits with significant barriers illustrates the need to approach mHealth research and development from a justice-oriented perspective, as Herington et al [24] argue in the context of digital health research that works on both decreasing risks and, importantly, developing specific, community-informed mechanisms to equitably share benefits.

The Role of mHealth in the Family

Participants also discussed the complex role of mHealth within family dynamics. Many identified relational benefits of using mHealth devices to make personalized predictions about risk when used in a family setting, providing caregivers of children and older adults with peace of mind. At the same time, participants acknowledged that their family members, particularly older adults, may view such monitoring as interfering with their autonomy. Some also worried about the risk of undermining interpersonal relationships from relying too heavily on technology. These dynamics reflect the value of considering a "family informatics" approach to mHealth design, which explicitly recognizes the interrelatedness of family members and their health [38]. Family connectedness and commitment are core cultural values that may shape how Latinx individuals approach their use of mHealth devices [23,39]. Thus, family informatics may be particularly relevant for ensuring devices are culturally appropriate. In addition, to navigate concerns for overreliance on technology, developers should consider hybrid solutions that integrate the benefits of automated technology alongside human input [40].

Data Sharing and Privacy Concerns

A key issue in the use of mHealth is how data are shared, including whether and how artificial intelligence incorporates user data [41]. In discussions of data sharing, participants identified specific benefits in the use of data sharing to facilitate emergency responses and improve personalized prediction accuracy. Although disclosing individual data was generally seen as acceptable for these beneficial uses, this was balanced with privacy considerations, particularly around location data and sensitive health information. Privacy concerns and the risks of breaches of privacy may be heightened among individuals from marginalized groups, who differentially experience harmful impacts from discriminatory social structures [24,42]. Primary language is one relevant dimension of marginalization; a recent survey of parents of children with asthma found that Spanish-speaking parents were more likely than their English-speaking counterparts to report privacy concerns about digital health tools [17].

XSL•FO
RenderX

Participants suggested solutions to limit data access to only those necessary to produce the benefits identified as valuable. Discussion about data sharing for purposes of improving predictions more generally was limited but similarly focused on benefits and risks. A key way to accomplish this appropriate balance will be to ensure that the benefits of artificial intelligence–enabled devices do, in fact, reach the communities that are taking on privacy risks [41,43]. Future work should continue to examine the nuances of community members' perspectives on this benefit-risk balance in the context of predictive technologies.

Limitations

Our study represents the views of community members drawn from a specific region of the United States; people with other life experiences, cultural, ethnic, or national backgrounds [44], and values may have different perspectives. Of note, most (43/48, 90%) participants were women, and most (35/48, 73%) reported that Mexico was their country of origin. Nevertheless, by situating our findings within the broader literature on community perspectives about mHealth and other health technology, we aim to provide nuance from the perspective of this underrepresented group.

Further, although we explored topics related to the use of mHealth by children and older adults, children were not eligible to participate in this study, and participants were in midadulthood on average. Additional perspectives would be important to include in guidance on devices targeted at additional age groups. Future work is also needed to explore mHealth as applied to specific conditions, such as mental health conditions that may raise additional privacy considerations.

Finally, while our case examples illustrated artificial intelligence–enabled mHealth tools and focus group discussions built on these examples, we were not able to fully explore the complexities of attitudes about artificial intelligence within this study. Future work should continue to seek ways to engage with community members about these topics and their implications.

Conclusions

This focus group study with Hispanic and Latinx community members illustrates the importance of developing mHealth with input from underrepresented communities. The in-depth perspectives of these participants highlight the necessity of developing and implementing tools with attention to barriers, family context, and privacy concerns to avoid exacerbating disparities in the use and value of health technology. Future work should incorporate these perspectives into guidance to support mHealth developers in creating tools that meet community needs and advance equity.
