Goals 1 (ie, having shared knowledge among all users) and 5 (ie, respecting perpetrators' freedom of speech while educating them about the negative impact of their words) can be achieved by using approaches that focus on educating people about microaggressions and their harmful effects, as well as explaining why certain comments are considered microaggressions. By highlighting the harmful consequences of microaggressions, such approaches can help perpetrators evaluate the ramifications of their comments and reconsider causing future harm.

Explanations of what microaggressions are and their harmful impacts make current perpetrators aware of the problem and provide them with a chance to become proper allies by reexamining their own and others' roles and responsibilities [25,31,32]. Potential allies or perpetrators, especially those of the same gender who are experiencing similar oppressions or have overcome them, need to be more aware of their roles and responsibilities in reducing web-based in-group microaggressions. When people normalize oppression rather than acknowledging it, they unintentionally reinforce it with further microaggressions [10,22]. In contrast, when those who have overcome oppression offer empathy, support, or acknowledgment of the harm, they help others recover and learn [10,22]. As suggested by our study participants, we deem the rephrasing suggestions feature helpful in preventing unintentional harm or discouragement of support, even by those experiencing similar oppressions.

Support for encouraging perpetrators or potential allies to rethink their messages can be found in counter speech research [36-38,72]. Unlike content moderation, counter speech does not suppress free expression but aims to reduce hate through persuasion [37]. Counter speech involves 2 main approaches to responding to and deflecting hate speech. The first approach is a nonaggressive response to abusive content, deconstructing stereotypes and misinformation with thoughtful reasoning and fact-bound arguments [38,72]. The second approach, sometimes termed counternarratives, involves creating positive stories to encourage tolerance and disprove the assumptions underlying hate speech [36-38]. Counternarratives focus on triggering positive feelings, such as empathy for targets that could lead to attitude changes [36-38].

Participants were concerned that perpetrators might feel unappreciated and think moderation was unjust or frustrating, potentially leading to retaliation. While participants did not strongly advocate for counter speech explicitly, they thought educational explanations would support users "who have a good heart" [P12] to become allies and adopt rephrasing suggestions. This supports using counternarratives, which aim to foster empathy toward microaggression targets and prompt perpetrators to rethink their actions without feeling wronged.

Furthermore, goals 1 and 5 were influenced by participants' cultural characteristics, rejecting approaches that would burden their social support network. Participants' definition of social support includes current allies and microaggression perpetrators

XSL•FO
RenderX

who have supportive intentions. Participants noted that the fine line between harmful comments and hard-hearted advice can be hard to identify. Through thoughtful reasoning and positive narratives, counter speech can support unmarried people's extended support network, such as microaggression perpetrators with supportive intentions. Moreover, counter speech would help perpetrators feel empathy for targets and reconsider their delivery of support, which is currently difficult to achieve for "gray area" moderation cases [30,31].

Goal 4 (ie, having forum-approved experts guide the discussions) offers further insight into who should lead counternarratives. By having forum-approved medical experts and experienced users lead discussions, participants thought counternarratives could help re-evaluate factually wrong, disrespectful, or invalidating content. Leading critical and logical reactions to microaggressions by experienced users is supported by strategies for dealing with racial microaggressions [72]. Eschmann [72] suggested web-based counter spaces—where "activisty" students of color challenge dominant paradigms—highlight and critically react to experiences with microaggressions, providing ample support and counteraction for targets. In these counter spaces, "activisty" students lead critical reactions using counternarratives, similar to the "older sister" [P9] role suggested by our participants.

To nudge authors to revise or delete offensive text, recent work identifies offensive parts of a message [73] and suggests less-offensive alternatives through paraphrasing and style transfer [74,75]. Style transfer aims to translate abusive text into nonabusive while preserving its nonoffensive meaning [33,75,76]. Our study participants also advocated for low-effort approaches. This appreciation of reducing effort for potential allies is supported by other studies on web-based microaggression counteraction strategies [69,73]. Heung et al [69] recommended reactive approaches providing corrective information in response to microaggressions, similar to counternarratives [5,72]. However, participants also expressed concern about making microaggression perpetrators (ie, potential allies) feel unjustly attacked. Thus, public or private rephrasing through style transfer should be further studied to determine whether it could be interpreted as harmful in certain contexts.

Most approaches limit education and explanations to perpetrators, but our participants suggested that all users be educated on microaggressions, how to cope with or address them, and how to find and receive support after experiencing them. They recommended that explanations for flagged comments be made public and include pointers to support groups and resources. They also suggested that educational resources and support groups be added under the microaggression content alert feature for those who do not want to be exposed to microaggressions at all. Thus, social media platforms should extend their educational approaches to benefit *all* users and not just perpetrators.

Limitations and Future Directions

One potential limitation stems from the interviewer also being an unmarried Korean woman and the study participants being attained using snowball sampling. In investigating the design needs of the population that the interviewer is in and may have weak ties to, the participants may have felt a connection with the interviewer and enabled thoughtful responses. However, they may also have felt pressure to be portrayed as strong, independent women who did not need emotional support, especially when asked how they would alter or not alter their designs if they were the only post author users. Future studies should explore how having a design session facilitator who is not an unmarried Korean woman and does not have weak ties with the participants affects the participants' designs. In addition, we acknowledge that the findings of our study are based on a small number of participants. Although we reached saturation with 14 participants, the microaggression counteraction designs from this study could still be expanded upon. Thus, we encourage future studies to explore co-designing with a larger number of participants to reach further consensus on the microaggression counteraction designs.

Moreover, we suggest future studies delve into how the proposed microaggression counteraction designs could potentially be weaponized against those who are already susceptible. In this study, the focus was to co-design with unmarried Korean women to counteract the microaggressions suppressing their health care and to explore how the corrosive harm of microaggressions and social and cultural norms were reflected in their needs and preferences. We acknowledge the possibility of weaponization of the microaggression counteraction features. For example, automatically deleting a comment after a set number of negative reactions from the community may easily enable orchestrated actions to take nonharmful comments down. In addition, individualized messages to targets could be used to annoy the target if sent automatically by triggering multiple messages. Furthermore, an expert with a badge who writes microaggressions may encourage higher acceptance of the microaggressions. We suggest subsequent studies investigate how to protect people from the potential weaponization of their designs to ensure their safety.

Conclusions

In this study, we co-designed with unmarried Korean women participants with the aim to create a resilient and safe space for support on stigmatized SRH by preventing and counteracting web-based microaggressions that suppress women's health care. During the co-design sessions, we identified 6 goals participants had for counteracting web-based microaggressions that discourage SRH care support seeking. Connecting back to these goals, we also encourage educational, rather than the more common punitive detection and deletion designs that counteract microaggressions. We should help targets and allies cope with microaggressions, and help perpetrators reflect on the consequences of their words. With these design strategies and examples, we hope to encourage new moderation approaches within web-based communities. These approaches should support women in seeking essential care for stigmatized SRH, while reducing the occurrence and detrimental impact of microaggressions on their health and well-being.

Acknowledgments

The authors would like to thank the participants whose experiences formed the basis for this research and the University of Washington iMed Research Group for their insightful feedback on the development of the co-design session guide.

Data Availability

The datasets generated and analyzed during this study are not publicly available due to them being transcripts with personally identifiable information and sensitive disclosures about their sexual and reproductive health support–seeking experiences.

Authors' Contributions

HR and WP were responsible for conceptualization. Data curation was done by HR. Formal analysis was done by HR and WP. WP was responsible for funding acquisition. Investigation was done by HR. HR and WP were responsible for methodology. HR was responsible for project administration, resources, and supervision. HR and WP were responsible for writing the original draft. HR was responsible for review and editing of the manuscript.

Abstract

Background: Genetic testing has become a common way of identifying a woman's risk of developing hereditary breast and ovarian cancer; however, not all medical providers have the necessary information to support patients interested in genetic testing, nor do they always have the proper information for patients once they have been diagnosed. Therefore, many "previvors"—the name given to those who have tested positive for the *BRCA* genetic mutation—have taken to social media to inform others about the importance of genetic testing and explain to them how to understand their test results. Historically, those desiring to speak about their medical issues online have sought out structured support groups or chat rooms; however, many previvors today are instead posting on their own personal social media accounts and creating more niche communities.

Objective: This study aimed to examine why *BRCA* previvors are sharing content on their personal social media accounts and how posting online in this way serves a purpose for their larger community.

Methods: A total of 16 semistructured interviews were conducted with individuals who posted about their experience being diagnosed with the *BRCA* genetic mutation and their subsequent treatment on their personal social media accounts, specifically for followers interested in their medical journey. The interviews were recorded, transcribed, and coded by an experienced qualitative researcher and a graduate student using inductive techniques, and a reflexive thematic analysis was applied to the transcripts.

Results: The results suggest *BRCA* previvors want to control the narrative around their personalized medical experiences rather than participating in existing groups or chat rooms. Controlling their own story, rather than adding to existing narratives, gives previvors a sense of control. It also allows them to set boundaries around the types of experiences they have online when sharing their medical journey. Finally, previvors said they feel they are serving the larger *BRCA* community by each sharing their individual journeys, to hopefully avoid stereotyping and homogenizing the experience of patients with *BRCA* genetic mutations.

Conclusions: Research with the objective of understanding the experiences of *BRCA* previvors should include exploring how and why they talk about their journeys, especially due to the lack of knowledge *BRCA* previvors say many of their medical providers have. We suggest further research should examine how other patients with the *BRCA* genetic mutation, especially racial and ethnic minority patients, are navigating their own content creation, especially considering content moderation policies that social media platforms are continuing to implement that directly impact users' ability to share about their medical experiences.

Introduction

As the world's most commonly diagnosed cancer, the urgency to address breast cancer and support those with an increased risk of developing this disease has become even more important [1]. In 2020, the World Health Organization reported 2.3 million globally diagnosed cases of breast cancer, along with 685,000 deaths attributed to the disease [1]. In many cases, breast cancer occurs sporadically. However, genetic factors do play an influential role in 10% to 15% of all cases [2]. Like breast cancer, the risk of ovarian cancer also increases in women with age, along with having inherited genetic traits such as a *BRCA1* or *BRCA2* gene mutation [3]. In 2020, ovarian cancer was the third most prevalent and lethal gynecological cancer worldwide [4-6].

With continued research and treatment of breast and ovarian cancer, it has become more common for medical providers to encourage genetic testing, especially for those whose relatives who have been diagnosed with cancer [7-9]. Women who test positive for a *BRCA* genetic mutation are at a higher risk of developing hereditary breast and ovarian cancer, which impacts their health, reproductive choices, and identity [10,11]. Within their lifetime, individuals with a *BRCA* mutation have up to a 75% increased risk in developing breast or ovarian cancer [12]. Those who do test positive for a *BRCA* genetic mutation and have not yet been diagnosed with cancer are known as "previvors," a distinction for those at higher risk for developing cancer [10].

Due to the aggressive nature and reduced life expectancy associated with breast and ovarian cancer, it is necessary that the public, especially those who have a family history of breast and ovarian cancer and those who have already tested positive for the genetic mutation, are informed about the risks associated with the mutation that they carry and its impact on one's health and family planning [7]. However, previously published research suggests not all medical providers have the information previvors are looking for [7]. Previvors are looking for medical information and resources from various in-person and online sources regarding the options available to them should they desire to undergo surgery and reconstruction, just undergo surgery, or simply monitor themselves over time [11]. However, they are also looking for emotional support from loved ones, especially those who also have this genetic mutation and can provide advice and social support [7,11]. Social media and the ability to create content is a convenient and valuable tool for such purposes, and thus, researchers are exploring how social media is used by those with a *BRCA* genetic mutation [7,11,13].

BRCA previvors, cancer survivors, and those living with cancer use social media, online blogs, and internet chat rooms to connect with others [7,11,14,15]; however, much of the research on these communities is done through the lens of those seeking information, support, and connection rather than creating it [16,17]. When patients first began searching for information and for others in similar situations, they often did so through online platforms that afford a built-in community like chat rooms or message boards [15]. More recently, however, patients are using their own personal social media accounts to tell their stories on an individual level, hoping to build community on their own terms [7,11,13]. Individuals with breast and ovarian cancer communicate information that is personal or social on their individual accounts, with two-thirds of posts conveying actual experiences or providing support to others [18]. Using social media in this way distracts users from the stresses they may be experiencing that are caused by new, recurring, or terminal illnesses [19].

As a shift has occurred from group-centered platforms to individual storytelling spaces, there remain significantly fewer social media posts engaging with *BRCA* and genetic testing [11]. However, there are social media users increasing the amount of *BRCA* content being created, and health communication and internet scholars must pay attention to these individuals and their content [7,11]. As mentioned earlier, most research on social media and *BRCA* previvors has examined how previvors find information, rather than create it themselves, although the lens through which scholars are examining this content is shifting [7,11]. Considering the limited information available, this study aims to add qualitative insights regarding the creation of content by and for *BRCA* previvors. To accomplish this, we conducted semistructured interviews with *BRCA* previvors who create social media content related to their health condition and identity as previvors. Trends and themes were analyzed across the interview transcripts regarding *BRCA* previvors, social media, content creation, and connection within digital spaces. At the start of this study, we asked the following research questions: (1) Why do *BRCA* previvors create content on their personal social media accounts rather than in the digital communities created for *BRCA* previvors such as Facebook (Meta) groups? and (2) How do *BRCA* previvors perceive their social media content creation serving a purpose to their larger community?

Through qualitative interviews with a selective group of *BRCA* previvors who post personal medical experiences on their own social media accounts, this study offers a novel perspective on the trend of sharing health information online. Through prioritizing the words of our participants, we believe this study provides insight into the thoughts, feelings, and experiences of individual *BRCA* previvors and can help researchers and health care providers understand the ongoing needs of patients with *BRCA* genetic mutations.

Methods

Recruitment and Data Collection

To examine *BRCA* previvors' experiences creating social media content for themselves and for their larger community, we used a qualitative interview approach. We prioritized recruiting individuals living in the United States who have been found to carry a *BRCA1* or *BRCA2* genetic mutation, resulting in an increased risk for developing breast or ovarian cancer, and publicly shared about their medical experiences on social media, specifically Instagram (Meta). First, the primary investigator conducted a purposive sample by searching for *BRCA* previvors active on Instagram through hashtags including "#brca," "#brca1," "#previvor," "#brcagene," and "#breastcancerprevivor." Once the accounts were populated,

XSL•FO
RenderX

the investigator reached out to potential participants who listed their email addresses publicly on their Instagram accounts. We acknowledge that the algorithm on social media platforms like Instagram may have played a role in our sample procedure; however, we were interested in interviewing individuals who acted as influencers, opinion leaders, and public figures in *BRCA* online communities and, therefore, recognized that the most popular accounts may be the most accessible by using this purposive sampling method. Upon finding these individual accounts with publicly listed email addresses, the primary researcher sent an email detailing the study objectives and requesting potential participants to respond if interested. Of the total study participants (N=16), 15 identified as women and 1 identified as nonbinary. The nonbinary participant noted that they are often perceived as female and check "woman" as the gender on their medical paperwork for insurance purposes. All participants were White presenting; however, 2 identified as Hispanic and 2 identified as Ashkenazi Jewish. The latter group noted their ethnicity as important to their *BRCA* status, as 1 in 40 Ashkenazi Jewish women have a *BRCA* genetic mutation [20]. Participants were all over the age of 18 years at the time of the interview, and all confirmed that they are actively posting about their *BRCA* experiences publicly on one or more social media platforms.

Participants who met all eligibility criteria were then scheduled for a virtual, semistructured interview over Zoom (Zoom Video Communications). Consent forms were signed before the interview was scheduled, and verbal consent was confirmed once again before the interview began. All interviews were conducted by the primary investigator, and each participant was provided the opportunity to turn their camera off before the interview began to further protect their identity. The interviews included questions related to the participants' experiences with *BRCA*, their desire to create content on their personal social media accounts, their interactions with the *BRCA* community, their understanding of their previvor identity, and their relationship with health care providers. Each interview lasted between 45 and 60 minutes. The interviews were audio recorded for accuracy, and upon completion of the discussion, each interview audio file was labeled with a participant number. After all personal identifying information was removed from the files and the audio recordings, they were transcribed by a professional transcription service.

Data Analysis

Reflexive thematic analysis [21,22] was applied by the principal investigator and supported by a graduate research assistant. This analysis method has been applied in recent studies of women with *BRCA* genetic mutations and how they share social media content, build community, and understand their identity as *BRCA* previvors [7,10,11]. First, the principal investigator and graduate research assistant split up the 16 transcripts and manually coded 8 each. They then met and discussed overlapping patterns in the data related to why *BRCA* previvors post on social media about their previvor experiences and the role content creation plays in the act of community building and caring for oneself through various *BRCA* experiences. After the first meeting, the principal investigator and graduate research assistant switched transcripts and coded the other set of 8 transcripts. They then met a second time to finalize the themes present that related to the initial research questions. The team elected to follow this 2-stage coding process recommended by previous researchers to maintain the rigor of the method. All direct quotes provided in the results section below are anonymized and referred to by participant number.

Ethical Considerations

As this study involved human participants, the University of Utah's institutional review board approved the study protocol (IRB_00144720) before we began. An informed consent document was sent to each participant for review before they elected to participate. The document described the nature of the study, the types of questions asked, the protocol researchers followed to protect participant anonymity, and information regarding their rights as research participants including the opportunity to decline to answer any question and stop the interview at any time. The primary researcher kept a password-protected document on an external hard drive, which included the demographic information of each participant, including their name and participant number, to protect their identity but provided a reference sheet for use when needed. All personal identifying information was removed from the files and the audio recordings. The participants who completed the interview process were compensated in the form of a US $50 gift card.

Results

Posting on Social Media Fills a Gap in the Narrative of BRCA Previvorship

The *BRCA* previvors we interviewed said they create content on their personal social media accounts rather than in digital communities, such as Facebook groups, because they like to be able to control the narrative around their own personal journey and fill a gap in society's understanding of what it means to be someone living with a *BRCA* genetic mutation. *BRCA* previvors desire connection beyond existing previvor and survivor communities, and many noted they create content because they want to share every step in their journey with others, regardless of whether those watching have *BRCA* genetic mutations or not. One previvor explained that in her opinion, nothing is off limits when you share about *BRCA* on your own personal page.

> *I've shared every step of the way and there's nothing, in my opinion, that I shouldn't share.* [P11]

Similarly, many of the previvors interviewed have shared in-depth videos and photos of surgery scars, drain removals, breast reconstruction, nipple tattoos, and more.

Sharing whatever they choose, whenever they choose results in previvors feeling a deeper sense of autonomy over their lives and control over when and how they talk about *BRCA* genetic mutations. They do not want to talk strictly about the clinical aspects of their genetic mutation; they want to talk about sex, desire, hormones, body image, and how testing positive for *BRCA* genetic mutations impacts their identity as a wife, daughter, sister, mother, and friend. One previvor explained that she wanted other women with *BRCA* genetic mutations who follow her to understand that they may change, both inside

XSL•FO
RenderX

and out, but they can still be the same woman they were before being diagnosed and they do not have to allow their *BRCA* genetic mutation to take away who they once were.

> *I took people on my journey to show them that you can be strong enough to go through it and come out on top of it and no matter what you look like, it's still you.* [P14]

When discussing *BRCA* genetic mutations from the clinical perspective, previvors say they sometimes feel like their condition is overgeneralized, which results in feelings of homogeneity, especially in the eyes of their health care providers. In previous studies, previvors noted some providers make assumptions about the care they desire and do not always leave space for individuals to request a treatment plan that works best for them [7]. One previvor shared her experience defending her decision to forego reconstructive surgery in favor of a flat chest, something she did not know was possible from only speaking to her providers. She found other options through social media and now posts on her Instagram account to help others.

> *I hope people see (my chest) and they're like 'Oh, we can go so many different directions for our BRCA decisions. We don't just have to have reconstruction or like just a flat chest like'—there's things where you can make it feel more like you or learning how to make your body feel like yours.* [P15]

Showing a personalized perspective of the previvor experience on social media, previvors say, offers others a chance to see what daily living with *BRCA* genetic mutations is like, especially for those diagnosed at a young age. Previvors interviewed noted that many young patients with *BRCA* genetic mutations have different goals regarding their lifestyle, and Facebook groups and online chat rooms do not reflect those previvors and their understanding of *BRCA* genetic mutations. One previvor noted:

> *Facebook is just a different type of platform; people are posting pictures or questions or lamenting some situation. Whereas Instagram, it's more of a story of my life and not just a way to complain. So, I do think it was more helpful to be able to control the content on Instagram and not have anybody disqualify my experience. I think that was my biggest irritation with the Facebook groups. I felt like I was being questioned for whatever decision I was leaning towards. And this way I could just be like, 'This is what I'm doing. These are my risks. Just wanted you to know.' Not open for comment or questions or your opinions.'* [P17]

Younger previvors have turned to Instagram and TikTok (ByteDance) to find others with *BRCA* genetic mutations who have similar experiences and opinions regarding living with a genetic mutation and seeking possible treatments. For example, many younger previvors do not want to take the surgical route immediately after being diagnosed, as they are concerned about infertility, losing the opportunity to breastfeed a future child, and how their future may be dictated by decisions they are making from a young age. One previvor shared that she began posting because she felt like nobody was discussing *BRCA* genetic mutations from the perspective of a younger woman, especially a woman who wanted to have kids one day.

> *I started relying on social media to not only like see what other people were saying, especially people my age, but then being able to start talking about it from my personal perspective because I know my friends especially before 30 are like not thinking about (having kids) yet.* [P18]

For this previvor, posting on her social media accounts specifically on what young previvors need to be thinking about is important because she may be able to help another young patient with *BRCA* genetic mutations make a decision that was not offered by their health care provider.

Previvors View Content Creation as an Act of Self and Community Care

For *BRCA* previvors, creating content on their own social media accounts focused on their experiences helps them build a sense of autonomy over having a *BRCA* genetic mutation while taking care of themselves and offering support to others with a genetic mutation. This act of self-care and care for the community was a common explanation for why our interviewees started posting on their personal social media accounts. As one previvor said:

> *I wanted women to see that they're not the only ones going through it, that there are other women out there and that it will be okay and that you're beautiful even with all the scars and that you're still a woman.* [P14]

Many previvors said their understanding of themselves as a woman shifted once they were diagnosed, and they believe this shift is common among patients with *BRCA* genetic mutations. *BRCA* previvors expressed feeling afraid when initially diagnosed and unsure of what the future would hold for them as women, mothers, wives, daughters, and friends. Posting on social media allowed them to discuss their understanding of womanhood after diagnosis, which became an act of self-care and a way to give back to others in their community. Later in the interview, the same previvor shared how she felt upon being diagnosed and how her social media content creation helped her feel more like herself.

> *For a long time, you don't know who you are anymore. BRCA is—you were dealt this card, and you try to deal with it, but everything that makes you a woman is taken away from you. You don't know—it's like I know my body or my breasts or my ovaries don't define me as a person or a woman, but that is what makes us a woman and when that's taken away from you, you have to kind of learn to love yourself again in a different way.* [P14]

Posting on social media provided an outlet for previvors while they learned to love their new bodies, minds, and spirits after diagnosis. In the interviews, some participants said they felt like their *BRCA* genetic mutation initially stole their voice and that they no longer had a say over their own lives. However, sharing on social media gave them the opportunity to speak about whatever they were going through whenever they felt like they needed to. For one previvor, the posting was a form of therapy.

XSL•FO
RenderX

> *For me, it was almost like a journal, kind of therapeutic to put it out there in the world and be very open about it and then have—I was surprised how many of my friends and people that follow me that have had breast cancer, how supportive they were. I really expected them to be like the nursing staff, like 'Oh, you don't have real cancer,' but they were all super supportive.* [P03]

The therapeutic nature of posting on individual social media accounts was more helpful for these creators than sharing in chat rooms or Facebook groups, many said. Previvors felt like some chat rooms and online groups have become spaces where toxic positivity runs rampant but, at the same time, can be a place where previvors are judged by others regarding their care and treatment decisions. In the interviews, some previvors described the breast cancer survivor community, and more recently, the previvor community, as a space where media and large organizations "pink-wash" the disease and, thus, take away from the authentic lived experiences of breast cancer survivors and previvors [23]. These actions, while they can result in financial gain for some, do not provide the kind of support many previvors say they are looking for. Another previvor explained that the lack of authentic experiences publicized through media outlets and large organizations does a disservice to all people.

> *There was just a lack of representation and of candid, honest representation. I wanted someone that I could relate to. It wasn't just like this sob story because like parts of it were funny and weird and so full of love. I know that my story is not everyone else's, but like somebody's going to be able to relate to that, right? And also…(I wanted to) talk about sex and like all these things that I'm so used to talking about openly, but other people don't. So, I was like 'All right, I'll just write it all. Hopefully, it will help somebody.'*

Others agreed, saying:

> *it's so amazing to have the chance to share your voice, no matter what it be about," and "I post the ugly. I post the good and the bad. I want people to know there is the ugly part of it, but there can be a good part to it too.* [P16]

Ultimately, previvors agreed that sharing on their personal social media accounts is a form of community care and a way to continue building a supportive community. As one previvor noted:

> *I can take the fear that some women have, that I can show them that 'You can do it. You will come out on top of this. Don't let the BRCA run your life. You run BRCA. You can do something'* [P04]

Previvors on social media want others to know they are not alone and that there are spaces where they can be exactly who they are without judgment, even if they must create it themselves. As one previvor summarized:

> *I think if we keep (our journeys) to ourselves, then we're not doing any good* [P14]

Discussion

Principal Findings

Studies describing the content creation of *BRCA* previvors are a relatively understudied area of health communication and medical internet research. The previvors we interviewed noted that they post on their personal social media accounts rather than online spaces created specifically for group communication like chat rooms and Facebook groups because it allows them to control the narrative around their *BRCA* experience. This finding provides greater nuance to research that claims when patients interact online with others, they feel a sense of social support [7,11]. In addition, this finding provides a greater understanding of those individuals who not only seek health information online [16,17] but also create it themselves.

For previvors, controlling the narrative allowed them to speak on the topics they deemed most important and gave them the power to remove or block those who judged or critiqued their choices. This gave our participants a greater sense of power over their situation and reduced their fears around the possibility of pushback from other previvors. Some said they received negative responses from others with *BRCA* genetic mutations in spaces like Facebook groups but did not receive that feedback on their own social media accounts. *BRCA* previvors also believed that posting on their personal social media accounts served a greater purpose beyond themselves. They envisioned their content to serve the larger *BRCA* community in their quest to take care of each other, provide guidance regarding treatment plans and surgery options, and increase the visibility of *BRCA* genetic mutations itself. This finding extends previous studies that posit the discourse within online spaces has the potential to extend offline and impact the care patients receive [7,11,13,16,17].

While our study participants did not bring up any potential risks or negative consequences to sharing their personal health stories online, it is important to consider privacy concerns when one shares personal health information on social media platforms [24,25]. In addition, there is potential for misinformation to spread in these online health spaces, especially as patients continue to share their experiences on individual accounts that are more difficult to monitor [26,27]. While our participants did not mention misinformation as being common within *BRCA* spaces, as the communities grow, the issue will be important for researchers to consider when evaluating the benefits and risks of these individual storytelling spaces.

Conclusion

This study was strengthened by the in-depth interviews given by each participant, but the study was limited by the number of interviews conducted and the interview process itself. Due to COVID-19 limitations, all interviews were conducted through videoconference, often reducing the opportunity for the interviewer to analyze participants' body language. In addition, the reliance on virtual interviews means that while we were able to communicate with previvors across the country, each participant's experiences with their local health care system may differ [28]. In addition, this study relied on the most popular *BRCA* social media accounts to recruit participants. On platforms

XSL•FO
RenderX

like TikTok and Instagram, the algorithm may dictate whose content is promoted and whose is not, which results in a skewed sample, but this does not necessarily mean these stories are less worthy of being told. However, the algorithmic bias present on social media platforms can often result in a list of potential participants who are neither racially nor ethnically diverse. Our study skewed primarily toward White women, which mirrors results found in other recent studies of *BRCA* previvors on social media [7,11]. We recognize the lack of scholarship exploring racial and ethnic minority patients who have been diagnosed with the *BRCA* genetic mutation, especially analysis of their online presence and their desire to create digital spaces for the needs of their specific community, and we urge scholars to continue prioritizing these individuals.

Future research should also consider the practice of moderating and censoring of medical conditions based on platform policies, as some of our participants noted their concerns around content being removed or accounts being closed altogether because platforms may deem their content regarding reconstruction and recovery as sexual in nature. Social media platforms are evolving, and the results of their impact on health behaviors and outcomes remain mixed. Therefore, we believe researchers should continue to examine the therapeutic and supportive role of personal social media content across acute and chronic health conditions [29]. In addition, social media literacy continues to be key in improving health decisions, and research suggests platforms themselves can help in this process [30], especially as more patients share about their health conditions on their personal accounts. As more *BRCA* previvors take to social media platforms to share their stories and experiences with genetic testing, treatment, patient-provider interactions, and more, researchers should consider conducting studies that rely on quantitative, qualitative, and critical rhetorical methodologies to provide a larger body of work in this specific subfield.

Acknowledgments

The authors would like to acknowledge the financial support provided by the National Human Genome Research Institute that made this study possible. The authors would also like to thank the anonymous reviewers and editors for their helpful feedback in revising this manuscript. Generative artificial intelligence was not in any portion of the study or in the creation of this manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Abstract

Background: Stroke and other acquired brain injuries (ABIs) can present challenging experiences for individuals, both in recovery of functions affected by visible or invisible impairments and in learning to live with the new situation. Research has shown that sharing experiences face-to-face in peer groups can be beneficial during recovery. However, there is limited knowledge about the lived experiences of people with ABI who participate in online peer-to-peer groups.

Objective: The aim of our study was to explore the lived experiences of participating in online peer-to-peer groups for people with ABI, where participants themselves set the agenda.

Methods: Members of 2 Facebook groups (FBGs) for people with ABI were invited to participate in this study, and 20 individuals were included (14 women and 6 men; age range 24-74 years). One FBG focused on stroke and the other on fatigue caused by ABI. One group was private, and the other group was public. Data were collected through semistructured interviews, in which participants were encouraged to describe their experiences of engaging in FBGs in detail. The interviews were conducted over telephone or Zoom and digitally recorded. The audio recordings were then transcribed verbatim, resulting in 224 pages of text, and analyzed using the empirical phenomenological psychological method.

Results: The analysis presented a common meaning structure with 1 main characteristic that is, “validating self,” common for all 20 participants, and 3 subcharacteristics, that is, “learning—having one’s own experiences confirmed,” “adjusting self—building competence and self-compassion,” and “supporting others—becoming a valued lived-experience expert/authority.” Together, the subcharacteristics reflected a process of validating self from newcomer to lived-experience expert or authority. In this process, members of FBGs moved from being newcomers with pronounced needs for support and to learn and to have their experiences confirmed by others with similar experiences. Thus, participants were building competence and developing self-compassion. Gradually, they assumed the role of advisors, mentors, or coaches, acknowledging their experiences and competence as valuable to others, thereby validating themselves as compassionate lived-experience experts or authorities in supporting others.

Conclusions: Participation in online peer-to-peer groups can offer unique opportunities for individuals with ABI to validate self through processes that involve learning, developing self-compassion and compassion for others, and offering support to others with similar experiences. Given that rehabilitation after an ABI is often of limited duration and that positive experiences can be achieved over time through involvement in digital peer-to-peer support, health care professionals should assist patients by providing information and directing them to digital networks for people with ABI. However, when recommending the use of online peer-to-peer support, impairments and insufficient digital competence that may complicate or prevent the use of social media should be assessed and support provided when relevant.

Introduction

An acquired brain injury (ABI) is brain damage that occurs after birth and can be either due to a trauma or a nontraumatic cause, for example, a stroke [1]. ABI can impact body functions and lead to impairments that are either visible (eg, reduced motor control) or invisible (eg, impaired memory, fatigue [1], ie, a profound sense of tiredness and a lack of mental and physical energy). Fatigue has been reported as one of the most common and challenging invisible consequences to manage [2]. Stroke is a leading cause of disability, and the disability-adjusted life-years for stroke indicate that it increases both mortality and the risk of living with lifelong disabilities [3]. Life after a stroke can entail challenging experiences for the stroke survivor, both in the recovery of functions as well as in learning to live with visible or invisible disabilities, which may persist and impact their own lives [4-6] as well as those of their loved ones [7]. Stroke survivors frequently report feelings of emptiness, abandonment [8], and a lack of information about stroke, its consequences, recovery, secondary prevention, and medication [9,10]. They also express a need for recurrent support from health care and community services [9,11]. A synthesis of qualitative studies on embodied experiences after stroke describes a 3-phase process: an initial phase of disconnection between oneself, others, and the world; followed by a transitional period exploring and negotiating; and a third phase of reconnecting with oneself, others, and the world [12]. These poststroke recovery processes can be long-lasting [5,13,14].

Support after a stroke can come from different stakeholders, for example, health services, family, social networks, and peers [15]. Peer support is defined as a system of giving and receiving help founded on key principles of respect, shared responsibility, and mutual agreement of what is helpful [16]. It has been proposed that peer support can address affirmational, emotional, and informational needs by validating concerns, offering a place of belonging and providing relevant knowledge to solve everyday problems [17,18]. Being among peers has been reported to contribute to feelings of safety, understanding, and community [19,20].

Traditionally, peer support is organized through physical meetings, often involving health care professionals working together with peer leaders [17,18,21-23]. However, groups led entirely by stroke survivors have also been reported [24]. A meta-analysis of peer support groups for individuals with ABI found limited evidence of their effectiveness but highlighted positive experiences among participants. These experiences were summarized as “being connected, interacting with others, and providing and receiving support” [25].

Over the past decade, an increasing number of studies have examined peer support organized through social media (eg, for young mothers [26] or related to illness such as multiple sclerosis [27], cancer [28], or Parkinson disease [29]). Similar to in-person peer support groups, online peer support groups can be led either by health care professionals or by individuals with lived experience of the topic in focus. In addition, self-formed online communities are emerging on social media, addressing diverse health concerns. Such communities are referred to as online peer-to-peer support [30,31]. However, there is a lack of knowledge regarding the experiences and meaning of participating in online peer-to-peer support networks for individuals with ABI. Hence, our study aims to explore the lived experiences of participating in online peer-to-peer groups for people with ABI on social media, where participants themselves set the agenda.

Methods

Study Design

This study was conducted as part of the research project “Participation in Society After an Acquired Brain Injury,” with the overall purpose of exploring how individuals with ABI share experience-based knowledge in different contexts. The project had a participatory approach, involving 3 individuals with lived experiences of ABI as co-researchers. These co-researchers identified Facebook as an important arena for people with ABI to share their experiences. A phenomenological approach [32] was chosen, as the aim was to explore the phenomenon, meaning, or essence of participating in online peer-to-peer support groups on social media, specifically related to stroke or fatigue after an ABI. The phenomenological approach allowed the researchers to explore the lived experiences of participants and gain a deeper understanding of the phenomenon. The method requires researchers to be open to the original and immediate experiences of the participants while reflecting on their own previous knowledge. The COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist is provided in Multimedia Appendix 1.

Participants

All participants in this study were recruited among members of 2 Facebook groups (FBGs). The FBGs were suggested by the co-researchers and deemed relevant to the study. One FBG focused on stroke, and the other on fatigue caused by ABI. One group was private, and the other group was public. The private group was initiated and moderated by individuals with lived experience of stroke. The public group was initiated and administrated by a researcher/health care professional, who occasionally posted information about upcoming lectures or events relevant to the group but did not otherwise interact with members or respond to posts.

The researchers MT and LH contacted the administrators of both FBGs and informed them about the study. The administrators granted permission for MT and LH to recruit participants within their respective groups and posted information about the study provided by the researchers. The posted information asked members interested in being

XSL•FO
RenderX

interviewed regarding their experiences in the FBG community to contact the researchers by email or telephone. Members were informed that, if interested, they would receive further details and be given the opportunity to schedule an interview.

Altogether, 12 members of the stroke FBG and 8 members of the fatigue FBG—all with lived experience of stroke or fatigue, respectively—expressed interest in being interviewed. None of the members were known to the researchers. All those who had shown an interest were contacted by the researchers, and they provided oral and written information about the study. Participants were then asked if they preferred to be interviewed by telephone or by videoconference software (Zoom) and to schedule a time for the interview. When the interview started, participants were once again informed about the study and how data were to be handled. Thereafter, oral informed consent was obtained and recorded.

Data Collection

Data were collected through semistructured interviews [33] using an interview-guide prepared beforehand. The open-ended questions (Multimedia Appendix 2) were intended to encourage participants to describe their experiences of participating in the FBG community in a narrative manner [34]. They were asked to provide concrete details regarding their participation, including how they became members, how they interacted with FBG, and to describe their experiences and feelings in the beginning, over time, and at the time of the interview. Prompts and follow-up questions (eg, could you please tell a bit more?) were used to encourage further elaboration.

MT and LH, both PhD holders, females, and experienced researchers, performed all the interviews. They are both experienced in working professionally with patients/clients with ABI and in collaborating with individuals with ABI in research projects. LH interviewed all the participants from the stroke FBG, while MT interviewed all the participants from the fatigue FBG. Fifteen interviews were conducted by telephone and 5 over Zoom, and all interviews were digitally recorded. The audio recordings were then transcribed verbatim, resulting in 224 pages of text.

Ethics Approval

All participants gave informed consent after having received detailed information about the study. Data were deidentified. This study explores the meaning of participating in FBGs that were created to allow members to support each other and share experiences for their benefit and well-being. Thus, it was essential to conduct the study in a way that considered both the integrity of the participants and the wider FBG community. To minimize the risk of identification, he/him and she/her have been replaced with he/she and him/her, respectively, in the results section. This study was approved by the Swedish Ethical Review Authority (2018/407-31, 2021-03548, 2022-03207-02).

Data Analysis

The transcribed text was analyzed using the empirical phenomenological psychological method [32], which aims to describe the essence, structure, and character of the phenomenon under study. To discover essential descriptions during the analysis, the authors set aside any theoretical frameworks outside phenomenology that could plausibly explain or account for the phenomenon. Thus, the texts were handled unconditionally, allowing the phenomenon to present itself in the participants' narratives. The analysis was performed in 5 steps. Steps 1 through 4 were performed for each interview separately.

In the first step, the authors read through the transcribed interview to gain a general understanding of the concrete facts, events, and feelings pertaining to the participants' original experiences.

In the second step, based on their understanding of the whole transcribed interview, the authors divided the text into smaller segments, that is, meaning units. A new meaning unit was identified each time there was a shift in meaning within the text.

In the third step, the authors interpreted each meaning unit while considering the whole interview and the phenomenon under study. The hidden meaning, often referred to as the transformed meaning [32], was the focus of the interpretation, specifically in relation to the experience of participating in an FBG.

The fourth step entailed synthesizing the transformed meaning units into a situated structure of meaning [32] in a separate summary for each interview. In the situated structure, the authors arranged the features of the phenomenon in a phenomenologically meaningful way based on their interpretation of the meaning of participating in the FBG community.

In the fifth and final step, the authors analyzed the summaries from step 4 across participants to identify shared experiences of participating in an FBG. Hence, the analysis moved from the situated structure of meaning to a general structure of meaning [32] that spanned all participants.

The authors revisited and reviewed the original interviews throughout the analysis to validate their interpretations. The most valid interpretation was chosen to represent the meaning of participating in an FBG, as experienced by the participants. The analyses were performed by AWW, LvK, and MT. AWW and LvK, both PhDs, have professional experience working with patients/clients with ABI, and are experienced in conducting phenomenological research on individuals with ABI. Together, they conducted all 4 steps of the analyses for 2 interviews. For the remaining 18 interviews, steps 1 through 4 were conducted separately by AWW, MT, or LvK. Step 5 was performed by AWW, MT, and LvK together. All steps of the analysis were recorded in web-based Word documents, which were shared between the authors via a web platform accessible only to them.

To enhance trustworthiness throughout the analysis, the authors reflected iteratively on their interpretations, while considering their previous knowledge, clinical experience, understanding, and theories about the phenomenon under study. The findings were presented and discussed with the co-researchers, who had their own experiences of being members of Facebook communities for individuals with ABI, to ensure credibility, that is, that the descriptions of the characteristics made sense and were recognized as plausible interpretations. To further safeguard trustworthiness, the findings were reviewed and

XSL•FO
RenderX

discussed with LH. The analysis was then revised based on the feedback received, with the authors repeatedly returning to the original interviews and revisiting the different steps of the analyses.

Results

Participant Characteristics and Analysis of the Lived Experiences

Our study was performed with 20 participants, aged between 24 and 74 years. Fourteen participants were women, and 6 were men. In this study, participants in the stroke FBG are referred to as participants 1-12, and those in the fatigue FBG are referred to as participants 13-20.

The analysis of the lived experiences of participating in an FBG for individuals with stroke or fatigue after an ABI presented a common meaning structure, with 1 main characteristic, that is, "validating self" and 3 subcharacteristics, that is, "learning—having one's own experiences confirmed," "adjusting self—building competence and self-compassion," and "supporting others—becoming a valued lived-experience expert/authority."

The meaning structure and the main characteristic "validating self" were seen across all participants. Together, the subcharacteristics reflected a process of validating self from newcomer to lived-experience expert or authority. In this process, members of FBGs moved from being newcomers with pronounced needs for support to learn and to have their experiences confirmed by others with similar experiences. Thus, participants were building competence and developing self-compassion. Gradually, they assumed the role of advisors, mentors, or coaches, acknowledging their experiences and competence as valuable to others and thereby validating themselves as compassionate lived-experience experts or authorities in supporting others. Learning processes were present in all subcharacteristics—moving from seeking information to the ability to apply and relate knowledge, both drawn from lived experiences and gained within the FBG community. Furthermore, challenges related to navigating health care and social support systems were present in all subcharacteristics. Here, participants moved from asking for information pertaining to their own situations to using their growing expertise to take initiatives for changes at societal or political levels.

Most participants had found FBGs when googling, while others were recommended to join by peers. A few participants in the FBG community for fatigue had been recommended to join the community by health care professionals. Interaction with the FBG community varied among participants, but the main characteristic "validating self" was present, regardless of how individuals interacted with the group. Most participants described how their level of interaction had changed over time. Nearly all were or had been actively engaged in writing posts and comments since joining the FBG community, and most of them had been more active in the beginning. A few participants, however, had mostly read posts and comments and had rarely, if ever, written anything themselves.

Learning: Having One's Own Experiences Confirmed

A prominent aspect of this subcharacteristic of the lived experience of participating in an FBG was the participants' feelings of being lost, alone, and longing for understanding and guidance. Initially, they searched for information pertaining primarily to their own health and condition. The issues they addressed were driven by individual needs and focused on symptoms, emotions after stroke, life in the context of fatigue, available health care, and support.

> *...I thought, where can I connect and see how others live, how others did? That's where I went to the Facebook group.* [Participant 11]

Participants described feeling different from their previous selves.

> *...You get a new personality when something happens in your head, so you can share different experiences and how to deal with everyday life in general.* [Participant 4]

Participants followed posts and comments made by others to get acquainted with the FBG community, experiencing a sense of connectedness and belonging to a community of people with similar experiences. Some participants emphasized the importance of the friendly atmosphere and the opportunity to laugh together with each other rather than at each other. The community became a safe haven where they felt comfortable expressing their concerns and received valued and comforting responses.

> *...It is a kind of community around a common topic. Specifically, not feeling alone in a situation like this. There are others who have similar problems. I think you can feel that there is a sense of participation in it all. I think it is good. Yes, otherwise, I wouldn't be there myself.* [Participant 13]

Participants had previously used Facebook to interact socially for pleasure, but following their illness, it took on a different meaning and more significant role in meeting the basic needs in their daily lives.

> *…But before I was ill, I used Facebook too. But then, it wasn't very important. Then it was just for fun. But now, it was different when I started looking for information like this, connected to stroke.* [Participant 7]

Issues raised in the FBG community had sometimes been discussed in other contexts but without satisfactory answers. Participants were also grateful for the guidance they received on how to access services they needed and were entitled to. They also expressed appreciation for the 24/7 accessibility of the FBG community, the possibility of receiving valuable answers rapidly and around the clock, and for some, the option to participate anonymously.

> *…I get an answer, instead of having to constantly search for everything myself. It is actually very comforting to have someone in the same boat, someone who is awake and can just write back, where*

XSL•FO
RenderX

> *you can get a small, embracing hug if that is what you need.* [Participant 1]

The meaning of participating in the FBG community was rooted in the participants' experiences of connecting with others who truly understood their situation, that is, a community of individuals with similar experiences. They shared experiences and knowledge gained from their lived experiences, which differed from the information, advice, and support provided by those without similar experiences (eg, health care professionals). It was comforting to learn through comments from others who really knew what it was like and who could offer an insider's perspective. Many participants expressed that before joining the FBG community, they had felt as though no one else was like them.

> *…You can calm each other down in many ways. And there are so many who write the same thing. So, it's not just one person who says, "yes, but it's completely normal." Instead, everyone writes, "yes that is my experience too."* [Participant 18]

Many participants emphasized the importance of experiencing a sense of normality.

> *...There is confirmation that you're not crazy. It's really normal not to be normal. Still, it's normal. No, but I think, it means a lot to encourage each other.* [Participant 17]

Some participants rarely or never wrote their own posts or comments but still learned about themselves by comparing their experiences with those presented by others. One participant who had reading difficulties also found the information in the FBG community easier to understand than information from health care.

> *…When I read the hospital brochures, then they were too long. And then I couldn't read them. So, that's why I use Facebook instead; I was able to take in the information bit by bit.* [Participant 7]

Participants also expressed that certain members of the FBG community who had long-standing experience were particularly valued and respected.

> *...In these groups, those who answer know what they are talking about, many times.* [Participant 14]

Adjusting Self: Building Competence and Self-Compassion

This subcharacteristic illustrates how participants in the FBG communities compared and related their own experiences of managing life after a stroke or with fatigue. They exchanged experiential knowledge through posts and comments with others. Interacting and exchanging information in the community helped them apply this knowledge, build competence, and to look at themselves with kindness and self-compassion as well as at others with compassion.

> *…And sometimes, I hope, that if I write something kind to someone, or share a piece of advice, that it means something. And it has meant a lot to me too when I read about others. Sometimes I am touched, and sometimes I am happy. I think it is valuable.* [Participant 2]

In comparing and relating their experiences with those of others, the participants had their own experiences and competence confirmed. They came to recognize that they had, so far, achieved what could be expected of them and at times more than what could be expected of them, giving them a sense of control. One participant had overcome many obstacles to be where he/she now was in life and valued his/her experiences highly, which was also his/her reason for joining the FBG community.

> *…Then, my motive for joining the group was precisely wanting to see, what did I do differently to get this far when others are so limited.* [Participant 11]

This participant did not actively interact with the FBG community, but by following posts and comments in the community, he/she experienced him/herself as competent, which appeared to strengthen his/her self-compassion. The FBG community was used as a reference point to compare his/her approach to managing challenges in rehabilitation and everyday life, reinforcing his/her self-perception and belief that he/she had managed the situation better than others. The participant expressed that he/she had a lot to offer to others in the community but did not need support from others in similar situations.

> *…My only need, if I should even call it need, is precisely that I want to help people. I want to help people and show them that, unfortunately, they have to do the hard work. That's the only way they will get their life back. Otherwise, they won't. It's not that I expect anything in return, or that they should help me. That's why I say, unfortunately, a bit cocky, that I don't feel I need much from others.* [Participant 11]

Relating personal experiences of success and building self-compassion could also evoke mixed emotions for some FBG members.

> *...I notice that, among us younger, there is a kind of envy. I know I've felt that way myself at some point. But I can still rejoice in the person's success, even if I myself am not there yet.* [Participant 13]

Despite feelings of envy toward those who had made more progress, participants could also distance themselves, express compassion, and rejoice with others. Overall, FBG was experienced as a meaningful supportive community where participants could express both self-compassion and compassion for others.

> *...Yes, it's still great to know that there are others who get to stand up for their own, new personality.* [Participant 4]

Another participant with aphasia expressed the importance of being a member of the community not only by reading but also by contributing through writing their own posts or comments. The participant longed for the moment when he/she would be able to write a comment or post independently.

XSL•FO
RenderX

> *…I hope I'll get a little better at writing, I've gotten better. But I haven't gotten that cocky yet. I might, I think, I will dare to write a little.* [Participant 7]

Some participants, on the other hand, may not have realized that there were others in the FBG community with communication difficulties due to stroke or ABI, and they expressed a dislike when comments were limited to emojis.

Supporting Others: Becoming a Valued Lived-Experience Expert/Authority

A prominent aspect of this subcharacteristic in the lived experience of participating in an FBG was the participants' empathetic understanding and compassion for the situations of other members in the Facebook community. The participants expressed that they had come to realize and understand that there could be large variations in challenges after a stroke or living with fatigue, and they considered this knowledge when interacting in the FBG community. They were careful to acknowledge that their knowledge stemmed from their lived experience, as opposed to medical expertise.

> *...Above all, I feel that many others feel that I am very credible, that I am worth listening to. And that makes what I say actually have an effect. At the same time, it means that I am very careful with what I say.* [Participant 10]

The participants had their own experiences to share as well as knowledge they had gained from other members in the Facebook community who had different lived experiences from their own. They could also share insights based on a long-term perspective, and they often conveyed compassion and hope to support the self-compassion of others.

> *...Then I wrote, if I won't be able to drive again, then I got tips and advice there. And many who had to wait, and some did not get it (driver's license) back at all.* [Participant 8]

The participants' experiences could also help newcomers find words to describe their experiences.

> *...They get explanations and vocabulary for things they have not been able to, things they have known and experienced but have not been able to explain or express.* [Participant 14]

Furthermore, participants could use their experiential knowledge to describe, explain, or provide arguments for the challenges they faced (eg, how devastating fatigue could be in everyday life). Such information could be shared within the FBG community to help describe the lived experience to an employer or family, in hopes that they could gain a better understanding. Even though the family was often very supportive, the participants expressed that it was impossible for someone who did not have similar experiences to fully understand their situation.

The knowledge they shared was deemed valuable by others and validated their sense of self as knowledgeable individuals and authorities within the Facebook community. Several participants described a few members in their FBG who had taken on a role to organize and support others, regularly presenting topics to stimulate discussion, which was highly appreciated. A researcher would occasionally present new research findings regarding fatigue, which the participants found valuable.

The lived experience expertise in this subcharacteristic was also recognized and appreciated outside the FBG community. For instance, a few participants with this expertise was engaged in medical education.

Although the participants had been part of the FBG community for quite a while, they expressed that it was both interesting and rewarding, and they were still learning. They enjoyed being part of the Facebook community, following posts and comments, and sharing their own experience-based knowledge, even though they participated less frequently than at the beginning.

> *…It's almost six years since I had my stroke, but I enjoy seeing people who have just had a stroke and have just been able to get up from the wheelchair and take their first steps. And then you send hearts, and I remember I was like that too. It's moving forward, and keep it up, and well done! So, I like to see when people step it up a notch.* [Participant 9]

This subcharacteristic also describes how participants were cautious when interacting within the FBG community, choosing with whom and how to write. They carefully chose which posts to comment on by reflecting on whether their input could be of value to the person who had written the post. Some participants had chosen to comment on posts made by one particular individual and to specifically follow that person taking on the role of a mentor or coach. One participant described how he/she had continued his/her mentoring outside the FBG community in a private email conversation. Nevertheless, participants reported having few real life contacts or friendships with members of the FBG community outside the digital community.

The participants were thoughtful and considerate about how they wrote their comments to posts made by others—whether newcomers or more experienced members. Creating their comment was experienced as a balancing act; they aimed to offer hope, encouragement, and practical tips on the one hand and being realistic on the other. This required them to draw on their experience-based knowledge of how people react after a stroke/ABI or in living with fatigue. They also exercised patience and tolerance, avoiding negative comments, even when, for example, a member of the FBG community repeatedly asked the same question. In their comments to posts, they assumed the role of mentors with compassion or humble lived-experience authorities, always reflecting on how to avoid being perceived as condescending experts.

Experiences and insights gained through interactions in the FBG community inspired participants to act beyond themselves and the FBG community, as ombudsmen for people with stroke or fatigue. One example was that through the sharing of experiences in the FBG groups, participants realized there were large differences in the availability and access to services between municipalities and regions in the country. The inequalities in access to care and the unmet needs expressed within the FBG community inspired some participants to act for future improvements. One participant, for example, took on

XSL•FO
RenderX

a leadership role in a patient organization and even become involved in local politics.

Discussion

Principal Findings

Our study shows that people who had experienced a stroke or who had developed fatigue after an ABI and had participated in online peer-to-peer groups on social media revealed 1 main characteristic, that is, "validating self," common for all 20 participants, and 3 subcharacteristics, that is, "learning—having one's own experiences confirmed," "adjusting self—building competence and self-compassion," and "supporting others—becoming a valued lived-experience expert/authority." A learning process was integral to the overall process of validating self. Our findings are discussed in relation to theories of self-validation, self-compassion, compassion, and experiential knowledge. Although all analyses were performed with plausible theories set aside, we acknowledge that other applicable theories may also be relevant to the findings of our study.

The meaning of participating in an FBG for people with stroke or for people with fatigue after an ABI presented 1 common main characteristic: validating self. The self-validation theory focuses on the subjective sense that one's thoughts are valid or appropriate to use [35], as opposed to the objective truth of those thoughts. According to this theory, individuals tend to rely on their thoughts more when they perceive them as likely to be true (cognitive validation) or because when they feel good about the thought (affective validation). Self-validation is furthermore described as a process in which a wide array of factors can influence the perceived validity of one's thoughts. These factors include individual aspects such as self-esteem and situational factors such as body posture at a particular time [35]. The theory of self-validation is proposed to apply to any type of thought, for example, self-efficacy [36], which refers to the belief in one's ability to produce outcomes or achieve goals [37]. By participating in FBGs, all participants reported having their experiences and thought of themselves after a stroke living with fatigue confirmed and validated, both cognitively (ie, recognizing that their experiences were normal) and affectively (ie, not feeling alone). However, the meaning of "what validated the self" varied across the subcharacteristics and differed between participants who recently experienced a stroke and participants with longer lived experiences of stroke or fatigue after an ABI.

Together, the participants described a process in which they initially sought answers for their troubling experiences and lack of information. By posting their concerns in the FBG community and receiving comments and answers, they appeared to learn and find comfort, as their experiences and thoughts were validated by others. The participants gained an understanding of themselves and were able to view themselves with kindness and self-compassion as well as view others with compassion. Nevertheless, we acknowledge that the outlined process could also be supported in other contexts and that entry into the FBG community can take place at different points in time after an ABI, still supporting self-validation. At least one participant appeared to have joined the FBG community at a later stage, where his/her lived experiences were related to the subcharacteristic "adjusting self." Moreover, it is uncertain whether all participants will eventually experience aspects of the subcharacteristic "supporting others."

The development of self-compassion and compassion was prominent in 1 subcharacteristic. Self-compassion is described as being supportive toward oneself when experiencing suffering or pain [38]. The experiences of the study participants resonate with Neff's theory of self-compassion, which entails being present in one's own suffering, understanding and supporting oneself, and feeling connected to others who are also suffering [38]. Self-compassion has 3 interrelated elements that work together to alleviate suffering: the emotional response to suffering, how it is understood cognitively, and how the person pays attention to their suffering. It is conceivable that all elements, along with the development of self-compassion, were supported through experiences of being connected to and learning from others in the Facebook community. One example is that participants seemed to be supported in both standing up for themselves and practicing self-compassion when they received confirmation that others also needed to stand up for their new selves. The theory postulates that when we respond to suffering with kindness toward ourselves, feelings of unworthiness decrease in a similar manner to how we feel when we receive kindness from others [38].

Compassion is described as feelings that arise when witnessing others' suffering and a subsequent desire to help and is different from empathy, which refers to the vicarious experience of another's emotion. Unlike feeling pity or sympathy for someone, compassion includes feelings of connection with others who are suffering [39]. Hence, compassion arises when individuals are connected to others with similar experiences, which was a prominent experience for the study participants.

Our results show that the main characteristic, that is, validating self and its subcharacteristics involve learning processes. These learning processes align well with the 4 epistemic patterns of experiential knowledge pertaining to the lived experience of illness, as previously described by Halloy et al [40]. In the first pattern, the authors suggest that the individual experiences the disability or illness. Our study participants' initial experiences of disability led to feelings of being lost and alone, which appeared to be the reason they sought more knowledge, to learn, and to better understand themselves. They learned that they were not alone, and as proposed by Halloy et al [40], in the second pattern of experiential knowledge, they gained a know-how based on their individual experiences. The third epistemic pattern of experiential knowledge was also evident among the study participants. In this pattern, the experiential knowledge, according to Halloy et al [40], becomes more formalized and tends to be developed at a collective level. Hence, the FBG community appeared to provide the arena for the participants to reflect on their experiences and knowledge, thereby developing experiential knowledge, whether they were interacting with other members of the FBG community or simply reading posts and comments made by others. Undoubtedly, some participants in this study had developed experiential expertise, which corresponds to the proposed fourth pattern of experiential knowledge. Experiential expertise entails the ability

XSL•FO
RenderX

to transfer knowledge between different epistemic worlds, as exemplified in the findings by the transfer from the microlevel within the FBG community to the macro and metalevels, such as in the roles of politicians and contributors to education.

The advantages of online peer-to-peer support over face-to-face peer groups, previously suggested in the literature [30,31], were confirmed in the findings of this study. For example, participants were able to validate themselves simply by following posts and comments made by others, without necessarily interacting with the community or providing/receiving support. This highlighted the possibility of controlling the level of interaction with the Facebook community, which is one of the key advantages of online peer-to-peer support [30]. Another highly appreciated advantage reported by several participants was the around the clock accessibility of the community. Participants felt they could reach out to the Facebook community for support at any time and that their concerns would be addressed promptly. Furthermore, the unrestricted access to the FBG communities allowed participants with long and vast lived life experiences after stroke or with fatigue after an ABI to remain active members of the Facebook community, even if most of them interacted less frequently. They were highly appreciated sources of knowledge and understanding, which were not readily available elsewhere.

The number of participants and the wide variation in age and experiences upon which the results are based is a strength of this study. All participants who contacted the researchers were interviewed, and the large amount of data gathered provided rich, detailed, and relevant descriptions of the phenomenon supporting meaning saturation [41]. However, the recruitment procedure, that is, asking members of FBG communities to sign up voluntarily, may have led to the recruitment of participants with mostly positive experiences. Those who were disappointed had negative experiences and hence did not find meaning in participating in the FBG community may not have signed up for the study or may no longer have been active in the FBGs under study. Nevertheless, the results align with previously reported stages of the embodied recovery process after stroke, which includes an initial phase of disconnection between oneself, others, and the world, followed by exploring and negotiating, and then reconnecting with oneself, others, and the world [12]. They also align with the way experiences of peer group support have been summarized previously, that is, “being connected, interacting with others, and providing and receiving support” [25]. The explicit aim of this study was to explore the meaning of participating in an online peer-to-peer support group. Additional studies are needed to explore how, when, and why experiences may be perceived as negative, and how the process described in this study can be interrupted or fail to take place.

Implication for Practice

Given that rehabilitation after an ABI is often of limited duration and that positive experiences can be achieved over time through involvement in digital peer-to-peer support, health care professionals should assist patients by providing information and directing them to digital networks for people with ABI. When recommending the use of online peer-to-peer support, impairments and insufficient digital competence that may complicate or prevent access to such support for individuals with ABI must be evaluated. Given the increasing digitalization of the society and the need to interact through online activities in everyday life, rehabilitation professionals should regard online activities equivalent to other daily activities and consequently assess and support individuals’ ability to perform such activities. Hence, ensuring that patients can engage in online peer-support according to their preferences can be one way of equipping them with tools to manage their new life situation after an ABI by being part of a context with the potential to support learning processes and the recovery process beyond the rehabilitation phase.

Conclusion

We conclude that participation in an FBG can offer unique opportunities to validate self through processes that involve learning, the development of self-compassion, compassion for others, and supporting others with similar experiences of life after a stroke or living with fatigue after an ABI. Furthermore, this process contributes to the building of experiential knowledge and expertise, which may be applicable beyond the online peer-to-peer support groups.

Acknowledgments

A special thanks to Fredrik Sandman, Jeanette Nelson, and Mikael Åkerlund for suggesting Facebook as an important context for sharing experiences and knowledge, identifying the relevant Facebook groups, and providing feedback during the discussion of the manuscript draft. No generative artificial intelligence has been used in any part of this study. This study was funded by Forte (2020-00685).

Abstract

Background: Acute kidney injury (AKI) is a common complication in hospitalized older patients, associated with increased morbidity, mortality, and health care costs. Major adverse kidney events within 30 days (MAKE30), a composite of death, new renal replacement therapy, or persistent renal dysfunction, has been recommended as a patient-centered endpoint for clinical trials involving AKI.

Objective: This study aimed to develop and validate a machine learning–based model to predict MAKE30 in hospitalized older patients with AKI.

Methods: A total of 4266 older patients (aged ≥ 65 years) with AKI admitted to the Second Xiangya Hospital of Central South University from January 1, 2015, to December 31, 2020, were included and randomly divided into a training set and an internal test set in a ratio of 7:3. An additional cohort of 11,864 eligible patients from the Medical Information Mart for Intensive Care Ⅳ database served as an external test set. The Boruta algorithm was used to select the most important predictor variables from 53 candidate variables. The eXtreme Gradient Boosting algorithm was applied to establish a prediction model for MAKE30. Model discrimination was evaluated by the area under the receiver operating characteristic curve (AUROC). The SHapley Additive exPlanations method was used to interpret model predictions.

Results: The overall incidence of MAKE30 in the 2 study cohorts was 28.3% (95% CI 26.9%-29.7%) and 26.7% (95% CI 25.9%-27.5%), respectively. The prediction model for MAKE30 exhibited adequate predictive performance, with an AUROC of 0.868 (95% CI 0.852-0.881) in the training set and 0.823 (95% CI 0.798-0.846) in the internal test set. Its simplified version achieved an AUROC of 0.744 (95% CI 0.735-0.754) in the external test set. The SHapley Additive exPlanations method showed that the use of vasopressors, mechanical ventilation, blood urea nitrogen level, red blood cell distribution width-coefficient of variation, and serum albumin level were closely associated with MAKE30.

Conclusions: An interpretable eXtreme Gradient Boosting model was developed and validated to predict MAKE30, which provides opportunities for risk stratification, clinical decision-making, and the conduct of clinical trials involving AKI.

KEYWORDS

major adverse kidney events within 30 days; older; acute kidney injury; machine learning; prediction model

Introduction

Acute kidney injury (AKI) is a clinical syndrome characterized by a rapid decline in renal function [1]. The incidence of AKI has been reported to be about 10%-15% in hospitalized patients and over 50% in critically ill patients [2-4]. AKI is common in older individuals, associated with increased morbidity, mortality, and health care costs [5-7]. The prevalence of multiple comorbidities as well as age-related changes in the kidneys, systemic vasculature, and immune system render older patients more susceptible to kidney damage and less likely to recover [5,8]. Given the already high and increasing incidence of AKI in the older, there is a tremendous need to develop clinical tools for risk stratification of postAKI outcomes in this age group.

Major adverse kidney events within 30 days (MAKE30), a composite of death, new renal replacement therapy (RRT), or persistent renal dysfunction (PRD), has been recognized as a key metric of post-AKI outcomes [9,10]. Patients with no renal recovery during hospitalization show a higher risk of long-term adverse outcomes than those who recovered [11,12]. Furthermore, the initiation of RRT after AKI onset is associated with long-term renal dysfunction and death [13,14]. Previous studies have confirmed MAKE30 as a common, feasible to measure, and clinically meaningful endpoint in clinical trials involving AKI [15-17]. The prediction of MAKE30 can be critical for evaluating patient prognosis, guiding clinical decision-making, and facilitating the conduct of clinical trials.

Clinical prediction models are mathematical tools that are primarily intended to assist physicians in their clinical decision-making [18]. Recently, the rapid development in medical big data and advances in computer science have sparked a growing interest in applying machine learning techniques to develop clinical prediction models [19]. Compared with traditional statistical methods, advanced machine learning algorithms can better integrate large amounts of clinical data, fit complex nonlinear relationships, and analyze high-order interactions. The eXtreme Gradient Boosting (XGBoost) algorithm, an efficient implementation of the gradient boosting framework, represents one of the notable advances in machine learning and is widely used in the medical field [20-23]. XGBoost excels in preventing overfitting during the training process, enhancing predictive performance and robustness in complex data scenarios.

Therefore, the objective of this study was to develop and validate a clinical prediction model for MAKE30 in hospitalized older patients with AKI using the machine learning XGBoost algorithm.

Methods

Study Design

This study identified older patients (aged ≥ 65 years) with AKI who were admitted to the Second Xiangya Hospital of Central South University from January 1, 2015, to December 31, 2020. AKI was defined according to the Kidney Disease: Improving Global Outcomes criteria as an increase in serum creatinine (SCr) by ≥26.5 μmol/L within 48 hours or to ≥1.5 times baseline within 7 days [24]. Baseline SCr was defined as the lowest creatinine in the past 7 days. AKI was determined every time a SCr measurement occurred based on the changes in SCr over the past 48 hours and 7 days. Patients were excluded if they were diagnosed with end-stage renal disease, had a hospital stay of less than 48 hours, had an initial SCr≥353.6 μmol/L at admission, or required RRT before the diagnosis of AKI.

In addition, a cohort containing eligible patients from the Medical Information Mart for Intensive Care Ⅳ (MIMIC-Ⅳ) database was used for model external validation [25]. MIMIC-Ⅳ is a relational database containing comprehensive information for intensive care unit (ICU) admissions at the Beth Israel Deaconess Medical Center (BIDMC) from 2008 to 2019.

Data Collection

Data on demographics, diagnoses, laboratory tests, interventions, and medications were collected. A total of 53 candidate predictor variables were identified that were considered clinically relevant to MAKE30, were available in the electronic health records (EHRs), and had a proportion of missing values less than 30% (Multimedia Appendix 1). Comorbidities were determined based on diagnoses encoded in the *ICD-9* (*International Classification of Diseases, Ninth Edition*) or *ICD-10* (*International Statistical Classification of Diseases, Tenth Revision*). The burden of comorbidities was assessed by the Charlson comorbidity index [26,27]. Laboratory tests were recorded as the measurements within 48 hours of and closest to the diagnosis of AKI. Medications were identified according to the Anatomic Therapeutic Chemical classification system and included if administered within 48 hours after the diagnosis of AKI [28]. The use of mechanical ventilation within 48 hours after the diagnosis of AKI was also collected.

Outcome Measures

The primary outcome was MAKE30, defined as a composite of death, new RRT, or PRD at hospital discharge or at 30 days after the diagnosis of AKI, whichever occurred first [9,10]. PRD was defined as a final inpatient SCr value ≥2 times baseline. Secondary outcomes were length of hospital stay as well as death within 30 days and 1 year after discharge. Survival data were extracted from the Chinese Center for Disease Control and Prevention cause-of-death reporting system.

RenderX

Statistical Analysis

Statistical analyses were performed using R software (version 4.1.2; R Foundation for Statistical Computing). Categorical data are presented as numbers and percentages and were analyzed with the chi-square test or Fisher exact test, as appropriate. Continuous data are described with median (IQR) and were compared using the Mann-Whitney *U* test. Survival data were analyzed with the Kaplan-Meier method, and differences in survival were evaluated by the log-rank test. The 2-sided α level was set at .05. Missing data were analyzed by the missForest method, which is a nonparametric missing value imputation for mixed-type data [29]. The description of missing data can be found in Multimedia Appendix 2.

Patients from the Second Xiangya Hospital were randomly divided into a training set and an internal test set in a ratio of 7:3. The cohort of patients from the MIMIC-Ⅳ database was used as an external test set.

Feature Selection

To build a parsimonious model, feature selection was performed on the training set. First, we removed the predictor variables with near-zero variance. Near-zero variance was defined as a situation where a variable exhibits very little variation or almost no variability across its values, characterized by over 95% of its values being identical. Then the Boruta algorithm was used to select the most important predictor variables [30]. Boruta is an all-relevant feature selection wrapper algorithm, capable of working with classification methods that output variable importance measures; in this study, the Random Forest model was used. There were 30 variables ultimately selected for inclusion within the machine learning model (Multimedia Appendix 1).

Model Development and Validation

A machine learning XGBoost model was established on the training set to predict the development of MAKE30 [31]. XGBoost is an optimized implementation of the gradient boosting framework, which sequentially adds weak models (decision trees) to iteratively improve the overall prediction. XGBoost improves upon traditional gradient boosting algorithms by offering scalability, regularization techniques, optimized tree construction, and customization options. A set of model hyperparameters were optimized by running 5 random shuffles of 5-fold cross-validation, including eta, max_depth, min_child_weight, gamma, colsample_bytree, and subsample. The descriptions and search ranges for the hyperparameters are listed in Multimedia Appendix 3. The XGBoost model can be accessed at [LuoXiaoqin123/MAKE30-in-elderly-AKI] (GitHub).

The performance of the XGBoost model was evaluated on the internal and external test sets. Model discrimination was assessed by the area under the receiver operating characteristic curve (AUROC), which is an assessment metric that remains unaffected by incidence or threshold selection. Model calibration was evaluated using the calibration plot aggregated by deciles and the Brier score. The area under the precision-recall curve (AUPRC) was calculated, considering that it is a useful metric for class-imbalanced data in a problem setting where finding the adverse outcome is crucial. A decision curve analysis was performed to illustrate the clinical use of the model. In addition, we determined the optimal cutoff by the receiver operating characteristic (ROC) curve and the maximum Youden index (sensitivity + specificity – 1) in the training set. The sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), positive likelihood ratio (PLR), and negative likelihood ratio (NLR) at the optimal cutoff were calculated.

In the external validation set, there were 9 predictor variables with a proportion of missing values exceeding 50% (Multimedia Appendix 2). In this case, we simplified the model to include 21 variables, with model development performed as described above using the same training set.

Model Interpretations

We used the SHapley Additive exPlanations (SHAP) method to interpret model predictions [32]. SHAP is a game theoretic approach that helps in explaining the output of any machine learning model. It can provide consistent and locally accurate attribution values, the SHAP values, for each feature within a model. A positive SHAP value represents a higher risk of the outcome, whereas a negative SHAP value represents a lower risk of the outcome. The contribution of a feature to the predicted risk of the outcome can be explained by the cumulative effects of feature attribution in each observation.

Sensitivity Analyses

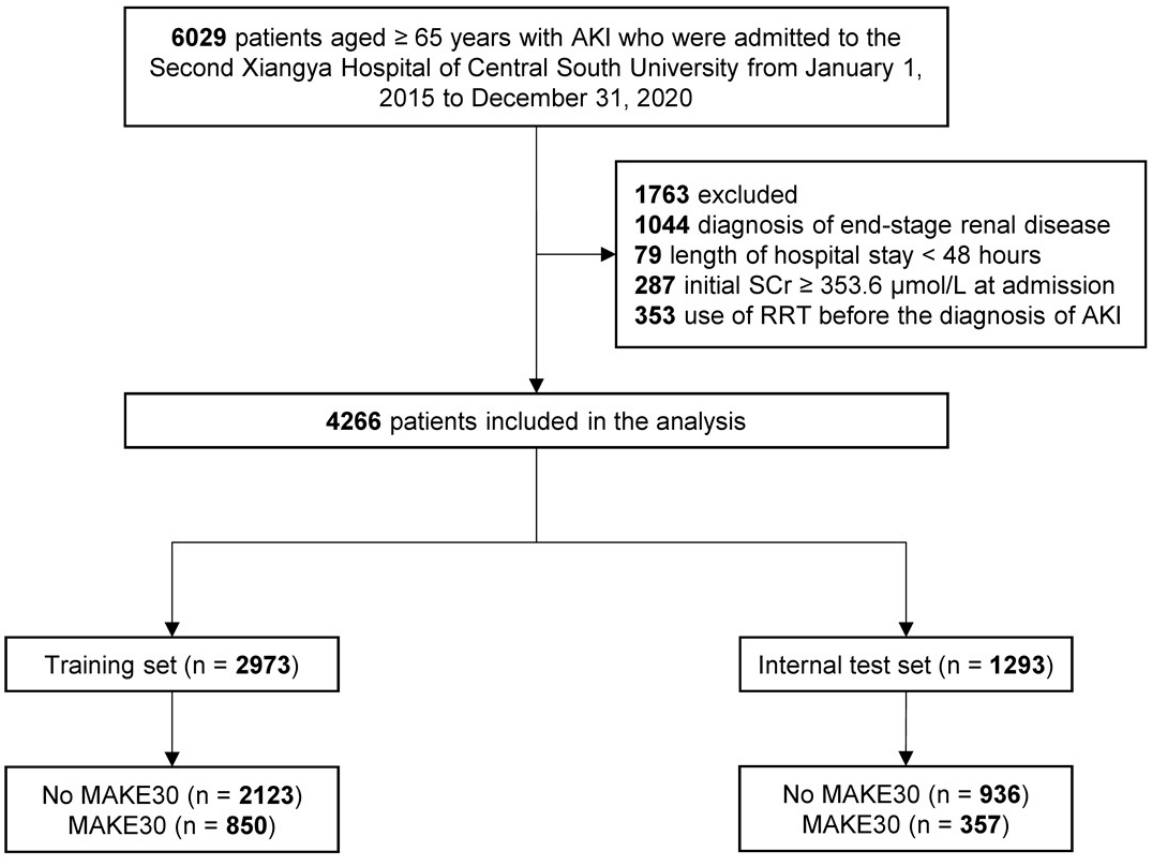
In order to mitigate the potential impact of age on our findings, we further conducted sensitivity analyses to assess the model's robustness across patients stratified by age. We evaluated the model's performance in distinct age groups: <70 years, 70 to 80 years, and ≥80 years.

Ethical Considerations

The medical ethics committee of the Second Xiangya Hospital of Central South University approved the study protocol (2022-K031) and waived the requirement for informed consent. This project has been registered in Chinese Clinical Trial Registry (ChiCTR2200061610). The institutional review boards of BIDMC and the Massachusetts Institute of Technology approved the project and waived the requirement for informed consent. The study followed the Declaration of Helsinki and the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis statement [33].

Results

Patient Characteristics



A total of 4266 patients from the Second Xiangya Hospital were enrolled, including 2973 patients in the training set and 1293 patients in the internal test set (Figure 1). The overall incidence of MAKE30 in this medical center was 28.3% (95% CI 26.9%-29.7%), including 12.3% (95% CI 11.4%-13.4%) with death, 10.2% (95% CI 9.3%-11.1%) with new RRT, and 17.7% (95% CI 16.6%-18.9%) with PRD. The external test set contained 11,864 patients from the MIMIC-Ⅳ database, 26.7% (95% CI 25.9%-27.5%) of whom developed MAKE30 (Multimedia Appendix 4). The incidence of death, new RRT,

XSL•FO
RenderX

and PRD were 18.9% (95% CI 18.2%-19.6%), 4.9% (95% CI 4.5%-5.3%), and 12.8% (95% CI 12.2%-13.4%), respectively.

Table 1 shows the characteristics of patients from the Second Xiangya Hospital stratified by MAKE30. Patients with MAKE30 were older, had a higher burden of comorbidities, and had greater disease severity than patients without MAKE30. Compared with the nonMAKE30 group, the MAKE30 group had shorter length of hospital stay as well as higher 30-day and 1-year mortality after discharge. Multimedia Appendix 5 shows the Kaplan-Meier survival curves of death within 30 days and 1 year for patients alive at discharge stratified by PRD or RRT. Patients with versus without new RRT or PRD had higher 30-day and 1-year mortality after discharge (log-rank P<.001). Multimedia Appendix 6 provides the characteristics of patients from the MIMIC-Ⅳ database stratified by MAKE30. Multimedia Appendix 7 provides the characteristics of patients in the training, internal test, and external test sets.

Figure 1. Flow diagram of patient selection from the Second Xiangya Hospital. AKI: acute kidney injury; MAKE30, major adverse kidney events within 30 days; RRT: renal replacement therapy; SCr: serum creatinine.

[e]NSAID: non-steroidal anti-inflammatory drug.

[f]There were 165 patients with missing postdischarge survival data.

[g]A total of 526 patients who died at hospital discharge or 30 days, whichever occurred first, were excluded.

Model Performance

Figure 2 shows the ROC curves of the model in the training set and internal test set. The model exhibited good discrimination on both datasets, with the AUROC being 0.868 (95% CI 0.852-0.881) and 0.823 (95% CI 0.798-0.846), respectively. Figure 3 shows the calibration plots of the model in the training set and internal test set. The Brier scores on the 2 datasets were 0.127 and 0.145, respectively. Notably, despite the lower Brier score on the training set, the calibration plot exhibits pronounced deviations from the diagonal, especially at higher probability thresholds. In contrast, the calibration plot for the internal test set appears to demonstrate more consistent alignment with the ideal diagonal line across various probability ranges. Figure 4 shows the precision-recall curves of the model in the training set and internal test set. The model achieved an AUPRC of 0.778 and 0.639 on the 2 datasets, respectively. Figure 5 shows the decision curves of the model in the training set and internal test set. When the threshold probability was between 0.06 and 0.97, the model improved clinical decision-making in the training set. Similarly, within a narrower threshold probability range of 0.09 to 0.76, the model improved clinical decision-making in the internal test set. At the optimal cutoff of 0.350, the model achieved a sensitivity of 67.5%, a specificity of 82.5%, a PPV of 59.5%, and a NPV of 86.9% in the internal test set (Table 2).

Multimedia Appendix 8 presents the performance of the simplified model in the training set, the internal test set, and the external test set. It includes ROC curves, calibration plots, precision-recall curves, decision curves, and model performance at the optimal cutoff. The simplified model achieved an AUROC of 0.851 (95% CI 0.834-0.866) on the training set, 0.818 (95% CI 0.792-0.843) on the internal test set, and 0.744 (95% CI 0.735-0.754) on the external test set.

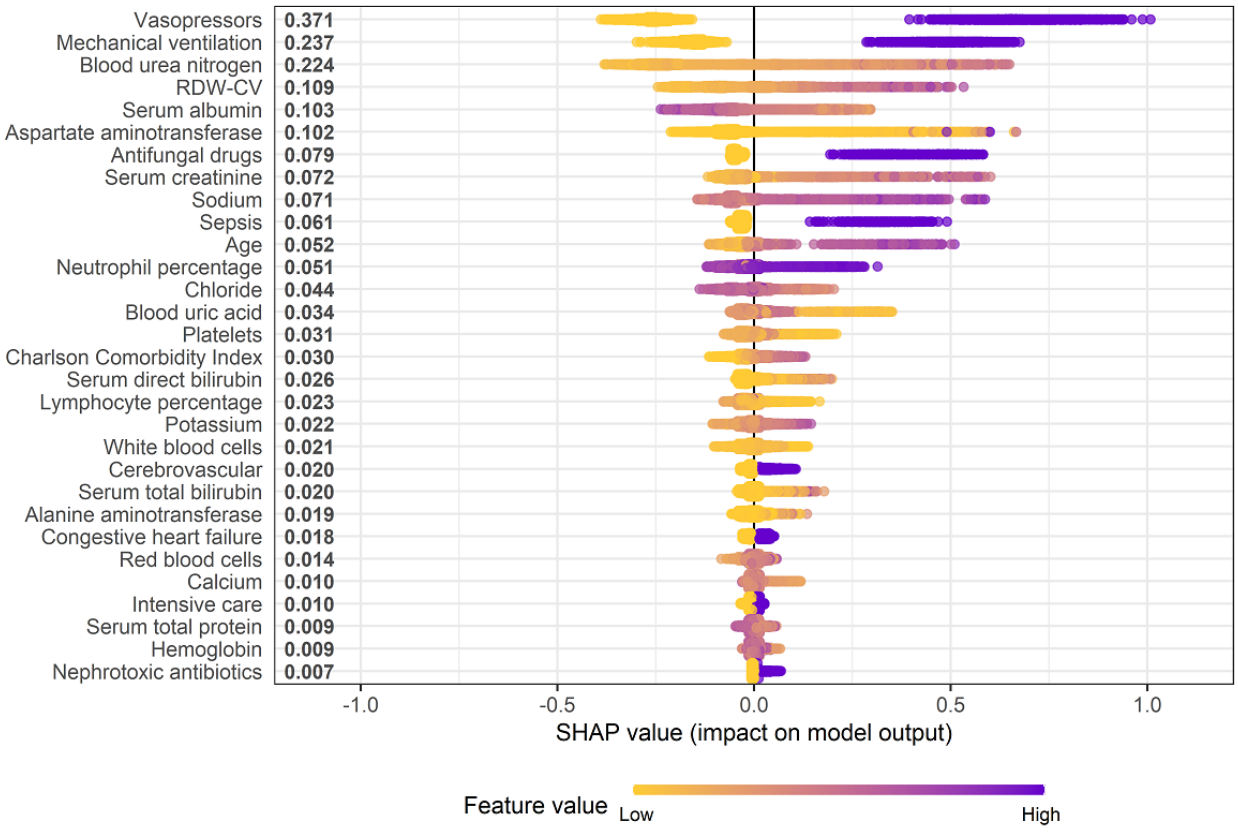
Table 2. Model performance at the optimal cutoff in the training and internal test sets.

Performance metrics	Training set	Internal test set
Cutoff value[a]	0.350	0.350
Sensitivity (%)	71.9	67.5
Specificity (%)	86.6	82.5
PPV[b] (%)	68.3	59.5
NPV[c] (%)	88.5	86.9
PLR[d]	5.37	3.86
NLR[e]	0.32	0.39

[a]The optimal cutoff was determined by the receiver operating characteristic curve and the maximum Youden index (sensitivity + specificity – 1) in the training set.

[b]PPV: positive predictive value.

[c]NPV: negative predictive value.



[d]PLR, positive likelihood ratio.

[e]NLR, negative likelihood ratio.

Model Interpretations

Figure 6 shows the SHAP summary plots of the model. The use of vasopressors, requirement for mechanical ventilation, increased blood urea nitrogen level, increased red blood cell distribution width coefficient of variation, decreased serum albumin level, elevated aspartate aminotransferase level, use of antifungal drugs, and increased SCr level were identified as important predictor variables associated with an increased risk of MAKE30. Multimedia Appendix 9 provides the SHAP dependence plots of the model that visualize how changes in each variable can affect model output.

Figure 6. SHapley Additive exPlanations summary plot of the model. RDW-CV: red blood cell distribution width-coefficient of variation.

Sensitivity Analyses

Multimedia Appendix 10 shows the ROC curves of the model and the simplified model in distinct age groups. In the internal test set, the model achieved AUROCs of 0.827 (95% CI 0.786-0.862), 0.835 (95% CI 0.794-0.869), and 0.770 (95% CI 0.708-0.837) in patients aged <70 years, 70 to 80 years, and ≥80 years, respectively. When assessing the simplified model

XSL•FO
RenderX

across distinct age groups in the external test set, its performance exhibited overall stability.

Discussion

Principal Findings

This study showed that MAKE30 is common in hospitalized older patients with AKI. The main deliverable of this study is the development and validation of a machine learning–based model to predict MAKE30, representing a pioneering effort to address the critical need in this vulnerable population. The XGBoost model (or its simplified version) achieved adequate predictive performance in both internal and external validation. The model could be a useful tool for prognostic assessment, clinical decisionmaking, and the conduct of clinical trials involving AKI.

A National Institute of Diabetes and Digestive and Kidney Diseases Workshop recommended a composite of death, provision of dialysis, or sustained loss of kidney function at a discrete time point as a meaningful endpoint for trials [9]. This endpoint was later expanded to be MAKE30, which occurred at hospital discharge truncated at 30 days [34,35]. MAKE30 has been shown to be common, easily measurable, and a promising endpoint for patients with AKI. Our study further confirmed that MAKE30 is a prevalent endpoint among hospitalized older patients with AKI, with its nonfatal components being associated with long-term outcomes.

The prediction of MAKE30 is essential for risk stratification and clinical management of hospitalized older patients with AKI. While several prediction models for MAKE30 have been developed, none specifically focus on this population. A recent study developed a logistic regression model specifically for predicting MAKE30 among critically ill adults [36]. Our previous studies established machine learning–based models to predict MAKE30 in hospitalized children with AKI [37] and older patients in critical care [38]. To the best of our knowledge, this study is the first to use machine learning algorithm to predict MAKE30 in hospitalized older patients with AKI. This demographic often experiences impaired recovery of kidney function, resulting in significantly increased morbidity and mortality. By developing a prediction model tailored to this population, we aimed to enhance clinical outcomes and facilitate more effective interventions. The model can be seamlessly integrated into electronic medical record systems, assisting health care providers in risk stratification and informed clinical decision-making. In addition, in clinical trials involving AKI, the model can identify high-risk groups that are more likely to benefit from the intervention.

Compared with the existing studies, this study has several strengths. First, by using state-of-the-art XGBoost machine learning algorithm, our model represented a significant advancement over previous studies that primarily relied on clinical rationale and simpler statistical methods. XGBoost is particularly effective due to its ability to process large amounts of data and identify intricate patterns within complex datasets. Its gradient boosting framework enhances predictive accuracy by combining the strengths of multiple weak learners, leading to more robust and reliable outcomes. Furthermore, XGBoost's flexibility allows for easy tuning of hyperparameters, enabling us to optimize the model for our specific dataset and improve its performance in predicting MAKE30 in hospitalized older patients with AKI.

Second, this study used a larger sample size and conducted external validation to evaluate the model's performance. Notably, the results of the external validation showed that the simplified version of the model exhibited a gap of approximately 10% in AUROC between the training set and the external test set. However, the performance of the simplified model on the internal test set was comparable to that of the full model, suggesting that the observed gap may be attributed to the use of a different test set with distinct characteristics. Compared with the training set, the external test set comprised critically ill patients from various ethnic backgrounds and with distinct patient characteristics and data quality. These findings underscore the necessity for comprehensive testing across diverse datasets to ensure the model's reliability and applicability in real-world settings. Another noteworthy observation is that, although the Brier scores for both the training and test data suggested acceptable calibration, a deeper examination through visual inspection uncovered disparities. Factors contributing to the observed discrepancies may include overfitting during training, differences in underlying data distributions, model complexity, or nuances in evaluation methodology. Further investigation into the factors contributing to the observed discrepancies is warranted.

Finally, this study delved into the interpretability of the model. A major challenge in the clinical implementation of machine learning is how to uncover its "black box" nature. Usually, data come in and decisions go out, but the process between input and output is opaque. The advantage of our study is the use of SHAP method to explain the critical aspects of the data and fully understand the model. The SHAP method identified important predictor variables associated with the development of MAKE30, which could allow early intervention of modifiable factors to mitigate the risk of MAKE30. Another notable finding is the nonlinear relationship between the predictor variables and the risk of MEKE30, as shown in the SHAP dependence plots. This relationship is often ignored by traditional regression analysis, which requires a linearity between the independent variables and the outcome.

Limitations

Our study has several limitations. First, the MIMIC-Ⅳ database only contained data from critically ill patients admitted to the ICU. Model performance awaits further validation in larger samples of patients at different medical centers. Second, it remains unclear whether the model will perform well in individual prognostication and whether its clinical application will improve patient prognosis. Thus, clinical impact studies are needed to confirm the effectiveness of the model. Third, the unavailability of preadmission SCr data could lead to the omission of patients who could have been diagnosed with AKI, that is, community-acquired AKI. Fourth, the urine output criteria were not used to define AKI because hourly urine output data were unavailable for most patients. Finally, the missForest

XSL•FO
RenderX

method, as a single imputation method, might affect the SHAP results by not considering sufficient variation for the imputation of missing data.

Conclusions

MAKE30 is common in hospitalized older patients with AKI. An interpretable machine learning XGBoost model was developed and validated to predict MAKE30. The model exhibited adequate predictive performance, which provides opportunities for risk stratification, clinical decision-making, and the conduct of clinical trials involving AKI. Future studies are needed to support the robustness and clinical effectiveness of the model.

Authors' Contributions

SBD designed and supervised the study and revised the manuscript. XQL performed the data extraction, analyzed and interpreted the data and drafted the manuscript. NYZ performed the data extraction and revised the manuscript critically for important intellectual content. YHD, HSW, and YXK interpreted the data and critically revised the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Monitoring vital signs in hospitalized patients is crucial for evaluating their clinical condition. While early warning scores like the modified early warning score (MEWS) are typically calculated 3 to 4 times daily through spot checks, they might not promptly identify early deterioration. Leveraging technologies that provide continuous monitoring of vital signs, combined with an early warning system, has the potential to identify clinical deterioration sooner. This approach empowers health care providers to intervene promptly and effectively.

Objective: This study aimed to assess the impact of a Remote Patient Monitoring System (RPMS) with an automated early warning system (R-EWS) on patient safety in noncritical care at a tertiary hospital. R-EWS performance was compared with a simulated Modified Early Warning System (S-MEWS) and a simulated threshold-based alert system (S-Threshold).

Methods: Patient outcomes, including intensive care unit (ICU) transfers due to deterioration and discharges for nondeteriorating cases, were analyzed in Ramaiah Memorial Hospital's general wards with RPMS. Sensitivity, specificity, chi-square test for alert frequency distribution equality, and the average time from the first alert to ICU transfer in the last 24 hours was determined. Alert and patient distribution by tiers and vitals in R-EWS groups were examined.

Results: Analyzing 905 patients, including 38 with deteriorations, R-EWS, S-Threshold, and S-MEWS generated more alerts for deteriorating cases. R-EWS showed high sensitivity (97.37%) and low specificity (23.41%), S-Threshold had perfect sensitivity (100%) but low specificity (0.46%), and S-MEWS demonstrated moderate sensitivity (47.37%) and high specificity (81.31%). The average time from initial alert to clinical deterioration was at least 18 hours for RPMS and S-Threshold in deteriorating participants. R-EWS had increased alert frequency and a higher proportion of critical alerts for deteriorating cases.

Conclusions: This study underscores R-EWS role in early deterioration detection, emphasizing timely interventions for improved patient outcomes. Continuous monitoring enhances patient safety and optimizes care quality.

Introduction

Ensuring patient safety is vital in health care, whether in regular wards or critical care units. Swift detection of vital sign changes allows prompt adjustments in care levels. Delayed intervention for patient deterioration is linked to increased morbidity and mortality [1,2]. Hospitals use aggregate score based early warning systems (EWS) to detect vital sign deterioration. However, these rely on instantaneous measurements conducted hours apart [3], lack historical trends, and have sensitivity <80%

XSL•FO
RenderX

for patient deterioration [4-6]. EWS based on continuous monitoring of the vital signs of hospitalized patients is expected to overcome the constraints of conventional, intermittent vital measurements. Multiple studies have shown that continuous vital signs monitoring is pivotal in identifying at-risk patients and facilitating timely interventions [7-14]. An automated system based on continuous monitoring of hospitalized patients' vital signs in combination with EWS besides enhancing patient safety, has the potential to save health care practitioners (HCPs) time [11,15-17] mitigate errors [18], facilitate information sharing with relevant stakeholders for informed decision-making [19], and reduce costs [20].

To ensure patient safety, and enhance health care services, Ramaiah Memorial Hospital (RMH), has implemented an advanced commercial remote patient monitoring system (RPMS) in its wards. This system is designed for continuous monitoring of vital signs, featuring an EWS (R-EWS). Before the introduction of R-EWS, ward monitoring depended on manual spot checks every 4 hours to calculate the modified early warning score (MEWS), while continuous monitoring in intensive care units (ICUs) relied on a threshold-based alerting system. The implementation of the R-EWS significantly increased the time available for patient care by reducing the time nurses spent on routine monitoring, communication, and coordination. Majority of HCPs reported improvements in the level of care and overall patient safety, with many also noting an enhanced patient experience [21].

After several months of implementing R-EWS, the hospital sought to assess the system's performance against previous monitoring practices. To this end, a retrospective analysis was conducted to evaluate its effectiveness in identifying patient deterioration. The performance of R-EWS was also benchmarked against simulated versions of MEWS (S-MEWS) and the ICU's continuous threshold-based alert system (S-Threshold). The primary objective of this study was to determine how well the R-EWS, S-Threshold, and S-MEWS systems ensure patient safety by accurately distinguishing between deteriorating patients needing ICU transfer and stable patients ready for discharge.

Methods

Materials

The RPMS is a continuous, vital parameters monitoring system. It uses sensor sheets placed under the mattress that uses ballistocardiography technology to capture microvibrations from which heart rate (HR), respiratory rate (RR), and systolic blood pressure (SysBP) are computed in a noncontact manner [22-25]. Accessories like a pulse oximeter and temperature probe are used for contact-based measurements of oxygen saturation (SpO_2) and temperature. The system incorporates a configurable and customizable multitiered EWS (R-EWS) for severity assessment, complemented by a user-friendly web dashboard and mobile app for centralized and remote ward monitoring. The hospital leverages this R-EWS for patient monitoring, reporting, and clinical decision-making.

Study Design

This is a retrospective cohort study, conducted without blinding. It uses data from patients under R-EWS monitoring implemented in the general wards of RMH, a tier 1 city's private hospital with over 500 beds. The study covers the period from December 1, 2022, to May 31, 2023. This study retrospectively analyzed the performance of the R-EWS in distinguishing between patients requiring ICU transfer and those stable enough for discharge. The study also retrospectively compared the R-EWS performance against 2 simulated frameworks: the S-MEWS and a S-Threshold. The vital signs data generated by the RPMS served as input for these simulated frameworks for the alert generation. Detailed descriptions of these frameworks are provided in the following subsections. To reduce bias all patients who satisfied the inclusion and exclusion criteria were used for analysis.

Ethical Considerations

This study was approved by the RMH ethics committee (DRP/EFPl034/2023).

R-EWS Framework

The R-EWS uses a dynamic 3-tiered alert (tier 1, tier 2, and tier 3) system to prioritize alerts based on the severity of vital signs deviations. This ensures that alerts are raised only when a patient's condition deteriorates significantly. Each tier in the alert system is defined by specific threshold settings for monitored vital signs, as detailed in Table 1. The R-EWS focuses on observing trends over a set period rather than relying on isolated values. This observation window helps confirm sustained deviations in vital signs before triggering an alert. In addition, the tiers incorporate a cool-down period during which no alerts are generated, unless a higher tier is breached. This mechanism prevents frequent and redundant alerts. For tiers 1 and 2, the cool-down period is set at 3 hours. In contrast, tier 3 has no cool-down period and generates alerts every 10 minutes if the patient's condition continues to meet the threshold criteria. This ensures that critical conditions are continuously monitored, allowing for immediate medical intervention when necessary.

[f]T: temperature.

S-MEWS Framework

The S-MEWS simulations used vital sign values from the ranges defined in Table 2, excluding clinical signs such as urine output and mental status. To reduce bias, S-MEWS used the same vital signs scoring criteria as the MEWS previously used in the hospital, with scores calculated 4 times a day (12 AM, 6 AM, 12 PM, and 6 PM). The hospital-initiated notification and escalation protocols for a threshold of 4 or higher. Similarly, S-MEWS was calculated every 4 hours using a 1-hour median calculation for all vitals, triggering a positive alert for a score of 4 or higher. The vital signs data generated by the RPMS served as input for this simulated framework for alert generation.

Table 2. Vital signs threshold and the scoring system for simulated modified early warning system framework.

Parameters	3	2	1	0	1	2	3
Respiratory rate	—[a]	8≥	8< and ≤14	14< and <21	21≤ and <25	25≤ and <31	≤31
Heart rate	—[a]	40≥	40< and ≤60	60< and ≤100	100< and <111	111≤ and <130	≤131
Blood pressure	69≥	70≤ and ≤80	80< and ≤110	110< and <140	140≤ and <170	170≤ and <200	≤200
Oxygen saturation	91≥	91< and ≤93	93< and ≤95	95< to 100	—[a]	—[a]	—[a]

S-Threshold Framework

This EWS simulates traditional ICU monitors that provide continuous monitoring and trigger alarms whenever a specific vital sign exceeds its threshold. These single breach point thresholds can typically be muted for up to 2 minutes. The breach points for various vitals are as follows: High HR >120, Low HR <40, High RR >29, Low RR <8, High SysBP >157, Low SysBP <102, Low SpO_2 <92, High *t*>38.33, and Low *t*<36. To ensure comparability with R-EWS, these threshold values correspond to the tier 1 breach points of R-EWS detailed in Table 1. Similar to S-MEWS, the vital signs data generated by

XSL•FO
RenderX

the RPMS served as input for these simulated frameworks for alert generation.

Study Participants

The study examined retrospective data from individuals who met the specific inclusion and exclusion criteria outlined as follows (Textbox 1).

Textbox 1. Eligibility criteria for study participants.

Inclusion criteria

- All adult patients monitored on Remote Patient Monitoring System (RPMS) system from December 01, 2022, to May 31, 2023.
- Patients with complete intake and discharge information from hospital records.

Exclusion criteria

- All adult patients who were not monitored on the RPMS system.
- Patients aged <18 years.
- Patients whose data were less than 4 hours.

Variables

The 2 study groups were deteriorating patients defined as requiring transfer to the ICU and nondeteriorating patients deemed stable for discharge from the hospital without ICU admission. The total, mean, and median number of alerts in the last 24 hours were calculated for each group for the 3 EWS frameworks. In addition, the average time from the first alert to deterioration was calculated for each framework within the final 24 hours. Specifically for the R-EWS framework, the proportions of patients receiving alerts and the number of alerts at various tiers and combination of vital alerts in both groups during the last 24 hours were computed.

Sensitivity and specificity values were calculated by classifying deteriorating participants with even one alert as true positives, deteriorating participants without alerts as false negatives, nondeteriorating participants without alerts as true negatives, and nondeteriorating participants with even one alert as false positives.

Data Analysis

Descriptive statistics were used to provide the demographic alert counts of the study groups. It is expected that there may be some differences in demographics and significant difference in proportion of participants in each group as it represents the real patient population where only 4%-5% are expected to require advanced care.

A chi-square test assumed equal alert frequency distribution in both groups, with statistical significance indicated by $P<.05$. Using 6 degrees of freedom and a 1-tailed threshold of 12.592, the test assessed if the RPMS system effectively discriminates by generating more alerts in deteriorating patients than nondeteriorating ones.

Results

From December 01, 2022, to May 31, 2023, 922 patients in general wards were monitored using RPMS. For this study, 905 patients met the predefined inclusion and exclusion criteria. Among them, 38 patients experienced deteriorations and were transferred to the ICU. The demographic information of the deteriorating and nondeteriorating group is given in Table 3. The age, gender ratio, and the average length of stay between the 2 groups are similar except the proportion of patients in each group. The median length of stay is 3 days.

Table 4 displays the descriptive alert statistics for the 2 groups across various frameworks. In addition, it illustrates the earliness of each framework in generating alerts for deteriorating group. Across different EWS the deteriorating group consistently showed higher average alerts per patient and median alerts compared with the nondeteriorating group. Specifically, in the R-EWS groups, the deteriorating group had 2.64 times higher alerts, S-Threshold had 2.69 times higher alerts, and S-MEWS had 3.4 times higher alerts. Continuous monitoring based on R-EWS and S-Threshold, produced more alerts for both deteriorating and nondeteriorating groups than the intermittent monitoring S-MEWS. The first alert to deterioration in continuous monitoring systems occurred at least 18 hours before ICU transfer, compared with 11 hours in intermittent monitoring.

In Figure 1, for R-EWS, a depiction of 24-hour cumulative alerts is presented, illustrating the generated data from 5 participants in each category, those undergoing deterioration and those experiencing nondeterioration. The cumulative alerts were generated for the last 24 hours that lead to either a discharge or ICU transfer. These alerts were calculated every hour for the past 24 hours. The figure demonstrates the importance and discriminatory nature of the frequency of alert patterns in R-EWS for both groups. It clearly shows that more than 10 alerts in a day are primarily seen in patients whose conditions worsened and were subsequently transferred to the ICU, rather than in those who were discharged home.

Figure 1. Representative 24-hour cumulative alerts generated in 5 participants each of those experiencing deterioration and nondeterioration in the R-EWS.

The specificity and sensitivity of the different frameworks across the time points are given and the chi-square analysis is given in Table 5. R-EWS demonstrated high sensitivity (97.37%) but lower specificity (23.41%). S-Threshold achieved perfect sensitivity (100%) but had very low specificity (0.46%). In contrast, S-MEWS had moderate sensitivity (47.37%) and the highest specificity (81.31%), balancing fewer false positives with a lower detection rate. All frameworks showed statistically significant discriminative abilities (P<.001).

Table 6 presents data regarding the tier-wise alert numbers and the proportion of patients who received these alerts in both the deteriorating and nondeteriorating categories in the R-EWS framework. The deteriorating group received a significantly higher proportion of alerts across, especially in tier 2 and 3, compared with the normal discharge group. In tier 1, the deteriorating group had 1.36% high HR alerts, 3.35% high RR alerts, and 14.34% low SpO_2 alerts, whereas the nondeteriorating group had 0.85% high HR alerts, 4.35% high RR alerts, and 26.05% low SpO_2 alerts. In tiers 2 and 3, the deteriorating group shows consistently higher alert proportions, especially for critical parameters like SpO_2. In tier 3, the deteriorating group received 73.61% low SpO_2 alerts, compared with 54.84% in the nondeteriorating group. In addition, 26.32% of the deteriorating participants received high HR alerts in tier 1 versus 5.88% of the nondeteriorating participants, and 42.11% received high RR alerts versus 4.35%. Similarly, in tier 3, 76.32% of the deteriorating participants received low SpO_2 alerts compared with 41.41% of nondeteriorating participants.

Table 7 displays information on the vital alert numbers, both individually and in combination, along with the percentage of patients who received these alerts in both the deteriorating and nondeteriorating categories within the R-EWS group. Deteriorating group had a higher percentage of alerts across all vital signs compared with the nondeteriorating group. In total, 87.95% of alerts in the deteriorating group were low SpO_2, compared with 80.89% in the nondeteriorating group In addition, combinations of alerts, such as HR and SpO_2 and RR and SpO_2, were significantly more prevalent in the deteriorating group. Notably, 26.32% of ICU transfer patients had HR and SpO_2 alerts, whereas only 5.07% of normal discharge patients experienced these alerts. The presence of all 4 vital signs alerts (HR, RR, SysBP, and SpO_2) is higher (21.05%) in the deteriorating group compared with only 2.31% in the nondeteriorating group. As a single parameter, HR generated the fewest alerts (504 alerts in total) but had the highest discriminatory nature, with alerts in escalated patients being 4.7 times more likely than in nonescalated patients.

Discussion

Principal Findings

This study aimed to evaluate the effectiveness of the R-EWS in ensuring patient safety by identifying deterioration in patients. Our findings reveal that R-EWS demonstrated a high sensitivity in identifying patients who were deteriorating and in need of ICU transfer. This was achieved with a relatively lower specificity from a single alert. In R-EWS, ICU transfer patients received a higher number of alerts, including alerts classified as critical, compared with their normal discharge counterparts.

As seen in Table 3, both groups had similar demographics though vastly different group sizes (38 deteriorating and 867 nondeteriorating). This is consistent with the expectation of ICU transfers or Death in wards to be 2%-6% [26]. Continuous monitoring identifies more patients developing complications than intermittent monitoring. This is supported by data in Table 5 where both R-EWS and S-Threshold, based on continuous monitoring, demonstrated a high sensitivity in alerting to potential patient deterioration. This is in stark contrast to the S-MEWS system, which, relying on intermittent hourly monitoring, showed a sensitivity of only 47%, a rate not clinically acceptable as it would miss deterioration in the majority of patients. These results align with existing literature indicating that continuous monitoring is more effective than intermittent and manual monitoring in early identification of complications and improving patient outcomes [27-29]. There is also established research showing that EWS based on 3- to 6-hour spot checks, a standard of care practice in most hospitals, can have sensitivity as low as 40% [4,5]. While the sensitivity of S-Threshold was 100% the specificity was nearly zero,

XSL•FO
RenderX

indicating a high rate of false alerts for nondeteriorating patients. Alerting frequently on every patient is as ineffective as alerting on no patient, as these alarms are likely to be ignored and lead to alarm fatigue for health care workers. In this context, the R-EWS, with its balanced approach to minimal alerts with high sensitivity and moderate specificity emerges as a better choice.

The study highlights that continuous monitoring systems generate more alerts than intermittent systems as shown in Table 4 due to their higher frequency of measurements, a trend also observed in the scientific literature [29]. This study found that the intermittent monitoring-based S-MEWS generated 342 alerts which is 39 times less alerts than the 13,502 alerts generated in R-EWS and 194 times less than the 66,510 S-Threshold. By using a tier-based alerting with a cool down period R-EWS produced 5 times less alerts than S-Threshold. This reduction in alert number is important because alarm fatigue can occur when health care professionals become desensitized to the constant stream of alerts, potentially leading to slower response times or even missed alarms. This overload not only increases the workload but also pushes health care professionals toward burnout, a serious issue highlighted by Kristinsson et al [30] in 2022. The findings indicate that, on average, R-EWS generates 15 alerts per patient per 24 hours. This is a more manageable workload for health care professionals compared with the overwhelming 73 alerts per patient per 24 hours generated by the S-Threshold system. Considering it takes approximately 4 mins to assess an alert, addressing every alert would lead to spending 4.9 hours or over 50% of a standard shift on alerts which is impractical. In the case of R-EWS, an average of 15 alerts are generated per patient in 24 hours resulting in HCP spending about an hour collectively which is reasonable. In addition, this time is made up through the time saved from needing to manually check vitals and document and report the same for every patient.

The study also highlights that continuous monitoring systems provide alerts earlier than intermittent systems. As demonstrated in Table 4, one of the significant findings of our study is the ability of the R-EWS and S-Threshold systems to provide alerts an average of at least 18 hours before an ICU transfer. This represents a substantial improvement over the S-MEWS, which provides alerts an average of only 11 hours in advance. These results are consistent with what has been reported in the literature. For instance, continuous vital sign monitoring has been shown to warn of upcoming deterioration 8.3 hours in advance compared with 5.2 hours for periodic EWS [29]. Early detection of clinical deterioration enables timely and effective interventions, which not only improves patient outcomes but also has the potential to reduce associated health care costs [20,31].

The study highlights the effectiveness of the R-EWS system in distinguishing between patients at risk of deterioration and those with stable conditions. The discriminatory nature of the R-EWS is further evidenced by its trend of increased alerts in the deteriorating group compared with the nondeteriorating group seen in Table 4. This increased number of alerts in the deteriorating group aligns well with what is reported in the literature, where a higher frequency of alerts is typically associated with patients experiencing clinical deterioration [22].

R-EWS also demonstrated, as seen in Table 6, a higher proportion of patients receiving critical alerts (tier 2 and tier 3) among those experiencing deterioration compared with those without any escalations in care. Figure 2 shows the importance and discriminatory nature of the frequency of alert patterns in a random sampling from each group (deterioration and nondeterioration). In the last 24 hours health care providers can make more informed decisions based on whether a patient is improving or worsening. As shown in Figures 1 and 2, frequency of greater than 10 alerts in a day is primarily seen in patients whose conditions worsened and were transferred to the ICU, rather than in those who were discharged home. This can serve as a metric for daily evaluations and clinical decision support of discharge, observe further, or transfer or prepare for critical care.

Our findings as detailed in Table 7, highlight the critical importance of not only the volume but also the pattern and type of alerts. SpO_2 alerts combined with HR or RR alerts are twice as likely in deteriorating patients compared with nondeteriorating ones, The integration of SpO_2 alerts, especially in combination with HR or RR alerts, can provide a valuable early warning system for patient deterioration. SpO_2 alerts combined with HR or RR alerts are 5 times and 2 times as likely in deteriorating patients compared with nondeteriorating ones, Furthermore, while all four vital alerts appeared in only 21% of deteriorating patients, they appeared in just 2% of nondeteriorating patients, underscoring this pattern as a critical marker. These findings suggest that monitoring systems should not rely solely on the volume of alerts but should also consider the context and combination of these alerts. Therefore, the development of alert algorithms that take into account the interdependence of various vital signs may enhance the predictive value of these systems.

While the study did not specifically focus on the cost-benefit aspect, it is worth noting the RPMS's potential in reducing direct costs. Manual monitoring incurs high labor expenses and is prone to errors [32,33]. RPMS can lower these costs by automating monitoring and reducing HCP workload, particularly at this hospital with a 1:6 HCP-to-patient ratio. Early detection of patient deterioration, even if it prevents only 2%-5% of ICU admissions, can lead to substantial savings. ICU stays and emergency interventions are costly, with ICU costs (US $132.5 per day) far exceeding general ward costs (US $25 per day [34,35]. Despite the initial investment, RPMS's cost-effectiveness in settings like this hospital is evident. It offers a viable solution for improving patient care and maintaining financial sustainability in Indian health care.

Mobilization is crucial for patient recovery. Traditional monitoring methods, which use wired sensors, restrict movement and are time consuming to set up, making mobilization difficult. The RPMS overcomes this by measuring 3 vital signs namely, HR, RR, and BP remotely, eliminating the need for tethering and allowing patients the freedom to move. During the study period, SpO_2 and temperature were measured with wired sensors; these can be easily removed and reattached, minimizing disruption. Thus, RPMS significantly enhances patient mobility while ensuring continuous monitoring. RPMS is now equipped

XSL•FO
RenderX

with wireless sensors for these measurements, which further enhances mobility without limitations. The contactless measurement of the 3 vital signs saves nursing time by eliminating the need to detach and reattach sensors each time the patient leaves and returns to bed. There is still a limitation in the current system because it only measures vitals when the patient is on the bed and not during ambulatory activities.

There are practical challenges associated with continuous monitoring for every patient that need consideration; high initial setup costs, the necessity for comprehensive staff training, and potential resistance to new technology to name a few. Integration with existing hospital systems can be complex, requiring technical expertise to ensure reliability and accuracy. Patient comfort and compliance are also crucial. Alarm fatigue from frequent alerts is another concern along with data privacy and security [36,37]. There is also a risk of overreliance on automation, which could lead to neglect of thorough patient assessments, deskilling which can lead to missing subtle signs of deterioration [38]. Addressing these challenges and fine-tuning RPMS in the future is necessary for the successful adoption and sustainability of RPMS in health care settings.

Limitations

The limitations of the study include the fact that the study wards had a diverse patient demographic. Such diversity, while reflective of a real-world scenario, could introduce variables that affect the generalizability of the findings. The comparison between the frameworks is unequal due to the inherent nature of each framework, which results in different sets of observations. The simulation of the MEWS only used vital signs, due to the unavailability of data on urine output and consciousness levels. The inclusion of these parameters could potentially have enhanced S-MEWS's sensitivity, though it does speak to the need for a more labor-intensive approach for MEWS compliance.

Conclusions

The study underscores the transformative impact of the RPMS using continuous monitoring and R-EWS alerting system on patient safety, emphasizing early deterioration. Despite certain limitations, the RPMS proves to be effective for improving patient safety, advocating for broader implementation. To further validate these findings, controlled trials are essential. In addition, more detailed costing data are crucial for a comprehensive cost of care analysis and to better understand the system's overall efficiency. Future studies should also involve collaboration with machine learning and artificial intelligence experts to optimize the system's specificity and sensitivity.

Abstract

Background: Clinical guideline development preferentially relies on evidence from randomized controlled trials (RCTs). RCTs are gold-standard methods to evaluate the efficacy of treatments with the highest internal validity but limited external validity, in the sense that their findings may not always be applicable to or generalizable to clinical populations or population characteristics. The external validity of RCTs for the clinical population is constrained by the lack of tailored epidemiological data analysis designed for this purpose due to data governance, consistency of disease or condition definitions, and reduplicated effort in analysis code.

Objective: This study aims to develop a digital tool that characterizes the overall population and differences between clinical trial eligible and ineligible populations from the clinical populations of a disease or condition regarding demography (eg, age, gender, ethnicity), comorbidity, coprescription, hospitalization, and mortality. Currently, the process is complex, onerous, and time-consuming, whereas a real-time tool may be used to rapidly inform a guideline developer's judgment about the applicability of evidence.

Methods: The National Institute for Health and Care Excellence—particularly the gout guideline development group—and the Scottish Intercollegiate Guidelines Network guideline developers were consulted to gather their requirements and evidential data needs when developing guidelines. An R Shiny (R Foundation for Statistical Computing) tool was designed and developed using electronic primary health care data linked with hospitalization and mortality data built upon an optimized data architecture. Disclosure control mechanisms were built into the tool to ensure data confidentiality. The tool was deployed within a Trusted Research Environment, allowing only trusted preapproved researchers to conduct analysis.

Results: The tool supports 128 chronic health conditions as index conditions and 161 conditions as comorbidities (33 in addition to the 128 index conditions). It enables 2 types of analyses via the graphic interface: overall population and stratified by user-defined eligibility criteria. The analyses produce an overview of statistical tables (eg, age, gender) of the index condition population and,

XSL•FO
RenderX

within the overview groupings, produce details on, for example, electronic frailty index, comorbidities, and coprescriptions. The disclosure control mechanism is integral to the tool, limiting tabular counts to meet local governance needs. An exemplary result for gout as an index condition is presented to demonstrate the tool's functionality. Guideline developers from the National Institute for Health and Care Excellence and the Scottish Intercollegiate Guidelines Network provided positive feedback on the tool.

Conclusions: The tool is a proof-of-concept, and the user feedback has demonstrated that this is a step toward computer-interpretable guideline development. Using the digital tool can potentially improve evidence-driven guideline development through the availability of real-world data in real time.

Introduction

Multimorbidity is the presence of 2 or more long-term health conditions in a person [1]. Typically, multimorbidity was considered a problem for older populations but is increasingly recognized as a challenge in younger people as well [2]. Multimorbidity is associated with worse physical and mental health function, higher service use, and higher mortality [3-5].

Health care services and research often focus on health conditions in isolation, but aging populations mean that both care and research need to better account for multimorbidity. A key point of the intersection of research evidence and care is clinical guideline development, which is where a systematic review of research evidence is used to derive recommendations for clinical practice.

Clinical guideline development preferentially relies on evidence from randomized controlled trials (RCTs). RCT is a gold-standard method to evaluate the efficacy of treatments because they have the highest internal validity [6]. However, the external validity of trial evidence may be limited in the sense that their findings may not always be applicable to or generalizable to clinical populations or population characteristics [7]. This is because RCTs commonly exclude large proportions of patients treated in normal practice. In a systematic review of eligibility for 305 RCTs of treatments for physical conditions, half of the trials excluded more than three-quarters of people with the condition, most commonly older people and people with significant comorbidity (conditions apart from the target of the trial treatment) or coprescribing (of treatments for other conditions) [6,8].

The problem of exclusion from trials is commonly recognized but less commonly quantified. Systematic review guidelines state that generalizability should always be considered and discussed, but rarely is, even in Cochrane systematic reviews [9,10]. The Grades of Recommendation Assessment, Development, and Evaluation (GRADE) recommendations for guideline development also include a method for considering the "directness" of evidence [7]. In principle, guideline developers following GRADE [11] already consider applicability as part of the assessment of indirectness. However, judgments about applicability are often implicit, and the generalizability of estimates (eg, of intervention effect) from RCT evidence is more often assumed than explicitly examined. In practice, clinical guidelines rarely refer to comorbidity or its implications [12], and guidelines rarely mention treatment interactions even though following single-condition guideline recommendations for treatment in a person with multiple conditions commonly leads to potentially serious drug-disease and drug-drug interactions [13], and the cumulative impact of individually rational guideline treatment recommendations can easily be irrational or contradictory in people with multimorbidity [13-17].

Better accounting for multimorbidity and polypharmacy in single-condition guidelines requires robust judgments about the applicability and generalizability of RCT evidence. Such judgments have to be informed by an epidemiological understanding of the clinical population and how it compares to the population studied in RCTs. However, guideline developers are constrained by the lack of tailored epidemiological data analysis designed for this purpose due to data governance, consistency of disease definitions, and reduplicated effort in analysis code. Here, we present a proof-of-concept digital tool using UK health care data to systematically characterize the index condition population, supporting the reuse of existing disease definitions and analysis and integrated disclosure control to ensure governance requirements. A key motivation was to develop an efficient tool that did not require expert data manipulation or technical skills.

Methods

Study Design

We worked with domain experts in guideline development (groups from the National Institute for Health and Care Excellence [NICE] and the Scottish Intercollegiate Guidelines Network [SIGN]) to understand what clinical evidence would be useful for the epidemiological understanding of the disease in terms of overall population and clinical trial eligible or ineligible populations. The Clinical Practice Research Datalink (CPRD) GOLD [18] was used as a primary care data source. The CPRD GOLD is a structured data set extracted from primary care electronic health records (INPS Vision software; In Practice Systems Limited) in the United Kingdom, where key data quality standards are met [19]. In the following subsections, an overview is provided of the data set, details of the requirements

XSL•FO
RenderX

gathering process, the design of the underpinning data structure to support real-time querying, the development of the software tool, deployment of the tool within a Trusted Research Environment (TRE; a secure data and analytics environment), the ethical approval process, and an evaluation of the tool.

Data Set (Primary Care Data Linked with Hospitalization and Mortality)

Data were extracted from the CPRD GOLD data set, consisting of primary care data from general practice electronic health records (EHRs) linked to administrative data for hospital admissions and mortality registration—the organization that manages the CPRD GOLD data extract provided linked data [20]. Data included all permanently registered patients at participating practices on November 30, 2015 (1.17 million), with at least 2 years of prior registration. Clinical conditions were measured any time before the index date, while data on prescriptions were restricted to the previous year due to the size of the data files and clinical relevance for guideline development. Follow-up data for hospital admission and death were available for 3 years (ie, until November 30, 2018). The presence of 161 long-term conditions was ascertained using Read codes and ICD10 (International Classification of Diseases 10th Revision) codes recorded on or before November 30, 2015, using published code lists from the Health Data Research UK phenotype library [21,22]. Read codes and ICD10 coding systems have been used for coding patient data across the UK National Health Services in primary and secondary care services, respectively. For each patient, the electronic frailty index (eFI) [23] and the Charlson Comorbidity Index score [24] were calculated. The raw data set used for this study was provided by the organization that manages CPRD, which explained the data quality and validation checks in place [25]. For study-specific cohort quality and validity, the first and second authors of this paper conducted separate analyses for several conditions, and the cohort sizes generated through the tool and analysis scripts were observed to be the same.

Requirements Gathering (Live Guideline Development Group Consultation)

Tool development was done in conjunction with the guideline development group (GDG) for the NICE gout guideline (subsequently referred to as the NICE gout GDG); therefore, gout was used as an exemplar index condition. Gout is a form of arthritis caused by urate crystal deposition in joints that causes severe joint inflammation and pain, which can be prevented by long-term medication to reduce blood urate levels [26,27]. Initial interviews with GDG were used to define requirements and active engagement with the NICE gout GDG throughout its life cycle, including providing bespoke analysis upon request to help prompt reflection on the use of different kinds of data at different points in guideline development. The bespoke analysis provided is published as an appendix to the guideline [28]. In parallel, a prototype data analysis tool was designed and demonstrated to the NICE gout GDG and other guideline developers in NICE and SIGN to seek their feedback and more detailed requirements in terms of data analysis they wished to have access to as they considered the evidence and drafted recommendations. It was agreed to capture the following two high-level output types:

1. Index condition population analysis: A general view of the population with the underlying condition.
2. Clinical trial population analysis: A modified view allowing explicit comparison of patients eligible or ineligible for a particular clinical trial (or a notional clinical trial), where the user inputs inclusion or exclusion criteria to define the 2 populations: eligible versus ineligible.

Both types of analysis were agreed to produce summaries as tables of numbers for age, gender, ethnicity, and indices of multiple deprivations (IMD) groupings for the selected condition. These summaries were also expanded to demonstrate frailty (measured by the eFI), comorbidity (measured with the Charlson score), the prevalence of comorbidities, and current drug prescription. Additionally, it was highlighted to produce rates of hospitalization and mortality.

Four further requirements included: (1) making the analysis pipeline available for other chronic conditions (because of perceived value across different health conditions by GDGs); (2) supporting the selection of hierarchical groupings of comorbidities and drug prescriptions; (3) statistically disclosure controlled outputs to make egressing of the outputs faster (for instance, by rounding all numbers to nearest 10 and percentages to discrete numbers) to ensure patient confidentiality and to satisfy data governance approvals; and (4) generation of printable reports to use as evidence within the guideline development process, and for subsequent publication as part of the guideline.

Optimizing the Data Structure

A major challenge when developing digital tools that use large data sets is the query processing time. For example, the CPRD GOLD data set has approximately 1.17 million patients in the patient file and approximately 254 million entries in the clinical table (storing codes documenting interactions with the practice). Extracting comorbidities for an index condition based on age, gender, and other features required intensive computation power and storage capacity when dynamic linking the patient and clinical tables. The same challenge was seen for other data analyses. To optimize query processing time, we designed new tables in the Microsoft SQL server, which included only the necessary entries for analysis (eg, for the presence of a condition, then only the first Read code recording its presence and the date recorded is required, rather than all such codes). Similarly, eFI and the Charlson scores were precalculated. However, even with an optimized data structure, the performance of processing queries will increase given the cohort size for a selected index condition unless we increase the computing power and memory. The details of the new data structure design and the rationale for generating each table are given in Multimedia Appendix 1.

Development of the Informatics Tool Using R Shiny

The study has developed an R Shiny (R Foundation for Statistical Computing) proof-of-concept digital informatics tool. R Shiny uses R packages to build graphical, interactive

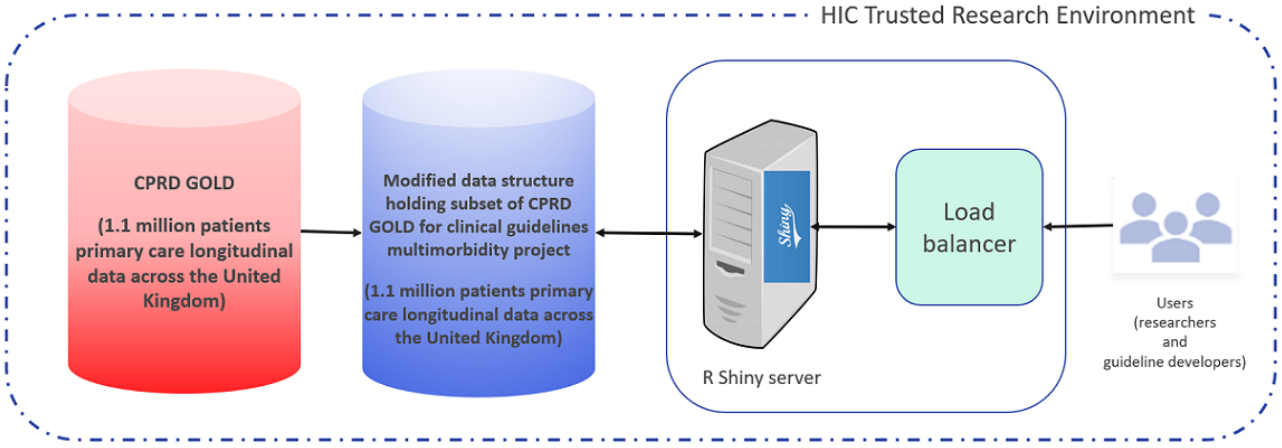
XSL•FO
RenderX

dashboards for data exploration [29]. Dashboards can be rapidly configured, making R Shiny an ideal tool for prototyping.

The tool dashboard design has considered the novices to analyze and extract useful information without knowledge of writing analysis scripts in R. The dashboard enables analysis of all patients with a chosen index condition (for instance, everyone with gout on November 30, 2015) and clinical trial analysis in terms of eligible and ineligible populations as defined in the requirements gathering process. Further descriptions of the analysis types with input and output of each type are presented in Multimedia Appendix 2.

Comorbidities and Prescriptions Analyses

A key requirement of the tool output was to support a selection of comorbidities and drug prescriptions at different hierarchical grouping levels for the selected index condition of interest. The hierarchical groupings of conditions for comorbidities analysis were determined by 2 expert clinicians (authors) and are provided in Multimedia Appendix 3, whereas the British National Formulary (BNF) [30] was used to hierarchically group drugs. Diseases are classified into 3 hierarchical levels: body system, condition group, and individual conditions. The body system is the top level in the hierarchy of diseases. Further down the hierarchy are condition groups, which are subcategories of the body system and are made up of individual conditions. For example, the "cancers" body system has condition groups such as "hematological cancers," "solid organ cancer (primary)," or "solid organ cancer (secondary)," and "hematological cancer" is a condition group made up of individual conditions such as "Hodgkin lymphoma," "leukemia," "myelodysplastic syndrome," "non-Hodgkin lymphoma," "plasma cell malignancy," and "polycythemia vera."



When presenting comorbidities at the body system level, if a patient has one or more comorbidities, under the hierarchical subcategories of the body system, they will be counted as 1 disease or condition. The tool's design considers a selection of any level of comorbidities in the disease's hierarchy.

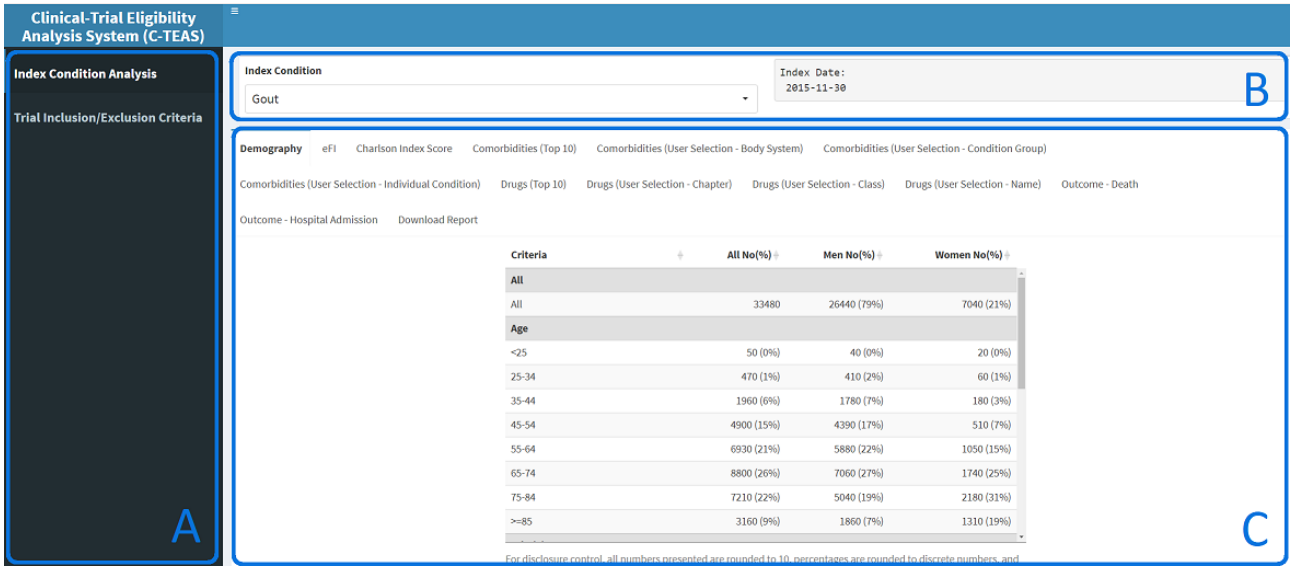
For prescription data within CPRD GOLD, drug codes are given as BNF codes so that drug classification was used instead of the World Health Organization (WHO) Anatomical Therapeutic Chemical classification, which is the de facto drug coding standard in clinical trials [31]. In the BNF, drugs are classified into 3 hierarchical levels: drug chapters, drug classes, and individual drugs.

Deployment of the R Shiny Tool

The R Shiny tool was developed and deployed within the Health Informatics Centre (HIC) of the University of Dundee TRE, which was only accessible to authorized members of the study (Figure 1). The tool is an R Shiny application, and it can be accessed simply through a web browser within the TRE. The tool applies disclosure controls to the results displayed by rounding all numbers to the nearest 10 and providing percentages as discrete numbers, thereby avoiding accidental patient reidentification through inference without introducing bias in prevalence estimates. All data presented here fulfills the disclosure control requirements.

Figure 1. A schematic view of the deployed R Shiny tool. A load balancer allows multiple users to interact simultaneously with an R Shiny server. CPRD: Clinical Practice Research Datalink; HIC: Health Informatics Centre.

Ethical Considerations



The study only used deidentified data, with integrated disclosure control within the tool to avoid accidental patient reidentification through inference, and was approved by the CPRD Independent Scientific Advisory Committee (ISAC; protocol 20_018) [32]. To ensure patient privacy, CPRD provided anonymized data for this study.

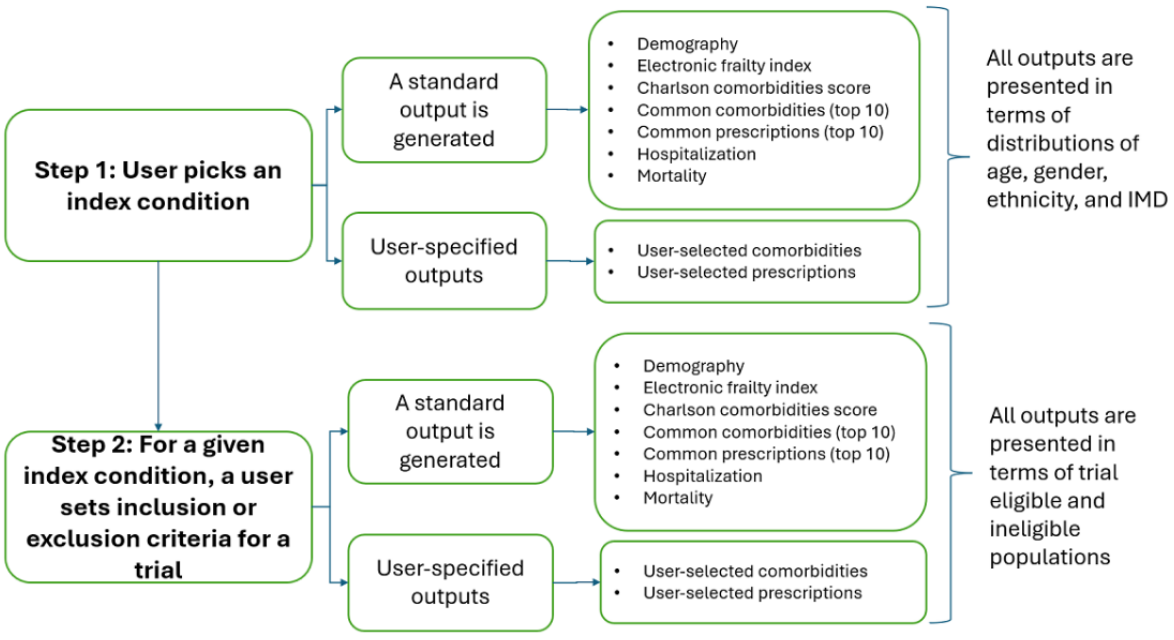
Evaluation of the Tool

Throughout the development of the tool, we performed iterative usability testing by demonstrating updated versions to the domain experts to confirm the applicability of the evidence. The domain experts included gout GDG, the study advisory group (which included representatives from NICE and SIGN), the European Respiratory Society, and public contributors. For the final evaluation, the project team members and external users from NICE and SIGN were given controlled access to trial the tool within the HIC TRE. Simple three-step instructions were shared with users: (1) logging into the HIC TRE virtual machine, (2) typing a given URL in a browser to access the tool, and (3) conducting analysis using the GUI (Figure 2) as described in requirements gathering section earlier.

XSL•FO
RenderX

Figure 2. A screenshot of the R Shiny tool for clinical population analysis. The left sidebar (A) has 2 menu items: index condition population analysis and trial eligible or ineligible population analysis. The top section (B) enables users to choose an index condition of interest from the drop-down list. The bottom right section (C) shows the results of the selected index condition in different tabs focusing on different outputs such as demographic distributions, comorbidities, and coprescriptions.

Results



Overview

During the analysis phase of the index conditions of interest, we considered factors in designing and developing an R Shiny tool that can be widely applicable to many conditions in CPRD GOLD. The tool supports the selection of 128 conditions as index conditions and 161 conditions as comorbidities (the 128 index conditions plus 33 other chronic health conditions), which are individual conditions in the hierarchical groupings and the associated higher-level groupings in the hierarchy (details of the supported index conditions and comorbidities are presented in Multimedia Appendix 3). CPRD is broadly representative of the UK population [33], and data quality is high, including gout [34].

Overview of R Shiny Tool

The R Shiny tool supports a 2-step analysis process as described in the methodology section (Figure 3). First, a user performs population-level analysis for the condition of interest from the list of supported index conditions (Multimedia Appendix 3). Second, a user sets the trial inclusion and exclusion criteria to understand trial eligible or ineligible populations. A screenshot of the R Shiny tool is presented in Figure 2, highlighting three areas: (1) Figure 2A has 2 menu options that allow users to switch between analysis types; (2) Figure 2B is the area that allows the user to select the condition of interest from the drop-down list to generate population analysis; and (3) Figure 2C is the results area where multiple tabs are provided to enable switching between different types of outputs.

Figure 3. A workflow of an R Shiny tool. IMD: index of multiple deprivations.

Index Condition Population Analysis in Gout

The tool was designed to be flexible and provide many selection options to the end user to support guideline development; given the many combinations of results with 13 output tabs available, only a few examples are shown here.

We present results for gout as an index condition for demonstration purposes. Table 1 shows an analysis of the whole population with gout: any patient diagnosed with gout on or before the index date (November 30, 2015) is included in the analysis. Details are provided for distributions of patients' characteristics, including age, gender, ethnicity, IMD, and time since diagnosis (prevalent and recently incident populations) at the index date. From a population of 1,168,620 patients from the CPRD GOLD data set, a cohort with gout of 33,480 (2.86%) was identified. The cohort with gout was proportionately older (aged greater than 64 years; 75%). The CPRD GOLD data set is mostly a White ethnic population (68%) and a relatively higher percentage (81%) is observed in the population with gout. For other ethnicity groupings: South Asian (3% vs 2%), Black (2% vs 1%), Chinese or Mixed or Other (2% vs 1%), missing (24% vs 15%). Based upon IMD, a higher percentage of those with gout were richer (26% in the least deprived category) versus poorer (13% in the most deprived category). For many diseases, the opposite trend is observed; however, gout has historically been known as "a rich man's disease" [35-37], a generalization that is evidenced by this data.

Table 1. An example output of population with gout from the R Shiny application describing the distribution of patients' characteristics, including age, gender, ethnicity, IMD[a], and time since diagnosis (prevalent and recently incident populations).[b]

Criteria (feature)	All, n (%)	Men, n (%)	Women, n (%)

[a]IMD: index of multiple deprivations.

[b]For disclosure control, all numbers are rounded to 10, percentages are rounded to discrete numbers, and percentages presented are column percentages (except the row titled "All," where the percentages are row percentages). Totals may not add up exactly to 100%.

Once an index condition is defined, the tool presents the most frequently observed comorbidities and prescriptions in separate tabs. Tables 2 and 3 present the top 5 comorbidities and prescriptions as exemplars for demonstration purposes (the default in the tool is the top 10 comorbidities and top 10 prescriptions). The individual counts are stratified by the

XSL•FO
RenderX

demographic characteristics in Table 1 and shown as relative percentages. As can be seen in Table 2, "disease of the circulatory systems" is the most common comorbidity, being present in 68% of the population with gout, followed by "musculoskeletal conditions" (42%), "diseases of the genitourinary system" (39%), "diseases of the digestive system" (38%), and "diseases of the endocrine system" (36%). As can be seen in Table 3, "02 cardiovascular system" is the most common prescription by drug chapter, being present in 67% of the population with gout, followed by "10 musculoskeletal and joint disease" (45%), "01 gastrointestinal system" (36%), "04 central nervous system" (35%), and "06 endocrine system" (27%). For the top 5 comorbidities and top 5 prescriptions, people with gout over the age of 65 years have higher overall comorbidity and prescriptions than younger age groups. For example, overall, 68% of the population with gout had a comorbidity of "disease of the circulatory systems," whereas for age groups such as "65-74" and "75-84" the proportion with the same comorbidity was much higher; 79% and 89% respectively. When compared to the overall percentages, in some cases, women showed greater than 10 percentage points difference for the comorbidity or drug chapter. For example, overall, 68% of people with gout had a comorbidity for "disease of the circulatory system," whereas this was 79% for women. Similarly, this can be seen for "musculoskeletal conditions" (42% vs 63%), "diseases of the digestive system" (38% vs 47%), and "diseases of the endocrine system" (36% vs 51%). An exception of a lower percentage of comorbidity was observed in women with "diseases of the genitourinary system" comorbidity (39% vs 32%).

[a]IMD: index of multiple deprivations.

[b]For disclosure control, all numbers presented are rounded to 10, percentages are rounded to discrete numbers, and percentages presented are row percentages of the "All" column in Table 1, so totals will not be added exactly.

Different ethnic groups with gout showed different percentages of comorbidities for different diseases. For example, 47% of the White ethnic group had a musculoskeletal condition comorbidity, whereas this was only 34% of those within the Black ethnic group. However, the comorbidity of "diseases of the endocrine system" was observed in 49% of the Black ethnic group in comparison to 38% of the White ethnic group. There was a general observation that the higher the level of deprivation, the higher the percentage of the population with each comorbidity and prescription.

Such differences are easily highlighted in the tool for guideline developers aiding their workflows regardless of index conditions and parameters specified.

Alternatively, it is possible to view the most frequent comorbidities and prescriptions at the lower level of granularity given in the hierarchical groupings (ie, comorbidities as condition groups and/or individual conditions and prescriptions as BNF classes and/or individual drugs).

In addition to viewing the most common top-level comorbidities and prescriptions for the condition of interest (gout in this case), there is an option for the user to select comorbidities and prescriptions of interest from the complete list of comorbidities and prescriptions. This user selection feature is supported at each hierarchical level of comorbidities (ie, body system, condition group, and individual condition) and prescriptions (ie, drug chapter, drug class, and individual drug). Table 4 demonstrates user selection of comorbidities at the "condition

XSL•FO
RenderX

group" level and prescriptions at "drug class" levels. Selected drug class level statistics were requested by the NICE gout GDG. There were similar trends observed in the data for this lower level of granularity.

Table 4. An example of the user-selected comorbidities (ie, condition groups) and prescriptions (drug classes) from the R Shiny application describing the distribution of patients' characteristics, including age, gender, ethnicity, IMD[a], and time since diagnosis (prevalent and recently incident populations).[b]

[a]IMD: index of multiple deprivations.

[b]For disclosure control, all numbers presented are rounded to 10, percentages are rounded to discrete numbers, and percentages presented are row percentages of the "All" column in Table 1, so totals will not be added exactly.

As per the requirements, the tool supports the generation of printable reports in HTML format. The individual outcomes to save and print (and then save as PDF) are user selectable, as shown in Figure 4.

XSL•FO
RenderX

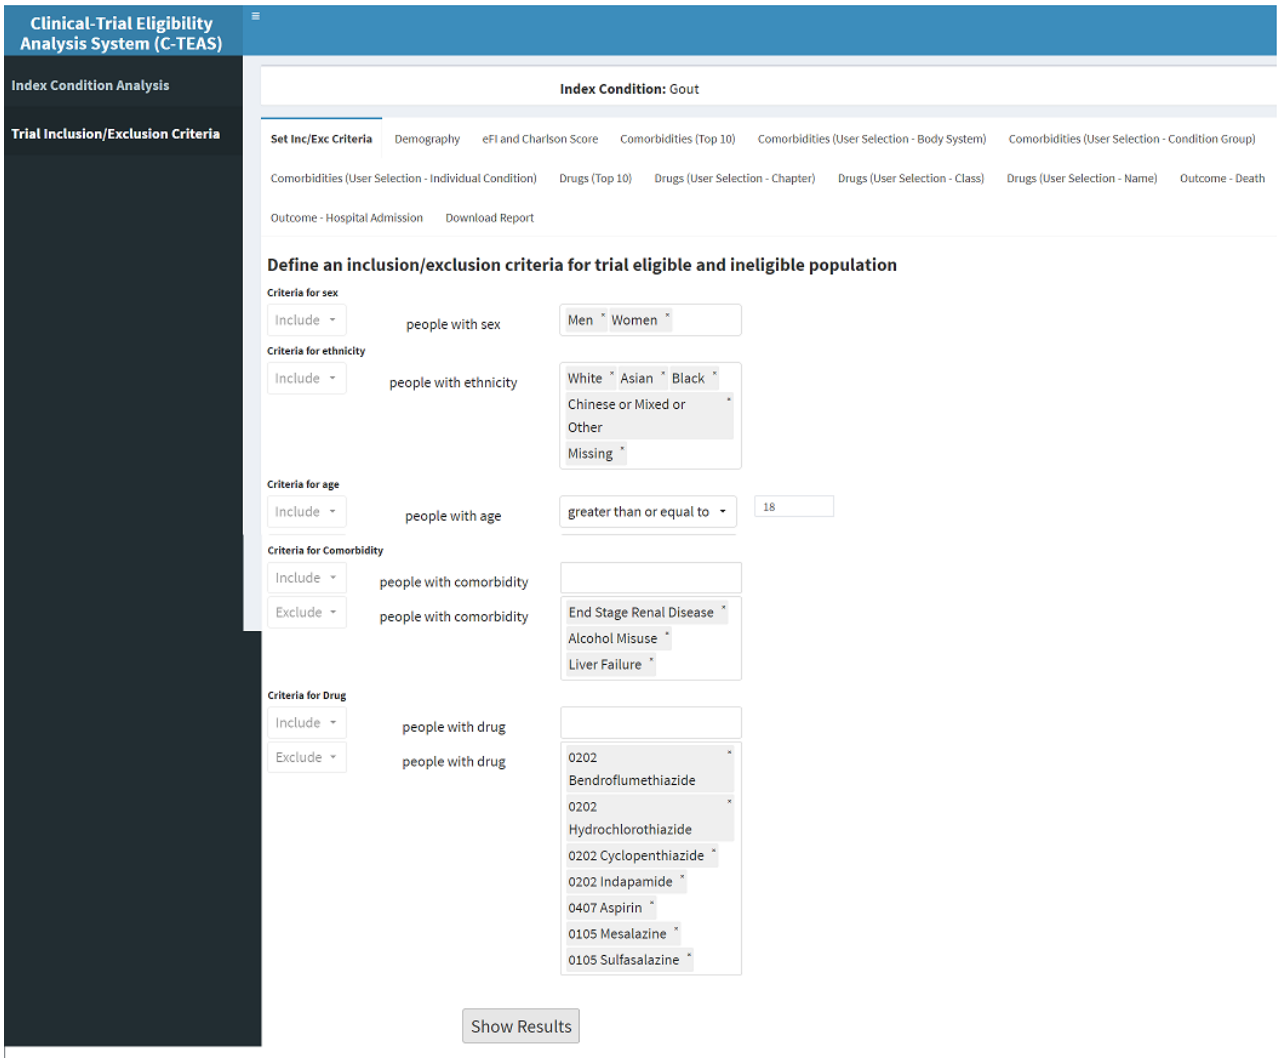

Figure 4. A screenshot of the report generation page.

Clinical Trial Population Analysis

The R Shiny tool enables comparisons between trial eligible and ineligible populations using inclusion and exclusion criteria. As illustrated in Figure 5, a user can set inclusion and exclusion criteria based on five main criteria: gender, ethnicity, age, comorbidities (only for individual conditions from hierarchical groupings of conditions), and drug prescription (only for individual drugs).

Figure 5. A screenshot of the R Shiny tool. Setting up inclusion and/or exclusion criteria to analyze eligible and ineligible populations.

XSL•FO
RenderX

The results of a trial eligible and ineligible query are shown in Table 5. The criteria were adapted as best possible given the different sources of data from a published gout trial in the literature [38].

Table 5. Output generated for an example trial taken from the literature.[a]

Criteria (feature)	All, n (%)	Eligible, n (%)	Ineligible, n (%)
All	33,480	27,080 (81)	6400 (19)
Age (years)			
Younger than 25	50 (0)	40 (85)	10 (15)
25-34	470 (1)	420 (91)	40 (9)
35-44	1960 (6)	1740 (89)	220 (11)
45-54	4900 (15)	4220 (86)	680 (14)
55-64	6930 (21)	5580 (81)	1350 (19)
65-74	8800 (26)	6850 (78)	1960 (22)
75-84	7210 (22)	5610 (78)	1600 (22)
85 and older	3160 (9)	2610 (83)	550 (17)
Gender			
Men	26,440 (79)	21,520 (81)	4920 (19)
Women	7040 (21)	5560 (79)	1480 (21)
eFI[b]			
Fit	13,650 (41)	12,020 (44)	1630 (25)
Mild frailty	10,220 (31)	7850 (29)	2370 (37)
Moderate frailty	6210 (19)	4620 (17)	1590 (25)
Severe frailty	3400 (10)	2600 (10)	810 (13)
Comorbidities (condition group)—user selected			
Hypertension	20,540 (61)	15,320 (57)	5230 (82)
Ulcer and upper gastrointestinal acid conditions	12,120 (36)	9330 (34)	2780 (43)
Chronic lung disease	7260 (22)	5600 (21)	1660 (26)
Coronary heart disease	6980 (21)	5370 (20)	1620 (25)
Prescriptions (drug class)—user selected			
Statins	13,740 (41)	10,400 (38)	3340 (52)
Angiotensin receptor blockers	4750 (14)	3450 (13)	1300 (20)
Oral anticoagulants	3380 (10)	2660 (10)	720 (11)
Thiazide diuretics	3050 (9)	70 (0)	2980 (47)

[a]For disclosure control, all numbers are rounded to 10, percentages are rounded to discrete numbers, and the percentages are column-wise percentages except for a special case of age and gender where percentages in the eligible and ineligible columns are row-wise percentages based on the totals (for each age group or gender type) in the column "All"), and so totals will not add exactly.

[b]eFI: electronic frailty index.

The inclusion criteria are as follows: (1) age (18 years and older); (2) gender (men and women); and ethnicity (any). The exclusion criteria are as follows: (1) comorbidities (end-stage renal disease, alcohol misuse, and liver failure) and (2) drugs (bendroflumethiazide, hydrochlorothiazide, cyclopenthiazide, indapamide, aspirin, mesalazine, and sulfasalazine).

Table 5 illustrates the output collated from multiple output tabs of the tool, capturing demographics, eFI, comorbidities (user selected), and prescriptions (user selected) in terms of trial eligible and ineligible populations. Overall, 81% of the population with gout were eligible, and 19% were ineligible based upon the specified inclusion and exclusion criteria—the current version of the tool is a proof-of-concept and supports a subset of the criteria specified in the published gout trial [38]. In comparing the eligible and ineligible columns, the trialist can assess biases between the cohorts regarding any inherent demographic, comorbidity (commonest and user selected), and prescriptions (commonest and user selected). It should be noted that the total percentage within the eFI, comorbidities, and prescriptions in eligible and ineligible columns do not add up to 100% (as they do for "All," "Age (years)," and "Gender"

XSL•FO
RenderX

groupings) as individuals may have less than 1 or 0 comorbidities or prescriptions, and the results presented are not as a proportion of all of the population with gout (as they are for "All," "Age (years)," "Gender," and "eFI" groupings) against the "All" column instead they are based on total eligible and ineligible populations.

Integrated Disclosure Control and Report Generation

Accidental disclosure of low-count data was avoided by built-in rules, which rounded values to the nearest 10 and percentages to integers. The integrated disclosure-control mechanism was not only helpful in ensuring patients' confidentiality when guideline users were conducting analysis using the tool within the TRE but also enabled rapid egressing of the reports from the TRE—as the TRE output checking staff already knew that outputs generated from the tool were nondisclosive.

Completed analyses can be saved as reports. Printable versions of the completed results across tabs for the overall population and trial eligible or ineligible population analyses are presented in Multimedia Appendices 4 and 5, respectively.

Guideline Users Feedback

To evaluate the tool's functionality, several users from NICE and SIGN guideline developers were given access to the tool within HIC TRE. They found the tool to be very useful while developing guidelines to enable the use of real-world evidence about the nature of the population for whom different treatments were being recommended. They have shown significant interest in the R Shiny tool in its current form due to its simplest navigation functionality for generating analysis and reports at pace and in further development into a production version. The tool supports many different outputs, for example, demography statistics, top comorbidities statistics, user-selected comorbidities, and prescription statistics. There was a general consensus across users testing the functionality that the generation of a range of outputs for the chosen disease/condition within a few minutes is highly advantageous. One of the users (ie, a health economist from NICE) was of the view that generating statistics on comorbidities could be helpful for the study of the burden of comorbidities on the health systems. One of the users of the tool from NICE expressed his views about the tool:

> *The tool enables us to assess the relevance of RCTs and observational studies to real-world UK patients, by comparison between real-world patient characteristics and study eligibility criteria. This provides a new lens through which committees and developers could critically assess studies captured in evidence reviews. There are interesting potential applications of the tool inform surveillance, scoping, and NICE research recommendations. The tool is interactive and returns results immediately. This maximises its potential impact for guideline development, as extended waits for data access and results may mean analyses come too late to be usefully considered by guideline committees working to tight deadlines. The clear format, where most common conditions and prescriptions can be viewed at a level of granularity chosen by the user, is ideal. NICE's 2021-26 Strategy emphasizes increased use of real-world evidence and more rapid and responsive guideline development. This tool aligns well with these ambitions. We hope there will be opportunities to further test the tool in guideline development in future.* [User #1, male]

Key Features of the Tool

Factors such as ease of use of the tool by novice users, the query processing time to extract the required data, integral disclosure control mechanism, and standardized outputs across various chronic conditions were among the challenges addressed when developing the application. The tool is simple to use, with only 2 menu options and minimum input required to generate results for both types of analysis using a graphical interface. To optimize the performance of query processing, we designed an intermediate data structure populated by the data from the CPRD GOLD subset. This resulted in retrieving results from each type of analysis within approximately a couple of minutes compared to a much longer time when running a query against the raw CPRD GOLD data set (eg, generating population-level results at the demography level took more than 3-5 minutes running on the raw data set versus only a few seconds on the optimized data structure). The outputs were designed in consultation with the project advisory group and the gout GDG, but they are generalizable to other chronic conditions and are usable by other GDGs.

Limitations of the Tool

The tool has limitations in its current form: (1) it only allows index condition selection at the lower level in the hierarchical groupings of conditions (such as gout, asthma, and atrial fibrillation); (2) trial criteria selection only allows age, gender, ethnicity, comorbidities (lower level in the hierarchical groupings of conditions), and prescriptions (individual drug names, for instance, bendroflumethiazide, aspirin, and mesalazine); (3) only statistics around hospitalization and mortality are included (and not the patients outcomes from hospitalization and mortality); (4) there are limits to demography-based cross-tabulation across all output for a selected index condition; (5) the tool only includes primary care data for generating evidence; (6) the data it uses are retrospective and relies on Read codes which are being retired in UK primary care electronic records, but with mapping to Systematized Medical Nomenclature for Medicine–Clinical Terminology which is replacing them; (7) it does not allow users to extract information based on user-defined disease definitions (phenotype algorithms); instead it uses predefined disease definitions (phenotype algorithms); (8) users are required to access the tool within a TRE for generating evidence although it generates aggregate level information which meets disclosure control mechanisms in place; and (9) it performs slower for the diseases or conditions that have bigger cohort sizes, even with a subset of around 1 million patient data using an optimized data structure.

Discussion

Principal Findings

This study describes a proof-of-concept tool for analyzing clinical populations with various comorbidities in terms of the overall population and trial analysis. The tool was developed for use by guideline developers to develop clinical evidence–driven guidelines, using the specific example of gout. Typically, clinical guideline recommendations are developed using the evidence available in the published literature, mainly relying on RCT results or, in case of nonexistence of such studies, the experience of the people developing guidelines is used when preparing guideline recommendations [39].

The WHO has envisaged a future that uses clinical data in the development of recommendations [40]. The WHO's Standard-based, Machine-readable, Adaptive, Requirements-based, and Testable framework focuses on transformation from paper-based systems to smart digital systems. Recently, the focus has been shifted to computer-interpretable guideline development, highlighting the need for EHR integration with clinical practice guidelines as one of the emerging themes [41]. However, the challenges of using the computer-interpretable guidelines for patients with multimorbidity would be complex [42].

The tool described here is intended to be used by guideline developers with minimal understanding of the structure or coding of the underlying data, which makes it distinct from tools like Atlas, which are more flexible because users can define cohorts in detail, but require greater baseline knowledge and skills [43]. In the longer term, large guideline developers like NICE might find the flexibility of tools like Atlas helpful, but it is likely that smaller guideline developers with fewer resources would benefit from having access to tools that require less baseline knowledge and skills. The tool developed here addresses the issue of generating evidence from a relevant clinical population by using linked EHR data, thereby assisting guideline developers in better understanding the clinical population and making guideline recommendations. The use of such a tool can enhance the quality of the guidelines, which have often struggled to be generalizable in terms of external validity or lack of evidence from the clinical population.

Future development will focus on: (1) supporting the selection of the index condition at a higher level in the hierarchical groupings (ie, condition group and body system); (2) enhancement of the choice of trial eligibility criteria (eg, laboratory tests), more complex combination of comorbidities and prescription selection such as allowing user to select comorbidities (ie, body system, condition group, and individual condition) and prescriptions (ie, drug chapter, drug class and individual drug) with different hierarchal levels both for inclusion and exclusion criteria; (3) inclusion of outcomes data of hospitalization and mortality; (4) allowing user choice of cross-tabulation as the current form of the tool cross-tabulate everything by demography automatically (for example, data on prescribing drugs for gout be stratified by chronic kidney disease stages 3-5 and non-chronic kidney disease population stage 1-2); (5) for some guidelines, primary care is not the ideal source of data, so enhancement of the tool to query other data sets (eg, rare disease registries or specialist routine care data sets); (6) capability of supporting different coding systems other than Read code/ICD10 for disease or condition definitions using the ontological approach, such as Read codes mapping to Systematized Medical Nomenclature for Medicine-Clinical Terminology, and prescriptions based on BNF (or matching international standards to BNF); (7) enabling the capability of bringing disease or condition cohort definition algorithms other than the listed definitions supported by the tool; (8) enabling the tool to save outputs using and load results offline for analyzing within and outside the TRE after the required governance mechanism in place results from the precomputed instead of using individual patient-level data; (9) making the codebase of the tool publicly available after cleaning it, so researchers interested in generating evidence from the EHR data could benefit. As of now, the codebase in its current form is available on request; and (10) the majority of RCTs in people with physical conditions exclude more than half of the patients with the target condition. The tool is developed as a proof-of-concept to facilitate guideline developers generating evidence from the routinely collected primary care clinical data [8]. This proof-of-concept tool was intended to support guideline developers to better understand how to generalize RCT findings to the wider population, but future work could also explore its use by trialists to understand the implications of the choice of inclusion or exclusion criteria for generalizability.

We have provided access to the tool for assessment by the guideline users from NICE and SIGN. Their qualitative feedback was very encouraging, and they viewed the tool as very useful, but further evaluation of use is needed. They like to use it as an integral part of the guideline development process. The tool was developed as a proof of concept rather than a production tool. We are currently assessing how we can develop the tool further so that it can be provided as a service for guideline development groups across the United Kingdom to make more effective guideline recommendations based on evidence generated from the clinical population.

Conclusions

We have demonstrated a tool for generating evidence from clinical populations that could be used to inform clinical guideline development. The challenge of query performance on the raw CPRD GOLD data source was resolved by designing and implementing an optimized database structure. An exemplary case study of gout demonstrated that large sets of data relevant to and tailored to guideline development can be rapidly generated using the tool. The requirements for the prototype tool were determined with input from guideline developers. The final prototype version was evaluated by the guideline developers from NICE and SIGN. They responded positively and discussed how this could be made available as a service for them, which was not under the project's remit due to governance approvals in place for the study. Despite the mentioned limitations, the tool is already capable of reducing data bottlenecks of guidance development.

Authors' Contributions

SM wrote the manuscript and developed the software (R Shiny tool); MM wrote the scripts to generate the intermediate data structure and populated it with the study-specific data from the CPRD GOLD dataset; CC, DAM, DRM, EJ, and BG led the project by developing the methodology, and also supervised the team; CG, CH, and MG managed the CPRD GOLD data and helped to conduct analysis and provided infrastructure support; HH and BG contributed to writing an introduction for the manuscript and overseeing the study outcome; EJ and BG also led the funding acquisition. All authors reviewed the final manuscript.

Conflicts of Interest

CC has received research funding from Astra Zeneca for an unrelated project.

Abstract

Background: Delayed cerebral ischemia (DCI) is a primary contributor to death after subarachnoid hemorrhage (SAH), with significant incidence. Therefore, early determination of the risk of DCI is an urgent need. Machine learning (ML) has received much attention in clinical practice. Recently, some studies have attempted to apply ML models for early noninvasive prediction of DCI. However, systematic evidence for its predictive accuracy is still lacking.

Objective: The aim of this study was to synthesize the prediction accuracy of ML models for DCI to provide evidence for the development or updating of intelligent detection tools.

Methods: PubMed, Cochrane, Embase, and Web of Science databases were systematically searched up to May 18, 2023. The risk of bias in the included studies was assessed using PROBAST (Prediction Model Risk of Bias Assessment Tool). During the analysis, we discussed the performance of different models in the training and validation sets.

Results: We finally included 48 studies containing 16,294 patients with SAH and 71 ML models with logistic regression as the main model type. In the training set, the pooled concordance index (C index), sensitivity, and specificity of all the models were 0.786 (95% CI 0.737-0.835), 0.77 (95% CI 0.69-0.84), and 0.83 (95% CI 0.75-0.89), respectively, while those of the logistic regression models were 0.770 (95% CI 0.724-0.817), 0.75 (95% CI 0.67-0.82), and 0.71 (95% CI 0.63-0.78), respectively. In the validation set, the pooled C index, sensitivity, and specificity of all the models were 0.767 (95% CI 0.741-0.793), 0.66 (95% CI 0.53-0.77), and 0.78 (95% CI 0.71-0.84), respectively, while those of the logistic regression models were 0.757 (95% CI 0.715-0.800), 0.59 (95% CI 0.57-0.80), and 0.80 (95% CI 0.71-0.87), respectively.

Conclusions: ML models appear to have relatively desirable power for early noninvasive prediction of DCI after SAH. However, enhancing the prediction sensitivity of these models is challenging. Therefore, efficient, noninvasive, or minimally invasive low-cost predictors should be further explored in future studies to improve the prediction accuracy of ML models.

Introduction

Subarachnoid hemorrhage (SAH) is the third most common type of stroke and is usually associated with the rupture of an aneurysm [1]. The incidence of SAH is approximately 7.9 (95% CI 6.9-9.0) per 100,000 person-years globally, 8.3 (95% CI 7.2-9.5) per 100,000 person-years in Europe, 10.4 (95% CI 5.9-18.6) per 100,000 person-years in Asia, and 8.5 (95% CI 7.1-10.2) per 100,000 person-years in North America [2]. Recently, a discernible decline has been observed in global SAH incidence, which is potentially attributable to effective public health initiatives and the promotion of healthy lifestyles, especially effective management of certain modifiable risk factors (eg, reduction in smoking prevalence, management of hypertension) [3]. However, aneurysmal SAH continues to pose significant challenges, as evidenced by an in-hospital mortality rate of nearly 20% [4]. Of these, delayed cerebral ischemia (DCI) is the leading cause of death, with a prevalence of approximately 29% (95% CI 26%-32%) [5,6].

The early identification of DCI risk continues to pose significant challenges in clinical practice, with a notable absence of recognized and effective early predictive tools. Previous studies have explored diverse methods for the early prediction of DCI, such as transcranial Doppler (TCD) ultrasonography [7], computed tomography perfusion parameters [8], and continuous cranial electroencephalography monitoring [9]. Recent advancements in computational technologies and the ongoing improvement of statistical theory have facilitated the integration of artificial intelligence into clinical practice, mainly for the diagnosis of disease states, assessment of disease courses, and prediction of prognosis [10]. In this context, some studies have attempted to develop machine learning (ML) models for the early prediction of DCI after SAH; however, its accuracy remains debatable [11-14]. In addition, there is a lack of systematic investigations on effective predictors for the early prediction of DCI. Therefore, we conducted this meta-analysis to systematically discuss the accuracy of ML models in DCI prediction after SAH and to offer evidence for advancing the application of artificial intelligence in this field.

Methods

Study Registration

This study follows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) checklist [15]. This study protocol was registered in the International Prospective Register of Systematic Reviews on July 6, 2023 (CRD42023438399).

Eligibility Criteria

The inclusion criteria were as follows: (1) patients with SAH, with the outcome event being DCI; (2) complete construction of an ML model for DCI prediction; (3) primary studies even without independent external validation or any kind of independent validation set; (4) published studies that constructed different ML models based on the same dataset; (5) cohort studies, case-control studies, or cross-sectional studies; and (6) studies published in English. The exclusion criteria were as follows: (1) meta-analysis, guidelines, review, or expert comments; (2) primary studies that analyzed risk factors/independent predictors only, without complete construction of an ML model; (3) absence of any outcome indicators for estimating the prediction accuracy of ML models, including the area under the receiver operating characteristic curve, concordance index (C index), accuracy, sensitivity, specificity, precision, confusion matrix, and F_1-score; and (4) studies with sample size <20.

Data Sources and Search Strategy

PubMed, Cochrane, Embase, and Web of Science databases were systematically searched up to May 18, 2023, by using Medical Subject Headings (MeSH) and free-text words, with no restrictions on publication year or country. The search strategy is described in Multimedia Appendix 1.

Study Selection and Data Retrieval

The retrieved studies were imported into EndNote, and duplicates were excluded through software automarking and manual marking. Then, the titles or abstracts of the remaining studies were scanned, followed by full-text reviews to obtain the final eligible studies. A standardized table was established before data retrieval, and the extracted information included title, first author, publication year and country, study type, DCI cases, total cases, DCI cases in the training and validation sets, cases in the training and validation sets, generation method of the validation set, methods for tackling overfitting and missing data, variable screening methods, model type, and predictors. Literature screening was implemented independently by 2 researchers (HZ and PZ) and then cross-checked. Debatable studies were discussed with a third researcher (PL) to make a final decision.

Assessment of Study Quality

The risk of bias in the primary studies was appraised using PROBAST (Prediction Model Risk of Bias Assessment Tool), which contains many questions on participants, predictors, outcomes, and statistical analyses, reflecting the overall risk of bias and applicability [16]. These domains had 2, 3, 6, and 9 specific questions, with 3 responses (yes/probably yes, no/probably no, and no information) for each question. A domain was regarded as having a high risk of bias if it had at least one no/probably no answer or a low risk of bias if all answers were yes or probably yes. The overall risk was assessed as low with all domains at low risk and high with at least one domain at high risk. Two researchers (HZ and PZ) assessed the risk of bias independently based on PROBAST and cross-checked at the end. If there was a debatable result, a third researcher (PL) was asked to assist in the assessment.

Outcome Indicators

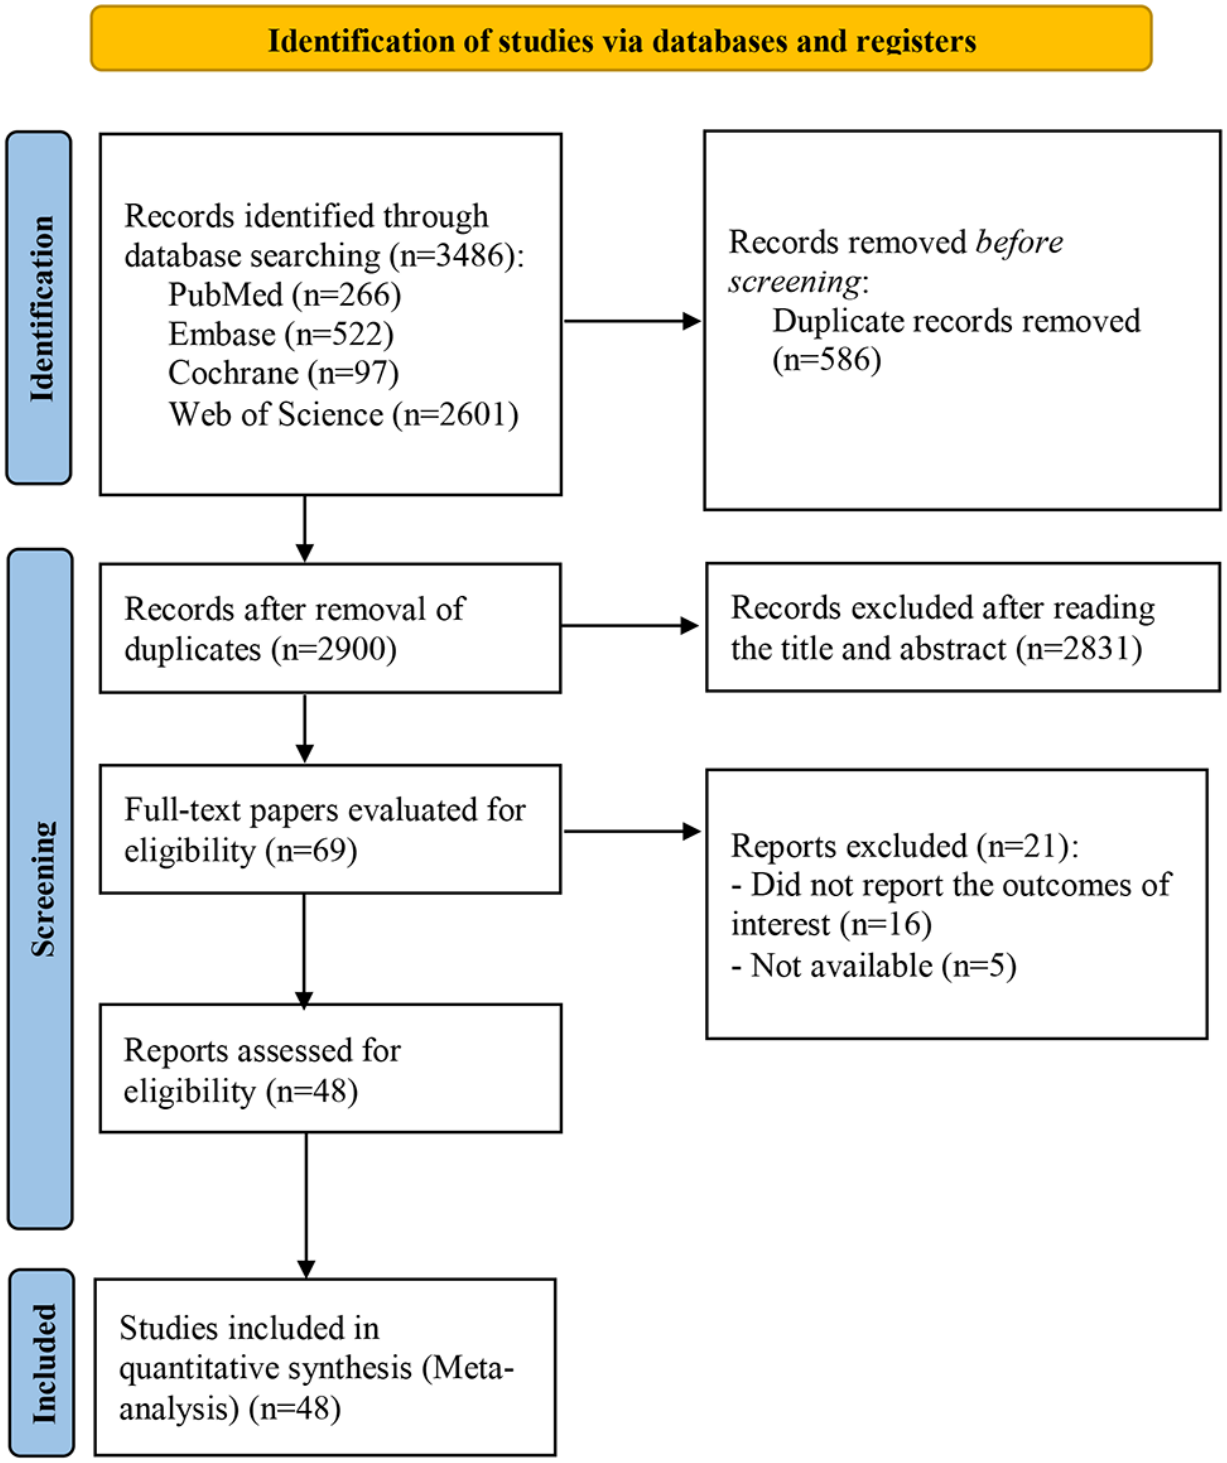
Currently, the C index is an important outcome index for assessing the prediction accuracy of ML models. However, in case of severe imbalance in case number (grossly too few cases for DCI), the C index can hardly explain the specific accuracy of the model for both positive and negative events, and thus, our primary outcome indicators also included sensitivity and specificity at the optimal thresholds of the model.

XSL•FO
RenderX

Statistical Analysis

In some primary studies, when 95% CIs and standard errors were absent in the C index, we referred to Debray et al [17] to assess its standard error. As ML models contained different variables and inconsistent parameters, we gave priority to random-effects models in the meta-analysis of C index. The C index is currently an important end point metric for evaluating ML performance, especially in binary classification and survival analysis [18,19]. Many current binary classification ML studies have used the C index as the main metric for assessing model performance. In addition, ML obtains the probability of positive events. We also need to understand the sensitivity and specificity of ML prediction of positive events under the optimal risk probability cutoff threshold. Therefore, we need to perform a meta-analysis of the sensitivity and specificity based on the diagnostic 2×2 table.

A bivariate mixed-effects model was applied for the meta-analysis of sensitivity and specificity based on the diagnostic fourfold table. Most primary studies did not report the diagnostic fourfold table; therefore, the following 2 ways were used to calculate the diagnostic fourfold table: (1) using sensitivity, specificity, precision, and case number and (2) using sensitivity and specificity extracted based on the optimal Youden index as well as case number. In the meta-analysis of the C index, sensitivity and specificity evaluation were performed in Stata 15.0, and the program packages involved were metan and midas. The meta-analysis of the incidence of DCI was performed in R4.4.1 (R development Core Team). Because of the meta-analysis of the incidence, we need to transform the distribution of the incidence, and the R language packages involved are metafor and meta.



Results

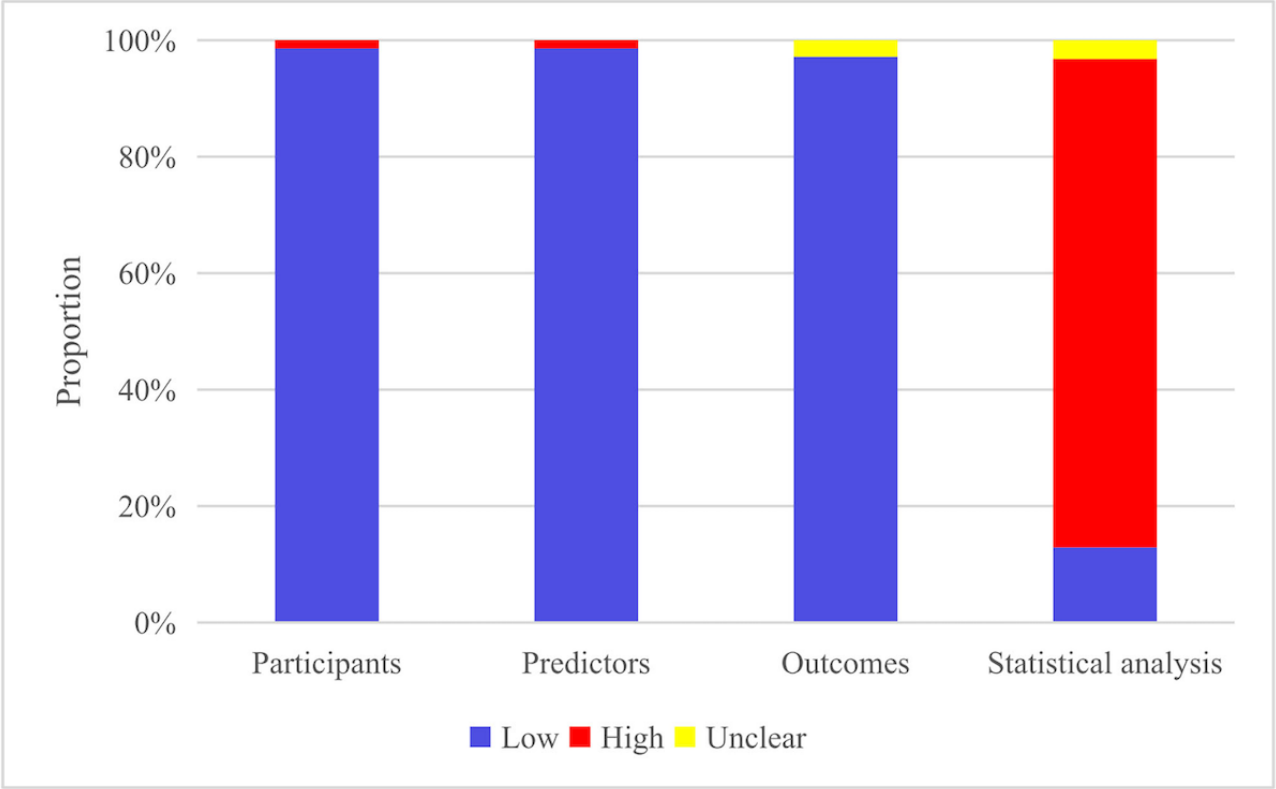
Study Selection

We searched 3486 studies (97 from Cochrane, 266 from PubMed, 522 from Embase, and 2601 from Web of Science) and eliminated 586 duplicates. After reading the title or abstract, we excluded 2831 studies. Among the remaining 69 studies, 48 eligible primary studies [11-14,20-63] were finally included after reviewing the full texts (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) literature screening flowchart.

Study Characteristics



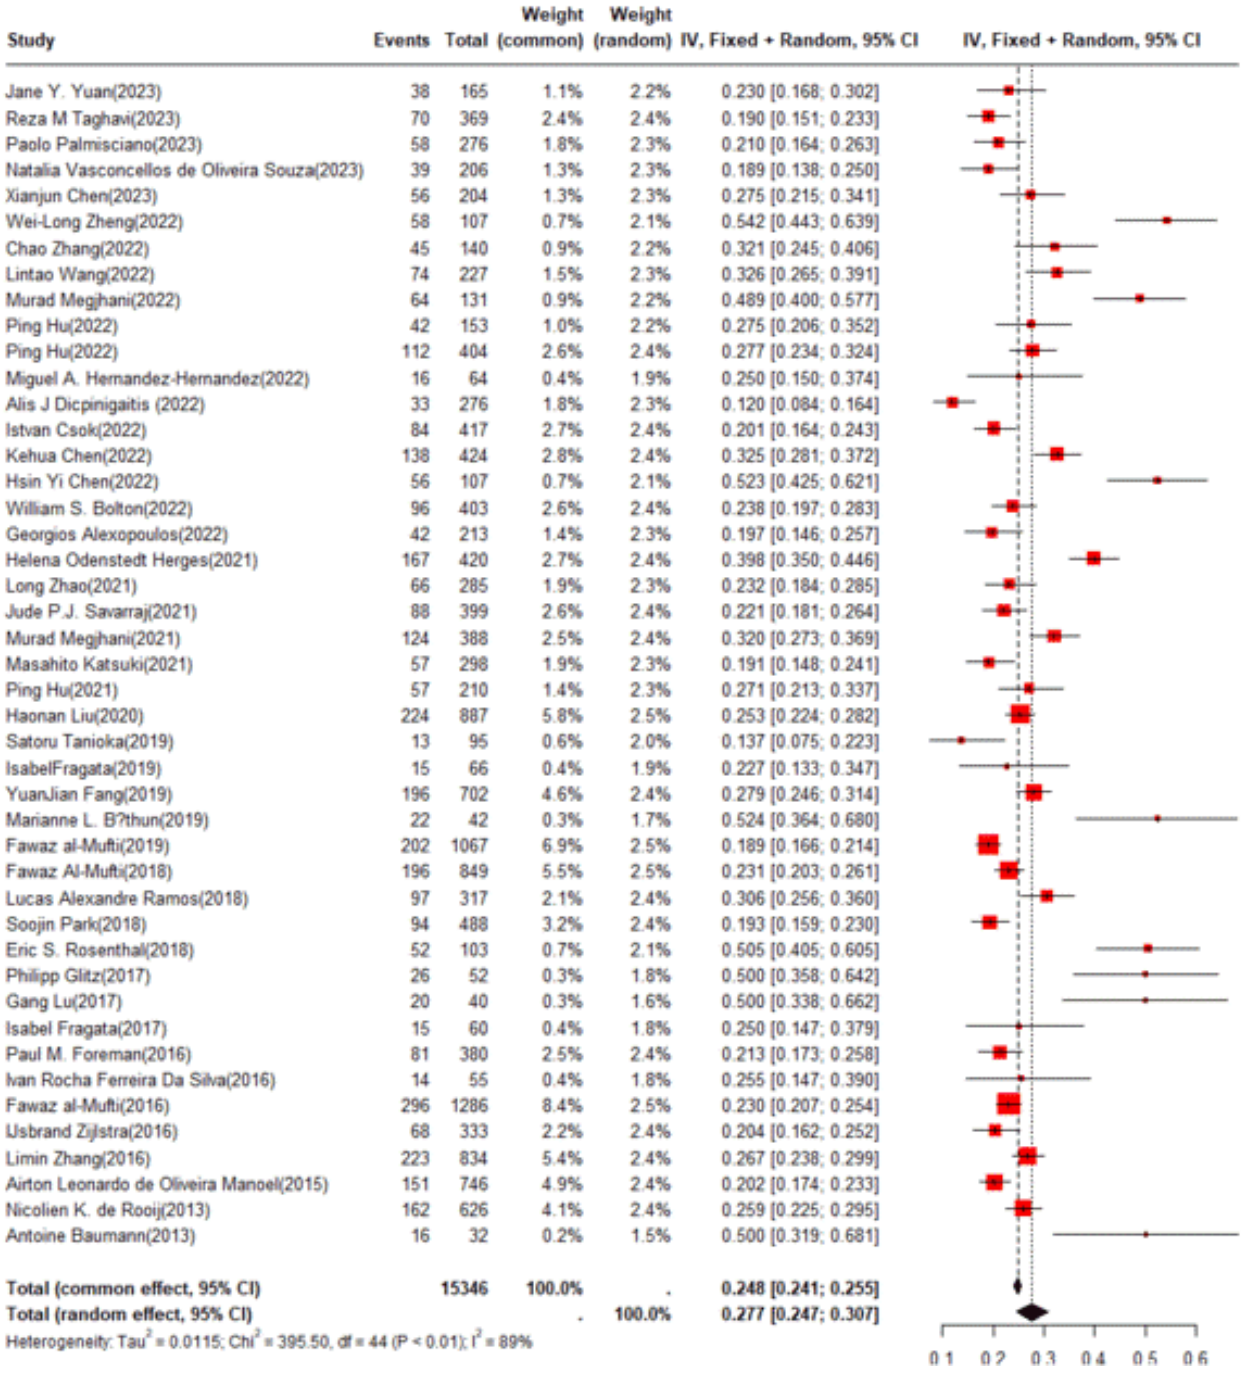
The 48 primary studies were published between 2013 and 2023, including 15,346 patients with SAH, of which 3863 patients had DCI. These primary studies were from 13 countries, including the United States [11-13, 21,24, 28, 31, 33, 36, 37, 46, 47, 49-51, 55, 57], China [20, 22, 23, 25, 26, 30, 35, 39, 41, 44, 53, 59], and the Netherlands [40,48,58,62]. In addition to one case-control study [11], the others were cohort studies. Ten studies were multicentered [24-26,28,37,39,40,42,58,61], and the remaining were one-centered. Besides, 21 studies [14, 21, 22, 27, 28, 30, 32, 33, 43, 45-47, 50, 52, 56-61, 63] lacked an independent validation set, and 25 studies [12, 20, 21, 23, 25, 26, 31, 35-42, 45, 47-51, 53-55, 62] reported the methods to avoid overfitting. Nineteen studies [12, 14, 20, 22, 24-26, 30, 31, 33, 34, 36-38, 48-51, 62] had missing data, which were mainly resolved by deletion, mean value imputation, and missing value imputation. In terms of variable screening, only 1 study [50] used a single-factor screening method (Multimedia Appendix 2).

XSL•FO
RenderX

Risk of Bias

The 48 primary studies contained 71 ML models. In the assessment of participants and predictors, a high risk of bias was mainly derived from the ML models constructed in 1 case-control study. In the assessment of outcomes, only 1 model in the case-control study was rated as unclear risk. As for the statistical analyses, the models were mainly rated at high risk since most models did not satisfy modeling sample size estimation, that is, events per variable were >20 in the training set (DCI cases were greater than 20 times that were ultimately included in the model) and needed an independent validation set with over 100 validated cases. In addition, the methods for tackling overfitting and underfitting were not clearly described. The methods for handling missing data during quality assessment remained a concern, as PROBAST only recognized the multiple imputation method as low risk of bias (Figure 2).

Figure 2. Risk of bias of the included machine learning models.



Meta-Analysis

Of the 48 studies included, 45 explicitly reported the numbers of DCI and total SAH, and the prevalence of DCI, which was pooled using a random-effects model, was 27.7% (95% CI 24.7%-30.7%) (Figure 3 [11-14,20-39,41-50,52-59,61-63]).

Newly Developed ML Models

C Index

In the training set, C index was reported in 45 ML models, with an overall C index of 0.786 (95% CI 0.737-0.835). The 31 independent validation cohorts manifested an overall C index of 0.767 (95% CI 0.741-0.793). Among them, the logistic regression–based predictive nomogram was the main model, with an overall C index of 0.770 (95% CI 0.724-0.817) in the training set and 0.757 (95% CI 0.715-0.800) in the validation set (Table 1, Figure 4 [1,26,27,32,37,38,41,42,44,49,50,54], Figure 5 [12,20,26,27,30,34-37,39-43,50,52]).

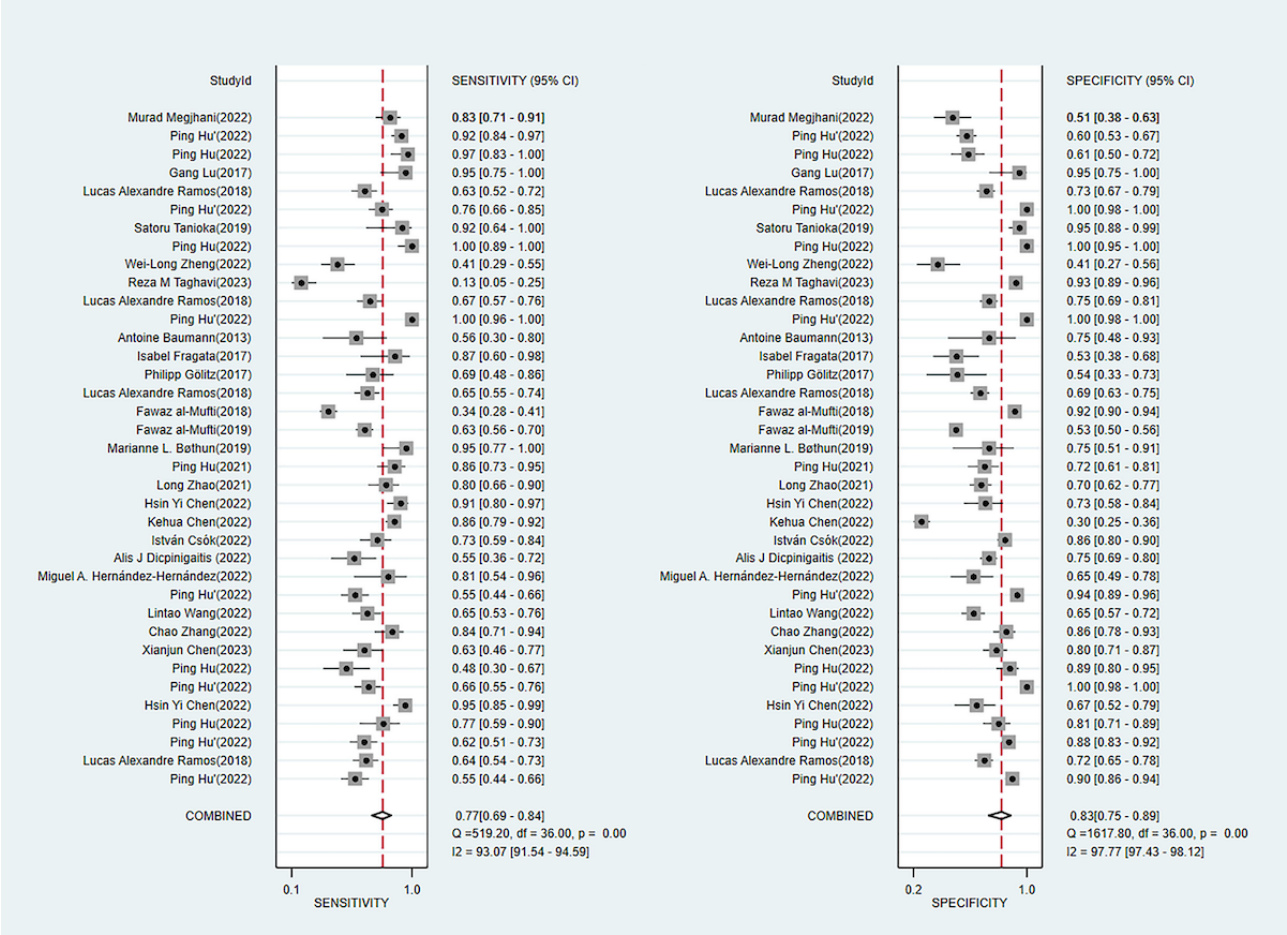
Sensitivity and Specificity



In the training set, we extracted diagnostic 2×2 tables from 37 ML models, with overall sensitivity of 0.77 (95% CI 0.69-0.84) and overall specificity of 0.83 (95% CI 0.75-0.89). The diagnostic 2×2 tables were also extracted from 23 independent validation cohorts, with overall sensitivity of 0.66 (95% CI 0.53-0.77) and overall specificity of 0.78 (95% CI 0.71-0.84). Among them, the logistic regression–based predictive nomogram had overall sensitivity of 0.75 (95% CI 0.67-0.82) and overall specificity of 0.71 (95% CI 0.63-0.78) in the training set and 0.59 (95% CI 0.57-0.80) and 0.80 (95% CI 0.71-0.87), respectively, in the validation set (Table 2, Figure 6 [12,20-22,24-32,36,40,43,46-49,53-55,63], Figure 7 [13,20,26,27,30,34-37,40,45]).

Predictors

A total of 59 predictors were reported in the included ML models, and the top 10 were age (53 models), gender (46 models), Hunt and Hess score (41 models), modified Fisher scale (40 models), World Federation of Neurological Surgeons (35 models), aneurysm location (32 models), hypertension (29 models), coiling or clipping (28 models), smoking/drinking history (28 models), diabetes (23 models), and laboratory results (21 models). All modeling predictors are shown in Multimedia Appendix 3.

Discussion

Main Findings

Our study systematically explores the accuracy of ML for DCI prediction after SAH, and the results showed that ML had a relatively ideal C index for DCI prediction; however, the sensitivity still needs improving. The logistic regression–based nomogram was the main model. The predictors in the 71 models were mainly age, gender, Hunt and Hess score, modified Fisher scale, World Federation of Neurological Surgeons, aneurysm location, hypertension, coiling or clipping, smoking/drinking history, diabetes, and laboratory results.

Comparison With Previous Studies

Continuous investigations have been undertaken to find reliable approaches for the early detection of DCI risk, mainly focusing on imaging techniques. Kumar et al [7] conducted a systematic review of 17 primary studies and reported the accuracy of TCD for predicting vasospasm for the diagnosis of DCI, with an overall 90% (95% CI 77%-96%) sensitivity and 71% (95% CI 51%-84%) specificity. Although their study demonstrated high sensitivity and relatively good specificity, we found that they included many retrospective studies, which may exaggerate the results. Therefore, more randomized diagnostic trials are also needed for validation. Han et al [8] provided evidence for the early prediction of DCI by using computed tomography perfusion parameters, with 97% sensitivity and 89% specificity. A systematic review by Scherschinski et al [9] described the prediction accuracy of continuous cranial electroencephalography monitoring for DCI (sensitivity 11.1%, 95% CI 3.1%-26.1% and specificity 82.9%, 95% CI 66.4%-93.4%). In addition, a systematic review by Kumar et al [64] described the prediction of DCI by cerebral angiography (sensitivity 57%, 95% CI 40%-81%; specificity 68%, 95% CI 61%-76%). Of these imaging tools, Doppler ultrasound appears to have high prediction accuracy, especially with high sensitivity.

Furthermore, Santana et al [65] reported the accuracy of ML in DCI prediction after SAH through a systematic review, which, however, only included 6 primary studies. Their results demonstrated that the overall sensitivity of logistic regression was 0.71 (95% CI 0.57-0.84) and specificity was 0.63 (95% CI 0.42-0.85), and other ML models had a pooled sensitivity of 0.74 (95% CI 0.61-0.86) and specificity of 0.78 (95% CI 0.71-0.86). However, the training and validation set results did not seem to be considered in their studies. In our systematic review incorporating 48 primary studies, the overall C index in the validation set was 0.767 (95% CI 0.741-0.793), with sensitivity of 0.66 (95% CI 0.53-0.77) and specificity of 0.78 (95% CI 0.71-0.84). Meanwhile, logistic regression was the main model, with low sensitivity in the validation set.

In clinical practice, the interpretability of the model and the prediction accuracy for outcomes should be considered; however, it is hard to choose between them [66]. Some models with high interpretability, that is, logistic regression (converting linear combinations of predictor variables into probability values for positive events via logistic functions), decision trees (generating rules by recursively splitting variables in the dataset), and LASSO (least absolute shrinkage and selection operator) regression (selecting variables and reducing model complexity by L1 regularization), which adds a penalty term proportional to the absolute value of coefficients of the features for feature selection and model construction, often have too low prediction accuracy for outcomes. Others with too little explainability, that is, extreme gradient boosting (XGBoost; combining multiple weak learners to form a strong learner with efficient computational power and excellent prediction performance), artificial neural network (an algorithm that simulates the neuronal structure of the human brain and learns complex patterns of data through multilayer nonlinear transformations for various ML tasks such as classification, regression, and clustering), and support vector machines (a supervised learning method to maximize the spacing between different classes by finding optimal hyperplanes for classification and regression tasks) have very high prediction accuracy, especially deep learning models [67]. Among ML models constructed based on common clinical features, models with better interpretability are preferred, which can explicitly explain the relationship between common clinical features and outcomes and thus provide real-time interventions. This may also explain why logistic regression was most frequently used in the included studies. However, in image-based artificial intelligence, models with higher prediction efficiency are preferred, mainly since medical images have many confounding factors and types of imaging devices, as well as a high level of device parameterization [10,68]. Our study shows that XGBoost in the validation set had the best C index of 0.826 (95% CI 0.770-0.882), with sensitivity and specificity of 0.78 (95% CI 0.27-0.97) and 0.55 (95% CI 0.37-0.71), respectively. Although XGBoost can rank the variables' importance, its interpretability remains a serious challenge. In addition, random forests seem to exhibit desirable accuracy, with C index, sensitivity, and specificity of 0.784 (95% CI 0.730-0.838), 0.81 (95% CI 0.46-0.96), and 0.78 (95% CI 0.63-0.88), respectively. The c-indices of logistic regression, LASSO regression, and decision tree based on models with better interpretability were 0.757 (0.715-0.800), 0.705 (0.610-0.799), and 0.817 (0.661-0.973), respectively. This shows the differences in the prediction accuracy of different models, where the less interpretable XGBoost and random forest seem to have better accuracy, especially random forest, which has desirable sensitivity and specificity.

Our study shows that existing ML has a more favorable C index for the prediction of DCI; however, the overall sensitivity seems to be unfavorable. Although random forest has high sensitivity

XSL•FO
RenderX

and specificity, the included models are limited, which may limit the interpretation of results. In constructing ML models, we need to consider data balance. For unbalanced modeling, some results tend to show a high C index, which is due to negative results. Our pooled incidence of DCI for the included studies was 27.7% (95% CI 24.7%-30.7%), which may have some implications for low sensitivity. In addition, some models obtain the probability of DCI, and the probability thresholds are often chosen based on the optimal Youden index. The effect of sensitivity is often not considered when choosing the optimal Youden index, which may also have some effect on low sensitivity. Therefore, the balance of modeling data and the reasonableness of positive probability thresholds need to be considered in future studies.

When constructing clinical prediction models, the number of included cases and the selection of predictors are often neglected. Models derived from a restricted number of cases exhibited low stability, and some included studies had a limited sample size. In addition, efficient predictors are key to enhancing model accuracy, and our summary of the current modeling predictors provides important references for subsequent studies. A systematic review by Jabbarli et al [69] explored the biomarkers for the early prediction of DCI, which greatly differed from the markers we summarized. Efficient predictors should be further explored in subsequent studies.

Limitations of This Study

Our study has the following limitations. First, there may be some differences in the definition of DCI among studies, which may impose some limitations on the interpretation of our results to some extent. Second, the included studies contain a diversity of models. However, except for logistic regression, the other types of models are limited in number. Third, there is a high risk of bias in primary studies, mainly owing to the limited cases for modeling and the avoidance of overfitting. Fourth, the validation methods for the models in the primary studies are mainly random sampling or k-fold cross-validation, with rare external validation. Fifth, in a very small number of studies, validation sets can be used to try out different hyperparameters to improve the algorithm; test sets are essentially raw data. It is not clear in the original studies we included whether the models were optimized in this way. Therefore, we were not able to discuss this in greater depth in our review. Sixth, even though we conducted a systematic search and literature screening, no studies were found on image-based ML for predicting DCI in patients with SAH. Therefore, deeper exploration should be conducted in future studies.

Conclusion

The ML constructed in the original studies that we included was primarily based on the baseline characteristics of patients at admission. Our meta-analysis shows that ML had a relatively desirable predictive value. In subsequent studies, more efficient predictors can be explored and better-performing prediction tools can be developed based on the ML approach to enable treating physicians to enhance daily TCD monitoring. Prioritizing TCD monitoring in resource-limited settings lowers the threshold for performing more invasive diagnostic procedures such as catheter angiography.

Abstract

Background: To reduce the mortality related to bladder cancer, efforts need to be concentrated on early detection of the disease for more effective therapeutic intervention. Strong risk factors (eg, smoking status, age, professional exposure) have been identified, and some diagnostic tools (eg, by way of cystoscopy) have been proposed. However, to date, no fully satisfactory (noninvasive, inexpensive, high-performance) solution for widespread deployment has been proposed. Some new models based on cytology image classification were recently developed and bring good perspectives, but there are still avenues to explore to improve their performance.

Objective: Our team aimed to evaluate the benefit of combining the reuse of massive clinical data to build a risk factor model and a digital cytology image–based model (VisioCyt) for bladder cancer detection.

Methods: The first step relied on designing a predictive model based on clinical data (ie, risk factors identified in the literature) extracted from the clinical data warehouse of the Rennes Hospital and machine learning algorithms (logistic regression, random forest, and support vector machine). It provides a score corresponding to the risk of developing bladder cancer based on the patient's clinical profile. Second, we investigated 3 strategies (logistic regression, decision tree, and a custom strategy based on score interpretation) to combine the model's score with the score from an image-based model to produce a robust bladder cancer scoring system.

Results: We collected 2 data sets. The first set, including clinical data for 5422 patients extracted from the clinical data warehouse, was used to design the risk factor–based model. The second set was used to measure the models' performances and was composed of data for 620 patients from a clinical trial for which cytology images and clinicobiological features were collected. With this second data set, the combination of both models obtained areas under the curve of 0.82 on the training set and 0.83 on the test set, demonstrating the value of combining risk factor–based and image-based models. This combination offers a higher associated risk of cancer than VisioCyt alone for all classes, especially for low-grade bladder cancer.

Conclusions: These results demonstrate the value of combining clinical and biological information, especially to improve detection of low-grade bladder cancer. Some improvements will need to be made to the automatic extraction of clinical features to make the risk factor–based model more robust. However, as of now, the results support the assumption that this type of approach will be of benefit to patients.

Introduction

Bladder cancer ranks as the 9th most prevalent cancer worldwide, and it is the 13th leading cause of cancer-related deaths, claiming over 13,000 lives annually [1,2]. In 2017, bladder cancer was the 5th most frequently diagnosed cancer in men, with an incidence 4 times higher than that in women [3]. Detecting bladder cancer at an early stage significantly enhances the chance of successful treatment, while late-stage detection presents more challenges. Current treatments involve surgical procedures and auxiliary chemotherapy but come with a relatively poor 5-year prognosis [4]. More precisely, the 5-year survival is 69.5% for localized disease. The survival rate decreases to 36.3% for regional disease and only 5% for metastatic bladder cancer [5]. Today, periodic cystoscopy associated with urine cytology is the gold standard for the diagnosis of bladder cancer or to monitor for recurrence [6]. However, cystoscopy is an expensive and invasive procedure usually associated with discomfort. Urine cytology is a test to detect abnormal cells in urine samples. Although urine cytology is the most widely used noninvasive test, it has poor sensitivity, especially for low-grade tumors [7,8].

Thus, to reduce the mortality associated with bladder cancer, new diagnostic tools need to be proposed for early detection of the disease [3]. At the same time, newly proposed methods should be noninvasive and inexpensive to allow large-scale dissemination. Research is currently focusing on this objective through better identification of risk factors or development of more effective diagnostic tools.

Recently, new diagnostic tools based on the detection of specific biomarkers in urine tests were proposed [9-11]. ADXBLADDER is a urine test to detect the mini chromosome maintenance 5 protein in voided urine [9]. It has a sensitivity of 83% and specificity of 77%. Urodiag is based on genetic and epigenetic analysis using multiplex quantitative real-time polymerase chain reaction and consists of detecting 4 mutations of the fibroblast growth factor receptor 3 gene [10]. It has a sensitivity of 95% and specificity of 76%. URO17 is an immunocytochemical test designed to evaluate keratine 17 expression and has a sensitivity of 100% and specificity of 96% [11]. These tests show promising performance but have only been studied in small cohorts (from 26 to 71 patients).

Increasing interest in deep learning algorithms has also led to the emergence of new diagnostic strategies based on image processing (see [12,13] for reviews). Although most of them have been developed from cystoscopy images, some aim to propose noninvasive techniques and have exploited images obtained from urine cytology [14-16]. The authors report good to very good performance, including a sensitivity of 79.5% and specificity of 84.5% [14]; area under the receiver operating characteristic (ROC) curve (AUC) of 0.83 [15]; and sensitivity of 81.0% and specificity of 98.0% [16]. However, studies were conducted either with populations composed mainly of patients with high-grade cancer [14] or with a small amount of data and a limited number of patients (ie, only 398 slides in [15] and 68 patients in [16]). Moreover, a lack of generalization power, as expressed by a decrease in performance when applying the model to new data and especially new data sources, hinders deployment in clinics [13]. In addition, the main challenge is detecting patients with low-grade cancer to improve their chance of survival.

On the other hand, several risk factors were identified as strong determinants of bladder cancer. First, demographic information, such as age and sex, was identified as a strong factor [5]. In 2012, Letašiová et al [17] also highlighted that smoking; exposure to arsenic (in water, air, or food); and exposure to aromatic amines and 4,4'-methylenebis in chemicals that are typically contained in dyes, hair dyes, paints, fungicides, cigarette smoke, plastics, metals, and motor vehicle exhaust are the most notable environmental risk factors [17]. An association with diabetes has also been described [18]. In addition, positive associations between bladder cancer and a family history in first- and second-degree relatives [19] and hypertension [20] were found. In a more general context, having experienced stroke [21] or heart failure [22] was also associated with a higher risk of developing cancer.

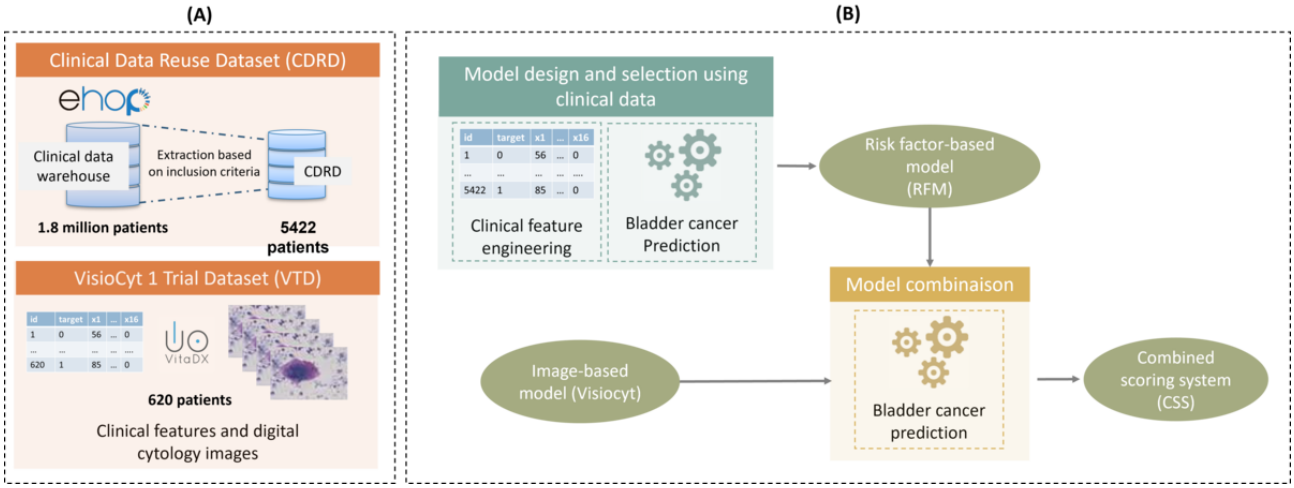
The widespread adoption of electronic health records now provides an opportunity to capture granular patient information in large populations. The data can be used to develop machine learning models that could be incorporated in decision support systems. By incorporating risk factors, such models have the potential to identify at-risk patients more accurately, enhancing patient profiles for image-based analysis.

In this paper, we proposed combining knowledge about risk factors and cytology processing software to investigate the benefits that this could provide for bladder cancer detection. To do this, our team worked with a model developed by the company VitaDX [23]. This image-based model, called VisioCyt, integrates image cell processing and deep learning algorithms to predict bladder cancer from voided urinary cytology. In this study, our focus was on building a detection model based on risk factors extracted from our local clinical data warehouse (CDW). We hypothesized that a model trained on a large data set, offering a probability of bladder cancer based on a patient's clinical profile, can complement the VisioCyt scoring system and enhance detection, especially for low-grade cases.

Methods

Ethical Considerations

Our study followed the relevant guidelines and regulations, in accordance with the Declaration of Helsinki. The extracted data did not contain any nominative data, and all information was



XSL•FO
RenderX

deidentified in accordance with the protocol established for the improved project. Agreement from the French Commission Nationale de l'Informatique et des Libertés was obtained (agreement number 2206739).

Study Design

The proposed workflow for bladder cancer prediction is depicted in Figure 1. As a first step, 2 distinct prediction models were built: one based on risk factors (risk factor–based model [RFM]) and the other using cytology images (VisioCyt). The scores given by each model were then combined to provide a composite score.

Figure 1. Overview of the designed workflow for the scoring of bladder cancer using risk factors and cytology images, including a description of the (A) data sets and (B) data processing.

To set up and evaluate our approach, 2 data sets were considered: Clinical Data Reuse Dataset (CDRD) and VisioCyt 1 Trial Dataset (VTD).

CDRD was extracted according to the inclusion criteria from eHOP [24], the CDW developed and deployed at Rennes University Hospital. This database was used to design and select the bladder cancer prediction model based on risk factors (ie, the RFM). For that purpose, clinical features were retrieved and preprocessed to be used as inputs for the machine learning approaches. In the end, several models were compared to identify the best model.

The second data set contained clinical data and cytology images that were acquired during the VisioCyt 1 Trial (NCT02966691). Images from this data set were first used to set up the bladder cancer prediction model based on cytology images and deep learning (ie, VisioCyt). This model was internally developed by VitaDX. In this study, we focused on the combination of this model with an RFM. To evaluate and adopt the best strategy for the combination, the whole data set (ie, images and clinical data from VTD) was used.

In the following sections, each stage of this workflow is described. First, we introduce the study population with the associated inclusion criteria. It is followed by a description of the data sets. Methods to set up the risk factor–based predictor are presented, and a description of the Visiocyt model is given. Finally, the combination strategies to build the final bladder cancer predictor are described.

Study Population

The eligibility criteria were defined in the VisioCyt 1 Trial [23] and used to extract data from the CDW.

The inclusion criteria were the following: older than 18 years, affiliation with a social security system, negative urine culture, programmed bladder endoscopy for a suspicion of bladder cancer (de novo, monitoring, or relapse) or exploration of the lower urinary tract excluding a suspected bladder cancer or prostate cancer.

The exclusion criteria were as follows: ongoing, untreated urinary tract infection; presence of bladder cancer excluding urothelial carcinoma; carcinoma of the high urinary tract, associated; history of lithiasis pathology; had undergone a renal transplantation.

Data Sets

Clinical Data Reuse Data Set

With eHOP, administrative and clinical data from electronic health records are collected, including unstructured (eg, clinical notes) and structured (eg, drugs, laboratory results) data. Data are deidentified, and a unique anonymous identifier allows the linkage among hospital stays of a given patient. The eHOP CDW currently allows users to search 80 million unstructured data elements and 430 million structured elements. All these data cover more than 1.8 million patients. CDRD was extracted from the eHOP database. All data on hospital stays at Rennes University Hospital between 2015 and 2017 were considered.

In this study, we considered people who had undergone endoscopy for vesical tumor resection or had a histology examination that was positive for bladder cancer. People considered negative for bladder cancer were those who had undergone a bladder endoscopy and had a negative histological examination.

XSL•FO
RenderX

For this extraction, we used the following data: demographic data; drugs administered (codification used by the French hospital information system to identify a drug and date of administration); Programme de Médicalisation des Systèmes d'Information (PMSI) data (French diagnosis-related groups) including International Statistical Classification of Diseases, Tenth Revision (ICD-10) codes, procedure codes, mortality, and length of stay; laboratory results described with local terminology; medical reports.

The extraction resulted in 5422 eligible patients: 1351 bladder cancer positives and 4071 bladder cancer negatives.

VisioCyt 1 Trial Data Set

The VisioCyt 1 Trial is registered in clinicaltrials.gov (NCT02966691). This clinical study was designed to evaluate the diagnostic performance of the VisioCyt test, which would improve the early diagnosis of bladder cancer. The diagnostic method used by the VisioCyt device is based on the analysis by transmission of urinary cytology slides prepared according to the protocol outlined for VisioCyt [23].

In addition to the inclusion criteria presented in the Study Population section, other criteria specific to that trial were considered. Additional inclusion criteria were the ability of the patient to understand the protocol and signature of a consent form before beginning the study, while people deprived of liberty or under guardianship were excluded. In addition, patients included in the same hospital as that from which CDRD was extracted were also excluded to avoid double inclusion.

In VTD, patients were considered to have bladder cancer if they had positive urine cytology and positive histology. This resulted in 620 patients, that is, 409 bladder cancer positives and 211 bladder cancer negatives. Among the positive patients, 220 patients with low-grade cancer and 189 patients with high-grade cancer were included. We collected 2 types of data. First, VisioCyt 1 provides urinary cytology digital slide images at a size of 50,000 × 50,000 pixels. They were acquired over 3 focal plans and contain cells of different types (eg, malpighian cells, urothelial cells, neutrophilic polynucleosis, artifacts, blood cells). For each VTD patient, the following demographic variables were retrieved: age, sex, weight (kg), and height (cm). The following risk factors and comorbidities were also collected: smoking status (never, former, or current smoker), diabetes, history of heart failure, hypertension, history of stroke, chronic obstructive pulmonary disease (COPD), family history of cancer, and professional exposure to a carcinogenic factor.

Risk Factor–Based Model (RFM)

Clinical Feature Extraction and Preprocessing

For each CDRD patient, the same features as those collected for VTD patients were retrieved. They were extracted from the data warehouse using structured and unstructured data. For structured data, standardized codes of several terminologies and local codes were used. For unstructured data (ie, medical reports), regular expressions and some more advanced techniques based on embeddings (ie, using spacy modeling from python) were implemented or used [25].

Missing data imputation was performed for weight and height by using k-nearest neighbor identification (k=10) based on age, sex, and weight or height according to the feature to be imputed. Standard scaling was first applied to ensure an equivalent impact on the distance measurement for numerical variables. For binary variables, we assumed that patients did not have the feature if it was not retrieved through the queries used on the data warehouse. A BMI feature was added and computed as weight divided by height squared.

A missing data indicator feature was added for each of the original features except for age and sex, which were complete. In the end, the clinical feature set had 29 clinical features.

Bladder Cancer Prediction From Clinical Data

We investigated 3 supervised classification algorithms, namely random forest (RF), logistic regression (LR), and support vector machine (SVM), to identify patients likely to have bladder cancer based on their clinical data.

A 2-step strategy, depicted in Figure 2, was designed to identify the best modeling approach.

First, the most optimal hyperparameters were identified using 3-fold cross-validation and a random grid search on 80% of CDRD (100 iterations). The best set of hyperparameters was defined as the one leading to the highest averaged AUC on the validation sets. During training, class imbalance was handled using class-weighting to mitigate the risk of bias toward the majority class in splits (ie, no bladder cancer patients). This process was repeated for each machine learning algorithm. This resulted in 3 candidate models composed of a standardizer, missing data imputer, and classifier ready to be applied to new data.

Second, model candidates were applied on 20% of CDRD to verify their generalization power. From there, the best classification approach was identified by comparing the performance using AUC, sensitivity, and specificity. At the end of this step, training using all CDRD data, the best hyperparameter set, and the best approach was conducted and resulted in the RFM.

XSL•FO
RenderX

Figure 2. Identification of the best classification model using 2 steps: (A) The first was training, a selection of the best set of hyperparameters and fit of a model candidate to use for each classification approach, and (B) the second was testing, identification of the best model among the 3 candidates. AUC: area under the receiver operating characteristic curve; CDRD: Clinical Data Reuse Dataset; LR: logistic regression; RF: random forest; SVM: support vector machine.

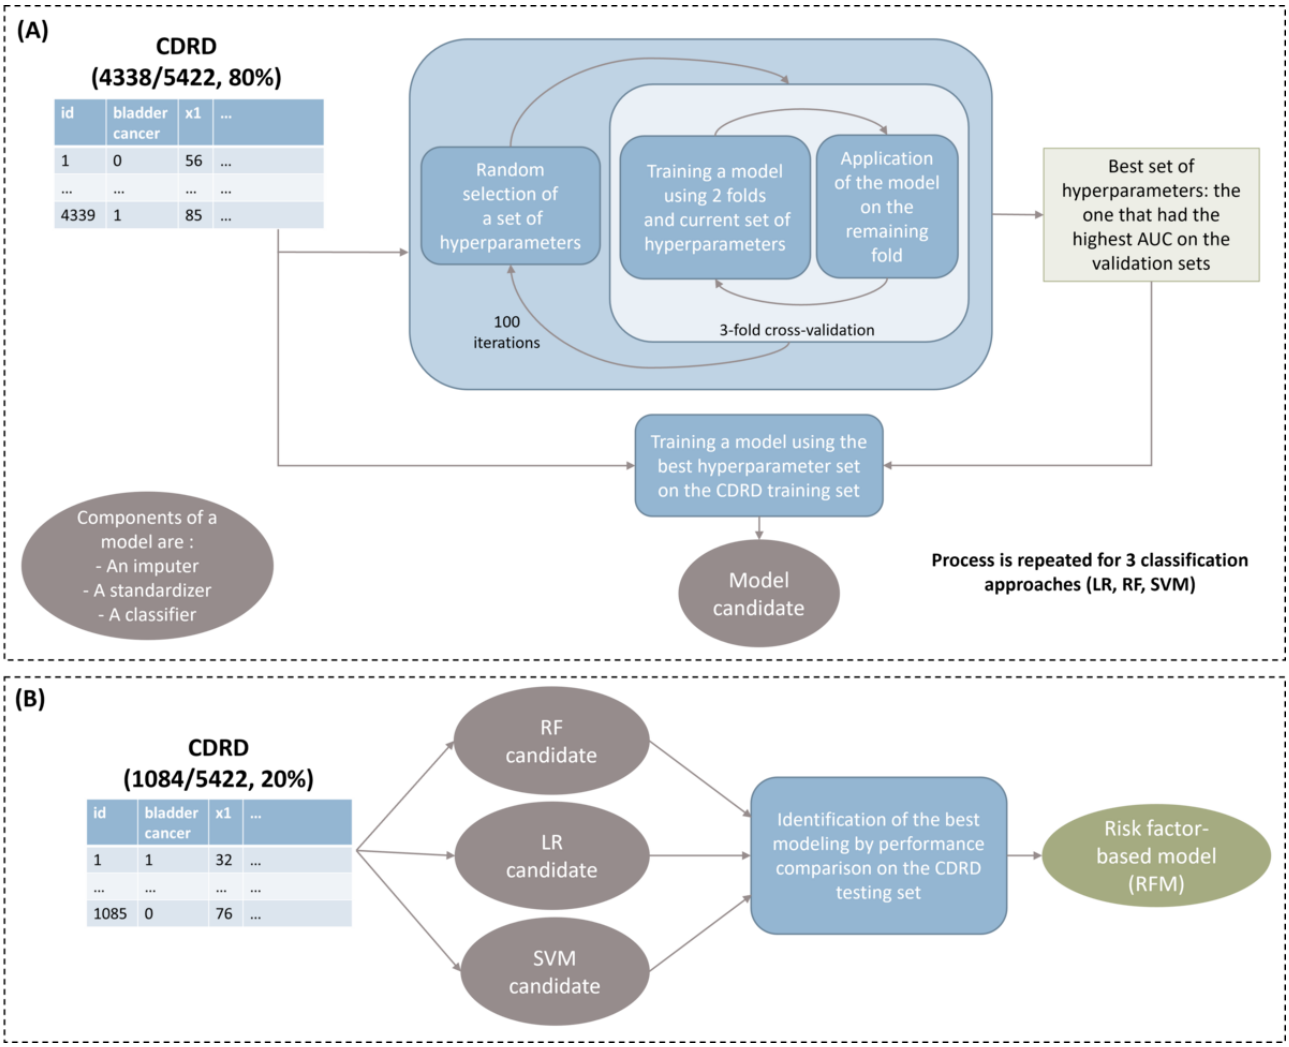


Image-Based Model

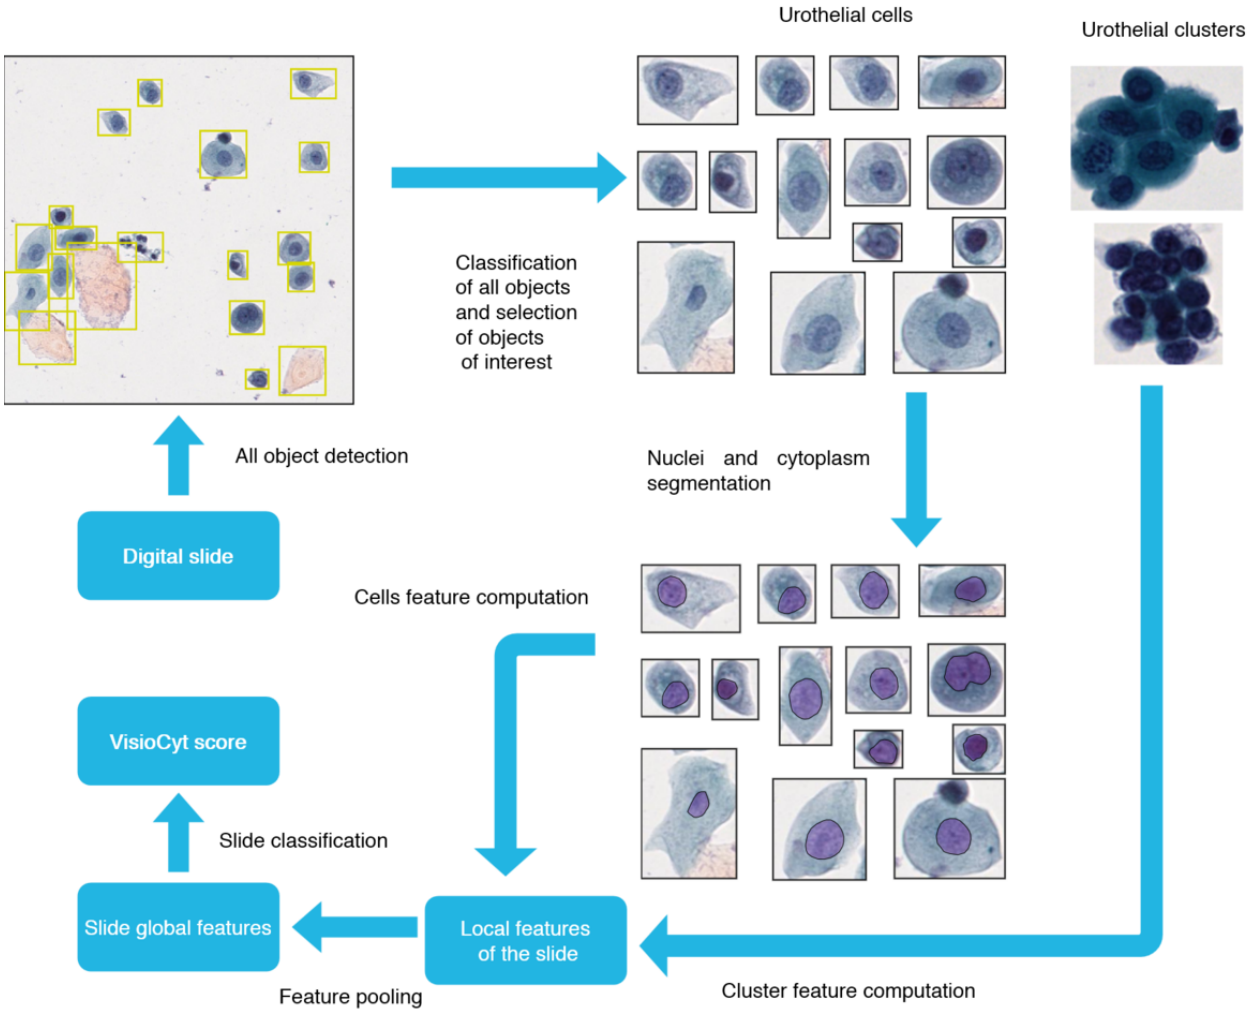
The image-based model works in 5 main steps going from checking the quality of the data to prediction of bladder cancer from segmented cell images. The process is depicted in Figure 3.



The process begins with a quality check of the slide, discarding any that are not properly prepared nor digitized. Following this, the biological elements on the slide are detected and classified, retaining only individual urothelial cells and clusters of these cells. A second quality assessment is then carried out to confirm the presence of a sufficient number of urothelial cells.

These cells are subsequently segmented to identify the nucleus and cytoplasm, and the characteristics of the nucleus are calculated based on established criteria and atypia parameters [23]. Urothelial clusters are classified using a detector for atypical urothelial clusters, and the classification score is used as a feature of the cluster.

Features of both individual urothelial cells and urothelial clusters are combined into a vector representing the features of the slide. This vector is ultimately classified by an RF classifier to determine the VisioCyt slide's score.

Figure 3. Workflow of the image-based model.

Combination of Image-Based and Risk Factor–Based Models

At this stage, prediction scores obtained from the RFM and VisioCyt are available. To combine these 2 scores and provide the final combined scoring system, 3 strategies were investigated using the output probabilities of both models as inputs: custom, LR, and decision tree (DT).

Experiments and evaluations were performed using the VTD. At first, stratified random selection, based on grade, was performed to allocate 520 patients to a training set and 131 patients to a test set. The most optimal hyperparameters of LR and DT were then identified using 3-fold cross-validation and a random grid search on the training set as described in the Bladder Cancer Prediction From Clinical Data section. The best models were then applied to the test set. For the custom method, the behaviors of the RFM and VisioCyt scores to build a decision rule adapted to our data were examined on the training set.

VisioCyt and RFM were not trained but simply applied on the training and test sets to compare their performance with those of the combination approaches.

Statistical Analysis and Evaluation Metrics

The relationships between the clinical variables and target variable in both CDRD and VTD were investigated. First, the correlations between bladder cancer status (ie, positive or negative) and continuous variables were studied using the point-biserial correlation test. According to Vogt et al [26], only features with point biserial values >0.25 were considered significantly correlated with the target variable. Chi-square tests were conducted for categorical features. This test consists of a null hypothesis that supposes the independence between the binary feature and bladder cancer status. Using Bonferroni correction, we considered that a $P<.003$ indicated a rejection of the null hypothesis and therefore implied a correlation between the binary variable and bladder cancer status.

ROC curve and AUC analyses were carried out to evaluate the performance of models. In addition, commonly used performance metrics such as balanced accuracy, specificity, and sensitivity were assessed for the RFM. They were measured using the optimal threshold given by the ROC as the combination maximizing the difference between the true positive and false positive rates. To better understand how the models made the predictions, the importance of the features on the predictions was investigated. Although intrinsically present in RF and DT models [27], this information is not directly available

XSL•FO
RenderX

for other approaches such as SVMs. In such cases, the permutation feature importance was computed [27].

Software and Platforms

All experiments were implemented in Python, version 3.8.8. Statistical analyses were performed using scipy 1.7.3. Scikit-learn 1.0.2 was used to train and evaluate the classification models.

Results

The results are presented in 3 sections. First, examination of the clinical features was undertaken to assess their univariate predictive capability for bladder cancer and to evaluate their consistency or heterogeneity across the 2 studied data sets. Second, the performances achieved during the design of the RFM are outlined. Last, the results obtained from the combination of the 2 scoring systems are discussed.

Clinical Feature Analysis

First, the distribution of the clinical features can be discussed by comparing either populations (ie, negatives vs positives) or data sets (ie, CDRD vs VTD). The statistics were grouped within these objectives and are reported in Table 1.

Table 1. Distribution of variables across positive and negative bladder cancer status for each data set.

Clinical features	Positive status		Negative status	
	CDRD[a] (n=1351)	VTB[b] (n=409)	CDRD[a] (n=4071)	VTB[b] (n=211)
Continuous variables, mean (SD)				
Age (years)	69.8 (12.9)	70.7 (10.0)	58.8 (17.7)	63.9 (13.1)
Weight (kg)	74.6 (13.8)	76.1 (14.9)	73.4 (33.1)	74.6 (16.1)
Height (cm)	168.2 (7.5)	170.0 (7.1)	167.2 (7.1)	168.0 (10.0)
BMI (kg/m^2)	26.4 (4.5)	26.0 (4.2)	26.3 (11.6)	26.2 (4.7)
Binary variables, n (%)				
Sex (male)	1069 (79.1)	321 (78.5)	2189 (53.8)	118 (55.9)
Smoking status				
Never smoked	482 (48.8)	83 (20.5)	641 (17.7)	114 (54.8)
Active smoker	109 (37.2)	91 (22.5)	384 (25)	27 (13)
Former smoker	301 (15.4)	231 (57)	201 (6.9)	67 (32.2)
Diabetes	243 (21.9)	86 (21)	389 (19.3)	19 (9)
Heart failure	150 (35.1)	91 (22.2)	380 (30.2)	9 (4.3)
Hypertension	311 (69.1)	210 (51.3)	830 (52.1)	55 (26.1)
Stroke	87 (16.3)	22 (5.4)	261 (14.7)	1 (0.5)
COPD[c]	95 (17.9)	83 (20.3)	140 (10.1)	18 (8.5)
Professional exposure	40 (2.7)	101 (24.7)	80 (1.3)	23 (10.9)
Family history of cancer	13 (0.9)	67 (16.4)	35 (0.8)	40 (19)

[a]CDRD: Clinical Data Reuse Dataset.

[b]VTD: VisioCyt 1 Trial Dataset.

[c]COPD: chronic obstructive pulmonary disease.

The distributions of continuous features (age, weight, height, and BMI) were equivalent in both data sets and between negatives and positives. For binary features, 3 scenarios emerged: Some display equivalent percentages and trends (ie, sex and COPD), while others only shared similar trends (active smoker, former smoker, heart failure, and hypertension) and others exhibited differences in both percentages and trends (never smoked, diabetes, stroke, professional exposure, and family history of cancer).

For sex and COPD, percentages and trends were similar in CDRD and VTD. There were more men with bladder cancer than without (with cancer: 1069/1351, 79.1% in CDRD and 321/409, 78.5% in VTD; without cancer: 2189/4071, 53.8% in CDRD and 118/211, 55.9% in VTD), and there was a higher occurrence of COPD among individuals with bladder cancer (95/1351, 17.9% in CDRD and 83/409, 20.3% in VTD) than in individuals without bladder cancer (140/4071, 3.4% in CDRD and 18/439, 8.5% in VTD).

For features with only similar trends, such as being an active smoker, heart failure, and hypertension, the percentages were generally higher in CDRD than in VTD, except for being a former smoker, where lower percentages were observed in CDRD than in VTD (Table 1).

XSL•FO
RenderX

For features considered to have different percentages and trends (never smoked, diabetes, stroke, professional exposure, and family history of cancer), the key observation was the equivalence between positives and negatives in CDRD, while a more pronounced difference existed between positives and negatives in VTD.

Statistical analyses were performed to observe relationships between features and bladder cancer status in each data set. The results are reported in Table 2.

Table 2. Statistical analyses performed to evaluate the correlations between the clinical features and bladder cancer status for each data set.

Clinical features	Clinical Data Reuse Dataset (CDRD)		VisioCyt 1 Trial Dataset (VTD)	
	Statistic	*P* value	Statistic	*P* value
Continuous variables, r_{pb}[a]				
Age	0.276	<.001	0.276	<.001
Weight	0.018	.18	0.051	<.001
Height	0.059	<.001	0.133	<.001
BMI	0.004	.74	–0.025	.54
Binary variables, χ^2 (*df*)[b]				
Sex	108.534 (1)	<.001	10.005 (1)	<.001
Smoking status				
Never smoked	0.659 (1)	.42	49.854 (1)	<.001
Active smoker	53.680 (1)	<.001	6.535 (1)	<.001
Former smoker	81.775 (1)	<.001	17.705 (1)	<.001
Diabetes	3.375 (1)	.04	11.879 (1)	<.001
Heart failure	7.824 (1)	<.001	27.911 (1)	<.001
Hypertension	52.403 (1)	<.001	20.809 (1)	<.001
Stroke	1.710 (1)	.17	9.027 (1)	<.001
COPD[c]	51.868 (1)	<.001	11.822 (1)	<.001
Professional exposure	13.198 (1)	<.001	13.242 (1)	<.001
Family history of cancer	0.073 (1)	.92	0.535 (1)	.46

[a]Values >0.25 considered significant.

[b]*P* values <.003 considered significant.

[c]COPD: chronic obstructive pulmonary disease.

For 8 features (ie, age, sex, active smoker, former smoker, heart failure, hypertension, COPD, and professional exposure), relationships with bladder cancer were highlighted in both CDRD and VTD, while 3 others were only considered related to bladder in VTD (diabetes, never smoked, and stroke). Finally, 4 features (weight, height, BMI, and family history of cancer) were not considered significant in any of the data sets.

Bladder Cancer Prediction Using Clinical Features

This section is dedicated to the investigations of the RFM. First, the best hyperparameters for each classification approach are reported. The performance between model candidates is then compared. To finish, the importance of each feature in the best model is investigated.

Hyperparameter Tuning

During the training phase, hyperparameters were tuned for each of the 3 classification approaches (RF, SVM, LR; Table 3).

In the end, the RF model candidate was composed of 45 trees with a maximum depth of 10 splits, minimum sample split of 10, and minimum sample leaf at 30 samples each. The RF model had an average AUC of 0.76 (SD 0.02). The SVM candidate was a linear kernel with a margin at 10 and 0.01 for gamma and had an average AUC of 0.77 (SD 0.02). The LR candidate embedded a margin at 0.01 with an l1 penalty and performed with an average AUC of 0.77 (SD 0.02). Model candidates were finally trained using these hyperparameters on the CDRD training set.

XSL•FO
RenderX

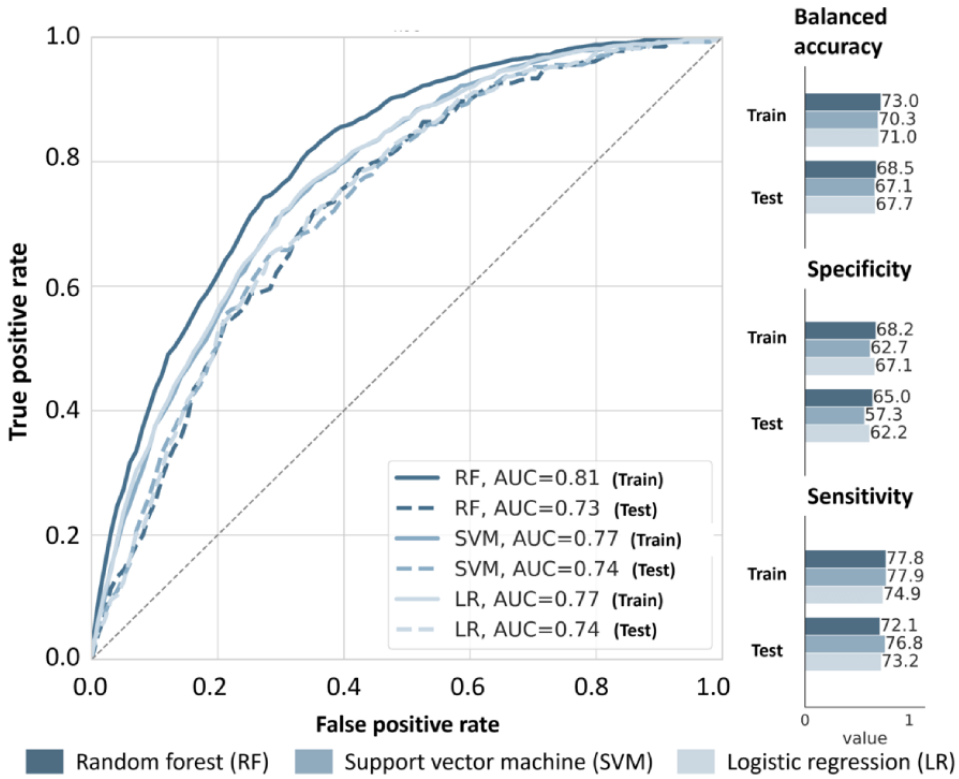

Table 3. Summary of the tuning of the hyperparameters.

Classifier and tuned hyperparameters	Tested values	Best AUC[a], mean (SD)
Random forest		0.76 (0.02)
number of trees	(10, 14, 18, 23, 27, 32, 41, 45[b], 50)	
maximal depth	(5, 6, 7, 8, 10[b], 13, 20)	
minimal sample split	(5, 10[b])	
minimal sample leaf	(4, 10, 30[b], 50)	
Support vector machine		0.77 (0.02)
kernel	(linear[b], radial basis function)	
margin	(0.001, 0.01, 0.1, 1, 10[b], 100)	
gamma	(0.001, 0.01[b], 0.1, 1, 10, 100)	
Logistic regression		0.77 (0.02)
margin	(0.001, 0.01[b], 0.1, 1, 10, 100)	
penalty	(l1[b], l2, none)	

Performance Comparison

To identify the best candidate to be deployed, performance on the training set (80% of CDRD) and applied once to the test set (20% of CDRD) were compared for each modeling approach. The resulting performances are reported in Figure 4.

Figure 4. Receiver operating characteristic (ROC) curve comparing the performance of risk factor–based classifiers in terms of the area under the ROC curve (AUC), balanced accuracy, specificity, and sensitivity for both the training and test sets.

When looking at the AUC, all approaches succeeded, with values above 0.73 on the test set. However, there was a stronger overfitting with the RF candidate (ie, a drop of 0.08 between the training and test sets was observed). The other 2 models had similar AUCs on the training and test sets: 0.77 for SVM and 0.74 for LR. This indicates that these models generalized the problem better. Regarding the other evaluation metrics, the LR candidate had a better sensitivity-specificity balance (ie, sensitivity of 73.2% and specificity of 62.2% on the test set) than the SVM (ie, sensitivity of 76.8% and specificity of 57.3%

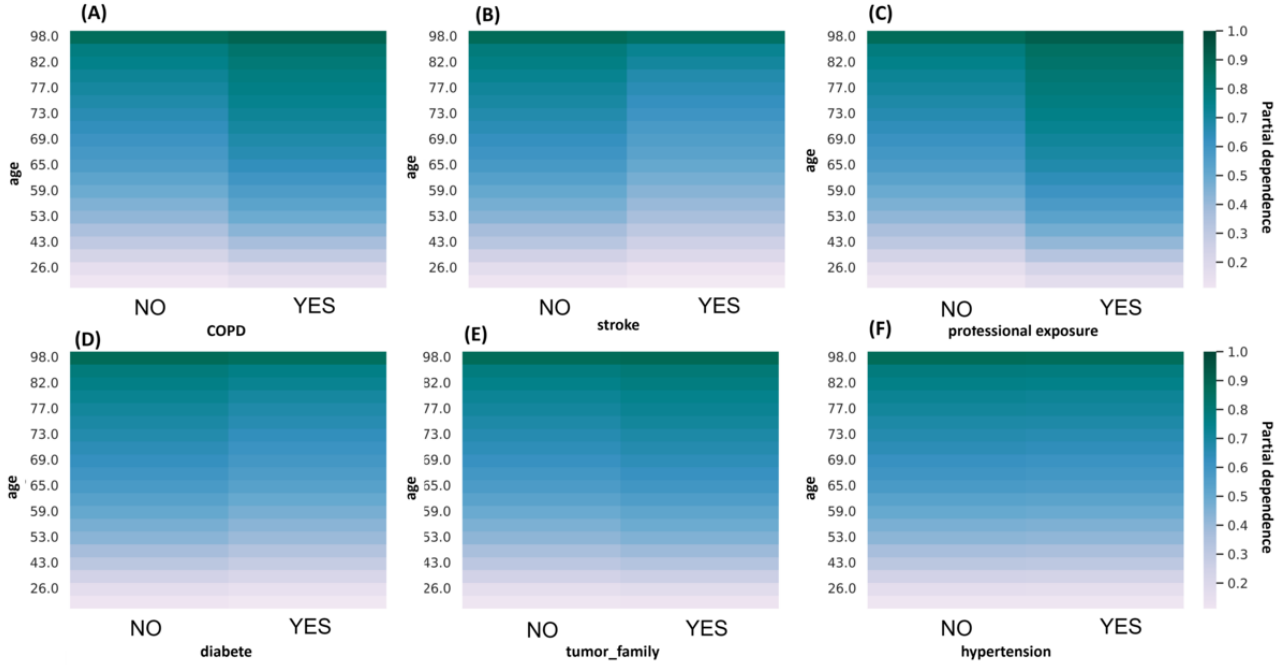
XSL•FO
RenderX

on the test set). In the end, the LR candidate was chosen for further investigation as the RFM (ie, feature importance analysis and combination with VisioCyt).

Impact of Clinical Features on Predictions

The individual importance of each feature for the prediction with LR is reported in Table 4.

Table 4. Feature importance of the risk factor–based model.



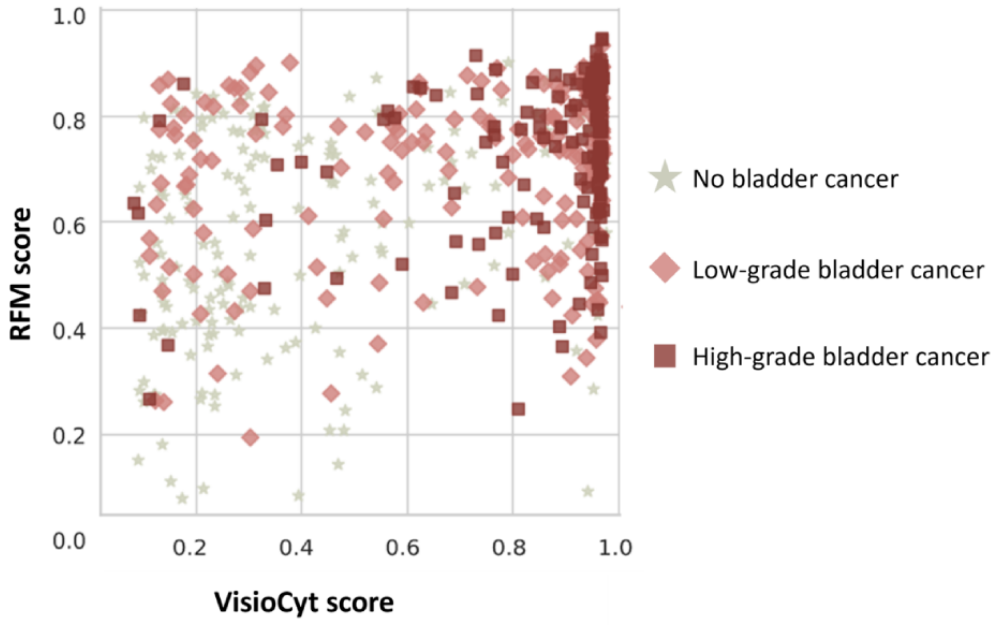
Feature	Importance model
age	0.14
sex	0.05
BMI_was_missing	0.03
smoking_status_active	0.03
smoking_status_former	0.01
heart_failure	0.01
weight	0.01
BMI	0.01
COPD	<0.01
stroke	<0.01
smoking_status_never	<0.01
professional_expo	<0.01
diabetes	<0.01
height	<0.01
COPD_was_missing	<0.01
hypertension_was_missing	<0.01
heart_failure_was_missing	<0.01
stroke_was_missing	<0.01
professional_expo_was_missing	<0.01
height_was_missing	<0.01
smoking_status_active_was_missing	<0.01
tumor_family_was_missing	<0.01
smoking_status_former_was_missing	<0.01
weight_was_missing	<0.01
sex_was_missing	<0.01
diabetes_was_missing	<0.01
smoking_status_never_was_missing	<0.01
tumor_family	<0.01
hypertension	<0.01

Unsurprisingly, age and sex were associated with the highest importance values (0.14 and 0.05, respectively). Information on patients' smoking status, through *smoking_status_active* and *smoking_status_former* features, had an impact on the predictions. In addition, weight and BMI were taken into consideration along with information on the presence or absence of BMI features (*BMI_was_missing*). Finally, the impact of a history of heart attacks (*heart_failure*) was also considered by the model. All other features had negligible univariate significance.

However, we could assume that the associations between these variables are the important factor in the model rather than when they are considered 1 by 1. Looking at 2-feature partial dependence plots allows us to explore this hypothesis. The combinations of age with features of low importance were investigated (ie, COPD, stroke, *professional_expo*, diabetes, *tumor_family*, and hypertension) and are presented in Figure 5.

XSL•FO
RenderX

Figure 5. Partial dependence plots for 6 feature combinations of age with (A) chronic obstructive pulmonary disorder (COPD), (B) stroke, (C) professional exposure, (D) diabetes, (E) tumor family, and (F) hypertension.



Patient age played an important role. Indeed, the highest probabilities (in dark green) were observed in the oldest patients. Higher risks (darker areas on the right than on the left of figures) were associated with COPD, professional exposure, and a family history of bladder cancer (*tumor_family*). This suggests that the model successfully captured the effects associated with these risk factors commonly identified in the literature. A history of stroke and the presence of diabetes were also considered but with the opposite effect than expected (absence increases risk). No impact of the hypertension feature was observed here.

Bladder Cancer Prediction by Combining RFM and VisioCyt

Building the Custom Method

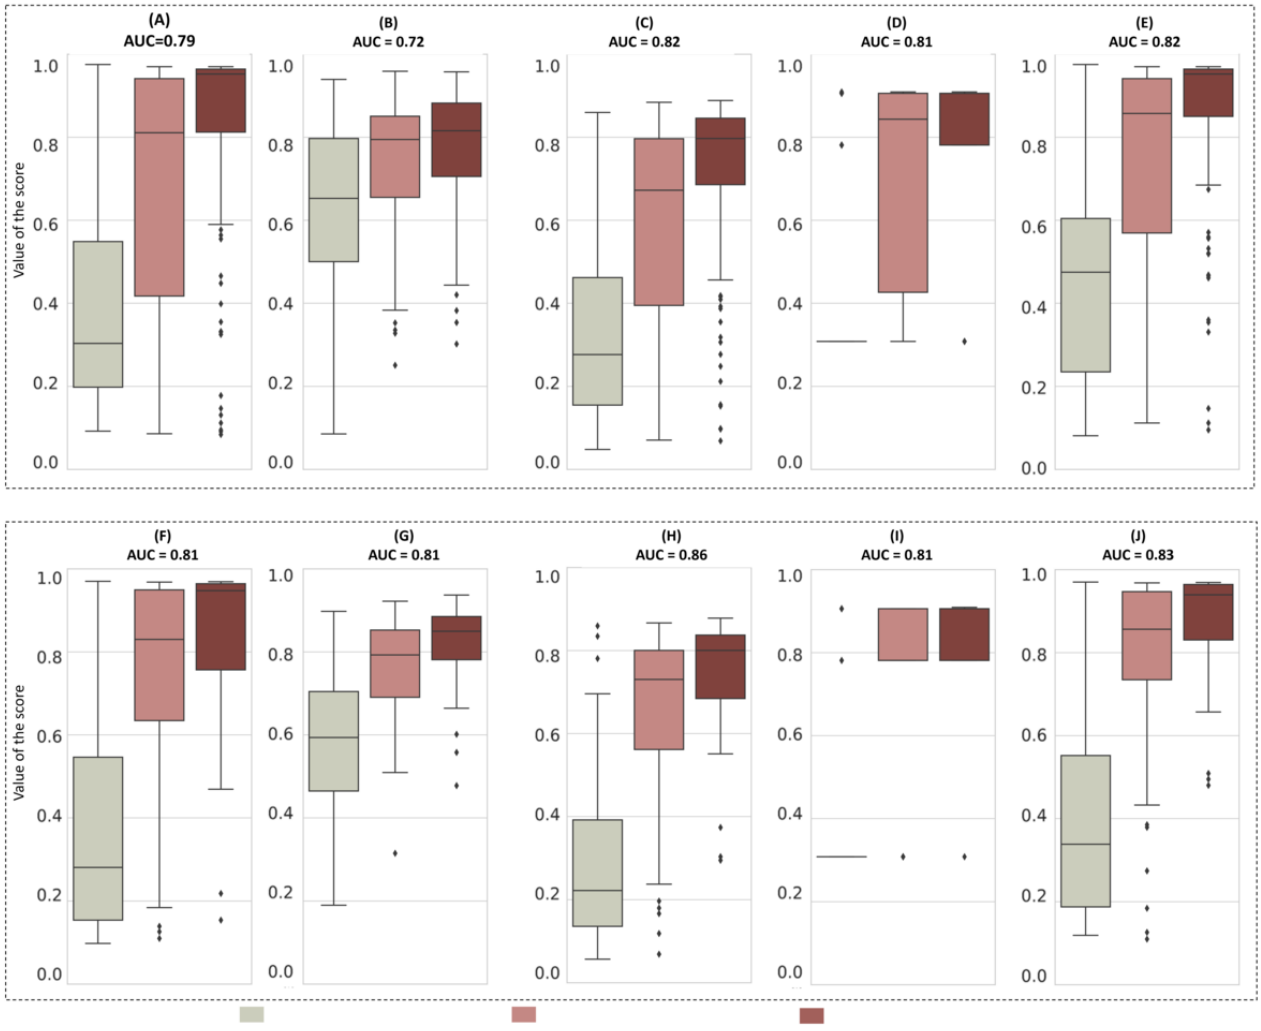
The resulting scores for the VTD training set are reported in Figure 6.

Figure 6. 2D plot of risk factor–based model (RFM) and VisioCyt scores on the VisioCyt 1 Trial Dataset (VTD) training set.

The first possible observation was that the detection of high-grade cancer was broadly identifiable by the high values of both scores. A VisioCyt score >0.6 indicates a high probability of cancer. In fact, very few patients without bladder cancer were in this zone of the scatter plot. Below this threshold, detection of low-grade cancers seems more difficult using the insight from VisioCyt alone. However, the RFM score was often

XSL•FO
RenderX

higher than 0.6 for these patients. From these observations, the custom combination rule was defined as follows:



Identification of the Best Modeling Approach

At first, the LR and DT models were subjected to 3-fold cross-validation on the training set to identify the best hyperparameters. LR with l1 regularization and a margin of 78.8 led to an AUC of 0.81 (SD 0.02) on the validation sets. DT with a minimum sample leaf of 5, maximum depth of 2, and a *Gini* criterion resulted in an AUC of 0.78 (SD 0.02). These hyperparameters were used to retrain the 2 approaches on the VTD training set.

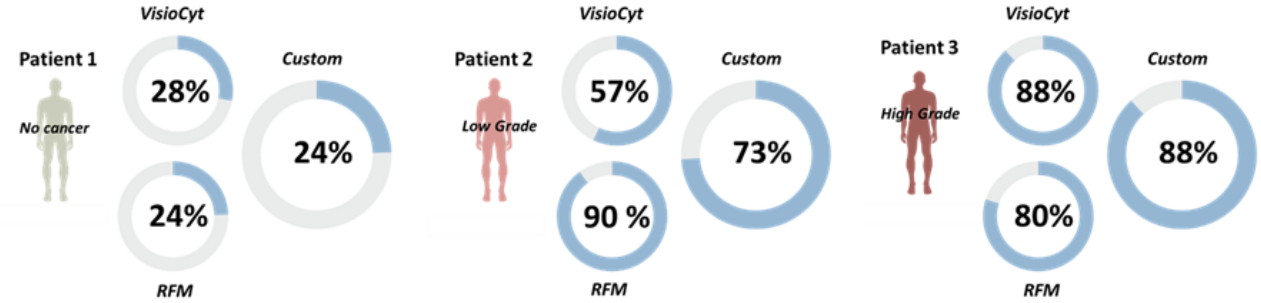
The comparison between the 5 bladder cancer predictors is illustrated in Figure 7. It compiles the AUCs and score distributions according to bladder cancer severities of the image-based model, the RFM, and the 3 strategies for score combination: LR, DT, and custom. Initial scores obtained with VisioCyt and RFM are reported on the left, while scores from the combination using LR, DT, and custom lie on the right. Values obtained on the training and test sets of VTD were included to discuss the generalization of both approaches.

Figure 7. Distribution of the scores by bladder cancer grade for the VisioCyt 1 Trial Dataset (VTD) training set using (A) VisioCyt, (B) the risk factor–based model (RFM), (C) logistic regression (LR), (D) decision tree (DT), and (E) a custom strategy and for the VTD test set using (F) VisioCyt, (G) RFM, (H) LR, (I) DT, and (J) a custom strategy.

The first element to be noted is that combinations of the image-based model and RFM resulted in better performances in terms of AUC independent of the combination strategy (LR, DT, or custom). Indeed, the AUCs were higher for the training set (0.82 for LR and custom and 0.81 for DT vs 0.79 for VisioCyt and 0.7 for RFM) and higher or equivalent on the test set (0.86 for LR, 0.81 for DT, and 0.83 for custom vs 0.81 for VisioCyt and RFM). In the light of these sole observations, it was difficult to define the most relevant approach between LR, DT, and custom. To explore this further, we proposed studying boxplots of the VisioCyt, CBM, DT, and custom scores on the VTD training and test sets.

The median values of the scores obtained with LR were distinct for the 3 groups: (1) for patients without bladder cancer: 0.28 on the training set and 0.23 on the test set; (2) for patients with low-grade cancer: 0.68 on the training set and 0.72 on the test set; (3) for patients with high-grade cancer: 0.80 on the training set and 0.81 on the test set. The positive effect of this combination was a slight reduction in the overlap of scores

XSL•FO
RenderX



between low-grade patients and those without cancer observed with VisioCyt. However, the IQRs remained quite wide.

The median DT scores showed that DT scores were well separated for patients without (0.30) and with bladder cancer (0.84 for low-grade cancer and 0.78 for high-grade cancer). At first glance, these scores appeared to be more discriminating than the VisioCyt score alone. However, on the test set, IQRs of the DT scores were null for no bladder cancer and equivalent for low-grade and high-grade cancers, which does not allow for continuity in the measurements. This behavior does not allow for accurate interpretation. The doubt about this behavior was confirmed by the fact that the DT scores obtained for these patients during training resulted in a high IQR of 0.42, making it difficult to be sure that patients with low-grade cancer will be correctly associated with a high score. This edge effect also arose because a tree depth of 2 was selected during hyperparameter tuning, limiting the model's capacity to create more granular splits and accurately differentiate between subgroups in the population.

Regarding the custom approach, the scores associated with low-grade cancer (0.86 on the training set and 0.86 on the test set) and high-grade cancer (0.95 on both sets) were higher than the scores for patients without bladder cancer (0.47 on the training set and 0.34 on the test set). The range of scores for high-grade cancer was narrower with custom than with VisioCyt, indicating that several scores were improved and increased. Regarding patients with low-grade cancer, the median scores were higher with custom (eg, 0.89 on the test set) than with VisioCyt (eg, 0.83 on the test set). In addition, on the test and training sets, the overlap between scores for no bladder cancer patients and for patients with low-grade cancer was weaker than for VisioCyt scores for no cancer. The latter scores were also higher but remained distinct from those of the other 2 categories.

In light of these observations, the custom combination seems to be the most effective approach. The 95% CIs for the output scores were 0.33 to 0.52 for no bladder cancer, 0.68 to 0.83 for low-grade cancer, and 0.8 to 0.91 for high-grade cancer in the test set. The main advantage of the custom combination was improved detection of patients with low-grade cancer and increased certainty of the presence of high-grade cancer. One patient in each category was randomly drawn from the test set to illustrate what may be provided to clinician decision-making (Figure 8).

Figure 8. Illustration of the scores given by VisioCyt, the risk factor–based model (RFM), and the custom model for 3 patients in the VisioCyt 1 Trial Dataset (VTD) test set.

For patient 1, who did not have bladder cancer, the 2 initial scores were quite equivalent: 28% for VisioCyt and 24% for RFM. This also resulted in a low combined risk (28%). For patient 2, who had low-grade bladder cancer, the Visiocyt score was 57%, and the RFM score was 90%, giving a combined score of 73%. For patient 3, who had high-grade bladder cancer, the VisioCyt score was 88%, and the RFM score was 80%, leading to a combined score of 88%. The behaviors of the scores for these 3 patients were well in line with their actual diagnoses.

Although our goal was to create a decision support tool, not a bladder cancer detector, we evaluated the sensitivity and specificity by evaluating the thresholds of the scores obtained with the custom approach. The optimal cut-off point, which maximized the difference between true and false positive rates, was identified through ROC curve analysis. This yielded a threshold of 0.61 which results in 81% sensitivity and 73% specificity on the training set and 76% sensitivity and 83% specificity on the test set.

Discussion

Principal Findings

In this study, our team aimed to reuse large-scale clinical data to improve the performance of an image-based model to predict bladder cancer.

As a first step, an RFM was developed using clinical features from 5422 patients whose data were extracted from the CDW. Clinical features were selected because they were identified as important risk factors in the literature. The best RFM, based on LR, succeeded, with an AUC of 0.74, at classifying patients with or without bladder cancer from clinical features. The most predictive factors were age, sex, and smoking status (active or former). We also saw that risk factors such as COPD, professional exposure, and family history of bladder cancer, when combined with age, impacted the model's predictions. This model is simple and easily interpretable, successfully passing both internal (mean AUC 0.72, SD 0.02 during cross-validation and 0.74 on the CDRD test set) and external (AUC 0.81 on the VTD test set) validation tests.

In the second step, several combinations of this model with an image-based model were proposed. Classical approaches based

XSL•FO
RenderX

on LR and DT were proposed and supplemented by a custom approach grounded in RFM and VisioCyt score interpretation. We saw that all combinations gave a better AUC than RFM or VisioCyt alone. However, to identify the best combination, we stratified the performance by grade and chose the one that improved low-grade bladder cancer detection. The custom method (with an AUC of 0.83 on the VTD test set) provided the best results by assigning a median score of 0.34 to patients with no cancer, 0.86 to patients with low-grade cancer, and 0.95 to patients with high-grade cancer. Finally, we proposed observing the VisioCyt, RFM, and custom scores for 3 randomly selected patients, 1 from each of the 3 categories.

The resulting scores are supplementary and hold potential for enhancing the decision-making process. Indeed, they offer valuable insight into the patient's clinical profile, further improving image-based tools. Although the AUC bears resemblance to the figures observed in the studies conducted by Sanghvi et al [14] and Awan et al [15] (ie, 0.80 and 0.81, respectively), direct comparison was not feasible due to the focus on patients with high-grade cancer in those studies, which did not encompass an evaluation of performance for patients with low-grade cancer. Nevertheless, it is essential to underscore that the RFM is not designed for competitive purposes but rather to serve as a complementary component to these tools, much in the same manner as it did with VisioCyt. Combining RFM with these models may result in an even more robust composite score.

These results show the value of reusing data to propose better bladder cancer scoring strategies. Indeed, the strength of learning on thousands of patients has allowed us to propose a model that enhances the scoring by an image-based model for more accurate identification of patients with low-grade cancer.

Limitations

Some limitations of this work should be noted. First, the multiple missing values during clinical feature extraction raise concerns about the quality of the process. Multimedia Appendix 1 provides insight on the availability of each feature before imputation. This is an inherent problem in data reuse, which is not the primary purpose of the collection, because the information is not collected by default. Indeed, we are uncertain if these concepts are consistently present in all patient documents, as some data are recorded subjectively by clinicians. This is particularly true for variables such as COPD or a family history of cancer, features for which our data collection was limited in this study.

However, sometimes the information may still be hidden in unstructured data, which we are unable to exploit today. We used relatively straightforward extraction methods, possibly resulting in incomplete information retrieval from the reports. To address this, we plan to explore more advanced natural language processing methods like bilateral long short-term memory models or large language models [28], but their implementation and evaluation will be challenging due to limited annotations of the specific clinical concepts we sought to extract and the criticality of the confidentiality of electronic health records.

This last point could explain why we obtained feature distributions in CDRD that were sometimes different from those in VTD. However, they also may be explained by the fact that CDRD is larger than VTD since it includes a broader population. In fact, the percentage of patients with cancer was higher in VTD (66%) than in CDRD (25%). Overall, both data sets had the same characteristics, and most of the features were significant for bladder cancer detection. Some differences were nevertheless observed, and we will have to remain vigilant on these variables (ie, never smoked, stroke). We also observed the opposite behavior to what might be expected for diabetes and stroke in the RFM. Hypertension, though recognized as important in the literature, was not considered by the model. These are elements that deserve to be studied in greater detail once extraction methods are more robust.

Moreover, only 29 features were used, and they were often binary. Obtaining more complete information by either adding other clinical features (ie, biological measurement) or using a finer scale (ie, the type of diabetes or the number of cigarettes smoked per day) is an improvement not to be neglected and may increase the specificity of RFM. The same strategy can be used to refine the target. Indeed, it may be relevant to classify patients according to grade rather than in a binary way. Similarly, the proposed model was only based on features that we found to be linked with bladder cancer in the literature, but it will be interesting to add other comorbidities that may be cofounding factors (such as having another type of cancer).

In addition, we observed that the custom approach worked best. Within one of the defined score intervals, a simple average of the 2 scores was performed. A weighting may be integrated to fuse scores through an optimal fusion strategy [29].

Finally, although we carefully evaluated our models with regards to our available data sets, a concern for generalization may be observed later since only 1 data set with both cytology and clinical data (VTD) was investigated. First, we expect to enrich our RFM model by working on all the Hugo network's health data warehouses [24]. We also intend to deploy the combined model on new data to verify its stability and ensure relevance in routine care. Indeed, at the moment, the proposed combination has not yet been tested and approved by clinicians. However, it is important to consider that the collection of cytology images associated with clinical data requires the implementation of new acquisition protocols and that it will require time.

Conclusions

The results of this study are encouraging. This is the first time that the contribution of a prediction model based on risk factors identified in the literature and on the reuse of massive data has been studied. We observed that it can reinforce recent tools such as urine cytology–based models. Specifically, it may improve low-grade bladder cancer detection.

Abstract

Background: Gastrointestinal bleeding (GIB) is a severe and potentially life-threatening complication in patients with acute myocardial infarction (AMI), significantly affecting prognosis during hospitalization. Early identification of high-risk patients is essential to reduce complications, improve outcomes, and guide clinical decision-making.

Objective: This study aimed to develop and validate a machine learning (ML)–based model for predicting in-hospital GIB in patients with AMI, identify key risk factors, and evaluate the clinical applicability of the model for risk stratification and decision support.

Methods: A multicenter retrospective cohort study was conducted, including 1910 patients with AMI from the Affiliated Hospital of Guangdong Medical University (2005-2024). Patients were divided into training (n=1575) and testing (n=335) cohorts based on admission dates. For external validation, 1746 patients with AMI were included in the publicly available MIMIC-IV (Medical Information Mart for Intensive Care IV) database. Propensity score matching was adjusted for demographics, and the Boruta algorithm identified key predictors. A total of 7 ML algorithms—logistic regression, k-nearest neighbors, support vector machine, decision tree, random forest (RF), extreme gradient boosting, and neural networks—were trained using 10-fold cross-validation. The models were evaluated for the area under the receiver operating characteristic curve, accuracy, sensitivity, specificity, recall, F_1_score, and decision curve analysis. Shapley additive explanations analysis ranked variable importance. Kaplan-Meier survival analysis evaluated the impact of GIB on short-term survival. Multivariate logistic regression assessed the relationship between coronary heart disease (CHD) and in-hospital GIB after adjusting for clinical variables.

Results: The RF model outperformed other ML models, achieving an area under the receiver operating characteristic curve of 0.77 in the training cohort, 0.77 in the testing cohort, and 0.75 in the validation cohort. Key predictors included red blood cell count, hemoglobin, maximal myoglobin, hematocrit, CHD, and other variables, all of which were strongly associated with GIB risk. Decision curve analysis demonstrated the clinical use of the RF model for early risk stratification. Kaplan-Meier survival analysis showed no significant differences in 7- and 15-day survival rates between patients with AMI with and without GIB (P=.83 for 7-day survival and P=.87 for 15-day survival). Multivariate logistic regression showed that CHD was an independent risk factor for in-hospital GIB (odds ratio 2.79, 95% CI 2.09-3.74). Stratified analyses by sex, age, occupation, marital status, and other subgroups consistently showed that the association between CHD and GIB remained robust across all subgroups.

XSL•FO
RenderX

Conclusions: The ML-based RF model provides a robust and clinically applicable tool for predicting in-hospital GIB in patients with AMI. By leveraging routinely available clinical and laboratory data, the model supports early risk stratification and personalized preventive strategies.

KEYWORDS

acute myocardial infarction; gastrointestinal bleeding; machine learning; in-hospital; prediction model

Introduction

Acute myocardial infarction (AMI) remains one of the leading causes of mortality worldwide and is a significant contributor to long-term disability and health care resource use [1]. Nosocomial gastrointestinal bleeding (GIB), as a common complication of patients with AMI, may lead to a large number of morbidity and mortality and remains one of the key factors affecting the prognosis of patients [2,3]. The high incidence and profound clinical implications of GIB have made it a focal point of concern in the management of patients with AMI [4].

Existing studies have established a close association between AMI and the occurrence of GIB, particularly in patients undergoing antiplatelet or anticoagulant therapy [5]. In patients with AMI, the development of GIB not only complicates in-hospital treatment but also markedly increases mortality rates during hospitalization [6]. However, the precise mechanisms underlying GIB in patients with AMI have yet to be fully elucidated. Potential mechanisms include gastrointestinal mucosal injury induced by anticoagulant therapy, stress-related ulceration, and inflammatory responses [7,8]. In addition, underlying comorbidities such as coronary heart disease (CHD), diabetes mellitus, and hypertension may also play significant roles in the development of GIB [9,10].

Although several studies have investigated the incidence and clinical manifestations of GIB in patients with AMI, there is still a lack of systematic analysis regarding its potential risk factors [11]. Previous research has identified common risk factors for GIB in patients with AMI, including anemia, renal insufficiency, advanced age, and polypharmacy [12,13]. However, many of these studies rely on traditional univariate or multivariate statistical methods, which may be limited in addressing the complexity of multifactorial interactions [14]. With the increasing application of machine learning (ML) methods in medical research, there is an opportunity to leverage advanced algorithms for more precise prediction and identification of GIB risk factors in patients with AMI.

In this real-world study, we aimed to integrate ML methods with traditional statistical analysis to comprehensively evaluate the risk factors for in-hospital GIB in patients with AMI. The objectives were to develop and validate an effective predictive model and to assess the impact of GIB on short-term prognosis, ultimately providing more robust guidance for clinical practice.

Methods

Data Source

Participants were retrospectively included based on their admission to the Affiliated Hospital of Guangdong Medical University between January 2005 and June 2024. A total of 10,046 patients with AMI were initially screened for eligibility. Patients were excluded if they had a history of GIB within 1 month before admission or if more than 20% of their data were missing. After applying these criteria, 1910 eligible patients with AMI were included (more details in the patient selection flowchart in the *Results* section). The cohort was divided based on the admission date: patients admitted before January 1, 2023, were assigned to the training cohort (n=1575), and those admitted after this date were included in the testing cohort (n=335).

Data for external validation were extracted from the publicly available, single-center Medical Information Mart for Intensive Care IV (MIMIC-IV) database (version 3.0). A total of 1801 patients with AMI from MIMIC-IV were initially screened. After applying the same exclusion criteria as in the training cohort, a total of 1746 patients with AMI were included in the external validation cohort. The Beth Israel Deaconess Medical Center and the Massachusetts Institute of Technology have approved MIMIC-IV. The diagnosis of AMI was based on the *Fourth Universal Definition of Myocardial Infarction*, including both ST-segment elevation (ST elevation) and non–ST-segment elevation (non-ST elevation) AMI. GIB was defined as a clinically significant bleeding event diagnosed by a physician (manifesting as coffee-ground emesis, hematemesis, melena, or hematochezia) or the presence of blood in the upper or lower gastrointestinal tract identified during endoscopic evaluation.

Data and Variables

The extracted variables included demographic characteristics, duration of hospital stay, discharge status, basic vital signs, and laboratory parameters. Cardiac injury biomarkers were recorded at their peak levels. Blood and biochemical test results were collected on the first day of admission. In cases where multiple test results were available for a specific variable, the first measurement was used in the analysis.

Model Construction and Validation

The Boruta algorithm was used in this study to select significant variables from the training dataset. Boruta is a feature selection method based on random forests (RFs) that determines the importance of each variable by comparing its *z* score with that of its “shadow” counterparts [15]. During the algorithm’s execution, all real features were duplicated and randomly

XSL•FO
RenderX

shuffled to generate *z* scores. If a real feature's *z* score consistently exceeded the maximum *z* score of the shadow features across multiple independent tests, it was deemed important and included in subsequent ML model construction.

The important variables screened by the Boruta algorithm were incorporated into 7 different ML algorithms for model construction, including logistic regression (LR), k-nearest neighbor (KNN), support vector machine (SVM), decision tree (DCtree), RF, extreme gradient boosting (XGBoost), and artificial neural network (NNET) [16]. Hyperparameter tuning was conducted using grid search combined with 10-fold cross-validation to optimize the performance of all ML models. Key parameters such as the number of trees, maximum tree depth, and minimum samples per leaf were systematically varied during the grid search. To prevent overfitting, the dataset was divided into 10 folds, with 9 folds used for training and 1 fold for validation. This process was repeated across all folds to identify the combination of hyperparameters that yielded the highest area under the curve (AUC).

The model with the highest area under the receiver operating characteristic (ROC) curve was selected to determine model performance. Model discrimination was further assessed using sensitivity, specificity, recall, accuracy, and F_1-score metrics. Decision curve analysis (DCA) was conducted to evaluate the clinical use of the models [17]. The best-performing model was subsequently used for further interpretive analysis. After training the model on the training cohort, all model parameters were fixed, and the model's performance was further evaluated using the testing and validation cohort.

To better understand the decision-making process of the best-performing model, Shapley additive explanations (SHAP) were used [18]. Based on cooperative game theory's Shapley values, SHAP rationally allocates contributions to the model's output among individual input features. SHAP also reveals feature importance and visually displays the direction and magnitude of each feature's contribution to the predictive outcome, thereby providing a deep understanding of the model's decision-making process. In this study, SHAP analysis was instrumental in identifying risk factors associated with GIB in patients with AMI and evaluating their consistency and accuracy in clinical applications using the testing and validation cohort.

Statistical Analysis

Multiple imputation was used to address missing data, including variables with a missing ratio of less than 20%. Continuous variables were expressed as medians and IQRs, while categorical variables were expressed as total numbers and percentages. Chi-square (χ^2) tests, Wilcoxon rank-sum tests, or Fisher exact tests were used as appropriate. For survival analysis, Kaplan-Meier curves were used. Logistic regression analysis was also performed to evaluate the association between CHD and the occurrence of GIB in patients with AMI. Propensity score matching (PSM) was also conducted using the nearest neighbor method with a 1:1 ratio without replacement and a caliper width of 0.15. The analyses were performed using R software (R Foundation for Statistical Computing; version 4.2.2). Statistical significance was determined by a 2-tailed *P* value of less than .05.

Ethical Considerations

This study was approved by the Institutional Review Board of the Affiliated Hospital of Guangdong Medical University (approval PJKT2024-176). The study used deidentified, retrospective clinical data, and informed consent was waived as the original consent obtained during initial data collection included provisions for secondary analysis. All patient data were anonymized, and confidentiality was strictly maintained. For the external validation cohort, database access was granted upon the completion of an online course and exam. As this portion of the study used a publicly accessible, deidentified database, informed consent was not required. Both data sources complied with all applicable ethical guidelines and privacy protection standards. The data from the training and testing cohorts were anonymized, eliminating the need for informed consent. In addition, the health information obtained from the MIMIC-IV database was deidentified, and therefore, patient consent was not required.

Results

Comparative Analysis of Clinical Profiles in Patients With AMI With and Without In-Hospital GIB

A total of 1575 patients with AMI were included in the training cohort (Figure 1), of whom 775 experienced in-hospital GIB. To minimize potential confounding factors, PSM was performed on variables such as sex, occupation, blood type, marital status, age, and length of hospital stay, achieving a balanced distribution of these selected characteristics between the groups. Table 1 compares the baseline characteristics before and after matching. After PSM, no statistically significant differences were observed between the groups for the matched variables (*P*>.05), indicating that the matching process effectively reduced confounding bias.

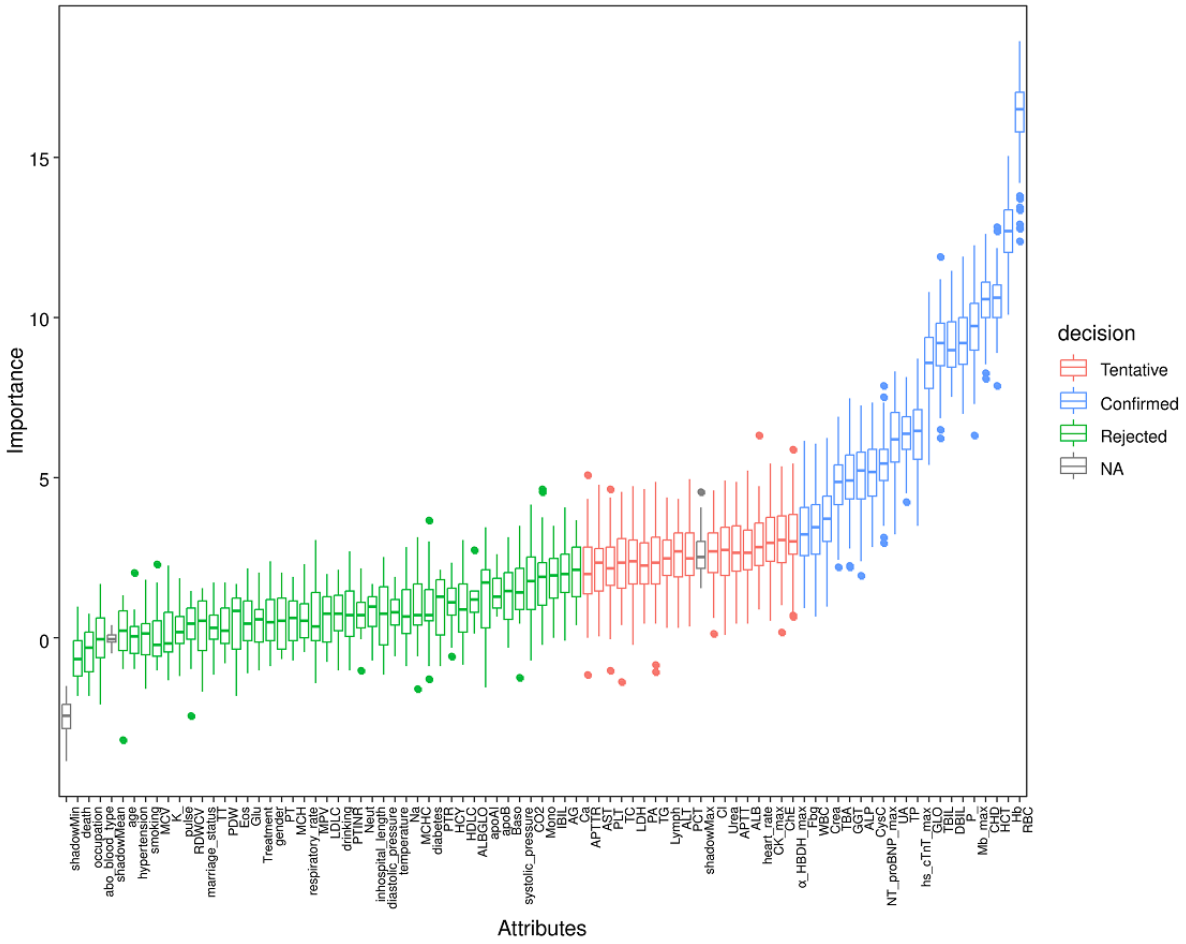
[a]GIB: gastrointestinal bleeding.

The detailed demographic and baseline clinical characteristics of the PSM-adjusted training cohort are summarized in Table S1 in Multimedia Appendix 1. The results revealed significant differences in several laboratory parameters between patients with and without GIB. Specifically, patients with GIB exhibited significant differences in red blood cell count (RBC), hemoglobin, gamma-glutamyl transferase (GGT), total bilirubin (TBIL), direct bilirubin (DBIL), indirect bilirubin, albumin, total protein (TP), calcium, chloride, phosphorus, and N-terminal pro-brain natriuretic peptide maximum (NT-proBNP max), suggesting distinct clinical profiles related to anemia,

XSL•FO
RenderX

cardiovascular status, liver function, electrolyte imbalance, and coagulation function.



The analysis suggests that patients with AMI who experience in-hospital GIB may have distinct clinical profiles, particularly in terms of anemia, cardiovascular health, liver function, electrolyte balance, and coagulation, which could inform more targeted management strategies.

Key Predictor Identification Using Boruta Algorithm for In-Hospital GIB Risk in Patients With AMI

To identify key variables associated with GIB occurrence in patients with AMI, the Boruta algorithm was used for feature selection. Figure 2 illustrates the *z* scores of each variable, demonstrating how this analysis enhanced model optimization by concentrating on the most relevant features. A total of 20 variables were identified as important, including CHD, white blood cell count, RBC, hematocrit, hemoglobin, GGT, TBIL, DBIL, globulin, TP, total bile acids, creatinine, uric acid, phosphorus, alkaline phosphatase, cystatin C, fibrinogen, NT-proBNP max, maximal myoglobin, and maximal high-sensitivity cardiac troponin T, indicating their strong explanatory power in predicting GIB occurrence.

These variables were incorporated as primary predictors in the subsequent model construction and analysis, providing a solid foundation for developing predictive models.

Figure 2. Feature selection for predicting gastrointestinal bleeding in patients with acute myocardial infarction using the Boruta algorithm. The horizontal axis displays the names of each variable, while the vertical axis displays the corresponding z scores of each variable. The box plot shows the z score of each variable during model calculation. The blue boxes represent important variables, the red represents tentative variables, and the green represents rejected variables. The RF Model Outperforms Other ML Models in Predicting In-Hospital GIB in Patients With AMI

The performance of 7 ML models in predicting GIB in patients with AMI was compared, and their ROC curves and DCA results were presented for the training cohort (Figure 3). The ROC curves (Figure 3A) demonstrate the discriminative ability of the various models, with the RF model achieving the highest AUC value (0.77, outperforming the others. The XGBoost (0.74) and SVM (0.72) models followed, while the DCtree model performed the poorest, with an AUC of 0.66. DCA (Figure 3B) assessed the clinical use of the models, further confirming that the RF model provided the highest net benefit across most threshold ranges, particularly within the intermediate range, highlighting its superiority in predicting GIB. The RF model demonstrated the best overall performance, with the highest AUC and net benefit, indicating its superior predictive capability for GIB. While other models, such as XGBoost and SVM, also performed well in certain scenarios, they were overall less effective than the RF model.

Figure 3. (A) Receiver operating characteristic curve and (B) decision curve analyses for 7 machine learning models predicting gastrointestinal bleeding in patients with acute myocardial infarction (training cohort). DCtree: decision tree; KNN: k-nearest neighbors; LR: logistic regression; NNET: neural network; RF: random forest; SVM: support vector machine; XGBoost: extreme gradient boosting.

Further detailed performance metrics for each model, including sensitivity, specificity, recall, accuracy, and F_1-score, are provided in Table 2. The RF model emerged as the top performer, with an accuracy of 0.66; an F_1-score of 0.65; and balanced recall and specificity of 0.64 and 0.67, respectively, indicating its strong ability to distinguish between patients with and without GIB. The XGBoost model excelled in specificity, reaching 0.73, but its recall was lower at 0.58, resulting in an overall accuracy of 0.65 and an F_1-score of 0.62. The SVM model achieved the highest recall (0.73) but suffered from low specificity (0.45), yielding an overall accuracy of 0.59 and an F_1-score of 0.64. In contrast, the LR and KNN models exhibited similar performance, with accuracies of 0.61 and 0.60 and balanced recall and specificity around 0.60, reflecting moderate ability in distinguishing patients with GIB. The DCtree model reached a specificity of 0.73 but had lower recall (0.51), leading to an overall accuracy of 0.62 and an F_1-score of 0.57. The NNET model performed the worst, with an accuracy of only 0.55 and an F_1-score of 0.52, suggesting it may not be suitable for GIB prediction in this dataset.

Table 2. Performance comparison of machine learning models for predicting gastrointestinal bleeding in the training cohort.

Model	Accuracy	Sensitivity	Specificity	Recall	F_1_score
RF[a]	0.66	0.64	0.67	0.64	0.65
XGBoost[b]	0.65	0.58	0.73	0.58	0.62
SVM[c]	0.59	0.73	0.45	0.73	0.64
NNET[d]	0.55	0.49	0.62	0.49	0.52
KNN[e]	0.60	0.60	0.60	0.60	0.60
LR[f]	0.61	0.61	0.60	0.61	0.61
DCtree[g]	0.62	0.51	0.73	0.51	0.57

[a]RF: random forest.

[b]XGBoost: extreme gradient boosting.

[c]SVM: support vector machine.

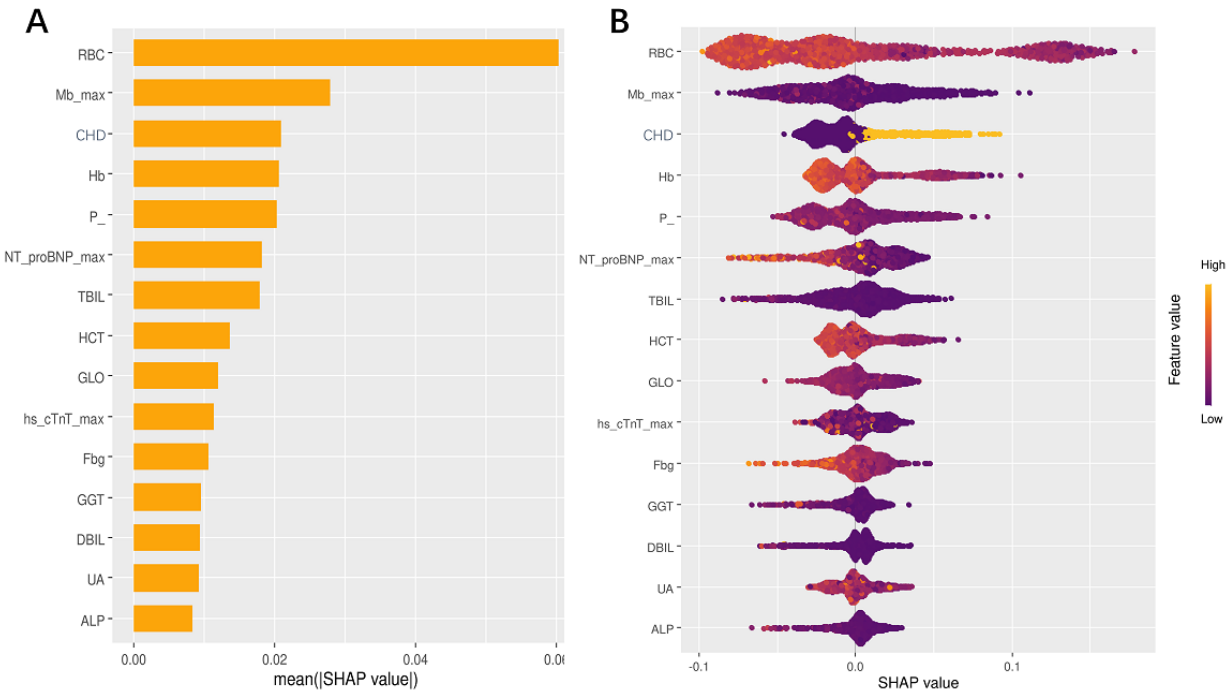
[d]NNET: neural network.

[e]KNN: k-nearest neighbors.

[f]LR: logistic regression.

[g]DCtree: decision tree.

Additional evaluations were conducted using both the testing and validation cohorts to assess the robustness of the models (Figures S1 and S2 in Multimedia Appendix 1; Tables S2 and S3 in Multimedia Appendix 1). The model's performance was consistent, with an ROC value of 0.77 in the testing cohort and 0.75 in the validation cohort, demonstrating its generalizability and reliability across different datasets.



Overall, the RF model consistently outperformed other ML models in both predictive accuracy and clinical use, making it the most reliable tool for predicting in-hospital GIB in patients with AMI across multiple datasets.

SHAP Analysis Quantifies Feature Contributions to In-Hospital GIB Risk in Patients With AMI

The SHAP analysis was used to interpret the predictions of the best-performing model, the RF. SHAP analysis highlighted the impact of 15 key features on the GIB prediction model in patients with AMI, ranked by SHAP values (Figure 4A). Features with positive SHAP values were associated with higher predicted GIB risk, while negative SHAP values indicated a lower risk. Darker colors represent decreases, while lighter colors indicate increases in the respective parameters, with all predictive factors positively correlated with GIB. The SHAP analysis also emphasized the importance of specific variables and provided insights into their directional influence on the prediction outcomes. RBC exhibited the strongest predictive influence, with lower values significantly increasing the predicted risk, followed by myoglobin maximum, CHD, hemoglobin, phosphorous, and NT-proBNP max, which also contributed to the prediction. TBIL and hematocrit further demonstrated their significance in the model. Other influential features included globulin, highly sensitive cardiac troponin T maximum, fasting blood glucose, GGT, DBIL, uric acid, and alkaline phosphatase. With varying SHAP values, these features illustrated their multidimensional impact within the predictive model (Figure 4B).

XSL•FO
RenderX

Figure 4. (A) SHAP (Shapley additive explanations) analysis of the top-15 predictors for gastrointestinal bleeding (GIB) in patients with acute myocardial infarction (AMI) using a random forest model ranked by mean absolute SHAP value, and (B) the impact of SHAP values on the occurrence of GIB in patients with AMI. ALP: alkaline phosphatase; CHD: coronary heart disease; DBIL: direct bilirubin; Fbg: fibrinogen; GGT: gamma-glutamyl transferase; GLO: globulin; HCT: hematocrit; Hb: hemoglobin; Hs cTnT Max: high-sensitivity cardiac troponin T maximum; Mb max: myoglobin maximum; NT proBNP max: N-terminal pro b-type natriuretic peptide maximum; P: phosphorus; RBC: red blood cell; TBIL: total bilirubin; UA: uric acid.

These features provided insights into the driving factors for GIB occurrence in patients with AMI, playing a crucial role in GIB prediction and understanding the underlying mechanisms. Notably, the SHAP values for CHD history indicated that an increase in this variable significantly heightened the risk of GIB, suggesting that CHD may play a crucial role in the pathophysiological mechanisms underlying GIB.

Kaplan-Meier Analysis Shows No Significant Impact of GIB on Short-Term Survival in Patients With AMI

To assess the impact of GIB on short-term survival in patients with AMI, a Kaplan-Meier survival analysis was performed. Figure S3 in Multimedia Appendix 1 shows the survival curves for patients with and without GIB at 7 and 15 days. The results indicated that while overall survival rates were lower in the GIB group compared to the non-GIB group, the differences did not reach statistical significance (P=.83 for 7-day survival and P=.87 for 15-day survival). This suggests that in the study population, the occurrence of GIB did not significantly affect short-term survival in patients with AMI.

These findings suggest that while GIB is associated with lower survival rates, it does not significantly influence short-term mortality in patients with AMI within the study population.

CHD Identified as a Significant Predictor of In-Hospital GIB Risk in Patients With AMI

Multivariate logistic regression was used to analyze further the association between CHD and in-hospital GIB in patients with AMI. The results, presented in Table 3, showed a significant association between CHD and the occurrence of GIB during hospitalization. In the unadjusted crude model, CHD was significantly positively associated with GIB (odds ratio [OR] 2.88, 95% CI 2.29-3.63; P<.001). After PSM, the association remained significant, with the OR slightly reduced to 2.50 (95% CI 1.98-3.17; P<.001). Even after stepwise adjustment for additional confounding variables, including sex, occupation, ABO blood type, marital status, age, and length of hospital stay (Model 1), hypertension, diabetes, smoking, alcohol consumption, body temperature, pulse, heart rate, respiratory rate, blood pressure (Model 2), and all laboratory parameters (Model 3), the significant association between CHD and GIB persisted. The OR values remained consistent across the different models, all retaining statistical significance (P<.001), indicating that CHD is an important risk factor for GIB during hospitalization in patients with AMI.

Furthermore, Figure 5 presents the results of subgroup analysis and interaction tests conducted using the LR model to further explore the moderating effects of various characteristics on the relationship between CHD and GIB. Stratified analyses by sex, age, occupation, marital status, and other subgroups consistently showed that the association between CHD and GIB remained robust across all subgroups. This underscores the generalizability of CHD as a significant risk factor for GIB in patients with AMI, highlighting the importance of considering this risk factor in diverse patient populations.

Discussion

Principal Findings

This study systematically analyzes the risk factors associated with GIB in patients with AMI. Using the Boruta algorithm, significant variables were selected and compared across various ML models to construct an effective RF model for predicting GIB occurrence. This research not only enhances understanding of the mechanisms behind GIB in patients with AMI but also provides clinicians with a robust predictive tool aimed at reducing patient complications. In addition, Kaplan-Meier survival analysis was used to assess GIB's impact on short-term survival rates and analyze the association between CHD and GIB, as well as its prognosis implications.

Comparison With Previous Work

In comparison with existing literature, our study exhibits several unique advantages. First, we found that patients with GIB had significantly lower RBC, hemoglobin, and multiple liver function indicators compared to patients without GIB, aligning with previous research findings [19,20]. For instance, Martí et al [21] similarly identified anemia and hepatic dysfunction as pivotal risk factors for GIB in patients with AMI. Furthermore, Holster et al [22], through systematic review and meta-analysis, underscored the heightened risk of GIB associated with anticoagulant use, particularly among patients with underlying hepatic or hematologic conditions. This study further substantiates the significance of these factors through multivariable analysis and enhances prediction accuracy using ML methods. However, models from different studies exhibit variability in predicting GIB occurrence. For example, Chin et al [23] model heavily relies on traditional multivariable regression analysis, identifying significant risk factors such as advanced age, renal impairment, and anticoagulant use, albeit with limited predictive performance [23]. In contrast, our study's adoption of the Boruta algorithm for feature selection and integration of the RF model not only enhances model robustness but also significantly improves predictive performance with an AUC value of 0.771. This underscores the capability of ML methods to offer precise risk prediction when handling complex, high-dimensional data.

Furthermore, through multivariable logistic regression analysis, this study further confirms a significant association between CHD and GIB occurrence, which persists even after adjusting for various confounding factors. Consistent with previous research, this suggests that patients with CHD may face increased GIB risk due to heightened inflammatory response and the necessity for anticoagulant therapy [24]. Subgroup analysis underscores the consistent impact of CHD across different patient demographics, emphasizing the need for heightened management attention, particularly in administering antiplatelet and anticoagulant therapies, which may necessitate stricter monitoring and personalized adjustments [25,26]. Kaplan-Meier survival analysis results indicate that although GIB is a common complication in patients with AMI, it does not significantly impact short-term survival rates. This finding aligns with the observations by Nikolsky et al [27] in patients after coronary artery bypass graft, suggesting minimal short-term prognosis effects among actively treated patients [27]. However, this does not negate the potential long-term impacts of GIB on patient outcomes, warranting further investigation.

Strengths and Limitations

This study represents an innovative application of ML techniques to predict GIB in patients with AMI, integrating both clinical and laboratory data. The multicenter design, coupled with external validation using the MIMIC-IV database, enhances the generalizability of the findings across diverse patient populations. Robust validation methods, including PSM and the use of independent datasets, further strengthen the reliability of the predictive models and mitigate potential biases.

This study has several limitations that should be acknowledged. First, although it used a multicenter retrospective cohort design, the sample size may still be insufficient to fully capture the variability and complexity of GIB in patients with AMI. External validation using the MIMIC-IV database partially mitigates this limitation by increasing the generalizability of the findings. However, larger, multicenter prospective studies are needed to further validate these results across diverse populations. Second, some important variables, such as dietary habits and medication adherence, were not included in the analysis. These unmeasured confounding factors could influence the occurrence of GIB and limit the comprehensiveness and clinical applicability of the model. Incorporating additional predictors, such as dietary habits, medication adherence, and genetic markers, in future studies could enhance the model's accuracy and provide a more holistic understanding of GIB risk. Third, the retrospective nature of the study introduces inherent limitations, including potential selection bias and reliance on existing medical records, which may include missing or incomplete data. In addition, in datasets where the limit of detection is an important factor, alternative imputation methods, such as minimal imputation, may provide more accurate processing of missing data. While this is not the main focus of this study, future studies could explore advanced imputation techniques tailored to specific missing mechanisms to improve the robustness of predictive models. To address this, PSM was applied to minimize confounding factors, and multiple imputation techniques were used to handle missing data. Despite these efforts, prospective studies with real-time clinical data collection would provide stronger evidence, reduce bias, and further validate the findings. In addition, leveraging advanced ML techniques and incorporating real-time clinical data may improve the model's predictive performance and facilitate early intervention for high-risk patients.

Conclusion

In summary, ML models, particularly the RF model, offer reliable tools for predicting GIB in patients with AMI and lay the groundwork for future research into its pathophysiology and prevention.

Abstract

Background: Septic shock (SS) is a syndrome with high mortality. Early forewarning and diagnosis of SS, which are critical in reducing mortality, are still challenging in clinical management.

Objective: We propose a simple and fast risk-stratified forewarning model for SS to help physicians recognize patients in time. Moreover, further insights can be gained from the application of the model to improve our understanding of SS.

Methods: A total of 5125 patients with sepsis from the Medical Information Mart for Intensive Care-IV (MIMIC-IV) database were divided into training, validation, and test sets. In addition, 2180 patients with sepsis from the eICU Collaborative Research Database (eICU) were used as an external validation set. We developed a simplified risk-stratified early forewarning model for SS based on the weight of evidence and logistic regression, which was compared with multi-feature complex models, and clinical characteristics among risk groups were evaluated.

Results: Using only vital signs and rapid arterial blood gas test features according to feature importance, we constructed the Septic Shock Risk Predictor (SORP), with an area under the curve (AUC) of 0.9458 in the test set, which is only slightly lower than that of the optimal multi-feature complex model (0.9651). A median forewarning time of 13 hours was calculated for SS patients. 4 distinct risk groups (high, medium, low, and ultralow) were identified by the SORP 6 hours before onset, and the incidence rates of SS in the 4 risk groups in the postonset interval were 88.6% (433/489), 34.5% (262/760), 2.5% (67/2707), and 0.3% (4/1301), respectively. The severity increased significantly with increasing risk in both clinical features and survival. Clustering analysis demonstrated a high similarity of pathophysiological characteristics between the high-risk patients without SS diagnosis (NS_HR) and the SS patients, while a significantly worse overall survival was shown in NS_HR patients. On further exploring the characteristics of the treatment and comorbidities of the NS_HR group, these patients demonstrated a significantly

XSL•FO
RenderX

higher incidence of mean blood pressure <65 mmHg, significantly lower vasopressor use and infused volume, and more severe renal dysfunction. The above findings were further validated by multicenter eICU data.

Conclusions: The SORP demonstrated accurate forewarning and a reliable risk stratification capability. Among patients forewarned as high risk, similar pathophysiological phenotypes and high mortality were observed in both those subsequently diagnosed as having SS and those without such a diagnosis. NS_HR patients, overlooked by the Sepsis-3 definition, may provide further insights into the pathophysiological processes of SS onset and help to complement its diagnosis and precise management. The importance of precise fluid resuscitation management in SS patients with renal dysfunction is further highlighted. For convenience, an online service for the SORP has been provided.

septic shock; early forewarning; risk stratification; machine learning

Introduction

Sepsis is a syndrome or group of symptoms associated with infection rather than a single disease [1]. Reportedly, approximately 48.9 million cases of sepsis occurred globally in 2017, with approximately 11 million sepsis-related deaths, accounting for approximately 19.7% of all deaths worldwide [2]. According to the Third International Consensus on Sepsis and Septic Shock held in 2016 [1], sepsis is defined as life-threatening organ dysfunction caused by a dysregulated host response to infection, and septic shock (SS) is defined as an advanced state of sepsis in which severe circulatory, cellular, and metabolic abnormalities lead to a greater risk of death than sepsis alone, with a mortality rate estimated to be as high as 45% [3,4]. Kumar et al [5] found that patients with SS treated within the first hour of diagnosis had a 79.9% survival rate, but each hour of delay in treatment was associated with a 7.6% increase in mortality. Therefore, early forewarning of the onset of SS and timely treatment can help reduce the morbidity, mortality, and length of intensive care unit (ICU) stay. However, early forewarning is challenging due to the complexity of the disease in the clinical context [6,7] and the heterogeneity of the sepsis population [8].

Recently, machine learning techniques have been applied to electronic health record data to develop models for risk prediction [9,10], clinical phenotyping [11-13], and early forewarning [14-19]. While several studies have focused on early forewarning of SS in the ICU, practical limitations remain [20-24]. Many models required extensive clinical features from multiple examinations [21,22], increasing the complexity and time for data collection, which can delay forewarnings. Efforts to reduce the feature number often relied on distributed examinations [23] and left limited time for intervention [24]. Additionally, many studies prioritized predictive performance [25-27] while neglecting clinical interpretability. Specifically, limited attention has been given to the triggers of inconsistent predictions, a crucial factor for improving models and the understanding of disease diagnostic criteria. To enhance clinical applicability, models must offer straightforward actionable insights rather than complex algorithms that burden clinicians.

Therefore, we developed a real-time risk-stratified forewarning model for SS that minimized the need for extensive clinical examinations, enabling physicians to quickly and easily assess the patient's risk and facilitate timely intervention. Furthermore, after stratifying patients based on the risk scores provided by the model, we further analyzed the clinical characteristics of patients in different risk groups, with a particular focus on high-risk (HR) patients. A public web application was deployed that enables easy access and use of our proposed model [28].

Methods

Datasets and Participants

To improve the quality and reproducibility of reporting, we prepared a checklist (Multimedia Appendix 1) according to the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines [29].

Data were collected from an open-source dataset released for sizeable critical care databases, including the Medical Information Mart for Intensive Care-IV (MIMIC-IV) [30] and the eICU Collaborative Research Database (eICU) [31]. The MIMIC-IV contains comprehensive and high-quality data on deidentified patients admitted to ICUs at the Beth Israel Deaconess Medical Center (BIDMC), with more than 76,000 admissions between 2008 and 2019. The eICU is a multicenter publicly available database containing deidentified highly granular medical data for more than 200,000 patients in 335 ICUs from 208 hospitals across the United States between 2014 and 2015. Both databases include vital signs (VSs), laboratory results, diagnosis, treatment, care plan documentation, severity of illness measures, and other information.

Patients aged 18 years or older who were admitted for the first time and stayed in the ICU for more than 24 hours were included in the analysis. To reduce the impact of complicating factors in defining SS, patients designated as "do not resuscitate" or "encounter for palliative care" according to the International Classification of Diseases (ICD) were excluded. Moreover, patients in the coronary care unit were excluded to reduce the impact of cardiogenic shock. A final cohort of 5125 patients (including 766 SS patients) in the MIMIC-IV and 2180 patients (480 SS patients) in the eICU was obtained. The MIMIC-IV data were randomly partitioned into training (60%), validation (20%), and testing (20%) sets. The eICU data were used for external validation.

Ethical Considerations

The MIMIC-IV and eICU databases are publicly accessible, deidentified, and transformed, and have been approved for use

XSL•FO
RenderX

by the institutional review boards at BIDMC and the Massachusetts Institute of Technology, in accordance with the Declaration of Helsinki. Both databases received waivers for informed consent due to the deidentification of all protected health information. Access to these databases was granted upon completion of human research ethics training and signing of a data use agreement with PhysioNet (certification number 38539898).

Definitions of Sepsis and SS

The Third International Consensus Definitions for Sepsis and Septic Shock (Sepsis-3) [1] were applied to determine the onset time of sepsis and SS. Specifically, all episodes of suspected infection ($t_{suspicion}$) were identified by the timestamp of antibiotic administration or blood culture, whichever was earlier, within a specific period. If the antibiotic was administered first, the culture sampling was required to be obtained within 24 hours. If the culture sampling occurred first, the antibiotic was required to be ordered within 72 hours. The onset time of sepsis (t_{sepsis}) was defined as an episode of suspected infection with a change in the Sequential Organ Failure Assessment (SOFA) score of 2 or more points from up to 48 hours before to up to 24 hours after $t_{suspicion}$. Patients with SS were identified by a clinical construct of sepsis with persisting hypotension requiring vasopressors to maintain mean arterial pressure ≥65 mmHg and with a serum lactate level >2 mmol/L (18 mg/dL) despite adequate volume resuscitation [1]. Specifically, adequate fluid resuscitation was defined as a total fluid volume greater than 30 mL/kg or 1000 mL within a 3-hour window before the initiation of vasoactive drugs or hypotension. The first lactate level needed to be greater than 2 mmol/L within 6 hours after adequate resuscitation. The onset time of SS ($t_{septic\ shock}$) was the earliest time when all criteria for SS were met. Due to a lack of information on the starting and ending times of fluid resuscitation, SS, according to Sepsis-3, could not be defined in the eICU data. Instead, we used the ICD code labels in the "diagnosis.csv" table to determine SS onset.

Data Processing

Given the characteristics of time-series data and the need for real-time monitoring for SS risk, this study defined a 6-hour retrospective window, whereby data collected during the 6 hours prior to the current state of the patient were used to provide a forewarning of the SS risk in the next 6 hours. We discretized the features of high-frequency detection, such as VSs, and the features of low-frequency testing, such as laboratory test data, to an hourly value. If multiple measurements were performed in the same hour, their mean value was calculated as the value for this hour of the feature. The forward-filling method was used to fill in missing measurements (with the early measurement), if there was no measurement in this hour.

Next, several time intervals were defined to assess and compare differences among risk groups (derived from the Septic Shock Risk Predictor [SORP] risk scores) in terms of patient pathophysiology (based on VSs and laboratory testing features), clinical characteristics, etc. The time of SS onset is defined as 0. Considering this, –1 indicates 1 hour before onset and +1 indicates 1 hour after onset, and the risk prediction time is –6. Three primary time intervals were delimited, namely, –12 to –6, –6 to 0, and 0 to +6, representing the look-back interval, the preonset interval, and the postonset interval, respectively, where the look-back interval was the time interval used for data collection for risk calculation by the model. For easier comparison among risk groups, the mean value of a clinical feature was used to represent its value within a specified time interval.

Notably, information on patient comorbidities (eg, chronic kidney disease [CKD]) was taken from ICD codes, and invasive procedures (eg, dialysis-continuous renal replacement therapy [CRRT]) were taken from the procedures documented ("procedureevents" table).

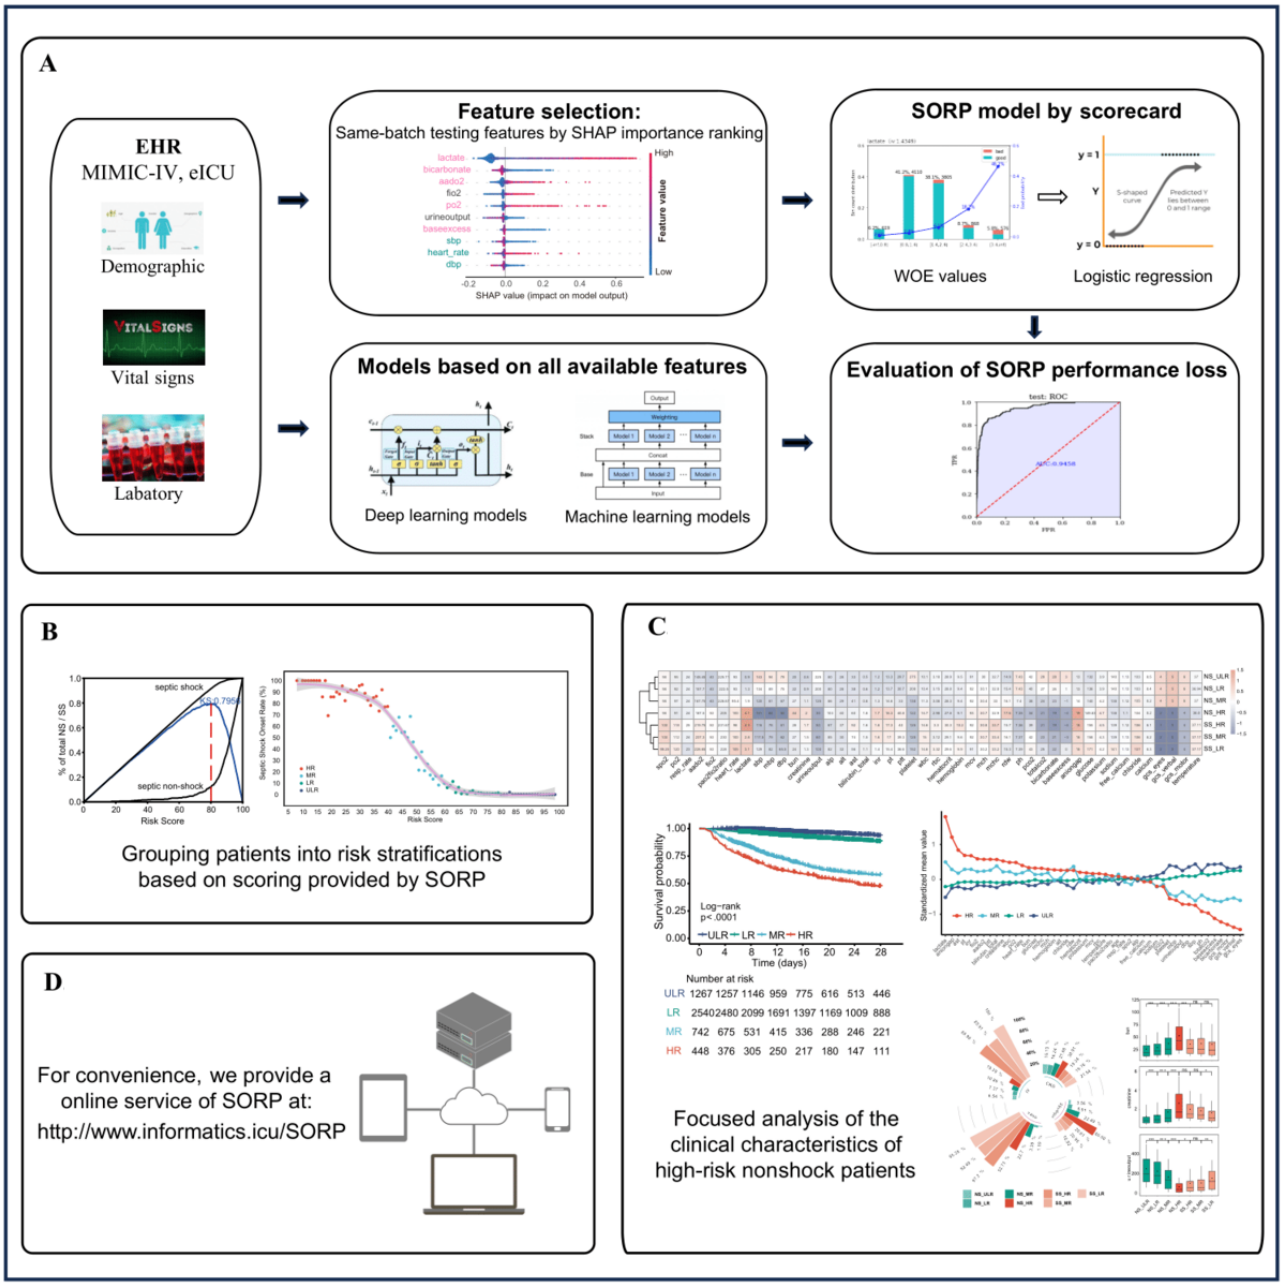
Risk Model

To facilitate clinical application, we filtered the features and then developed a scorecard [9,10] to evaluate SS onset risk by logistic regression (LogR). Next, to present the patient's risk more visually, we stratified the risk scoring and assessed the characteristics of patients in each risk group. The workflow is shown in Figure 1.

The scorecard was constructed as follows. The scorecard allowed for transferring continuous variables into multiple bins, and each feature was divided into multiple bins. In this study, we used the weight of evidence (WOE) to measure the probability of illness in each bin and determine the most appropriate number of bins by detecting the change in information value (IV) under each bin. The WOE and IV were calculated according to equations 1 and 2, respectively. Specifically, first, features were divided into 10 bins, making sure that each bin contained both SS patients and nonshock (NS) patients. Subsequently, the chi-square test was performed on 2 neighboring bins, traversing and merging those bins with the largest *P*-value until the number of bins met the expectation. Then, the final number of bins was determined based on the IV. After the binning was completed, the WOE value of each bin was calculated, and then, the WOE was mapped back to the original dataset to build the LogR model.

where i represents each subgroup, $DistributionNS_i$ denotes the proportion of septic NS patients in group i to the NS patients in the entire feature, and $Distribution\ S_i$ denotes the proportion of SS patients in group i to the SS patients in the entire feature.

The scorecard points were calculated using the following equations:



XSL•FO
RenderX

where *P0* and *PDO* (points to double odds) are the score ranges that were set manually, woe_j can be calculated with equation 1, β_i denotes the coefficient of the *i*th feature in LogR, α is the intercept term from LogR, *n* is the number of features, and *k* is the number of bins in each feature.

The scorecard was adjusted to a range of scores between 0 and 100. The final scorecard consisted of a base score and a score for each bin in each feature (Multimedia Appendix 2).

Figure 1. The flowchart of this study. The study flowchart comprises 4 stages. (A) Model development: Electronic health record (EHR) data were collected from the Medical Information Mart for Intensive Care-IV (MIMIC-IV) and eICU Collaborative Research Database (eICU), and multiple forewarning models were constructed. Using Shapley Additive Explanations (SHAP) analysis, we identified key features within the same test batch, which were then used to build the Septic Shock Risk Predictor (SORP) model. The performance of the SORP was compared to that of models based on all available features to evaluate whether the SORP performance loss is acceptable. (B) Risk stratification of septic shock (SS): Patients were stratified into risk groups based on SORP scores. (C) Clinical characteristics of the risk groups: We analyzed clinical characteristics across risk groups, with a focused analysis on high-risk nonshock patients. (D) Model deployment: An online tool was developed for clinical use. HR: high risk; LR: low risk; MR: medium risk; ULR: ultralow risk; WOE: weight of evidence.

Statistical Methods

We employed the Shapley Additive Explanations (SHAP) [32] method to calculate the importance of clinical features for SS in the look-back interval. SHAP assigns a value to each feature in the given prediction. These values are calculated for each prediction separately and do not provide general information about the entire model. Higher absolute SHAP values indicate higher importance, whereas values close to 0 indicate low significance of a feature.

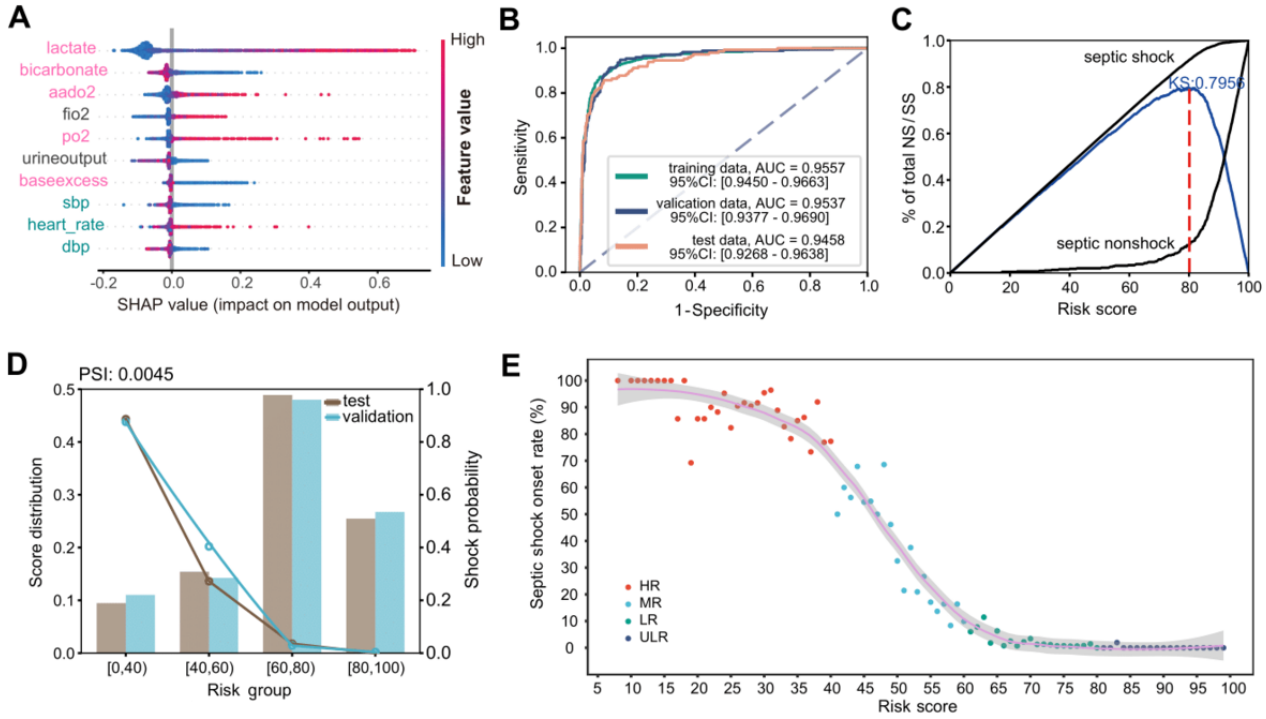
XSL•FO
RenderX

To facilitate observation and evaluation and determine risk intervals, we employed the Kolmogorov-Smirnov (KS) curve to describe the overall score distribution. The KS curve illustrated the changes in the sample proportion of SS patients, the proportion of septic NS patients, and the trend of differences between SS and NS patients (blue line) with a score from 0 to 100. From the KS curve, it could be seen that the proportion of SS patients in the low score accumulated faster, while the proportion of NS patients in the high score accumulated faster. The blue curve showed the variation process of the difference between SS and NS patients at each score point. At the highest point of the blue curve, the ability to distinguish between SS and NS patients was the strongest. Therefore, to provide a more direct scoring effect, based on the distributions described above, the scores were divided into 4 risk groups: HR, medium risk (MR), low risk (LR), and ultralow risk (ULR), with score intervals of 0-40, 40-60, 60-80, and 80-100, respectively.

The Population Stability Index (PSI) was used to evaluate the stability of risk group distribution across different datasets in the postonset interval. A smaller PSI value indicates a minor difference between 2 distributions and more consistency. In addition, the area under the curve (AUC) was calculated to evaluate the performance of each model. Estimation and comparison of the survival curves among risk groups were performed using Kaplan-Meier survival analysis and log-rank tests, respectively. The Local Polynomial Regression Fitting (locally estimated scatterplot smoothing [LOESS]) method was used to fit the relationship between the risk score and SS onset rates at 6 hours. Hierarchical clustering was used to assess the similarity between risk groups. All statistical analyses and algorithm approaches in this study were performed using Python (Python Software Foundation) and R (R Project for Statistical Computing).

Results

Development of the SORP



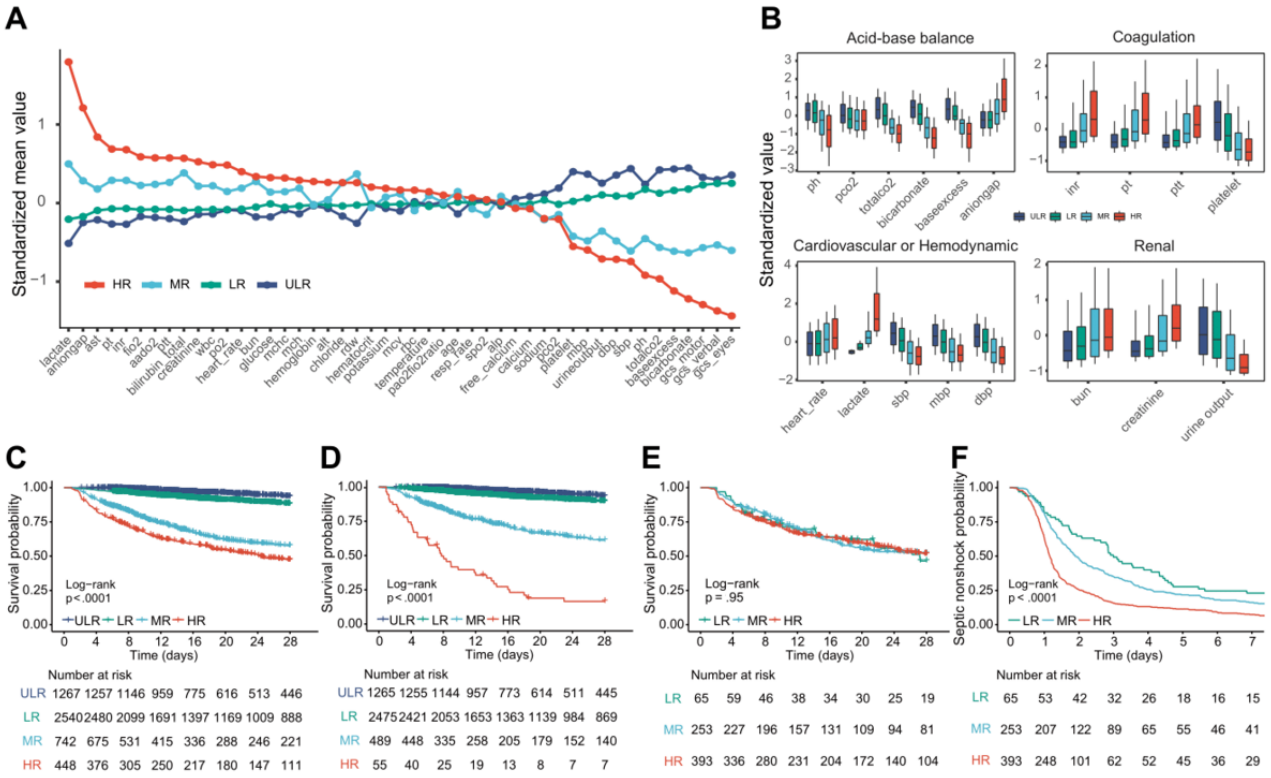
Since a particular time window is required for early forewarning of SS, the longer it takes to collect the necessary data for the model, the less time is left for physicians to intervene. Therefore, we calculated the importance of each feature in the early forewarning of SS in the look-back interval and selected the top-ranked feature set that could be accessed in the same testing batch. In particular, we observed that 8 of the 10 most important clinical features for SS prediction were arterial blood gases (ABGs) and VSs (Figure 2A). Notably, point-of-care ABG testing results could be obtained even within 5-10 minutes in the ICU, and VS features could be obtained at any time from the monitor. This result indicated that septic preshock core pathophysiological shifts could be mainly monitored by ABG and VS features, allowing us to quickly obtain essential features for early forewarning of SS and providing a prompt assessment.

Since features obtained simultaneously from an ABG test might have a certain degree of complementarity, we included 8 ABG and 7 VS features collected in the MIMIC-IV and eICU in the subsequent analysis. An SS risk predictor (SORP) based on a scorecard was constructed by combining LogR with WOE in the look-back interval (detailed in the Methods section). According to the scorecard, a patient's SS risk score could be obtained by adding interval scores to the base score (Multimedia Appendix 2). Lower total scores indicated a higher risk of SS onset. In the training, validation, and test datasets, the AUCs were 0.9557, 0.9537, and 0.9458, respectively (Figure 2B). Meanwhile, based on all available clinical features, multi-feature complex models were constructed, including deep learning and machine learning models (Figure 1A; Multimedia Appendix 3). These features are related to acid-base balance, coagulation, renal aspects, hepatic aspects, pulmonary aspects, hematologic aspects, the Glasgow Coma Scale, etc. The predictive performance of the SORP is only slightly lower than that of the optimal complex model. In the test datasets, the AUCs of the SORP and the optimal complex model were 0.9458 and 0.9651, respectively. It indicated that the construction of the SORP was reasonable and had strong early forewarning ability.

To facilitate observation and evaluation and determine risk intervals, according to the KS curve plot (Figure 2C), the scores were divided into 4 risk groups as detailed in the Statistical Methods subsection. The distribution of SS was highly consistent and stable among the training, validation, and test datasets (PSI <0.01; Figure 2D; Multimedia Appendix 4). In total, the incidences of SS for the HR, MR, LR, and ULR groups in the postonset interval were 88.6% (433/489), 34.5% (262/760), 2.5% (67/2707), and 0.3% (4/1301), respectively (Figure 2D; Multimedia Appendix 5). A total of 88.6% (433/489) of HR patients developed SS, and 90.7% (695/766) of SS patients were classified into the HR or MR group. Further, a curve was fitted for the relationship between the risk score and SS onset rate at 6 hours (Figure 2E; Multimedia Appendix 6), and the result showed a clear stratification and monotonicity, with an increase in the SS onset rate with increasing risk (decreasing risk score). These results suggest that the SORP exhibits a great early forewarning performance.

XSL•FO
RenderX

Figure 2. Construction of the Septic Shock Risk Predictor (SORP) and derivation of patient risk stratification. (A) Shapley Additive Explanations (SHAP) summary plot for the top 10 clinical features contributing to the XGBoost model. The position on the y-axis is determined by the feature, in which "hotpink" represents blood gases and "cyan" represents vital signs, and that on the x-axis is determined by the Shapley value. The color from blue to red represents the feature values from low to high. (B) Receiver operating characteristic curve and area under the curve (AUC) for SORP forewarning performance. (C) Kolmogorov-Smirnov (KS) curve shows the difference between the cumulative proportion of septic shock (SS) patients and the cumulative proportion of septic nonshock (NS) patients as the risk score increases (blue line). (D) Stability of SS distribution across datasets. (E) A fitted curve showing the monotonic relationship between the risk score and SS probability in the postonset interval, according to the locally estimated scatterplot smoothing (LOESS) method. HR: high risk; LR: low risk; MR: medium risk; PSI: population stability index; ULR: ultralow risk.

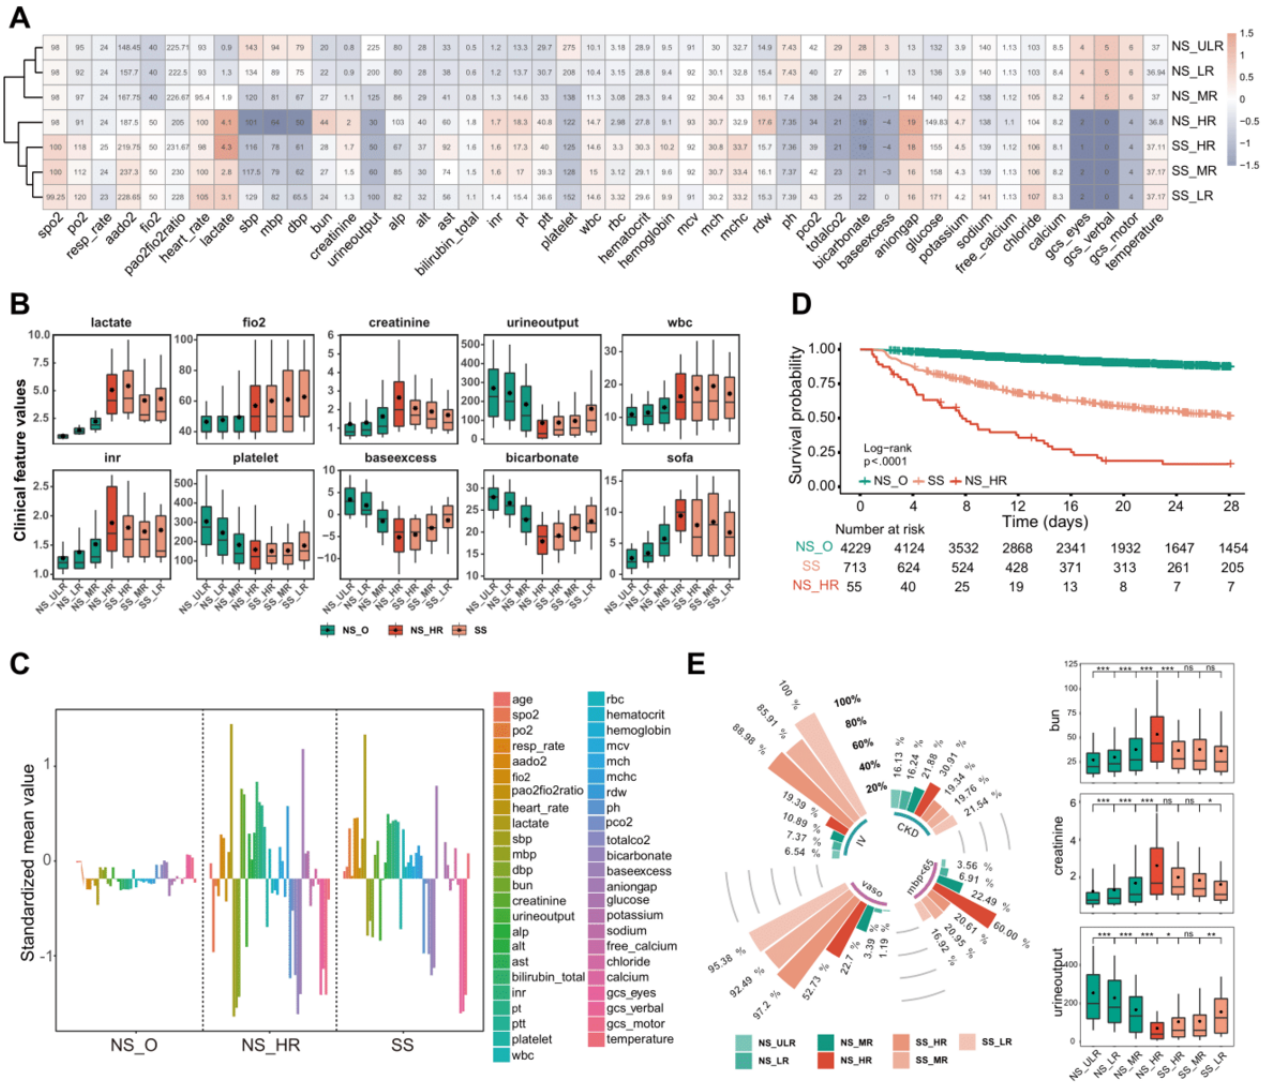


Characteristics of Different Risk Groups After SS Onset

To verify the rationality of risk stratification, we explored the differences in clinical features among risk groups in the postonset interval. Remarkably, increased abnormal values for standardized means of ranking continuous features, especially features related to the SS definition (such as lactate and blood pressure), kidneys, acid-base balance, and coagulation (Figure 3A and 3B; Multimedia Appendix 7), were observed in HR patients when compared with those in other risk groups. The degree of abnormality of these features further increased as risk increased (Figure 3A). For all patients, Kaplan-Meier survival curves progressively declined as patient risk increased (Figure 3C). An even more rapid progressive decline was observed in NS patients in the HR group (Figure 3D), but there was no difference for SS patients (Figure 3E). Furthermore, the length of time from sepsis to SS was significantly reduced with increasing risk (Figure 3F). These results suggest that disease severity increased with increasing risk groups and that the SORP has a reliable risk stratification capability.

XSL•FO
RenderX

Figure 3. Characteristics of different risk groups in the postonset interval. (A) The clinical features are standardized such that all means are scaled to 0 and SDs to 1. A value of 1 for the standardized mean value (y-axis) signifies that the mean value for the risk group was 1 SD higher than the mean value for the 4 risk groups shown in the graph as a whole. (B) Boxplot showing the changing trend for each clinical feature with risk groups. The y-axis shows the standardized value for each clinical feature. (C-F) Kaplan-Meier curves and survival analysis. (C) Overall survival for all patients. (D) Overall survival for septic nonshock patients. (E) Overall survival for septic shock patients in different risk groups. (F) Time from sepsis to septic shock. HR: high risk; LR: low risk; MR: medium risk; ULR: ultralow risk.



Are NS_HR Patients Truly Septic NS Patients?

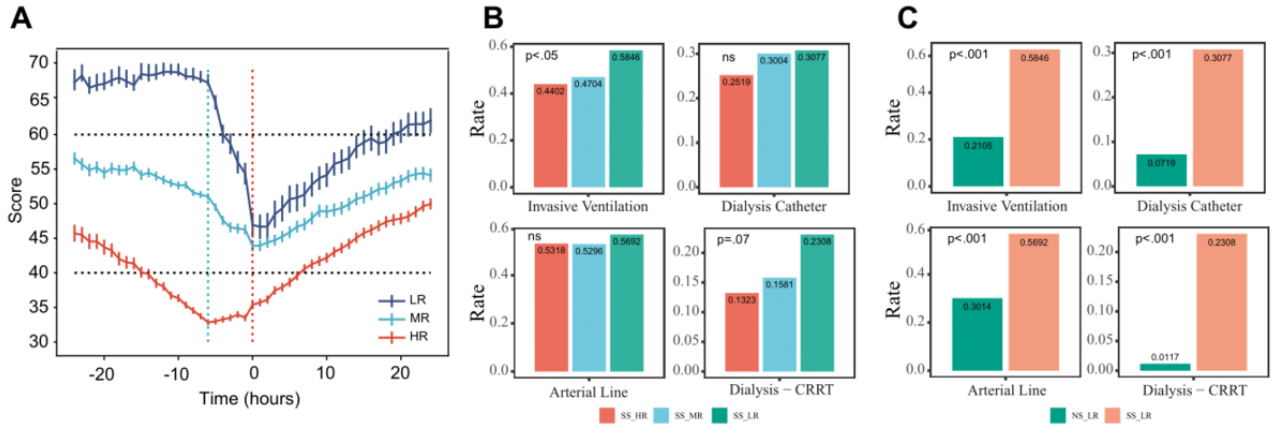
Among the HR patients identified by the SORP, 11.5% (56/489) did not meet the SS definition according to the Sepsis-3 criteria [1] and were labeled NS_HR. To further confirm the disease status of these patients, the distribution of features in the postonset interval for NS_HR patients was compared to that for SS and other NS (NS_O) patients. In clustering analysis and heatmap visualization, NS_HR patients clustered with the SS groups but not with the other 3 NS groups (Figure 4A). This result indicates that the NS_HR group was more similar to SS patients in terms of clinical features, such as lactate, the SOFA score, and features related to renal function (creatinine and urine output), coagulation (prothrombin time, international normalized ratio, and platelet count), and acid-base balance (base excess, bicarbonate, total CO_2, and anion gap) (Figure 4B). Compared to NS_O patients, both NS_HR and SS patients displayed a consistently higher degree of variation in clinical features (Figure 4C). The distribution and variation of features demonstrated that both HR_NS and SS patients had similar levels of disorder compared with NS_O patients. Moreover, both NS_HR and SS patients had significantly shorter overall survival than NS_O patients (Figure 4D). In total, NS_HR patients were highly similar to SS patients and distinct from NS_O patients. In addition, we queried the patients' ICD codes, and 35% (19/55) of NS_HR patients were labeled with "septic shock," which implied that a proportion of NS_HR patients might meet the previous criteria for SS.

Notably, the overall survival of NS_HR patients was significantly worse than that of SS patients (Figure 4D), and we explored the potential factors contributing to this survival difference. SS-associated treatments, such as vasopressors and fluid resuscitation, were evaluated. Compared to the SS group, the NS_HR group had a significantly higher incidence of mean blood pressure (MBP) <65 mmHg and a significantly lower rate of vasopressor use and infusion volume (all *P* values <.001; Figure 4E; Multimedia Appendix 8). Furthermore, NS_HR patients showed the highest percentage of CKD (*P*=.006) and the most abnormal kidney-related features (Figure 4E; Multimedia Appendix 8). According to this finding, one of the reasons for high mortality in NS_HR patients might be inadequate treatments, including both vasopressor use and infusion. One of the reasons NS_HR patients did not receive adequate fluid resuscitation might be severe kidney injury, as physicians may reduce fluid infusion in these patients to protect them from further severe kidney damage.

XSL•FO
RenderX

Figure 4. Characteristics of septic nonshock high risk (NS_HR) patients. (A) Clustering heatmap showing the similarity among risk groups. Standardized values were used for clustering (ie, each feature is centered at the sample mean and scaled by its SD), and "Euclidean" and "average" were used for clustering distance and clustering method, respectively. The values in the box are the median raw values of the features. (B) Boxplots showing the distribution of clinical features across risk groups. Red indicates NS_HR patients, orange indicates septic shock (SS) patients, and green indicates septic nonshock (NS) patients. (C) The degree of variation in the features of the risk groups. The y-axis shows the standardized mean for each clinical feature. (D) Overall survival for SS, NS_HR, and NS_O (other risk groups of NS). (E) Bar plot of the polar coordinate showing the proportion of clinical events in each risk group of patients. The boxplot shows the values of kidney-related features during the look-back interval. We transformed the infusion volume (IV), used SS_LR's IV as a reference (3815.25 mL), and expressed the IV in other risk groups as a percentage of that of SS_LR patients. CKD: the rate of patients with chronic kidney disease; HR: high risk; IV: the mean infusion volume of patients from the preonset interval to the postonset interval; LR: low risk; MBP <65: the rate of patients with mean blood pressure (MBP) <65 mmHg from the preonset interval to the postonset interval; MR: medium risk; ns: not significant (P>.05); ULR: ultralow risk; vaso: the rate of patients treated with vasopressors from the preonset interval to the postonset interval. *P≤.05, **P≤.01, ***P≤.001.

Application of the SORP in Real-Time Risk Monitoring for SS



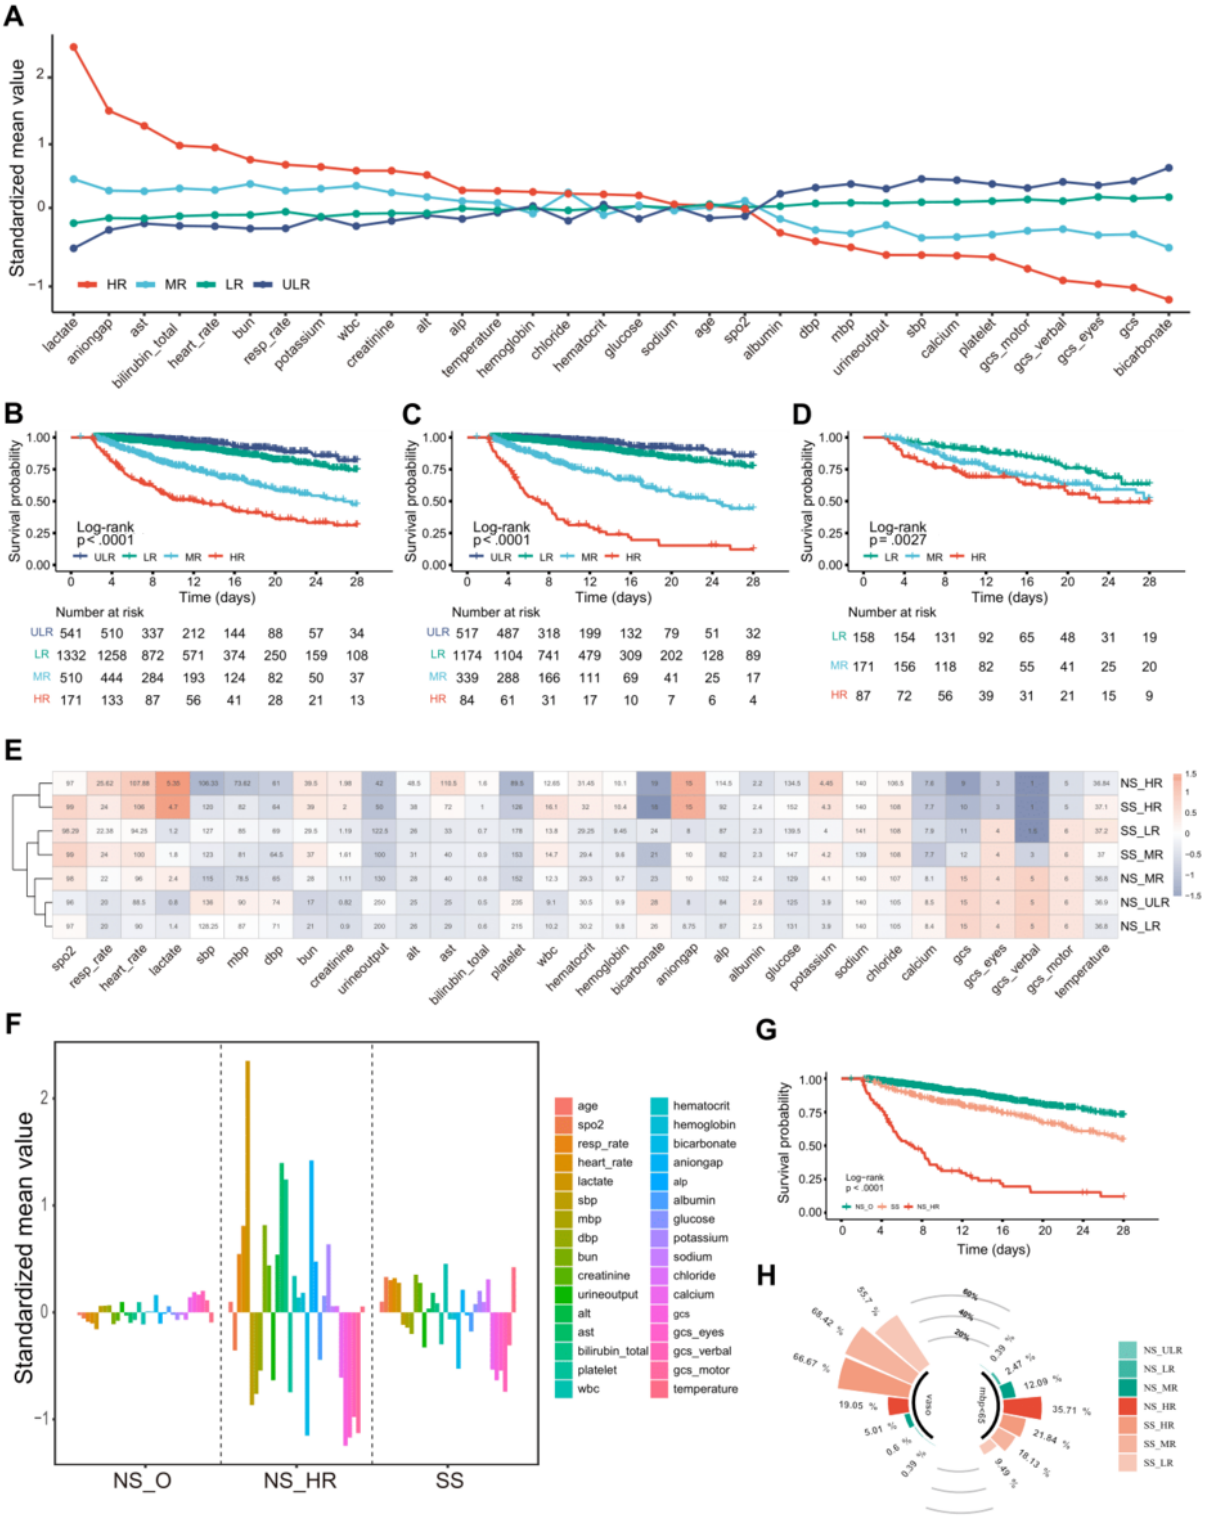
The SORP showed great performance in sepsis stratification, and we further evaluated its feasibility as a real-time monitoring risk score for patients with sepsis. The hourly risk score for SS onset was calculated by the SORP, and the patient's risk scores and trends throughout the ICU process were fully displayed. Two patients, one with NS and another with SS, are shown in Multimedia Appendix 9. The NS patient had a progressively lower risk (increasing score) nearing discharge. In comparison, the SS patient had an increasingly higher risk until SS onset, with entry into the HR zone 6 hours before onset, and a gradual reduction in risk after onset, which might also reflect the role of treatment. Furthermore, based on continuous real-time scoring, we found that 50.0% (383/766) and 74.9% (574/766) of SS patients with risk scoring entered the HR zone 13 hours and 6 hours before onset (IQR 6-26), respectively. In addition, hourly risk scores were shown for each risk group during the 48-hour period before and after SS onset (Figure 5A). The risk gradually increased (risk score gradually decreased) as septic patients progressed to shock and decreased with treatment intervention (after SS onset), demonstrating that the SORP can monitor the patient's risk for SS in real-time (Figure 5A).

In contrast to the gradual increase in risk in the other 2 groups, SS_LR patients maintained a relatively stable risk during and

XSL•FO
RenderX

before the look-back interval but demonstrated an extremely rapid increase in risk (risk scores decreased) in the preshock interval (Figure 5A). Further analysis demonstrated that SS_LR patients had a higher rate of invasive procedures than other SS patients (Figure 5B; Multimedia Appendix 10), which was significantly higher than that of other LR patients (Figure 5C; Multimedia Appendix 11). Therefore, we speculated that this might be one of the reasons for the rapid progression of SS_LR patients: invasive procedures can introduce additional microorganisms into the body, which can exacerbate the infectious response and lead to rapid deterioration. Analysis showed that 52% (35/67) of SS_LR patients were recognized by the SORP as their risk group increased from LR to MR 3 hours before SS onset. Therefore, we recommend that LR patients exposed to invasive procedures should be assessed more frequently for the timely recognition of SS.

Figure 5. Characteristics of septic shock low risk (SS_LR) patients. (A) Mean value line and unbiased standard error bar for septic shock (SS) patients. Risk groups derived by the Septic Shock Risk Predictor (SORP) 6 hours before SS, and the change in risk over time for each group. The cyan dashed line represents 6 hours before the onset of SS, and the red dashed line represents the onset time of SS. (B) The rate of invasive procedures of each risk group in SS patients. *P* values are derived from SS_LR patients compared to other SS patients (details in Multimedia Appendix 10). (C) The rate of invasive procedures of each risk group in LR patients identified by the SORP. Here, events are measured from 12 hours before the prediction to the time of the prediction. *P* values are derived from SS_LR patients compared to other septic nonshock low risk (NS_LR) patients (details in Multimedia Appendix 11). CRRT: continuous renal replacement therapy; HR: high risk; LR: low risk; MR: medium risk; ns: not significant.



Reliability and Robustness of the SORP

To further verify these findings, we additionally used multicenter eICU data for validation. Consistently, in the look-back interval, eICU patients were grouped into 4 risk groups. Although the proportion of SS patients was reduced in the HR group in the postonset interval (Multimedia Appendix 12), which might be due to different definitions, the distribution of SS was consistent and stable in both the eICU dataset and the MIMIC-IV dataset (PSI <0.05; Multimedia Appendix 13). Similar to the MIMIC-IV, the patients' features became increasingly abnormal as risk increased, especially features related to the SS definition (eg, lactate and blood pressure), kidneys, acid-base balance, and coagulation (Figure 6A; Multimedia Appendix 14). For overall survival, the 4 risk groups also showed significant differences, even in NS patients and SS patients (Figure 6B-D). SS_LR patients, similar to MIMIC-IV patients, underwent significantly more invasive procedures than the other LR patients (Multimedia Appendix 15), but there was no significant difference from the other SS patients (Multimedia Appendix 16). NS_HR patients, similar to MIMIC-IV patients, significantly differed from NS_O patients in clinical features and survival, being more similar to SS patients but with a more severe status (Figure 6E-G). Regarding treatment, as the eICU did not provide start and end times for infusion, we could not obtain accurate infusion volumes for eICU patients within a certain interval, so we focused only on vasopressor use. Compared to SS patients, NS_HR patients showed significant hypotension and less vasopressor use, which were similar to the results of the MIMIC-IV (Figure 6H; Multimedia Appendix 17). Although this analysis was based on a different definition of SS, similar results were still observed, further confirming the robustness of the SORP and the reasonability of the risk stratification system.

In summary, the SORP has a reliable and robust ability to not only provide early forewarning but also stratify patients with potentially different risks of SS. For convenience, we provide an online service of the SORP [28]. The "Help" section in the navigation bar of the website contains detailed instructions on how to use the online tool.

Figure 6. Reproducibility of findings in external independent eICU Collaborative Research Database (eICU) data. (A) The clinical features are standardized with all means scaled to 0 and SDs to 1. A value of 1 for the standardized mean value (y-axis) signifies that the mean value for the risk group was 1 SD higher than the mean value for the 4 risk groups shown in the graph. (B-D) Overall survival for all patients, septic nonshock (NS) patients, and septic shock (SS) patients. (E) Clustering heatmap showing the similarity among risk groups. Standardized values were used for clustering (ie, each feature is centered at the sample mean and scaled by its SD), and "Euclidean" and "average" were used for clustering distance and clustering method, respectively. Red indicates higher levels, and blue indicates lower levels. (F) Characteristics of risk groups. The y-axis shows the standardized mean for each clinical feature. (G) Overall survival for SS, NS_HR, and NS_O (other risk groups of NS). (H) The bar plot of the polar coordinate shows the proportion of clinical events in each risk group of patients. The starting and ending times of patient infusions are not provided in the eICU, and thus, it was not possible to estimate the infusion volume of patients within a specific interval. HR: high risk; LR: low risk; MBP <65: the rate of patients with mean blood pressure (MBP) <65 mmHg from the preonset interval to the postonset interval; MR: medium risk; ULR: ultralow risk; vaso: the rate of patients treated with vasopressors from the preonset interval to the postonset interval.

Discussion

Principal Findings

Timely forewarning and early intervention are especially important for patients who are developing SS, and clinically applicable forewarning tools for SS are still lacking. In this study, we constructed the SORP, a simplified model, that not only provides real-time risk stratification for patients but can also easily trace the SS risk of patients during the entire ICU process and forewarn SS onset with a median of 13 hours in advance. The SORP can precisely assess the risk of SS 6 hours in advance by using only ABG and VS features, with an AUC of 0.9458 in the test set. Compared to the findings in previous studies, the SORP remarkably reduces both time and economic costs by using easily available ABG and VS features that can be accessed within minutes and can achieve competitive predictive performance (Multimedia Appendix 18). In contrast, other studies require additional tests, such as biochemical tests, SOFA score calculations, and specific urine output measurements, which extend data collection by several hours. While some studies reduce the number of features through feature engineering methods, these features may still be distributed across test batches, which may not effectively shorten the overall time and costs needed for assessments. Moreover, in addition to being available through the web service [28], the patient's risk score can be simply and quickly calculated manually using a scorecard (Multimedia Appendix 2). The ease of data collection and the simplicity of use will greatly enhance the usefulness of the SORP in clinical applications. Furthermore, we focused more on the clinical characteristics of HR patients, especially septic NS patients, and the assessment of newly discovered NS_HR patients, overlooked by the Sepsis-3 definition, may provide further insights into the pathophysiological processes of SS onset and help to complement its diagnosis and precise management.

In this study, 4 risk groups were identified by the SORP. For these risk groups, we observed distinct clinical features and a significantly stratified risk for SS onset rates and survival status. For SS patients in different risk groups, the time from sepsis onset to SS decreased as their risk increased. Significant survival differences were observed in NS patients across different risk groups, but these same differences were not observed in SS patients (Figure 3E). This may be because of the active guideline-directed resuscitation treatment of SS patients. These findings confirm the effectiveness of the current SS resuscitation treatment guidelines and further affirm the accuracy of risk stratification and the reliability of the SORP.

Interestingly, despite the high agreement between SS patients diagnosed by the Sepsis-3 definition and those identified by the SORP, we still identified 2 relatively distinct groups. One group was SS_LR, where patients were defined as having SS by Sepsis-3 but were identified as LR by the SORP. The overall survival of these patients was not significantly different from that of other SS groups, but rapid progression and an extremely increased risk were demonstrated within 6 hours before SS onset (Figure 5A). In addition, 52% (35/67) of SS_LR patients showed an increase from LR to MR 3 hours before SS onset. Thus, although these patients could not be identified 6 hours in advance, their risk changes were captured in real-time, which highlights the high sensitivity of the SORP. Further analysis showed that SS_LR patients underwent more invasive procedures than other SS patients and much more than other patients in the LR group, such as "invasive ventilation," "dialysis catheter," "arterial line," and "dialysis-CRRT" (Figure 5B and 5C). Thus, we speculate that invasive procedures might be one of the causes of the rapidly exacerbating patient status. We recommend that LR patients undergoing invasive procedures should be evaluated more frequently to recognize rapid exacerbation in a timely manner.

Another notable group was NS_HR, where patients were not defined as having SS by Sepsis-3 but were identified as HR by the SORP. This prompted us to further analyze this particular patient group, and the results showed that these patients had the following characteristics: (1) NS_HR patients were quite similar to SS patients in terms of clinical phenotypes (Figure 4A-C); (2) NS_HR patients had the worst overall survival, which was significantly poorer than even that of SS_HR patients (Figure 3C and 3D; Figure 4D); (3) NS_HR patients did not receive sufficient fluid resuscitation or timely vasopressor administration (Figure 4E), which might be a key factor that resulted in their noncompliance with the SS diagnosis and their higher mortality; and (4) NS_HR patients had more significant abnormalities in renal-related features (Figure 4E), which reflect higher incidences of renal malfunction, such as CKD (Figure 4E). The literature has shown that excessive fluid resuscitation in patients with severe renal disease exacerbates renal injury and leads to poorer outcomes [33,34]. Therefore, cautious and conservative strategies might be adopted by physicians, resulting in a much higher likelihood of insufficient fluid resuscitation in these patients. Hence, precise fluid resuscitation management is crucial in SS patients with renal dysfunction. In total, NS_HR patients share a similar pathophysiologic process with SS patients but experience a more aggressive clinical outcome due to insufficient treatment.

Compared to previous versions, the Sepsis-3 shock definition is more focused on tissue-organ hypoperfusion and metabolic dysfunction and the corresponding therapeutic response, which largely ensures the authenticity and reliability of SS diagnosis, showing a significant increase in specificity but at the cost of sensitivity [35]. Studies have shown that a proportion of patients who met the previous version of the SS criteria, but not the Sepsis-3 shock criteria, had significant organ failure and high mortality [36], with a value of up to 31.6% [37]. In this study, we identified a group of patients (NS_HR) with poor survival and a similar clinical phenotype to SS. In addition to low vasopressor use, the NS_HR group had inadequate fluid resuscitation due to severe renal disease, thus failing the Sepsis-3 shock definition. These patients are missed by the current SS definition, but they are at HR and are worthy of attention. Therefore, for more precise diagnosis and management of SS patients, "adequate fluid resuscitation" in the SS definition may have different criteria in different populations. The need for fluid personalization has emerged as an admirable goal, especially in SS [38].

Limitations

In this study, the designed SS risk early forewarning and stratification model, SORP, can easily and quickly provide ICU physicians with the patient's risk status and its changing trend, which can provide valuable support for the early identification of patient deterioration. However, it should be noted that there are limitations in this study. The current data sources are relatively limited in terms of geographic regions, which to some extent hinders the study of differences in different regions. Future studies should collect data from different regions to test the accuracy of the SORP for early forewarning, analyze the impact of regional differences on risk factors for SS, and establish a more accurate early forewarning system. Moreover, it is crucial to regularly monitor and assess the early forewarning capability and stability of the system and to make necessary adjustments as additional data becomes available. In addition, in the eICU dataset, we were unable to define SS by the Sepsis-3 criteria due to data limitations, which resulted in the incomparability of performance metrics such as AUC. However, based on a different SS definition, we were still able to observe results similar to those with the MIMIC-IV data, which further confirms the robustness of the SORP and the rationality of the risk stratification system.

Summary and Outlook

Early forewarning and diagnosis of SS are essential for reducing mortality. To support this, we developed the SORP early forewarning model, which offers several key benefits: (1) easy and rapid feature collection within minutes; (2) ease of use via online tools or a scorecard (Multimedia Appendix 2); (3) excellent predictive performance (Figure 2B); (4) continuous status monitoring for risk deterioration or improvement; and (5) identification of HR patients, including those with similar symptoms who may not fully meet diagnostic criteria. In clinical practice, the SORP can be easily integrated into sepsis management as an auxiliary monitoring tool (Multimedia Appendix 19). For MR patients whose SORP score is still decreasing, it is recommended to increase the frequency of blood gas testing for timely monitoring. For those identified as HR, the SS determination process can be initiated ahead of time, facilitating the early administration of appropriate treatments, such as fluid resuscitation.

Future research should further explore the applicability of the SORP model in diverse clinical settings, including validation with additional datasets. We have also planned a prospective trial to evaluate its impact on prognosis and survival, particularly in NS_HR patients. These efforts aim to advance early SS identification and management, ultimately improving patient outcomes.

Abstract

Background: Immunotherapy has become a game changer in cancer treatment. The internet has been used by patients as a platform to share personal experiences and seek medical guidance. Despite the increased utilization of immunotherapy in clinical practice, few studies have investigated the perceptions about its use by analyzing social media data.

Objective: This study aims to use BERTopic (a topic modeling technique that is an extension of the Bidirectional Encoder Representation from Transformers machine learning model) to explore the perceptions of online cancer communities regarding immunotherapy.

Methods: A total of 4.9 million posts were extracted from Facebook, Twitter, Reddit, and 16 online cancer-related forums. The textual data were preprocessed by natural language processing. BERTopic modeling was performed to identify topics from the posts. The effectiveness of isolating topics from the posts was evaluated using 3 metrics: topic diversity, coherence, and quality. Sentiment analysis was performed to determine the polarity of each topic and categorize them as positive or negative. Based on the topics generated through topic modeling, thematic analysis was conducted to identify themes associated with immunotherapy.

Results: After data cleaning, 3.6 million posts remained for modeling. The highest overall topic quality achieved by BERTopic was 70.47% (topic diversity: 87.86%; topic coherence: 80.21%). BERTopic generated 14 topics related to the perceptions of immunotherapy. The sentiment score of around 0.3 across the 14 topics suggested generally positive sentiments toward immunotherapy within the online communities. Six themes were identified, primarily covering (1) hopeful prospects offered by immunotherapy, (2) perceived effectiveness of immunotherapy, (3) complementary therapies or self-treatments, (4) financial and mental impact of undergoing immunotherapy, (5) impact on lifestyle and time schedules, and (6) side effects due to treatment.

Conclusions: This study provides an overview of the multifaceted considerations essential for the application of immunotherapy as a therapeutic intervention. The topics and themes identified can serve as supporting information to facilitate physician-patient communication and the decision-making process. Furthermore, this study also demonstrates the effectiveness of BERTopic in analyzing large amounts of data to identify perceptions underlying social media and online communities.

Introduction

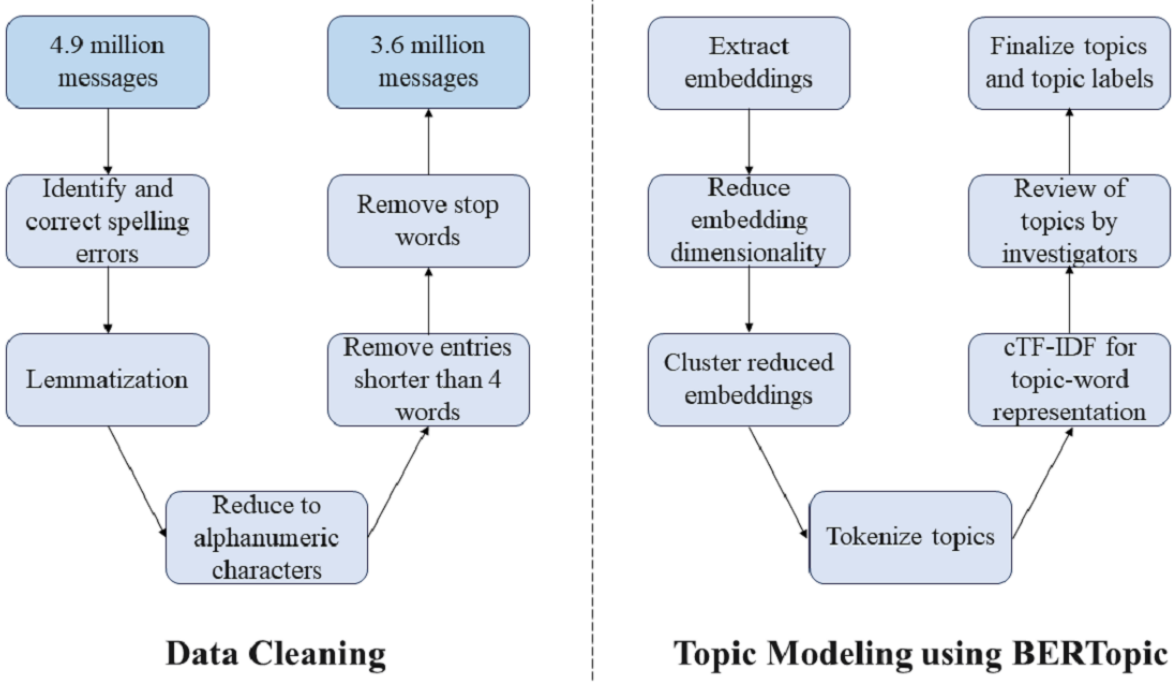
In recent years, immunotherapy has emerged as one of the most promising therapeutic approaches for treating cancer. It works by activating the innate immune system to identify and attack cancer cells. Immunotherapy encompasses various strategies, including immune checkpoint inhibitors, T-cell transfer therapy, monoclonal antibodies, treatment vaccines, and immune system modulators [1]. These immunotherapeutic strategies have received approval for the treatment of several cancer types such as lung cancer, prostate cancer, chronic lymphocytic leukemia, and non-Hodgkin lymphoma [2]. Immunotherapy offers substantial benefits in terms of precision, specificity, and long-term survival improvements, representing a significant breakthrough in cancer treatment [3].

Immunotherapy has made remarkable progress and demonstrated clinical value. However, there are drawbacks that may hinder its clinical use and acceptance by patients with cancer. One notable limitation is the variability in individuals' responses to immunotherapy. Although the treatment may be effective in some patients with specific types of cancers, it may not be as effective for others with the same cancer types [4]. Besides, immunotherapy-related adverse events (irAEs) have been observed with the increasing frequency and duration of immunotherapy usage. Patients' decisions to undergo immunotherapy are influenced by a range of factors, including their perceptions of its efficacy, side effects, procedural aspects, costs, their levels of knowledge about the treatment, and the comprehensiveness of advice provided by health care providers [5,6]. These findings highlight the importance of understanding patients' perspectives regarding immunotherapy to manage the uncertainties faced by patients and to make informed decisions on whether to proceed with immunotherapy.

The internet has become an indispensable source of health information for patients [7]. Many patients scour the internet for medical guidance, share their personal experiences, and interact on social media platforms [8]. The internet, therefore, provides a valuable platform for capturing diverse perspectives. Several studies have explored these perspectives by collecting data from social media platforms and forums [9-13]. For example, through analyzing posts from social media, a study revealed that pain and fatigue were the most commonly discussed symptoms among patients with non–small-cell lung cancer regarding the use of immunotherapy [10]. Another study found that 55% of patients' posts and 37% of caregivers' posts expressed positive perceptions of immunotherapy for treating advanced bladder cancer [11]. Notably, these previous studies usually extracted posts from a single site and analyzed only a small portion of the available posts. Moreover, these studies primarily focused on patients with specific cancer types, and thus, the findings may not be generalizable to patients with other cancer types for which immunotherapy has been approved [12].

One challenge in analyzing data from the internet and social media posts is dealing with vast amounts of unstructured text, which necessitates extensive preprocessing measures prior to analysis. Different machine learning techniques have been explored to increase the efficiency of online text analysis. BERTopic, a topic modeling technique that is an extension of the Bidirectional Encoder Representation from Transformers (BERT) machine learning model, has been used to identify the underlying public perceptions within social media posts. It has demonstrated the capability to unveil latent patterns and extract topics from large datasets [14-16]. Compared to other models, BERT models provide a stronger understanding of the contextual meaning of each word in document representations, which is attributable to their bidirectional training of transformers [17]. This enables the generation of more accurate topics than those generated using traditional statistical models. Moreover, the BERT model is continuously trained and updated by researchers, ensuring ongoing improvements [18]. However, no study has employed this technique to explore the viewpoints of the online cancer community on immunotherapy.

With the objective of understanding the perspectives of online cancer communities regarding immunotherapy, this study used BERTopic to analyze a large number of posts extracted from multiple social media and online forums. The findings of this study may offer valuable insights for clinicians, patients, and researchers to enhance decision-making processes when considering immunotherapy as a treatment option.



Methods

Overview

This was a retrospective study that involved analyzing texts collected from social media platforms and online forums. The study proceeded through 4 primary methodological phases: (1) collecting textual data, (2) cleaning and processing the extracted texts, (3) performing and optimizing topic modeling, and (4) conducting thematic analysis. The study process workflow is illustrated in Figure 1.

Ethics Approval

This study exclusively utilizes anonymized data from publicly available sources. The quotes presented in this report are modified or paraphrased to prevent any potential identification and direct linkage to the original posts/quotes. All identifiers or pseudo identifiers have been removed from the report. This study was approved by the Survey and Behavioral Research Ethics Committee of the Chinese University of Hong Kong (reference SBRE-20-864).

Data Sources and Collection

For this study, textual data were collected from online forums and social media platforms. For consistency and minimal translation concerns, only English-language texts were included. The posts from these platforms dated before November 15, 2022, were included, with varying start dates. For social media platforms, posts were extracted from Facebook, Twitter, and Reddit. These platforms were chosen for their popularity and the substantial textual content they contain [19]. For cancer-related online forums, the selection criteria have been detailed in a previous study [20]. To describe briefly, we first used the top search engines (Google, Microsoft Bing, Yahoo, and Yandex) to search for health forums by using different combinations of search terms (cancer, tumor/tumour, patient, and forum) [21]. The search results were extracted and examined by the investigators. Web forums were included if they (1) appeared in more than one search result, (2) were open access (ie, no membership or passwords were needed to access the messages), (3) were active for at least the past 5 years, (4) had at least 10 messages posted to the group within the past 30 days from the date of the search, and (5) enabled web scraping of posts or feeds using Python (Python Software Foundation) or R (R Foundation for Statistical Computing). Finally, 16 different online cancer-related forums, including Cancer Chat, Cancer Survivors Network, Cancer Council Online Community, and other forums, were included for the analysis (Table 1). Search terms related to immunotherapy were identified from multiple authoritative websites, including the American Cancer Society, Cancer Research UK, and the National Cancer Institute (Table S1 in Multimedia Appendix 1). Site-provided search engines were utilized to identify related posts.

Macmillan Cancer Support [36]	2008
HealthUnlocked [37]	2013

[a]In cases where the start dates of certain online health forums were not explicitly provided, an estimation was made based on the published date of the first post available.

Data Preprocessing

Spark NLP, a natural language processing library for Python built on top of Apache Spark, was utilized to preprocess the textual data [38]. The texts extracted from the forums and social media sites were subjected to a thorough cleaning process to enhance their suitability for further analysis. The cleaning process involved multiple steps, including checking and correcting spelling errors, lemmatization, removal of stop words, and elimination of short entries (Figure 1). Each text message was first spell-checked, and the vocabulary was reduced to its base root form by using Spark NLP. After that, each word vocabulary was reduced to alphanumeric characters that contained only letters from “a to z,” “A to Z,” and “0 to 9.” For a precise and semantically meaningful text corpus, any message composed of fewer than 4 words as well as commonly occurring words (eg, the, a, and, in) that carried little or no meaning in the message were removed. Finally, the cleaned text messages were processed using the medical language models from Healthcare Spark NLP, a pretrained pipeline to recognize medical terminologies within the messages [39].

Topic Modeling

The next step involved the extraction of topics from the data. Topic modeling, an unsupervised machine-learning approach, was employed to unveil hidden semantic structures and extract distinct topics from the extracted textual data [40]. In this study, we first evaluated 10 common topic modeling techniques, namely, Latent Dirichlet Allocation, Latent Semantic Analysis, Non-Negative Matrix Factorization, Principal Component Analysis, Random Project, K-Means, Top2Vec, BERT + K-Means, BERT, and Latent Dirichlet Allocation + BERT to determine the appropriate topic modeling approach. Topic diversity (indicating the model’s ability to capture differences between generated topics), coherence (the frequency of descriptive words of the topic within each cluster), and quality (topic diversity multiplied by topic coherence) were used as metrics to evaluate the effectiveness of isolating topics from the texts [41,42]. Finally, we used BERTopic to extract quality topics from the data based on the modelling performance. All texts were passed through the BERT model to create embeddings that converted text messages into numerical representations by using BERTopic. The dimensions of the embedding vectors were reduced due to the “Curse of Dimensionality” [43]. The bisecting K-means algorithm was used to group the reduced-dimension embedding vectors into clusters until optimal silhouette scores were achieved [44]. Various numbers of topics, ranging from 5 to 25, were tested to determine the optimal metrics.

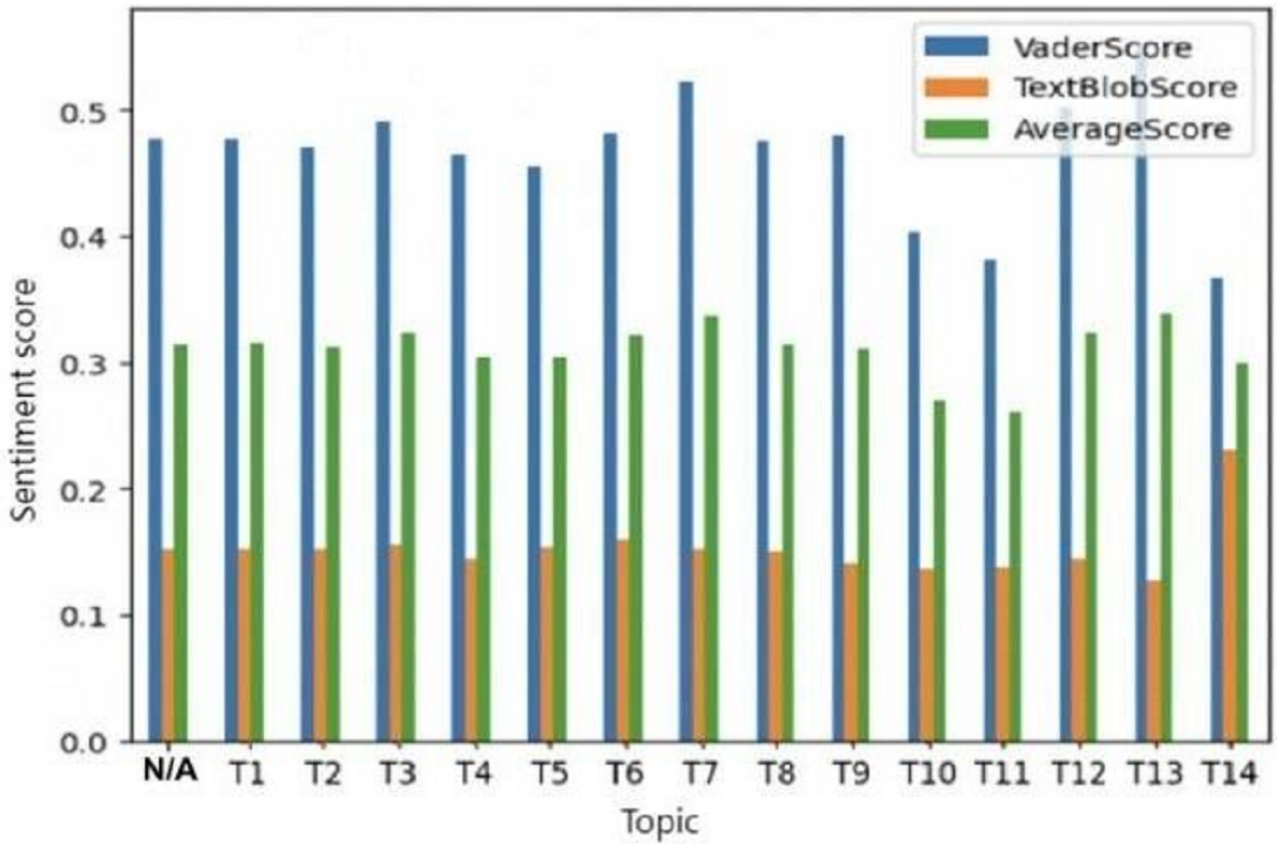
Following the identification of clusters with the highest topic quality, the 20 most frequent words from each topic were extracted. BERTopic modeling was conducted using the Worcester Polytechnic Institute’s Turing cluster, which has high computing power for large volumes of data processing by using multiple physical computers simultaneously. The Turing cluster consists of a 4-node hyperconverged head that controls 79 compute nodes and is located at Worcester Polytechnic Institute. The total central processing unit/random access memory/graphics processing unit counts across all computer nodes were 5224, 49 TB, and 84, respectively [45].

XSL•FO
RenderX

Sentiment and Thematic Analysis

Sentiment analysis was performed using 2 popular libraries, VADER (Valence Aware Dictionary and Sentiment Reasoner) and TextBlob [46,47]. Both libraries were used to enhance the accuracy of the results and minimize potential biases that may arise from relying on a single library. The sentiment scores obtained from each library were then averaged to derive a final sentiment score, which ranged from –1 (indicating a very negative sentiment) to 1 (indicating a very positive sentiment). Based on the topics generated through BERTopic modeling, thematic analysis was conducted by 2 investigators (XW and CSL) to identify themes associated with immunotherapy. The thematic analysis in this study involved the following steps: familiarization with the posts, inductive analysis, theme generation, and theme review among domain experts in the research team (including oncologists and oncology pharmacists) [48]. First, 2 investigators (XW and CSL) familiarized with the posts and encoded them independently. Then, the codes were compared, the same codes were merged, and any discrepancies were addressed through discussion with a third investigator (YTC). The themes were generated through the identification and refinement of the codes, which were grouped by perceived thematic similarities. The final themes were identified by achieving consensus among domain experts. The consensus process involved multiple rounds. The experts rated their level of agreement for each theme: themes with 75% agreement were retained, and themes without consensus were discussed, adjusted, and rated in the next round until 75% agreement was reached.

Results



Overview

A total of 4.9 million posts were gathered from online forums and social media platforms. After data cleaning, 3.6 million posts remained for further analysis (Figure 1).

Number and Quality of the Topics

In comparison with other topic modeling techniques, BERTopic demonstrated the most satisfactory performance, with a topic diversity score of 81.11%, a topic coherence score of 80.48%, and a topic quality score of 65.28% (Table S2 in Multimedia Appendix 1). Table S3 in Multimedia Appendix 1 presents BERTopic's performance across different numbers of topics to determine the optimal value. Fifteen topics achieved the highest overall topic quality, scoring 70.47% (with the highest topic diversity at 87.86% and a high topic coherence of 80.21%). We also used these metrics to assess the quality of individual topics generated by the model, yielding topic quality scores ranging from 78% to 88% (Figure S1 in Multimedia Appendix 2). One topic (Topic 15) was excluded due to the mismatch between its extracted words and the topics related to immunotherapy. Based on the sentiment analysis results, the average sentiment score of around 0.3 across the 14 topics preliminarily suggested generally positive sentiments toward immunotherapy within the online community (Figure 2). A more comprehensive interpretation of the specific topics is presented in the subsequent sections.

Figure 2. Sentiment analysis results. Sentiment score (a measure of how positive or negative the tone of the quotes is) was analyzed for each topic. The sentiment score ranged from –1 (indicating a very negative sentiment) to 1 (indicating a very positive sentiment). N/A: not applicable; T: topic.

XSL•FO
RenderX

Themes and Topics

A total of 6 themes were identified (Table 2). The quotes in Table 2 have been modified to prevent any potential identification and direct linkage to the original posts. Theme 1 centered on the feelings of hope and positivity among patients treated with immunotherapy. This theme highlighted the belief that immunotherapy offers hope for patients with cancer to lead normal lives and provides a potential cure for cancer with minimal side effects. Theme 2 described immunotherapy as a more effective treatment option after other treatments have failed. Patients may have tried other cancer treatments such as chemotherapy and radiotherapy but only found successful results with immunotherapy. Besides, patients believe combining immunotherapy with other conventional therapies, particularly chemotherapy, can lead to higher efficacy in treating cancer than using a single treatment approach. Theme 3 suggested that patients receiving immunotherapy also explore diets or complementary medicines to manage their symptoms or side effects from treatment or the cancer itself. For example, patients may employ mind-body practices such as massage and meditation or use herbal medicines to alleviate certain physical and psychological side effects caused by immunotherapy. Probiotics were frequently mentioned by users as a potential way to boost the effectiveness of immunotherapy. In Theme 4, the potential ineffectiveness, worse outcomes, and high cost of treatment were frequently mentioned among patients, which acted as hindrances to the use of immunotherapy. Theme 5 suggested that immunotherapy can disrupt patients' normal daily lives, particularly for those enrolled in immunotherapy trials. Additionally, the treatment may negatively impact their activities of daily living, such as taste changes, dietary restrictions, and time consumption. Theme 6 indicated that immunotherapy may cause physical and psychological symptoms and side effects such as rash, inflammation, and nephrotoxicity. These adverse effects may sometimes pose greater challenges compared to those arising from other treatments or the cancer itself. Some patients acknowledged that these symptoms may be unavoidable alongside the curative effects of immunotherapy.

XSL•FO
RenderX

Table 2. Topics and selected posts under each theme.

Theme, topics and related keywords	Samples of modified quotes[a]
Theme 1: Hopeful prospects offered by immunotherapy	
Topic 1: good, time, hope, love, great, feel, work, lot, treatment, start	• …help not to feel alone during treatment. • …hope stop the growth of cancer quickly. • …the new treatment offers new hope.
Topic 3: fight, hope, positive, news, treatment, glad, beat, good, feel, life	• …immunotherapy through clinical trials has shown positive results. • …wish to continue with immunotherapy after completing treatment. • …use the inert immune system to combat cancer cells. • …reduced damage compared with chemotherapy or radiotherapy.
Topic 5: hope, day, love, morning, huge, satisfy, glad, feel, good, love	• …hope of one day curing all cancers without side effects. • …develop immunotherapy tailored to the individual. • …the day when immunotherapy will be available to all. • …eradicate unique cancer cells
Topic 6: saint, faith, family, love, god, strength, miracle, wonderful, hope, glad	• …a miracle for patients to keep the cancer at bay. • …a miracle to help someone with very advanced diseases.
Theme 2: Perceived effectiveness of immunotherapy	
Topic 4: gallbladder, liver, bile, symptom, surgery, scan, remove, problem, ultrasound, test	• …a tremendous response with significant improvements. • …the tumors on my adrenal glands, lungs and liver have shrunk after immunotherapy. • …tried immunotherapy as one last hail Mary pass and it seems to be working.
Topic 13: risk, study, benefit, favorable, evidence, effect, patient, data, high, treat	• …immunotherapy appears to be successful in that the CT scan shows the cancer has shrunk. • …have a favorable response against the melanoma. • …immunotherapy has given lives back.
Topic 8: antioxidant, radiation, chemo, protect, treatment, dose, effect, radical, kill, interfere	• …better results with less side effects. • …combine chemo with immunotherapy gives the potential for long term remission and even a cure for advanced cancers. • …very effective in treating liver tumors.
Theme 3: Complementary therapies or self-treatments	
Topic 2: acupuncture, pain, feel, needle, massage, neuropathy, flash, hot, session, side	• …encouraged to get massage and acupuncture. • …had acupuncture to help with side effects of immunotherapy, such as abdominal pain, muscle pain, and severe neuropathy.
Topic 10: keto, diet, food, organic, probiotic, supplement, eat, weight, sugar, body	• …dependent on good gut bacteria. • …anyone undergoing immunotherapy is recommended to take probiotics concurrently. • …tried anything else, eg, diet, nutrition, supplements, etc.
Theme 4: Financial and mental impact of immunotherapy	
Topic 7: diagnosis, feel, anxiety, traumatic, stress, cost, experience, time, depression, therapist	• …expensive drugs with nasty side effects. • …immunotherapy costs a lot that can’t afford it. • …dealing with progression is profoundly stressful. • …more depressed and weaker when waiting long for treatment.
Theme 5: Impact on lifestyle and time schedules	
Topic 9: simulation, schedule, treatment, appointment, ill, week, start, time, plan, session	• …involve an eight-week program after the previous treatments. • …take a break and/or reduce dosages rather than quit altogether. • …spent 5 weeks to decide on a new treatment plan. • …don’t have too much flexibility.
Theme 6: Side effects due to treatment	
Topic 11: ill, swell, weak, surgery, compression, feel, wear, inflame, tight, back	• …surprised at how the side effects returned so quickly. • …resulted in inflammation of lungs. • …the treatments can result in worst side effects than the disease itself.

XSL•FO
RenderX

Theme, topics and related keywords	Samples of modified quotes[a]
Topic 12: immune, damage, skin, fever, burn, kill, system, therapy, tissue, body	• …developed an acute kidney injury. • …had a very hard time with auto immune reaction • …had several other side effects, but not a rash.
Topic 14: pain, symptom, hope, painful, colitis, arthritis, response, issue, experience, costochondritis	• …back pain mentioned as a side effect. • …have a rash on the back of neck and serious neuropathy. • …found a cream that helps along with pain meds.

[a]The quotes have been modified or paraphrased to prevent any potential identification and direct linkage to the original posts.

Discussion

Principal Findings

We analyzed a large dataset comprising 3.6 million posts from 3 social media platforms and 16 online cancer forums, providing a comprehensive overview of perceptions regarding immunotherapy within English-speaking online cancer communities. A cutting-edge natural language processing technique, BERTopic, was used to generate interpretable topics, ensuring robust data analysis. The identification of different themes underscores the diverse attitudes toward immunotherapy across various aspects. The posts show the positive attitudes of the patients toward immunotherapy and its perceived effectiveness and benefits. However, there are also concerns about the side effects of immunotherapy and potential disruptions to patients' lifestyle. These themes may offer valuable insights into the facilitators and barriers to the adoption of immunotherapy. In addition, the results showed that using machine learning techniques to analyze patient-generated online textual data can enhance our understanding of perspectives on newer cancer treatments, and such information may facilitate communication between patients and clinicians when discussing immunotherapy as a therapeutic option.

Comparison to Current Evidence

The positive factors that encourage the utilization of immunotherapy included its comparatively mild side effect profile and the potential to instill hope in patients by offering a viable treatment option when other methods have failed. Our findings also indicated that online cancer communities seem to be well-informed, with some patients well-versed in the benefits of immunotherapy. Laypeople now access medical information on the internet independently and acquire firsthand information about advances in cancer treatment. Access to online health information assists patients in making health-related decisions, leading to more professional consultation, improved treatment compliance, and better self-care [49]. However, the internet should not be viewed as a replacement for professional health information sources [50]. The guidance and advice of health care professionals remain indispensable in helping patients make complex medical decisions [51]. Online health information cannot provide detailed diagnoses or personalized treatment plans for patients; moreover, the presence of misinformation on websites might mislead patients about treatment [52]. Taken together, our results highlight the rising health literacy of online cancer communities, especially those involving younger generations. Future efforts should focus on enhancing the accuracy of online health information by using reliable rating tools, effective search engine ranking, and progress in crowdsourcing websites.

Although immunotherapy has shown clinical benefits in several trials, there are still potential barriers to its utilization. The high cost associated with immunotherapy emerges as a frequently discussed concern among patients with cancer, emphasizing the need for revising drug valuations and reimbursement models [53]. Many quotes were related to patients' descriptions of their physical symptoms induced by immunotherapy and how it has impeded their activities of daily living and disrupted their normal lives. In addition to physical irAEs, the long-term use of immunotherapy has also been associated with psychiatric side effects such as fatigue, insomnia, anxiety, and depression [54,55]. Hence, it is important for oncology practitioners to manage patients' expectations and communicate with patients regarding the potential side effects of immunotherapy before initiating treatment. This proactive approach allows patients to better understand the benefits and risks of the treatment, which may prevent them from discontinuing treatment because of known adverse reactions.

Relevance to Clinical Practice

Several clinical practice guidelines have been proposed to address the evaluation and management of immunotherapy-induced toxicity [56] and the diagnosis and treatment of toxicity associated with immune checkpoint inhibitor therapy in specific organ systems [57]. The provision of high-quality supportive care from a multidisciplinary team of health care professionals can help identify and manage irAEs [58]. In practice, patients may turn to self-management strategies to cope with these symptoms. We found that some patients mentioned in online posts that they used traditional, complementary, and integrative medicine modalities such as probiotics, herbal remedies, and meditation to self-manage the toxicity induced by immunotherapy. Recently, some studies have evaluated how complementary medicines may enhance the efficacy of immunotherapy and alleviate immune toxicity [59,60]. For example, the treatment of irAEs often necessitates the long-term use of high-dose corticosteroids [61]. Integrating complementary modalities into the management of irAEs may reduce corticosteroid use. Our group has previously reported that patients with cancer frequently seek advice on the use of complementary medicines on social media platforms [20]. At this juncture, clinicians should focus on initiating effective communication regarding the use of complementary medicines and help patients establish realistic expectations while being well-informed about the limited evidence supporting these approaches.

Limitations

Our study has several limitations. First, the data used in this research were collected from English-language online cancer communities, which may limit the generalizability of the findings to data posted in other languages. Social media and cancer forums may be used distinctly in different countries, and the types of immunotherapeutic approaches may also vary among regions. Future studies could conduct a thorough investigation into whether distinct concerns regarding immunotherapy exist among patients from different countries and regions of practice. Second, perceptions regarding immunotherapy on social media and cancer forums are dynamic and may be influenced by current news or events. Therefore, future research can consider exploring the fluctuations in posts on these platforms over varying time periods. Third, although the performance metrics (topic diversity and topic coherence scores) quantified from our models suggest that BERTopic is effective at unveiling latent patterns within large datasets, this approach requires validation. Nevertheless, our study demonstrates that applying artificial intelligence to analyze social media data can facilitate our understanding of patients' perspectives as well as the effectiveness of machine-learning techniques in processing substantial volumes of data retrieved from social media platforms and online forums.

Conclusions

This study captures comprehensive insights and perspectives of online communities regarding immunotherapy through BERTopic modeling. The identified themes and topics may facilitate the understanding of immunotherapy utilization and serve as valuable supporting information when making treatment decisions. The posts have shown the positive attitudes of the patients and their perceived effectiveness and benefits of immunotherapy. Although immunotherapy presents a beacon of hope and a viable treatment option, its side effects and the accompanying potential lifestyle disruptions cannot be ignored and are major concerns perceived by the online communities. It is essential for clinicians to inform patients of the undesirable effects of immunotherapy and establish realistic expectations, thereby enabling patients to make an informed decision considering the benefits and risks associated with the treatment, which may ultimately lead to more optimal treatment outcomes with immunotherapy.

Acknowledgments

We would like to thank Worcester Polytechnic Institute's Turing cluster hosted by the Worcester Polytechnic Institute for the implementation of the computing process.

Abstract

Background: Amiodarone treatment requires repeated laboratory evaluations of thyroid and liver function due to potential side effects. Robotic process automation uses software robots to automate repetitive and routine tasks, and their use may be extended to clinical settings.

Objective: Thus, this study aimed to develop a robot using a diagnostic classification algorithm to automate repetitive laboratory evaluations for amiodarone follow-up.

Methods: We designed a robot and clinical decision support system based on expert clinical advice and current best practices in thyroid and liver disease management. The robot provided recommendations on the time interval to follow-up laboratory testing and management suggestions, while the final decision rested with a physician, acting as a human-in-the-loop. The performance of the robot was compared to the existing real-world manual follow-up routine for amiodarone treatment.

Results: Following iterative technical improvements, a robot prototype was validated against physician orders (n=390 paired orders). The robot recommended a mean follow-up time interval of 4.5 (SD 2.4) months compared to the 3.1 (SD 1.4) months ordered by physicians (P<.001). For normal laboratory values, the robot recommended a 6-month follow-up in 281 (72.1%) of cases, whereas physicians did so in only 38 (9.7%) of cases, favoring a 3- to 4-month follow-up (n=227, 58.2%). All patients diagnosed with new side effects (n=12) were correctly detected by the robot, whereas only 8 were by the physician.

Conclusions: An automated process, using a software robot and a diagnostic classification algorithm, is a technically and medically reliable alternative for amiodarone follow-up. It may reduce manual labor, decrease the frequency of laboratory testing, and improve the detection of side effects, thereby reducing costs and enhancing patient value.

Introduction

Amiodarone is a potent antiarrhythmic drug widely used for both severe supraventricular and ventricular arrhythmias. However, careful follow-up is necessary during treatment due to potentially serious adverse effects and toxic reactions in the thyroid gland, liver, lung, and heart. Approximately 15% of patients will experience adverse effects during the first year of amiodarone use and 50% during long-term treatment, most often thyroid and liver dysfunction [1]. Reported frequencies of amiodarone-induced hypothyroidism (AIH) and amiodarone-induced thyrotoxicosis (AIT) vary between 1%-32% and 0.8%-37.8%, respectively [2-4], with hypothyroidism typically occurring sooner than hyperthyroidism. A careful study showed median time-to-onset at 183 days for AIH and 720 days for AIT [2]. In addition, AIT is often more resistant to treatment due to the complex effects of amiodarone on the thyroid involving hyperthyroidism, thyroiditis, and iodine overload. Hepatotoxicity, with slight elevations of serum transaminase levels, occurs in about 25% of patients whereas hepatitis, cirrhosis, or hepatic failure occurs in less than 3% [5,6].

Amiodarone carries electrophysiological characteristics of all Vaughan Williams classes, although most importantly class 3, which consists of prolongation of the third phase of the action potential in myocardial cells [7]. It is an iodinated benzofuran derivative that is structurally similar to thyroid hormones. It contains about 37% organic iodine, resulting in 40 to 100-fold iodine excess into the systemic circulation [4,8], overloading the thyroid. Amiodarone accumulates in adipose tissue, due to its high lipid solubility, and in highly perfused organs such as the liver, lung, and skin [6]. These properties of amiodarone contribute to the considerable excess risk of primarily thyroid and liver side effects. Additionally, due to the prolonged biological half-life of amiodarone, up to 40-142 days, toxicity can occur in the thyroid and lung even after the treatment is stopped, thus requiring follow-up after discontinuation of therapy [3,8].

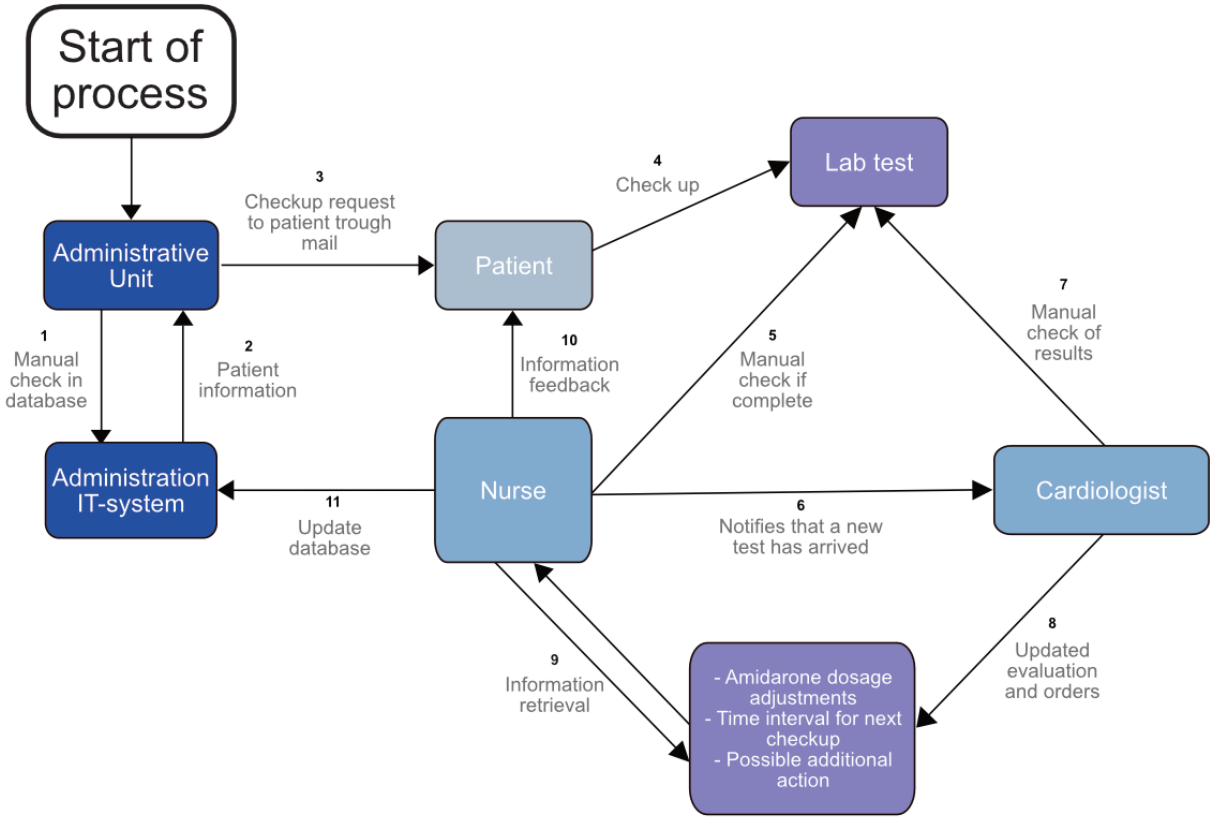
Monitoring recommendations during amiodarone treatment according to the North American Society of Pacing and Electrophysiology include thyroid and liver function tests at baseline and every 6 months, supplemented with recurrent radiographic and functional testing [9]. The American Thyroid Association recommends analysis of thyroid-stimulating hormone (TSH) and thyroxine levels at baseline and thereafter every 3-6 months [10]. The most recent updated consensus management guide recommendations, by Epstein et al [1], are in accordance with the North American Society of Pacing and Electrophysiology, proposing follow-up every 3-6 months for the first year and every 6 months thereafter.

Repeated notifications to patients on amiodarone for necessary follow-ups with laboratory testing, examinations, evaluations, and prescriptions for continued medication is a time-consuming and repetitive process. To ensure that no patients are missed, clinical controls with patient-doctor meetings and systematic laboratory follow-ups of side effects are organized independently. Thus, if patients fail to appear or postpone doctor's meetings they will still be on the administrative waiting list for amiodarone laboratory controls and be regularly summoned for testing. The overall administrative workload for health care professionals is considerable, contributing to workplace stress and a shortage of available personnel. The development of streamlined automated work processes is therefore an attractive option for amiodarone treatment follow-up.

In this study, we present a model for the automation of repetitive follow-up of patients with amiodarone treatment. First, we constructed an automated solution including the whole surveillance process, using a robotic process automation (RPA) software tool. We then compared the RPA to standard manual amiodarone follow-up as presently practiced.

Methods

Patients



All patients on, or who recently finished amiodarone treatment (N=198), followed at the outpatient clinic of the Department of Cardiology, Sahlgrenska University Hospital/Östra for surveillance, were included in this study. Clinical background data were collected from patient records and stratified by the type of arrhythmia constituting indication for therapy. All patients received annual in-office appointments with a cardiologist for their clinical condition. Complementary follow-up with laboratory testing owing to the amiodarone treatment was carried out according to routine, irrespective of clinical follow-up. Before the start of the therapy, the standard clinical routine at Sahlgrenska University Hospital/Östra was performed, including the following: thyroid function tests with TSH, free thyroxine, free tri-iodothyronine, liver function tests for aspartate aminotransferase, alanine aminotransferase, ECG, chest x-ray, and a pulmonary function test, including diffusion capacity. After initiation of amiodarone treatment, updated thyroid and liver laboratory blood tests were performed at 3 months, 6 months, and thereafter routinely every 6 months as per local guidelines [1,10], or at the discretion of the cardiologist. The routine further prescribed a complementary test of TSH receptor antibodies or thyroid peroxidase antibodies when a thyroid function test was abnormal. Patients who developed AIT were referred to an endocrinologist, whereas patients who presented with AIH were referred to primary care. Side effects already present at baseline as well as those sustained during follow-up were recorded.

Process Mapping in the Design of the Robot

To define the actions that should be included in the RPA procedure, all steps of the laboratory thyroid and liver function surveillance process were mapped by a multiprofessional team (specialized cardiology nurse, cardiologist, administrative personnel, and solution architect; March 2021) and presented in Figure 1. In brief, the manual existing routine in use included the following: (1) patients were manually identified by secretarial personnel from an administrative listing ("amiodarone controls"); (2) orders for blood tests were issued and a time slot for sampling was sent by post to the patients; (3) arrival of completed laboratory analyses were manually monitored from patient records by nurses, and notifications sent to a cardiology specialist; (4) after reviewing the laboratory results the cardiologist decided and recorded the future dose of amiodarone, time interval to next follow-up and possible actions depending on side effects; and (5) the orders were manually transferred to a nurse for execution and notification of the patient. For absent laboratory results the nurse issued a reminder to the patient. This process was typically repeated 2-4 times a year per patient. This routine was maintained during the whole study and included all physicians' orders assembled in the following analysis, that is, the manual routine constituted the real-world follow-up, and was compared to the robot.

Figure 1. Process map of established manual workflow and steps of the laboratory amiodarone surveillance process. lab: laboratory.

Automation Tool

A commercially available RPA was programmed to perform tasks following a predetermined set of rules and interact with various information systems (UiPath), thereby performing structured and repetitive tasks quickly and reducing the need for manual human work [11]. It thus mimicked human behavior in repetitive and rule-based work [12], and operated by mapping a process in the RPA tool language for the software robot to follow, with runtime allocated to execute the script by a control dashboard [13].

Construction of Initial Prototype

Based on the process map, an initial prototype was constructed. The patient administrative system (ELVIS, Insieme Consulting AB) with the acquisition of listed patients for "amiodarone controls," and the laboratory system (LabBest, CareDialog AB) for access to laboratory results, were integrated. Additionally, an algorithm with reference values for TSH, free thyroxine, free tri-iodothyronine, aspartate aminotransferase, and alanine aminotransferase was built into the process. Three color-coded classes, corresponding to the level of urgency, were created based on reference values. The output was designed as a recommendation for a decision-making cardiologist, serving as a human-in-the-loop, indicating one of three possible actions for each output: class 1: overall normal outcome values (green color) recommending next follow-up test in 6 months, class 2: minor deviation from normal values of uncertain significance (yellow color), recommending follow-up testing in 1 month, and class 3: definite laboratory pathology indicating clear side effect (red color), recommending prompt management by a physician, along with detailed recommendations for management (dose adjustment, discontinuation of amiodarone medication, or consultation of a specific specialist).

XSL•FO
RenderX

Iterative Improvement of Initial Prototype

The first RPA algorithm (robot 1) was tested by comparing the automated output with the real-world manual procedure from April 2021 to December 2021, including iterative adjustments for clinical optimization. Importantly, the new algorithm incorporated expert clinical advice developed by experienced specialists, 2 endocrinologists (HFN and KT) and 1 gastroenterologist (NP), ensuring state-of-the-art recommendations for assessing and managing both normal and pathological findings. Simultaneous technical adjustments optimized performance and reliability. The resulting algorithm was used for validation studies in the final prototype (robot 2) and is presented and explained in detail in Multimedia Appendix 1.

Final Prototype for Validation

For validation and comparative testing, a final prototype, robot 2, was constructed based on the aforementioned adjustments. For comparative analyses, we defined robot 2 as "ground truth," that is, constituting the accurate data used as a reference to validate the system, comparing endocrinologist and gastroenterologist experts' clinical advice against real-world handling by a cardiologist. We considered experienced endocrinologists and gastroenterologists to have more expertise in hormonal or hepatological evaluations compared to the general cardiologist. Furthermore, the output from robot 2 included written instructions for abnormal findings and is presented as supplementary information including specific clinical routines and references to detailed guidelines (Multimedia Appendix 1). The final prototype, robot 2, was tested from February 2022 to February 2023. Notably, the existing routine process remained in operation during the whole period, with the manual routine executed without awareness of the robot, such that the physician's orders constituted the real-world outcome and robot 2 worked in parallel producing outcomes only available to the research team. Paired orders, from the physician and robot 2, were compared.

Comparative Analysis of the Final Prototype for Validation

The comparative analyses' primary outcomes were the following: (1) the time interval between recommended laboratory testing and (2) the detection of side effects. The distribution of recommended time intervals for follow-up and disagreements between robot and physician were analyzed. First, a strict comparison between the number of months to the next follow-up ordered by the robot and the physician was made. Second, each order made by the physician was classified and labeled per robot 2, as follows: after completion of the test period, all dates for the paired test were retrieved from the robot and laboratory results and patient records were examined by one of the authors (HS) and classified as correct or incorrect according to the rules of the algorithm, when compared to the decision made by the physician responsible for managing the case. This evaluation was made without knowledge of the robot classifications. If patient records were ambiguous consultations were made with another author from the team (BIJ). The results from robot classifications were then retrieved for the pairing of outcome classifications and comparative analysis.

We used a confusion matrix as a performance estimate of the physician's classification compared to the robot. A confusion matrix is a statistical tool used to evaluate the performance of a classification model. In this context, it was used to visualize the accuracy of the physician-predicted side effects based on the laboratory test results, comparing the physician-derived orders with the orders by robot 2. The labels applied on classification were the following: (1) true positive (TP) for pathological laboratory results (corresponding to class 2-3, yellow or red), (2) true negative (TN) for normal laboratory results (corresponding to class 1, green), (3) false positive (FP) for follow-up tests ordered by the physician for a time interval >1 month shorter than that ordered by robot 2 (ie, judged as more urgent than ground truth by the physician), and (4) false negative (FN), follow-up tests ordered for a time interval >1 month longer than that ordered by robot 2 (ie, judged as less urgent than ground truth by the physician) or when a definitely pathological test result was not noticed by the physician. Paired orders were compared (n=390 observations). All labels given by the robot and physician were combined into a data frame and presented in the confusion matrix. If the time interval to follow-up test between the algorithm and physician differed ≤1 month the same labels were given. As robot 2 was judged as ground truth, the confusion matrix is limited to true labels (TP and TN) for actual outcomes.

Analysis of Differing Classifications Between the Robot and Physician

To further compare robot 2 and physician estimations, we analyzed the distribution of months to the next follow-up. To investigate which classifications (classes 1-3) contributed the most to the disagreements, that is, the false classifications observed in the confusion matrix, all observations were grouped based on the 3 robot classifications and sorted according to the labels given in the confusion matrix. If the label given by the physician matched the label given by robot 2 the observation was judged as correct. If the physician had given any label other than robot 2, the observation was considered to be incorrect. Classes 1-3 were converted to a month-based scale. Outcome class 3 (red color) was classified as "0 month" since red represented the highest urgency calling for "directly to physician for handling."

Detection of Side Effects

For patients who suffered side effects diagnosed in the patient record during this study, we compared the likelihood of detection between robot 2 and the physician. For robot 2, the correct detection of a side effect was judged as class 3 (red). The correct response to a side effect by the physician (comparable to class 3 [red]), was defined as at least one of the following noted in the patient record: (1) the diagnostic side effect was acknowledged by the cardiologist, (2) the indication for amiodarone was reevaluated, (3) adjustment or termination of medication was undertaken, or (4) referral or consultation with the appropriate specialist was undertaken. Incorrect or questionable action (yellow) was assessed when a new laboratory test was carried out without any of the aforementioned actions.

XSL•FO
RenderX

Statistical Analysis

Data are presented as numbers and percentages, mean (SD) for normally distributed variables tested with the Shapiro-Wilk test or median (IQR), unless otherwise stated. For comparison between groups, the Wilcoxon signed rank test was used. The demographic data includes the population participating during the robot 2 evaluation period.

Ethical Considerations

This study was performed per the principles of the Declaration of Helsinki. The project was approved by the Swedish Ethical Review Authority (2021-01962). This study was observational and informed consent was waived, as the presented robot 2 outcome represents a simulation, and the regular manual routine was upheld.

Results

Demographics of Cohort

Between April 9, 2021, and February 28, 2023, a total of 198 patients, with a mean age of 73 (SD 12) years and 62.6% (n=124) men, were under follow-up routines due to amiodarone prescription and were included in this study. Indications for amiodarone were atrial (n=145, 73.2%) or ventricular (n=53, 26.8%) arrhythmias. The most frequent comorbidities were heart failure (n=142, 71.7%), hypertension (n=127, 64.1%), and coronary artery disease (n=67, 33.8%). Of patients with atrial or ventricular arrhythmias, 23.4% (n=34) and 41.5% (n=22), respectively, had a left ventricular ejection fraction <40%. At baseline, 79.8% (n=156) were on β-blockers, 62.6% (n=124) on novel oral anticoagulants, and 17.2% (n=34) on thyroid hormone (levothyroxine; Table 1).

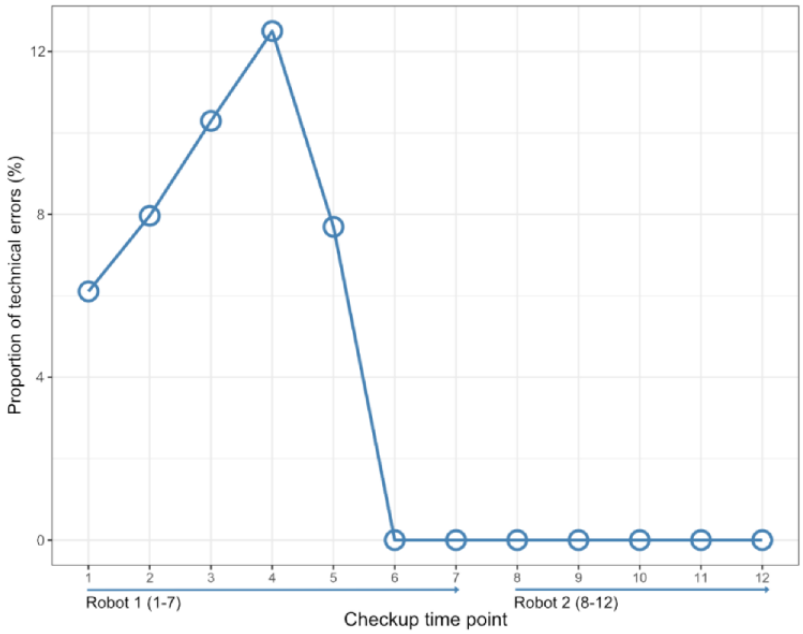
[a]Values are presented as the number of observations (percentage of population) if not otherwise specified.
[b]COPD: chronic obstructive pulmonary disease.
[c]HFpEF: heart failure with preserved ejection fraction.
[d]HFmrEF: heart failure with midrange ejection fraction.
[e]HFrEF: heart failure with reduced ejection fraction.
[f]ACEI-ARB: angiotensin converter enzyme inhibitors or angiotensin receptor blockers.
[g]ARNI: angiotensin receptor neprilysin inhibitor.
[h]SGLT2: sodium-glucose transport protein 2.
[i]IU: international units.
[j]AST: aspartate aminotransferase.
[k]ALT: alanine aminotransferase.
[l]LVEF: left ventricular ejection fraction.

Construction of the Prototype for Validation



The first prototype, robot 1, was developed from April 2021 to December 2021 through iterative adjustments, eliminating technical errors and improving the medical algorithm until obtaining satisfactory performance as judged by the multiprofessional team, resulting in the final prototype for validation, robot 2 (Figure 2). The technical improvement and reduction of errors over time are presented, with an error defined as an output from the robot not resulting in classification 1, 2, or 3 (Figure 3).

Figure 2. Process map of workflow and procedures included in the prototype robot (robot 2). ALT: alanine aminotransferase; AST: aspartate aminotransferase; PIN: personal identification number; T4: thyroxin; TSH: thyroid stimulating hormone.

XSL•FO
RenderX

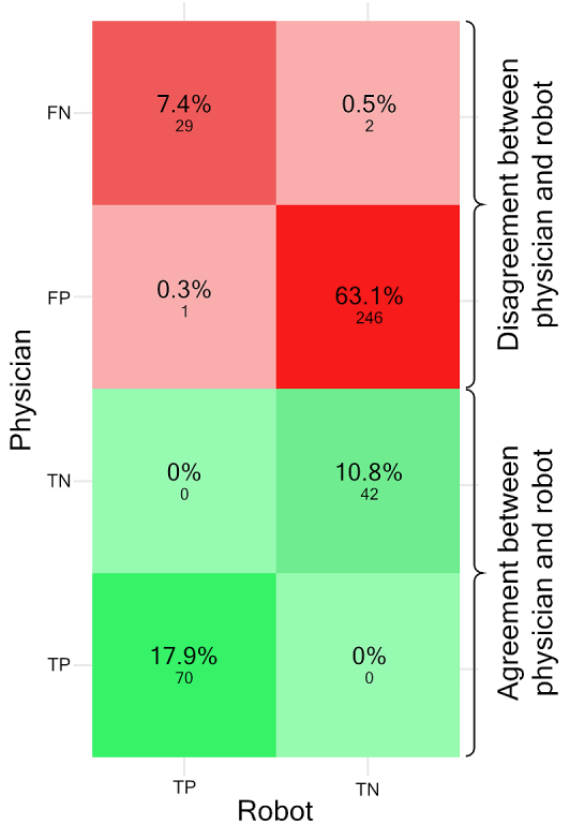


Figure 3. Proportion of technical robot errors over time (checkup time points).

Comparative Analysis of the Final Prototype for Validation

The primary finding of this study (Multimedia Appendix 2) was a significant difference in the ordered time interval to the next follow-up between robot 2 and the physician (robot: mean 4.5, SD 2.4 months; physician: mean 3.1, SD 1.4 months; $P<.001$). To analyze the model's accuracy in predicting each class, paired orders from robot 2 and physicians (n=390 observations) were compared using a confusion matrix, which displays the actual versus predicted classifications. Based on robot 2 output defined as ground truth, the robot labels represent the actual values and the physician's labels the predicted values (Figure 4). Of the observations, 112 (28.7%) corresponded between robot and physician. The most pronounced difference between the robot and the physician occurred for actual TNs according to the robot, which was judged as positive (predicted FP) by the physician in 246 (63.1%) observations.

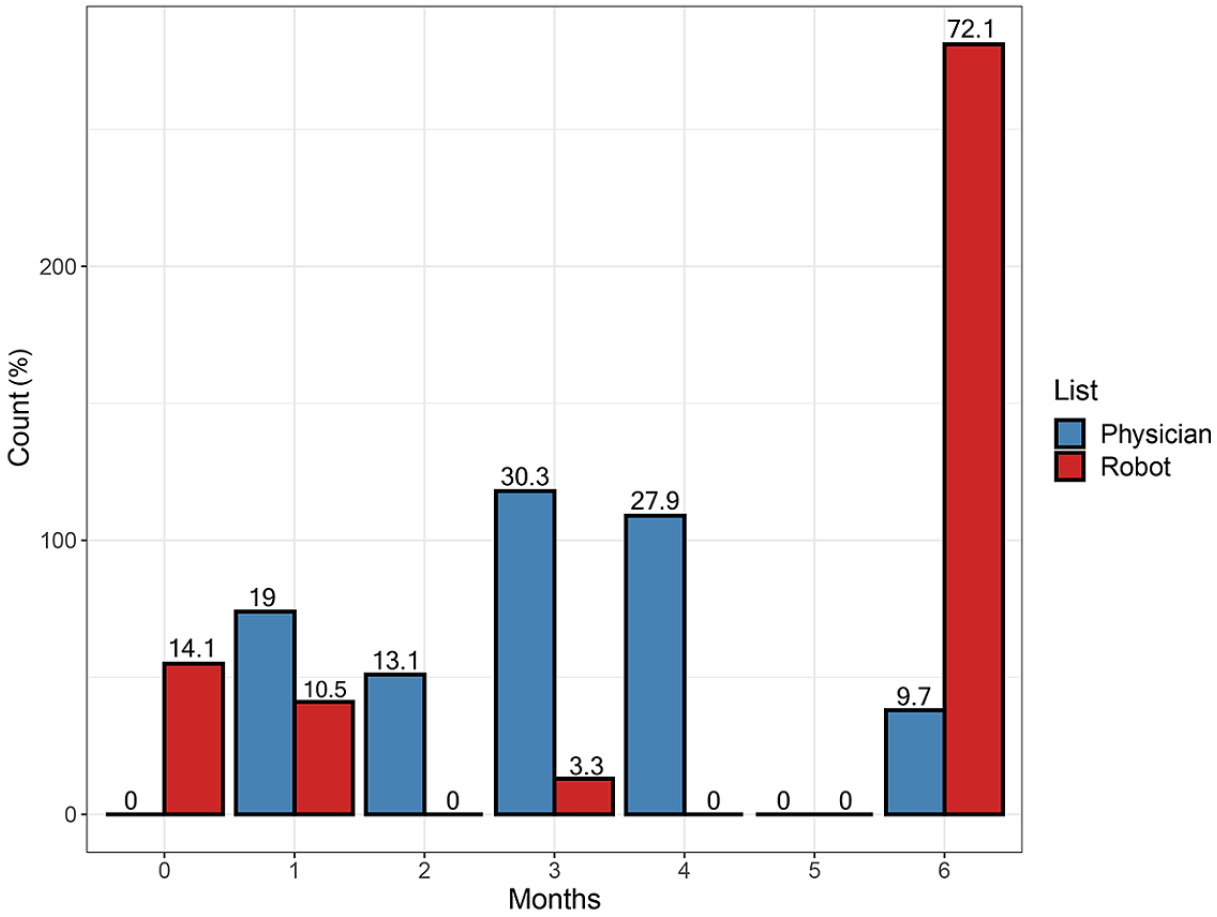

Figure 4. Confusion matrix of physician (predicted) and robot (actual) labels. Robot labels are judged as ground truth. Percentages of labels are shown in each square and the numbers of paired observations are below. FN: false negative; FP: false positive; TN: true negative; TP: true positive.

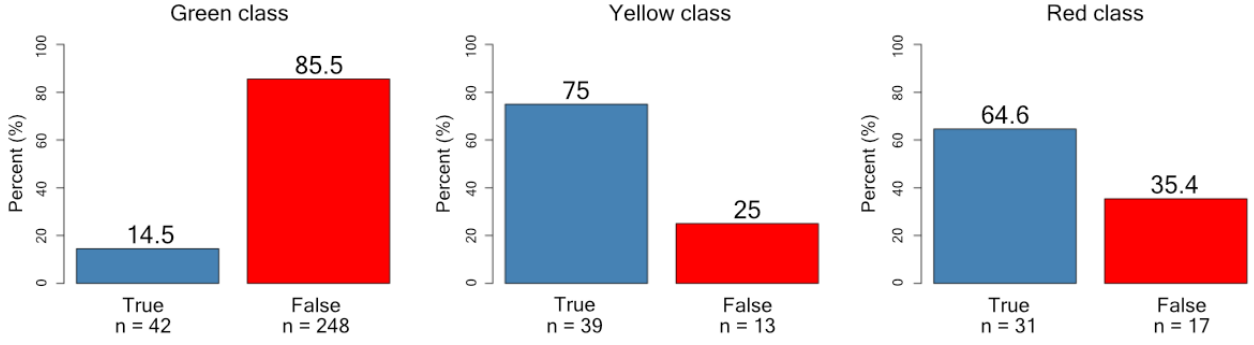
XSL•FO
RenderX



The bar chart, illustrating the difference between robot 2 and the physician's orders, demonstrates the largest visual difference in ordered times for follow-up as the robot ordered 6 months to the next control (ie, corresponding with normal laboratory values) in 281 (72.1%) observations, compared to physician's orders in 38 (9.7%). The remaining robot orders were concentrated in lower time intervals (0 months, ie, recommending immediate physician's action, and 1 month), whereas physician's orders peaked at the 3-month interval (n=118, 30.3%), followed by 4 months (n=109, 27.9%; Figure 5).

Figure 5. Bar chart of frequencies of patients who were ordered a time interval for follow-up by physician or robot, interval ranging from 0 to 6 months, on the x-axis. The absolute counts are shown on the y-axis and the percentage of physician and robot counts, respectively, is marked above the stacks (based on n=390 observations). For the robot, a red outcome implied a referral directly to the physician, which translated to "zero months.".

Complementary analysis showed the largest discrepancy for cases with the lowest degree of urgency (class 1: green, follow-up in 6 months) where false decisions greatly outweighed the true ones. When more urgent action was called for (classes 2 and 3: yellow and red colors), the robot and physician orders were more aligned, especially for class red (clearly pathological findings; Figure 6).

Figure 6. Discrepancies in outcome labels by the physician compared to the robot for the 3-color coded classes (representing different levels of aberration vs normality): (1) green class: normal laboratory values, (2) yellow class: minor deviation from normal or uncertain significance, (3) red class: definite laboratory pathology. "True" represents that the physician's classification matched the robot (ground truth). "False" represents that the physician's classification differed from ground truth. The height of the stacks represents the percentage of outcome labels (y-axis), and the absolute number of observations appears below the stacks.

XSL•FO
RenderX

Detection of Side Effects

During the 1-year evaluation, 12 patients developed side effects detectable in laboratory analyses (AIT n=8, AIH n=3, and hepatic side effects n=1). The robot assessed all these as class 3 (red), that is, a correct diagnosis and action. The physician's assessment was red in 8 and yellow in 4 (repeat ordering of follow-up laboratory tests after 1-3 months) of the corresponding cases (Figure 7).

Figure 7. Diagnostic side effects during study of robot 2 and assessment by robot versus physician. Observation of a correct response to a side effect by the physician required that (1) the diagnostic side effect was noted in medical records by the physician, (2) the indication for amiodarone was reevaluated, (3) adjustment or termination of medication was undertaken, or (4) referral or consultation with an appropriate medical specialist was done. Incorrect or questionable action represented that new laboratory tests were ordered without any of these actions. For repeated laboratory tests only, the interval of months ordered is noted in the boxes. Observation of a correct response to a side effect (red) by the robot required that the outcome reading was of the highest alert (red) ordering referral to a physician for action. *The physician reduced the dosage of amiodarone and ordered repeated testing after 1 month but documented no rationale for the action. F: female; M: male; mo: months.

Discussion

Overview

This study demonstrates that an automated process for decision-making based on thyroid and liver laboratory values outperformed a physician-operated manual routine for amiodarone follow-up, leading to reduced frequency of laboratory testing and more rapid detection of side effects. Amiodarone is the most effective antiarrhythmic drug to prevent recurrences of atrial fibrillation (AF) when other antiarrhythmic drugs have failed, are contraindicated, or when ablation of AF or ventricular arrhythmias is not an alternative [14]. In our cohort, AF constituted the most common arrhythmia. The efficiency of amiodarone paired with the considerable risk of side effects supports the rigorous follow-up routines prescribed in international recommendations [1,10], resulting in repetitive and time-consuming manual work in general cardiology practice.

Using automation through a software robot, an RPA, appears as one feasible solution to replace human labor and ensure compliance with guidelines. Software robots work with information systems via the front end, that is, via the presentation layer, and do not impact the underlying data infrastructure [15]. An RPA is suitable for a process that follows a standardized and rule-based structure (does not require cognitive or judgment effort), is conducted both often and manually by humans and requires multiple-system access [16].

XSL•FO
RenderX

Notably, this is not an artificial intelligence tool. The prototype provides recommendations to the physician as a human-in-the-loop. This retains the responsibility as a control mechanism, as all recommendations must be confirmed by physician's orders. Human exception management is necessary to solve problems where cognition, intuition, and situational decisions are needed [17].

Main Findings

Most notably, the robot ordered significantly longer intervals between tests compared to the physician which is especially pronounced in the low-risk cases. Using the robot may thus serve to reduce manual labor, lessen inconvenience and worry in patients, and liberate testing personnel for other care tasks. Additionally, the robot identified all laboratory-diagnosed side effects, as opposed to the physician, who initially missed 1 of 3. Thus, the use of the robot appeared to increase the safety of the procedure, based on more prompt recognition of side effects. Together, these findings support that monitoring recommendations based on appropriate expert clinical advice are superior to handling only by a cardiologist.

Detailed Analysis

Based on the outcomes defined by ground truth, we found that the most prevalent disagreement between the robot and physician occurred when laboratory values were normal (TN), whereas the physician classified normal findings as pathological (FP). This resulted in physicians ordering a significantly shorter time for the next laboratory follow-up than as motivated by guidelines or laboratory findings. Interestingly, the physicians' orders tended to cluster around the mean eligible choice, 3-4 months in almost 60%. This supposedly caused considerably more frequent laboratory follow-ups for patients when guided by the physician, leading to increased testing costs, manual labor, inconvenience, pain, and possible worries for the patients without contributing to a better quality of care.

In contrast, the robot-physician orders were better aligned for the more urgent laboratory results, indicating that clearly pathological findings would not be missed. Still, the detailed analysis showed that the robot was superior as it identified all side effects, compared to 1 of 3 missed at first presentation by the physician. Although the results appear indicative of a more rapid detection of side effects by the robot compared to the physician, this study was not designed or powered to evaluate the performance regarding the detection of side effects. As for the patterns of physician's ordering, we can only speculate but lack empirical support. The shorter control intervals ordered, despite knowledge of guidelines, may reflect a precautionary principle and hesitation to choose intervals at the recommended scale's margins. Other explanations may be decision fatigue and working under time constraints, which may result in excessive caution. The seemingly inferior detection of side effects by the physician may be due to the algorithm being based on expert clinical advice in thyroid and liver disease, and the physicians responsible for monitoring were cardiologists, not mastering the best practices in these disciplines.

The categorization of laboratory values based on an expert-guided algorithm, as created for robot 2 for validation, appeared crucial. Notably, the algorithm was specifically formulated by experienced clinicians with considerable experience in the laboratory effects of amiodarone medication, as no composite guidelines exist for this specific situation. This procedure secured appropriate recommendations for the management of pathological findings and also incorporated a margin for expected deviations due to amiodarone medication per se.

Plans

Following the satisfying outcome, our process for monitoring amiodarone treatment has gained approval as an in-house manufactured medical device for introduction at our health care institution, the Sahlgrenska University Hospital, per Regulation 2017/745 of the European Parliament, Article 5(5) concerning medical devices [18]. We are currently implementing the robot in clinical practice, under follow-up and supervision. However, evolving technology presents new avenues for development, such as the integration of a locally hosted large language model in the robot for increased accuracy and clinical relevance. This would enable both compilation of laboratory outcomes and individual recommendations for the patient at hand, possibly also incorporating consideration of clinical information. Another goal, outside the scope of this study, is to perform a more detailed analysis of physicians' behavior. This could be done through surveys or interviews with physicians, to explore the underlying reasons for not strictly following guidelines, such as stress or decision fatigue involved in decision-making in clinical situations.

Strengths and Limitations

One strength of our study was that the robot was carefully iteratively tested and designed to address technical and medical issues before launching the optimized prototype, robot 2, for validation during a year of final testing. Thus, our study presents detailed information on feasibility and safety in a real-world setting. Notably, the procedure will only identify the most common side effects, detectable in blood laboratory tests, whereas the remaining risks must still be considered in clinical visits. The robot does not replace the clinical consultation but constitutes an automated safety net as clinical consultations are regularly less frequent than the need for follow-up laboratory testing.

One weakness was that the final testing was carried out in parallel with real-world monitoring, providing a simulated outcome as a randomized controlled trial was outside the scope of this study. Additionally, the sample size of 390 paired orders was relatively small, which may limit the generalizability and statistical power of the findings, although including a complete cohort of all patients receiving amiodarone prescriptions at our health care institution. For example, this study was not powered to evaluate the performance between methods regarding the detection of side effects, although the robot appeared to outperform physician recommendations. Additionally, the results imply positive health economic outcomes, which have not been explored in this study.

XSL•FO
RenderX

Conclusion

This study aimed to design and test an automated process for amiodarone treatment monitoring, mastering the manual tasks, currently performed by nurses and physicians, with preserved patient value. After iterative design and technical improvements, a prototype for validation was tested for 1 year. We found that the automated process provided a reliable alternative to the present manual management of amiodarone treatment monitoring. The results indicated that the robot may reduce manual labor and frequency of laboratory testing and detect side effects with increased precision compared to the physician, thereby reducing costs, and enhancing patient value.

Acknowledgments

We would like to acknowledge cardiology nurses Maria Samuelsson, RN, Malin Lindqvist, RN, specialist nurse Inger Martinsson, RN, deputy director Markus Jonebrant, RN, Department of Medicine, Geriatrics and Emergency Medicine, Sahlgrenska University Hospital/Östra, and librarian Emelie Mellbrand, MA, Sahlgrenska Research Library, and the Wallenberg Centre for Molecular and Translational Medicine, University of Gothenburg, for their valuable and constructive contributions in this work. This study was financed by grants from the Swedish state under the agreement between the Swedish government and the county councils regarding the education of physicians and research, the ALF agreement from the Healthcare Board, Region Västra Götaland (grant ALFGBG-790271) to HFN; ALFGBG-971608 to ML; and the Innovation Platform, Region Västra Götaland, Sweden (grant 993954) to HS. We are grateful to Jamie D Kraft, PhD, for scientific editing and language review.

Data Availability

The data underlying this paper cannot be publicly shared to protect the privacy of this study's participants but will be made available upon reasonable request to the corresponding author. The software code for the RPA is available upon request to JL.

Abstract

Background: The internet has emerged as a primary source of health-related information for people living with multiple sclerosis (MS). However, given the abundance of misinformation found on the web, this behavior may pose a significant threat to internet users.

Objective: This study aims to explore the knowledge and information-seeking behavior of people living with MS followed at a specialized MS clinic where education is a cornerstone of care.

Methods: This cross-sectional survey–based study comprised 20 true or false statements, covering both scientific facts and popular misinformation about MS treatments. A “scientific fact score” and a “misinformation score” were calculated by attributing a scoring system to each point in the survey: +1 point was attributed to correct answers, –1 point was attributed to incorrect answers, and 0 point was attributed to “I don’t know.” Furthermore, the survey inquired about participants’ health-seeking behaviors.

Results: The mean age of the 69 participants was 48.4 (SD 10.9) years, 78% (54/69) were female, 81% (56/69) were highly educated, 90% (62/69) were receiving a disease-modifying therapy, and 52% (30/58) had experimented with alternative therapies. The mean score for answering the scientific and misinformation questions correctly was 69% (SD 2.4%) and 22% (SD 4.5%), respectively (P<.001). Notably, when questioned about misinformation, answering correctly dropped significantly (P<.001), while indecision (P<.001) and answering incorrectly (P=.02) increased. Sociodemographic factors and medical questions were not significantly associated with scientific and misinformation scores (all P>.05); however, misinformation scores did significantly correlate with levels of education (P=.04). The main sources of health-related information were from expert-led MS websites (48/58, 82%) and health care professionals (34/58, 59%). Low-reliability sources were less used; however, word of mouth seemed to be prevalent (14/58, 24%), followed by Facebook (10/58, 17%). On average, people with MS reported having consulted 3 high- to moderate-quality sources and only 1 low-quality source.

XSL•FO
RenderX

Conclusions: Education at the clinic and consulting primarily moderate- to high-quality sources did not safeguard against misinformation, indicating a need for more misinformation-geared education at the clinic. Notably, there is a need to proactively educate patients about misinformation commonly found on the web, and more importantly, create space for them to discuss the information without prejudice. As novel educational methods may be relatively more time-consuming, implementing change may be challenging. Furthermore, age, sex, education level, and health literacy might not safeguard against misinformation. Herein, we were unable to identify correlations associated with scores obtained on the questionnaire other than educational level. Although the educational level did seem to impact the misinformation score, this did not stop participants from experimenting with alternative therapies. Although studies are exploring novel ways to effectively deal with health misinformation on the web, more research is needed to fully understand this highly complex social phenomenon.

KEYWORDS

multiple sclerosis; chronic illness; misinformation; web-based searches; education; health information; social media; health literacy; patient-doctor relationship; health-related information; information-seeking behavior

Introduction

Although patients can acquire information regarding health from a multitude of sources such as health care professionals, pharmaceutical companies, books, pamphlets, radio, and television, the majority will tend to get their information on the web [1-3]. Given the large number of unreliable sources and inaccurate information currently flooding the internet, patients can easily become misinformed [3]. Misinformation can be defined as information that is not in accordance with the leading scientific consensus [4]. Although misinformation is widespread across the web-based sphere, social media sources including Twitter, YouTube, Facebook, and WhatsApp have been found to be the predominant outlets of misinformation [3,5]. With most of the health information on the web assessed as being of low-quality, inaccurate, and incomplete [6,7], users are at an increased risk of being deceived by misinformation. This is further exacerbated by the fact that false information diffuses significantly farther, faster, deeper, and more broadly than veracious information [8-10]. While web-based searches can empower patients [11] and improve their knowledge, health literacy, capacity to manage their health [12], and the patient-doctor relationship [13], misinformation may also lead individuals to erroneous conclusions and potential harm [4]. Patients may be particularly vulnerable to hopes of recovery driven by misinformation, myths, and unproven therapies [4].

For those living with multiple sclerosis (MS), the internet is becoming an important source of health-related information as well as a source of community support through the exchange of lived experience [14-19]. For people with MS, information found on the internet may help in coping with the disease and provide some reassurance in their chosen therapeutic modality [15]. More than half of people with MS used mass media sources rather than interpersonal information sources such as health care providers and advocacy organizations, among others [14]. Thus, addressing the reliability of the information found on the internet is a critical issue [18] as people with MS are likely to be affected by misinformation [20,21]. Notably, a recent study evaluating the quality of YouTube videos regarding MS found that more than half lacked high-quality content [20]. Nevertheless, studies have indicated that people with MS still believe the most trusted information source to be their physician [14,18], and a large proportion remain skeptical about the quality of the information they gather on the web [14,17], with 40% stating they had concerns [14].

With both web-based information and the global population with MS on the rise [22], a growing number of people with MS are exposed to potential harm through unverified therapies, potentially impacting their security and health [23]. Indeed, most people with MS will use complementary and alternative medicine seen on various social media platforms [24-26]. Although seemingly well tolerated, these unproven therapies may interact adversely with medical treatments, pose harm, and incur financial costs [23,25]. The purpose of this study was to evaluate if people with MS at a specialized MS clinic were able to correctly answer questions about their illness as well as identify misinformation about alternative therapies. Other objectives were to identify where people with MS get their health-related information and identify correlations associated with questionnaire scores.

Methods

Research Design

People living with MS and followed at the MS clinic in Moncton, New Brunswick, Canada, were invited to take part in the survey-based study between April and July 2023. More specifically, participants who agreed to be contacted by the research team were telephoned and informed of the study. To be included, people with MS had to be aged 19 years or older to provide informed consent.

Ethical Considerations

The study was approved by the Vitalité Health Network Research Ethics Board (101729). If the participant decided to participate, they were asked to sign the consent form after which they were invited to fill out the survey questionnaire. Data was de-identified to ensure privacy and confidentiality. Participants were not compensated.

Participant Demographics

Participants included 69 people living with MS followed at a specialized MS clinic providing management, education, and treatment of MS. More specifically, 90 potential participants were contacted for the study and 69 were accepted: giving a

XSL•FO
RenderX

participation rate of 77%. At the clinic, people living with MS are followed by a clinical team comprised of 1 neurologist and 3 nurses as well as neurologists on standby. They have access to the clinical team 5 days per week, which they can readily contact by telephone or by email. Initial consultations are comprised of a thorough educational session that relays information about the disease such as physiopathology, symptoms, disease evolution, as well as medication. During this session, they are given resources to consult for disease-related information; they are also encouraged to contact their clinical team if they have any questions and to be wary of nonexpert sources. Subsequent visits are supplemented with information on relevant symptoms, disease evolution, and medication tailored to their specific needs.

Survey Instrument and Data Collection Procedure

A 20-item "true or false" survey was developed by neurologists and nurses, which comprised 10 scientific facts and 10 popular misinformation statements regarding MS (Multimedia Appendix 1). Scientific facts and misinformation statements were distributed at random in the questionnaire. For each item, participants were asked to respond if they considered the statement to be true, partially true, do not know, partially false, or false. The 10 scientific facts consisted of accurate scientific truths about MS, while the 10 misinformation statements consisted of erroneous statements about the efficacy of alternative medicine in the treatment of MS. The latter was developed based on purportedly effective alternative medicine options found on the web and on social media. Hence, the correct answers for this survey were true for all scientific facts and false for misinformation statements. A "scientific fact score" and a "misinformation score" were calculated by attributing a scoring system to each point in the survey: +1 point was attributed to correct answers (true or partially true for facts and false or partially false for misinformation statements), –1 point was attributed to incorrect answers, and 0 point was attributed to "I don't know." A range of –10 to 10 points could therefore be obtained for each of the scientific fact score and misinformation score. The survey also collected sociodemographic information, the participants' use of disease-modifying therapies and alternative medicine, and the sources used to get health-related information. The sources used to get health-related information were classified as either high to moderate reliability or low reliability. The classification was done by the neurologist and nurses at the clinic and was based on source expertise (ie, the ability of the source to give accurate information) and trustworthiness (ie, the willingness of the source to provide accurate information). Education was classified as either "high" or "low"; high education included all postsecondary education diplomas (ie, university and college diplomas) and low education included high school–level diplomas or less.

Statistical Analysis

ANOVA post hoc Sidak was used to compare means between multiple groups and the nonparametric Mann-Whitney *U* test was used to test between 2 samples. Multiple regression analysis was used to analyze the relationship between scores and several independent variables. All statistical tests were performed using GraphPad Prism (version 10.1.0; GraphPad Software Inc). Parametric tests were used after data passed normality tests (D'Agostino-Pearson omnibus, Anderson-Darling, Shapiro-Wilk, and Kolmogorov-Smirnov).

Results

Overview

The mean age of the 69 participants was 48.4 (SD 10.9) years and the mean time of MS diagnosis for participants was 10.9 (SD 7.8) years (Table 1). A total of 78% (54/69) of participants identified as female, 20% (14/69) as male, and 1.4% (1/69) as nonbinary (Table 1). A total of 81% (54/69) of participants were classified as highly educated (Table 1). Additionally, 90% (62/69) of participants were receiving disease-modifying therapies and 52% (30/58) reported experimenting with alternative medicine (Table 1).

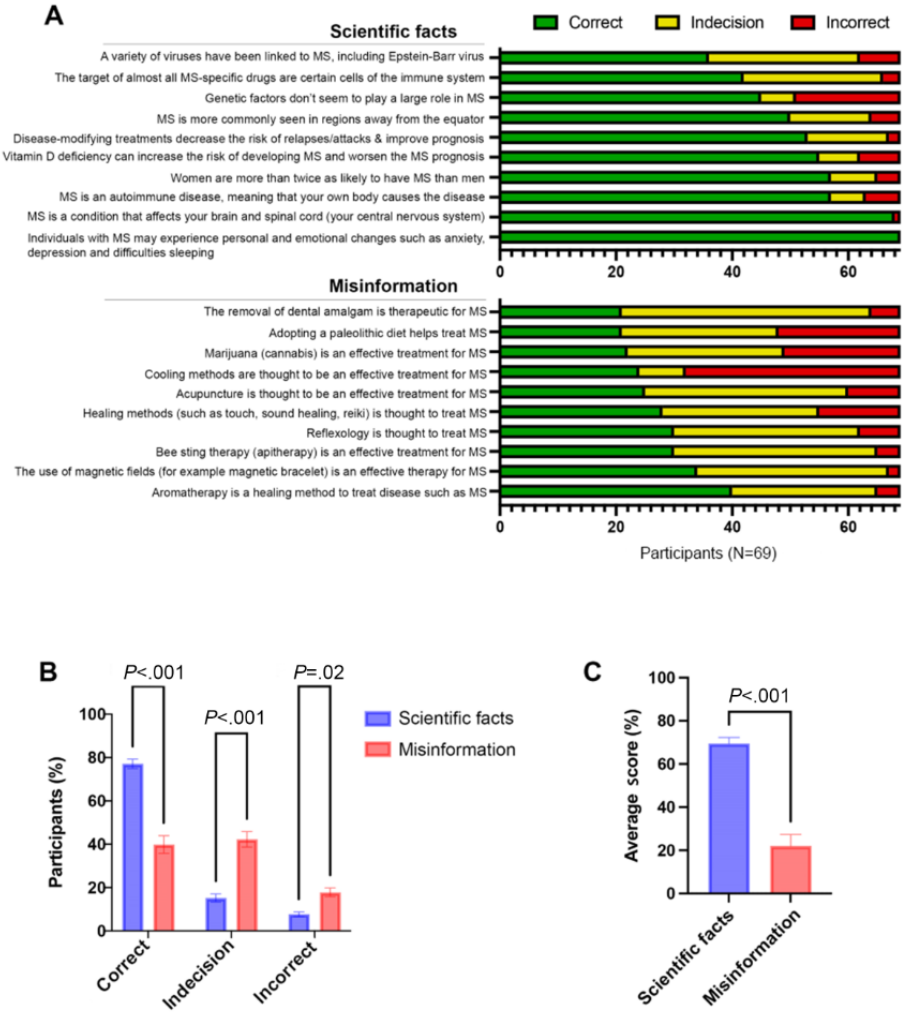
Using alternative medicine[b], n (%)	
Yes	30 (52)
No	28 (48)

[a]MS: multiple sclerosis.



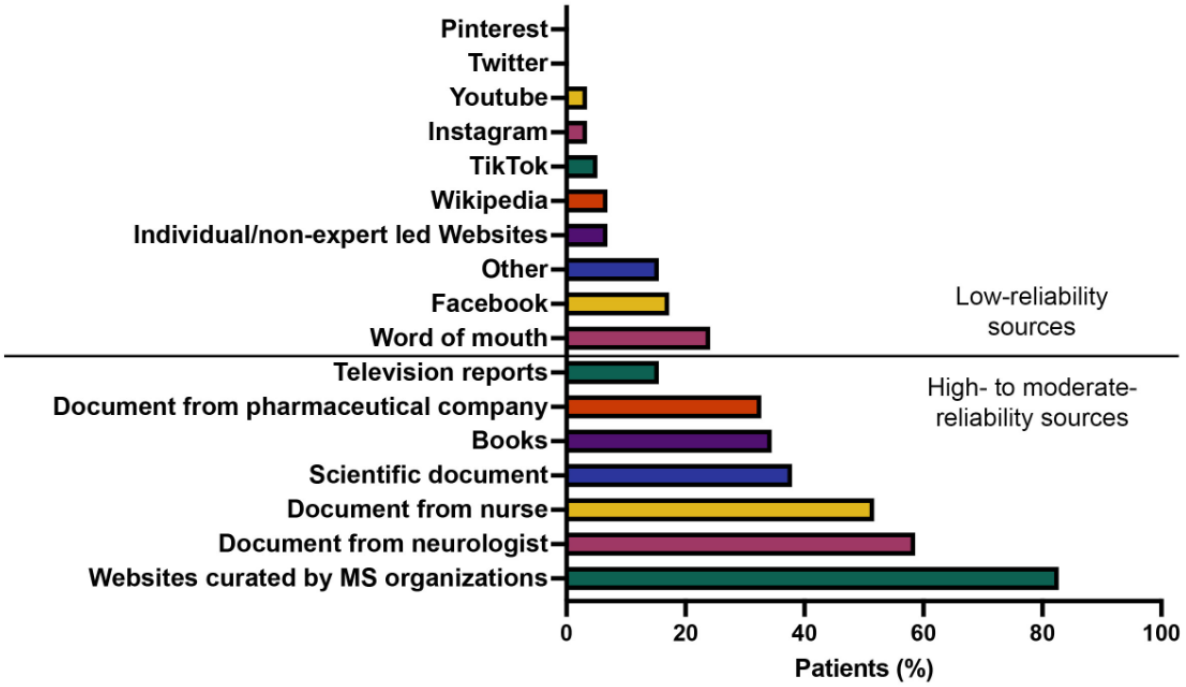
[b]Out of the total 69 patients, only 58 answered this question.

People With MS Were More Knowledgeable About Scientific Fact Than Misinformation

Overall, when asked whether scientific facts about their disease were true or false, most people with MS were able to answer correctly (Figure 1A). Comparatively, relatively fewer participants could accurately identify misinformation. Notably, all participants correctly answered that "individuals with MS experience personal and emotional changes such as anxiety, depression, and difficulties sleeping," and almost all participants correctly answered that "MS is a condition that affects your brain and spinal cord (your central nervous system)." More complex facts, such as "genetic factors don't seem to play a large role in MS," "a variety of viruses have been linked to MS, including Epstein-Barr virus," and "the target of almost all MS-specific drugs are certain cells of the immune system," seemed to be lesser known. The most incorrectly answered misinformation statements were that "cooling methods are thought to be an effective treatment for MS," "adapting a paleolithic diet helps treat MS," and that "marijuana (cannabis) is an effective treatment for MS."

XSL•FO
RenderX

Figure 1. Scientific facts and misinformation identification by people with MS. (A) Answer distribution (correct, indecision, and incorrect) for scientific facts and misinformation per question. (B) Differences in answer distribution between scientific facts and misinformation (Mann-Whitney U test). (C) Average score differences between scientific facts and misinformation (ANOVA, post hoc Sidak). MS: multiple sclerosis.



When comparing the scientific fact and misinformation score, participants were better able to correctly answer scientific facts (*P*<.001), indecision (answering "I do not know") was more prevalent for misinformation statements (*P*<.001), and answering incorrectly significantly increased in the case of misinformation (*P*=.02; Figure 1B). Correspondingly, the average scientific fact and misinformation scores of people with MS were 69% (SD 2.4%) and 22% (SD 4.5%), respectively (Figure 1C).

People Living With MS Used High- to Moderate-Reliability Sources for Their Disease-Related Information and Minimal Low-Reliability Sources

People living with MS were asked to share where they got their health-related information about their illness. The sources were classified as either high- to moderate-reliability sources or low-reliability sources (Figure 2). The great majority of participants from the specialized clinic reported getting their information from high- to moderate-reliability sources, notably, from trustworthy and expert-led MS websites (48/58, 82%) and health care professionals, namely, neurologists and nurses (34/58, 59% and 30/58, 52%, respectively). Participants also got their information from scientific documents (22/58, 38%) like peer-reviewed publications, books (20/58, 34%), and pharmaceutical companies (19/58, 33%). Low-reliability sources were less used; however, word of mouth seemed to be prevalent (14/58, 24%), followed by Facebook (10/58, 17%). On average, people with MS reported having consulted 3 high- to moderate-quality sources and only 1 low-quality source.

XSL•FO
RenderX

Figure 2. Sources used to get disease-related health information about MS. Health-related information sources are divided into 2 categories depending on their reliability: low-reliability and high- to moderate-reliability sources. MS: multiple sclerosis.

In linear regression analyses, we did not find that scientific score correlated with age, sex, level of education, use of disease-modifying therapies, alternative therapies, nor the use of high- to moderate- or low-reliability sources (Table 2). Misinformation score also did not correlate with age, sex, use of disease-modifying therapies, alternative therapies, or the use of high- to moderate- or low-reliability sources (Table 3). However, we observed that lower levels of education were associated with significantly fewer correct answers in the misinformation score (P=.04).

Discussion

Principal Findings

We investigated the knowledge and information-seeking behaviors of people living with MS at a specialized MS clinic. Taken together, participants generally correctly identified scientific facts as being true but had greater difficulties identifying misinformation about alternative therapies as false.

Given that participants were followed by a specialized clinic, where education is a cornerstone of care, the high scoring associated with scientific facts was expected. However, even when equipped with education and a team of experts to answer questions and concerns, participants still scored relatively poorly when faced with misinformation. This may indicate a need for more misinformation-geared education but also a certain wariness of health care on the part of participants. Indeed, it was previously reported that although 82% of people with MS gathered information on the web, only 36% discussed this information with their physician [16]. It was proposed that wariness of health care may lead to patients opting out of communicating and discussing information found on the web with health care professionals, which in turn may lead to therapeutic nonadherence. Overall, this may indicate the need to proactively educate patients about misinformation commonly found on the web, and more importantly, talk openly with patients about misinformation in hopes of creating space for them to discuss information found on the web without prejudice. Indeed, people presented with accessible evidence-based corrections can reduce their belief in misinformation [4]. Although participants scored lower on the portion of the questionnaire dealing with misinformation, they more often chose to answer “I do not know.” This cautiousness was also previously documented in people with MS surveyed about web-based searches [14,17]. This healthy skepticism could represent a facilitator when educators are tasked with discrediting misinformation.

In addition, patients often will have difficulty understanding and remembering information communicated by their health care provider [27-29]. Unfortunately, understanding complex health information and applying it to everyday life, that is, health literacy, is pivotal to self-management and improved health outcomes [30,31]. Gaps in understanding may be explained by the overuse of medical terminology while gaps in recall may be due to inadequate educational methods and interventions used by health care professionals [32-34]. Therefore, compounding the issue of misinformation are the challenges that come with educating patients. It has been shown that health care professionals tend to overestimate their own ability to communicate clearly with patients [27-29,35]; thus, being aware of such gaps in communication and implementing new strategies could ameliorate patient understanding of misinformation. There are also many barriers and issues in access to health care. One commonly identified barrier for neurologists in the care of people living with MS is time constraints and availability of appointments [36]. As educational methods may be relatively more time-consuming, implementing change may be challenging [37].

Health literacy is the ability to seek, find, and understand health information on the web to help support decision-making about one’s health [4]. Low health literacy may increase a patient’s susceptibility to misinformation; however, the great majority of people consult low-quality websites for health-related information regardless of their health literacy level [4]. This could be explained by the fact that low-quality sources may be more easily understood or more engaging by eliciting stronger feelings [8]. Health literacy is also correlated with the individual’s educational level [4]. In this study, 81% (56/69) of participants had a high level of education (college or university level diplomas); thus, we could assume that the health literacy of participants was adequate. Furthermore, as MS disproportionally affects female over male individuals, the surveyed population was mostly comprised of the former. In this highly educated group, mostly comprised of female individuals, half had experimented with alternative therapies. In the realm of cancer, those most likely to use alternative medicine are indeed educated female individuals from higher-income households [38]. Furthermore, social media platforms have gained in popularity among health information seekers regardless of age or sex [39]. Consequently, age, sex, education level, and health literacy might not safeguard against web-based misinformation. Herein, we were unable to identify correlations associated with scores obtained on the questionnaire other than educational level. Although the educational level did

XSL•FO
RenderX

seem to impact the misinformation score, this did not stop participants from experimenting with alternative therapies.

The belief that cannabis or diet interventions may be effective treatment alternatives for MS was notable in the surveyed population. This is of some concern as there is little data currently supporting the use of these avenues in the treatment of MS. Although some cannabinoid products may help reduce the severity of spasticity short term, it is still uncertain what the effects are on chronic neurological pain and health-related quality of life [40]. Furthermore, cannabinoids may cause adverse effects leading to treatment discontinuation as well as nervous system and psychiatric disorders [40]. More studies are needed to evaluate the efficacy and safety of using these products. Likewise, the effects of dietary interventions for MS-related outcomes remain uncertain [41]. Misconceptions relating to cannabis use and special diets have previously been identified as prevalent health misinformation for all individuals seeking health information on the web [5], demonstrating that widespread misinformation may affect a broad spectrum of individuals. This may indicate a need for larger-scale antipropaganda government initiatives. Many participants also believed that cooling methods are effective treatments. Although these modalities have demonstrated some effectiveness, no study has assessed comfort and adherence. Moreover, these methods are costly, not accessible, and have not been widely tested [42]**.**

Interestingly, participants in this small cohort mostly used high to moderate web-based sources for their MS-related health information; yet the majority were still subject to misinformation. Other than the lack of misinformation-geared education, this may be explained by the fact that people might not know where they pick up misinformation [4]. For instance, misinformation might cross one's attention while casually scrolling on social media. Belief in misinformation may also be explained by the fact that people with MS will report an improvement in their fatigue and mood with the use of alternative therapies. Hence, it is plausible that study participants who have tried alternative therapies with some positive outcomes may earnestly believe in their efficacy and subsequently be susceptible to misinformation. Unfortunately, these alternative treatments are not without risk, as they may also negatively impact the effectiveness of disease-modifying therapies [25]. Furthermore, although all patients at the specialized MS clinic received disease-related documents to consult with their health care provider, only about half referred to these when searching for information about MS. This may illustrate a need to make health information distributed by health care professionals more engaging and accessible to people with MS, and this for a diverse group of people.

Science and health misinformation can be defined as information that is not in accordance with the leading scientific consensus. This process of delineating what is considered true or false is highly dynamic and is subject to change based on current evidence. MS is a complex disease with many unanswered fundamental questions relating to causation and susceptibility, and although disease-modifying treatments are available for relapsing-remitting MS, there remains a paucity of effective treatments for the progressive forms of MS [43]. Hopes of finding answers to unaddressed questions may increase susceptibility to misinformation, and more importantly, the lack of effective therapeutic avenues in advanced disease may encourage experimenting with alternative medicine. Furthermore, as new data emerges, what is presently considered alternative medicine may become common practice with new research highlighting efficiency and safety. Notably, some recent work has demonstrated that a Mediterranean diet may help alleviate some MS symptoms; however, more robust data are needed to validate these findings [44]. Also, a recent study has demonstrated that the Epstein-Barr virus is linked to MS, but not other previously reported viruses [45]. This highly dynamic process and changing landscape may be challenging not only for people with MS but also for educators. Although studies are exploring novel ways to effectively deal with health misinformation on the web, more research is needed to fully understand this highly complex social phenomenon [4].

Study Limitations

This study is not without its limitations. Notably, the small sample size and the homogenous population may not accurately represent the whole population with MS. Indeed, with only 69 participants, extrapolation of the data to the larger population with MS would be precipitous; larger multicentric cohort studies are needed to better understand this phenomenon. Participants possessed a high level of education, a notable contrast to the 57.2% of Canadians with a similar educational background as reported in 2021, which may indicate that data may not be generalizable [46]. We also assume that education levels equate to health literacy; however, assessing health literacy may have been more informative. Further, participants in this study received education regarding their disease at a specialized MS clinic, suggesting that repeating this study with people with MS who have limited access to a neurologist or clinical team may yield even more worrisome results. Furthermore, some aspects of the questionnaire may have been difficult to understand for people outside of health care or the scientific field. More specifically, delineating the difference between disease-modifying and symptomatic treatments may have been challenging for some. For instance, marijuana and cooling may be considered potentially effective symptomatic treatments but not effective disease-modifying ones, which may have led participants to answer wrongfully. The wording in elements of the questionnaire may also have been confusing; the use of "seem" and "large" in "genetic factors don't seem to play a large role in MS" may have been too vague and thus confusing to respondents. Such misinterpretations may be avoided by using standardized survey tools for assessing susceptibility to misinformation; however, more research is needed to develop such tools in MS. Interestingly, a parallel may also be drawn between questionnaire understandability/clarity and patient education; how do we make information understandable, mitigate the risk of misinterpretation, whilst ensuring that the content remains engaging? In addition, how can we assess if patients have accurately assimilated the content?

In conclusion, we show that people with MS followed at a specialized MS clinic can readily answer questions regarding their disease; however, they are potentially still being impacted by misinformation. As web-based information has the potential

XSL•FO
RenderX

to improve the patient-doctor relationship and aid communication as well as help patients be more actively involved in decision-making, disparaging the use of the internet is not a reasonable solution to mitigate the potentially negative effects of misinformation. Rather, as a first line of defense, we propose that a portion of educational sessions be dedicated to thwarting misinformation as well as opening lines of communication between patients and physicians regarding information found on the web.

Acknowledgments

The authors would like to thank the participants, the Moncton City Hospital Multiple Sclerosis Clinic, and the Centre de formation médicale du Nouveau-Brunswick.

Data Availability

The datasets generated during and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

VD carried out data collection and drafted sections in the manuscript. DC collated and analyzed data, generated figures, and tables, drafted the Results section, and revised the manuscript. TT built the questionnaire and carried out data collection. NB revised and wrote sections of the manuscript. MB helped guide statistical analyses and reviewed the manuscript critically. LW, TJ, NM, and MG facilitated access to participant recruitment. LCW conceptualized and supervised the project and contributed to drafting and revising the manuscript. All authors contributed to the interpretation of results and revision of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Sepsis is an organ dysfunction caused by a dysregulated host response to infection. Early detection is fundamental to improving the patient outcome. Laboratory medicine can play a crucial role by providing biomarkers whose alteration can be detected before the onset of clinical signs and symptoms. In particular, the relevance of monocyte distribution width (MDW) as a sepsis biomarker has emerged in the previous decade. However, despite encouraging results, MDW has poor sensitivity and positive predictive value when compared to other biomarkers.

Objective: This study aims to investigate the use of machine learning (ML) to overcome the limitations mentioned earlier by combining different parameters and therefore improving sepsis detection. However, making ML models function in clinical practice may be problematic, as their performance may suffer when deployed in contexts other than the research environment. In fact, even widely used commercially available models have been demonstrated to generalize poorly in out-of-distribution scenarios.

Methods: In this multicentric study, we developed ML models whose intended use is the early detection of sepsis on the basis of MDW and complete blood count parameters. In total, data from 6 patient cohorts (encompassing 5344 patients) collected at 5 different Italian hospitals were used to train and externally validate ML models. The models were trained on a patient cohort encompassing patients enrolled at the emergency department, and it was externally validated on 5 different cohorts encompassing patients enrolled at both the emergency department and the intensive care unit. The cohorts were selected to exhibit a variety of data distribution shifts compared to the training set, including label, covariate, and missing data shifts, enabling a conservative

XSL•FO
RenderX

validation of the developed models. To improve generalizability and robustness to different types of distribution shifts, the developed ML models combine traditional methodologies with advanced techniques inspired by controllable artificial intelligence (AI), namely cautious classification, which gives the ML models the ability to abstain from making predictions, and explainable AI, which provides health operators with useful information about the models' functioning.

Results: The developed models achieved good performance on the internal validation (area under the receiver operating characteristic curve between 0.91 and 0.98), as well as consistent generalization performance across the external validation datasets (area under the receiver operating characteristic curve between 0.75 and 0.95), outperforming baseline biomarkers and state-of-the-art ML models for sepsis detection. Controllable AI techniques were further able to improve performance and were used to derive an interpretable set of diagnostic rules.

Conclusions: Our findings demonstrate how controllable AI approaches based on complete blood count and MDW may be used for the early detection of sepsis while also demonstrating how the proposed methodology can be used to develop ML models that are more resistant to different types of data distribution shifts.

Introduction

Sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection [1]. The progression from infection to sepsis is influenced by both host and pathogen features and, accordingly, is characterized by a high interindividual variability. Sepsis represents a medical emergency, with a strong time dependency, especially for septic shock [2,3]. Therefore, early detection is fundamental to improving the patient outcome by promptly starting treatment. However, sepsis, especially in the early stage, may be characterized by nonspecific signs and symptoms, mainly when diagnosis of infection is still uncertain. Thus, its early recognition is challenging, particularly in the emergency department (ED) and outside the intensive care unit (ICU), due to the lack of data needed to apply the Sepsis-3 criteria (ie, assessment of organ dysfunction due to Sequential Organ Failure Assessment Score [SOFA], plus probable or certain infection). Therefore, reliable tools to screen sepsis are strongly sought after. The UK National Screening Committee underlines that the aim of screening is to propose a test to a population who "do not necessarily perceive that they are at risk of, or are already affected by, a disease or its complications" [4]. In the scenario of sepsis screening, laboratory medicine could have a crucial role by providing biomarkers mirroring the pathophysiological mechanisms underpinning sepsis and whose alteration could be detected before the onset of clinical signs and symptoms [5].

To date, hundreds of biomarkers have been investigated, but several limitations have hampered the translation from research to clinical practice, such as cost and the request for additional blood samples [6]. Intensive scientific research is ongoing to discover accurate, affordable, easy-to-measure, and rapidly available biomarkers for guiding clinicians to identify patients at higher risk of sepsis, allowing close monitoring or early treatment.

In clinical practice, C-reactive protein (CRP) and procalcitonin are the most used sepsis biomarkers. However, they are not specific to sepsis, and their levels can increase in several clinical, noninfectious conditions. In addition, they are usually ordered when sepsis is clinically suspected, leading to a diagnostic delay [7] and making them unsuitable as a screening tool. The ideal biomarker for sepsis screening should have the following characteristics: (1) easy to measure, (2) high sensitivity and negative predictive value for sepsis, (3) low turn-around time, and (4) always available to clinicians, especially when sepsis is not (yet) suspected. Complete blood count (CBC) parameters fulfill all of these features [8]. Indeed, CBC is the first-level laboratory test most ordered in all clinical wards, from ED to ICU. It is easy to perform, cheap, and provides important clinical information on the health status. Beyond the classic CBC parameters, the new generation of hemocytometers provides cell population data, which reflect the morphological and functional characteristics of neutrophils, lymphocytes, and monocytes. In the last decade, the role for monocyte distribution width (MDW) as a sepsis biomarker has emerged [9]. MDW reflects the dispersion around the mean monocyte volume. It is automatically calculated by the last generation DxH hematology analyzer (Beckman Coulter, Inc) based on volume, conductivity, and scattering technology and is provided together with the basic CBC parameters. Noteworthy, MDW received approval from the Food and Drug Administration and European Community In-Vitro Diagnostic Medical Device as an early sepsis indicator in adult patients in the ED. MDW has great potential to be used in clinical practice because it is timely and fruitfully measured without further samples, additional costs, or even a different request from clinicians. Thus, it represents a cost-effective tool for early sepsis screening. This is an important feature in the health care of the third millennium. To date, several authors have shown good performance of MDW for early diagnosis of patients with sepsis in different clinical wards, especially the ED and ICU [10-17]. All studies have shown excellent specificity and negative predictive value (NPV) but suboptimal sensitivity and positive predictive value (PPV) [9]. Thus, while individual CBC biomarkers and MDW represent

XSL•FO
RenderX

ideal candidates for sepsis screening in general settings, their performance should be improved to be applied for sepsis screening.

Machine learning (ML) techniques offer the promise to potentially offset the limitations mentioned earlier by combining different parameters, beyond the capabilities of rule-based systems and humans, and increasing the performance of single laboratory parameters [18,19]. Indeed, in recent years, ML methods have been increasingly adopted in health care settings [20], including sepsis screening and prediction [21-24]. However, as also noted in the study by Shashikumar et al [25], most existing ML sepsis models have been developed and validated on data from a single hospital only, with no external validation. Thus, their robustness has not been proven, and their performance may degrade when applied in settings that differ from the one in which they are developed, due to either data or missingness shifts [26], limiting their generalizability and adoption in clinical practice. Indeed, widely applied commercially available models (eg, Epic) have been shown to be severely impacted by the aforementioned issues [27-30]. This is especially true for models based on laboratory parameters, wherein state-of-the-art models have not been externally validated [31]. Most notably, no previous work, to the best of our knowledge, combined the use of ML methods with MDW [32].

According to these premises, the aim of this study is to develop and externally validate ML models whose intended use is the early detection and screening of sepsis on the basis of CBC parameters, including MDW and other clinical and laboratory features commonly available in all clinical laboratories. In this multicentric study we used CBC data from an Italian hospital ED (training set) to develop ML models, by adopting both traditional ML models as well as more advanced techniques inspired by controllable artificial intelligence (AI) [33] (ie, cautious classification and explainable AI) that were successively validated by data from multiple settings (encompassing both ED and ICU settings, as well as different forms of data shifts) and different Italian hospitals, to evaluate their robustness and generalization.

Methods

Overview

Herein, we briefly summarize the adopted methodology, which is better detailed in the following sections. The reporting follows the Checklist for Assessment of Medical AI checklist [34] and the "Guidelines for Developing and Reporting Machine Learning Predictive Models in Biomedical Research" [35].

The study was conducted as a multicentric, retrospective study aimed at developing ML models for the classification problem of sepsis detection from clinical laboratory parameters. To this aim, ML models were trained on data from 1 patient cohort (Palermo, Emergency Department [PA-ED], coming from Palermo, Italy) and evaluated on 5 different patient cohorts (Palermo, Intensive Care Unit [PA-ICU], Padova, Intensive Care Unit [PD-ICU], Udine, Emergency Department [UD-ED], Arezzo, Emergency Department [AR-ED], and Ospedale Galeazzi Sant'Ambrogio, Intensive Care Unit [OGSA-ICU], coming from 5 different hospitals in Italy, respectively from Palermo, Padova, Udine, Arezzo, and Milano [refer to Dataset Collection, Description, and Processing section]), encompassing 5344 records for as many single patients. We decided to consider 5 different external validation cohorts to comprehensively assess the generalizability of the developed models, as well as their robustness to multiple forms of data variation (refer to the subsequent paragraphs). The 6 patient cohorts were collected at 5 different hospitals: 3 cohorts (PA-ED, UD-ED, and AR-ED) were from the ED setting, while the remaining 3 (PA-ICU, PD-ICU, and OGSA-ICU) were from the ICU setting. The PA-ED, PA-ICU, PD-ICU, UD-ED, and AR-ED datasets encompassed 19 features, including the following: demographic information (age and sex), the MDW, other laboratory test results (ie, the CBC, including the differential, and the CRP), together with a derived feature (the neutrophils-lymphocytes ratio). The OGSA-ICU dataset encompassed the same features as in the other cohorts, except for the MDW feature that was missing. The PA-ED cohort was used for training, hyperparameter optimization, and internal validation, while all the other cohorts were used only for external validation. The 5 external datasets allowed for the validation of the robustness of the developed models under different shift settings, including covariate shifts due to different clinical settings (ICU vs ED), label shifts (sepsis-2 vs sepsis-3), missingness shifts [26], and instantial variation [36]. In particular, the AR-ED cohort was used to evaluate the robustness of the developed models in a conservative scenario of label shift (refer to the Dataset Collection, Description, and Processing section), as the population of this dataset only encompassed patients who exhibited clinical signs for suspected sepsis. By contrast, the OGSA-ICU cohort was used to test the performance and robustness of non-MDW systems (that integrate the ML models described earlier) that can also be applied in settings that lack the MDW parameter; indeed, the laboratory parameters for the OGSA-ICU dataset did not contain the MDW feature as they were collected using a Sysmex (rather than the one by Beckmann Coulter, Inc) analyzer. Thus, this cohort was characterized by missingness shift [26] (ie, differences in the distribution of missing values) and differing analytical variation [36] (refer to the Non-MDW Systems Validation section). Notably, no dataset pooling was performed to ensure that the validation sets were entirely blind and guarantee an unbiased estimate of performance and generalizability; hence, each dataset was considered as an entirely separate cohort.

The PA-ED was split into 2 datasets according to a 75/25 split: the largest 75% set was used for training and hyperparameter optimization in cross-validation, while the remaining 25% set was used for internal validation. The split was stratified to preserve the proportion of sepsis and no sepsis cases in the 2 splits of the dataset. Further details on the models' design and development can be found in the Methods section. We considered 5 different classes of models, namely logistic regression (LR), support vector machine (SVM), random forest (RF), extreme gradient boosting (XGB), and decision trees (DTs). The performance of the models was evaluated according to different criteria, namely: area under the receiver operating characteristic curve (AUC), sensitivity, specificity, PPV, NPV,

XSL•FO
RenderX

and average PPV (A-PPV; as measures of discrimination power), Brier score (as a measure of calibration), and the standardized net benefit (sNB, as a measure of utility). Following the state-of-the-art development of medical decision support models for sepsis diagnosis [25], and as a way to increase generalizability and reduce overconfident predictions according to the tenets of controllable AI [33], we also considered *cautious classifiers* based on the trained models (refer to Cautious Classification Methods section). Such models can *abstain* from labeling instances, with the aim of implementing a trade-off between coverage (labels for which a prediction is available) and performance metrics (in particular, sensitivity and PPV). The cautious classifiers were evaluated in terms of their coverage, as well as with respect to the high-confidence (HC) metrics, which simply consider the metrics defined earlier only on the subset of the nonabstained-upon cases.

Dataset Collection, Description, and Processing

The PA-ED data refer to patients who were admitted to the ED of the University Hospital "Policlinico Paolo Giaccone" between September, 4, 2019, and November 30, 2019, as described in the study by Agnello [37]. The inclusion criteria were adult (aged ≥18 years) patients presenting to the ED, and whose initial evaluation included a CBC. Exclusion criteria were (1) aged <18 years, (2) incomplete data collection, (3) discharge from the ED within 2 hours from the ED presentation, (4) readmission to the ED within 12 hours, (5) inadequate blood samples (eg, analyzed >4 hours after collection), (6) failure to determine the MDW parameter, and (7) diagnosis of a hematological disorder. The sepsis diagnosis was made according to sepsis-2 criteria [38]. Demographical, clinical, and laboratory data of patients were recorded from the electronic health records of the hospital. Laboratory parameters were measured upon ED admission. MDW and CBC parameters were measured on blood samples collected in the EDTA-K3 tube by a UniCel DxH 900 hematology analyzer (Beckman Coulter, Inc) within 2 hours of collection, as recommended by the manufacturer, after the laboratory analysis ordered by clinicians was performed. CRP and procalcitonin were measured on serum by a fully automated platform (Cobas 8000, Roche Diagnostics).

The PD-ICU data refer to patients who were admitted to the ICU of the University Hospital of Padova and were collected between January 13, 2020 and April 8, 2020. The inclusion criteria were adult (aged >18 years) patients presenting to the ICU, who remained hospitalized for at least 24 hours, enrolled no more than once, with a CBC and differential testing performed at presentation and over the entire course of the length of stay, as part of standard medical care, and procalcitonin or CRP tests ordered at the same time. Exclusion criteria were an incomplete data collection, a failure to determine MDW at least once, and patients with hematological disorders. Sepsis diagnosis was made according to the sepsis-3 criteria, using the SOFA score. Septic shock was recognized in the cases with hypotension requiring vasopressors and with an elevated serum lactate (>2 mmol/L).

The PA-ICU data refer to patients who were admitted to the ICU of the University Hospital "P. Giaccone" between September 10, 2019, and March 19, 2020, as previously described in the study by Agnello et al [8]. The inclusion criteria were all consecutive adult (aged ≥18 years) patients who were admitted to the ICU. Exclusion criteria were (1) individuals aged <18 years; (2) incomplete data collection; (3) failure to determine the MDW parameter; and (4) underlying conditions potentially associated with deregulation of the immune system, including AIDS, organ or bone marrow transplantation, and hematologic diseases. Sepsis diagnosis was made according to sepsis-3 consensus criteria [1]. Laboratory parameters were measured upon ICU admission. MDW and CBC parameters were measured on blood samples collected in the EDTA-K3 tube by a UniCel DxH 900 hematology analyzer (Beckman Coulter, Inc) within 2 hours of collection, as recommended by the manufacturer, after the laboratory analysis ordered by clinicians was performed. CRP and procalcitonin were measured on serum by a fully automated platform (Cobas 8000, Roche Diagnostics).

The AR-ED data refer to patients who were admitted in the ED of the San Donato Hospital and were collected between July 5, 2019, and April 17, 2020. The inclusion criteria were all consecutive adult (aged ≥18 years) patients who were admitted to the ED and had a clinical presentation of suspected sepsis (at least 2 of the following signs: SOFA≥2, body temperature ≥38 °C or ≤36 °C, infection, respiratory rate ≥20 beats/min, heart rate ≥90 beats/min, or altered mental status). Sepsis diagnosis was made according to the sepsis-3 criteria. MDW and CBC parameters were measured by a UniCel DxH 900 hematology analyzer (Beckman Coulter, Inc) within 2 hours of collection and directly extracted from the analyzer. CRP was measured by a Cobas 8000 instrument (Roche Diagnostics) and manually extracted from the hospital's laboratory information system (LIS).

The OGSA-ICU data refer to patients who were admitted to the ICU of the Istituto di Ricovero e Cura a Carattere Scientifico Ospedale Galeazzi Sant'Ambrogio between January 1, 2023 and April 31, 2023. The inclusion criteria were adult (aged ≥18 years) patients who were hospitalized in the ICU for at least 2 days (to exclude patients who were temporarily admitted to the ICU because of specific intervention protocols) and for whom blood culture and procalcitonin were requested. All hematological parameters were measured by a Sysmex XN2000 blood analyzer and manually extracted from the hospital's LIS (BeSimpleLIS, Siemens SpA), using QlikView (Qlik, Inc). CRP and procalcitonin were measured by the Atellica IM Analyzer (Siemens) and manually extracted from the hospital's LIS using QlikView.

The UD-ED data refer to patients who were admitted to the ED of the University Hospital of Udine between November 1, 2019, and December 31, 2019. The inclusion criteria were adult (aged ≥18 years) patients who were enrolled in the ED and had a CBC exam (with differential) requested as part of the standard diagnostic pathway. Sepsis diagnosis was made according to the sepsis-2 criteria. MDW and CBC parameters were measured by a UniCel DxH 900 hematology analyzer (Beckman Coulter, Inc), and directly extracted from the analyzer. CRP was measured by the Cobas C analyzer (Roche Diagnostics) and manually extracted from the hospital's LIS.

Model Design and Development

We considered 5 different classes of statistical machine learning models, namely LR, SVM, RF, XGB, and DTs. These model classes were selected as they exhibited state-of-the-art in-sample [39] and generalization [40] performance on diagnostic tasks from laboratory data in previous work; particularly, we decided to not focus on deep learning models due to several limitations of these latter models on tabular data tasks [41-43], such as requiring extensive hyperparameter optimization and having subpar generalization performance.

The ML models were implemented in Python, using the scikit-learn library (version 1.0.2; Python Software Foundation). Particularly, all models were implemented as 3-step pipelines encompassing a feature scaling step (the scaling technique was selected as a hyperparameter during model training), a feature selection step (using the recursive feature elimination method with an LR model for feature scoring), and the classification step. The full set of hyperparameters, for all the evaluated models, is available in Table S1 in Multimedia Appendix 1. Particularly, except for model-specific hyperparameters, the set of common hyperparameters encompassed the scaling method to be used, the number of features to be selected, and class weights to manage label imbalance.

Model training, hyperparameter selection, and internal model validation were performed on the PA-ED dataset. Specifically, model training and hyperparameter selection were performed on the training fold of the dataset (which encompassed 75% of the total number of cases), while internal validation was performed on the test fold of the same dataset (which encompassed 25% of the total number of cases). Hyperparameter selection was performed by means of randomized search, with a budget of 1000 evaluations, in a 5-fold stratified cross-validation design (RandomizedSearchCV). The training set was split into 5 folds (each containing 20% of the cases in the training data and 15% of the total number of cases in the PA-ED dataset). Following this, for each of the 1000 randomized search evaluations, a random set of hyperparameters was selected and then the models with the specified hyperparameter values were evaluated by means of a 5-fold cross-validation procedure by which they were trained on 4 of the cross-validation folds and evaluated on the remaining fold. Stratified cross-validation was used to preserve the proportion of sepsis and no sepsis cases across all folds. Each evaluated hyperparameter configuration was scored by the average AUC score across the 5 cross-validation folds. For each model class, we selected the hyperparameter configuration that had the highest average AUC score.

After hyperparameter selection, the models were retrained on the entire training set and evaluated on the hold-out test set according to different evaluation criteria, namely sensitivity, specificity, PPV, NPV, AUC, A-PPV, Brier score, and sNB (with a threshold equal to 0.5). On the basis of the internal test set, we compared the developed ML models with 4 different baselines: a fixed MDW threshold (threshold value 23.5 [37]), a fixed CRP threshold (threshold value 80 [44]), a fixed Sepsis Index threshold (threshold value 1 [45]), and the state-of-the-art SVM model (MindraySVM) for sepsis diagnosis based on laboratory biomarkers proposed in the study by Aguirre and Urrechaga [31]. In regard to the latter model, due to the different laboratory instrumentation used in our study, we trained an SVM model using the hyperparameter settings specified in the study by Aguirre and Urrechaga [31] on the same training data used for our models. We also compared the developed models with the state-of-the-art Conformal Multidimensional Prediction of Sepsis Risk (COMPOSER) model proposed in the study by Shashikumar et al [25].

External Validation

The developed ML models were subsequently externally validated, after retraining on the entire PA-ED dataset, on the 4 external validation cohorts (AR-ED, PA-ICU, PD-ICU, and UD-ED), in terms of the same evaluation criteria used for internal validation. As described earlier, the considered external validation allowed us to evaluate the generalizability of the developed ML models in a variety of settings that differed in terms of hospital (4 different hospitals across different regions in Italy), reference population (ED vs ICU), as well as diagnostic criteria (sepsis-2 vs sepsis-3). Therefore, we decided to keep the external validation datasets separate from the internal training set (PA-ED) and did not perform any data pooling. In particular, the choice to consider 4 external validation datasets (as well as an additional external dataset for validation in settings with missing MDW) enabled us to comprehensively assess the robustness of the developed models under a varied selection of distribution shifts. We also evaluated the similarity between the PA-ED cohort and the 5 external validation cohorts, using the degree of correspondence metric (ψ) proposed in the study by Cabitza et al [46]. The ψ metric is a similarity measure used to compare 2 datasets and provides a P value for the hypothesis test that 2 datasets come from the same distribution. The ψ metric has been used as a way to evaluate the robustness of ML models in the context of out-of-domain generalization [40] by assessing the ability of ML models to report good performance also on datasets with low ψ value. We used the implementation of the ψ metric provided [47]. In the paper we used the ψ metric to assess the similarity between the training set (PA-ED) and the external validation cohorts, as well as how the performance of the models varied with respect to the value of ψ.

Validation of Non-MDW Systems

Because the MDW feature was not available in the OGSA-ICU cohort (missingness rate: 100%), we developed non-MDW ML systems for use in settings that lack the MDW parameter. These systems encompassed the ML models trained on the PA-ED cohort, without any retraining, as well as a preprocessing imputation model used to fill in the missing MDW values. The imputation model was derived from the data from the other cohorts (PA-ED, AR-ED, PA-ICU, PD-ICU, and UD-ED), which were used as a training set. The MDW was considered the target feature, while all the other features were used as predictors. The imputation model was an RF regression model with default hyperparameters and was implemented in Python using the scikit-learn library (version 1.0.2). To evaluate the goodness of fit of the imputation model, the training set was split into folds according to a 75/25 split: the 75% was used to

XSL•FO
RenderX

fit the imputation model, while the remaining 25% was used for model evaluation. The performance of the imputation model was assessed by means of the adjusted R^2 score computed between the predicted and true MDW values. After assessment, the imputation model was retrained on the entire training dataset and applied as a preprocessing step to the OGSA-ICU dataset to impute the MDW values for subsequent analysis.

The non-MDW systems were then evaluated by adopting the same methodology described in the Model Design and Development section on the OGSA-ICU cohort. Specifically, we simply applied the developed ML models to the imputed data from the OGSA-ICU cohort.

Cautious Classification Methods

To enable the models to detect a control loss [33] and abstain from providing a diagnosis, to control error rates and reduce misdiagnosis, we implemented cautious classification models based on the ML models trained on the PA-ED cohort. Cautious classification refers to a set of uncertainty quantification techniques that enable an ML model to abstain from providing a prediction, for a given case, whenever the model is not sufficiently confident [48]. Cautious classification has been successfully applied for error rate control in recent work [49,50], also in the context of sepsis diagnosis [25], and provides a simple approach to improve the performance and perceived utility of an ML model. Specifically, we adopted a simple, thresholding-based strategy to implement the cautious classification models: given any new case, the cautious classifiers provided the same diagnosis as the corresponding ML model if the confidence provided by this latter was >0.75; otherwise, it *abstained* from providing a diagnosis. Thus, for a given case, if the ML model would associate with the sepsis class a confidence score larger or equal to 0.75, the cautious classifier would also classify that case as sepsis; similarly, if the confidence score for sepsis was <0.25 (ie, the confidence score for the absence of sepsis was >0.75), the cautious classifier would classify the case as no sepsis; finally, if the confidence score was between 0.25 and 0.75, then the cautious classifier would be considered as abstaining from providing a diagnosis. We decided to apply this cautious classification strategy, rather than other approaches, such as 3-way decision [51] or conformal prediction [52], due to its increased efficiency (the computational complexity cost of the thresholding strategy is O(1), while it is on the order of O(log n), for n being the dataset size, for conformal prediction), ease of interpretation, and its equivalence, in the binary classification setting and under weak assumptions, with the 2 aforementioned methods [51]. Regarding the implementation of the cautious classifiers, we used the HC metrics implemented in the scikit-cautious library [53], and applied them to the ML models trained on the PA-ED dataset, setting the threshold hyperparameter (th) to 0.75. The HC metrics evaluate the performance of the models on the set of nonabstained cases; hence, they select the cases for which either the confidence score of sepsis or that of no sepsis is >0.75. We considered, particularly, the HC metrics for PPV, NPV, sensitivity, specificity, AUC, A-PPV, Brier score, and sNB, as well as the coverage (the percentage of nonabstained-upon cases).

Statistical Analysis

For all continuous variables, we reported mean and SD, while for all categorical variables, we reported the frequency of each value. The sNB was computed at the fixed threshold value of 0.5. CIs for sensitivity, specificity, PPV, and NPV were calculated using the Wald CI formula [54], namely,

(1)

where p is the estimated value, n is the sample size, and $z_{a/2}$ is the *(1- a/2)* quantile for the standard normal distribution. CIs for the AUC, A-PPV, and sNB were calculated based on the formulas defined in the study by Riley et al [55] for estimation of the SE and Wald CI formula, namely,

(2)

(3)

where v is the estimated AUC or A-PPV value, π is the proportion of patients with sepsis in a given cohort, and *sens* (respectively, *spec*) is the estimated sensitivity (resp. specificity). CIs for the Brier score were computed based on Hoeffding inequality [56] for bounding the difference between the sample estimate of a continuous, bounded random variable and its expected value, namely:

(4)

For each pair of developed ML models and each evaluation metric, we evaluated the hypothesis that the 2 classifiers had the same (null hypothesis) or different average performance: we used a 2-tailed chi-square test to test the hypotheses and computed the P values. For each developed ML model and each dataset, we evaluated the hypothesis that the cautious classifier provided an improvement in terms of sensitivity, specificity, PPV, or NPV compared to the corresponding standard ML model: we used a 1-tailed chi-square test to test the hypotheses and compute the P value. Finally, for each developed ML model, each external validation dataset, and each evaluation metric, we evaluated the hypothesis that the performance of the ML model was not worse than what was reported on the internal validation dataset. We used a 2-tailed chi-square test to test the hypotheses and compute the P values. To control the increased type I error (mistaken rejection of a null hypothesis) due to multiple hypothesis testing, we adjusted the computed P values using a false discovery rate correction procedure. Particularly, we used the optimal adaptive procedure by Gavrilov et al [57], which computes the k-th adjusted P value p_k (with the P values sorted in increasing order) as given in the following:

(5)

XSL•FO
RenderX

(6)

where $\alpha=0.05$ is the confidence threshold for null-hypothesis rejection, and $1 \leq k \leq m$, where m was the number of tested hypotheses. All code for statistical analysis was implemented in Python. We used *pandas* and *numpy* for data loading and management, *scipy* for implementation of the chi-square test, and *statsmodels* for implementation of the false discovery rate correction procedure. We used custom Python implementations of the CIs for the AUC, A-PPV, sNB, and Brier score.

Ethical Considerations

The collection of data at the different sites, as well as the multicentric study, was conducted in compliance with the guidelines established by the local ethics committees, relevant ethical and legal regulations, and in agreement with the World Medical Association Declaration of Helsinki. Regarding the ethics review, the study used only secondary data that had been previously collected at different sites in earlier studies, in accordance with an approved ethical framework from the local ethical boards. The present study does not introduce any new risks, burdens, or interactions with participants beyond those already considered and approved in the original ethical reviews. Since the study did not require any blood draws or procedures from the enrolled patients that would not already have been performed as part of standard medical care, and because the data was rendered anonymous before analysis, written informed consent and approval were exempted by the local committees, and no compensation was provided to the enrolled patients.

Results

Overview

The full information about the features' distribution, as well as the sample sizes, in the 6 datasets is reported in Table 1.

Internal Validation Results

The results of the models on the interval validation set are shown in Table 2 and Figures 1 to 3 (Figure S1 in Multimedia Appendix 1). XGB significantly outperformed all other models in terms of AUC, A-PPV, and sNB (Figure S2 in Multimedia Appendix 1). LR and XGB had greater sensitivity and PPV, respectively, than all other models, although not significantly so. XGB, RF, and LR significantly outperformed all the baseline comparison methods (ie, MDW [37], CRP [44], Sepsis Index [45], COMPOSER [25], as well as the SVM model developed in the study by Aguirre and Urrechaga [31]; Figures 1 and 2; Figure S1 in Multimedia Appendix 1) and did so across all possible decision thresholds. The importance of the most relevant features for the models with the highest AUC and PPV (XGB) and sensitivity (LR) are depicted in Figures 4 and 5. It was identified that MDW was the single most predictive feature (for all models), followed by the CRP, the neutrophils-lymphocytes ratio, the leucocytic formula composition, the hematocrit, and red blood cell count, which also had significant predictive power. An interpretable DT model is given in (Figure 5): after discussion with the clinical experts, we derived from the DT a highly interpretable, cautious decision rule model (Partial Decision Rule [PDR]) defined by the following rules: if MDW>24.1, then sepsis; if MDW ≤24.1 and neutrophils ≤8.6 then no sepsis; if MDW ≤20.5 and neutrophils >8.6 then no sepsis; otherwise abstain.

PDR had better PPV and specificity than the developed ML models, although not significantly so. In terms of sensitivity and NPV, it was significantly worse than only LR. Furthermore, among the nonidentified sepsis cases, most of them (14% of the total number of sepsis cases in the internal test set) were classified by the PDR model classified in the abstain group, while only 1 sepsis case was classified in the no sepsis group.

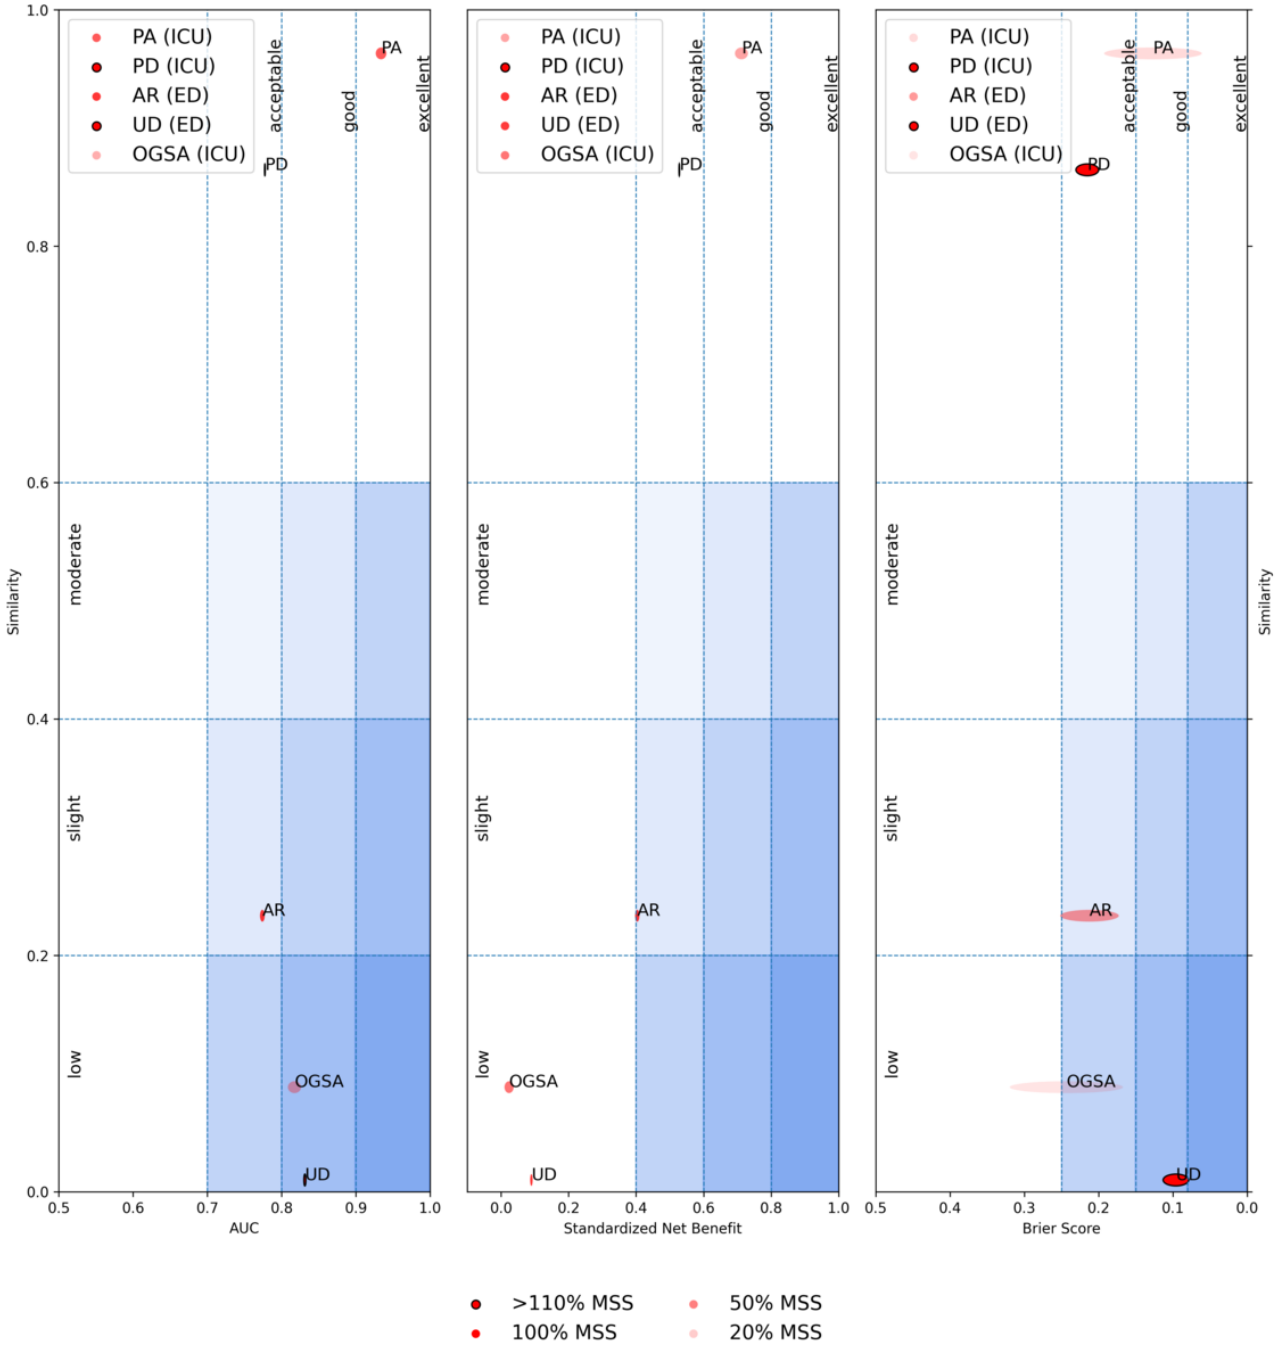
Figure 4. Feature importances for the logistic regression (LR; left) and extreme gradient boosting (XGB; right) models. The feature importance for the LR model represents the coefficients of the induced linear model, shown as bar plots. For each feature, the color represents the sign of the coefficient. The width of the bar represents the magnitude of the coefficient: larger width denotes greater importance. The feature importance for the XGB model was computed through the Shapley Additive Explanations method and is represented in terms of violin plots: for each feature, red denotes high values, while blue denotes low values; values at the right of the middle vertical bar denote an increased confidence score for the positive class (sepsis), while values at the left denote a decreases confidence score. CRP: C-reactive protein; MCHC: mean corpuscular hemoglobin concentration; MCV: mean corpuscular volume; MDW: monocyte distribution width; NLR: neutrophils-lymphocytes ratio; RBC: red blood cell; WBC: white blood cell; HCT: hematocrit test; HGB: hemoglobin; PLT: platelet count.

XSL•FO
RenderX

Figure 5. Interpretable decision tree: the color of each node denotes the majority class for the corresponding subset of instances (blue: sepsis and orange: no sepsis). Each non–leaf node contains 3 data elements: a selected feature and corresponding threshold (top); the proportion of samples corresponding to that node (middle); and the proportion of samples belonging to each class (bottom). Leaf nodes contain 2 data elements: the proportion of samples corresponding to that node (top) and the proportion of samples belonging to each class (bottom). MDW: monocyte distribution width; RBC: red blood cell; WBC: white blood cell.



External Validation Results

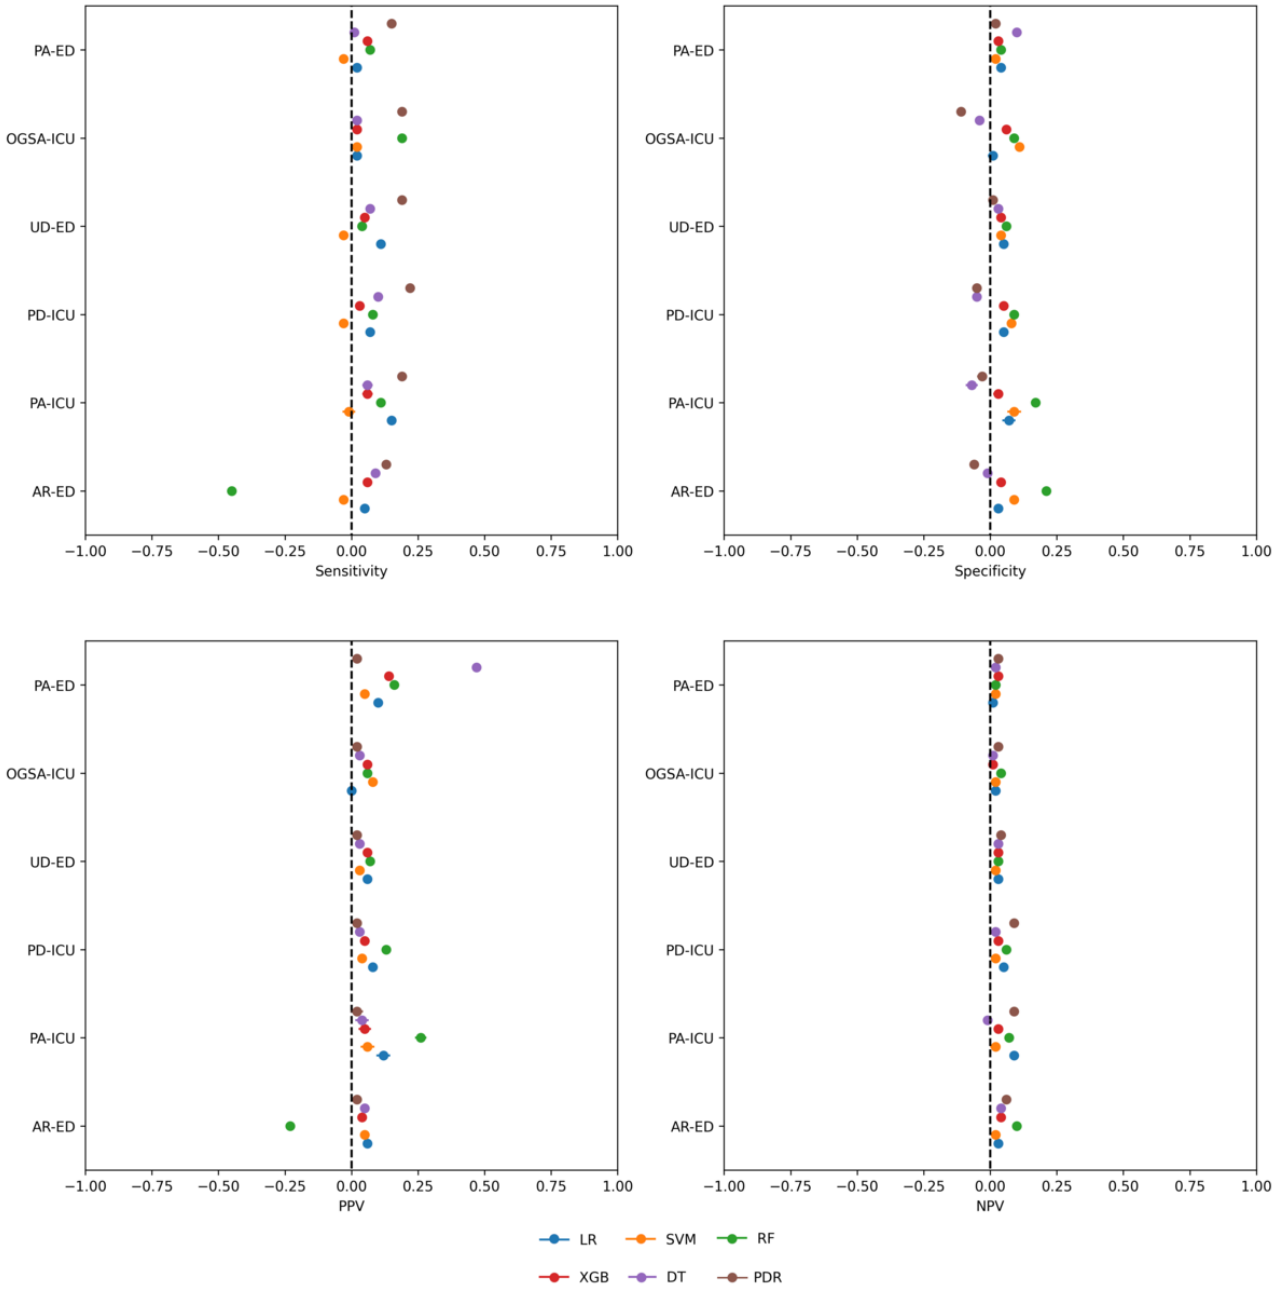
The results of all models, including the PDR model, on the external validation datasets (PA-ICU, PD-ICU, UD-ED, and AR-ED) are reported in Table S2 in Multimedia Appendix 1 and Figure 1, as well as in Figures S3 to S6 in Multimedia Appendix 1, in terms of receiver operating characteristic and sensitivity-PPV curves. The results of the external validation for the model with the highest AUC on the internal validation (XGB), are represented in Figure 6 in the form of an external performance diagram [40]. The XGB model achieved acceptable-to-excellent performance on all external datasets and with respect to all metrics, except for the sNB on the UD-ED: this dataset was, among the external validation datasets, the most dissimilar to the internal training set (PA-ED). The external performance diagrams for the other models are in Figures S7 to S10 in Multimedia Appendix 1. While the performance of all models worsened compared with the internal test sets, the differences were not significant, as shown in Figure S11 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 6. External performance diagram [40] for the extreme gradient boosting (XGB) model on the external datasets. The diagram illustrates the performance of the XGB model according to 3 different aspects: discrimination power (in terms of area under the receiver operating characteristic curve [AUC]), utility (in terms of standardized net benefit), and calibration (in terms of Brier score). The size of the ellipses associated with the datasets denotes the 95% CIs; the transparency of the ellipses denotes the achievement of the minimum sample size (the lower the transparency, the closer the sample size to the minimum sample size). The diagram has been produced with the tool available on the Metimeter website [58]. AR-ED: Arezzo, Emergency Department; OGSA-ICU: Ospedale Galeazzi Sant'Ambrogio, Intensive Care Unit; PA-ICU: Palermo, Intensive Care Unit; PD-ICU: Padova, Intensive Care Unit; UD-ED: Udine, Emergency Department.

Non-MDW Validation Results

The data from all cohorts except OGSA-ICU were used to develop an imputation model to predict the value of the MDW feature from all the other considered parameters. The developed imputation model was then used to impute the values of MDW in the OGSA-ICU dataset. The results of the imputation process are in Figure S12 in Multimedia Appendix 1, while additional detail about the implementation of the imputation model is in the Methods section.



The results of the non-MDW systems, on the OGSA-ICU cohort, are reported in Figure 1 as well as in Figure S13 in Multimedia Appendix 1, in terms of ROC and sensitivity-PPV curves. The results of the validation, for the system encompassing the model with the highest AUC on the internal validation (XGB), are represented in Figure 6 in the form of an external performance diagram [40]. The XGB-based system achieved low PPV and sNB on the OGSA-ICU dataset, as also shown in Figure S13 in Multimedia Appendix 1, which was also the second most dissimilar to the internal training set (PA-ED).

XSL•FO
RenderX

Analysis of Cautious Classifiers

The use of cautious classifiers reduced the amounts of error for almost all models, datasets, and metrics, as is shown in Figure 7 and Figure S14 in Multimedia Appendix 1. For XGB, PDR, RF, and LR (except for the OGSA-ICU dataset), cautious classification led to an improvement in both sensitivity and PPV and equivalent or better performance in terms of NPV. For all models and datasets, the coverage of the cautious classifiers was >50%, and, in all but 3 cases (all for the RF model), >70%. These results indicate that cautious classification could be useful to reduce false negatives, with minimal deleterious effects in terms of the increase of false positives or the number of undecided cases.

Figure 7. Difference between the performance of cautious models and the corresponding standard models: values greater than 0 denote an improvement in performance in the cautious inference model as compared with the corresponding standard one. The 95% CIs were computed using the pooled SD. Each model is represented by a colored circle. AR-ED: Arezzo, Emergency Department, DT: decision tree; LR: logistic regression; OGSA-ICU: Ospedale Galeazzi Sant'Ambrogio, Intensive Care Unit, PA-ED: Palermo, Emergency Department; PA-ICU: Palermo, Intensive Care Unit; PDR: Partial Decision Rule; PD-ICU: Padova, Intensive Care Unit; RF: random forest; SVM: support vector machine; UD-ED: Udine, Emergency Department; XGB: extreme gradient boosting.

Discussion

Principal Findings

Sepsis recognition, especially in the ED, is challenging due to the potentially limited data that can be timely collected and difficult logistic settings. The recognition of sepsis triggers the application of validated bundles (ie, fluid resuscitation, antibiotic administration, blood culture and collection of other relevant specimens, and lactate dosage) that can reduce mortality if applied timely [2]. However, there is a risk of overtreatment in the case of *false positive* cases, with potential detrimental effects of therapies and waste of resources.

In this study, we developed and validated 5 ML models, as well as an interpretable set of rules derived from the latter, for sepsis screening based on clinical and laboratory features. The main findings of our study can be summarized as follows: (1) XGB and LR models showed the best performance for sepsis screening; (2) the most important features for the XGB and LR model were MDW and CRP; (3) the ML models have been validated on 4 external datasets, showing good generalizability in terms of both discrimination power, calibration, and utility; (4) the interpretable, cautious decision rules had performance comparable to that of black-box ML models, while being more easily understandable by clinicians; (5) cautious classification techniques could further improve screening performance, with minimal impact on coverage; and (6) while the non-MDW ML systems achieved acceptable performance on the non-MDW validation test, the lack of MDW led to a large decrease in PPV. Noteworthy, 5 datasets were obtained from different Italian hospitals, in different periods, and different clinical wards (namely, ED and ICU), and exhibited widely varying characteristics in terms of covariate, label, and missingness distributions. In particular, the datasets exhibited a large variation in terms of sepsis prevalence in the corresponding populations, also due to differences between ED and ICU settings (wherein the latter have typically larger incidence than the former) or population characteristics (as an example, the OGSA-ICU cohort was obtained from a hospital specialized in orthopedics, a setting that typically has much lower sepsis' incidence than general hospitals [59]).

Comparison to Prior Work

In this study, we also compared the developed models against different state-of-the-art approaches, including commonly used clinical thresholds [37,44] and scores [45], as well as ML models [31,32]. Our models reported better performance than all the previous state-of-the-art approaches. In this sense, we believe that the most relevant innovations from the methodological point of view, enabling these results, were the inclusion of MDW in the panel of parameters, which resulted in being the most predictive characteristic for sepsis, and the use of controllable AI methodologies, which enabled us to obtain models that were more robust to various forms of distribution shifts. In this regard, to date, the lack of external validation is one of the most important criticisms of ML studies [40,60]. Indeed, although it is a fundamental step to strengthen model derivation and ensure generalizability, most published articles do not perform it, with potentially negative consequences in terms of robustness, generalizability, and real-world applicability. This issue has been markedly noted also in the context of sepsis screening and prediction, where one of the most commonly adopted proprietary decision support models for sepsis prediction (ie, EPIC) has been shown to be severely impacted by shifts and variabilities associated with varying settings [28-31]. Thus, along with the methodological novelties of our study, one of the main strengths of our study is the external validation on 5 different datasets. On the basis of the results of the external validation, we can conclude that the developed models are able to generalize better than the state-of-the-art, at least in the Italian settings, as they maintain the performance independently from covariate shifts (due to either different patient populations or locations, ED or ICU settings, or different measuring instruments), label shifts (sepsis2 or sepsis3 diagnostic criteria and different incidence of sepsis) as well as missingness shifts scenarios: this latter characteristic, specifically, is of particular interest since, despite its potential impact on model generalization, it has scarcely been investigated in medical ML studies [26]. In this study, we developed ML-based systems that could also be applied in settings where MDW was not available, with the aim of increasing the applicability of the developed ML models as well as of assessing the importance of the MDW parameter (which was the most relevant feature according to all the developed ML models). While, indeed, the obtained results show that acceptable results could be obtained even in the presence of significant missingness shift, the lack of MDW led to a relevant drop in performance, thus highlighting the need for collecting complete data in practical scenarios. By contrast, our models were shown to robustly generalize to different incidence rates, not only due to different clinical settings (ED vs ICU) but also to diagnostic criteria (sepsis-2 vs sepsis-3), allowing us to prove not only their effectiveness and robustness but also that varying incidence rates may have lower influence on performance compared to other variation sources (eg, lack of MDW, as described earlier, or selection criteria, as in the AR-ED cohort).

Strengths and Limitations

Strengths of this study are the external validation, the large sample size, and the use of several ML methods as well as several indicators to assess the model's performance. This study comes from the collaboration and cooperation among different professionals, including clinicians, engineers, biologists, and informatics. Each has made its expertise available with the common aim to develop a tool that could be usable in clinical practice.

Limitations of the study must also be mentioned. First, the use of sepsis-2 criteria for sepsis identification in the database used for derivation. However, the use of sepsis-3 criteria in the ED is costly in terms of resources and time-consuming and may be difficult to apply outside the ICU because full assessment of organ dysfunction is needed. Furthermore, the developed models have been shown to generalize well also in settings where sepsis-3 criteria were used for sepsis identification, showing good performance despite this label shift factor. Thus, despite this potential limitation, we believe that the aid of CBC laboratory biomarkers, easily obtainable and at a low cost, may help improve the specificity of both clinical criteria and initial

XSL•FO
RenderX

screening and support differential diagnosis in case of negative results. Second, we were not able to stratify patients according to the infectious focus (eg, lung, abdomen, central nervous system, soft tissue, blood, and urinary tract) or clinical severity (sepsis vs septic shock) due to the absence of serum lactate levels in our datasets. Both the type of infection and clinical severity may be potential modifiers of model performance and should be investigated in future work. More generally, lactate levels are important information for sepsis, especially in ICU settings. At the same time, lactates generally lack several characteristics of an ideal biomarker for sepsis screening, being more apt as a marker of severity in patients with high pretest probability of sepsis. The objective of the developed ML models was to provide clinicians with quick but accurate sepsis screening tests, especially in cases where sepsis is not yet suspected (patients accessing the ED): because lactates are not frequently requested during initial management, requiring them as features for our models would severely decrease their use (as an example, none of the 3 ED cohorts considered in our study encompassed lactates). Nonetheless, we believe that future studies should consider the combination of lactate levels and MDW (as well as other CBC parameters), which could potentially lead to even better performance. In addition, it should be highlighted that MDW can be obtained only using a particular hematological analyzer, while other available instrumentations do not allow for the calculation of this interesting index. This aspect is particularly relevant in light of the results of the non-MDW validation test, which highlighted the diagnostic power of the MDW parameter. Indeed, we noted that its lack was associated with a relevant drop in performance (especially as regards the PPV), thus showing the potential advantage to use the mentioned hematological analyzer to collect CBC biomarkers (including MDW). Finally, in this study we only validated our models on retrospective data; further research should evaluate the potential application of a clinical algorithm incorporating the results of our models in prospective studies and for clinical timely decision in screening patients for sepsis.

Conclusions and Future Directions

In clinical practice, because of their characteristics in performance and robustness, the ML models we developed and presented in this study may represent a reliable tool for supporting physicians in sepsis screening on patients of both sexes admitted to the ED and ICU. Parameters included in the models can be determined rapidly and cost-effectively. Furthermore, the excellent NPV of the models allows us to rule out sepsis with high accuracy, while they are also characterized by a good sensitivity and specificity. Noteworthy, such models significantly improved the specificity and PPV of MDW and CRP alone, as well as of the other considered state-of-the-art ML models, thus confirming our hypothesis that integrating several CBC parameters through the use of ML could significantly improve the performance of traditional biomarkers. Therefore, we conjecture that the developed models could be especially useful as a first-level test to detect sepsis. Accordingly, an increased value (of the confidence score produced by the model) may represent an alert for clinicians that they should perform further investigations to confirm the sepsis suspicion. Indeed, in the case of nonobvious infectious foci, an increased value may help physicians decide to evaluate further biomarkers, such as procalcitonin [61], both fundamental for the appropriate management of patients with sepsis, specifically for diagnosis and guiding treatment, respectively. To this latter aim, the ability to further isolate a group of predictions with higher PPV and good sensitivity, by using the cautious classification models and the interpretable decision rules, is especially interesting. Indeed, from the clinical point of view, it would enable the administration of aggressive therapies in a small sample of patients, but associated with extremely high confidence (90%), thus minimizing the risk of overtreatment and potentially leading to a significant improvement in the outcome. In our opinion, this is a valuable hypothesis to be validated in properly designed prospective trials. At the same time, the cases in which these models abstain could be useful to alert the clinicians of a possible control loss [33] and, hence, reduce the risk of automation bias or de-skilling [62]. In this sense, we conjecture that the developed interpretable decision rules could be particularly fruitful as a rapid and easy-to-use tool to support clinicians in promptly delivering appropriate treatment to the selected patients. Indeed, a recent line of research in the ML literature has noted how the black-box nature of modern ML models, and the consequent adoption of explainable AI techniques (such as model surrogates or feature attribution methods), could potentially increase automation bias (or also other cognitive biases related to the use of automation technology) [63], hence advocating for the use of simple and interpretable models in high-stake domains [64] where humans adopt AI tools in a human-AI teaming scenario [65]. In this sense, the developed decision rule model could address this need while still providing satisfying screening performance. Furthermore, from the clinical point of view, the decision rule model seems to confirm the important role of MDW and neutrophils in sepsis development [66] and provides a first combined screening model based on these 2 parameters that should be further investigated and validated in future studies.

Data Availability

The datasets generated during and analyzed during this study are available from the corresponding author on reasonable request. Access to the computer code used in this research is available upon reasonable request to the authors. Code for validation (internal and external), as well as the associated machine learning models, is accessible on the internet [67].

Abstract

Background: Stroke is a globally prevalent disease that imposes a significant burden on health care systems and national economies. Accurate and rapid stroke diagnosis can substantially increase reperfusion rates, mitigate disability, and reduce mortality. However, there are considerable discrepancies in the diagnosis and treatment of acute stroke.

Objective: The aim of this study is to develop and validate a stroke diagnosis and prediction tool using ChatGLM-6B, which uses free-text information from electronic health records in conjunction with noncontrast computed tomography (NCCT) reports to enhance stroke detection and treatment.

Methods: A large language model (LLM) using ChatGLM-6B was proposed to facilitate stroke diagnosis by identifying optimal input combinations, using external tools, and applying instruction tuning and low-rank adaptation (LoRA) techniques. A dataset containing details of 1885 patients with and those without stroke from 2016 to 2024 was used for training and internal validation; another 335 patients from two hospitals were used as an external test set, including 230 patients from the training hospital but admitted at different periods, and 105 patients from another hospital.

Results: The LLM, which is based on clinical notes and NCCT, demonstrates exceptionally high accuracy in stroke diagnosis, achieving 99% in the internal validation dataset and 95.5% and 79.1% in two external test cohorts. It effectively distinguishes between ischemia and hemorrhage, with an accuracy of 100% in the validation dataset and 99.1% and 97.1% in the other test cohorts. In addition, it identifies large vessel occlusions (LVO) with an accuracy of 80% in the validation dataset and 88.6% and 83.3% in the other test cohorts. Furthermore, it screens patients eligible for intravenous thrombolysis (IVT) with an accuracy of 89.4% in the validation dataset and 60% and 80% in the other test cohorts.

Conclusions: We developed an LLM that leverages clinical text and NCCT to identify strokes and guide recanalization therapy. While our results necessitate validation through widespread deployment, they hold the potential to enhance stroke identification and reduce reperfusion time.

Introduction

Background

Stroke ranks among the leading causes of morbidity and mortality worldwide. The overall burden of stroke, in terms of the absolute number of individuals affected or left disabled by the condition, has been increasing, particularly in China [1-3]. There are significant disparities in stroke incidence, prevalence, acute care, rehabilitation, risk factor management, and outcomes [4]. In recent years, substantial progress has been made in stroke diagnosis and treatment, with effective recanalization therapies for acute ischemic stroke established to significantly improve clinical prognosis [5,6]. However, treatment for acute ischemic stroke is highly time-dependent. Despite ample evidence supporting intravenous thrombolysis (IVT) and endovascular therapy for acute ischemic stroke, the number of patients who arrive at hospitals and are eligible for IVT remains limited, only 10% in the United States and 6% in China, with the global rate for IVT being lower than 5%. In addition, fewer than 100,000 thrombectomies are performed annually, despite the high incidence of ischemic strokes caused by large vessel occlusion (LVO). Access to recanalization therapies also varies across different regions [7,8]. Furthermore, the limited number of stroke neurologists is insufficient to meet the growing number of new stroke cases each year. Consequently, many patients in underdeveloped areas do not receive adequate care in the event of a sudden stroke. Inequities in stroke care are prevalent, and the costs also vary significantly [4,9-11].

The emergence of artificial intelligence (AI) and its application in health care has shown great promise in bridging existing gaps in medical practice [12,13]. Several studies have demonstrated the potential of large language models (LLMs) in managing various diseases [14,15]. In addition, LLMs have proven their effectiveness in medical diagnostics. For example, the Med-PaLM model illustrates the capabilities of LLMs in enhancing medical decision-making, achieving performance levels comparable to those required for US medical licensing examinations [16]. Furthermore, LLMs are used to extract summaries from electronic health records, making medical data more accessible and manageable for health care providers [17]. The integration of AI in clinical decision-making could reduce interrater variability in routine practice and facilitate the extraction of critical information, thereby improving the identification of patients with stroke, predicting treatment responses, and enhancing patient outcomes [14].

Objective

The objective of this study was to develop an acute stroke diagnosis tool that guides key therapies based on ChatGLM-6B and to verify its accuracy in diagnosing and predicting strokes. The application of this model in primary care could enhance the standard workflow for stroke diagnosis, identify patients who could benefit from recanalization, and facilitate risk prediction.

Methods

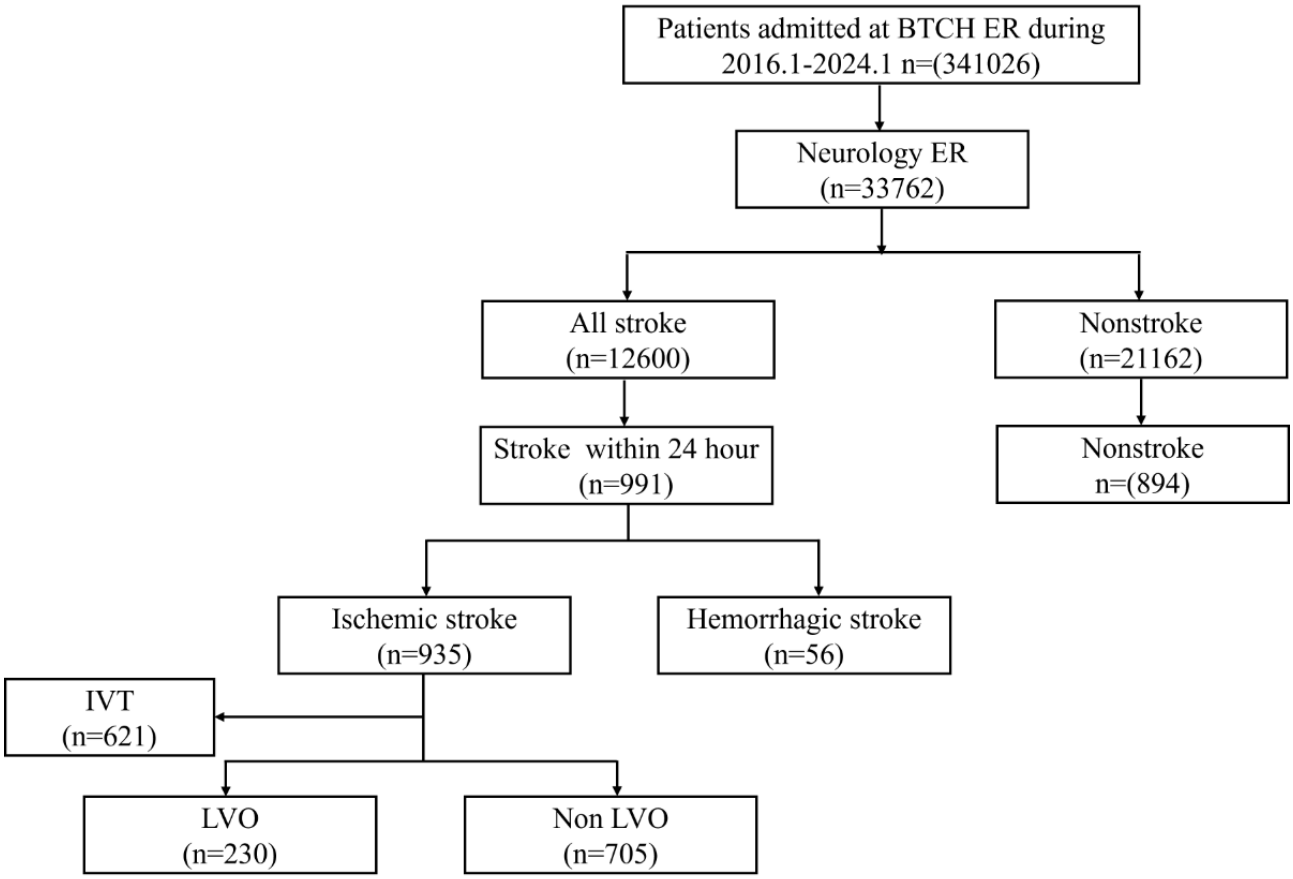
Study Design

We used a retrospective cohort for model training and internal validation while using a prospective cohort from various hospitals for external validation.

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Beijing Tsinghua Changgung Hospital Ethics Committee (23641-0-01). Written informed consent was waived due to the analysis of electronic health records, and all research data used in this study are anonymous.

Data Acquisition



Training data were obtained from Beijing Tsinghua Changgung Hospital, a comprehensive stroke center and teaching hospital. Subjects admitted to the emergency room (ER) between January 2016 and January 2024 were screened continuously. Of the 341,026 patients admitted to the study hospital's ER during this period, 33,762 presented with focal neurological symptoms and were referred to the neurology ER. Among these, 12,600 were diagnosed with cerebrovascular disease (*ICD-10* [*International Statistical Classification of Diseases and Related Health Problems* 10th Revision]), and 991 were diagnosed with stroke and exhibited symptoms within 24 hours. The control group was randomly selected from patients admitted to the neurology ER who were diagnosed with noncerebrovascular diseases, ensuring a match for age, sex, admission time, and attending physicians after removing duplicate admissions. A focal neurologic deficit refers to a dysfunction in the nerves, spinal cord, or brain that affects a specific area of the body, such as the left side of the face, the right arm, or even a localized region like the tongue. In addition, issues related to speech, vision, and cognitive function are also classified as focal neurological deficits; the number of cases in each symptom category was shown in Multimedia Appendix 1. A total of 1885 cases satisfying the criteria above were included to form the training set. An additional group of patients from the same hospital (n=230) and another hospital (n=105) over the course of another month was used for the external test.

Demographic characteristics, emergency clinical notes, radiological images and reports, as well as other relevant examination records, were obtained from the hospital information system. The subjects were categorized into stroke and nonstroke groups based on the discharge diagnosis. Among the patients with stroke, further classification was adopted to divide them into ischemic and hemorrhagic strokes. Patients with ischemic stroke who received IVT or had LVO, confirmed by computed tomography angiography or magnetic resonance angiography, were also identified, regardless of whether they underwent endovascular therapy. In this study, large vessel occlusion is defined as ischemia resulting from the obstruction of a corresponding large vessel, which includes the anterior cerebral artery, middle cerebral artery, posterior cerebral artery, basilar artery, and vertebral artery. A detailed description of the subject screening process is provided in Figure 1. All stroke

XSL•FO
RenderX

diagnoses and workflows adhered to the recommendations outlined in the acute ischemic stroke management guidelines [18].

Figure 1. Flowchart of training dataset inclusion. BTCH: Bingjing Tsinghua Changgung Hospital; ER: emergency room; IVT: intravenous thrombolysis; LVO: large vessel occlusion.

Data Preprocessing

Each record included demographic details such as age, sex, mode of arrival to the hospital (via emergency medical dispatch system or otherwise), main complaints, present medical history related to the current event, previous medical history, neurological examination, auxiliary examinations (including blood tests, electrocardiogram, and brain computed tomography as radiology reports), allergy history, marital and reproductive history, personal history, and family history. Notably, some records contained missing items for specific clinical parameters. We addressed these gaps by indicating "information not provided."

It was observed that some records included details such as past medical history and allergy history within the section on the history of the current illness. These details were extracted using methods such as regular expressions. In addition, information related to COVID-19 epidemiological investigations was present; however, since it was irrelevant to the diagnosis of the patient's condition, it was removed. All cases were randomly divided into training and internal validation datasets in a 9:1 ratio.

Foundation Model: ChatGLM-6B

To address the aforementioned challenges, we used ChatGLM-6B as the foundational model, which serves as the core of our acute stroke diagnosis tool, enabling high-precision analysis of clinical data. The ChatGLM-6B model was chosen due to its relatively low deployment requirements for hospital environments and its outstanding performance capabilities.

Prompt

The following prompt was used:

"As a neurology physician, please review the clinical notes and provide a final diagnosis based on the information provided. Kindly address the following questions: (1) Is the patient experiencing a stroke? (2) If so, is it ischemic or hemorrhagic? (3) If it is an ischemic stroke, does the patient require IVT? (4) If it is an ischemic stroke, is it caused by large vessel occlusion?" (see Figure 2 and Figure 3).

For clarity, when responding to the second, third, and fourth questions, we extracted specific subsets from the original dataset, ensuring that each question presented only two options. For example, when addressing the second question, we exclusively extracted records of stroke cases from the training, validation, and test sets.

Features of the Medical Records

The electronic medical records contain a wealth of information, including primary complaints, medical history related to the current event, previous medical history, and more. Based on the completeness of various entries, certain combinations of entries are manually configured to select the optimal combination for different tasks, as illustrated in the textbox below (Textbox 1).

Textbox 1. Different electronic health record entry combinations.

Electronic health record entry combinations

- （ALL) Age, sex, mode of arrival, main complaints, medical history for this event, previous medical history, neurological examination, auxiliary examination, allergy history, marital and reproductive history, personal history, and family history.
- Age, sex, mode of arrival, main complaints, medical history for this event, previous medical history, neurological examination, auxiliary examination, allergy history, marital and reproductive history.
- Age, sex, mode of arrival, main complaints, medical history for this event, previous medical history, neurological examination, and auxiliary examination.

In-Context Learning

In-context learning is a key ability of LLMs that allows them to handle new tasks with just a few examples. Few-shot learning is considered one of the most effective methods for in-context learning [19]. By using prompting techniques, foundational models can quickly adapt to a specific domain and learn to follow the task format with just a few demonstrations. This approach uses a mechanism to identify examples based on their similarity to the current case [20].

To identify representative few-shot examples, we followed this procedure: for each test example, we selected k training examples that are semantically similar using k-nearest neighbors clustering within the embedding space. Specifically, we used ChatGLM-6B to embed both training and test questions into vector representations. Then, for each test question (x), we retrieved its k-nearest neighbors from the training set. Unlike fine-tuning, dynamic few-shot learning uses the training data without requiring extensive updates to the model parameters.

Instruction Fine-Tuning and LoRA

In this study, we used instruction tuning and low-rank adaptation (LoRA) techniques to enhance the performance of LLMs on specific medical record tasks [21,22]. Instruction tuning is a training method that provides explicit task instructions to the model during the training process, enabling it to better understand and execute these instructions, thereby improving its performance on targeted tasks. Conversely, LoRA technology adapts the model's weight matrices through low-rank modifications, allowing for fine-tuning of model behaviors without the need to retrain the entire model. This approach improves both training and inference efficiency while preserving the model's complexity.

Specifically, we first developed distinct task instructions based on the four identified issues, which represent critical questions in the stroke diagnosis and treatment workflow (Figure 2). These instructions formed the instruction component of the directive. The primary entries from the medical records were concatenated to create the medical record text, which served as the Input component of the instruction. Finally, the labels corresponding to the questions were designated as the Output component of the instruction. To select the primary features from the medical records, combinations of features were manually chosen based on the completeness of various characteristics within the records (Textbox 1). The best-performing features under a zero-shot scenario, without fine-tuning, were then selected for use during the fine-tuning process. An example is provided below.

Tool Chaining with LLMs

Tool chaining with LLMs involves the integration of various pretrained tools, such as vision models, to enhance the capabilities of LLMs. This process does not necessitate additional model training. For instance, in implementations like Visual ChatGPT and X-GPT, an LLM can assign specific tasks to the appropriate tools to manage subtasks that exceed its inherent capabilities [23,24].

In this study, we provided noncontrast computed tomography scans along with the corresponding radiology reports. By using a toolchain approach, we integrated these examination results into the medical records text and input them collectively into the large model, thereby eliminating the need for any additional tools. Furthermore, we compared the model's performance with and without tool chaining, selecting the more effective option for various tasks.

Parameter

The parameter settings for LoRA fine-tuning are as follows: LoRA_rank is set to 8, batch size to 6, gradient accumulation steps to 1, max steps to 2000, fp16 is enabled, and the learning rate is set at 5e-5.

Results

Overview

A total of 1885 cases were included in the training set, comprising 991 stroke cases and 894 nonstroke cases. Among the stroke cases, there were 935 instances of ischemic stroke; of these, 621 patients received IVT, and 230 presented with large vessel occlusion, which was confirmed by magnetic resonance angiography or computed tomography angiography.

Performance on the Validation Set

We use the performance of the LLM in zero-shot and few-shot (3-shot) settings as the baseline, while the results obtained from fine-tuning serve as the final outcomes.

For zero-shot and few-shot scenarios, we experimented with various combinations of entries and the use of tools, ultimately selecting the most effective approach. For fine-tuning, we adopted the best method identified in the zero-shot scenario for adjustments and evaluated it under this framework. The primary results are presented in Table 1.

XSL•FO
RenderX

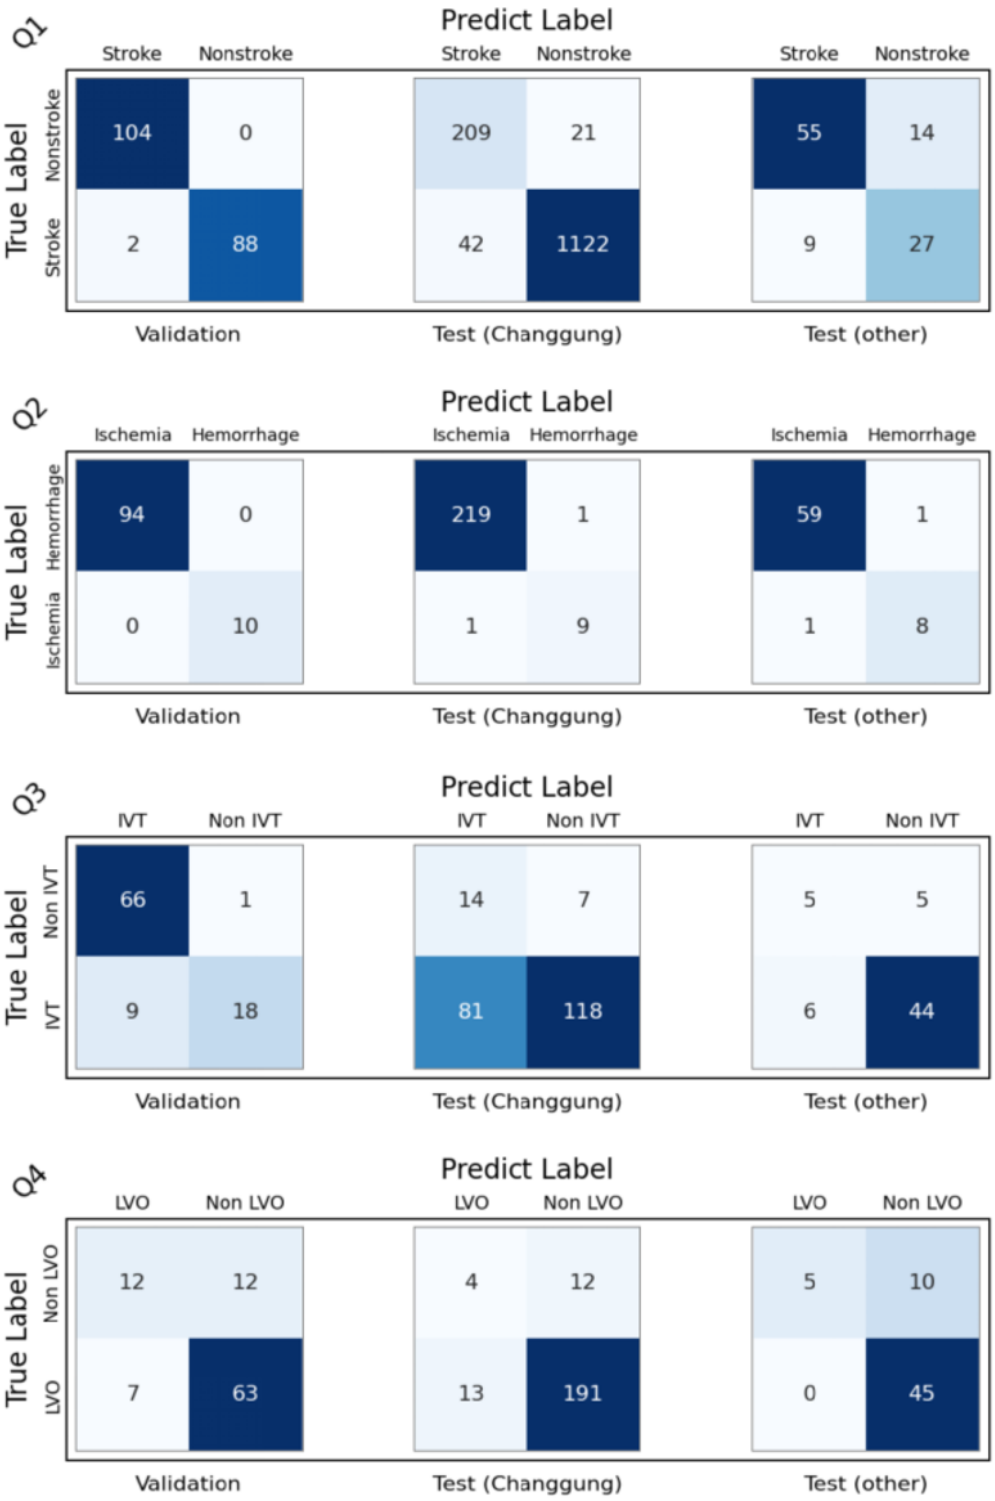
Table 1. Performance of large language models on stroke diagnosis on internal validation set using different methods.

Question and method	Approach	Accuracy	Sensitivity	Specificity
Whether it is a patient with stroke or not?				
Zero-shot	No.1[a]+Tool[b]	0.713	0.702	0.722
Few-shot (3)	No.2+Tool	0.784	0.837	0.722
Fine-tune	No.1+Tool	0.99	1	0.978
If yes, is it ischemia or hemorrhage?				
Zero-shot	No.1+Tool	0.606	0.564	1
Few-shot (3)	No.8	0.894	0.883	1
Fine-tune	No.1+Tool	1	1	1
If ischemic stroke, do they need intravenous thrombosis or not?				
Zero-shot	No.8+Tool	0.617	0.776	0.222
Few-shot (3)	No.3	0.649	0.776	0.333
Fine-tune	No.8+Tool	0.894	0.985	0.667
Is ischemic stroke caused by LVO or not?				
Zero-shot	No.8	0.585	0.625	0.571
Few-shot (3)	No.4+Tool	0.713	0.417	0.814
Fine-tune	No.8	0.8	0.5	0.9

[a]No.x: the xth entry combination shown in Textbox 1.

[b]Tool: using the tool chaining, ie, adding imaging examination results.

It can be observed that after few-shot learning, the model's performance significantly improved on questions 1, 2, and 4, with some improvement also noted for question 3. Following the application of LoRA, there was a substantial enhancement in performance across all questions.



Overall Performance Across Different Datasets

Using the fine-tuned weights, the same tests were conducted on the test set. Specifically, because the electronic medical records provided by other hospitals lacked information on the mode of arrival, marital status, and reproductive history, as well as imaging examination results, these components were excluded from the input. Instead, the "nervous system" data, which was available in this dataset but not originally included, was incorporated. The main results are presented in Table 2. For the key procedures in the stroke diagnosis workflow, the model demonstrates relatively satisfactory performance in stroke diagnosis, classification, and prediction.

The model demonstrates exceptionally high accuracy in stroke diagnosis, achieving 99% in the internal validation cohort. Further validation across different cohorts and other stroke centers indicates that the accuracy remains at 95.5% within the same hospital and 79.1% in other hospitals. This model exhibits excellent performance in identifying both ischemic and hemorrhagic strokes, with accuracy reaching as high as 100% in internal validation and 99.1% and 97.1% in external validation. Regarding IVT for ischemic stroke, the model's accuracy ranges from 60% to 89.4%. In addition, the model is capable of identifying large vessel occlusions, with prediction accuracy reaching up to 80% across different cohorts. However, it is important to note that while the model demonstrates high specificity, it has limited sensitivity (see Table 2 and Figure 4).

XSL•FO
RenderX

Figure 4. Confusion matrix of large language models on stroke diagnosis workflow key issues. IVT: intravenous thrombolysis; LVO: large vessel occlusions.

XSL•FO
RenderX

Table 2. Performance of large language models on stroke diagnosis based on low-rank adaptation on both internal validation and external test set.

Question and dataset	Accuracy	Sensitivity	Specificity
Whether it is a patient with stroke or not?			
Validation	0.99	1	0.978
Test			
Changgung (n=230)	0.955	0.909	0.964
Other (n=105)	0.791	0.812	0.75
If yes, is it ischemia or hemorrhage?			
Validation	1	1	1
Test			
Changgung (n=230)	0.991	0.996	0.9
Other (n=105)	0.971	0.983	0.889
If ischemic stroke, do they need intravenous thrombosis or not?			
Validation	0.894	0.985	0.667
Test			
Changgung (n=230)	0.6	0.667	0.593
Other (n=105)	0.817	0.5	0.88
If ischemic stroke, is it caused by LVO or not?			
Validation	0.8	0.5	0.9
Test			
Changgung (n=230)	0.886	0.25	0.936
Other (n=105)	0.833	0.333	1

We also conducted zero-shot and few-shot tests on the test set, using the optimal combinations selected from the validation set for both scenarios. The results were compared with those obtained from LoRA, as shown in Table S3 in Multimedia Appendix 2 and Table S4 in Multimedia Appendix 3.

Verify the Effectiveness of Selecting the Optimal Entry Combinations

Since fine-tuning with various entry combinations is time-consuming, we focus on fine-tuning based on the best combination identified from the zero-shot results. The optimal combinations for questions 1 and 2 consist of all entries combined with medical imaging examination results. We then compare the best combinations for questions 3 and 4 against the all-inclusive combination of entries and medical imaging examination results on the validation set. This comparison aims to demonstrate the effectiveness of selecting specific combinations rather than simply opting for the maximum number of entries (see Table 3). For question 3, the optimal combination yielded significantly better performance than using all available information. In question 4, while the accuracy of the optimal combination was slightly lower than that of the all-inclusive approach, it exhibited a more balanced performance in terms of sensitivity and specificity; the *P* values for the comparison between best and all among questions 3 and 4 were <0.001 and 0.017, respectively.

Table 3. Comparison between selecting the optimal combination and selecting all information on the validation set.

Question and method[a]	Accuracy	Sensitivity	Specificity
If ischemic stroke, do they need intravenous thrombosis or not?			
Best[a]	0.8936	0.9851	0.6667
All[b]	0.8404	0.9701	0.5185
If ischemic stroke, is it caused by LVO[c] or not?			
Best	0.8	0.5	0.9
All	0.8085	0.3333	0.9714

[a]Best: the best entry combinations for questions.

[b]All: all entries and medical imaging examination results.

[c]LVO: large vessel occlusions.

Discussion

Principal Findings

To the best of our knowledge, this is the first LLM developed for stroke diagnosis. Domain-specific models are typically more efficient than general-purpose models. Our model has demonstrated excellent performance in stroke diagnosis and classification. Compared to other LLMs, ChatGLM-6B has an affordable advantage in health care purposes, which is critically important in the medical domain. The easy deployment of our model could undoubtedly facilitate the wide-scale application in primary care.

A Review of Previous Stroke Diagnosis Tool and Their Limitations

Addressing inequities in acute stroke care necessitates a thorough examination of each component of regional workflow, particularly the collaboration among various stroke centers [19]. In addition to raising awareness of stroke symptoms among high-risk populations, the most critical step is to identify patients with stroke as early as possible at primary stroke centers. Although several scales existed for stroke diagnosis, they often exhibited limited sensitivity and specificity. The Cincinnati Prehospital Stroke Scale (CPSS) is a clinical evaluation tool for stroke diagnosis, comprising three items: facial droop, upper limb weakness, and speech difficulties. If a patient presents with one of these three symptoms, there is a 72% likelihood that they are experiencing a stroke; if all three symptoms are present, the probability increases to 85% [20,21]. The 3-Item Stroke Scale (3-ISS) is used to identify proximal vessel occlusion (specifically T-segment or M1-segment occlusion of the middle cerebral artery), with an overall accuracy of 86%, sensitivity of 67%, and specificity of 92% [22]. However, these evaluations are primarily based on clinical symptoms, which can lead to an underestimation of stroke diagnoses in atypical patients and an overestimation in individuals with other neurological conditions. In addition, there are several large vessel occlusion scales based on imaging techniques, such as the Alberta Stroke Program Early CT Score (ASPECTS) and multimodal perfusion imaging. Computed tomography perfusion is the most widely used multimodal imaging method in comprehensive stroke centers, and numerous automated postprocessing workstations, such as Rapid AI and Viz.AI, assist in LVO and penumbra calculations. These technologies can enhance LVO workflow to some extent and reduce door-to-groin time [12,23]. However, there are limitations to this assessment. First, computed tomography perfusion may not be available in some primary care settings. Second, automated postprocessing workstations are not universally implemented across all hospitals. Third, the varying algorithms used by different products can also impact the final diagnosis [24].

Clinical Implications

Our results demonstrated the significant potential of LLMs in stroke diagnosis and management, particularly in differentiating stroke mimics. The relatively low accuracy of stroke diagnosis in external validation may be attributed to discrepancies in the clinical notes template and deficiencies in radiology reports from other hospitals. Our model, which is based on initial visit records and brain computed tomography scans, achieved an accuracy of nearly 80% in identifying LVO and recommending IVT. This level of accuracy is comparable to that of an experienced stroke neurologist and surpasses the performance of the Alberta Stroke Program Early CT Score [25]. Previous studies also support the notion that multimodal LLMs, when used to evaluate the prognosis of hemorrhagic stroke, can significantly enhance predictive performance compared to single modalities, such as clinical notes or imaging [26]. In contrast to other disease-specific language representation models, such as stroke-BERT [27], ChatGLM-6B is a general-purpose language model with extensive capabilities in language understanding and generation. This allows it to capture semantic and contextual information more comprehensively when processing diverse medical records. In addition, the GLM framework supports multimodal data input and can integrate information from images, which is particularly crucial in the diagnosis of cerebrovascular diseases. When compared to traditional machine learning and deep learning models, LLMs often demonstrate superior performance across a range of language-based tasks. For instance, LLMs have been successfully applied in diagnosing medical conditions, assisting in medical education, and even generating medical documentation, where they can outperform more traditional models that require extensive feature engineering and fine-tuning for each specific task [17]. This is the first LLM tool in stroke diagnosis; the model can give some guidance on stroke diagnosis, classification, and management recommendations based on the primary information. As we know, there exist great discrepancies in stroke care across different hospitals. Stroke centers were more likely to receive thrombolytic therapy and had lower 30-day mortality rates [28]. Thus, the deployment of this model in primary care, especially where stroke neurologists are in high demand, could not only improve the ability of stroke diagnosis early and accurately, but also improve reperfusion therapy for patients who are very likely to have LVO, and they can be transferred to advanced stroke center as soon as possible, saving both time and economic costs. A previous study indicated that the use of artificial intelligence decision support in a hyperacute stroke pathway facilitates decision-making and can improve the rate and time of reperfusion therapies in a hub-and-spoke system of care [29]. There are also data supports that transfer-in patients had similar in-hospital mortality rates compared with front-door patients [30].

Limitations and Future Work

This study has several limitations. First, it only included data from two centers in the real world for external validation, and the data were exclusively from the Chinese population, which could introduce some data bias. We still need more data from different stroke centers to validate the accuracy of our model. Second, electronic health records may be fragmented and the clinical notes could also be subjective and depend on different physicians, which could possibly have an effect on the test results. However, the advanced language comprehension capabilities of LLMs enable them to extract crucial information from diverse and complex clinical notes, even when the documentation varies in style and contains incomplete data. This capacity significantly enhances the quality and efficiency

XSL•FO
RenderX

of medical diagnostics. Finally, despite the satisfactory performance of this model in stroke diagnosis, as an LLM, the hallucination is unavoidable. We strive to minimize the possibility by adjusting the temperature, paying more attention to the prompt project, and verifying the results in an external dataset. As an auxiliary diagnostic tool, we must interpret its suggestions with caution.

Conclusion

In this study, we developed an LLM for stroke diagnosis with quite good performance in in-context understanding and reasoning skills by selecting optimal entry combinations, using tools, and fine-tuning with LoRA, proving its effectiveness. Our model also performs well in handling missing values, whether individual data points lack information on certain entries or the dataset itself lacks corresponding entries. In general, AI holds promise as a tool to ease the stroke neurologist's shortage, improve daily workflow, and supply unique diagnostic insights by analyzing data simultaneously from several sources, including neurological history and examination, blood tests, and images.

Abstract

Background: Early complications increase in-hospital stay and mortality after intestinal obstruction surgery. It is important to identify the risk of postoperative early complications for patients with intestinal obstruction at a sufficiently early stage, which would allow preemptive individualized enhanced therapy to be conducted to improve the prognosis of patients with intestinal obstruction. A risk predictive model based on machine learning is helpful for early diagnosis and timely intervention.

Objective: This study aimed to construct an online risk calculator for early postoperative complications in patients after intestinal obstruction surgery based on machine learning algorithms.

Methods: A total of 396 patients undergoing intestinal obstruction surgery from April 2013 to April 2021 at an independent medical center were enrolled as the training cohort. Overall, 7 machine learning methods were used to establish prediction models, with their performance appraised via the area under the receiver operating characteristic curve (AUROC), accuracy, sensitivity, specificity, and F_1-score. The best model was validated through 2 independent medical centers, a publicly available perioperative dataset the Informative Surgical Patient dataset for Innovative Research Environment (INSPIRE), and a mixed cohort consisting of the above 3 datasets, involving 50, 66, 48, and 164 cases, respectively. Shapley Additive Explanations were measured to identify risk factors.

Results: The incidence of postoperative complications in the training cohort was 47.44% (176/371), while the incidences in 4 external validation cohorts were 34% (17/50), 56.06% (37/66), 52.08% (25/48), and 48.17% (79/164), respectively. Postoperative complications were associated with 8-item features: Physiological Severity Score for the Enumeration of Mortality and Morbidity (POSSUM physiological score), the amount of colloid infusion, shock index before anesthesia induction, ASA (American Society of Anesthesiologists) classification, the percentage of neutrophils, shock index at the end of surgery, age, and total protein. The random forest model showed the best overall performance, with an AUROC of 0.788 (95% CI 0.709-0.869), accuracy of 0.756, sensitivity of 0.695, specificity of 0.810, and F_1-score of 0.727 in the training cohort. The random forest model also achieved a comparable AUROC of 0.755 (95% CI 0.652-0.839) in validation cohort 1, a greater AUROC of 0.817 (95% CI 0.695-0.913) in validation cohort 2, a similar AUROC of 0.786 (95% CI 0.628-0.902) in validation cohort 3, and the comparable AUROC of 0.720 (95% CI 0.671-0.768) in validation cohort 4. We visualized the random forest model and created a web-based online risk calculator.

XSL•FO
RenderX

Conclusions: We have developed and validated a generalizable random forest model to predict postoperative early complications in patients undergoing intestinal obstruction surgery, enabling clinicians to screen high-risk patients and implement early individualized interventions. An online risk calculator for early postoperative complications was developed to make the random forest model accessible to clinicians around the world.

KEYWORDS

postoperative complications; intestinal obstruction; machine learning; early intervention; risk calculator; prediction model; Shapley additive explanations

Introduction

Early postoperative complications refer to newly occurring situations or events that are detrimental to the patient's health from the first postoperative day until discharge, causing irreversible damage or requiring a change in treatment policy [1]. The incidence of early postoperative complications in intestinal obstruction was reported to be as high as 23%-28%, which contributed to an increased length of hospital stay and mortality [2,3]. Early complications after intestinal obstruction surgery include postoperative infection, wound dehiscence, important organs' dysfunction, intestinal fistula, postoperative bleeding, and other surgery-related complications [3,4]. Surgery is a reliable means for relieving obstruction, but for frail individuals, surgery, anesthesia, and various perioperative interventions pose challenges as well. Accurate prediction of early postoperative complications is essential for proper preoperative selection of surgical patients, determination of the necessary postoperative vigilance level, guidance of perioperative decision-making, and early intervention.

Currently, studies have found that delayed surgery, American Society of Anesthesiologists (ASA) physical status classification, age, and surgical methods may be risk factors for its occurrence [4-6]. A study proposed using the Acute General Emergency Surgical Severity–Small Bowel Obstruction (AGESS-SBO) score [7] to predict the prognosis of small-bowel obstruction (SBO), but the current analysis and early intervention still depend on expert consensus and guidelines. A predictive model for identifying high-risk patients is required to optimize the treatment strategy for intestinal obstruction. However, the intricate etiology, pathophysiology, and perioperative changes of intestinal obstruction render traditional logistic regression models not applicable.

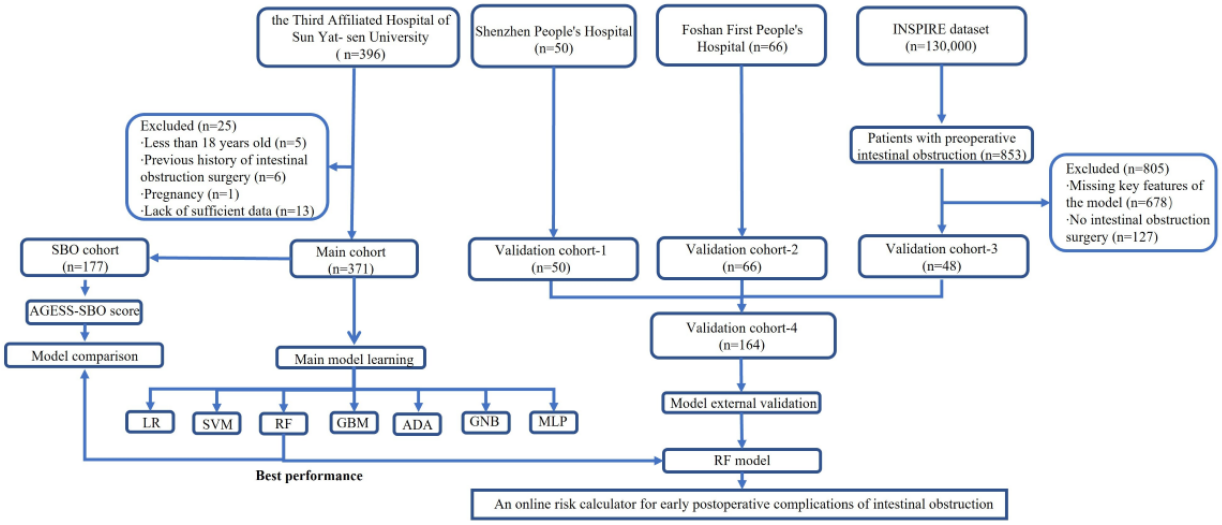
Data-driven machine learning (ML) modeling, a technology used to build data-driven artificial intelligence systems, has the ability to diagnose and predict the prognosis of patients. On the one hand, ML has the advantages of capturing nonlinear relationships more comprehensively and predicting the prognosis accurately [8]; on the other hand, with the increasing complexity and dimensions of modern medical datasets, ML can give full play to the advantage of a rich data volume in big data. These factors make it popular in medicine, including anesthesiology [9], cardiology [10], ophthalmology [11], and so on. ML has been used to predict postoperative complications. Some cohort studies have applied ML to diagnose intestinal obstruction [12], but it has not been applied to predict early postoperative complications. While the performance of ML models is superior to traditional scoring systems, the limitation of these models is that they are mostly designed on the basis of single-center data. What is important is that the ML prediction models have not been transformed into practical applications.

In this multicenter retrospective study, we developed an online risk calculator for early postoperative complications of patients with intestinal obstruction in an independent medical center and performed external validation through two independent medical centers, a publicly available perioperative dataset Informative Surgical Patient dataset for Innovative Research Environment (INSPIRE) and a mixed cohort consisting of the above 3 external validation datasets.

Methods

Source of the Data and Participants

This retrospective study was performed using a multicenter database of patients who underwent surgery for intestinal obstruction: the Third Affiliated Hospital of Sun Yat-sen University, Shenzhen People's Hospital, Foshan First People's Hospital, and the INSPIRE dataset. INSPIRE is a publicly available research dataset for perioperative medicine, which includes approximately 130,000 patients (50% of all surgical patients) who underwent anesthesia for surgery at an academic institution in South Korea between 2011 and 2020 [13,14]. To our knowledge, it is a new dataset that contains data for collaborative research and development in perioperative medicine.



The medical data collected from electronic medical record systems and perioperative databases included demographic data, preoperative comorbidities, laboratory results, drugs, intraoperative data, and diagnosis-related features.

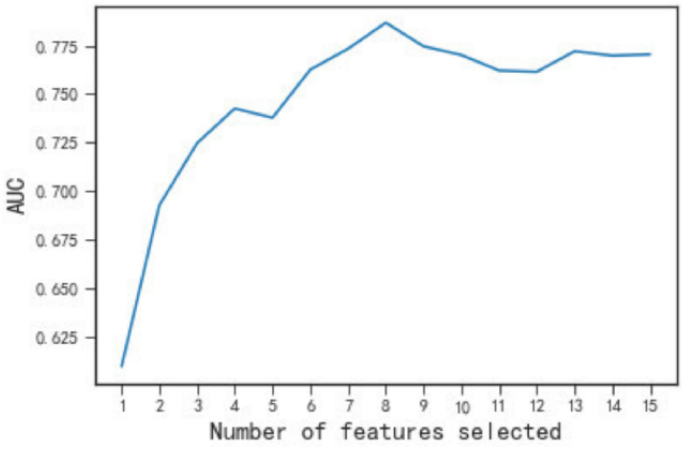
As a result, 396 patients who underwent surgery for intestinal obstruction from April 2013 to April 2021 were extracted. After excluding minors, pregnant women, patients who underwent secondary procedures for intestinal obstruction, and patients who lacked sufficient related records, 371 patients from the Third Affiliated Hospital of Sun Yat-sen University were included in the primary cohort for model development. A total of 116 patients who underwent surgery for intestinal obstruction meeting the same inclusion criteria from Shenzhen People's Hospital (50 patients, 2021-2022) and Foshan First People's Hospital (66 patients, 2020-2022) were exclusively extracted for the validation cohorts 1 and 2. We retrieved 853 patients with preoperative intestinal obstruction from the INSPIRE database of 130,000 patients. After excluding patients without key variables required for the model (678 patients) and

XSL•FO
RenderX

nonintestinal obstruction surgical patients (127 patients), the remaining 48 patients were selected as validation cohort 3. Finally, the patients from 3 external validation cohorts jointly formed the external validation cohort 4 (Figure 1).

Figure 1. Flowchart of patient enrollment. ADA: adaptive boosting classifier; GBM: gradient boosting machine; GNB: Gaussian Bayesian classifier; LR: logistic regression; MLP: multilayer perceptron; RF: random forest; SVM: support vector machine.

Model Outcome



The primary outcome was to assess early postoperative complications occurring from the first postoperative day until discharge. According to the definition provided by the Association of Surgeons of the Netherlands (ASN), we defined these complications as "a condition or an event that is detrimental to the patient's health, causing irreversible damage or requiring a change in treatment policy." The complications were identified using the *ICD-10* (*International Statistical Classification of Diseases and Related Health Problems 10th Revision*) diagnosis codes and only those labeled as "not present on admission" on the medical record were counted as postoperative complications to ensure that events within the composite outcome were newly developed. We classified these complications in accordance with the Clavien-Dindo [15] (Table S1 in Multimedia Appendix 1) classification and the patients' treatment strategies, to provide more information. Predictions of all levels of complications will be made. Specifically, sepsis was defined as a life-threatening organ dysfunction caused by the host's maladjusted response to infection. The diagnosis of sepsis is based on Sepsis 3.0 diagnostic criteria. Infections or suspected infections include lung infections, intestinal infections, abdominal infections, urinary system infections, and so on, and were manifested as positive pathogen culture or symptoms of infection, but without organ dysfunction. Poor wound healing included wound infection, fat liquefaction, and nonepithelial regeneration of the wound surface accompanied by hematoma, wound dehiscence, and excessive scar hyperplasia.

Predictors, Missing Data, and Selection

Variables with more than 30% missing data and patients with more than 50% missing variables were excluded from further analysis. After doing this, a total of 127 variables were chosen for the univariate analysis, mainly covering demographic characteristics, preoperative comorbidities, laboratory values, cause and complications of intestinal obstruction, as well as intraoperative incidents, shock index (SI), medication, and fluid infusion (Table S2 in Multimedia Appendix 1). Some classification variables were produced by imposing specific rules based on their definitions. According to the statistical analysis of data correlation, only features that had statistical significance ($P<.05$) in the univariate test were selected to minimize the potential overfitting caused by the high dimensions of features. A total of 71 variables were chosen, and then the missing values of these 71 variables were filled. The mode-filling method was used for categorical indicators, and the K-nearest neighbor algorithm was used for continuous indicators. After conducting univariate analysis, we next performed the least absolute shrinkage and selection operator (LASSO) regression analysis on the residual variables. Subsequently, we eliminated variables with LASSO coefficients below 0.02, resulting in the selection of 14 variables. On this basis, we used the wrapper method based on the model score to screen features again. We trained a support vector machine model with 14 variables to calculate their Shapley Additive Explanations (SHAP) values using the training set. We then sorted the variables in descending order according to their SHAP values. These variables were then successively added to the support vector machine model for retraining while monitoring the area under the receiver operating characteristic curve (AUROC) of the model on the validation set. Ultimately, upon selecting the initial 8 indicators, the model's AUROC on the training set reached its maximum (Figure 2).

XSL•FO
RenderX

Figure 2. The process of using a wrapper feature selection method to screen features. Upon the initial selection of the first 8 features, the model achieved its peak area under the receiver operating characteristic (AUROC) curve on the validation set. Subsequent addition of features did not result in a further increase of the AUROC. Consequently, we opted for the top 8 features with the highest Shapley Additive Explanations value.

Statistical Analysis

Python (version 3.9.12) was used as the base platform. Table processing was conducted using Pandas (version 1.3.5). The SciPy package (version 1.7.1) was used to analyze the data. The Sklearn software package (version 1.1.2) was used for data preprocessing and building the base models, including logistic regression, support vector machine, random forest (RF), gradient boosting machine implemented by a decision tree, adaptive boosting, the Gaussian Bayesian classifier, and multilayer perceptron.

The main cohort was randomly divided into a 70% development set and a 30% internal validation set. The bootstrap method was used to perform 1000 runs on the internal validation set to calculate confidence intervals for AUROC, accuracy, sensitivity, and specificity. Continuous variables were analyzed and expressed as median values with interquartile intervals and compared using the independent-sample *t* test or Mann-Whitney *U* test. Categorical variables are expressed in terms of quantity and percentage and were compared using a chi-square test. The SHAP method was implemented using the Python SHAP package.

Model Validation

The best-performing model was compared with the AGESS-SBO score, which is calculated by the American Association for the Surgery of Trauma (AAST) anatomical score, physiology score, and comorbidity score as the basis for risk stratification [7]. The ML model was also compared and validated on the data from two other independent cohorts, the INSPIRE dataset, and a mixed cohort to demonstrate its extrapolation and generalization. The prediction performances were compared in terms of AUROC, specificity, sensitivity, accuracy, and F_1-score.

Ethical Considerations

The study protocol followed the principles of the Declaration of Helsinki and was approved by the Institutional Ethics Committee of the Third Affiliated Hospital of Sun Yat-sen University on October 19, 2022 ([2022] 02-004-02). Study data were anonymous or deidentified. The requirements for informed consent and clinical trial registration were waived by the committee. No identification of individual participants in any images of the manuscript or supplementary material was possible.

Results

Univariate Analysis

Among the 396 patients undergoing intestinal obstruction surgery accessed from the EHRs, only 371 patients who met the inclusion criteria were included in the development cohort. The development cohort consisted of a majority of males (242/371, 65.22%), with a median age of 61 (IQR 47-70) years and a median BMI of 20.96 (IQR 19.03-23.81) kg/m^2. The flowchart of the study design is shown in Figure 1. Among the 371 patients included, 176 (47.44%) were diagnosed with early postoperative complications (complication group). The first 3 common postoperative complications were infection (26.95%), sepsis (16.17%), and poor wound healing (7.82%, Table 1). According to Clavien-Dindo's classification of complications [15], grade I had the highest incidence (15.63%, Table 1).

Table 1. The incidence of the 12 most severe and common postoperative complications in the development cohort and the classification of patients in the development cohort based on the Clavien-Dindo classification.

Postoperative complications[a]	Values (N=371), n (%)
Death	16 (4.31)
Sepsis	60 (16.17)
Infection or suspected infection	100 (26.95)
Heart failure	17 (4.58)
Respiratory failure	26 (7.01)
Pulmonary embolism	2 (0.54)
Acute hepatic insufficiency	12 (3.23)
Acute kidney injury	10 (2.7)
Gastrointestinal bleeding	21 (5.66)
Recurrent intestinal obstruction	20 (5.39)
Anastomotic fistula	8 (2.16)
Poor wound healing	29 (7.82)
Clavien-Dindo classification	
Grade I	58 (15.63)
Grade II	55 (14.82)
Grade IIIa	8 (2.16)
Grade IIIb	12 (3.23)
Grade Iva	13 (3.5)
Grade IVb	14 (3.77)
Grade V	16 (4.31)

[a]Some severe and common complications are listed here.

A total of 127 perioperative variables were analyzed by univariate analysis. Finally, only 71 variables with significant differences (P<.05) between the two groups were retained, including 37 preoperative variables and 34 intraoperative variables (Table S2 in Multimedia Appendix 1).

Compared with the patients without early postoperative complications, the time of first postoperative defecation, time of drainage tube retention, total hospitalization cost, total hospitalization days, postoperative hospitalization days, and ICU (intensive care unit) length of stay in the complication group was increased significantly (P<.05, Table S2 in Multimedia Appendix 1).

Internal Validation Performance

After the univariate analysis, the LASSO regression analysis, and the wrapper method based on SHAP, we selected 8 features, including the Physiological Severity Score for the Enumeration of Mortality and Morbidity (POSSUM physiological score), the amount of colloid infusion, SI before anesthesia induction, the ASA classification, the percentage of neutrophils, SI at the end of the surgery, age, and total protein to train our 7 models. To increase the robustness of the model prediction results during the training process, we used the integration idea for modeling [16] and finally established 7 common ML models. In the training set, the RF model achieved a relatively balanced AUROC (0.788, 95% CI 0.709-0.869) and specificity (0.810, 95% CI 0.715-0.884) and the highest sensitivity (0.695, 95% CI 0.570-0.811), accuracy (0.756, 95% CI 0.696-0.831) and F_1-score (0.727, 95% CI 0.633-0.812). Since GNB reached the greatest AUROC (0.805, 95% CI 0.730-0.878), its sensitivity was lowest (0.544, 95% CI 0.433-0.674). We eventually chose the RF model for further analysis and application.

Since the AGESS-SBO score is a scoring system for postoperative complications of SBO, we excluded patients with colorectal obstruction. Then, we validated and compared the performance of this score and ML predictor in a set excluding patients with colorectal obstruction. The AGESS-SBO score presented a higher specificity (0.889, 95% CI 0.750-1.0) with a lower AUROC (0.731, 95% CI 0.585-0.854), accuracy (0.653, 95% CI 0.531-0.776), F_1-score (0.537, 95% CI 0.320-0.718), and sensitivity (0.409, 95% CI 0.222-0.625). For predicting early complications of SBO, the RF model achieved the highest AUROC (0.912, 95% CI 0.809-0.986), accuracy (0.831, 95% CI 0.735-0.918), sensitivity (0.893, 95% CI 0.725-1.0), F_1-score (0.817, 95% CI 0.684-0.929), and balanced specificity (0.786, 95% CI 0.619-0.93; Table 2, Figures 3A and 3B).

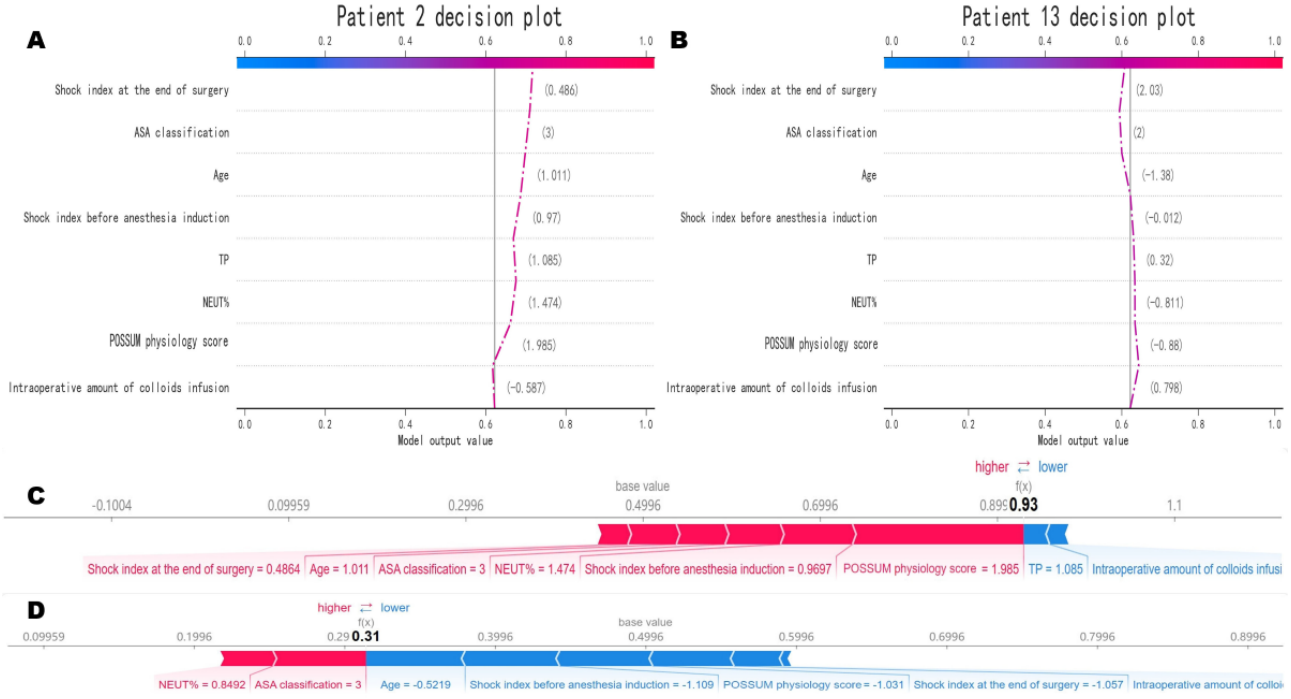
Figure 4. Use of Shapley Additive Explanations (SHAP) summary plot and SHAP dependence plot to demonstrate the importance and impact of variables on the random forest model. ASA: American Society of Anesthesiologists; SHAP: Shapley Additive Explanations; NEUT%: neutrophil percentage; POSSUM: Physiological and Operative Severity Score for the Enumeration of Mortality and Morbidity.

External Validation Performance

The external validation cohorts included 50 patients from Shenzhen People's Hospital (validation cohort 1), 66 patients from Foshan First People's Hospital (validation cohort 2), 48 patients from the INSPIRE dataset (validation cohort 3), and 164 patients from the above 3 datasets (validation cohort 4). In these 4 external validation sets, the incidence of early postoperative complications was 34%, 56.06%, 52.08%, and 48.17%, respectively. In the four validation sets, the RF model achieved a comparable AUROC (0.755, 95% CI 0.652-0.839), a greater AUROC (0.817, 95% CI 0.695-0.913), a similar AUROC (0.786, 95% CI 0.628-0.902) and a comparable AUROC (0.720, 95% CI 0.671-0.768; Table 2 and Figure 3C).

Feature Importance Evaluated by SHAP Values

The baseline for the SHAP value in this study is the average of all predicted early complication incidences in the internal validation set, which was 49.96%. Figure 4A shows the explanation of the ML model by SHAP. The SHAP summary plot demonstrated that the POSSUM physiological score, the amount of colloid infusion, SI before anesthesia induction, the ASA classification, the percentage of neutrophils, SI at the end of the surgery, age, and total protein were ranked as the top 8 important variables for RF. Both kinds of SHAP plots show that a higher POSSUM physiological score, larger amount of colloid infusion, larger SI before anesthesia induction, higher ASA grade, higher percentage of neutrophils, larger SI at the end of the surgery, older age, and lower total protein were associated with a higher SHAP value output in the RF model, indicating higher odds of early postoperative complications after surgery for intestinal obstruction.



We use a SHAP dependence plot to observe how a feature affects the prediction results of the model (Figure S1 in Multimedia Appendix 1; Figures 4B and 4C). For example, when the POSSUM physiological score is high, the SHAP value will change significantly, showing a positive correlation (Figure 4B). From the SHAP dependence plot, it can also be found that there is an obvious "truncation" in the SHAP value between ASA II and ASA III, indicating that ASA II and ASA III have a greater contribution to distinguishing the positive and negative samples (Figure 4C).

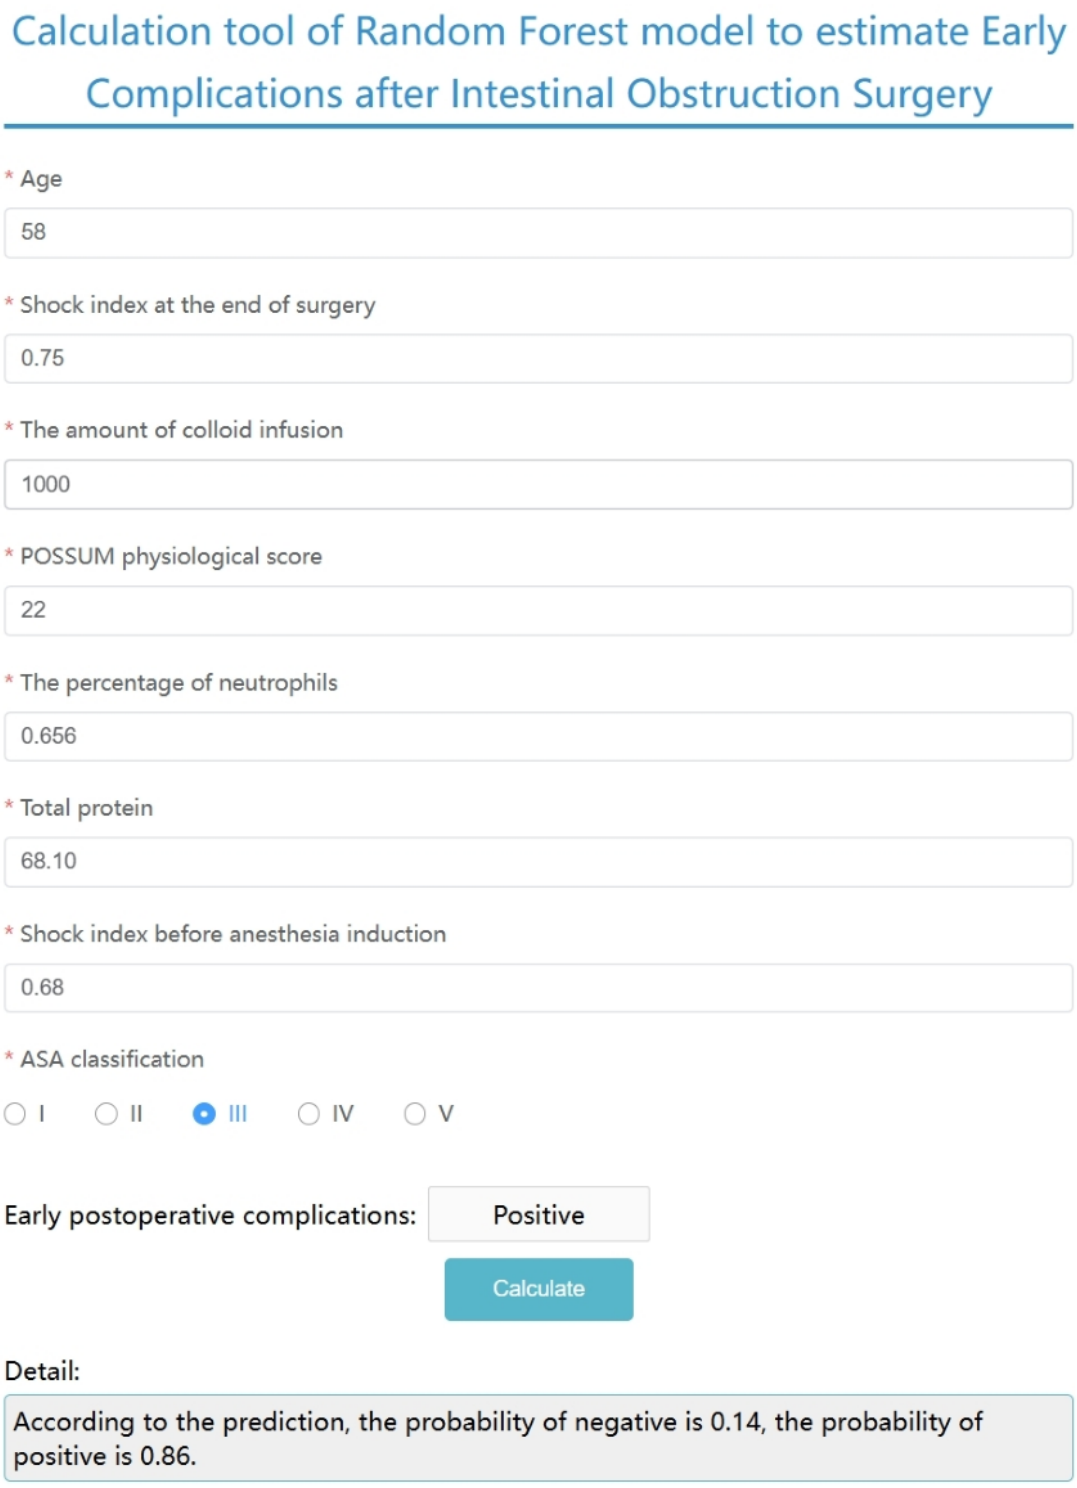
An example of correctly classified cases and an example of incorrectly classified cases were demonstrated as a SHAP decision plot (Figures 5A and 5B) and a force plot (Figures 5C and 5D). These plots increase the interpretability and transparency of the predictions made by RF algorithms. The SHAP decision plots showed how the model makes decisions

XSL•FO
RenderX

based on the availability of each feature in the electronic medical record and provided a decision path for each feature. The force plot mainly shows the major factors that contribute to the final model output of a specific individual.

Figure 5. Use the SHAP decision plots and SHAP force plots to demonstrate the decision pathways and feature importance of the RF model in specific patients.

In Figure 4A, the SHAP summary plot illustrates the overall impact distribution of each feature on the RF model. The features are sorted on the basis of the average absolute value of their SHAP values, with the importance of the features decreasing from the top to the bottom. The color scheme can aid in understanding how changes in feature values affect the results. Red indicates high eigenvalues, while blue signifies low eigenvalues. The greater the distance of a point from the zero reference SHAP value, the more significant its impact on the output. In Figure 4B, the SHAP dependence plot illustrates the SHAP values for the POSSUM Physiology Score across all samples, with each point representing an individual sample. From the graph, it can be preliminarily deduced that the POSSUM Physiology Score is positively correlated with the SHAP value. That is, under stable conditions for other features, an increase in the POSSUM Physiology Score corresponds to a larger SHAP value and a higher final prediction probability. In Figure 4C, the SHAP dependence plot illustrates the SHAP values for the ASA classification across all samples. The ASA classification demonstrates a positive correlation with the SHAP value. Specifically, under stable conditions for other features, an increase in the ASA classification corresponds to a larger SHAP value and, accordingly, a higher final prediction probability.



In Figure 5A, the SHAP decision plot of a correctly classified case. At the bottom of the SHAP decision plot lies the baseline value. From the bottom to the top, the contribution of each feature is visualized, with the connecting line denoting the predictive process from the baseline to the ultimate outcome. In Figure 5B, SHAP decision plot of an incorrectly classified case. In Figure 5C, the SHAP force plot of a correctly classified case. The SHAP value denotes the predictive associated features of an individual patient and the respective contributions of each feature to outcome prediction. The prominent numbers represent the probability-predicted values, while the underlying values are the predicted outcomes that have not been incorporated into the model. The red element (on the left) signifies the factor that augments risk, whereas the blue element (on the right) indicates the factor that mitigates risk. The length of the arrow reflects the extent of influence on the prediction, i.e., the longer the arrow, the more pronounced the effect. In Figure 5D, a SHAP force plot of an incorrectly classified case is given.

Model Visualization

We visualized the RF model and created a web-based online risk calculator [17]. The Python code of this online risk calculator is mentioned in Multimedia Appendix 2. By inputting the variables required for the RF model, the incidence of early postoperative complications for a certain patient can be predicted. As shown in Figure 6, after inputting the patient's age of 58 years, SI of 0.75 at the end of surgery, intraoperative colloid infusion volume of 1000 mL, POSSUM physiological score of 22, neutrophil percentage of 0.656, preoperative total protein of 68.10 g/L, SI of 0.68 before anesthesia induction, and ASA classification III, the probability of early postoperative complications for this patient was found to be 86%.

XSL•FO
RenderX

Figure 6. Calculation tool of random forest model to estimate early complications after intestinal obstruction surgery. After inputting 8 variables into the random forest model, the prediction model output for the case was “positive” with a probability of 86%.

Discussion

Principal Findings

Precisely forecasting the occurrence of postoperative complications in intestinal obstruction is of great significance for enhancing perioperative decision-making. The purpose of this study is to assess the risk of complications after intestinal obstruction surgery and provide an in-depth interpretation of the model’s decisions and their impact on variables using ML algorithms. Finally, we transformed the optimal model into a web-based risk calculator to assist clinicians in identifying high-risk patients. To the best of our knowledge, this is the first study to predict postoperative complications of intestinal obstruction surgery based on the ML algorithm. The findings show that compared with other testing algorithms, RF outperforms the strongest performance, with AUROC,

XSL•FO
RenderX

specificity, sensitivity, and accuracy of 0.788, 0.810, 0.695, and 0.756, respectively. Compared with the AGESS-SBO score, the RF model achieved a better AUROC of 0.912 in predicting postoperative complications of patients with SBO. This attributed to, on the one hand, our study cohort comprised solely of patients undergoing surgical intervention; on the other hand, the ML model incorporated some intraoperative variables, making it more suitable for patients undergoing surgical treatment.

Intestinal obstruction is frequently accompanied by symptoms such as fever, disruption of the internal environment, infection, poisoning, and shock [18], which can further exacerbate the condition in the context of surgery and anesthesia. Consequently, these patients often experience various complications postoperatively. However, there is a scarcity of reliable statistical data available to demonstrate the severity and harmfulness of these complications. Therefore, we first performed a comprehensive statistical analysis and classification. First, nearly half of the patients with intestinal obstruction had early postoperative complications, causing increased hospitalization costs, prolonged hospital stays, a huge medical burden, reduced functional abilities, and even death. The most common complication was an infection because in this kind of patient, it is easy to lose the barrier effect of the intestinal mucosa and wall on bacteria, leading to bacterial translocation [19]. Second, we used the Clavien-Dindo classification to demonstrate the distribution of different degrees of complications. To improve postoperative quality of life, the emergence of disease prediction models may provide a solution for the prevention of early postoperative complications.

In the real world, clinically generated data depend on hospitals and are diversely distributed. Therefore, it is difficult to develop a robust prediction model suitable for multiple institutions or even regions. However, this study showed that with a large amount of data available, a more robust model can be developed with only a few variables. Therefore, we selected many perioperative features to find new associations in the complex relationship between a large data volume and outcome. However, the substantial number of variables within a small cohort with limited events escalates the risk of errors, including overfitting, bias or variance, and data imbalance. To minimize these errors, we have adopted the following methods: (1) performed LASSO regression analysis for variable selection to decrease the number of variables processed by the model, thereby reducing feature dimensions and mitigating the risk of overfitting; (2) preprocessed the data, including filling in missing values and standardization, to ensure effective learning by the model; (3) used cross-validation techniques to assess model performance, which aids in detecting bias or variance issues and provides insights for model improvement; (4) used data from various regions and hospitals across different time periods for external validation to confirm its applicability across different cohorts and test for overfitting; (5) used ensemble learning techniques (RF) to reduce the risk of overfitting; (6) decreased the number of samples with majority negative outcomes to amplify the signal of minority positive outcomes, thereby balancing outcome distribution and enhancing model performance; and (7) selected multiple appropriate evaluation indicators to comprehensively evaluate its performance, such as AUROC, sensitivity, accuracy, F_1-score value, and so on.

Understanding how the RF model prioritizes specific features for prediction is essential to build trust among clinicians and integrate this tool into routine practice. RF is an ensemble learning method that combines multiple decision trees to improve the accuracy and robustness of predictions. Each tree in the forest is built from a random sample of the data with replacement, known as bootstrap sampling. At each node of the tree, only a random subset of features is considered for splitting, which helps prevent overfitting and increases diversity among the trees. The final prediction is made by aggregating the results of all trees. Moreover, RF provides a measure of feature importance by evaluating how much each feature contributes to decreasing impurity across all trees. Features causing significant decreases in impurity are considered more important.

The optimization of some potential intervenable variables is highly important in preventing early postoperative complications, such as SI. SI has more advantages than other vital signs in evaluating systemic perfusion, the timing of vasopressin selection, and prognosis [20,21]. Several studies [22,23] found that the incidence of hypotension in patients with a high SI increased after airway establishment. A larger amount of colloid infusion was associated with a higher incidence of early postoperative complications. On the one hand, patients with intestinal obstruction have a high probability of sepsis. Studies have confirmed that colloidal solution is not beneficial to sepsis and even increases the risk of acute renal injury [24]. On the other hand, severely insufficient blood volume during surgery often requires the infusion of more colloids. Several studies have also shown that ASA classification [3,25], age [26], and POSSUM physiological score [6,27] are independent risk factors for early postoperative complications. They have been widely applied to evaluate surgical tolerance and risk stratification. These findings are also supported by the results of this study. The percentage of neutrophils and total protein were found in a previous study to predict the occurrence of intestinal obstruction [28]. Our results indicate that they are sensitive biomarkers for predicting early postoperative complications of intestinal obstruction. Hematological parameters and markers have been widely used to predict the risk of postoperative complications [29,30].

The complex and diverse perioperative pathophysiology of patients with intestinal obstruction poses significant challenges for clinicians. Our constructed online risk calculator based on the RF model aims to facilitate timely decision-making and intervention in disease progression. However, the AUROC of the ML model seldom surpasses 0.8. This might be attributed to the fact that postoperative complications represent a mixed and complex diagnosis, with different complications potentially having specific predictive factors. Consequently, achieving higher performance indicators may be infeasible. Nonetheless, external validation results indicating a higher AUROC demonstrate the model's generalization capability. The inclusion of higher-dimensional information, such as image or video data, in the prediction of complications may potentially enhance the predictive abilities of the model.

XSL•FO
RenderX

In clinical practice, the acceptability and applicability of a scoring system or model are determined not only by its accuracy but also by its simplicity and universality. The online risk calculator, constructed using ML algorithms, possesses these characteristics. First, this online risk calculator incorporates only 8 features, which do not augment the workload or memory burden for clinicians. Second, the calculator's result requirements can be fulfilled during the routine clinical diagnosis and treatment process, obviating the need for additional tests or examinations and thereby avoiding any additional burden on patients. Finally, our findings indicate that the online risk calculator based on the RF model exhibits generalizability and demonstrates strong predictive capabilities across diverse regions, hospitals, and time periods. Facilitating clinicians' decision-making processes and enhancing patient prognoses at nearly zero cost is an essential value of a scoring system. This online risk calculator can help anesthesiologists predict patients' prognoses through partial preoperative and intraoperative information and increase clinical vigilance to make early interventions.

There are still several limitations of our study. First, it is a small sample study, and the predictive model requires a larger sample for further development and verification. Second, the current study is a retrospective study, in which there may be some confounding factors. In addition, the demographic diversity and clinical settings of the development set and validation set were not compared in this study. Future research needs to further compare more characteristics of the development and validation sets to clarify the "Reproducibility" or "Transportability" of the model. Furthermore, the model cannot be used for risk prediction of specific complications. In the future, we will construct a series of submodels for predicting the risk of specific postoperative complications in patients with intestinal obstruction. Finally, our research focused on early complications that may prolong the length of hospitalization and rehabilitation of patients after hospitalization, so there was no survival analysis. We will further explore them in the future.

Conclusions

We constructed an online risk calculator based on the RF model, which includes 8 variables, to assist clinicians in identifying high-risk patients after intestinal obstruction surgery.

Acknowledgments

We would like to thank the research participants, engineers, and other participating centers for their unreserved help. Finally, we thank those who support us directly or indirectly. Abstract

Background: Gastrointestinal bleeding is a serious adverse event of coronary artery bypass grafting and lacks tailored risk assessment tools for personalized prevention.

Objective: This study aims to develop and validate predictive models to assess the risk of gastrointestinal bleeding after coronary artery bypass grafting (GIBCG) and to guide personalized prevention.

Methods: Participants were recruited from 4 medical centers, including a prospective cohort and the Medical Information Mart for Intensive Care IV (MIMIC-IV) database. From an initial cohort of 18,938 patients, 16,440 were included in the final analysis after applying the exclusion criteria. Thirty combinations of machine learning algorithms were compared, and the optimal model was selected based on integrated performance metrics, including the area under the receiver operating characteristic curve (AUROC) and the Brier score. This model was then developed into a web-based risk prediction calculator. The Shapley Additive Explanations method was used to provide both global and local explanations for the predictions.

Results: The model was developed using data from 3 centers and a prospective cohort (n=13,399) and validated on the Drum Tower cohort (n=2745) and the MIMIC cohort (n=296). The optimal model, based on 15 easily accessible admission features, demonstrated an AUROC of 0.8482 (95% CI 0.8328-0.8618) in the derivation cohort. In external validation, the AUROC was

XSL•FO
RenderX

0.8513 (95% CI 0.8221-0.8782) for the Drum Tower cohort and 0.7811 (95% CI 0.7275-0.8343) for the MIMIC cohort. The analysis indicated that high-risk patients identified by the model had a significantly increased mortality risk (odds ratio 2.98, 95% CI 1.784-4.978; *P*<.001). For these high-risk populations, preoperative use of proton pump inhibitors was an independent protective factor against the occurrence of GIBCG. By contrast, dual antiplatelet therapy and oral anticoagulants were identified as independent risk factors. However, in low-risk populations, the use of proton pump inhibitors (χ^2_1=0.13, *P*=.72), dual antiplatelet therapy (χ^2_1=0.38, *P*=.54), and oral anticoagulants (χ^2_1=0.15, *P*=.69) were not significantly associated with the occurrence of GIBCG.

Conclusions: Our machine learning model accurately identified patients at high risk of GIBCG, who had a poor prognosis. This approach can aid in early risk stratification and personalized prevention.

machine learning; personalized medicine; coronary artery bypass grafting; adverse outcome; gastrointestinal bleeding

Introduction

Approximately 1.5 million people worldwide undergo cardiac surgery each year, with coronary artery bypass grafting (CABG) being the most common procedure [1,2]. The incidence of gastrointestinal bleeding (GIB) after CABG (GIBCG) ranges from approximately 0.39% to 5.5% [3-8], increasing between 5% and >10% in patients treated with dual antiplatelet agents [9]. In the study by Yang et al [10], the observed incidence rate reached 22.4%. However, once GIBCG occurs, the mortality rate rises significantly, ranging from 8.8% to 38.0% [3-8], which is notably higher than that of surgical patients without GIB.

GIBCG has delayed and insidious characteristics that make early recognition difficult [4-6]. These patients often experience adverse events such as respiratory or renal failure and cardiac insufficiency, which can mask its clinical signs. Postoperative sedation may also obscure typical abdominal symptoms [6]. Following a GIBCG episode, continued administration of antiplatelet agents can exacerbate bleeding, whereas discontinuing antiplatelet therapy is associated with a higher risk of cardiovascular events and increased mortality rates [11]. Therefore, preventing and diagnosing GIBCG early are essential in clinical practice.

The PRECISE-DAPT (Predicting bleeding complications in patients undergoing stent implantation and subsequent dual antiplatelet therapy) score is one of the most commonly used clinical tools for predicting bleeding risk in patients with acute coronary syndrome. It assesses the risk of bleeding within 12 months following percutaneous coronary intervention [12]. Unlike percutaneous coronary intervention, CABG may cause GIB through different mechanisms, such as the effects of extracorporeal circulation and stress [5,13]. However, the applicability of these scores in patients undergoing CABG remains unclear.

Machine learning (ML), a subset of artificial intelligence, effectively identifies nonlinear relationships, deciphers intricate interactions, and manages multicollinearity among predictor variables [14-16]. ML has been widely applied in medicine, leveraging large volumes of patient data to build risk models. These models can predict disease onset, assess condition severity, and evaluate disease prognosis [17-19]. ML outperforms traditional scores in predicting GIB risk after antithrombotic therapy [20]. However, GIB risk prediction after cardiac surgery remains understudied. To date, only 1 study—a single-center, small-sample, traditional risk prediction model using intraoperative and postoperative clinical features—has reported on GIBCG risk prediction, but it does not allow for preoperative risk assessment [10]. In this study, we aimed to develop and evaluate ML-driven risk prediction models using preoperative clinical features to identify individuals at a high risk of GIBCG, thereby enabling proactive preventive measures.

Methods

Ethical Considerations

The Medical Ethics Committee of Beijing Anzhen Hospital, affiliated with Capital Medical University, approved the study protocol (approval number KS2023020). This study is retrospectively registered in the Chinese Clinical Trial Registry (ChiCTR2400086050), which includes GIB as the primary outcome along with other gastrointestinal complications. GIB was the main focus of this study due to its high morbidity and lethality. Informed consent was obtained from all participants. DJ obtained access to and download permission for the Medical Information Mart for Intensive Care IV (MIMIC-IV) database (ID: 59888302). All data have undergone deidentification processing to ensure anonymity.

Patients and Study Design

The study included patients from 4 hospitals in China, with the inclusion criteria being CABG during hospitalization, age over 18 years, and availability of complete key information. Data were also obtained from the American Critical Care database, the MIMIC-IV, which met the same inclusion criteria [21]. Patients hospitalized at Beijing Anzhen Hospital between January 2018 and May 2023, Beijing Luhe Hospital between July 2019 and May 2023, and Beijing Chaoyang Hospital between May 2022 and April 2024 were included in the derivation cohort. Additionally, 3466 patients prospectively recruited at Beijing Anzhen Hospital between May 2023 and April 2024 were included as a prospective cohort within the same derivation cohort. Patients hospitalized at Nanjing Drum Tower Hospital between October 2010 and May 2023, along with data from MIMIC-IV, were included in the external

XSL•FO
RenderX

validation cohort. The exclusion criteria were as follows: patients diagnosed preoperatively with GIB and those whose bleeding cause could not be identified due to comorbidities such as severe liver disease or gastrointestinal malignancy. Figure S1 in Multimedia Appendix 1 details the patient selection process for the derivation and external validation cohorts.

Sample Size Calculation

When developing prediction models, a common practice for determining the required sample size is to ensure at least 10 events per candidate predictor parameter. Additionally, we followed the 4-step procedure proposed by Riley et al [22] to calculate the required sample size. The calculation process, formulas, and results are presented in Table S1 in Multimedia Appendix 1.

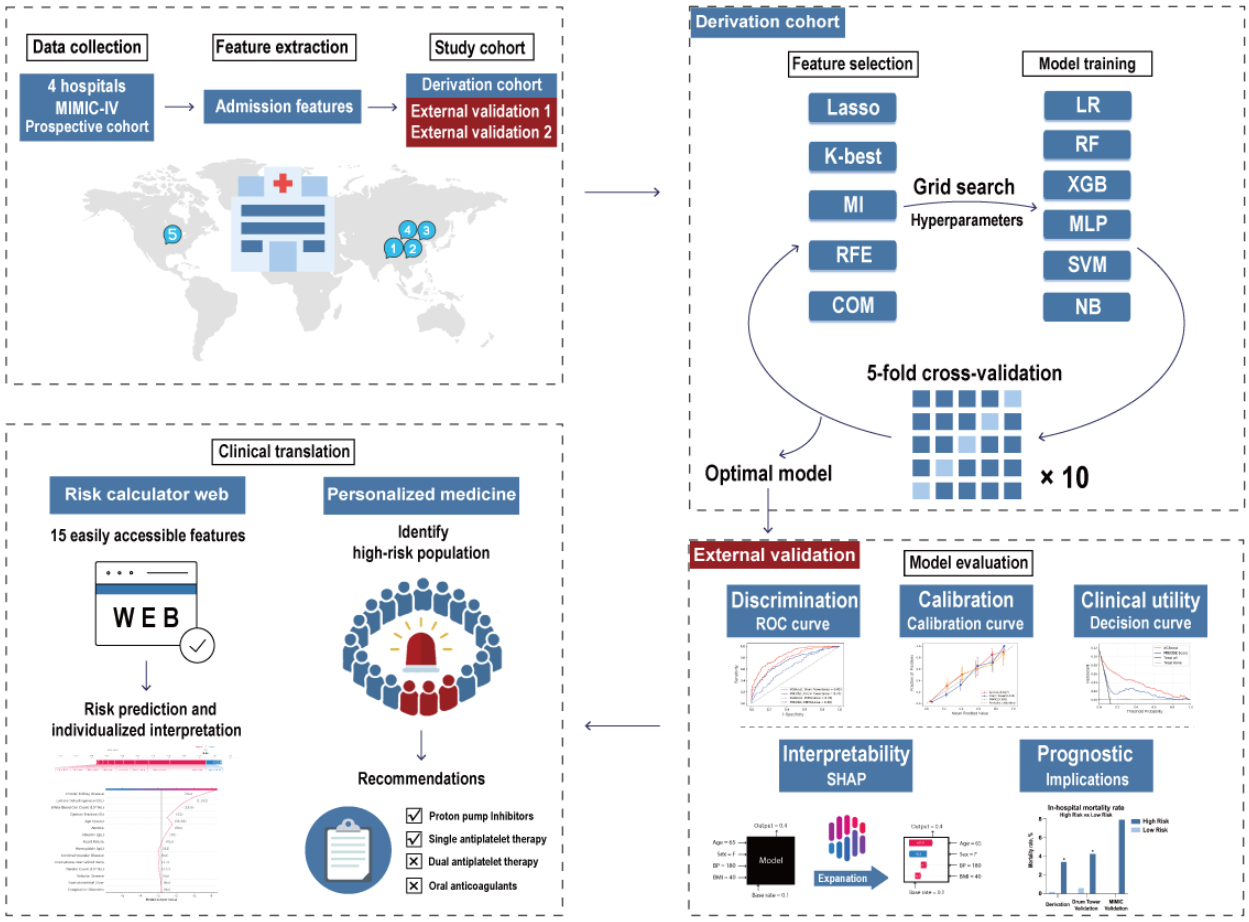
Definition of Outcome

The primary outcome was the occurrence of GIB after CABG, defined as (1) hematemesis (including bright red blood or coffee-ground emesis), melena, hematochezia, or positive occult blood tests in either gastric fluid or stool; and (2) bleeding foci identified during endoscopic examination [23-25]. The secondary outcome was the in-hospital mortality rate.

Predictive Features

Admission variables were used as predictive features. Table S2 in Multimedia Appendix 1 provides the definitions of each feature. Data extraction for patients undergoing CABG and the diagnosis of comorbidities were based on International Classification of Diseases 9th/10th Revision (ICD-9/10) disease codes (Table S3 in Multimedia Appendix 1).

Statistical Analysis



Data analysis was performed using SPSS Statistical Software version 26.0(IBM Corp.). Normally distributed continuous variables are presented as means with SDs, while skewed continuous variables are presented as medians with IQRs. For statistical analysis, the independent samples *t* test was used to compare normally distributed continuous variables, and the Mann-Whitney *U* test was used for skewed distributions. Categorical variables are presented as numbers with percentages and were compared using the chi-square or Fisher exact test. Significant variables from the univariate analysis were selected for multivariate unconditional logistic regression. Differences were considered statistically significant at $P<.05$. Missing values were imputed using multiple imputation methods in R version 4.1.0 9 (R Foundation). Subsequent feature screening and model construction were performed using Python version 3.7.0 (Python Foundation). Table S4 in Multimedia Appendix 1 presents the data types and missing values for each feature.

Feature Selection

Figure 1 presents the complete study flowchart. We employed 4 distinct feature selection methods to identify candidate features for model development: least absolute shrinkage and selection operator (LASSO), k-best feature selection (K-Best), random forest recursive feature elimination (RFE), and the mutual information algorithm [26]. A fifth method was a combined approach that selected features appearing in at least three of the four feature selection methods.

XSL•FO
RenderX

Figure 1. Flowchart of the study. The study process is summarized as follows: data were collected from multiple centers, patient admission features were extracted, and the study cohort was defined. A derivation cohort was formed from 3 centers and a prospective cohort, which were used for feature screening and model construction. The optimal model was selected using multiple evaluation metrics and externally validated with the Drum Tower and MIMIC cohorts. Finally, the model was developed into a user-friendly web page to facilitate clinical use and guide treatment decisions. Abbreviations: COM: combined method, including features appearing more than three times in the first four feature selection methods; K-Best: k-best feature selection; LASSO: least absolute shrinkage and selection operator; LR: logistic regression; MI: mutual information; MIMIC IV: medical information mart for intensive care IV; MLP: multilayer perceptron; NB: naive Bayes; RF: random forest; RFE: recursive feature elimination; ROC curve: receiver operating characteristic curve; SHAP: Shapley additive explanations; SVM: support vector machine; XGB: XGBoost (extreme gradient boosting).

Model Development and Validation

Based on feature engineering, we applied 6 supervised ML algorithms: multilayer perceptron, naive Bayes, random forest, Extreme Gradient Boosting (XGBoost; also called XGB), logistic regression, and support vector machines. By combining 5 feature selection methods with these 6 classifiers, we built 30 models (5 × 6 = 30) and optimized hyperparameters for each model using a 5-fold grid search cross-validation on the derivation cohort. Grid search systematically explores all possible combinations of hyperparameters, while 5-fold cross-validation evaluates each combination's performance across different validation subsets. The optimal hyperparameter combination for each model was selected based on the highest performance across cross-validation folds. The hyperparameter settings, ranges, and rationale for each algorithm are detailed in Table S5 in Multimedia Appendix 1. The final model selection was based on a comprehensive evaluation of multiple performance metrics, including the average and SD of both the area under the receiver operating characteristic curve (AUROC) and the Brier score [27]. AUROC measures the model's ability to distinguish between different classes, which is particularly important in imbalanced data sets. A higher AUROC value indicates better class discrimination. The Brier score, by contrast, assesses both the accuracy and calibration of predicted probabilities by quantifying the difference between predicted probabilities and actual outcomes. Using these metrics provides a well-rounded evaluation of model performance in terms of both discriminative power and predictive accuracy. The average and SD of AUROC and Brier score were calculated based on all validation results from 5-fold, 10-time cross-validation. The ideal model performance is characterized by an average AUROC close to 1, a Brier score close to 0, and low SDs for both metrics. To quantify overall model performance, we first normalized the average AUROC. Next, we normalized the average Brier score and the SDs of both AUROC and Brier score by subtracting them from 1. The comprehensive model score was then obtained by averaging these 4 values. Based on this score, we selected the optimal combination of the feature selection method and ML model for further evaluation in external validation.

Model Evaluation

In the external validation cohort, we further assessed the performance of the final prediction models using AUROC,

XSL•FO
RenderX

calibration plots, and decision curve analysis (DCA). Model discrimination was evaluated using AUROC, and we compared the discriminative performance of the optimal ML model with PRECISE-DAPT scores. Calibration was demonstrated through calibration plots and quantified using the Brier score, while clinical utility was assessed using DCA [28]. We categorized bleeding severity, defining severe GIB as the presence of marked symptoms such as hematemesis, melena, or hematochezia, or the identification of bleeding foci during endoscopic examination. Patients with positive occult blood tests in gastric fluid or stool were classified as having mild bleeding. Additionally, we assessed the model's ability to predict severe bleeding within each study cohort.

Model Interpretations

ML modeling often operates in a "black box" environment, where the complexity and multidimensionality of algorithms make it difficult to clearly elucidate the internal mechanisms driving accurate predictions for specific patient groups. To enhance model interpretability, we used the Shapley Additive Explanations (SHAP) algorithm [29,30]. SHAP is a game theory-based model explanation method that provides consistent and locally precise attribution values—known as SHAP values—for each feature in the model. This approach highlights the significance of individual features and explains the model's decision-making process. Higher SHAP values indicate a greater likelihood of GIBCG.

Clinical Application

We determined the model's optimal cutoff values by identifying the maximum Youden index (sensitivity + specificity – 1) in the derivation cohort. Using these cutoff values, patients were classified into high- and low-risk groups. Subgroup analyses were conducted based on preoperative medication use across different risk groups. Finally, we developed a web-based interface integrating the optimal ML model, which utilizes questionnaire-guided responses for risk assessment.

Results

Patient Characteristics

The calculated sample size was 5667. However, to meet the requirements of ML training, we used a data set that far exceeded this minimum to ensure optimal model performance. In total, we included 16,440 patients, with 13,399 in the derivation cohort and 3041 in the external validation cohort. Baseline characteristics for these groups are presented in Table 1. In the derivation cohort (N=13,399), 803 patients (5.99%) developed GIBCG. The external validation cohort comprised data from Nanjing Drum Tower Hospital and MIMIC, incorporating both Chinese and American centers. The Drum Tower data set (n=2745) was designated as external validation cohort 1, in which 179 patients (6.52%) developed GIBCG. The MIMIC data set (n=296) was designated as external validation cohort 2, with 176 patients (59.5%) developing GIBCG. Baseline characteristics stratified by GIBCG occurrence are compared in Tables S6-S8 in Multimedia Appendix 1.

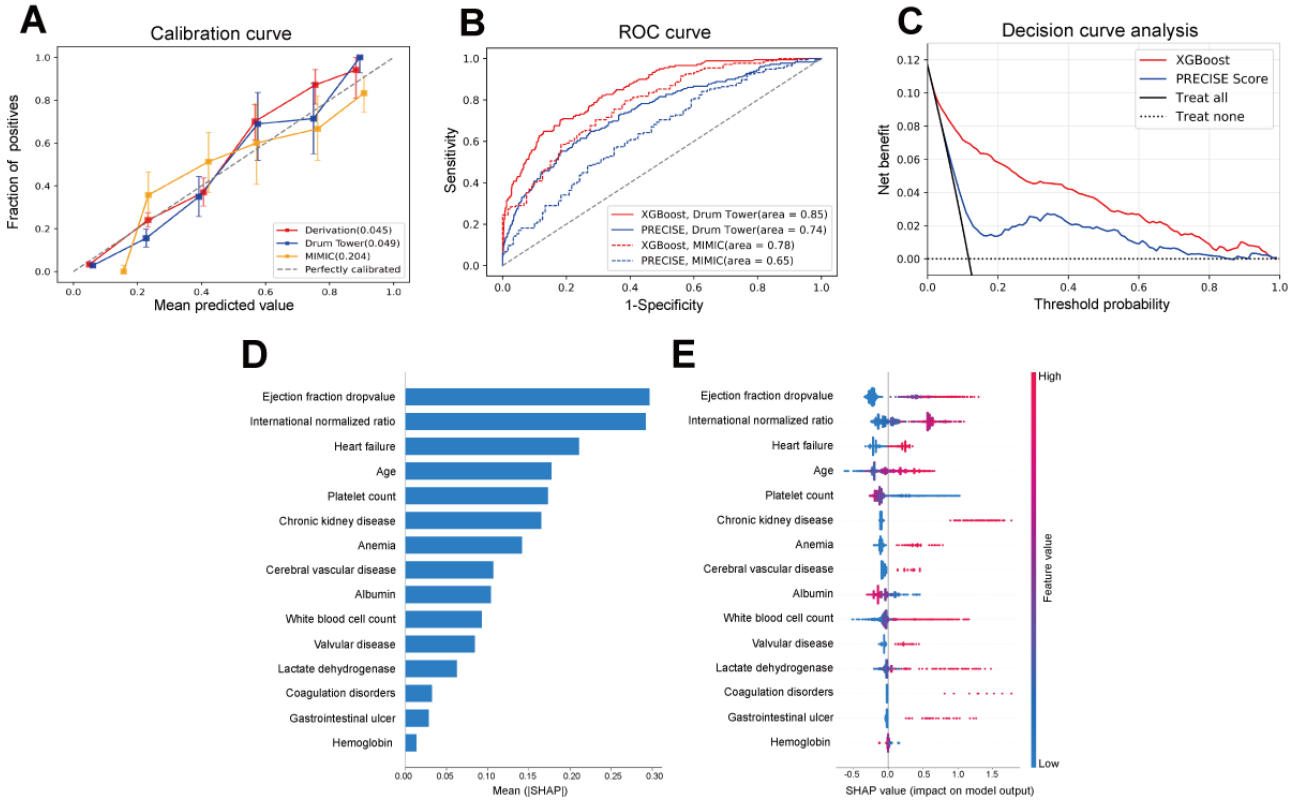
Predictive Features

Five feature selection methods—LASSO, K-Best, RFE, mutual information algorithm, and a combined approach—were used to optimize the feature set (Table S9 in Multimedia Appendix 1). The features identified through these methods were incorporated as predictors of GIBCG and subsequently used in the ML model for further evaluation.

Model Performance

Using grid search and cross-validation, we identified the optimal hyperparameters for each model configuration (Table S10 in Multimedia Appendix 1). Table S11 presents the average AUROC and its 95% CI for each model in the training set, constructed from 4 folds of the 5-fold cross-validation in the derivation cohort. Table S12 displays the AUROC for the internal validation set, which consists of the remaining fold. Similarly, Tables S13 and S14 report the mean Brier score and its 95% CI for the training and internal validation sets, respectively. We constructed 6 models for each of the 5 feature selection methods, yielding 30 (5×6) models. Figure 2A presents a heatmap of comprehensive scores, ranging from 0.1789 to 0.9938. Vertically, models developed using the LASSO method achieved an average score of 0.8709, outperforming those built with other feature selection techniques. Horizontally, XGBoost demonstrated superior performance across feature selection methods, with an average score of 0.9128. Notably, the LASSO-XGBoost combination attained the highest score of 0.9938, making it the top-performing model. Figure 2B illustrates the AUROC of models following LASSO feature selection, with XGBoost achieving the highest AUROC of 0.8482 (95% CI 0.8328-0.8618, bootstrap), outperforming all other models.

Figure 2. Performance of machine learning models. (A) Heatmaps illustrating the predictive performance (model score) of different combinations of feature selection methods (rows) and classification algorithms (columns). (B) Receiver operating characteristic curves of various models following LASSO feature selection. Abbreviations: COM: combined method; K-Best: k-best feature selection; LASSO: least absolute shrinkage and selection operator; LR: logistic regression; MI: mutual information; MLP: multilayer perceptron; NB: naive Bayes; PRECISE: "predicting bleeding complications in patients undergoing stent implantation and subsequent dual antiplatelet therapy" score; RF: random forest; RFE: recursive feature elimination; SVM: support vector machine; XGB: XGBoost (extreme gradient boosting).



Model Evaluation

The final prediction model was evaluated using 2 independent external cohorts from China and the United States. Figure 3A presents calibration plots for the XGBoost model across the derivation cohort and both external validation cohorts. Given the higher positive rate in the MIMIC cohort, we applied Platt scaling to calibrate predicted probabilities for this data set. In

XSL•FO
RenderX

the derivation cohort, the XGBoost model achieved a Brier score of 0.0446 (95% CI 0.0419-0.0474). The Brier score was 0.0489 (95% CI 0.0431-0.0549) in the Drum Tower validation cohort and 0.2044 (95% CI 0.1787-0.2322) in the MIMIC validation cohort. These results indicate that our model demonstrates the highest calibration in the 2 Chinese cohorts while maintaining satisfactory calibration in the American cohort. Figure 3B compares the AUROC of the XGBoost model and the PRECISE-DAPT score within the Drum Tower validation cohort. The AUROC for XGBoost was 0.8513 (95% CI 0.8221-0.8782), exceeding that of the PRECISE-DAPT score (0.7427, 95% CI 0.7028-0.7836). Similarly, in the MIMIC validation cohort (dashed curves in Figure 3B), XGBoost achieved an AUROC of 0.7811 (95% CI 0.7275-0.8343), outperforming the PRECISE-DAPT score (0.6460, 95% CI 0.5863-0.7123). Figure 3C presents a DCA integrating both external validation cohorts, showing that the net benefit of XGBoost surpasses that of the PRECISE-DAPT score.

Figure 3. Evaluation of the optimal model and its interpretability. (A) Calibration plots of XGBoost (Extreme Gradient Boosting) in the derivation cohort and 2 independent external validation cohorts. The Brier score is reported in the lower-right legend (a smaller value indicates better calibration). (B) Comparison of the area under the receiver operating characteristic curve (AUROC) for XGBoost and the PRECISE-DAPT (predicting bleeding complications in patients undergoing stent implantation and subsequent dual antiplatelet therapy) score in the Drum Tower and MIMIC (Medical Information Mart for Intensive Care) validation cohorts. (C) Comparison of clinical decision curves for XGBoost and the PRECISE-DAPT score in the combined external validation cohort. (D) Bar chart of the mean absolute Shapley Additive Explanations (SHAP) value for each predictor.(E) SHAP summary plot. The SHAP value along the x axis serves as a standardized measure of feature influence within the model. Each row of critical features illustrates the contributions of all patients to the outcome, with dots in different colors: red representing high-risk values and blue representing low-risk values.

The proportion of patients with severe bleeding among those with GIBCG is presented for each study cohort (Figure S2 in Multimedia Appendix 1). The model demonstrated excellent discriminative ability for severe GIB, with AUROCs of 0.8912 (95% CI 0.8626-0.9196) in the derivation cohort, 0.8817 (95% CI 0.8249-0.9296) in the Drum Tower validation cohort, and 0.8388 (95% CI 0.7749-0.8931) in the MIMIC validation cohort (Figure S3 in Multimedia Appendix 1).

The MIMIC cohort consists of critically ill patients; therefore, we assessed disease severity using intensive care unit stay duration, Sequential Organ Failure Assessment (SOFA) score on the first day, and the Charlson Comorbidity Index for further subgroup analysis (Figure S4 in Multimedia Appendix 1). In the figure, the red line represents the intensive care unit stay duration cutoff, with the model's AUROC calculated for patients below this threshold. The blue and green lines indicate the SOFA score and the Charlson Comorbidity Index, respectively. Line charts illustrate AUROC changes across different cutoff values for these 3 indicators. The results show that as disease severity increases (ie, with higher cutoff values), the AUROC gradually decreases, suggesting that the model performs better in predicting less severe cases than more severe ones.

Model Interpretability Using SHAP Values

Figure 3D presents a bar chart displaying the average absolute SHAP values for each predictive feature, with higher SHAP values indicating greater feature influence. Figure 3E provides a SHAP summary plot illustrating how each predictive feature impacts the XGBoost model's predictions. A decrease in ejection fraction, international normalized ratio (INR), platelet count, albumin, and hemoglobin levels, and the presence of heart

XSL•FO
RenderX

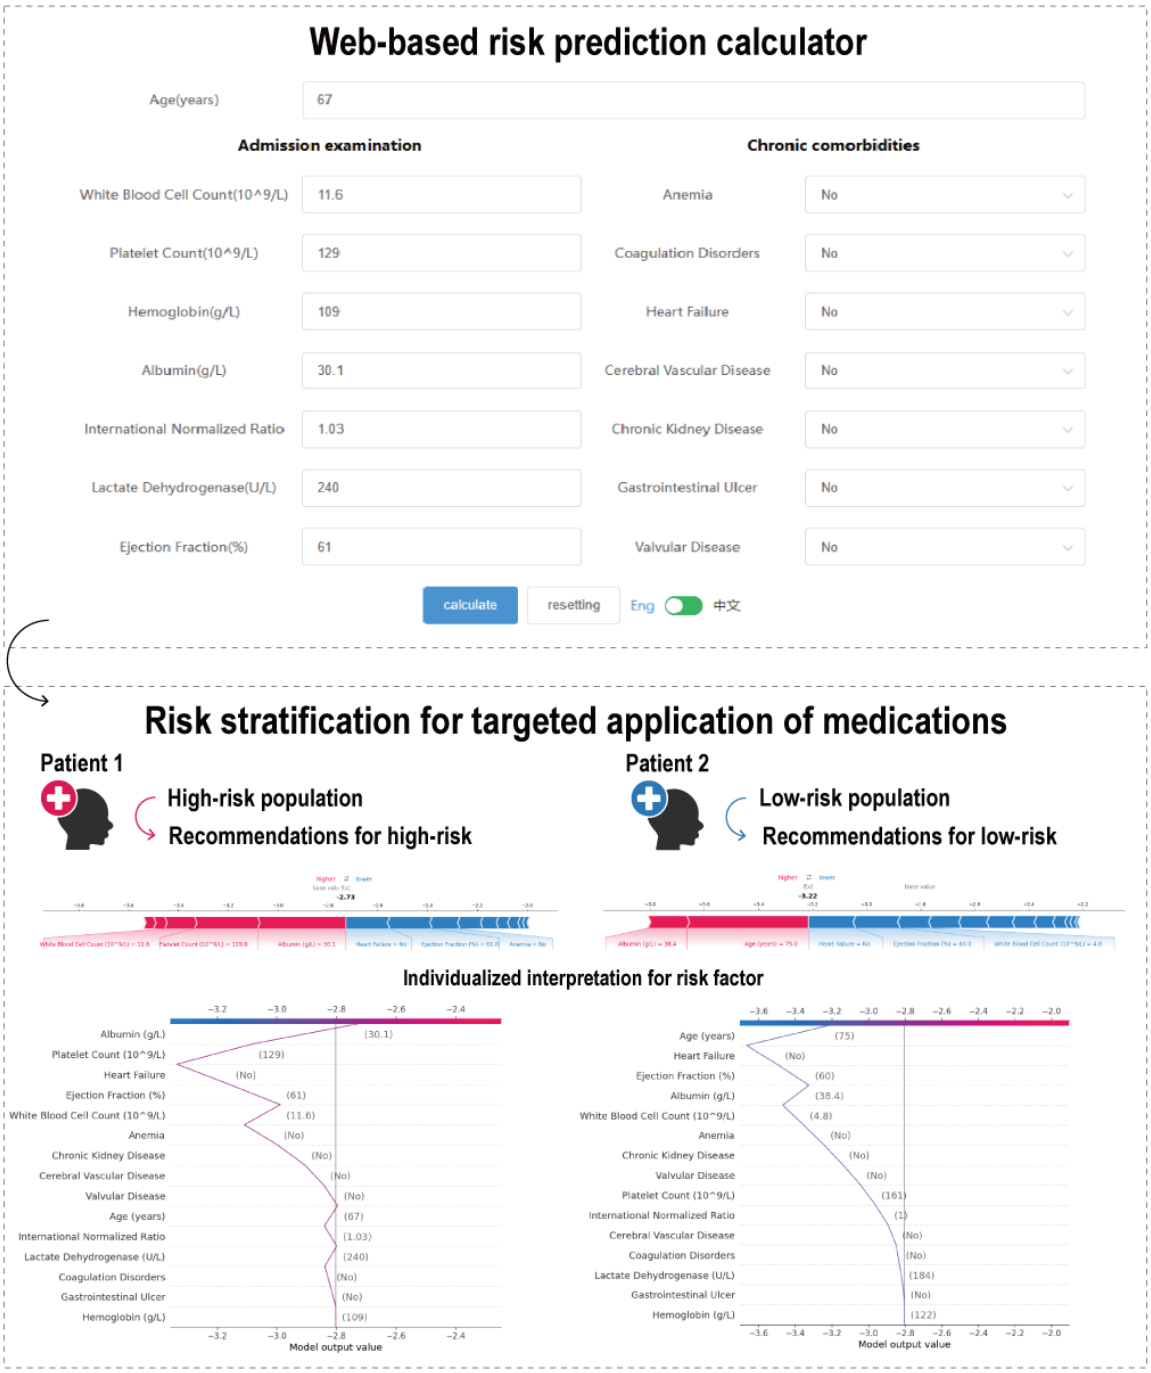
failure, advanced age, chronic kidney disease, anemia, cerebrovascular disease, valvular disease, elevated white blood cell count, increased lactate dehydrogenase levels, coagulation disorders, and gastrointestinal ulcer were associated with a higher predicted probability of GIBCG.

Prognostic Implications

We evaluated the prognostic implications across all 16,440 hospitalized patients from the derivation and external validation cohorts. In the derivation cohort, an optimal cutoff value of 0.0592 was identified based on the maximum Youden index to differentiate between high- and low-risk populations, and the same threshold was applied to the external validation cohort. Univariate and multivariate analyses of risk factors for mortality were conducted across all cohorts (Table S15 in Multimedia Appendix 1). The findings indicate that the model-identified risk levels (high risk vs low risk) serve as an independent risk factor for in-hospital mortality (odds ratio [OR] 2.98, 95% CI 1.784-4.978; *P*<.001). The model's risk probability output was also an independent risk factor for in-hospital mortality (OR 1.017, 95% CI 1.004-1.031; *P*=.009). Compared with the low-risk population, the high-risk population exhibited significantly higher mortality rates in the derivation cohort (106/4534, 2.34% versus 17/8865, 0.19%; χ^2_1=151.91, *P*<.001), Drum Tower validation cohort (60/1354, 4.43% versus 9/1391, 0.65%; χ^2_1=40.09, *P*<.001), and MIMIC validation cohort (22/278, 7.91% versus 0/18, 0%; χ^2_1=0.60, *P*=.44; Figure S5 in Multimedia Appendix 1). Although the PRECISE-DAPT score is an independent risk factor for in-hospital mortality (Table S15 in Multimedia Appendix 1), Figure S6 in Multimedia Appendix 1 presents the receiver operating characteristic curves for predicting in-hospital mortality using both our model and the PRECISE-DAPT score. The AUROC for the risk probability predicted by our model was 0.8642 (95% CI 0.8384-0.8860), compared with 0.7591 (95% CI 0.7266-0.7939) for the PRECISE-DAPT score, demonstrating the superior prognostic performance of our model.

Guiding Personalized Medicine

Given the substantial variations in prognosis across different risk populations, we conducted a subgroup analysis comparing preoperative medications between CABG patients with and without GIB to explore potential intervention strategies. In all cohorts, preoperative use of proton pump inhibitors (PPIs; χ^2_1=53.45, *P*<.001), dual antiplatelet therapy (DAPT; χ^2_1=16.53, *P*<.001), and oral anticoagulants (OACs; χ^2_1=29.87, *P*<.001) was significantly associated with the occurrence of GIBCG. However, in the low-risk population, PPIs (χ^2_1=0.13, *P*=.72), DAPT (χ^2_1=0.38, *P*=.54), and OACs (χ^2_1=0.15, *P*=.69) were not significantly associated (Table S16 in Multimedia Appendix 1). In the high-risk population, univariate analysis identified preoperative use of PPIs and single antiplatelet therapy (SAPT) as protective factors against GIBCG, whereas DAPT and OACs were associated with an increased risk. Furthermore, multivariate analysis confirmed that PPIs, DAPT, and OACs were independent correlates of GIBCG occurrence (Table S17 in Multimedia Appendix 1)



These findings were further validated in the Drum Tower and MIMIC validation cohorts (Table S16 in Multimedia Appendix 1), confirming the universality and robustness of our cutoff value. The analysis of GIBCG risk factors in the Drum Tower validation cohort aligned with those in the derivation cohort, particularly regarding preoperative medication (Table S18 in Multimedia Appendix 1). Although the MIMIC validation cohort, derived from the Critical Care Database, differed from the other 2 cohorts, its analysis yielded largely consistent results. Specifically, preoperative use of PPIs (OR 0.517, 95% CI 0.281-0.95; *P*=.03), SAPT (OR 0.56, 95% CI 0.342-0.915; *P*=.02), and DAPT (OR 2.821, 95% CI 1.12-7.106; *P*=.03) was significantly associated with GIBCG occurrence in the high-risk population (Table S19 in Multimedia Appendix 1).

Clinical Application

The XGBoost model was ultimately selected as the algorithm for the web-based calculator available on our website (Figure 4; also see [31]). Users input 15 admission features into the questionnaire interface, and the web page automatically predicts the patient's GIBCG risk level. The results section displays the predicted risk along with its classification. Simultaneously, the calculator generates a force plot to interpret the prediction, highlighting the features influencing the decision. SHAP values provide insights into the contribution of each feature to the predicted risk of GIBCG: blue features on the right drive the prediction toward "non-GIB," while red features on the left indicate a higher likelihood of "GIB." For example, when we entered the admission features of 2 patients from the Drum Tower cohort, the calculator provided their risk predictions along with corresponding interpretation plots (Figure 4). At the time of admission, patient 1 presented with decreased albumin, elevated white blood cell counts, and a low platelet count within the normal range. These 3 factors were identified as the primary contributors to the increased GIBCG risk and warrant special clinical attention. The model classified patient 1 as high risk and recommended a preventive strategy. Preoperative PPIs use may be considered, and for patients on DAPT or OACs, an early transition to SAPT or alternative therapies is advised. By contrast, although patient 2 is older, most of their predictive factors were within normal ranges, leading to a classification as low risk. For patients with indications, antiplatelet therapy can be continued until preoperative cessation to mitigate the risk of adverse cardiovascular events. This personalized medical approach may help reduce GIBCG risk, improve patient prognosis, and enhance the overall quality of health care services.

Figure 4. Web-based calculator of the XGBoost (Extreme Gradient Boosting) model for risk stratification and personalized medicine. The web-based risk calculator predicts risk accurately online and in real time, providing a convenient tool for clinical doctors. It utilizes 15 features, including patient age, comorbidities, and initial examination results upon admission, to predict the risk of gastrointestinal bleeding in cardiac surgery patients. Additionally, it provides individualized interpretations of risk factors, outputs the patient's risk level, facilitates risk stratification, and guides targeted medication use.

Discussion

Principal Findings

In this multicenter study, we developed and validated ML-based prediction models for GIBCG. After evaluating various feature selection methods and ML algorithms, we identified LASSO for feature selection and XGBoost for model development as the optimal combination. The final model, utilizing 15 admission features, demonstrated strong discriminative performance, calibration, and clinical utility across both the derivation and external validation cohorts. The top 5 predictive features for GIBCG were ejection fraction, INR, chronic heart failure, age, and platelet count, in that order. To our knowledge, this study is the first to develop a model that accurately predicts GIBCG using admission features. Furthermore, our model is prognostically relevant, as it identifies high-risk individuals with an increased postoperative mortality rate, underscoring the need for clinical vigilance. By enabling early risk stratification and targeted prevention, our ML model may help mitigate the risk of GIBCG.

In the derivation and Drum Tower validation cohorts, the prevalence of GIBCG was 803 out of 13,399 (5.99%) patients and 179 out of 2745 (6.52%) patients, respectively, slightly higher than previous epidemiological estimates. This

XSL•FO
RenderX

discrepancy may stem from our inclusion of patients with positive occult blood tests as positive cases. While these patients have no overt bleeding, early identification and preventive measures may help avert the progression to significant bleeding. Including occult blood positivity in the outcome definition enhances the model's sensitivity, enabling earlier risk detection and management. Furthermore, subgroup analysis demonstrated that the model performed better in identifying patients with more severe bleeding, reinforcing its utility for early screening of high-risk patients.

The model developed in the derivation cohort was validated in a large, independent external validation cohort (Drum Tower), consistently demonstrating excellent performance. In intensive care, stress-related GIB remains a significant concern [32,33]. To further assess the model's generalization capability across different populations, we tested it on the MIMIC cohort. This introduced potential biases in the following aspects: (1) the incidence of GIBCG in the MIMIC cohort was higher than in the other 2 cohorts, likely due to the greater severity of illness among these patients and the absence of fecal occult blood test results in some cases, which may have led to selection bias; (2) the AUROC for predicting GIBCG in the MIMIC cohort was lower than in the other cohorts. This discrepancy is primarily due to the higher proportion of critically ill patients in the MIMIC cohort. Analysis reveals that the model performs better for the mild subgroup than for the severe cases (Figure S4 in Multimedia Appendix 1). Furthermore, we conducted a subgroup analysis focusing on severe GIB (Figure S3 in Multimedia Appendix 1). When the outcome was defined as severe GIB, the model's AUROC in the MIMIC cohort improved substantially, reaching 0.8388. These findings demonstrate that the model has predictive value in critically ill patient populations, particularly in identifying patients at risk for severe GIB.

Currently, no dedicated tool exists for assessing GIB risk in CABG patients. To address this gap, we developed a new predictive model and compared it with the PRECISE-DAPT score, a commonly used tool in internal medicine for evaluating bleeding risk in patients receiving DAPT [12]. Across all study cohorts, our model demonstrated superior performance, as evidenced by its higher AUROC and greater net benefit, as shown in the receiver operating characteristic and DCA curves. Furthermore, our model has been validated as a predictor of patient prognosis. In addition, we compared its predictive performance for in-hospital mortality with that of the PRECISE-DAPT score, demonstrating a significantly higher AUROC for our model, underscoring its superior prognostic capability. The PRECISE-DAPT score, developed using Cox regression, is widely used to predict bleeding risk in DAPT patients. However, its reliance on clinical variables that exclude cardiovascular function and gastrointestinal status may limit its applicability in patients undergoing cardiac surgery or in predicting GIB risk. By contrast, ML excels at capturing nonlinear relationships and complex interactions between variables, enabling our model to focus specifically on predicting GIBCG with superior performance. However, our model has limitations. It requires validation in larger-scale prospective cohorts to further establish its reliability. Additionally, its interpretability remains a challenge, making it difficult for clinicians to fully understand the reasoning behind its predictions. To address this, we incorporated SHAP to enhance explainability, as detailed in the following sections.

High-risk patients with GIBCG identified by the model have a significantly increased risk of death and should receive heightened clinical attention. Early identification enables timely interventions, such as preventive medication and optimized perioperative management, to mitigate GIBCG risk and improve prognosis. Strategies include PPIs use, risk factor management, and *Helicobacter pylori* eradication, which have been shown to reduce antithrombotic therapy–associated GIB [34]. Current guidelines recommend prophylactic PPIs use in cardiac surgery patients to minimize gastrointestinal adverse events, with a class II a level of evidence [35].

Additionally, managing antithrombotic therapy in high-risk patients with GIBCG should be optimized. Aspirin and clopidogrel are the most commonly used antiplatelet agents, and patients experiencing acute GIB while on aspirin are generally advised to continue therapy whenever possible [36-38]. During the perioperative period of CABG, aspirin can typically be maintained, except in cases of extremely high bleeding risk [39,40]. For patients scheduled for elective CABG who are receiving P2Y12 receptor blockers (eg, clopidogrel, prasugrel, ticagrelor), guidelines recommend discontinuing these agents 5-7 days before surgery to reduce the bleeding risk [41,42]. In patients with an elevated bleeding risk, discontinuation of antiplatelet therapy may be considered even earlier [36,37,43]. Furthermore, the concomitant use of anticoagulants and antiplatelet agents should be avoided whenever possible due to the significantly increased risk of GIB [44]. Existing evidence suggests that prophylactic PPIs use may be beneficial for high-risk patients undergoing CABG. For those already receiving DAPT or OACs preoperatively, an earlier transition to SAPT or alternative therapies should be considered to mitigate bleeding risk.

Additionally, our findings reinforce this evidence, demonstrating that preoperative PPIs use independently protects high-risk patients from developing GIBCG, whereas DAPT and OACs independently increase the risk. The protective effect of PPIs is primarily attributed to their irreversible binding to proton pumps in the secretory tubules and vesicles of gastric parietal cells, leading to H^+/K^+-ATPase inhibition and subsequent suppression of gastric acid secretion [45]. This helps reduce gastric mucosal damage, prevent ulcer formation, and lower the risk of stress ulcer bleeding [46,47]. Moreover, the suppression of gastric acid secretion by PPIs significantly increases gastric pH, preventing the conversion of pepsinogen to pepsin, which helps maintain clot stability and promotes hemostasis [48,49]. By contrast, antiplatelet agents heighten the risk of GIBCG. Aspirin, for instance, disrupts the gastric mucosal protective layer and induces oxidative stress and apoptosis in epithelial cells, leading to direct gastrointestinal injury [50,51]. It also inhibits cyclooxygenase (COX)-1 and COX-2, reducing prostaglandin production via COX-1, which weakens mucosal protection and contributes to indirect gastrointestinal damage [52]. Additionally, aspirin may impact the gut microbiota,

XSL•FO
RenderX

triggering inflammation by stimulating the immune system through Toll-like receptor 4 [53]. Drugs such as clopidogrel and ticagrelor act indirectly on the gastrointestinal mucosa by inhibiting adenosine diphosphate receptors, reducing the release of vascular endothelial growth factors, inhibiting neovascularization, and hindering gastrointestinal mucosal repair, potentially promoting GIB [54,55]. Furthermore, DAPT has a synergistic effect that can further exacerbate gastrointestinal mucosal damage. OACs increase the risk of GIB through mechanisms such as their local anticoagulation effect, direct corrosive action, and mucosal repair inhibition [56-58]. They prolong clotting time and increase capillary fragility and permeability, thereby elevating the risk of bleeding. Gastrointestinal damage caused by OACs is associated with small intestinal mucosal permeability glycoproteins, which regulate OACs concentration in the gastrointestinal tract. An incompletely absorbed OACs in the gastrointestinal tract may exert a local effect on the mucosa, leading to bleeding [59]. The mechanisms outlined above suggest a potential link, highlighting the need for future experimental studies to further explore the molecular mechanisms underlying the relationship between preoperative medications and GIB risk.

ML technology is often regarded as a “black box,” with its prediction and reasoning processes lacking transparency. Therefore, understanding how ML models make decisions is crucial for clinicians to build trust in the model and identify potential biases. This underscores another key advantage of our study: the use of the SHAP method to provide both global and local explanations of the model [29,60]. In the global explanation, the SHAP summary plot illustrates the overall distribution of each feature’s impact on the model output. Moreover, in GIBCG prediction, the top 5 important admission features include cardiac function–related indicators (such as left ventricular ejection fraction and history of chronic heart failure), age, platelet count, and INR. Notably, left ventricular dysfunction and heart failure are among the most significant independent predictors of mortality and other major adverse events, including bleeding, following CABG [61,62]. The increased risk of postoperative GIB in patients with heart failure may be attributed to reduced cardiac output, which leads to gastrointestinal hypoperfusion, resulting in ischemia and hypoxia of the gastrointestinal mucosa and ultimately weakening its protective barrier function [63]. During ischemia-reperfusion, the release of oxygen-free radicals and inflammatory mediators further exacerbates gastric mucosal injury [64], thereby increasing the risk of ulcers and bleeding. Another important factor is age. Specifically, older adult patients are at a higher risk of GIBCG due to increased vascular fragility [65], impaired gastrointestinal mucosal barrier function [66], multiple comorbidities, and long-term use of gastrointestinal-damaging medications (eg, aspirin). Studies have shown that age over 65 years (OR 2.1) is a risk factor for gastrointestinal complications after CABG [67], while age (OR 1.04) is a predictor of bleeding and transfusion during surgery [68]. These findings align with the interpretation of features in our model, underscoring their clinical significance. Specifically, older adult patients or those with poor preoperative cardiac function are at an increased risk of developing GIB postoperatively and warrant heightened attention. For such populations, greater emphasis should be placed on GIB prevention during preoperative preparation, with enhanced perioperative monitoring, protection of cardiac function, and optimization of blood flow management. Furthermore, coagulation status is closely associated with the occurrence of GIB after cardiac surgery [69-73]. In particular, platelet counts [72] and INR [73] are key indicators of coagulation function that are simple to measure and readily accessible. Abnormal values at admission can help clinicians promptly adjust perioperative antithrombotic treatment strategies, thereby reducing the risk of GIBCG.

Local explanations provide personalized interpretations for each patient’s prediction, while force plots visualize the specific contributions of each feature to the predicted value. For example, in Figure 4, patient 1 is relatively young and has comparatively good cardiac function. However, decreased albumin, elevated white blood cell count, and slightly lower platelet levels (though within the normal range) are identified as the main factors contributing to the increased risk of GIBCG. Previous studies have shown that preoperative hypoalbuminemia is significantly associated with increased mortality [74,75] and postoperative complications, including bleeding [74], in cardiac surgery patients. Notably, an elevated white blood cell count reflects an underlying inflammatory state, which has been associated with increased mortality and complications following CABG [76,77]. Nutritional support, close monitoring of liver function, management of inflammatory responses, and optimization of antithrombotic therapy may help reduce the risk of GIBCG in this patient. Based on readily accessible features, our web platform enables early prediction of GIBCG risk and provides personalized explanations through force plots. This serves as a valuable reference for clinicians in making individualized decisions, thereby supporting the precise prevention of GIBCG.

ML is increasingly applied in personalized medicine and has the potential to improve patient outcomes. However, ethical and practical considerations warrant further discussion [78]. First, patient data privacy is critical. Even deidentified data can be reidentified through available data points [79] or triangulation with other data sets [80]. To mitigate this risk, strategies such as suppression (removing sensitive information), generalization (transforming specific data into ranges), and data minimization (collecting only essential data) are applied [78]. Second, obtaining consent from each patient poses a challenge in acquiring large-scale training data. Alternative methods, such as dynamic consent, broad consent, and implied consent with opt-out options, have been proposed. In our retrospective cohort, broad consent was obtained, allowing for the future use of anonymized data without specific knowledge of the studies [81]. Third, algorithmic bias is a significant concern in ML applications. As ML models are trained on historical data, any biases present in the training data (eg, related to race, gender, or socioeconomic status) may be perpetuated or even amplified in predictions [82]. In addition, experts involved in labeling the data may inadvertently introduce their own biases into the algorithm [83]. Addressing algorithmic bias requires ensuring the diversity and representativeness of the training data set. For instance, our study utilized multicenter data for model training. Moreover, enhancing model interpretability allows health care professionals to understand its decision-making process,

XSL•FO
RenderX

enabling them to identify and mitigate potential biases. Continuous monitoring and evaluation should also be conducted during the model's application. In future research, we plan to validate our model across different populations and refine it based on feedback [84]. Notably, surveys indicate that many American adults are uncomfortable with doctors relying on ML for decision-making [85]. Most ML systems are designed to assist clinicians in decision-making with oversight rather than functioning autonomously [86]. This approach helps alleviate public concerns about ML-driven decisions while ensuring health care quality and patient safety. Future efforts to integrate ML into health care should prioritize the development and implementation of standardized ethical frameworks and guidelines.

Recently, ML has made significant progress in the field of cardiovascular diseases and related surgeries [17,18]. Research has primarily focused on surgical risk assessment [87], prediction of postoperative complications [88-93], evaluation of patient prognosis [94,95], and guidance for personalized medicine [96]. Several ML models have been developed to predict postoperative complications in cardiac surgery, including bleeding [88,89], acute kidney injury [90,91], delirium [92], and major adverse cardiovascular and cerebrovascular events [93]. Furthermore, studies have shown that ML algorithms perform exceptionally well in predicting severe bleeding after CABG [89]. Additionally, ML has been demonstrated to outperform traditional risk-scoring methods in predicting the risk of GIB following antithrombotic therapy [20]. However, in the surgical field, ML models specifically targeting GIBCG remain unavailable. To date, only a single-center study has proposed a traditional risk prediction model [10], which does not enable preoperative prediction of GIBCG risk, thereby limiting early prevention efforts. To address this critical gap, we developed an ML model using multicenter data to predict the risk of GIBCG. The model was validated on 2 independent external cohorts, demonstrating its ability to accurately predict a patient's risk of GIBCG upon admission and guide personalized preventive measures. This approach may help reduce the incidence of this complication and improve patient outcomes. Furthermore, it highlights the significant value of ML in cardiovascular surgery for preventing complications and enhancing the quality of patient care.

Limitations

Our study has several limitations. First, the inclusion of retrospective cohorts may introduce selection bias. However, incorporating a prospective cohort in the model development, along with the use of rigorous selection criteria and a substantial sample size, may help mitigate this limitation. Second, the model was developed based on a Chinese population, and its generalizability to global populations remains uncertain. Nevertheless, its acceptable performance in critical care cohorts in the United States suggests its potential broader applicability. Future prospective validation is necessary to further refine and evaluate the model's performance. Third, the causal relationships between predictive features (risk factors) and GIBCG, as well as between preoperative medication and GIBCG, require further investigation. Randomized controlled trials are essential to determine whether interventions targeting these risk factors and modifications to preoperative medication can effectively prevent GIBCG. Lastly, this study was retrospectively registered, which may introduce biases in design and reporting. To address this, we ensured transparency by adhering to strict inclusion and exclusion criteria and providing a detailed methodology and results. The substantial sample size and multicenter design help mitigate potential biases from retrospective registration and enhance the study's reliability.

Conclusions

In this study, we successfully developed an XGBoost-based ML model for GIBCG risk prediction using 15 readily accessible admission features, facilitating precision prevention and personalized management of GIBCG. For high-risk patients identified by the model—who have an increased risk of in-hospital mortality and require heightened clinical attention—prophylactic PPIs administration and adjustments to antithrombotic therapy may help reduce the incidence of GIBCG. Moreover, the model demonstrated consistent and excellent performance across both the derivation and validation cohorts, confirming its robustness and scalability. To enhance clinical applicability, it has also been integrated into a web-based risk prediction calculator.

Abstract

Background: Most survivors of cancer have multiple cardiovascular risk factors, increasing their risk of poor cardiovascular and cancer outcomes. The Automated Heart-Health Assessment (AH-HA) tool is a novel electronic health record clinical decision support tool based on the American Heart Association's Life's Simple 7 cardiovascular health metrics to promote cardiovascular health assessment and discussion in outpatient oncology. Before proceeding to future implementation trials, it is critical to establish the acceptability of the tool among providers and survivors.

Objective: This study aims to assess provider and survivor acceptability of the AH-HA tool and provider training at practices randomized to the AH-HA tool arm within WF-1804CD.

Methods: Providers (physicians, nurse practitioners, and physician assistants) completed a survey to assess the acceptability of the AH-HA training, immediately following training. Providers also completed surveys to assess AH-HA tool acceptability and potential sustainability. Tool acceptability was assessed after 30 patients were enrolled at the practice with both a survey developed for the study as well as with domains from the Unified Theory of Acceptance and Use of Technology survey (performance expectancy, effort expectancy, attitude toward using technology, and facilitating conditions). Semistructured interviews at the end of the study captured additional provider perceptions of the AH-HA tool. Posttreatment survivors (breast, prostate, colorectal,

XSL•FO
RenderX

endometrial, and lymphomas) completed a survey to assess the acceptability of the AH-HA tool immediately after the designated study appointment.

Results: Providers (n=15) reported high overall acceptability of the AH-HA training (mean 5.8, SD 1.0) and tool (mean 5.5, SD 1.4); provider acceptability was also supported by the Unified Theory of Acceptance and Use of Technology scores (eg, effort expectancy: mean 5.6, SD 1.5). Qualitative data also supported provider acceptability of different aspects of the AH-HA tool (eg, "It helps focus the conversation and give the patient a visual of continuum of progress"). Providers were more favorable about using the AH-HA tool for posttreatment survivorship care. Enrolled survivors (n=245) were an average of 4.4 (SD 3.7) years posttreatment. Most survivors reported that they strongly agreed or agreed that they liked the AH-HA tool (n=231, 94.3%). A larger proportion of survivors with high health literacy strongly agreed or agreed that it was helpful to see their heart health score (n=161, 98.2%) compared to survivors with lower health literacy scores (n=68, 89.5%; *P*=.005).

Conclusions: Quantitative surveys and qualitative interview data both demonstrate high acceptability of the AH-HA tool among both providers and survivors. Although most survivors found it helpful to see their heart health score, there may be room for improving communication with survivors who have lower health literacy.

Introduction

Survivors of many common early-stage cancers are now more likely to die of cardiovascular disease than cancer, elevating the importance of addressing cardiovascular health (CVH) in routine survivorship care [1-6]. Over 90% of survivors have multiple cardiovascular risk factors [7], increasing their risk of both poor cardiovascular and cancer outcomes [8-16]. Compared to the general population, survivors of cancer have poorer CVH [17,18]. Over 85% of survivors do not meet the American Heart Association's healthy standards in multiple CVH components (BMI, physical activity, diet, smoking, blood pressure, cholesterol, and glucose) [7,19], many of which increase the risk for both cardiovascular disease and cancer [8,20]. Accordingly, better CVH among survivors is associated with improved survival [21] and reduced risk of both cardiovascular disease [20,22,23] and cancer recurrence [12-14].

Despite Institute of Medicine recommendations for prevention efforts and care coordination for survivors of cancer [24,25], up to 20% of survivors of breast and colorectal cancers may not see a primary care provider [26,27], heightening their risk for lack of preventive services and poor comorbidity management [27-29]. Claims data reveal that only 31%-39% of survivors of breast cancer received cholesterol screening, significantly fewer than women without breast cancer matched on age, ethnicity, sex, region, and comorbidity [29]. Together, these findings emphasize the importance of addressing CVH during routine oncology survivorship care. Both the American Society of Clinical Oncology [30] and the National Comprehensive Cancer Network guidelines [31] recommend cardiovascular risk assessment and discussion for patients with cancer. In our prior work [32] with 20 oncologists, 95% (n=19) reported CVH discussions to be "somewhat" or "very" important; however, 58% only "rarely" or "sometimes" discuss CVH with their patients [33]. Further, nearly 35% of survivors of cancer do not receive assistance from a health care provider for CVH-related lifestyle changes [2]. Similarly, fewer survivors who are at increased risk for health complications report provider discussions about CVH-related lifestyle behaviors (ie, physical activity, diet, and smoking) compared to those with no cancer history [34].

To address these gaps in posttreatment survivorship care and promote guideline adherence, our team developed and deployed a novel, easy-to-use, electronic health record (EHR)–embedded CVH assessment tool, the Automated Heart-Health Assessment (AH-HA) tool. This tool was first implemented in primary care and now incorporates EHR data on receipt of cancer treatments with cardiotoxic potential alongside a visual, interactive display of CVH risk factors, automatically populated from the EHR [35-37]. Before proceeding to future implementation trials, it is critical to establish the acceptability of the tool among oncology providers and survivors [38]. As part of a larger pragmatic trial to test and evaluate AH-HA in survivorship care [39], among practices randomized to the AH-HA tool, we assessed the acceptability of the AH-HA tool among both patients and providers during routine oncology care, along with provider perceptions of potential sustainability.

Methods

Ethical Considerations

This study (WF-1804CD) was approved by the National Cancer Institute (NCI) Central institutional review board (IRB). Each participating institution granted authority to the NCI Central IRB to serve as the IRB of record for NCI Community Oncology Research Program (NCORP) studies, in accordance with the National Institute of Health's single IRB policy. All participants provided consent. NCORP is a national network of community oncology practices with infrastructure to support the recruitment

XSL•FO
RenderX

of patients to clinical trials [40]. This study was facilitated through the Wake Forest NCORP Research Base (UG1CA189824). Study data were de-identified. Providers were offered a $10 gift card upon completion of the posttraining survey and a $20 gift card for participating in the qualitative interview. Survivors received a $10 gift card upon completion of the acceptability survey.

Study Eligibility and Recruitment Procedures

Weaver et al [39] show the complete eligibility criteria and methods for the larger randomized trial. NCORP practice eligibility criteria included (1) use of the Epic EHR, (2) willingness to incorporate the AH-HA tool in their EHR, (3) having two or more providers willing to be trained and use AH-HA, and (4) identified combined providers saw 100 or more potentially eligible patients for follow-up in prior 6 months. Providers were recruited and consented by cancer care delivery research leads within their practice. Eligible providers included physicians and advanced practice providers (nurse practitioners and physician assistants) willing to complete the AH-HA provider training. This manuscript focuses on providers within practices randomized to use the AH-HA tool in the pragmatic trial [39]. To identify eligible survivors, staff at NCORP sites screened clinic schedules and reviewed survivors' medical records. Survivors were contacted by phone, patient portal, or in-person and were eligible if they were at least 6 months post potentially curative cancer treatment for breast, prostate, colorectal, or endometrial cancers or Hodgkin and non-Hodgkin lymphomas and scheduled for a routine cancer-related follow-up care visit.

AH-HA Training and Intervention

A full description of the AH-HA tool and provider training is available in the protocol paper [41]. In brief, providers completed two 30-minute video trainings prior to the practice enrolling patients. The training covered (1) the importance of addressing CVH as part of routine posttreatment follow-up care for survivors of cancer, (2) the basics of the American Heart Association's Life's Simple 7 CVH factors [9] and overall CVH metric, (3) navigation of the AH-HA tool within the EHR, and (4) how to use the tool to guide discussions with survivors. The AH-HA tool was launched using a best practice alert for enrolled patients during a routine posttreatment outpatient oncology visit. Providers could choose to use the tool or not in accordance with their clinical judgment; examples of reasons for nonuse may include a competing clinical demand (eg, new symptom or concern for recurrence), patient distress, or perception that the patient would not be receptive to or benefit from a discussion (eg, in the unlikely case that all factors were ideal). Five of the CVH factors were automatically populated from the EHR when available (BMI, smoking, blood pressure, cholesterol, and hemoglobin A_{1c} or blood glucose); physical activity and diet data were collected on paper and entered directly into the tool by the provider. AH-HA color codes each CVH factor as red (poor), yellow (intermediate), or green (ideal) according to Life's Simple 7 classification framework [9] and also provides a total CVH score. Interactive slider bars can be used to demonstrate how improvements in CVH factors can lead to shifts in the categorization and overall CVH score. A second tab included information about the patient's receipt of cancer treatments with cardiotoxic potential (ie, anthracyclines, antimetabolites, hormone therapy, aromatase inhibitors, monoclonal antibodies, antimicrotubule agents, alkylating agents, and radiation) [3,42,43].

Data Collection and Measures

Providers and survivors provided information about sex, age, race, and ethnicity. Survivor cancer type and time since diagnosis were abstracted from the EHR. Survivor's health literacy was also assessed with 1 item ("How confident are you filling out medical forms by yourself?") with response options ranging from not at all confident to extremely confident. Prior research has demonstrated that this 1 item is effective at identifying health literacy skills [44]. Provider items also included provider type (physician, nurse practitioner, and physician assistant), years in current position, time spent providing direct patient care, time spent using the EHR for direct individual patient care, and proficiency with current EHR. Providers completed 2 surveys: one immediately after participating in the initial AH-HA training (posttraining survey) before participant enrollment and one after 30 patients were enrolled at the practice (postenrollment survey). Provider surveys assessed the acceptability of the training and AH-HA tool, and preferences for when and how often to use the AH-HA tool in the cancer treatment trajectory. Survivors completed one survey to assess the acceptability of the AH-HA tool immediately after the designated routine oncology appointment. Data collection occurred from December 2020 to March 2023. Survey items developed by our team are available upon reasonable request.

Provider Perspectives on Training

We developed a 7-item survey for the purpose of this study to assess various aspects of acceptability (eg, "The AH-HA training provided useful information about the importance of addressing CVH with cancer survivors" and "The AH-HA provider training will help me be more effective when discussing cardiovascular health with survivors") with response options ranging from 1=strongly disagree to 7=strongly agree. A composite score was calculated using the average of all 7 items. Also, 1 item assessed the acceptability of the AH-HA training duration (response options ranging from too short to too long). An additional item assessed comfort in discussing CVH with survivors following the training ("Please indicate your level of comfort discussing CVH with your posttreatment, good prognosis patients") with a 5-point Likert-scale (not at all comfortable to very comfortable). In a separate follow-up survey, providers were asked 1 item retrospectively about their preparedness to use the AH-HA tool at the time they completed the training ("Following the provider training, how prepared were you to use the AH-HA tool with patients?"). Response options included not at all prepared, somewhat prepared, and very prepared.

Provider Perspectives on the AH-HA Tool

Six items, used in prior work [32,36], assessed aspects of provider acceptability of the AH-HA tool (eg, "The information AH-HA provides is useful" and "AH-HA helps me be more

XSL•FO
RenderX

effective") with response options ranging from 1=strongly disagree to 7=strongly agree. A composite score was calculated using the average of all 6 items. We further assessed acceptability using items from the Unified Theory of Acceptance and Use of Technology (UTAUT) survey [45]. Specifically, 15 items assessed the performance expectancy (eg, "The AH-HA tool is useful in my job"), Effort expectancy (eg, "I find the AH-HA tool easy to use"), attitude toward using technology ("Using the AH-HA tool is a good idea"), and facilitating conditions (eg, "I have the resources necessary to use the AH-HA tool") domains of the UTAUT survey [5,45]. Response options ranged from 1=strongly disagree to 7=strongly agree. We calculated scores for each domain using the average of domain items [45]. An additional item that was developed for this study to assess potential sustainability asked providers to report the timing and frequency they would like to use the AH-HA tool ("After the study ends, how often would you like to use the AH-HA Tool when providing care to patients during: (1) initial treatment planning, (2) active treatment, and (3) posttreatment survivorship care") with response options including never or almost never, seldom or about half the time, most of the time, and always or almost always.

Survivor Acceptability

Five items previously used in our pilot work assessed overall acceptability of the AH-HA tool (eg, "I liked the heart health tool I used today with my provider" and "It was helpful to see my heart health score") with a 5-point Likert scale ranging from strongly disagree to strongly agree [32].

Providers also participated in a semistructured qualitative interview conducted via telephone at the end of patient enrollment at their practice to further understand perceptions of the AH-HA tool. Examples of interview content include the impact of AH-HA on the provider's practice ("How do you think having access to the tool impacted your practice, if at all?"), patients' responses to the tool ("How did patients respond or react to the tool?"), recommended changes to the tool ("What changes would you make to AH-HA so it will work effectively in your setting?"), impact on care provided to patients ("Overall, do you feel the tool helped improve the care you provide to patients? Why/why not?"), and benefits and drawbacks to continuing to use the tool ("What benefits and drawbacks do you see in continuing to use AH-HA in your practice after the study is complete?"). A full list of interview questions is available upon request.

Interviews were conducted by 2 trained qualitative research team members from the Qualitative and Patient-Reported Outcomes (Q-PRO) Shared Resource of the Atrium Health Wake Forest Baptism Comprehensive Cancer Center. Interviews lasted an average of 20 minutes and were audio recorded.

Analyses

Descriptive statistics were quantified with mean (SD) and frequency (%) for continuous and categorical outcomes respectively. Figures display mean and corresponding 95% CIs for providers' answers on a 1-7 scale. Total scores for scales are quantified with mean (SD) and range. Univariate associations of demographics characteristics (age, sex, race, ethnicity, and health literacy) and cancer type (breast, colorectal, prostate, endometrial, and lymphoma) with acceptance of the AH-HA tool (using the following items: (1) "It was helpful to see my heart health score" and (2) "I would like to use this tool to talk about my heart health with my oncology provider at a future appointment") were tested using Fisher exact tests. *P* values less than .05 were considered statistically significant.

Qualitative interviews were analyzed in collaboration with the Q-PRO Shared Resource of the Atrium Health Wake Forest Baptism Comprehensive Cancer Center. The interview audio was transcribed verbatim and 2 Q-PRO teammates and coauthors (AA and KW) reviewed the transcripts and developed a draft codebook. The study team reviewed the codebook and provided input, which was incorporated into a new version of the codebook. Transcripts were imported into ATLAS.ti [46] and the codebook was tested by coding several transcripts and revised as necessary. All interviews were independently coded by 2 Q-PRO teammates and coauthors (AA and KW) and compared; any discrepancies were discussed and resolved. Once all transcripts were coded, code reports were run and summaries for each report were written. Summaries for provider's perceptions of the AH-HA tool were synthesized and analyzed for patterns and themes.

Results

Overview

In total, 17 providers were recruited for the pragmatic trial to participate in the intervention arm; 1 provider did not use the AH-HA tool and 1 provider did not complete surveys. Thus, we report results on the 15 providers who used the AH-HA tool and completed the surveys from 4 community oncology practice groups (25% of practices located in the Midwest, 75% or practices located in the South; 25% minority or underserved NCORP, and 50% designated critical access hospital). A total of 13 providers (87%) completed the posttraining survey and 15 (100%) completed the postenrollment survey. Among the 15 providers who used the tool, together they saw 296 survivors (46% of survivors participating in the larger randomized trial). Of these, 245 reported seeing the AH-HA tool (33 did not see the tool and 18 were unknown).

Provider and Survivor Characteristics

Overview

Providers included physicians (n=8, 53%; Table 1), nurse practitioners (n=6, 40%), and a physician assistant (n=1, 7%). Most providers (n=10, 67%) reported spending 76%-100% of their time providing direct patient care and more than half (n=8, 53%) reported spending 76%-100% of their time using the EHR for direct patient care. Most providers (n=11, 73%) reported that they were "very proficient" with their current EHR.

Number of survivors that used AH-HA[b] per provider, mean (SD); range	19.7 (17.1); 2-56

[a]EHR: electronic health record.

[b]AH-HA: Automated Heart-Health Assessment.

Survivors (N=245; Table 2) completed treatment for breast (n=230, 93.9%), endometrial (n=1, 0.4%), or colorectal (n=9, 3.7%) cancers, or lymphoma (n=5, 2%) and were mostly female (n=239, 97.5%). Most survivors were White or Caucasian (n=203, 82.9%) and 13.1% (n=32) were Black or African American. Overall, 5.3% were Hispanic or Latino (n=13).

XSL•FO
RenderX

Survivors were an average age of 61 (SD 10.9) years and most commonly married or living as married (n=176, 71.8%). Most survivors had a college degree (n=111, 45.3%) or some college including vocational or technical school (n=82, 33.5%). The median time since diagnosis was 3.6 (IQR 2.1-5.2) years.

Provider Perspectives on AH-HA Training

Figure 1 depicts provider training acceptability findings. Overall, providers reported high acceptability (mean 5.8, SD 1.0), with the highest item acceptability rating (mean 6.1, SD 0.8) for the following item: "The AH-HA training provided useful information about the importance of addressing CVH with cancer survivors." Providers reported the lowest acceptability rating (mean 5.5, SD 1.3) for the following item: "I feel prepared to use the AH-HA tool in clinic with posttreatment, good

XSL•FO
RenderX

prognosis patients." More than half of providers reported that the duration of the AH-HA training was "about right" (n=7, 54%), followed by "a little too long" (n=4, 31%), "a little too short" (n=1, 8%), and "much too long" (n=1, 8%). At the conclusion of the training, all providers reported that they were somewhat (n=9, 69%) or very (n=4, 31%) comfortable discussing CVH with posttreatment patients with a good prognosis. When providers reflected on their preparedness after using the AH-HA tool, most reported they were "very prepared" (n=8, 57%) followed by "somewhat prepared" (n=6, 43%).

Figure 1. Provider acceptability of the AH-HA training session (N=13). AH-HA: Automated Heart-Health Assessment; CVH: cardiovascular health.

Provider Perspectives of the AH-HA Tool

Quantitative surveys and qualitative interview data converged to demonstrate provider acceptability of the AH-HA tool. Figure 2 shows survey results; providers reported being satisfied with the AH-HA tool (mean 5.5, SD 1.4) with the highest rating for 2 items: "The information AH-HA provides is useful" (mean 5.9, SD 1.2) and "The information in AH-HA is presented in a useful format" (mean 5.9, SD 1.1); and the lowest rating (mean 4.9, SD 1.8) for the following item: "AH-HA makes the information I want easier to access." Providers felt the interactivity and visuals provided in the AH-HA tool were particularly useful for patients. One provider stated, "I think the biggest thing is the visual aspect of the tool is really nice for them and the interactive-ness, the way you can slide the bars and show them if they achieve X, Y, or Z goal, how it can make a difference in their [CVH] score." One provider mentioned that having these data available would allow them to easily track their patients' progress: "it was something that, in a follow up visit, you could look—would be able to look back on to compare and talk with the patient and they can see how they made progress in this area or is there something we can continue to work on. It helps focus the conversation and give the patient a visual of continuum of progress." Providers reported acceptability of AH-HA (Table 3) for the performance expectancy (mean 4.0, SD 2.0), effort expectancy (mean 5.6, SD 1.5), attitude toward using technology (mean 4.8, SD 2.1), and facilitating conditions (mean 5.5, SD 1.5) domains of the UTAUT. Related to performance, providers felt AH-HA helped them have deeper discussions of cardiovascular risk with patients.

XSL•FO
RenderX

Figure 2. Provider acceptability of the AH-HA tool (N=15). AH-HA: Automated Heart-Health Assessment.

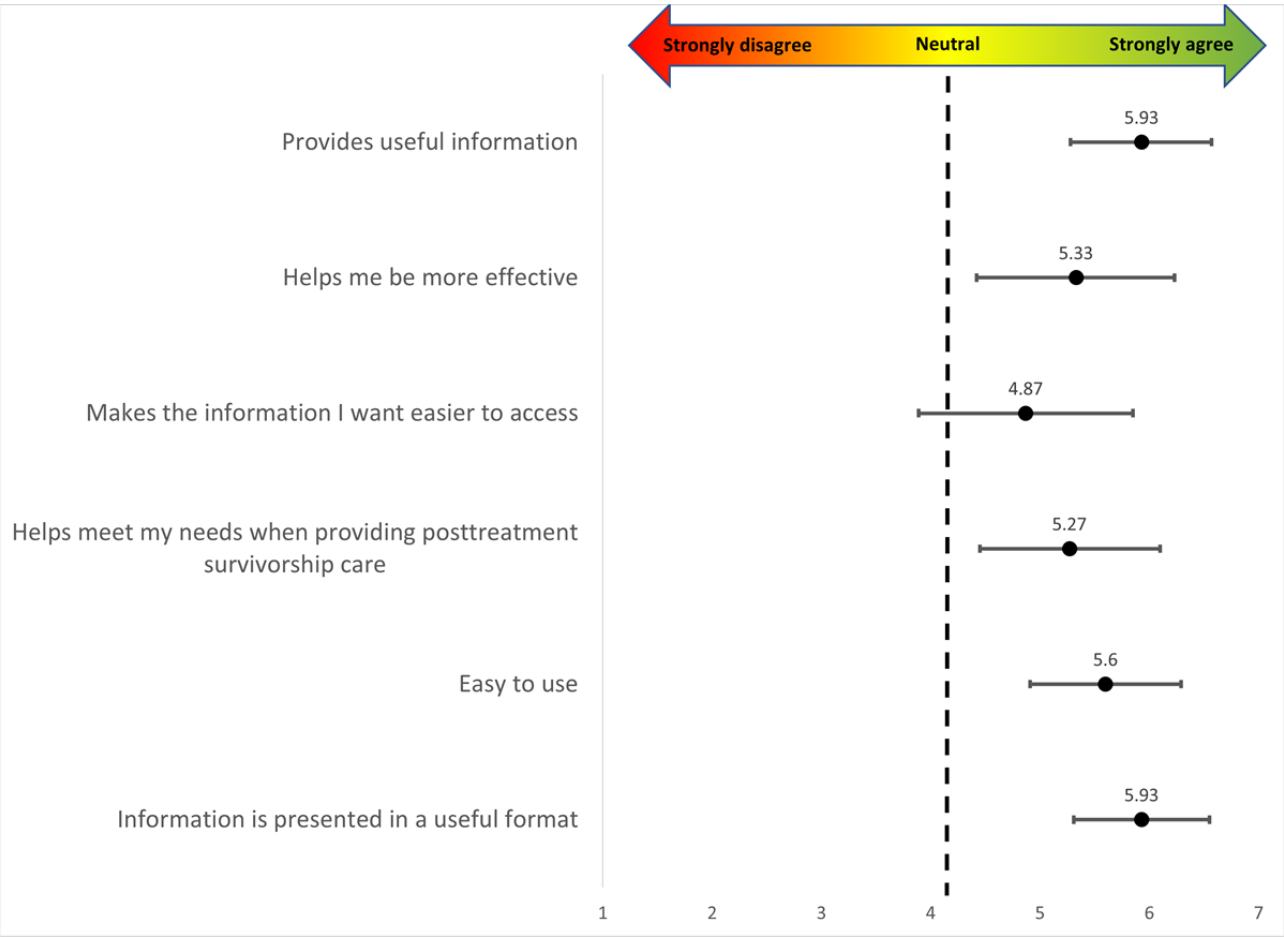

Table 3. Provider acceptability for the performance, effort, attitude, and facilitating conditions domains of the UTAUT[a] survey (N=13).

UTAUT domain	Mean (SD); range
Performance	3.98 (2.04); 1-7
Effort	5.62 (1.49); 2-7
Attitude	4.75 (2.06); 1-7
Facilitating conditions	5.54 (1.51); 2-7

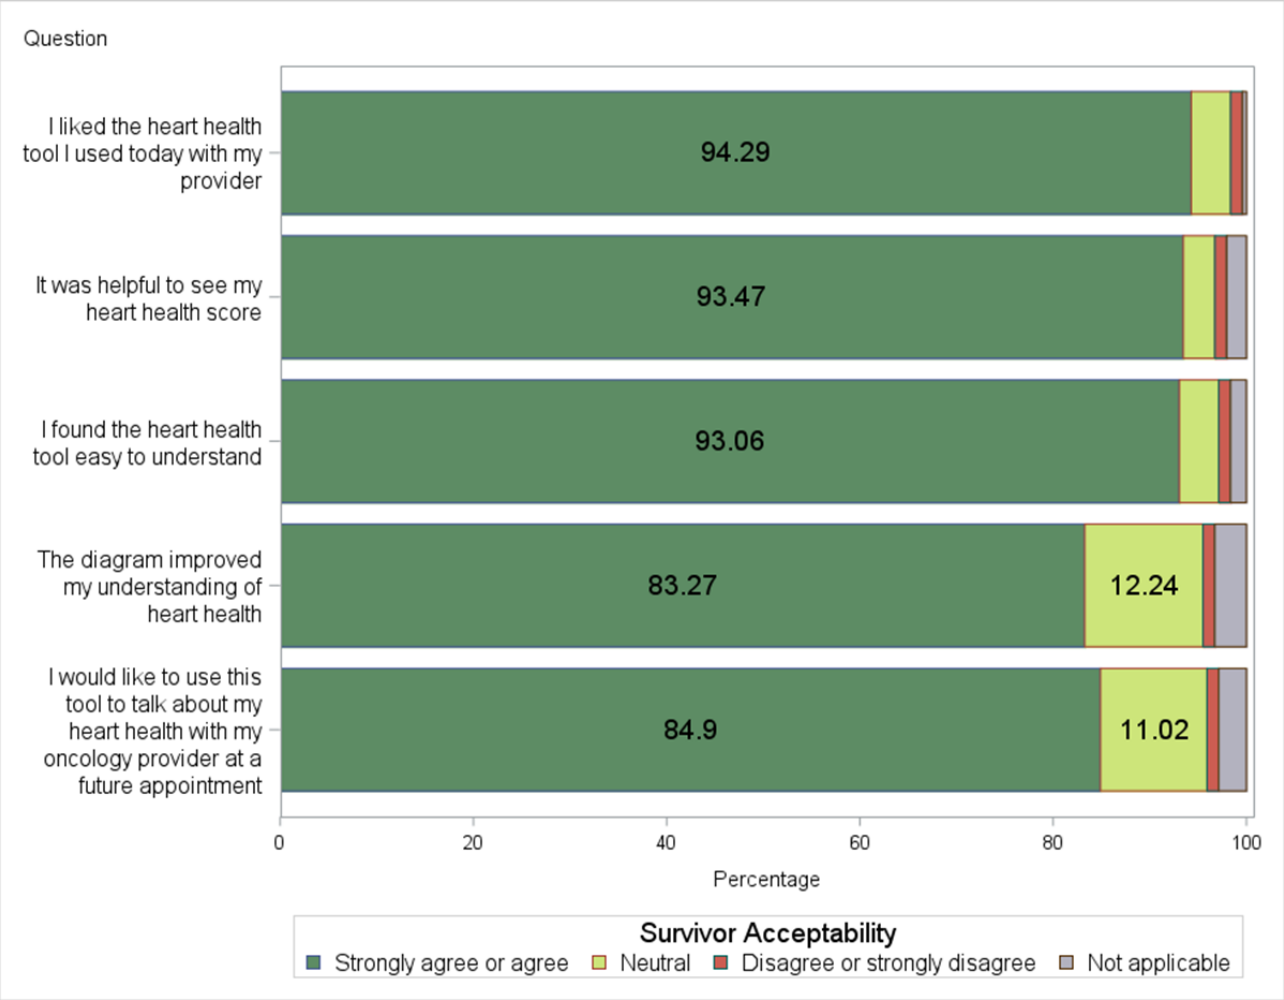
[a]UTAUT: Unified Theory of Acceptance and Use of Technology.

One provider stated, “Before, our CVH approach might have been more of a blanket statement about you are a breast cancer survivor, and you may have increased cardiovascular risks, so you need to optimize your blood pressure, cholesterol with your primary care doctor and what not, but this is a much more thorough tool.”

Some providers noted already having these conversations with patients, which made them less receptive to the tool. For example, 1 provider stated, “because I already do that anyway, I think it was just kind of time-consuming…to actually do it and make extra time in the visit to go through that particular part on the computer and have them ask—or answer very specific questions when we really kind of discuss all of this anyway.” In contrast, favorable effort expectancy was supported qualitatively as some providers noted that the tool was “very simple to use” and “user friendly.” Providers did feel it could be easier to use if it required less “maneuvering” or having to go back and forth” within the EHR.

Potential Sustainability of the AH-HA Tool

When asked about using the tool after the study ended, most providers reported interest in using the AH-HA tool for posttreatment survivorship care (always or almost always: n=3, 21%; most of the time: n=7, 50%; seldom or about half the time: n=2, 14%; and never or almost never: n=2, 14%). There was less interest in using the tool for patients in active treatment or during initial treatment planning for which results were the same (most of the time: n=2, 14%; seldom or about half the time: n=5, 36%; or never or almost never: n=7, 50%).



Survivor Acceptability of the AH-HA Tool

Figure 3 shows results for survivor acceptability of the AH-HA tool. Most survivors reported that they strongly agreed or agreed that they liked the AH-HA tool (n=231, 94.3%), it was helpful

XSL•FO
RenderX

to see their heart health score (n=229, 93.5%), AH-HA was easy to understand (n=228, 93.1%), the picture or diagram (of CVH risk factors) improved their understanding of their heart health (n=204, 83.3%), and they want to use AH-HA to talk about heart health with their oncology provider at a future appointment (n=208, 84.9%).

Figure 3. Survivor acceptability of the AH-HA Tool (N=15). AH-HA: Automated Heart-Health Assessment.

Associations With Survivor Acceptability of the AH-HA Tool

Health literacy was the only survivor demographic characteristic significantly associated with survivors' acceptability of the AH-HA tool. Survivors who indicated they were "extremely confident" filling out medical forms on their own (ie, high health literacy) strongly agreed or agreed that it was helpful to see their heart health score (n=161, 98.2%) compared to survivors with lower health literacy scores (n=68, 89.5%; *P*=.005). Yet, the perceived helpfulness of seeing the heart health score was generally high.

Discussion

Our mixed methods results support the acceptability of the AH-HA CVH assessment tool when used as part of routine posttreatment oncology care in community settings. Survivors of cancer were positive about using the tool in the clinic with their provider. Both oncology physicians and advanced practice providers across 4 community practices reported favorable perceptions of the AH-HA training and use of the tool with survivors of cancer. This suggests AH-HA may be well received in a variety of survivorship care models [47] (eg, advanced practice provider-led survivorship clinics or follow-up with the treating physician).

The overall high acceptability among both patients and providers supports the further implementation of the AH-HA tool, with a continued focus on posttreatment survivors of cancer. Most providers reported they would prefer to use the AH-HA tool for posttreatment survivorship care, and that they would rarely use AH-HA for patients in active treatment or during initial treatment planning. While CVH is important at all points in the cancer treatment trajectory, providers may want to prioritize oncologic treatment during the treatment planning and active treatment phases, and transition to health promotion during the posttreatment survivorship phase. Providers may also perceive that patients are able to more effectively focus on health behavior change without the logistical and psychosocial challenges that are heightened during the treatment phase [48,49]. It is also possible that providers preferred to use the AH-HA tool due to the framing effect of the trial (eg, only posttreatment patients were eligible and the study was focused on survivorship).

XSL•FO
RenderX

Our prior usability assessments considered the tool's appropriateness of the CVH tool for posttreatment survivorship care and we learned that oncology providers also wanted to see potential cardiotoxic treatments received by survivors [33], as incorporated in this study. Moving forward, if the tool is to be used for treatment planning, usability assessments should be repeated with consideration of possible future cardiotoxic effects of treatments incorporated in the design of the tool.

Despite overall positive feedback from both providers and survivors about the AH-HA tool, our results suggest there may be some room for improvement in communicating the heart health score to patients with lower health literacy. Provider training could be augmented to include tips for using the tool with patients who have different levels of health literacy along with scripts to help guide the discussion with patients. Research shows providers often overestimate patient's literacy levels, and patients may be too embarrassed about their limited health literacy to ask questions [50-53]. Increasing the provider's awareness of a survivor's health literacy may be an important step prior to initiating the CVH discussion with survivors. Although we assessed health literacy in this study, this information was not shared with providers. One potential strategy is to include an assessment of survivor health literacy as part of the AH-HA tool to help inform the CVH provider-survivor discussion. Additionally, providing basic information prior to the appointment on the components of CVH and their impact on a patient's overall health may better prepare patients for the upcoming discussion with the provider. Similarly, enhancing patient-facing information in the format of an after-visit summary of CVH recommendations may enhance understanding for patients with lower health literacy [54].

Other potential modifications to the tool may address provider desires for a more streamlined experience. Although most providers found the tool simple to use, others suggested refining AH-HA by requiring less maneuvering within the EHR, and quantitative findings suggested room for improving ease of access to desired information. One way in which the tool could be simplified for providers would be to collect the self-reported diet and physical activity data via the patient portal prior to the visit so that the data would be available in the EHR and callable by the tool. This method would be expected to streamline the use of the tool at the point of care if these data would not need to be manually entered into the tool. Such modifications may also impact providers' perceptions of how AH-HA will impact their job performance and interest in using the AH-HA tool, which corresponds to the UTAUT domains for which providers reported the lowest means.

There were notable strengths to this study. Provider feedback on AH-HA acceptability included both quantitative and qualitative data to provide a fuller picture of both overall acceptability and specific characteristics of the AH-HA tool, consistent with reported strengths of mixed methods research [55]. In this study, these data were complementary and enhanced understanding of provider acceptability. This study was also strengthened by the assessment of perspectives from both providers and survivors as the "end users" from 4 community oncology practices, to inform the next steps, and promote sustainability for AH-HA when implemented widely [56,57]. One limitation of the present study is the predominant enrollment of breast cancer patients despite broad inclusion criteria. This likely reflects the specialization of enrolling providers and the patient mix with respect to cancer type within survivorship programs. Our study team has reported interest in CVH discussions among survivors of gynecologic cancers, yet we acknowledge a more diverse survivor sample is needed to determine the generalizability of these results [58]. Although 15 providers participated and used the AH-HA tool, 2 providers (13%) did not complete the posttraining survey for unknown reasons. Due to the overall high acceptability of AH-HA, there was limited variability in detecting potential differences in patient acceptability by sex, age, or race and ethnicity. Further, although the sample size for our provider key informants was sufficient for theme saturation as our analytic approach [59], it also limited us from making comparisons in acceptability by provider type.

Building upon our strong acceptability findings, the next step for this line of research is to test the AH-HA implementation package to promote guideline-concordant CVH assessment and discussion among a larger and more diverse sample of oncology providers and patients. Tailoring the CVH discussion to meet the needs of patients with higher and lower health literacy will be an important factor to consider in this future direction. It will also be important to assess the sustainability of the AH-HA tool in community practice.

Acknowledgments

The authors would like to acknowledge the following the National Cancer Institute's Community Oncology Research Program (NCORP) sites for their participation: Cancer Research for the Ozarks NCORP, Baptist Memorial Health Care/Mid-South Minority Underserved NCORP, Geisinger Cancer Institute NCORP, Iowa-Wide Oncology Research Coalition NCORP, Wisconsin NCORP, and VCU Massey Cancer Center Minority Underserved NCORP. Abstract

Background: Traditional risk models for immunoglobulin A nephropathy (IgAN), which primarily rely on renal indicators, lack comprehensive assessment and therapeutic guidance, necessitating more refined and integrative approaches.

Objective: This study integrated network biomarkers with unsupervised learning clustering (k-means clustering based on network biomarkers [KMN]) to refine risk stratification in IgAN and explore its clinical value.

Methods: Involving a multicenter prospective cohort, we analyzed 1460 patients and validated the approach externally with 200 additional patients. Deeper metabolic and microbiomic insights were gained from 2 distinct cohorts: 63 patients underwent ultraperformance liquid chromatography–mass spectrometry, while another 45 underwent fecal 16S RNA sequencing. Our approach used hierarchical clustering and k-means methods, using 3 sets of indicators: demographic and renal indicators, renal and extrarenal indicators, and network biomarkers derived from all indicators.

Results: Among 6 clustering methods tested, the KMN scheme was the most effective, accurately reflecting patient severity and prognosis with a prognostic accuracy area under the curve (AUC) of 0.77, achieved solely through cluster grouping without additional indicators. The KMN stratification significantly outperformed the existing International IgA Nephropathy Prediction Tool (AUC of 0.72) and renal function-renal histology grading schemes (AUC of 0.69). Clinically, this stratification facilitated personalized treatment, recommending angiotensin-converting enzyme inhibitors or angiotensin receptor blockers for lower-risk groups and considering immunosuppressive therapy for higher-risk groups. Preliminary findings also indicated a correlation between IgAN progression and alterations in serum metabolites and gut microbiota, although further research is needed to establish causality.

Conclusions: The effectiveness and applicability of the KMN scheme indicate its substantial potential for clinical application in IgAN management.

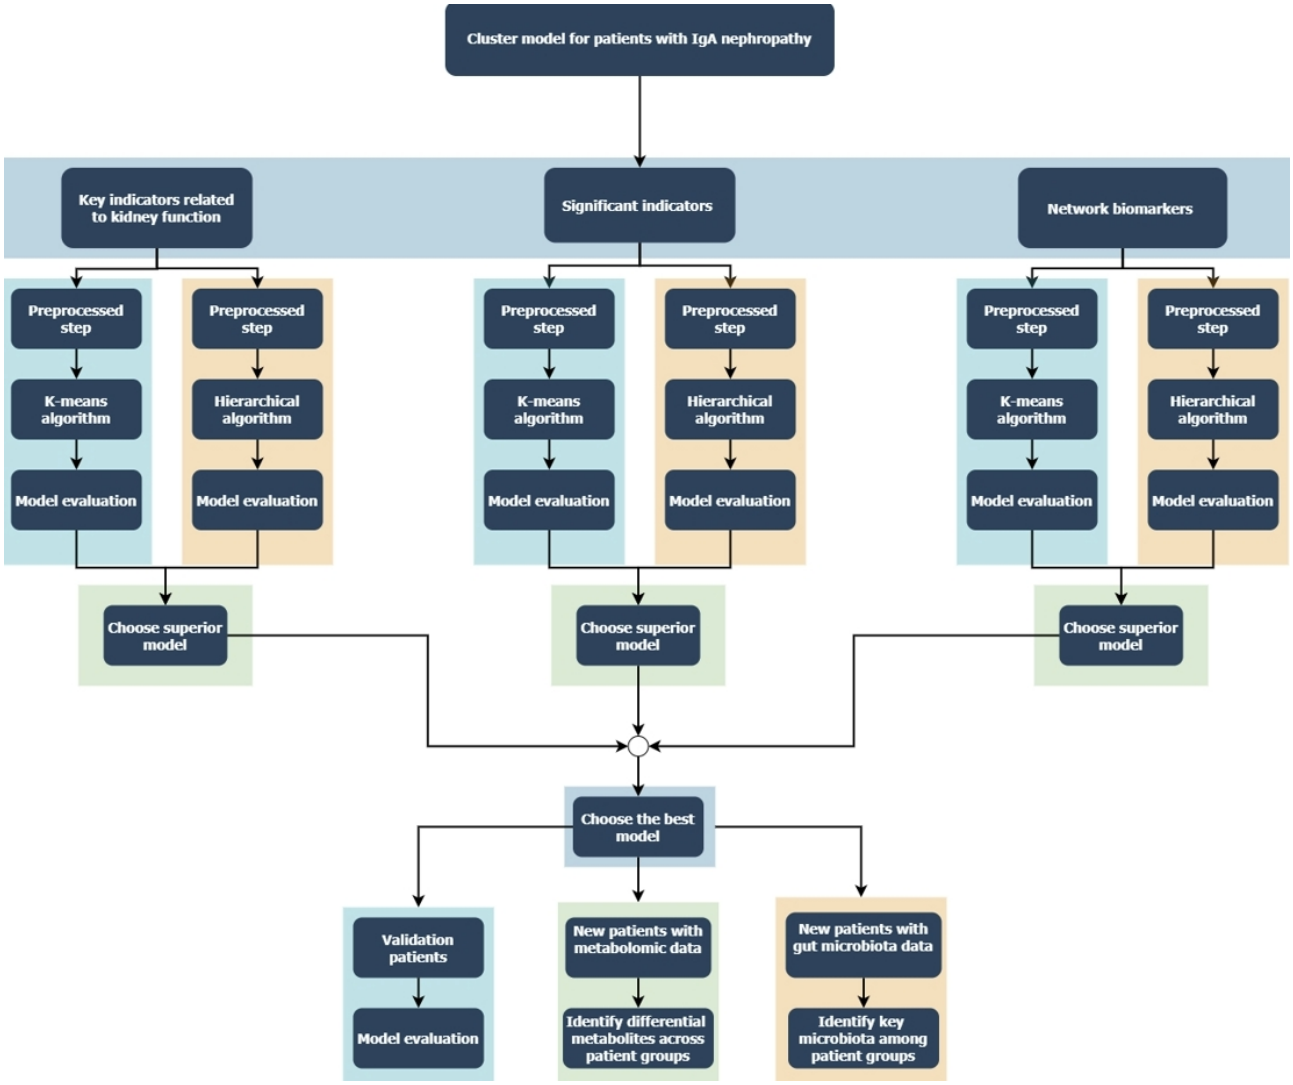
Introduction

Immunoglobulin A nephropathy (IgAN) is the predominant primary glomerular disorder globally, presenting across diverse demographics. The prognosis of IgAN shows notable heterogeneity, with approximately 40% of patients progressing to end-stage renal disease, posing challenges for clinical judgment and management [1]. Hence, investigating risk factors for IgAN has been a recent research hotspot. Alongside traditional kidney-related markers such as proteinuria [2], hematuria [3], estimated glomerular filtration rate (eGFR) slope [4], uric acid [5,6] and Oxford classification [7], emerging extrarenal indicators like smoking status [8], bilirubin [9], platelet-albumin index [10], and triglyceride-glucose index [11] are increasingly explored for their prognostic value in IgAN. This suggests that clinicians should assess IgAN holistically, not just focusing on the renal biomarkers.



To assess IgAN's prognosis, several stratification models have emerged, with the International Immunoglobulin A Nephropathy Prediction Tool (IIgAN-PT) by Barbour et al [12] being the most widely accepted. This model primarily focuses on traditional kidney-related indicators, such as the Oxford classification, treatment regimens, proteinuria, and blood pressure, and has been validated for prognostic accuracy by other research groups [13,14]. Recently, a Japanese cohort led by Koike et al [15] proposed the renal function–renal histology grading (RF-RG) stratification scheme for IgAN, primarily referencing the clinical grade (proteinuria and eGFR) and histological lesions to predict renal failure risk accurately, making it clinically promising due to its simplicity. Regrettably, these studies, while advancing IgAN risk stratification, are primarily retrospective, focusing mainly on traditional renal markers and often neglecting crucial extrarenal indicators. Consequently, these tools fail to differentiate prognosis among patients with similar renal damage who also have conditions like hepatitis B or diabetes—comorbidities that can impact outcomes. Moreover, while the classification schemes forecast prognosis risks, they provide minimal guidance for treatment, with IgAN guidelines largely relying on proteinuria, renal function, and limited histological data [16]. Therefore, current classification models for patients with IgAN are effective but need improvement.

Recent advancements in artificial intelligence, especially in unsupervised learning, have notably influenced various fields. This technique autonomously uncovers patterns and latent information within datasets, showing early successes in projects like gut microbiota classification and autism spectrum disorder stratification [17,18]. However, these applications often focus narrowly on isolated clinical metrics, missing broader interconnections. Simultaneously, the emergence of network biomarkers in precision medicine provides a deeper understanding of biological systems through the analysis of complex molecular interactions. This advanced approach improves our understanding of disease mechanisms, enhances prognostic accuracy, facilitates personalized treatments, and identifies critical stages in disease progression [19]. Yet, the potential of network biomarkers for clustering in biomedical research remains largely untapped, indicating a significant opportunity for further exploration and application in the field.

To address these issues, our study used a multicenter, prospective, observational cohort design to not only focus on traditional renal damage indicators but also incorporate extrarenal markers closely linked to the disease's progression. By leveraging interdisciplinary techniques such as unsupervised learning and network biomarkers, we derived and externally validated optimal classification models for IgAN risk stratification. Additionally, we investigated whether these models could be used for long-term follow-up and to guide treatment decisions in IgAN. Furthermore, we examined significant differences in the metabolomics and gut microbiota under this stratification model, both of which have been documented in literature as closely related to the onset and progression of IgAN [20-26], aiming to provide preliminary clues into the mechanisms of IgAN progression (Figure 1).

Methods

Participant Recruitment

This multicenter, prospective cohort study included 1768 cases of IgAN diagnosed via renal biopsy between 2009 and 2021 at 4 nephrology centers: West China Hospital of Sichuan University, the Affiliated Hospital of Zunyi Medical University, Zigong Third People's Hospital, and People's Hospital of Mianzhu City. Follow-up data were last updated in October 2023 and are maintained by specialized technicians. The study included patients with a confirmed IgAN diagnosis and complete biopsy and clinical data, with IgAN identified as the primary disease. We excluded patients with insufficient pathological data, biopsies containing fewer than 8 glomeruli, incomplete follow-up data, or diagnosed with secondary IgAN. A total of 1460 patients from West China Hospital of Sichuan University meeting the inclusion criteria underwent unsupervised clustering, with the resulting algorithm subsequently validated on an independent cohort of 200 patients from other centers.

To assess the potential clinical meanings of this clustering, we analyzed separate groups of 63 and 45 patients who met our study criteria. These participants underwent ultraperformance liquid chromatography-mass spectrometry for serum metabolomic profiling and 16S RNA sequencing to identify differences in gut microbiota. Participants were free from metabolic diseases, such as hyperthyroidism and diabetes, and had no history of smoking, alcohol misuse, drug abuse, or infectious diseases. They had not received steroids or immunosuppressants in the past 6 months nor had they taken any lipid-lowering, uric acid–lowering, or metabolism-impacting drugs in the previous week. Additionally, they had not ingested probiotics, antibiotics, or gastrointestinal motility drugs in the last month and showed no significant digestive symptoms or diseases. The study adhered to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for observational studies, ensuring comprehensive and transparent reporting of methods and results.

Ethical Considerations

Ethics approval for this study was obtained from the Ethics Committee of West China Hospital, Sichuan University (approval 2019-33), and all procedures strictly followed relevant ethical guidelines and regulations. Written informed consent was obtained from all participants, who were fully informed of their rights. Participant data were anonymized to ensure privacy and confidentiality, with securely stored, deidentified datasets accessible only to authorized researchers. No financial or

XSL•FO
RenderX

material compensation was provided to participants. The study did not involve the inclusion of any identifiable individuals in images or Multimedia Appendix 1.

Therapeutic Approaches and End Point

Adhering to KDIGO (Kidney Disease: Improving Global Outcomes) guidelines, our collaborative treatment approach between physicians and patients consists of 3 main protocols: supportive care with angiotensin-converting enzyme inhibitors (ACEIs) or angiotensin receptor blockers (ARBs), glucocorticoid administration starting at 0.5-1 mg/kg of prednisone with subsequent tapering, and a regimen of immunosuppressive agents, used with or without additional glucocorticoids [16]. Considering medication effects on the immune system, we merged glucocorticoid administration and immunosuppressive agents into immunosuppressive therapy (IST). The study aimed to evaluate composite outcomes, including end-stage renal disease, kidney transplantation, mortality, or significant declines in eGFR exceeding 50%.

Data Processing and Unsupervised Clustering

We conducted our analysis using k-means and hierarchical clustering, following data preprocessing that involved imputing missing values with a multilinear interpolation algorithm, standardizing data to zero mean and unit variance, and reducing dimensionality with uniform manifold approximation and projection [27,28]. The k-means algorithm clusters data by first randomly assigning centroids and then iteratively relocating them to minimize intracluster variance, stabilizing when centroid movement ceases. Hierarchical clustering generates a dendrogram through agglomerative or divisive strategies: agglomerative starts with individual points as clusters, merging the most similar until one remains, while divisive begins with a single cluster that is continually split until each data point is isolated.

Network Biomarkers

We conducted a perturbation analysis using a single sample-specific network approach to analyze individual samples, comparing their attributes with a reference group of 50 healthy individuals to identify distinctive features. Using graph feature engineering techniques, we extracted attributes at 3 network levels: node, subgraph, and global graph, to gain comprehensive insights. Node-level analysis included degree analysis to assess connectivity. At the subgraph level, we evaluated significant features like diameter and average clustering coefficient to identify disease-relevant patterns. At the global level, we analyzed node and edge counts and the number of connected components. Using the *Networkx* package (version 2.2) in Python (version 3.1.2; Python Software Foundation), we extracted 46 attributes for each sample's network, which were used for clustering analysis [19,29,30].

Interpretability Assessment of Unsupervised Clustering Algorithms

Unsupervised clustering algorithms, while powerful in detecting latent patterns, often lack interpretability. To address this issue, the subgroups identified by these algorithms were used as surrogate labels to develop a predictive framework through machine learning. This framework was refined using 10-fold cross-validation. An interpretability analysis was subsequently conducted on the proficient machine learning models using the Shapley Additive Explanations method, aiming to elucidate key indicators influencing classification outcomes [31].

External Validation and Subsequent Omics Validation Labels

We applied data standardization and uniform manifold approximation and projection dimensionality reduction to the entire dataset rather than individual data points, using the patient cohort from the cluster set as the reference dataset. Each new patient was then processed sequentially using the standardization and dimensionality reduction models that were initially trained on this cluster set. After dimensionality reduction, the clustering model—previously trained on the cluster set—was used to assign a corresponding cluster label to each patient. This methodology ensures consistent treatment of new data within the established framework.

Processing for Metabolomics Analysis

After fasting for at least 8 hours, about 5 mL of blood was drawn into anticoagulant-free vacutainers in the morning. These were left at room temperature to clot for 30 minutes before centrifuging at 3000 rpm for 10 minutes. The supernatant was then transferred to 1.5-mL Eppendorf tubes and stored at –80 °C for analysis.

Samples were thawed and prepared for ultraperformance liquid chromatography-mass spectrometry analysis, involving protein removal and reconstitution in a specific solvent. Hydrophilic interaction liquid chromatography was performed using a precise column and electrospray ionization for detection in both ionization modes. Mass spectrometry data were processed to identify peaks and extract ion features, with quality control measures to assess the variability of each metabolite, excluding those with a coefficient of variation over 20%. After sum normalization, data analysis included partial least-squares discrimination (PLS-DA) and calculation of variable importance in projection (VIP) values for each metabolite, considering VIP values >1 as statistically significant.

Processing of Gut Microbiota Data

Approximately 4 g of fresh fecal samples were collected in sterile containers and stored at –80 °C for high-throughput sequencing. DNA was extracted from the samples, and its quantity and purity were assessed. The 16S ribosomal ribonucleic acid (rRNA) V3-V4 hypervariable regions were then amplified using specific primers and sequenced on the Illumina MiSeq platform. Raw sequencing reads were quality-filtered and clustered into operational taxonomic units at a 97% similarity threshold using UPARSE. The 16S rRNA sequences were classified using the ribosomal database project classifier algorithm against the Silva (SSU123) 16S rRNA database. Quality-controlled and standardized abundance data were used for subsequent analysis at the genus level.

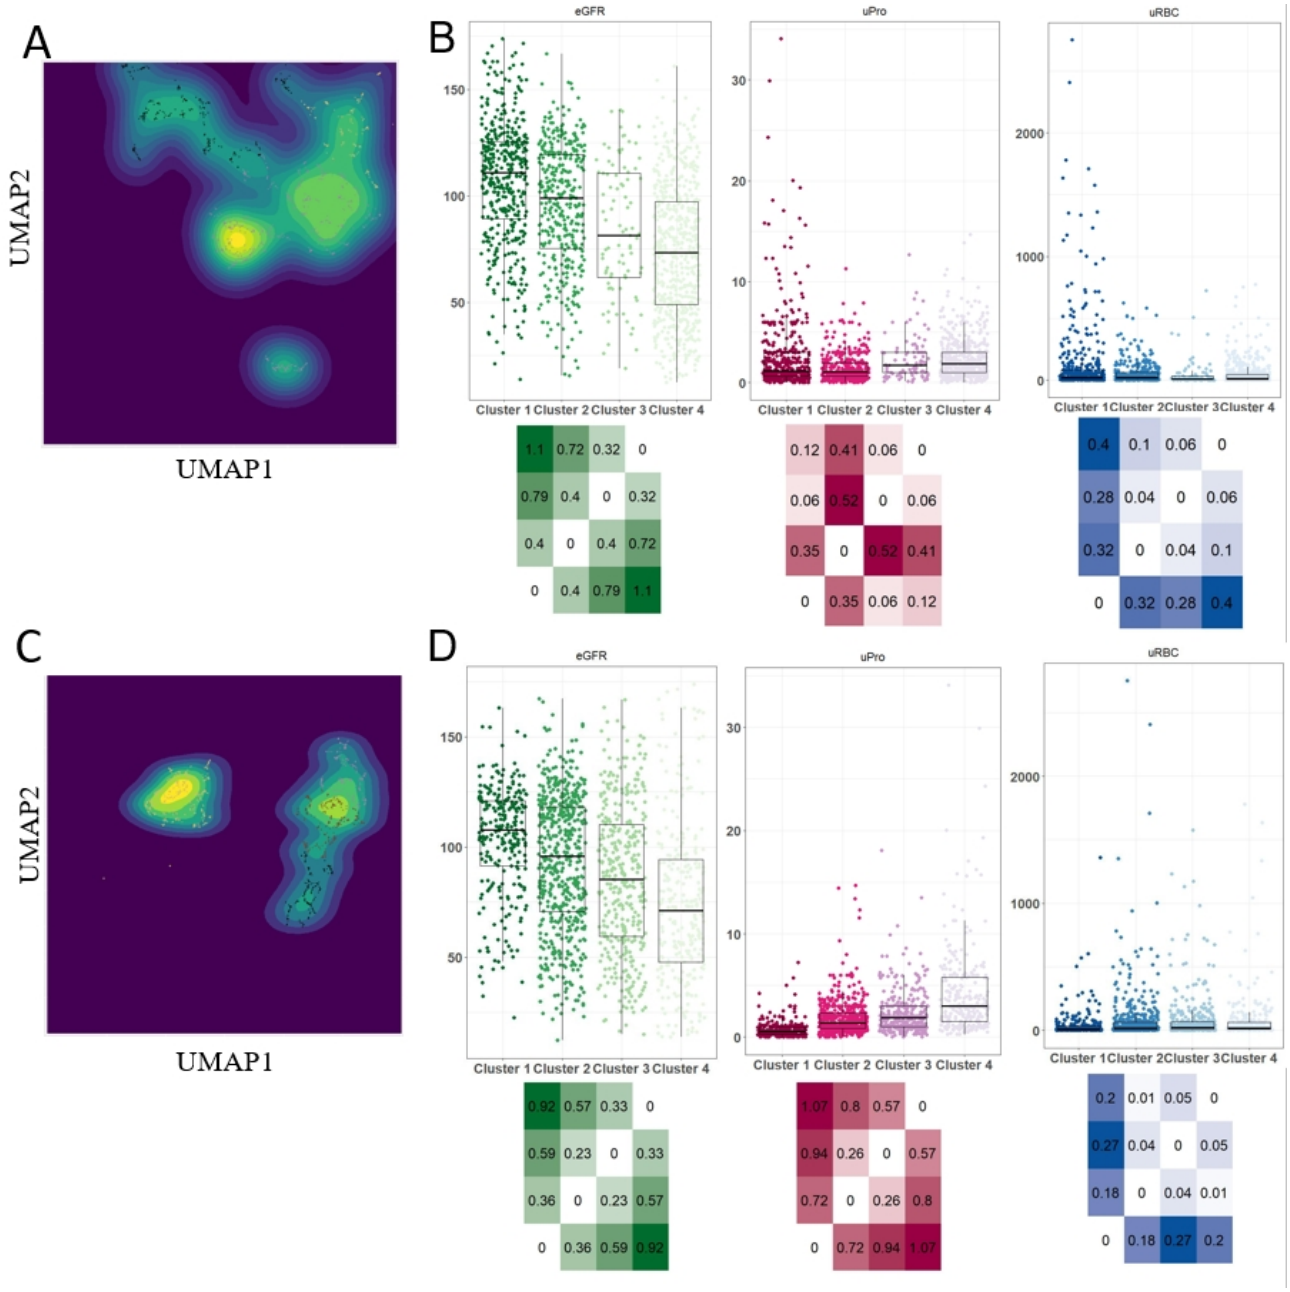
Statistical Analysis

Survival curves were generated using the Kaplan-Meier method, and differences between groups were assessed using the log-rank test. To estimate hazard ratios (HRs) and their 95% CIs, Cox

XSL•FO
RenderX

proportional hazards models were used, with *P* values less than .05 indicating statistical significance. Additionally, extreme gradient boosting models were used to explore the associations between cluster labels and primary outcomes, with model performance evaluated by the area under the receiver operating characteristic curves. The standardized effect size differences among subtypes were quantified using Cohen *d*. Correlation network figures were constructed based on Spearman or Pearson correlation analyses to examine interactions between various metabolites and gut microbiota; edges were added to the network for any correlation with a *P* value below .05. Furthermore, Mantel tests were applied to analyze the associations between groups of clinical indicators and either metabolites or gut microbiota.

Results



Enhanced Performance of K-Means Clustering With Network Biomarkers in IgAN Stratification Over Other Unsupervised Learning Approaches

We curated a cohort of 1460 patients from West China Hospital of Sichuan University, strictly adhering to stringent inclusion criteria for our clustering set. The average follow-up period was 58.8 (SD 28.8) months. Our comprehensive dataset included demographics, clinical records, pathology, and treatment details such as age, blood pressure, serum creatinine, eGFR, 24-hour urine protein, urine red blood cell count, uric acid, renal immunofluorescence markers, Oxford MESTC classification (M, S, E, T, C), global and arteriolar sclerosis, lifestyle factors (smoking and drinking), liver function, comorbidities (diabetes and hepatitis B), and lipid metabolism markers.

We used hierarchical clustering and k-means methods, which are widely used in the medical field for unsupervised clustering [17,32,33]. These methods used 3 sets of indicators: the first set included demographic and renal indicators, the second set combined renal and extrarenal indicators, and the third set comprised network biomarkers derived from all indicators. The objective was to explore whether classifications based on a broader range of systemic markers could outperform those focusing solely on renal indicators, aiming to address potential shortcomings in existing stratification schemes and guidelines. Network biomarker construction was based on references from our prior research [29]. All 6 clustering methods successfully categorized all patients with IgAN into 4 groups, as demonstrated in Figure 2 and Figures S1-S4 in Multimedia Appendix 1. As cluster numbers rose from 1 to 4, symptom severity increased, reflecting closely with clinical evaluations, as evidenced by declining mean eGFR values and rising mean proteinuria values. Although clinical intuition enabled physicians to categorize patients using all indicators, this experience-based and direct judgment alone was not consistently accurate in dividing patients into 4 groups, especially regarding cluster 2 and cluster 3.

XSL•FO
RenderX

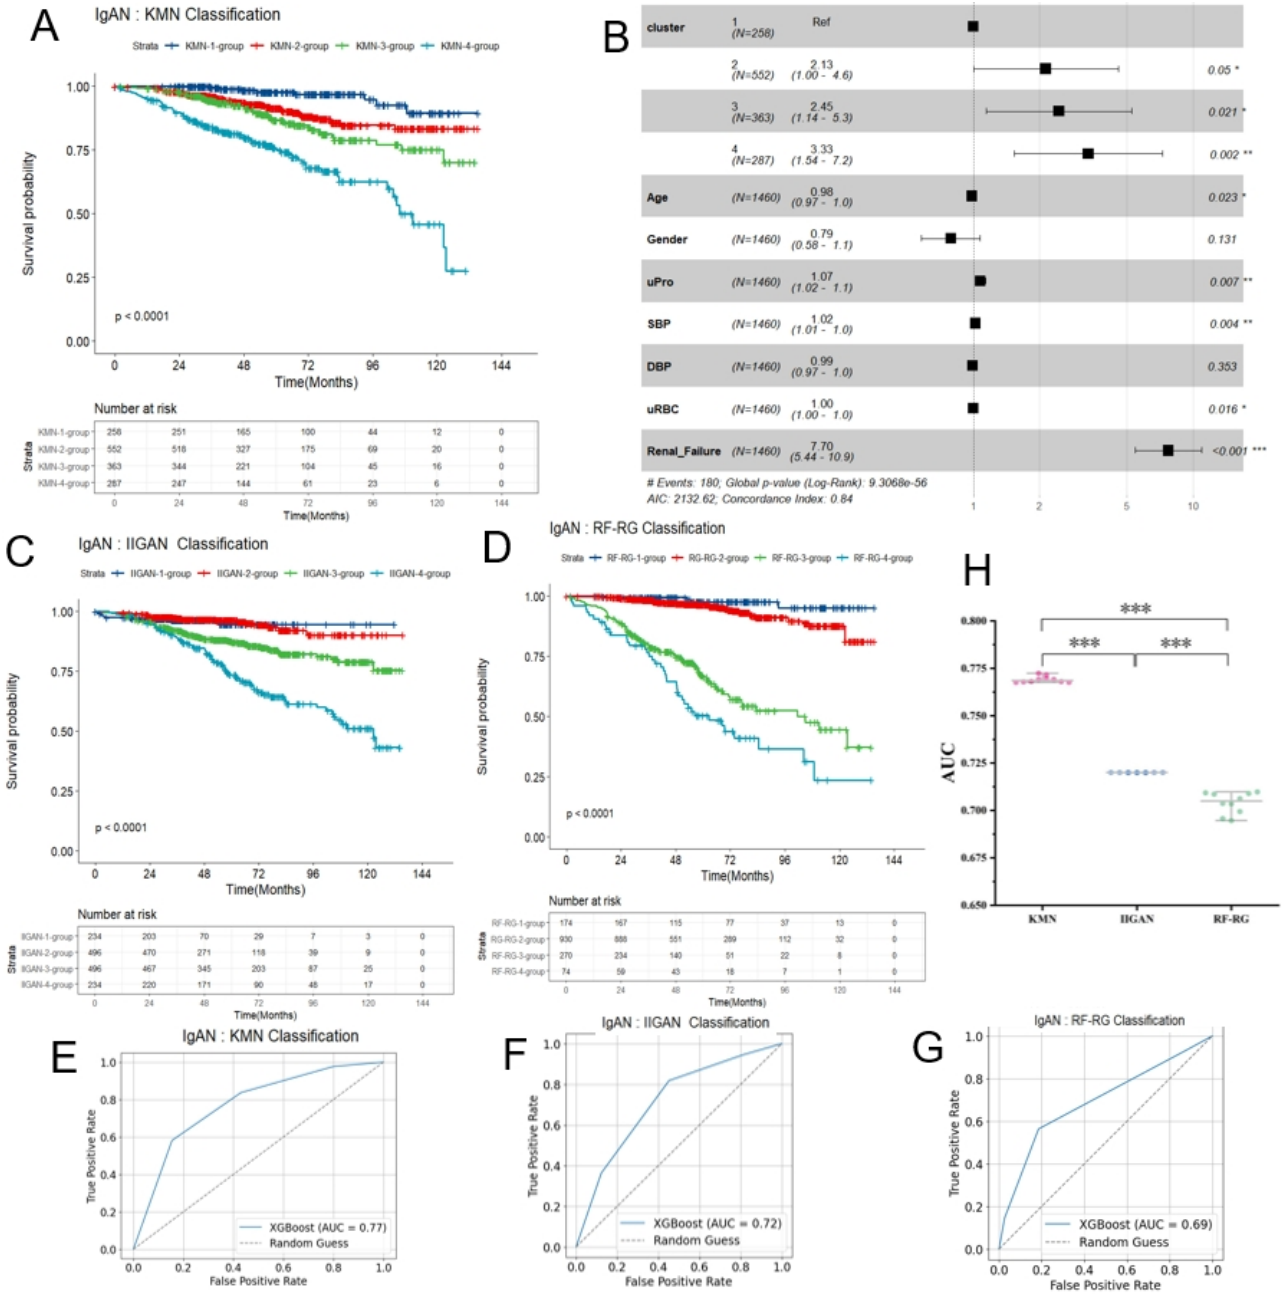


Figure 2. Clustering based on unsupervised learning with renal and extrarenal indicators and network biomarkers. (A) Visual representation of UMAP-reduced datasets integrated with k-means clustering, focusing on renal and extrarenal indicators. Each individual is stratified by subtype and depicted through density plots, highlighting the distribution within each group. (B) Analysis of the subtypes derived from the methodologies described in (A), presented using scatter boxplots and heatmaps. These illustrate the pairwise standardized effect size differences (Cohen d) between subtypes, facilitating a clear comparison of indicator levels across groups. (C) Visual representation of UMAP-reduced datasets combined with k-means clustering, focusing on network biomarkers. Individuals are stratified by subtype and depicted through density plots to showcase the clustering outcome. (D) Analysis of the subtypes derived from the methodologies described in (C), presented using scatter boxplots and heatmaps. These visualizations detail the pairwise standardized effect size differences (Cohen d) between subtypes, providing insights into the variation of network biomarkers across different groups. eGFR: estimated glomerular filtration rate; UMAP: uniform manifold approximation and projection; uPro: urine protein; uRBC: urine red blood cell count.

Unsupervised clustering not only accurately differentiated patients but also proved highly effective in evaluating IgAN prognosis. Among the 6 methods used, 3 stood out for effectively reflecting IgAN prognosis: hierarchical clustering based on renal indicators, k-means clustering based on all indicators, and k-means clustering based on network biomarkers (KMN). Kaplan-Meier curves for the 4 clusters showed significant differences (P<.0001; Figure 3A and Figure S5A and B in Multimedia Appendix 1), indicating their prognostic relevance, as supported by a multivariable Cox regression model adjusted for age, gender, urine protein, urine red blood cells, renal function, and blood pressure (P<.0001; Figure 3B and Figure S3C and D in Multimedia Appendix 1). Figure S6 in Multimedia Appendix 1 presents further prognostic parameters, reinforcing previous findings: notably, cluster 1 has the best prognosis, whereas cluster 4 has the worst, consistent with clinical categorizations.

XSL•FO

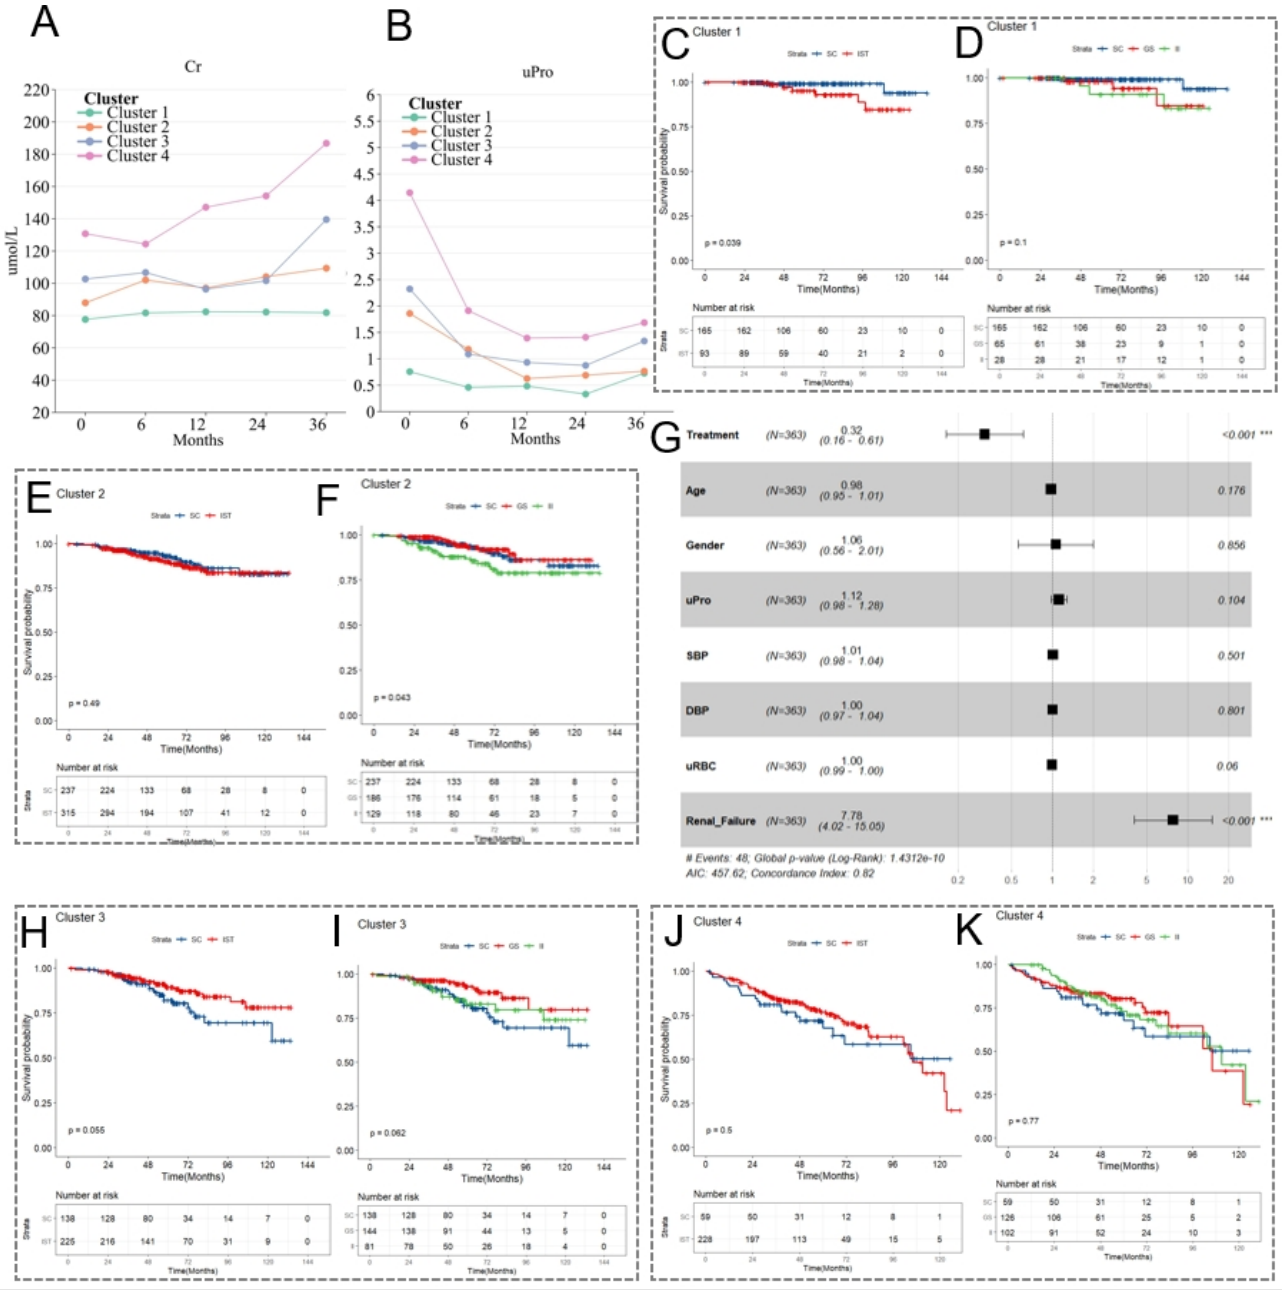
Figure 3. Survival analysis comparisons across different classification methods for IgAN. (A) Kaplan-Meier curves illustrating mortality rates in IgAN, stratified by KMN grouping. (B) Forest plot illustrating the results of a multifactor Cox regression analysis, stratified by KMN grouping. (C). Kaplan-Meier curves showing IgAN mortality rates, stratified by IIGAN grouping. (D) Kaplan-Meier curves detailing IgAN mortality rates, stratified by RF-RG grouping. (E) ROC curve for the KMN grouping, with an AUC value of 0.77. (F) ROC curve for the IIGAN grouping, featuring an AUC value of 0.72. (G) ROC curve for the RF-RG grouping, with an AUC value of 0.69. (H) Comparison of AUCs for classification schemes in IgAN risk stratification. **P*<.05, ***P*<.01, ****P*<.001. AIC: Akaike information criterion; AUC: area under the curve; DBP: diastolic blood pressure; IgAN: immunoglobulin A nephropathy; IIGAN: International Risk-Prediction Tool in Immunoglobulin A Nephropathy; KMN: k-means clustering based on network biomarkers; RF-RG: renal function–renal histology grading; ROC: receiver operating characteristic; SBP: systolic blood pressure; uPro: urine protein; uRBC: urine red blood cell count; XGBoost: extreme gradient boosting.



We evaluated the effectiveness of various clustering methods in reflecting IgAN prognosis solely by using cluster labels as input variables and assessing the area under the curve (AUC). This approach holds significant value in assessing the predictive performance of the model. Our study found that KMN exhibited the highest AUC at 0.77 (Figure 3E), outperforming hierarchical clustering based on renal indicators (0.71; Figure S5E in Multimedia Appendix 1) and k-means clustering based on all indicators (0.75; Figure S5F in Multimedia Appendix 1), indicating superior predictive power for KMN and surpassing methods that rely solely on renal indicators by 0.6. Therefore, the k-means clustering approach, based on network biomarkers, was recommended for stratifying IgAN risk.

To further investigate the impact of the KMN stratification on the prognosis of IgAN, we assessed the 3-year trajectories of urinary protein and serum creatinine across different patient groups. Figure 4A and B and Figures S7 and S8 in Multimedia Appendix 1 demonstrate that most patients in cluster 1 exhibited relatively stable average urinary protein levels and normal fluctuations in creatinine levels. Patients in cluster 2 had higher

XSL•FO
RenderX

baseline levels of urinary protein and creatinine than those in cluster 1 but exhibited a declining trend in urinary protein over time. Meanwhile, their creatinine levels increased slightly, with most remaining within chronic kidney disease stages 1, 2, or 3a by the third year. In cluster 3, patients experienced a reduction in urinary protein at the 6-month mark compared to baseline but maintained higher levels (around or above 1 g in 24 hours) throughout the 3 years, with both creatinine and urinary protein showing significant increases by the third year, indicating a potential rapid deterioration of their condition. Patients in cluster 4, having the most severe prognosis, showed a consistent yearly increase in creatinine, quickly progressing toward renal failure, and maintained high levels of urinary protein. These findings suggested that patients in different KMN stratifications had distinct trajectories, indicating that KMN stratification could serve as an effective prognostic marker for IgAN.

Superiority of KMN Stratification Over IIgAN-PT and RF-RG Schemes

To determine if our KMN scheme outperforms the globally used renal marker–based IIgAN-PT and RF-RG schemes [12,15], we first assessed the applicability of IIgAN-PT and RF-RG to our cohort. As shown in Figure 3C and D, the stratification of our cohort into 4 groups using RF-RG and IIgAN-PT classification methods clearly demonstrates significant disparities in the Kaplan-Meier curves (P<.0001), confirming the prognostic utility of these schemes for our cohort. Multivariable Cox regression analysis (Figure S9 in Multimedia Appendix 1) revealed that in IIgAN-PT, compared to cluster 1, the HRs for clusters 2, 3, and 4 were 0.79 (95% CI 0.35-1.79), 1.69 (95% CI 0.80-3.59), and 3.03 (95% CI 1.41-6.53), respectively. Similarly, for RF-RG, the HRs for clusters 2, 3, and 4 were 2.28 (95% CI 0.81-6.42), 6.60 (95% CI 2.08-20.96), and 8.54 (95% CI 2.55-28.63), respectively. These results suggest that all 6 of our clustering approaches outperformed the RF-RG and IIgAN-PT schemes. Considering potential collinearity between the primary indicators used in these models and the covariates adjusted in our Cox regression, we primarily assessed the models using AUC values. The AUC values for IIgAN-PT and RF-RG were 0.72 (Figure 3F) and 0.69 (Figure 3G), respectively, indicating that IIgAN-PT performs better than RF-RG but is inferior to our KMN model, which achieved an AUC of 0.77 (Figure 3E). We conducted 10 rounds of random sampling to generate AUC values for each classification scheme. A Mann-Whitney U test on the resulting AUC values revealed that the P values for differences between any 2 classification schemes were less than .001. These results confirm statistically significant differences between the methods, with our clustering approach outperforming both RF-RG and IIgAN-PT (Figure 3H).

External Validation of KMN Stratification

To assess whether our risk stratification could be applied to external cohorts, we conducted further validation by including 200 patients with IgAN who met the inclusion and exclusion criteria from the Affiliated Hospital of Zunyi Medical University, Zigong Third People's Hospital, and People's Hospital of Mianzhu City. Our findings indicated that the KMN-based stratification effectively categorized patients in these additional cohorts, with clinical symptoms and predictive performance consistent with previous results (Figure S10 in Multimedia Appendix 1).

Guidance of Treatment Decisions by KMN Stratification Scheme

The current treatment for IgAN predominantly relies on ACEIs or ARBs, with the option of IST for more severe cases. The KIDGO guidelines focus mainly on creatinine and urinary protein levels, offering less guidance on pathological indices or systemic status [16], and do not provide specific recommendations for therapies under the IIgAN-PT or RF-RG schemes [12,15]. Our study aimed to determine if our KMN stratification could effectively guide immunosuppressive treatment for IgAN, a topic currently under debate [34-36]. While recent studies have introduced new therapeutic options such as atacicept [37], telitacicept [38], sparsentan [39], irbesartan [40], and dapagliflozin [41], these were not used in our cohort, which primarily consists of patients followed for over 3-5 years before these drugs were fully available. We explored the utility of KMN stratification in guiding IST through Cox multivariable regression and survival curve analyses as shown in Figure 4 and Figure S11 in Multimedia Appendix 1.

The Kaplan-Meier curve shows significant differences in survival rates within cluster 1 between supportive care, primarily using ACEIs or ARBs, and various ISTs including glucocorticoids and other immunosuppressive agents, underscoring that these therapies might not confer any additional benefit for these patients.

In cluster 2, there was no significant difference between IST and supportive care (P=.49), with supportive care and glucocorticoids performing similarly and better than immunosuppressive agents (P=.04). Given the significant side effects of glucocorticoids and the negative results from multivariable Cox regression for immunosuppressants, supportive care remains the preferred treatment for this group.

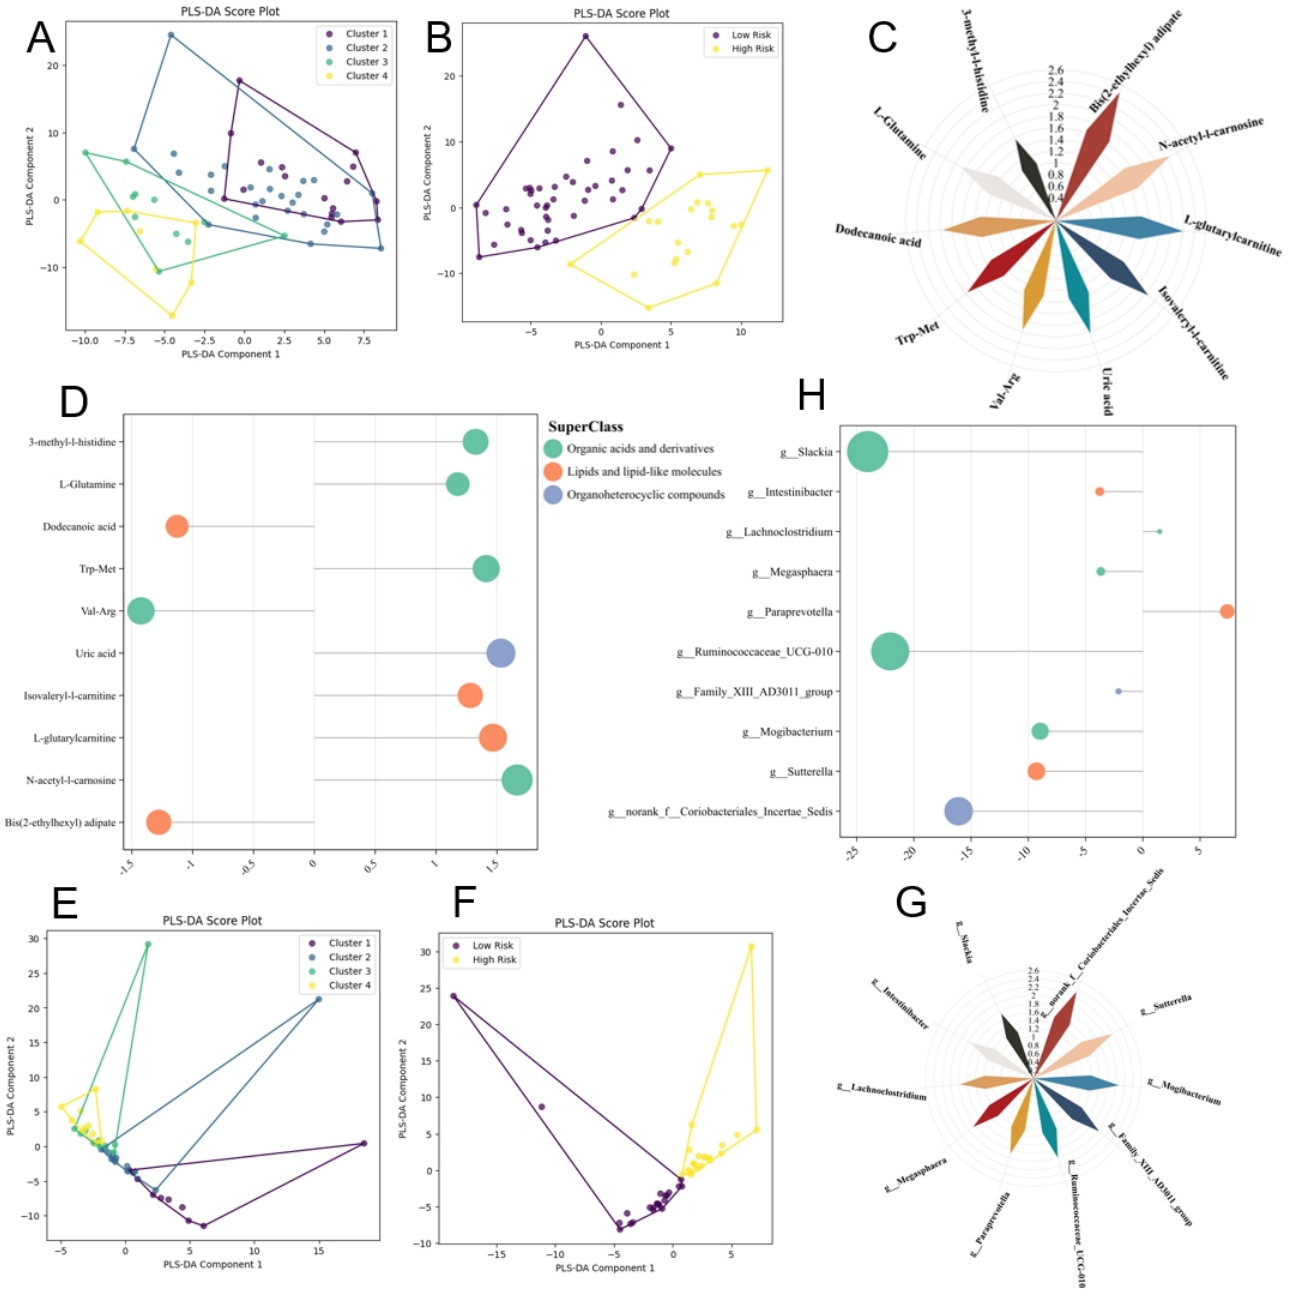
For cluster 3, glucocorticoids were found to slightly outperform other immunosuppressants, which themselves were marginally better than supportive care alone (P=.06). Combining glucocorticoids and immunosuppressants demonstrated a clear advantage over supportive care (P=.05). Multivariable Cox regression (Figure 4G) revealed a significant renal protective effect of this combined IST, with an HR of 0.32 (95% CI 0.16-0.61). Given the data showing poor prognosis and rapid renal deterioration typically within 3 years for cluster 3 patients, we strongly recommend immunosuppressive treatment, favoring glucocorticoids or, if intolerable, alternative immunosuppressants such as mycophenolate mofetil.

For cluster 4, which had the poorest prognosis, survival curves and Cox regression analyses showed no significant differences between immunosuppressive treatment and supportive care. However, upon closer examination, immunosuppressive treatment outperformed supportive care for up to 96 months, with intersections thereafter likely due to the small number of patients followed for this duration, which could explain the absence of statistical significance. Given the severity of their condition, immunosuppressive treatment should be considered for these patients if they could manage the side effects, with decisions tailored to individual circumstances.

Interpretable Analysis of KMN Stratification

Unsupervised clustering based on network biomarkers exhibited a "black box" nature; while effective in assessing clinical severity, prognosis, and treatment, it lacked intuitive interpretation. Therefore, we conducted an innovative interpretive analysis of the unsupervised clustering approach, which might offer additional insights for clinical practice. Figure S12 in Multimedia Appendix 1 highlights the key factors influencing the KMN classification, revealing significant network parameters such as diameter, nodes, and edges. Notably, the networks centered on urinary protein, red blood cells, age, and eGFR were particularly crucial for stratifying IgAN. We further analyzed the networks centered on these parameters for patients in clusters 1-4, discovering significant differences

XSL•FO
RenderX



among these groups (Figures S13-S16 in Multimedia Appendix 1). This suggested that not only did urinary protein, urinary red blood cells, age, and eGFR individually impact the prognosis of IgAN, but the relationships between these markers and other indicators also significantly correlated with outcomes. This aspect was often overlooked by traditional statistical methods, which had primarily focused on isolated indicators, especially renal-related ones, neglecting the statistical significance of these networks.

Metabolomic Diversity Analysis Based on KMN Stratification

To identify potential serum metabolomic markers for the progression of IgAN, we used the KMN method to stratify 63 new patients with blood metabolomics data into 4 clusters: cluster 1 with 17 individuals, cluster 2 with 27, cluster 3 with 11, and cluster 4 with 8. After quality control and normalization of the metabolomics data, we conducted a PLS-DA model analysis and observed a distinct separation trend among the 4 clusters (Figure 5A) [42]. Clusters 1 and 2 were then reclassified into a new cohort labeled the low-risk group, and clusters 3 and 4 into a high-risk group. Further PLS-DA analysis of the metabolomic data revealed significant disparities between the high-risk and low-risk classifications (Figure 5B). Additionally, we constructed metabolite interaction networks for the clusters, uncovering distinct intermetabolite relationships across them (Figure S17 in Multimedia Appendix 1). These findings indicated that the differences in serum metabolites between various risk levels of IgAN were significant and that changes in their interaction networks might also contribute to the disease's progression.

XSL•FO
RenderX

Figure 5. Differentiation of serum metabolites and gut microbiota in IgAN progression revealed by KMN grouping. (A) PLS-DA score plots vividly illustrating the separation trends of serum metabolites among the 4 KMN clusters (1, 2, 3, and 4). (B) PLS-DA analysis highlighting significant structural differences in serum metabolites between the high-risk IgAN groups (clusters 3 and 4) and low-risk IgAN groups (clusters 1 and 2). (C) Windrose visualization of variable importance in projection values for metabolites across the 4 grouped PLS-DA models, demonstrating the impact of key metabolites in differentiating the clusters. (D) Bar graph showing the fold changes of differential metabolites in high-risk groups compared to low-risk groups, indicating their increase or decrease in abundance. (E) PLS-DA score plots vividly showcasing the separation trends of gut microbiota among the 4 KMN clusters. (F) PLS-DA analysis indicating significant structural differences in gut microbiota between the high-risk IgAN groups and low-risk IgAN groups. (G) Windrose visualization of variable importance in projection values for gut microbiota across the 4 grouped PLS-DA models, highlighting the impact of key microbiota at the genus level in differentiating the clusters. (H) Bar graph illustrating the fold changes of differential gut microbiota on the genus level in high-risk groups compared to low-risk groups, showing their increase or decrease in abundance. IgAN: immunoglobulin A nephropathy; KMN: k-means clustering based on network biomarkers; PLS-DA: partial least-squares discrimination.

Through VIP analysis of the PLS-DA models for the 4 clusters, we identified the top 10 metabolites that most significantly differentiate the clusters (Figure 5C and D). Notably, levels of bis(2-ethylhexyl) adipate (3-dehydroepiandrosterone sulfate [DEHA]), Val-Arg, and dodecanoic acid were reduced in the high-risk group. DEHA, a plasticizer not typically found in the human body and primarily ingested externally, has no well-documented links to renal diseases, and its metabolic pathways in the body remain unclear. Some studies suggest DEHA could have carcinogenic effects, cause DNA damage, and disrupt steroidogenesis pathways [43-46]. We hypothesize that in high-risk IgAN, abnormal kidney function could decrease the renal excretion of microplastics, leading to their uptake by cells, potentially causing cellular damage, though further experimental evidence is needed to confirm this. Additionally, Val-Arg, a dipeptide involved in protein metabolism, and

XSL•FO
RenderX

dodecanoic acid, a medium-chain fatty acid, may indicate disruptions in protein and fatty acid metabolism in high-risk patients.

Conversely, levels of N-acetyl-L-carnosine (a dipeptide with antioxidant properties) [47], L-glutarylcarnitine and isovaleryl-L-carnitine (both involved in fatty acid metabolism) [48,49], uric acid, Trp-Met (a tryptophan and methionine complex indicating protein metabolism), L-glutamine (an amino acid vital for immune function) [50,51], and 3-methyl-L-histidine (a marker of muscle metabolism) [52] were elevated in the high-risk group, pointing to enhanced oxidative stress and altered protein and energy metabolism in these patients.

An interesting finding from our study was the strong correlation among metabolites, which suggested that their collective interactions might influence the severity of IgAN and potentially lead to poor outcomes (Figure S18A in Multimedia Appendix 1). Additionally, by focusing on these metabolites, we explored the metabolite networks across different clusters and observed distinct network patterns between them (Figures S19-S25 in Multimedia Appendix 1). These variations in metabolite levels and their interactions could provide insights into the mechanisms underlying IgAN progression, particularly in high-risk individuals.

Further investigation into the relationship between these metabolites and clinical indicators revealed that, except for Val-Arg, which demonstrated a statistical correlation with kidney function, the levels of other metabolites did not correlate with traditional renal function markers such as urinary protein, red blood cells, and pathological lesions. This finding suggests that classifications based solely on renal function markers might miss crucial metabolites that play a significant role in the disease's progression. Therefore, our KMN stratification offers a novel approach to understanding the complex mechanisms driving IgAN progression, highlighting the importance of broader biomarker profiles in disease analysis.

Gut Microbiota Diversity Analysis Based on KMN Stratification

Similarly, we recruited an additional 45 patients, stratified into 4 clusters using the KMN method: 9 individuals in cluster 1, 14 in cluster 2, 12 in cluster 3, and 10 in cluster 4. We conducted gut microbiome sequencing on these individuals. Subsequent PLS-DA model analysis of the reclassified cohorts revealed significant disparities between the high- and low-risk groups (Figure 5E and F), indicating substantial differences in the gut microbiomes among patients with varying risk levels. Additionally, the analysis of microbiome interaction networks (Figure S29 in Multimedia Appendix 1) clearly showed distinct intermicrobial relationships across the clusters, suggesting that changes in these interactions may be related to disease progression.

Through VIP analysis of the PLS-DA models for the 4 clusters, significant variances in gut microbiota were identified, delineating distinct profiles between high- and low-risk groups (Figure 5G and H). Elevated levels of *Paraprevotella* and *Lachnoclostridium*—the latter closely linked to kidney function (Figure S18B in Multimedia Appendix 1)—in the high-risk group suggest their role in exacerbating IgAN through gut dysbiosis, given their association with inflammatory processes [53,54]. Conversely, decreased levels of norank_f_Coriobacteriales_Incertae_Sedis, *Sutterella*, *Mogibacterium*, Family_XI AD3011_group, Ruminococcaceae_UCG-010, *Megasphaera*, *Intestinibacter*, and *Slackia* were noted. These genera might be involved in fermenting dietary fibers and producing short-chain fatty acids, essential for colon health and immune modulation [55,56]. Their reduced presence might suggest a loss of protective microbial functions in patients at higher risk of disease progression. Additionally, the interaction patterns between these microbiota batches underscore the potential of gut bacteria as biomarkers for stratifying IgAN risk and highlight the complex relationship between gut health and kidney disease (Figures S26-S34 in Multimedia Appendix 1). However, these causal relationships need to be substantiated by further studies.

Discussion

Principal Findings

Our study used network biomarkers combined with unsupervised clustering to develop a novel stratification scheme for IgAN, offering distinct advantages over existing approaches. By integrating a broad array of variables, including but not limited to renal indicators—such as liver function, lipid metabolism, comorbidities, and lifestyle factors—our method offers a more holistic assessment of patients. Additionally, we examined the interrelationships among these indicators, applying clustering techniques to their interaction vectors, which may more accurately reflect biological interactions. Our stratification scheme has undergone external validation, indicating potential applicability to diverse cohorts. Clinically, this stratification could assist in personalizing treatment, suggesting supportive ACEI or ARB treatment for patients in lower-risk groups (clusters 1 and 2) and potentially considering IST for those in higher-risk groups (clusters 3 and 4).

To our knowledge, our study was the first to integrate k-means clustering with network biomarkers. K-means clustering partitions patients into a predetermined number of clusters based on their similarity to cluster centroids, which is computationally efficient and well-suited for large datasets [32,57]. This makes it particularly effective for managing high-dimensional data in the classification of patients with IgAN. Network biomarkers, offering several advantages over traditional biomarkers, capture the intricate relationships between different biological factors and provide a nuanced understanding of disease heterogeneity [19,30]. They also offer a system-level view that highlights the interconnectedness of various physiological processes involved in IgAN pathogenesis.

By incorporating network biomarkers into k-means classification models, our method outperformed traditional molecular biomarker–based clustering in distinguishing varying degrees of clinical severity in IgAN. This approach not only more accurately categorized patients but also surpassed existing prognostic models, providing deeper insights into disease progression by our interpretable analysis. The innovative

XSL•FO
RenderX

integration of network biomarkers enhances our ability to capture complex biological interactions and systemic effects that traditional markers might overlook. This improves the accuracy of IgAN prognosis and suggests the method's applicability to other diseases with similar complex traits. The scalability and adaptability of this approach could significantly improve disease classification and management across various clinical cohorts, leading to more personalized and effective treatment strategies.

Previous metabolomic and gut microbiome studies have indicated structural changes in the metabolites and microbiota of patients with IgAN compared to healthy individuals [20,24,26]. However, clinical research exploring their impact on disease progression remains preliminary and simplistic. Most investigations into these substances have been conducted through animal or cell experiments to elucidate the changes in the gut-kidney axis and their influence on IgAN [22,24]. Building on this foundation, our study conducted further research, using the KMN stratification to more accurately predict clinical outcomes for these patients, moving beyond simple classifications based on proteinuria and creatinine. We observed significant differences in serum metabolite structures and gut microbiome compositions between high-risk and low-risk patients with IgAN. Importantly, the interaction networks between metabolites and microbiota also varied distinctly, suggesting that changes in these elements and their interactions are closely linked to the progression of IgAN. Preliminary clinical evidence from our study shows that a reduction in beneficial bacteria and an increase in potentially pathogenic microbes, along with environmental pollution, metabolic abnormalities in proteins and lipids, oxidative stress, and immune dysregulation, collectively contribute to the progression of IgAN [58,59]. These findings are consistent with other basic and clinical research, indirectly validating the clinical relevance of our KMN stratification.

Our study has several limitations that warrant discussion. First, our cohort consisted exclusively of Chinese individuals, lacking diversity in racial data. Given the heterogeneity of IgAN across different races, our existing classification scheme may not be directly applicable to other populations. However, other ethnic groups could potentially use our approach of unsupervised clustering based on network biomarkers to develop tailored classification schemes suited to their specific racial characteristics. Second, our analyses of the gut microbiome and metabolomics were essentially cross-sectional, which, despite using the KMN stratification scheme providing prognostic insights, does not establish causality. Additionally, the sample size was relatively small, meaning that our findings represented only a preliminary characterization of the gut microbiome and serum metabolites to validate the clinical value of our KMN stratification. Further in-depth studies are needed to explore the underlying mechanisms of these findings.

Conclusions

This study developed a novel risk stratification model for IgAN using network biomarkers and unsupervised clustering. The KMN scheme outperformed existing models in predicting disease progression and guiding personalized treatment. Our findings also highlight the potential role of systemic biomarkers, including serum metabolites and gut microbiota, in IgAN management. Further research is needed to validate these insights and enhance clinical applicability.

Abstract

Background: Hypertension is a major global health issue and a significant modifiable risk factor for cardiovascular diseases, contributing to a substantial socioeconomic burden due to its high prevalence. In China, particularly among populations living near desert regions, hypertension is even more prevalent due to unique environmental and lifestyle conditions, exacerbating the disease burden in these areas, underscoring the urgent need for effective early detection and intervention strategies.

Objective: This study aims to develop, calibrate, and prospectively validate a 2-year hypertension risk prediction model by using large-scale health examination data collected from populations residing in 4 regions surrounding the Taklamakan Desert of northwest China.

Methods: We retrospectively analyzed the health examination data of 1,038,170 adults (2019-2021) and prospectively validated our findings in a separate cohort of 961,519 adults (2021-2023). Data included demographics, lifestyle factors, physical examinations, and laboratory measurements. Feature selection was performed using light gradient-boosting machine–based recursive feature elimination with cross-validation and Least Absolute Shrinkage and Selection Operator, yielding 24 key predictors. Multiple machine learning (logistic regression, random forest, extreme gradient boosting, light gradient-boosting machine) and deep learning (Feature Tokenizer + Transformer, SAINT) models were trained with Bayesian hyperparameter optimization.

Results: Over a 2-year follow-up, 15.20% (157,766/1,038,170) of the participants in the retrospective cohort and 10.50% (101,077/961,519) in the prospective cohort developed hypertension. Among the models developed, the CatBoost model demonstrated the best performance, achieving area under the curve (AUC) values of 0.888 (95% CI 0.886-0.889) in the retrospective cohort and 0.803 (95% CI 0.801-0.804) in the prospective cohort. Calibration via isotonic regression improved the model's probability estimates, with Brier scores of 0.090 (95% CI 0.089-0.091) and 0.102 (95% CI 0.101-0.103) in the internal validation and prospective cohorts, respectively. Participants were ranked by the positive predictive value calculated using the calibrated model and stratified into 4 risk categories (low, medium, high, and very high), with the very high group exhibiting a 41.08% (5741/13,975) hypertension incidence over 2 years. Age, BMI, and socioeconomic factors were identified as significant predictors of hypertension.

Conclusions: Our machine learning model effectively predicted the 2-year risk of hypertension, making it particularly suitable for preventive health care management in high-risk populations residing in the desert regions of China. Our model exhibited excellent predictive performance and has potential for clinical application. A web-based application was developed based on our

XSL•FO
RenderX

predictive model, which further enhanced the accessibility for clinical and public health use, aiding in reducing the burden of hypertension through timely prevention strategies.

KEYWORDS

hypertension; desert; machine learning; deep learning; prevention; clinical applicability

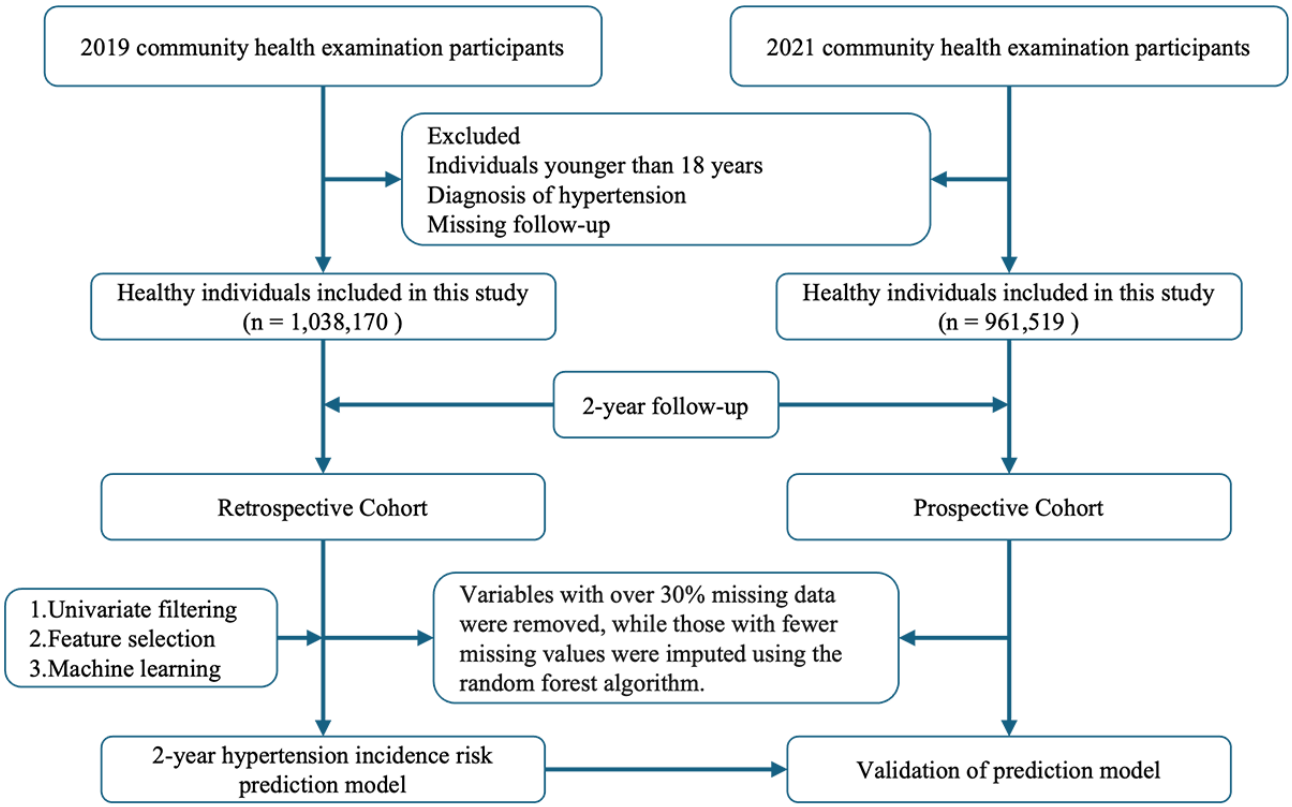
Introduction

Cardiovascular diseases are among the leading causes of chronic noncommunicable diseases worldwide and have become the primary cause of death globally [1]. Hypertension, a major preventable risk factor for cardiovascular disease, accounts for approximately 50% of all cardiovascular-related deaths globally [2]. In China, the prevalence of hypertension has been rising due to rapid urbanization, increasing affluence, and an aging population. Recent surveys estimate that approximately 244.5 million Chinese adults (23.2%) are affected by hypertension, with this number continuing to increase [3,4]. In northwestern China, populations residing in the Taklamakan Desert region face unique public health challenges, as harsh environmental conditions such as extreme temperature fluctuations, frequent sandstorms, particulate matter pollution, and limited greenspace are associated with an elevated prevalence of hypertension [5-7]. Given the increasing burden of hypertension, there is an urgent need for effective tools to identify high-risk individuals early and implement preventive measures.

Numerous hypertension risk prediction models have been developed using electronic health records based on a variety of methodological approaches, including traditional statistical techniques such as Cox regression and logistic regression, as well as machine learning and deep learning methods [8,9]. Although these models have demonstrated promising discriminatory power, several limitations persist. First, many studies have constructed models using small sample sizes or data from a single medical center, thereby limiting the external validity and generalizability of these models [10-14]. Second, a significant proportion of models lack validation on prospective datasets or independent external datasets, which impedes the comprehensive assessment of model robustness [12,15-18]. Additionally, some models incorporate an excessive number of variables or include variables that are not easily accessible in health examinations, thus hindering their practical application [19,20]. Finally, the majority of these models have been developed using data from European and American populations, thereby limiting their applicability to populations in other regions, including Asia.

Therefore, the objective of this study was to develop and prospectively validate a 2-year hypertension incidence risk prediction model by using health examination data collected from populations residing in 4 regions surrounding the Taklamakan Desert between 2019 and 2023. Our model aims to stratify individuals by their risk of developing hypertension, thus facilitating targeted prevention and early intervention strategies.

Methods



Data Source and Study Design

This retrospective cohort study utilized health examination data from adults collected between 2019 and 2021 at 1750 hospitals and community clinics across 4 regions surrounding the Taklamakan Desert of northwest China. Participants' health records were categorized into 3 components: personal and lifestyle information, standard physical examinations, and clinical measurements. Personal and lifestyle data included demographic details, personal and family medical histories, smoking and alcohol consumption habits, dietary patterns, and physical activity levels. Standard physical examinations recorded BMI, waist circumference, heart rate, and blood pressure, while clinical measurements assessed blood biochemical parameters.

A total of 2,872,837 participants were initially included. After applying the following exclusion criteria, that is, (1) individuals younger than 18 years, (2) individuals with a prior diagnosis of hypertension, and (3) participants with incomplete follow-up data, the final study cohort comprised 1,038,170 participants. For external validation, data from a prospective cohort (2021-2023) were employed, following the exclusion criteria outlined in Figure 1. Variables with more than 30% missing data were excluded from the analysis, following the methodology used in a previous study [21]. For variables with fewer missing values, the random forest algorithm was used for imputation. Multimedia Appendices 1 and 2 provide detailed information on the percentage of missing values for each variable in the retrospective and prospective cohorts prior to imputation.

Figure 1. Flowchart illustrating the exclusion criteria, missing data handling, feature selection, model building (2019-2021), and validation (2021-2023) for the 2-year hypertension risk prediction study across 4 Taklamakan Desert–adjacent regions in northwest China.

Ethics Approval

This study was approved by the Tsinghua University Science and Technology ethics committee (Medicine; project: 20240123). The data used in this research were collected and managed by the Xinjiang Uygur Autonomous Region Health Commission and were fully anonymized and deidentified before being accessed. According to ethical guidelines in China (Section 3.32), the secondary use of anonymized health data for research purposes is exempt from requiring additional informed consent from individual patients [22]. This exemption aligns with international research practices [23]. Researchers accessed the anonymized data through a designated, secure platform without internet connectivity, ensuring strict data privacy and security protocols. Neither the manuscript nor the supplementary materials contain identifiable information or images of participants, and no financial compensation was involved, as this study was based on secondary data analysis.

Definition of Hypertension

Blood pressure was measured by trained health care professionals by using standardized protocols. The average of 3 consecutive right-arm measurements, taken 30 seconds apart, was used for analysis. Hypertension was defined by any of the following criteria: (1) self-reported diagnosis of hypertension, (2) current use of antihypertensive medication, or (3) an average systolic blood pressure ≥140 mm Hg, diastolic blood pressure ≥90 mm Hg, or both [24,25].

Statistical Analysis

The Kolmogorov-Smirnov test was used to assess whether continuous variables followed a normal distribution. To compare baseline characteristics between participants with and without hypertension, we applied the chi-square test for categorical variables, while continuous variables were analyzed using either the independent-sample *t* test (2-sided) or the rank-sum test, depending on the distribution characteristics.

Prediction Modeling and Evaluation

Participants from the retrospective cohort were randomly assigned to training and internal validation sets in a 7:3 ratio. Feature selection commenced with univariate logistic regression analyses to identify independent risk factors. Subsequently, both light gradient-boosting machine (LightGBM)–based recursive feature elimination with cross-validation (RFECV) [26,27] and Least Absolute Shrinkage and Selection Operator (LASSO) methods were applied to further refine the feature set. The final predictive features were determined by selecting the intersection of variables identified by both LightGBM-RFECV and LASSO.

The final model was built using CatBoost, a high-performance gradient boosting algorithm [28]. Additionally, several other models, including logistic regression, random forest, extreme gradient boosting [29], LightGBM, and 2 deep learning methods (Feature Tokenizer + Transformer [30] and SAINT [31]), were constructed to compare predictive performance for hypertension incidence. Bayesian optimization via *Hyperopt* [32] was employed to fine-tune the hyperparameters, maximizing the area under the receiver operating characteristic (AUROC) curve across 5-fold cross-validation. Each model underwent 1000 optimization trials. The detailed parameters for each model are provided in Multimedia Appendix 3.

XSL•FO
RenderX

The optimal model was evaluated using AUROC, average precision, accuracy, sensitivity, specificity, and confusion matrix in the internal validation set. Calibration of the selected model on the training set was performed using isotonic regression [33] to improve predictive accuracy and reliability. The calibrated model was subsequently transformed to both the internal validation set and the prospective cohort. Calibration curves, constructed with 25 evenly spaced bins, were then used to evaluate the model's calibration and predictive performance across both validation sets.

To further refine risk stratification, we calculated the positive predictive values for individuals in the prospective cohort by using the calibrated model. Individuals were ranked by positive predictive values and categorized into 4 risk levels, ranging from low to very high risk. Univariate Cox regression was performed to validate the effectiveness of these risk categories.

Model Interpretation

Shapley Additive Explanations (SHAP) [34] was employed to interpret the contribution of each feature to the model's predictions. For highly weighted features such as age, gender, and BMI, we created subpopulations to analyze the distribution of risk categories within these groups. All analyses were conducted using Python software (version 3.8.0) with packages, including *CatBoost* (version 1.2.5), *Hyperopt* (version 0.2.7), and *SHAP* (version 0.44.1), as well as R software (version 4.0.2; R Foundation for Statistical Computing). A 2-tailed *P* value less than .05 was considered statistically significant.

Results

Clinical Baseline Characteristics

Table 1 outlines the baseline characteristics of the study cohorts. After applying the exclusion criteria, the retrospective cohort included 1,038,170 participants, aged 18-100 years, with baseline characteristics recorded between January and November 2019. The prospective cohort comprised 961,519 participants within the same age range, with baseline characteristics collected from January to November 2021. Over the 2-year follow-up period, the incidence of hypertension was 15.20% (157,766/1,038,170) in the retrospective cohort and 10.50% (101,077/961,519) in the prospective cohort. At baseline, compared to the nonhypertensive group, the hypertensive group had a higher proportion of males, resided in urban areas, and had lower education levels. The hypertensive group also had higher prevalence of hepatic steatosis and type 2 diabetes along with elevated waist circumference, BMI, systolic blood pressure, and diastolic blood pressure. Multimedia Appendices 4 and 5 provide a detailed comparison of the characteristics between individuals with and without incident hypertension in both cohorts.

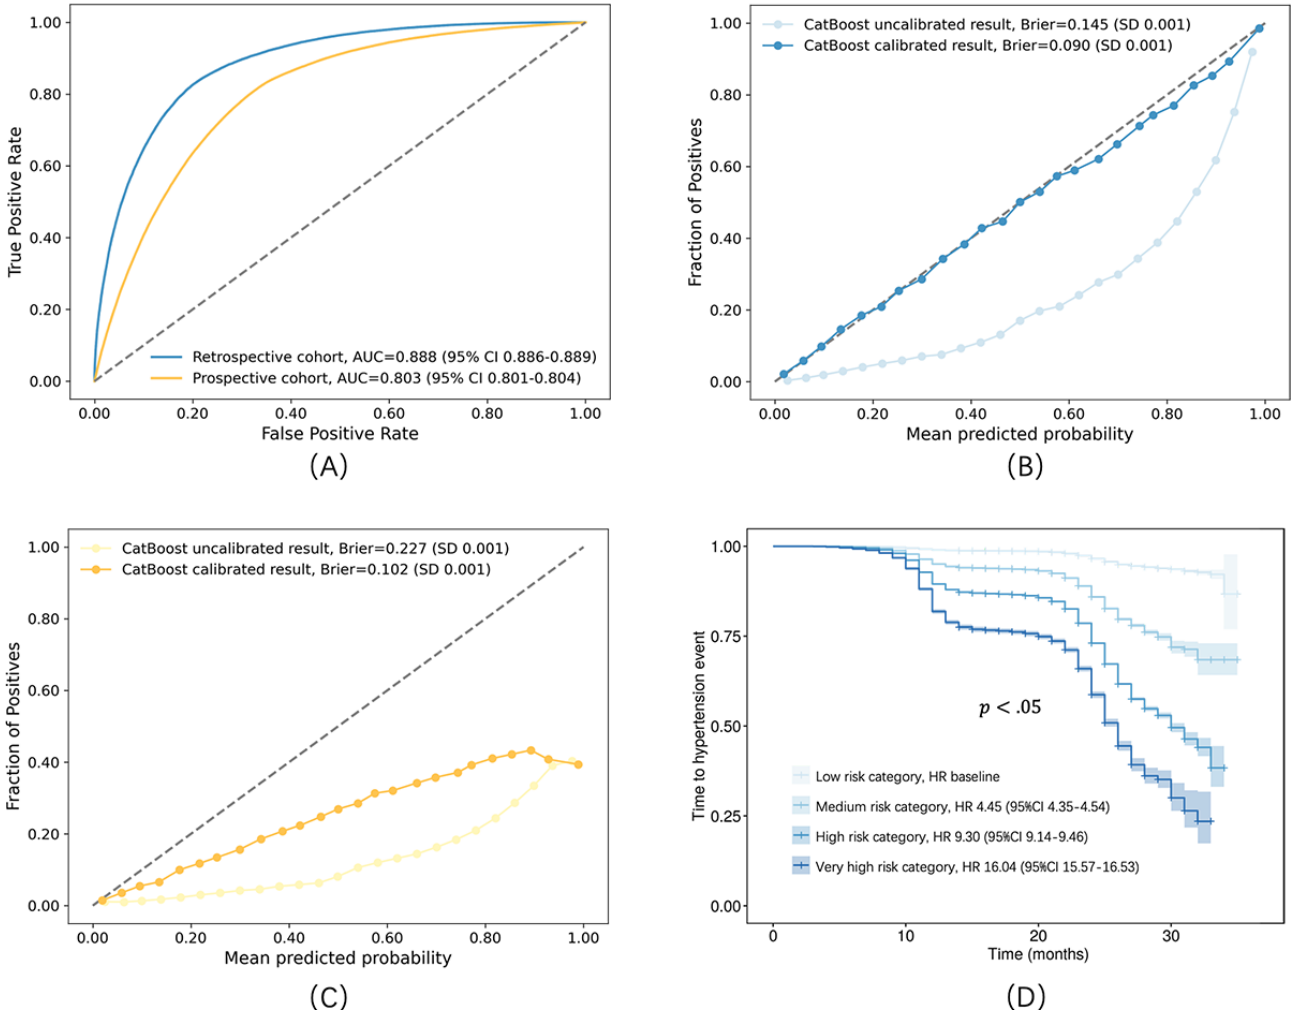
Development and Validation of Predictive Models

Recursive feature elimination is a widely used method for feature selection. It iteratively trains a model, assesses the importance of each feature, and removes the least important ones until the optimal number of features is identified. In this study, we used an enhanced version of recursive feature elimination, RFECV, which incorporates cross-validation to evaluate model performance at each iteration. Additionally, LASSO regression was employed, using L1 regularization to shrink the coefficients of less important features to zero, thereby further refining the feature set (Figure 2). Through the application of both LightGBM-RFECV and LASSO, we identified 26 and 27 potential risk predictors for hypertension, respectively. By intersecting the results of these 2 methods, we selected 24 key features for the final construction of the 2-year hypertension incidence risk prediction model.

Figure 2. Feature selection of the model. (A) Feature selection results based on light gradient-boosting machine–based recursive feature elimination with cross-validation. (B) Feature selection results based on Least Absolute Shrinkage and Selection Operator. AUROC: area under the receiver operating characteristic; LightGBM: light gradient-boosting machine; RFECV: recursive feature elimination with cross-validation.



Model Performance

We evaluated the performance of several machine learning and deep learning models. Among the models, CatBoost demonstrated the highest predictive accuracy, with an AUROC curve of 0.888 (95% CI 0.886-0.889). Extreme gradient boosting followed with an AUROC of 0.868 (95% CI 0.866-0.870). Detailed AUROC comparisons for each model are available in Multimedia Appendix 6, while the confusion matrix results are provided in Multimedia Appendix 7. A Mann-Whitney *U* test confirmed that CatBoost significantly outperformed the other algorithms in terms of predictive accuracy (P<.001) (Multimedia Appendix 8) [35]. Further validation of the CatBoost model was performed using the prospective cohort. Compared with the results from the internal validation set, the AUROC for the prospective cohort decreased to 0.803 (95% CI 0.801-0.804) (Figure 3). Isotonic regression was applied to calibrate the output probabilities, improving the accuracy of predicted probabilities in reflecting actual risks. After calibration, the model's performance metrics improved, with a Brier score of 0.090 (95% CI 0.089-0.091) on the internal validation set and 0.102 (95% CI 0.101-0.103) on the prospective cohort.

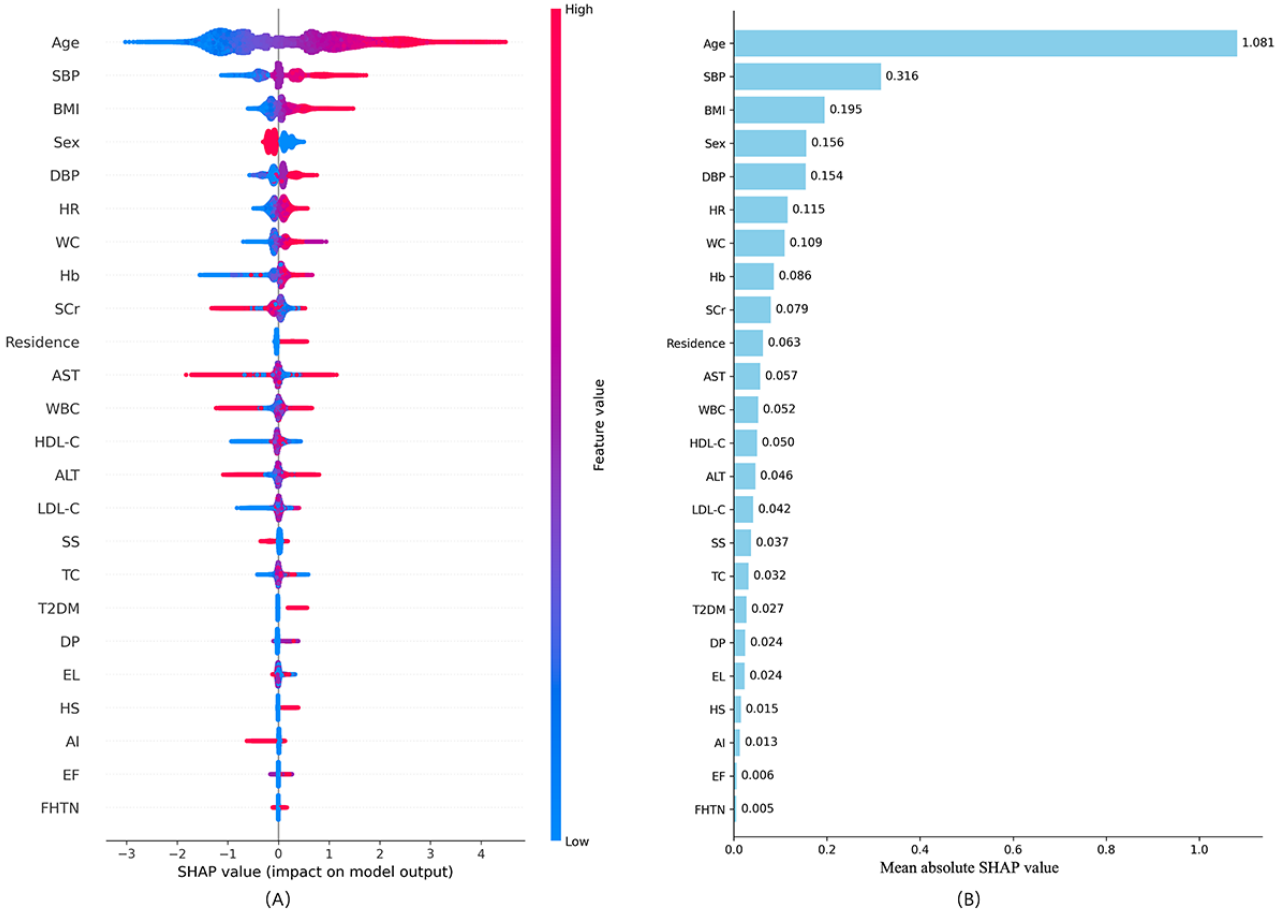
Figure 3. (A) Receiver operating characteristic curve of the CatBoost model in the retrospective and prospective cohorts. (B) Noncalibrated and calibrated curves of the CatBoost model in the retrospective cohort. (C) Noncalibrated and calibrated curves of the CatBoost model in the prospective cohort. (D) Survival curves for time-to-hypertension across 4 risk categories. AUC: area under the curve; HR: hazard ratio.



Following calibration, we calculated the positive predictive values for each individual and categorized participants into 4 risk levels: low, medium, high, and very high. In the low-risk group (risk score 0-0.15, n=570,742), only 2.87% (16,392/570,742) developed hypertension over the 2-year period. In contrast, 41.08% (5741/13,975) of the individuals in the very high-risk group (risk score 0.8-1, n=13,975) were diagnosed with hypertension within the same period (Multimedia Appendix 9). To further assess the differences in hypertension onset across the 4 risk categories, we performed univariate Cox regression to estimate time-to-hypertension for each group. The results showed significant differences between the risk categories (P<.05), with the hazard ratio for the very high-risk group being 16.4 (95% CI 15.57-16.53) compared with the low-risk group.

Feature Importance and SHAP Analysis

We used the distribution of SHAP values and the corresponding mean absolute SHAP values within the prospective cohort to interpret the contribution of each feature in the risk prediction model. The analysis revealed that the model's core predictive power derived primarily from basic biometrics (age, BMI, gender, and waist circumference), blood pressure indicators (systolic and diastolic blood pressure), and heart rate (Figure 4).

XSL•FO
RenderX

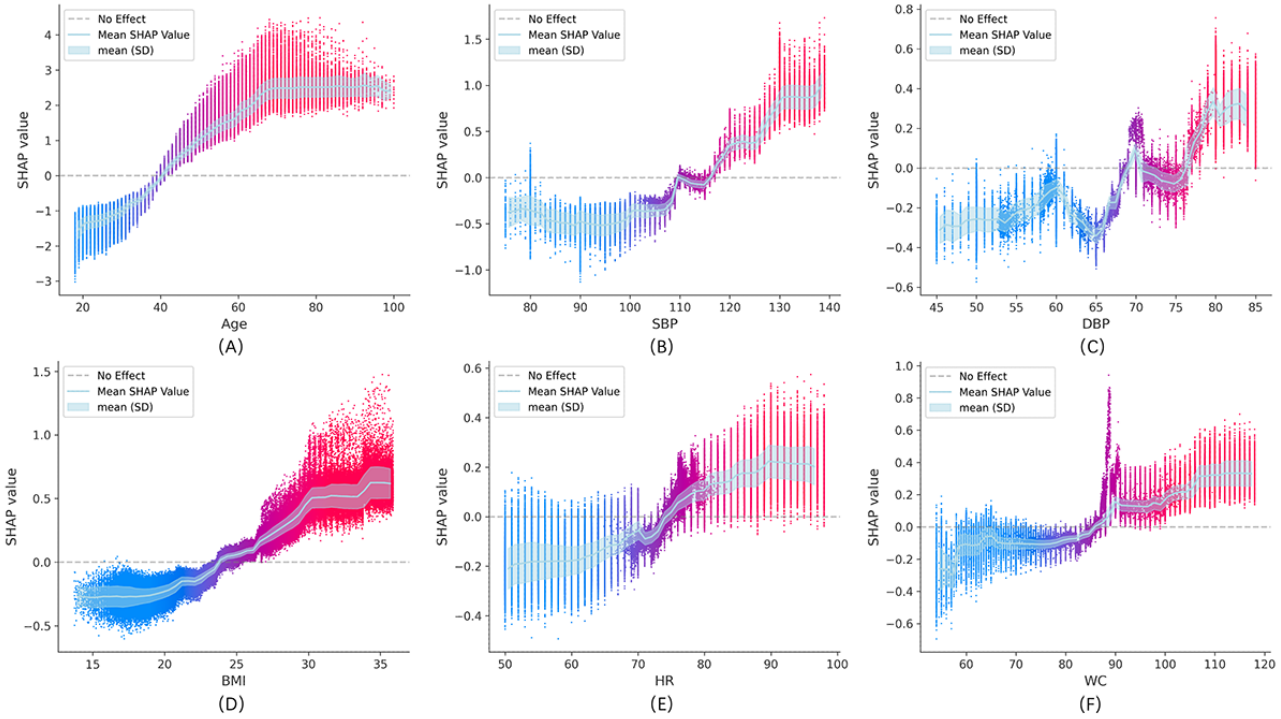


Figure 4. (A) Complete distribution of Shapley Additive Explanations values for all features in the prospective dataset. (B) Absolute contribution of all features based on Shapley Additive Explanations values for all features in the prospective dataset. AI: alcohol intake; ALT: alanine aminotransferase; AST: aspartate transaminase; DBP: diastolic blood pressure; DP: dietary pattern; EF: exercise frequency; EL: educational level; FHTN: family history of hypertension; Hb: hemoglobin; HDL-C: high-density lipoprotein cholesterol; HR: heart rate; HS: hepatic steatosis; LDL-C: low-density lipoprotein cholesterol; SBP: systolic blood pressure; SCr: serum creatinine; SHAP: Shapley Additive Explanations; SS: smoking status; T2DM: type 2 diabetes; TC: total cholesterol; WBC: white blood cell; WC: waist circumference.

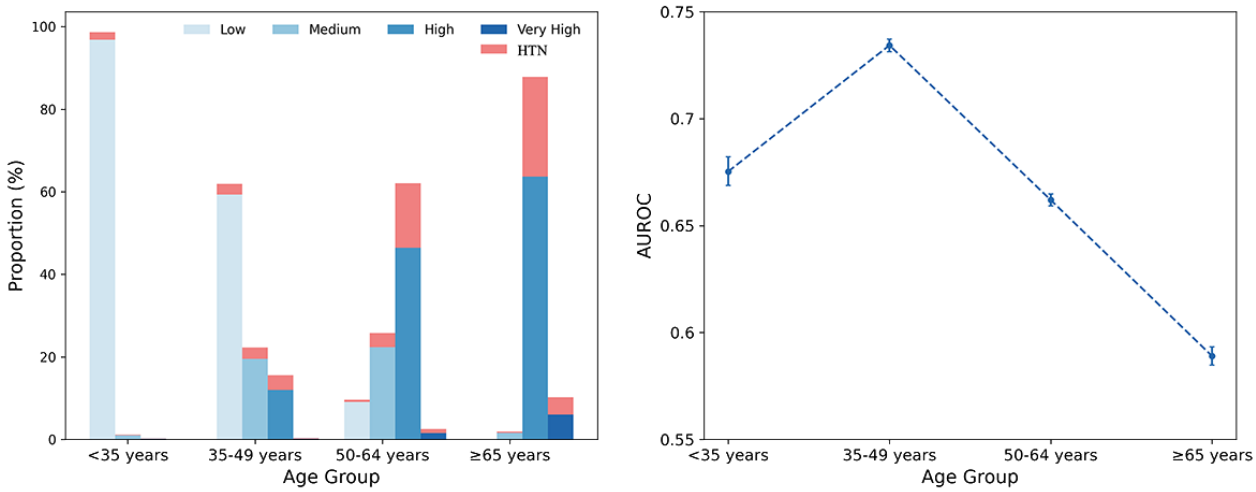
To better understand the impact of individual variables, we analyzed the SHAP values for the top 6 ranked continuous variables (Figure 5). We observed that as these feature values increased, their SHAP values transitioned from negative to positive, indicating that higher values significantly increased the likelihood of being classified as high-risk for hypertension.

XSL•FO
RenderX

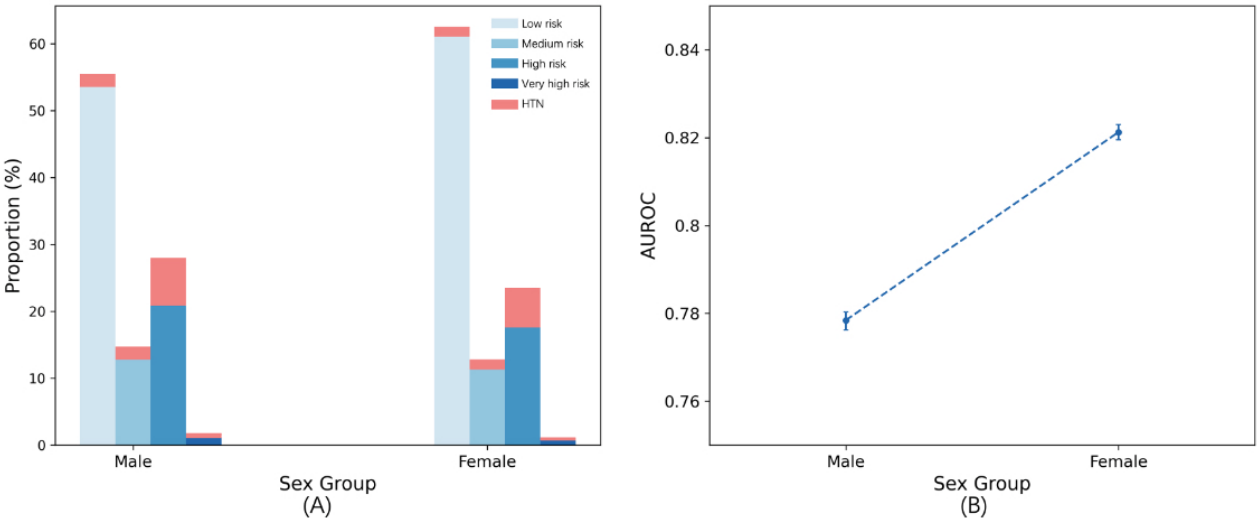
Figure 5. (A)-(F) Shapley Additive Explanations value dependence plots for 6 example features in the prospective dataset. DBP: diastolic blood pressure; HR: heart rate; SBP: systolic blood pressure; SHAP: Shapley Additive Explanations; WC: waist circumference.



Significant Features

In addition to analyzing SHAP values for individual features, we conducted a grouped analysis of the most influential basic biometrics (age, sex, and BMI) and socioeconomic factors (residence and education level) within the prospective cohort to assess the distribution of the samples across different risk levels and the model's predictive performance within these feature groups.

Based on prior research [19], we divided the population into 4 age categories. The analysis showed that the young population was predominantly in the low-risk category (343,394/347,996, 98.68%), while the older adult population was primarily composed of high-risk (68,238/77,664, 87.86%) and very high-risk (7939/77,664, 10.22%) individuals (Figure 6). Hypertension incidence within 2 years in the older adults (22,277/77,664, 28.68%) was significantly higher than that in the younger population (7154/347,996, 2.05%), confirming age as a key predictor of hypertension onset. Further analysis (Figure 6B) demonstrated that the model performed best in the 35-49 years age group, with an AUROC of 0.734 (95% CI 0.732-0.737), whereas performance was relatively weaker in the older adult population, with an AUROC of 0.589 (95% CI 0.585-0.593). This performance disparity may be attributed to the model's tendency to assign higher risk to older individuals, reducing its discriminatory power in this group.



XSL•FO
RenderX

Figure 6. (A) Proportion of 4 risk categories across different age group subsets. (B) Area under the receiver operating characteristic curve values evaluated for different age group subsets. AUROC: area under the receiver operating characteristic curve; HTN: hypertension.

Regarding gender, hypertension incidence within 2 years in women (49,855/529,695, 9.41%) was lower than that in men (51,222/431,824, 11.86%). A higher proportion of women were in the low-risk category, that is, 62.51% (331,122/529,695) of the women were in the low-risk category, while only 55.49% (239,620/431,824) of the men were in the low-risk category (Figure 7). Conversely, men were more likely to be in the high-risk (120,676/431,824, 27.95%) and very high-risk (7821/431,824, 1.81%) categories. Additionally, the model performed better in women, achieving an AUROC of 0.821 (95% CI 0.820-0.823) compared to men with an AUROC of 0.785 (95% CI 0.777-0.781).

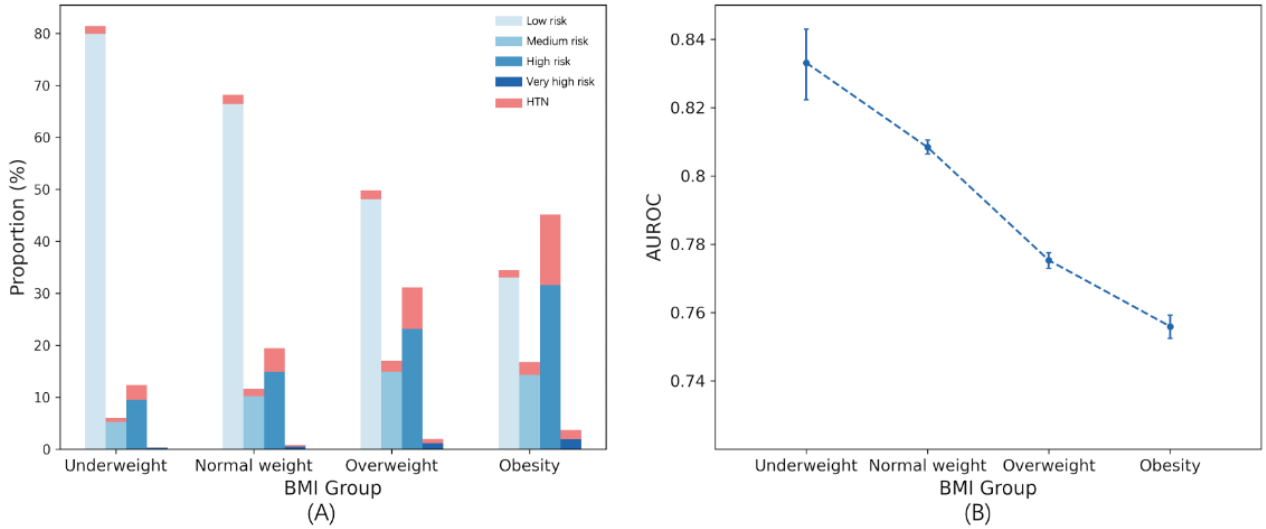


Figure 7. (A) Proportion of 4 risk categories across different sex group subsets. (B) Area under the receiver operating characteristic curve values evaluated for male and female subgroups. AUROC: area under the receiver operating characteristic curve; HTN: hypertension.

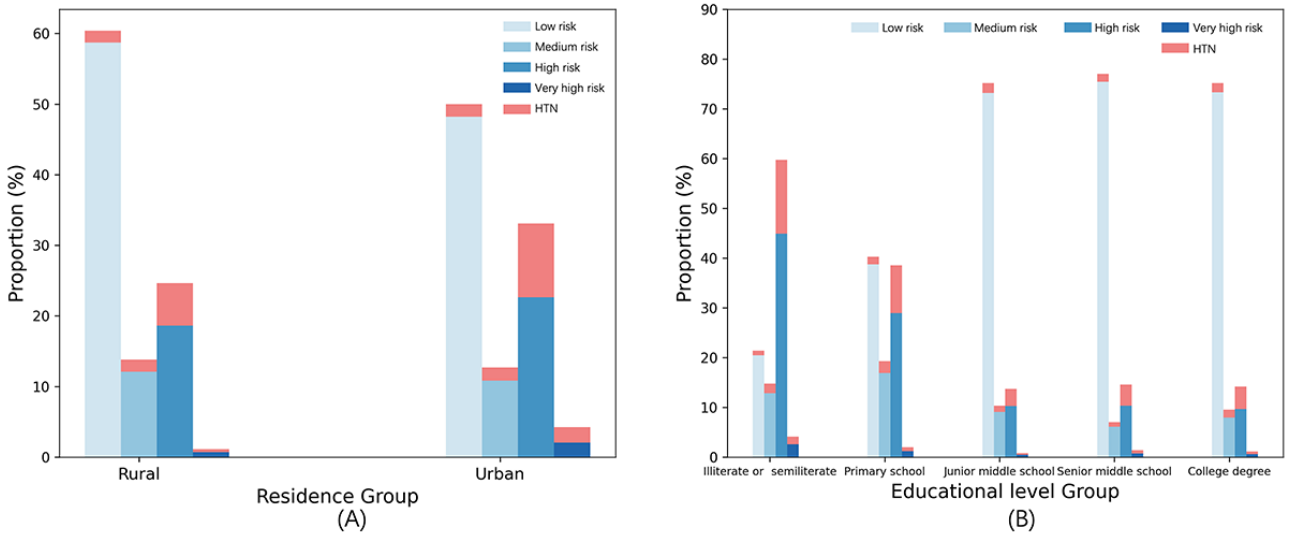
BMI was categorized according to the World Health Organization classification: underweight (BMI<18.5), normal weight (18.5≤BMI<25), overweight (25≤BMI<30), and obesity (BMI≥30). As BMI increased, the proportion of individuals in the high-risk and very high-risk categories also increased along with a corresponding increase in hypertension incidence. This indicates a strong association between obesity and hypertension risk (Figure 8).



XSL•FO
RenderX

Figure 8. (A) Proportion of 4 risk categories across different BMI group subsets. (B) Area under the receiver operating characteristic curve; values evaluated for different BMI group subsets. AUROC: area under the receiver operating characteristic curve; HTN: hypertension.

We also analyzed the impact of socioeconomic factors on hypertension risk (Figure 9). Among urban residents, the proportion of individuals classified as high risk (31,764/96,055, 33.07%) and very high-risk (4084/96,055, 4.25%) was greater than that among rural residents, where the high-risk group accounted for 24.66% (213,441/865,464) and the very high-risk group for 1.14% (9891/865,464). Hypertension incidence among the urban population (15,664/96,055, 16.31%) was also higher than that among rural residents (85,414/865,464, 9.87%). Similarly, individuals with lower levels of education (illiterate or semiliterate, primary school) had higher proportions in the high-risk (169,594/417,837, 40.59%) and very high-risk (9104/417,837, 2.18%) categories, with correspondingly higher incidence rates (61,741/417,837, 14.77%). These findings suggest that socioeconomic factors such as living environment and education level are closely linked to hypertension risk.

Figure 9. (A) Proportion of 4 risk categories across different residence group subsets. (B) Proportion of 4 risk categories across different educational level group subsets. HTN: hypertension.

Finally, we developed a web-based application based on our predictive model (see main interface in Multimedia Appendix 10) [36], designed for integration into routine clinical workflows. During health examinations, clinicians can input patient data into the application, which then instantly generates individualized hypertension risk assessments. Each patient is assigned to 1 of the 4 actionable risk levels (low, medium, high, very high), aiding in targeted clinical decision-making. The application also employs interpretable SHAP value visualizations, allowing clinicians to understand the key contributors to each patient's risk profile. The application is publicly accessible to encourage external validation by health care providers [36], and we have also released the corresponding open-source code (Multimedia Appendix 11) [37].

Discussion

Principal Findings

This study shows a 2-year hypertension risk prediction model using a retrospective cohort of over 1 million participants from populations residing in the desert regions of China, with both internal and external validation. Using feature selection techniques, we identified 24 significant variables. The CatBoost model demonstrated superior predictive performance, achieving an area under the curve (AUC) of 0.888 in the retrospective cohort and 0.803 in the prospective cohort, outperforming other machine learning and deep learning models. During the 2-year follow-up in the prospective cohort, the model effectively stratified individuals into 4 distinct risk categories, revealing significant differences in the hazard ratios for hypertension incidence among these groups. Analysis of the model's significant features indicated that the risk of hypertension is strongly influenced by basic biometrics (age, sex, and BMI) and socioeconomic factors (residence and education level). Furthermore, a web-based application was developed and made open-source, providing clinicians with a practical and accessible tool to assess hypertension risk and guide early intervention strategies.

According to the World Health Organization's report on global hypertension prevalence, approximately 1.1 billion adults aged 30-79 years have hypertension, with two-thirds residing in low- and middle-income countries [25]. China, as the largest middle-income country, has an estimated hypertension prevalence of 27.5% [38]. In this study, we observed an incidence rate of 56.30 per 1000 person-years, which is higher than the national average of 48.60 per 1000 person-years reported between 2011 and 2015 [39]. This discrepancy may be attributed to the geographic location of our cohort, composed of residents from 4 regions near the Taklamakan Desert in northwest China. Environmental factors, lifestyle choices, and dietary patterns specific to this area likely contributed to the higher incidence, underscoring a more severe public health challenge in these regions and highlighting the need for targeted prevention strategies.

CatBoost was chosen as the hypertension risk prediction model due to its superior performance compared to other gradient-boosting decision tree models, such as LightGBM and extreme gradient boosting. CatBoost's key advantage lies in its ability to efficiently handle high-dimensional categorical data, thanks to its unique target encoding and ordered boosting algorithms. These methods minimize data leakage and prevent the use of future information in current predictions, enhancing model generalizability and reducing the need for extensive preprocessing. Although recent advancements in deep learning for tabular data prediction have shown promise, the 2 deep learning models (Feature Tokenizer + Transformer and SAINT) evaluated in this study underperformed slightly compared to CatBoost. Feature Tokenizer + Transformer leverages feature tokenization, transforming features into tokens for the Transformer architecture, while SAINT introduces intersample attention mechanisms to capture relationships between samples. Despite their slightly lower performance in this dataset, these models demonstrated comparable results to other gradient-boosting decision tree models, indicating that deep learning approaches have strong potential for future application in tabular data prediction.

When contrasted with previous studies [10-16], this study represents an advancement in both sample size and model performance. Our dataset included data from 1750 hospitals and community clinics, encompassing a total of 2 million individuals, ensuring the reliability and robustness of the results. The CatBoost model achieved an AUC of 0.888 in the retrospective cohort and 0.803 in the prospective cohort. By comparison, López-Martínez et al [16] utilized the 2007-2016 National Health and Nutrition Examination Survey dataset to develop 2 predictive models: a logistic regression model reported in 2018, which achieved an internal validation AUC of 0.73 [15] and an artificial neural network model developed in 2020, which improved the AUC to 0.77.

Consistent with prior studies, our model identified age, gender, and BMI as the major predictors of hypertension [3,40,41]. We found that as age and BMI increased, the proportion of individuals in the high-risk category rose significantly, further emphasizing their importance in hypertension risk prediction. In terms of socioeconomic factors, our study showed that individuals residing in urban areas and those with lower education levels had higher incidences of hypertension over 2 years. This may be due to urban populations engaging in consuming diets high in salt and fat while lacking overall nutritional quality, less physical activity, and being exposed to more severe environmental pollution [42-44], while individuals with lower education levels may have reduced access to health care and limited health literacy, both of which increase their vulnerability to hypertension [45].

The clinical implications of this study are significant. To our knowledge, this is one of the first large-scale, prospective cohort studies focused on hypertension risk prediction in populations residing in regions surrounding a desert. The model relies on 24 basic clinical and biochemical features that are routinely collected during health checkups, making it practical for use in primary health care settings. Given the limited health care resources in desert regions, the model can assist health care providers in identifying high-risk individuals for hypertension up to 2 years in advance. This allows for optimized medical decision-making and resource allocation, promoting earlier intervention and potentially reducing the overall disease burden.

Furthermore, the development of a web-based application extends the model's utility, allowing for broader clinical implementation. This user-friendly tool provides an intuitive way for clinicians to assess hypertension risk predictions and the specific contributions of individual risk factors. Especially in resource-constrained regions, this model offers an opportunity for precision prevention and intervention, potentially reducing long-term health care costs and improving patient outcomes. These contributions collectively aim to address previous methodological and contextual limitations, expand the body of knowledge, and provide potential solutions to pressing public health challenges.

XSL•FO
RenderX

Limitations

This study has several important limitations that may affect the interpretation and generalizability of the findings. First, some of the health examination data contained missing values. Although we addressed this issue by using a random forest imputation method based on the training set, this approach may introduce bias, particularly if the missing data are not missing completely at random. Imputation can improve data completeness, but it may still impact the accuracy of the model's predictions and its external validity. Second, the range of variables included in this study was limited. Important factors such as psychological stress, genetic predisposition, and environmental influences were not incorporated into the model. These factors have been shown to contribute significantly to hypertension risk, and their omission may limit the comprehensiveness of the model. In addition, the model was developed using data from specific geographic region populations surrounding desert areas in northwest China. Although this provides valuable insights for these communities, the model's applicability to other populations, particularly those in different geographic and socioeconomic settings, may be limited. Lastly, certain lifestyle factors such as physical activity and diet were based on self-reported data, which are subject to recall bias and may not accurately reflect actual behaviors.

Conclusions

In conclusion, we developed and validated a 2-year hypertension incidence risk prediction model by using data from nearly 2 million individuals residing in regions surrounding the Taklamakan Desert. The model demonstrated strong predictive performance, with high accuracy in both retrospective and prospective cohorts. By stratifying individuals into distinct risk categories, the model identified significant variations in hypertension incidence rates between these groups, underscoring its potential as a valuable tool for risk stratification in clinical practice. To enhance clinical applicability, we further developed a web-based hypertension prediction application, facilitating early screening and intervention for high-risk populations. This study not only holds significant clinical value but also provides an efficient public health tool for regions with limited health care resources, supporting early prevention and precision management of hypertension.

Abstract

Background: Most artificial intelligence–based research on acute kidney injury (AKI) prediction has focused on intensive care unit settings, limiting their generalizability to general wards. The lack of standardized AKI definitions and reliance on intensive care units further hinder the clinical applicability of these models.

Objective: This study aims to develop and validate a machine learning–based framework to assist in managing AKI and acute kidney disease (AKD) in general ward patients, using a refined operational definition of AKI to improve predictive performance and clinical relevance.

Methods: This retrospective multicenter cohort study analyzed electronic health record data from 3 hospitals in South Korea. AKI and AKD were defined using a refined version of the Kidney Disease: Improving Global Outcomes criteria, which included adjustments to baseline serum creatinine estimation and a stricter minimum increase threshold to reduce misclassification due to transient fluctuations. The primary outcome was the development of machine learning models for early prediction of AKI (within 3 days before onset) and AKD (nonrecovery within 7 days after AKI).

Results: The final analysis included 135,068 patients. A total of 7658 (8%) patients in the internal cohort and 2898 (7.3%) patients in the external cohort developed AKI. Among the 5429 patients in the internal cohort and 1998 patients in the external cohort for whom AKD progression could be assessed, 896 (16.5%) patients and 287 (14.4%) patients, respectively, progressed to AKD. Using the refined criteria, 2898 cases of AKI were identified, whereas applying the standard Kidney Disease: Improving Global Outcomes criteria resulted in the identification of 5407 cases. Among the 2509 patients who were not classified as having AKI under the refined criteria, 2242 had a baseline serum creatinine level below 0.6 mg/dL, while the remaining 267 experienced a decrease in serum creatinine before the onset of AKI. The final selected early prediction model for AKI achieved an area under the receiver operating characteristic curve of 0.9053 in the internal cohort and 0.8860 in the external cohort. The early prediction model for AKD achieved an area under the receiver operating characteristic curve of 0.8202 in the internal cohort and 0.7833 in the external cohort.

Conclusions: The proposed machine learning framework successfully predicted AKI and AKD in general ward patients with high accuracy. The refined AKI definition significantly reduced the classification of patients with transient serum creatinine fluctuations as AKI cases compared to the previous criteria. These findings suggest that integrating this machine learning framework into hospital workflows could enable earlier interventions, optimize resource allocation, and improve patient outcomes.

KEYWORDS

acute kidney injury; machine learning; recovery of function; creatinine; kidney; patient rooms

Introduction

Acute kidney injury (AKI) is an escalating critical health and socioeconomic issue, marked by prolonged hospital stays, elevated medical costs, and high mortality rates [1]. AKI is a secondary condition arising from hospital interventions, such as medication, surgery, and infections, with a prevalence of 10%-15% among general inpatients [2]. Studies have shown that the duration of AKI correlates with increased risks of complications and mortality [3]. AKI and its progression to acute kidney disease (AKD) are associated with significant increases in postdischarge morbidity and mortality. The prolonged duration of AKI in general wards has been associated with higher risks of complications and increased mortality [3-5]. Early prediction of AKI and its progression to AKD using artificial intelligence (AI) models improve patient outcomes through timely intervention and personalized management strategies [5-7]. There are research findings indicating that applying a clinical decision support system for actual AKI occurrences has significantly improved patient outcomes [8-10]. However, there is a lack of standardized operational definitions for AKI, particularly in retrospective studies, where data collection may not be systematic [11,12]. This inconsistency in defining AKI, especially in terms of baseline serum creatinine (SCr) and recovery criteria for AKD, leads to ambiguity in labeling and makes it difficult to compare the performance of different AI models across studies [13,14]. The variability in baseline SCr determination further complicates the issue [14-16]. Studies that investigated the impact of baseline SCr on model performance are limited to the intensive care unit (ICU) setting and do not address real-time early prediction in general wards [17-19], in differing AKI labels for the same patient. Defining the recovery for AKD is even more challenging [4,20-23].

General ward patients typically exhibit milder disease severity, less frequent laboratory measurements, and different baseline characteristics compared with ICU patients [15,20,24-27]. Applying the criterion of baseline SCr being 1.5 times higher requires more caution, especially in cases with low SCr levels. For instance, in a patient with 3 SCr measurements within 48 hours showing values of 0.9 mg/dL, 0.6 mg/dL, and 0.9 mg/dL in chronological order, additional consideration may be needed to determine whether the patient should be classified as experiencing AKI. Furthermore, when the baseline SCr is set below 0.6 mg/dL, even small fluctuations can easily meet the 1.5-fold criterion within 7 days, leading to the classification of AKI occurrence [28]. This study aimed to develop and validate a machine learning-based framework for early prediction of AKI and AKD, applicable to general ward patients, using a refined operational definition of AKI.

Methods

Study Setting and Participants

This multicenter, retrospective study was conducted across the general wards of 3 different hospitals. Data were collected from patients admitted to Korea University Guro Hospital and Anam Hospital between January 1, 2015, and December 31, 2021 (internal cohort), and from Soonchunhyang University Cheonan Hospital between March 1, 2016, and March 31, 2021 (external cohort). Patients younger than 19 years, those with fewer than 3 SCr measurements during their hospital stay, and those with an estimated glomerular filtration rate (eGFR) ≤60 mL/minute on the first day of SCr measurement were excluded.

Operative Definition

AKI was defined based on the Kidney Disease: Improving Global Outcomes (KDIGO) criteria as follows [1].

- An increase in SCr level ≥0.3 mg/dL (or ≥26.5 μmol/L) within 48 h.
- An increase in SCr ≥1.5 times the baseline within 7 days.

The KDIGO criteria are widely used; however, they are sometimes modified based on the characteristics of the cohort or the objectives of the study [28]. Compared with ICU patients, general ward patients are in relatively better condition with less frequent measurements of vital signs and laboratory data. Additionally, individuals with healthy kidneys and low SCr levels can be identified as having AKI due to simple fluctuations [14]. There may be more bias in real-time predictions, as SCr estimation is more frequently performed for patients with missing SCr values. Therefore, to prevent these issues, we restricted the application of baseline SCr levels and refined the labeling. To improve the labeling criteria, baseline SCr was defined as the lowest SCr measured within the previous 7 days. If the patient's baseline SCr was ≥0.3 mg/dL lower than the median and recent SCr values, it was excluded as a baseline to avoid errors due to SCr measurement inaccuracies or temporary fluctuations caused by medication, measurement error, and other factors. AKI was defined as a minimum increase of 0.3 mg/dL to ensure appropriate identification without mislabeling due to minor variations [2,29,30]. AKD was defined as the persistence of AKI for more than 7 days. Cases in which SCr did not return to <1.5 times the baseline SCr within 7 days were identified as AKD [21,29-32]. None of the previous definitions or studies have taken these aspects into consideration.

To develop an early prediction model for AKI occurrence, data from 1 to 3 days before AKI onset were labeled as 1, and the remaining data were labeled as 0. The data from the day of AKI onset were not used. For patients who did not develop AKI, all data were labeled as 0. Days without SCr measurements within 7 days were excluded from training and evaluation. Additionally, patients with ambiguous AKI labeling were excluded from the training and evaluation. Data from the day of AKI onset were used to predict AKD progression. Patients were labeled 0 or 1 based on whether they recovered within 7 days post AKI onset. Patients with insufficient SCr measurements after AKI onset were excluded. Multimedia Appendix 1 illustrates the previous KDIGO criteria, the improved AKI criteria proposed in this study, and examples of AKI and AKD labeling.

RenderX

Data Preprocessing

The data collected from the electronic health records contained numerous missing values, including measurement values, times, and specific variables. To address this issue, data were summarized at 24-hour intervals, a method validated in previous studies [33]. Vital signs, laboratory data, and variables such as nephrotoxic drugs (eg, nonsteroidal anti-inflammatory drugs, nephrotoxic antibiotics [ANTIs], and cytotoxic chemotherapeutic agents), vascular imaging examinations, surgeries under general anesthesia, contrast-enhanced computed tomography (CECT), and ICU transfers within the past 7 days were collected.

Vital sign data measured multiple times within 24 hours were summarized using mean, maximum, and minimum values, and the number of measurements. The laboratory test results were determined based on recent measurements. Additionally, variables such as nephrotoxic drugs, vascular imaging examinations, surgeries under general anesthesia, CECT, and ICU transfers within the past 7 days were included. eGFR was calculated using the Chronic Kidney Disease Epidemiology Collaboration 2021 equation [34]. The "BUN/Cr ratio" was defined as blood urea nitrogen (BUN) level divided by serum creatinine level.

Robust scaling was applied to all continuous variables and one-hot encoding was used for categorical variables. Approximately 120 features were extracted from the electronic health records, including basic patient information, vital sign data, laboratory test results, and other factors. Through a comprehensive literature review and consultation with specialists, a feature selection process was undertaken [6,23,35], and 42 features were ultimately selected based on their correlation coefficients and missing value ratios.

To handle outliers, the data distribution for each feature was reviewed along with the individual patient records. Outliers for some numerical variables were determined using histograms and quantiles with input from clinical experts. The missing values were imputed in 2 stages. First, where feasible, missing values were replaced with previous values to maintain data continuity. For variables with low missing values (less than 20%), the multiple imputation by chained equations method was used [36,37]. For variables with a missing rate exceeding 20%, the missing indicator method was used to denote missing values as unknown [38]. Numerical variables were categorized into 2 to 4 groups based on data distribution and expert consultation, and missing values were assigned to the "missing" category. For laboratory test results not subjected to missing indicators, changes in each variable were calculated by subtracting the median of the previous values from the current value (Multimedia Appendix 2).

Model Training and Evaluation

Various traditional machine learning models have been used, including logistic regression [39], random forest [40], eXtreme gradient boosting [41], light gradient boosting machine [42], and categorical boosting (CAT) [43]. For detailed model training procedures (Multimedia Appendix 3). The model evaluation metrics included accuracy, precision, recall, specificity, F_1-score, the area under the receiver operating characteristic (AUROC), and the area under the precision-recall curve. The primary outcomes were the development of models for early AKI prediction within 3 days and its progression to AKD, along with the establishment of a framework. Simulations of the designed framework were repeatedly performed using the external validation cohort by dividing the period into 1-year increments and assessing the generalization performance of the models across different institutions and over time.

Statistical Analysis

Descriptive statistics were used to present the baseline differences between the days with and without AKI. The distribution of continuous and categorical variables was expressed as means and SDs and counts and percentages, respectively. Normally distributed continuous variables were evaluated using 2-tailed *t* tests. For those that did not follow a normal distribution, the Mann-Whitney *U* test was used. The chi-square test was used to analyze categorical variables. Statistical significance was set at $P<.05$. Calibration plots were used to assess the agreement between the predicted probabilities and observed outcomes [44]. The Cox proportional hazards model was used to compare hazard ratios (HRs) between patients with actual AKD and those predicted by the model [45].

Ethical Considerations

The study was conducted in accordance with the ethical principles of the Declaration of Helsinki and was approved by the institutional review boards of Soonchunhyang University Cheonan Hospital, Korea University Anam Hospital, and Guro Hospital (approvals 2019-10-023, 2023AN0145, and 2023GR0425, respectively). The need for individual consent was waived due to the retrospective nature of the study and the use of anonymized clinical data. To ensure privacy and data security, only fully anonymized data were used, and all analyses were conducted within a designated secure environment with restricted access. No financial compensation was provided to participants, as the study was purely observational and used deidentified retrospective data. All processes adhered to the guidelines developed for machine learning model development in the biomedical field [46] and followed the STROE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines for observational studies.

Results

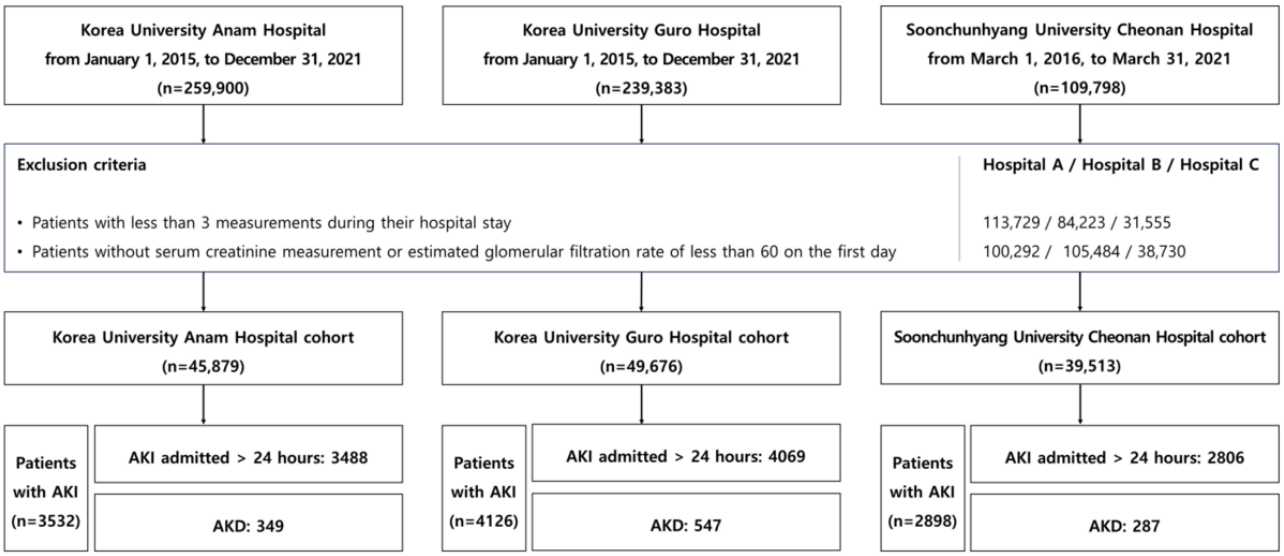
Labeling

Figure 1 is a flowchart of cohort formation and labeling. To compare the previous labeling criteria [7,32,47-49] with the labeling criteria used in this study, we developed and evaluated the model using the same methodology. Additionally, we calculated and presented the HRs for a 30% or 40% reduction in eGFR at the time of AKI onset (Figure 2 and Multimedia Appendix 4). In Table S7 in Multimedia Appendix 4, individuals with a baseline SCr<0.6 mg/dL were included, leading to the classification of AKI in patients with very low changes in SCr or very low baseline SCr levels. Additionally, subtracting the baseline median from the SCr at this point yielded a median of 0.10 (IQR 0.00-0.20).

XSL•FO
RenderX

Figure 2A illustrates this trend. Of the 2509 patients, 2242 (89.36%) had a baseline SCr<0.6 mg/dL at the time of AKI occurrence. The remaining 267 patients experienced decreased SCr levels before being diagnosed with AKI. This trend is illustrated in Figure S5 in Multimedia Appendix 4. Additionally, of the 2072 patients whose AKD status could be determined, only 50 (2.41%) progressed to AKD, and only 1 patient experienced a more than 30% decrease in eGFR within 30 days of AKI onset.

Figure 1. The data composition process. Hospitals A, B, and C refer to Korea University Anam Hospital, Korea University Guro Hospital, and Soonchunhyang University Cheonan Hospital, respectively. Since at least 1 day of data is required for model prediction, patients who developed AKI on the first day of hospitalization were excluded from the final cohort. AKI: acute kidney injury; AKD: acute kidney disease.



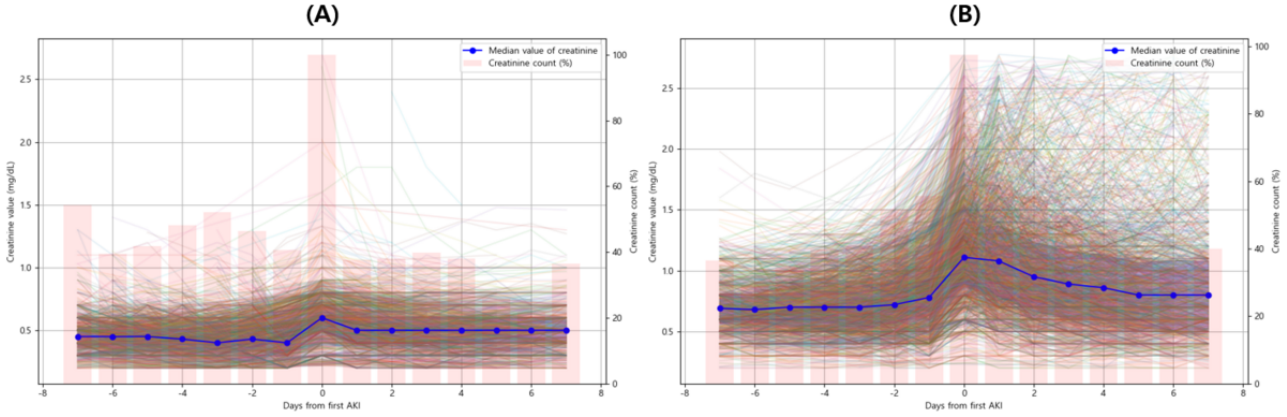


Figure 2. Serum creatinine trends in patients with AKI from the external validation cohort. (A) Results for 2509 patients who meet only the previous AKI criteria. (B) Results for 2898 patients who meet the refined AKI criteria. The blue line represents the median value for patients of each group, while the pink bar graph shows the proportion of serum creatinine measurements across all patients within 7 days before and after the day of acute kidney injury (day 0). The colored lines depict the serum creatinine levels for individual patients. AKI: acute kidney injury.

Early AKI Prediction Model

The final analysis included 95,555 and 39,513 cases in the internal and external cohorts, respectively. Within these cohorts, AKI was identified in 7658 (8.1%) and 2898 (7.3%) patients, respectively. The median length of hospital stay was 11 (IQR 7-20) days for the internal cohort and 10 (IQR 6-18) days for the external cohort. The median number of days to AKI occurrence from admission was 8 (IQR 3-17) days for the internal cohort and 7 (IQR 3-16) days for the external cohort (Multimedia Appendix 5). Tables S9 and Table S10 in Multimedia Appendix 5 present the basic statistics of patients with and without AKI. Comparing the days on which AKI occurred to the days on which it did not, there were statistically significant differences in most characteristics between the internal and external cohorts. However, differences in blood pressure and sodium and chloride levels were observed between the internal and external cohorts.

The models were evaluated based on the results of 5-fold cross-validation, with all performance metrics presented at a cutoff of 0.5. The CAT model demonstrated a strong predictive capability (AUROC=0.9134). The logistic regression model performed poorly (AUROC=0.7754). Model evaluation was conducted through both internal and external validations, showing a slight decrease in performance based on the AUROC (range 0.0097-0.0216). Table 1 presents the performance evaluation results of the early AKI prediction model. The hyperparameters used in the model are listed in Table S11 in Multimedia Appendix 5.

XSL•FO
RenderX

Figure 3 shows the Shapley additive explanations (SHAP) analysis for the early AKI prediction model. The interpretation of the CAT model using SHAP values indicated that the most important features were the SCr level and its changes. Other significant features included heart rate, BUN level, activated partial thromboplastin time (aPTT), total bilirubin level, and BMI, all of which increased the AKI risk. Conversely, lower eGFR, platelet count, body temperature, and pH were associated with a higher risk of AKI. Figure S7 in Multimedia Appendix 5 shows the results of testing the probability of the early AKI prediction model. Calibration plots were generated for both the internal and external cohorts. The slope of the calibration plot was 1.15 for the internal cohort and 1.08 for the external cohort, indicating a good calibration of the model's predicted probabilities. Additionally, the model probabilities were evaluated by dividing them into five groups, which demonstrated excellent calibration. A box plot of the probabilities in relation to the AKI status showed a clear distinction between AKI and non-AKI, further validating the predictive value of the model (Figure S8 in Multimedia Appendix 5).

Figure 3. SHAP values of the early prediction model for acute kidney injury. In the figure, red indicates higher values of the respective features, whereas blue indicates lower values. The position of the dots placed towards the right signifies a greater contribution of the feature value to the model's prediction of nonrecovery for the patient. For categorical variables, red dots represent a value of 1 and blue dots signify a value of 0. CT: computed tomography; SHAP: Shapley additive explanations.

Early AKD Prediction Model

For the analysis of AKD progression, 5429 and 1998 patients in the internal and external cohorts, respectively were included after excluding those with unclear AKD status. Among them, 896 (16.5%) patients in the internal cohort and 287 (14.4%) in the external cohort were diagnosed with AKD. The median duration from AKI to discharge was 10 (IQR 4-23) days in the internal cohort and 9 (IQR 3-21) days in the external cohort. For patients who recovered within 7 days post AKI, the median recovery time was 5 (IQR 3-7) days in both cohorts (Figure S9 in Multimedia Appendix 6). The characteristics of progression to AKD in each cohort are presented in Tables S12 and S13 Multimedia Appendix 6. Variables that demonstrated statistical significance in both cohorts included hemoglobin, albumin, SCr, eGFR, glucose, alanine aminotransferase, blood sugar, calcium, urine specific gravity, C-reactive protein (CRP), ANTIs, and surgery. Some variables such as sex, diastolic blood pressure (DBP), white blood cell (WBC) count, BUN/Cr ratio, and total carbon dioxide showed different trends between the cohorts.

The CAT model outperformed the other models in both the internal (AUROC=0.8202) and external validations (AUROC=0.7833). The external validation showed a slight decrease in performance based on the AUROC (range 0.0262-0.0416). Table 2 presents the performance evaluation results of the early prediction model for AKD. The hyperparameters used in the model are listed in Table S14 in Multimedia Appendix 6.

Figure 4 shows the SHAP analysis of the early-stage AKD prediction model. For AKD prediction, an increase in SCr level at the time of AKI was a strong predictor of delayed recovery. Exposure to ANTIs, high DBP, CRP, aPTT, low eGFR, low pH, and elevated alkaline phosphatase were associated with an

XSL•FO
RenderX

increased risk of AKD. Patients who underwent surgery or CECT tended to recover quicker from AKI.

Figure S10 in Multimedia Appendix 6 shows the results of testing the probability of the early AKD prediction model. Calibration plots for both the internal and external cohorts were generated to assess model performance. The slopes of the calibration plots were 1.27 for the internal cohort and 1.20 for the external cohort, indicating a good calibration of the model's predicted probabilities. The evaluation of the model probabilities by box plots showed excellent calibration, similar to that of the early prediction model for AKI (Figure S11 in Multimedia Appendix 6).

Framework

The framework to assist in managing AKI is shown in Multimedia Appendix 7. Figure 5A presents the framework simulation results for the early AKI prediction model. The designed framework was simulated using an external validation cohort at yearly intervals of 5 years. Among the 7284 patients included annually in the external validation cohort, 501 (6.9%) experienced AKI. Of these, 439 (87.68%) were predicted at least 1 day in advance. The F_1-score showed a decreasing trend after 2018 compared to evaluations between 2016 and 2018, with a minimum of 0.39 and a maximum of 0.46. Figure 5B presents the framework simulation results for the early prediction model for AKD. Excluding patients with insufficient SCr tracking from an average of 410 patients annually, 64 (15.6%) did not recover from AKI within 7 days. Among them, approximately 38 (58.4%) were predicted early.

XSL•FO
RenderX

Figure 5. Simulation results of the framework to assist in the management of AKI using external validation data. (A) Results of the early prediction model for AKI, and (B) results of the early prediction model for AKD. Blue indicates patients included in the yearly prediction, orange indicates event occurrence, green indicates patients successfully predicted by the model, and red indicates events successfully predicted by the model compared with actual events. AKI: acute kidney injury; AKD: acute kidney disease.

Discussion

Principal Findings

In this study, we developed a framework to assist in the management of AKI. The early AKI prediction model demonstrated high performance with an AUROC of 0.9053, while the early AKD prediction model achieved an AUROC of 0.8202. External validation results showed excellent model performance, although slight variations over time were observed, likely due to changes in disease incidence rates. Our study represents an integrated effort to identify patients with AKI early and, in cases where AKI occurs, classify them into high-risk and low-risk groups. Furthermore, we successfully refined and applied the KDIGO criteria to retrospective data, addressing its limitations and enhancing its applicability for AKI-related research in general ward patients.

Furthermore, our model predicted AKD in patients with AKI and showed an adjusted HR of 2.03 (95% CI 1.38-3.00) for events where eGFR decreased by 30% within 30 days from the onset of AKI. This adjusted HR was higher than that of the model developed using previous criteria, which had an HR of 1.66 (95% CI 1.17-2.34). This indicates that the refined criteria more precisely identify high-risk groups and suggests that the model developed using these criteria performs better. The AKI incidence was higher using the previous criteria, whereas the AKD incidence was higher using the refined criteria. This indicated that the previous criteria identified milder cases. Despite including milder cases, the model developed using the refined criteria showed a higher risk of a poorer prognosis than the previous criteria. Among patients tracked for more than 30 days after AKI, there were 934 and 482 patients before and after criteria advancement, respectively, with 138 and 103 showing poor prognosis. In other words, before the criteria advancement, 35 more patients with a poor prognosis were identified, but 452 additional AKI cases were identified. As shown in Figure S5 in Multimedia Appendix 4, many patients who met only the previous criteria included those whose AKI status was difficult to determine owing to the significant sensitivity to fluctuations. Regardless of how the baseline SCr level is imputed, it is

XSL•FO
RenderX

important in general wards to set a minimum increase criterion when applying a relative standard. Additionally, it is crucial to ensure that the baseline SCr level does not become too low when the SCr decreases. Advancements in labeling criteria should consider both patient prognosis and clinical settings. Excessive identification of AKI can lead to the detection of more patients with poor prognoses but may also result in inefficient allocation of medical resources.

Using the SHAP, factors contributing to AKI and AKD were identified and quantitatively measured. These results are largely aligned with the trends suggested by previous studies on risk factors and variable tendencies. Factors indicating poor patient status, such as low albumin or high alkaline phosphatase levels, were associated with increased AKI and AKD risks. Specifically, albumin is considered a critical biomarker closely related to renal function and may decrease in conditions associated with liver dysfunction [50]. Elevated WBC, heart rate, body temperature, and respiratory rate may indicate infection in patients [51], while the use of nephrotoxic drugs such as ANTIs, nonsteroidal anti-inflammatory drugs, and cytotoxic chemotherapeutic agents increases the risk of AKI [52,53]. Analysis of SHAP for AKD risk factors indicated that patients with increased WBC and high BT tended to recover renal function relatively quickly. Resolving infections appears to reduce the risk of AKD development in patients with AKI. ANTIs have emerged as significant risk factors for AKI and AKD. The difficulty in discontinuing these drugs due to patient conditions may exacerbate negative outcomes. Patients undergoing surgery are closely associated with AKI, although AKI following general anesthesia appears to show transient SCr fluctuations and overall health improvement following surgical resolution [54]. Renal function emerged as a crucial factor, consistent with existing clinical studies that state that baseline renal function is well-known as a major factor in AKI [55]. Additionally, higher age, heart rate, respiratory rate, total T-bil, aPTT, and CRP showed increased AKI risk, indicating that poorer patient condition may correlate with increased AKI incidence.

Similarly, poor renal function has been identified as a major risk factor for AKD. Elevated DBP reflects a tendency toward increased blood vessel volume after AKI, suggesting a possible correlation between increased volume and AKD [56,57]. AKI accompanied by surgery may recover relatively quickly due to transient hemodynamic changes during surgery, while cardiac surgery is known to have a relationship with AKI [58]. Contrast-induced nephropathy often shows peak levels approximately 3-5 days after exposure and often returns to baseline within 7-14 days, indicating relatively good recovery [59,60]. Conversely, ANTIs are associated with intrinsic AKIs such as acute tubular necrosis and slower recovery despite expected renal function impairment [61-63]. A high urine specific gravity suggests dehydration, which can often be corrected through fluid supplementation alone, leading to fast recovery [64,65]. Indicators reflecting infection showed that higher values tended to be associated with good renal recovery, while the significant infection marker CRP yielded ambiguous results. Because the interpretation of our model aligns with that of previous clinical studies, the patterns learned by the model are reasonable. Although biomarkers such as cystatin-C are commonly suggested in various studies, they were not used in this study due to their low measurement frequency. Future research should expand the features used in this study to include such biomarkers [66-68].

Limitations

This study had several limitations. First, owing to the lack of consensus on the AKI recovery criteria, the definitions had to rely on previous research findings. Second, there was a lack of data related to dialysis or kidney transplantation, which was addressed by excluding patients with an eGFR<60 mL/minute. As a result, caution is required when applying and interpreting the model for patients with preexisting chronic kidney disease or poor kidney function from the initial stages of hospitalization. However, the primary aim of this study was to predict “unexpected AKI.” Therefore, the analysis focused on patients with relatively preserved kidney function, who were considered to be at lower risk of AKI. Third, the study did not account for interventions or treatments before or post-AKI, which is crucial because patients’ preexisting conditions are significant factors in AKI and AKD. Fourth, in this study, the model was applied only in cases where AKI occurrences could be clearly identified, specifically when baseline SCr could be estimated at a specific time point and SCr measurements were available at that time. However, the proportion of AKI labels may differ from the actual occurrences. Therefore, despite the frequent measurement of SCr, caution is needed when applying and interpreting the model in situations where SCr measurements have not been conducted. Fifth, although our study used data extracted from different hospital information systems in various regions, it predominantly included data from Korean individuals. Therefore, we could not sufficiently consider racial diversity. Since there may be various differences, including kidney function, depending on ethnicity, future studies should include a multiethnic population.

Conclusions

This study introduces a machine learning framework aimed at assisting in the early management of AKI in general ward patients. To develop the model, we used retrospective data from general wards, refining the operational definition of AKI and externally validating our approach. Our findings demonstrate that AI-driven methods can enhance risk stratification and enable timely interventions. Beyond improving predictive accuracy, this study underscores the potential of AI to streamline clinical workflows, optimize resource allocation, and ultimately reduce the burden of AKI-related complications. Integrating such models into routine hospital practice may support proactive decision-making, allowing physicians to implement tailored interventions based on individual patient risk profiles. Future research should focus on prospective validation, real-time clinical integration, and incorporating additional biomarkers to improve model generalizability and clinical relevance.

Data Availability

The dataset used in this study and the models developed are not publicly available due to ethical restrictions, patient confidentiality, and institutional policies. However, they can be made available on reasonable request to the corresponding author.

Authors' Contributions

HL had full access to all the data in the study and was responsible for data integrity and the accuracy of the data analysis. This manuscript was written and edited entirely by the authors without the use of any generative AI tools. NC played a key role in conceptualizing and designing the study, contributed substantially to data acquisition, conducted statistical analyses, and drafted the manuscript. IJ focused on the study design, performed in-depth data analysis, and contributed to manuscript drafting. SA assisted with manuscript preparation and provided administrative and technical support. HG was instrumental in the study's concept and design, provided critical data, and supervised the research process. HL provided significant data for the study, secured funding, and offered administrative and technical support. All authors participated in data interpretation, critically reviewed the manuscript for important intellectual content, and approved the final version.

Abstract

Background: Primary care physicians' (PCP) referral rates to digital health programs are highly variable. This study explores whether knowledge of the digital remote blood pressure monitoring (RBPM) program and information on referral patterns influence PCPs' intention to refer patients.

Objective: This study aims to examine the relationship between PCPs' knowledge of the digital RBPM program and information on their own prior referral rates versus their own with their peers' referral rates and their likelihood to refer patients to the digital RBPM program.

Methods: This is a mixed methods study integrating quantitative analysis of electronic health record data regarding the frequency of PCPs' referrals of patients with hypertension to a digital health program and quantitative and qualitative analyses of survey data about PCPs' knowledge of the program and their intention to refer patients. PCPs responded to a clinical vignette featuring an eligible patient. They were randomized to either receive their own referral rate or their own plus their peers' referral rate. They were assessed on their intent to refer eligible future patients. Descriptive and multivariable linear regression analyses examined participant characteristics and the factors associated with their intent to refer patients. Narrative reasons for their intention to refer were thematically analyzed.

Results: Of the 242 eligible PCPs invited to participate, 31% (n=70) responded to the survey. From electronic health record data, the mean referral rate of patients per PCP was 11.80% (SD 13.30%). The mean self-reported knowledge of the digital health program was 6.47 (SD 1.81). The mean likelihood of referring an eligible patient (on a scale of 0 to 10, with 0 being not at all, and 10 being definitely) based on a vignette was 8.54 (SD 2.12). The own referral data group's mean likelihood to refer was 8.91 (SD 1.28), whereas the own plus peer prior referral data group was 8.35 (SD 2.19). Regression analyses suggested the intention to refer the vignette patient was significantly associated with their knowledge (coefficient 0.46, 95% CI 0.20-0.73; P<.001), whereas the intention to refer future patients was significantly associated with their intent to refer the patient in the vignette (coefficient 0.62, 95% CI 0.46-0.78; P<.001). No evidence of association was found on receiving own plus peer referral data compared with own referral data and intent to refer future patients (coefficient 0.23, 95% CI –0.43 to 0.89; P=.48).

XSL•FO
RenderX

Conclusions: Physicians' intention to refer patients to a novel digital health program can be extrapolated by examining their intention to refer an eligible patient portrayed in a vignette, which was found to be significantly influenced by their knowledge of the program. Future efforts should engage PCPs to better inform them so that more patients can benefit from the digital health program.

Introduction

Hypertension is a leading independent and modifiable risk factor for several adverse cardiovascular outcomes including coronary artery disease, stroke, heart failure, and chronic kidney disease, as well as a wide variety of mental and metabolic conditions [1]. Long-term control of hypertension can be achieved through proven interventions including regular blood pressure (BP) monitoring [2]. Accurate BP measurements in the office can be a challenge, particularly if the patient has white coat syndrome [3].

Digital technology including digital remote blood pressure monitoring (RBPM) allows health care to conduct remote monitoring for many chronic diseases [4,5]. RBPM is expanding and shows increasing efficacy [6], cost savings, reduction in health care access disparities, reduced patient and physician burden, and ease in securing the diagnosis of white coat hypertension [7]. RBPM became more widely accepted during the COVID-19 pandemic when patients often avoided coming in for appointments [8] and health care providers were faced with a significant barrier to adequately care for their patients with hypertension and other chronic diseases. Many eligible patients with hypertension were not being seen in the office, and therefore could not be adequately or efficiently managed. Inevitably, there were also many patients developing new and sometimes uncontrolled hypertension that went unrecognized due to missed appointments. With the COVID-19 pandemic, broad legislative permissions facilitated at-home and telemedicine interventions necessary to pragmatically manage the pandemic, which led to an increase in at-home digital health care programs [9-11]. In 2020, the University of California San Diego (UCSD) implemented Project 1000 (P1000) an electronic health record (EHR)-integrated Bluetooth-enabled and team-based telemonitoring RBPM program available free for patients with uncontrolled hypertension. In this study, we explore whether knowledge of and information on referral patterns influence primary care physicians' (PCPs') adoption of the program through intention to refer patients to P1000.

We developed a physician survey to explore the reasons behind diverse referral patterns and analyzed the results. We hypothesize that (1) more knowledge of the digital health program is positively associated with physicians' proclivity to refer eligible patients, and (2) information on their own prior referral rates versus their own and their peers' referral rates could influence their likelihood to refer future patients. Using a mixed methods approach, we examined factors associated with physician intention to refer patients to P1000.

Methods

UCSD P1000 Program

P1000 is an innovative free EHR-integrated, Bluetooth-enabled, and team-based telemonitoring RBPM program piloted to 1000 patients whose in-office BP measured 140/90 or greater. Due to success, the program was expanded. PCPs were initially introduced to the digital RBPM program by the Population Health Services Organization (PHSO) on how to refer eligible patients. The original method of outreach was through automated phone calls, which resulted in low enrollment. An adjustment to the recruitment approach was made to involve patients' PCPs using direct electronic referrals within our Epic (Epic Systems) EHRs system. Once the referral is entered, a digital health program team member reviews eligibility, acknowledges the referral in the EHR, and reaches out to the referred patient. Participating patients are shipped a Bluetooth-enabled digital BP cuff that automatically transmits BP data to the patient portal of the EHR via a smartphone app. Enrollees are supported by a digital health specialist via telephone or in the patient's home for device setup and any technical issues. The devices are provided free to all enrollees and retrieved or replaced only in the case of a defective device, or if the devices are having accuracy issues and used for more than one year. The EHR system stratifies BP measures into 3 risk groups: normal, high or priority, and critical, and presents them on a daily dashboard. Nurse care managers review the dashboard and make treat-to-target adjustments per protocol, encompassing medication adjustments and behavioral change recommendations. Outcomes of the referral are documented by the team member reviewing the patient dashboard and a message is sent back to the referring provider. Since 2020, over 2500 patients have been referred to the program. BP control data analyzed since the inception of this program has shown improvement in BP control for those referred to the program regardless of participation in or continuation with the digital RBPM program [12]. However, analysis of referral patterns suggested heterogeneous referral rates among PCPs. PHSO funded the cost of the program, which remains ongoing at UCSD.

Assessing Factors in Digital Health Adoption

Literature suggests that adoption of new primary care practices is influenced by many factors including knowledge of available resources and programs, implementation of strategies that target the needs of the PCP's practice [13,14], and attitudes and perspectives of the clinician [7,15-17]. In particular, physician uptake of digital health care initiatives hinges upon clearly

XSL•FO
RenderX

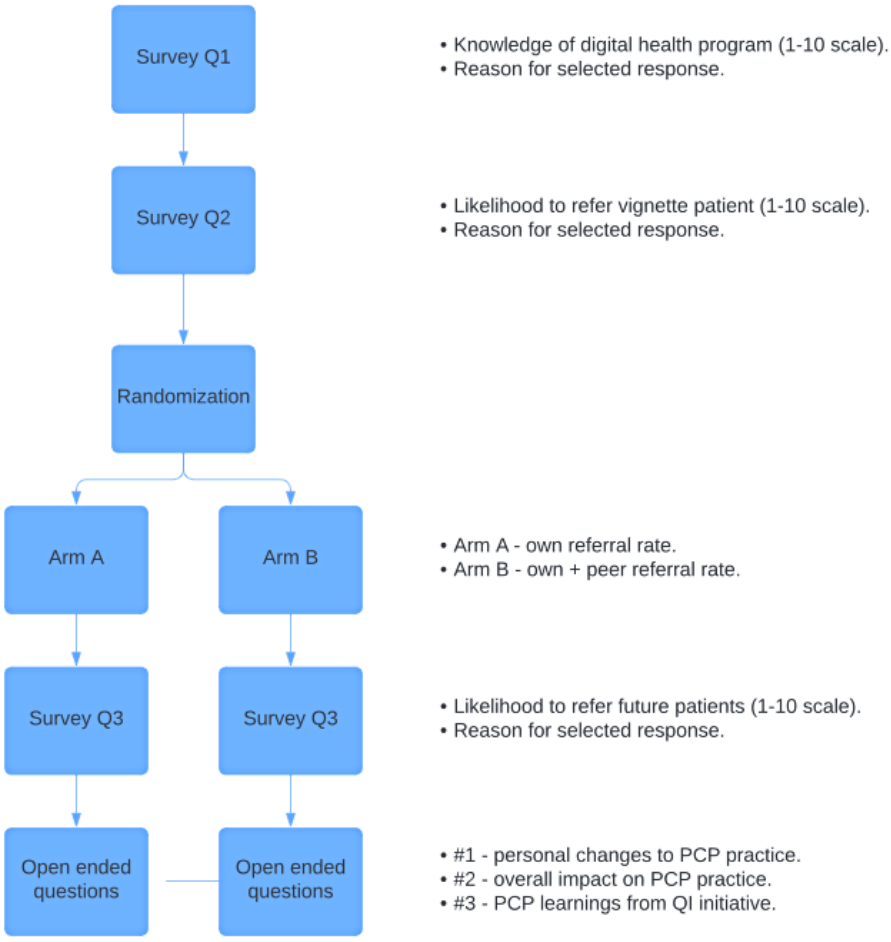
demonstrated clinical improvements for their patients, ease of integration with their clinical workflow, and easy-to-use technology that is also amply supported with technical assistance [18]. In addition, the adoption of new treatment options can be influenced by knowledge of or observation of their peer's behavior in the case of pharmaceuticals [19], but not in other instances, for example, the uptake of EHRs [20]. Notably, PCPs are likely to be early adopters of digital health care initiatives [21]. Therefore, performance data on referral rates was deliberately included to study the influence of current performance data on the decision to refer.

We explored the reasons behind such diverse practice patterns by developing a physician survey. We had three goals: (1) assess physicians' knowledge of the digital health program, (2) explore their proclivity to refer patients who clearly meet eligibility criteria, as portrayed in a vignette, and (3) inform them of their own prior referral rates, or their own and their peers' referral rate, and reassess their likelihood to refer future patients.

Design

We used an exploratory, sequential design for this mixed methods study. PCPs were recruited from Family Medicine (FM), General Internal Medicine (GIM), and Community Care (CC) at UCSD Health. Referral data for physicians in these departments were provided by an Epic analyst. Each physician was sent an individual survey link via email.

Various outreach approaches were used. FM physicians received a 10-minute presentation on the survey project and were given time to complete the survey, which was sent prior to the meeting from the FM Clinical Services Chief. GIM, Geriatrics, and CC practice physicians were informed at departmental meetings that an invitation to participate would be emailed to them and encouraged them to reply. They did not receive a formal presentation nor allotted time to answer the survey. As such, outreach to GIM, Geriatrics, and CC was less extensive.



All eligible physicians were randomized using simple randomization via a random number generator in the CRAN package of statistical analysis software "R" (R Core Team) into 1 of 2 study arms, with a link to a personalized survey that included either their own referral data (Arm A) or their own referral data plus their peers' (own+peer) referral rates (Arm B). Two email reminders were sent to PCPs who had not responded. All PCP identifiers were kept confidential.

In the context of a quality improvement (QI) program, the initial introduction of the digital health program to PCPs in 2020 was the QI intervention. The survey in late 2023 assessed what changes they had made to their practice, what impact it had had on their practice, and what they had learned as a result of this QI intervention. Responses to the survey satisfied the requirements for maintenance of certification (MOC) credits for their boards.

The survey contained 5 stages (Figure 1). First, PCPs rated their knowledge of the digital health program on a scale of 0 to 10 (0 being no knowledge and 10 being extremely knowledgeable) and provided a free text response explaining their score (Q1). Second, they assessed their likelihood to refer an eligible patient on a scale of 0 to 10 (0 being not at all and 10 being definitely) by their response to a clinical vignette, a valid method for distinguishing between physician practice [22]. The vignette portrayed a patient that meets the inclusion criteria of the digital health program—a 65-year-old Black male with hypertension whose BP was 150/95, and whom the provider had worked with for 2 years during which time BP remained elevated (Q2). Third, based upon random assignment, PCPs were either shown information on their own referral rate (Arm A) or shown their own and their peers' referral rates concurrently (Arm B). The referral rates presented to respondents covered the period from October 2020 to October 2022 and were pulled from EHR data. In the fourth stage, their intention to refer future patients to the digital health program was assessed again (Q3). Fifth, qualitative reflections were gathered on what they learned, understood, and planned to change in their future practice regarding the digital RBPM program. Survey questions are included in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. The sequence of survey questions, including at what point randomization bifurcates available data (own or own+peer) participants could view when answering survey questions. PCP: primary care physician; QI: quality improvement.

Analysis

Univariate and bivariate descriptive statistics were examined. Multivariable linear regression models were used to assess factors associated with the intention to refer the patient in the vignette and the likelihood to refer future patients after seeing own versus own+peer referral rates. For the qualitative analysis, one member (RG) of the research team developed 4 codebooks (knowledge, vignette, future referral likelihood, and program takeaways) using an inductive grounded theory approach [23]. This involved iteratively refining and condensing themes extracted from a random subset of the qualitative data. In partnership with a second team member (AW), these codes were adjusted and refined. Then, these 2 research team members coded a subset of the data to ensure interpretive alignment (Cohen κ=0.84), before the remaining data were thematically coded.

Ethical Considerations

The project was reviewed by the UCSD Aligning and Coordinating Quality Improvement, Research, and Evaluation (ACQUIRE) Committee. The ACQUIRE Committee approved this project as a QI project and its approval included a decision that the project would satisfy the requirements for maintenance of certification (MOC) credit through UCSD's MOC Portfolio Program. Physicians who completed the survey were eligible for MOC credit. No additional compensation was provided to participants.

All PCP identifiers were kept confidential. The project manager (AW) distributed unique survey links via Qualtrics, ensuring that each physician received their individual or individual-plus-peer referral data. Survey responses were stored in a HIPAA-compliant OneDrive folder accessible only to the project manager. Prior to sharing with the research team, responses were deidentified. An identified dataset was shared solely with the Senior Health Professions Education Specialist, Accreditation and Educational Development, for the purpose of processing MOC credit. Our survey satisfied the Checklist for Reporting the Result of Internet E-Surveys (CHERRIES) [24], shown in Multimedia Appendix 2.

Results

Participant Characteristics and Quantitative Results

Table 1 provides an overview of the sample (N=70). The median range of years in practice was 12.5 (IQR 11-15). In total, 57% (n=40) of respondents were female, 64% (n=45) of respondents were from academic FM, 24% (n=17) of respondents were from academic GIM and Geriatrics, and 11% (n=8) of respondents were from CC (comprised of Internal Medicine or FM physicians). The average prior familiarity with the Digital Health Program was 6.47 (SD 1.81). The average likelihood of referring

XSL•FO
RenderX

the patient from the vignette (on a scale of 0 to 10, with 0 being extremely unlikely and 10 being extremely likely) was 8.54 (SD 2.12). A total of 54% (n=38) of the sample received their own+peers' referral rates, while 46% (n=32) of the sample received their own referral rates. The average referral rate of physicians from EHR data was 11.80% (SD 13.30%), while the average peer referral rate was 11.90% (SD 9.60%). The average likelihood of referring patients in the future was 8.61 (SD 1.83). Participants were randomized into 2 treatment groups—whether they were shown only their own referral rate (Arm A), or their own+peers' referral rates (Arm B).

Table 2 compares the likelihood of referring patients within the 2 treatment groups—whether they were shown only their own referral rate, or their own and their peers' referral rates.

Table 3 displays results from multivariable linear regression analyses to assess factors that could be associated with physicians' likelihood to refer an eligible patient presented in the vignette (model 1) and eligible patients in the future (model 2). Explanatory variables in model 1 included length of practice (dichotomized by ≤10 years, and >10 years), PCP gender (dichotomized by female, and male or N/A or prefer not to answer), prior knowledge of the digital RBPM program, and department (reference group was FM). Prior knowledge of the digital RBPM program was significantly associated with the likelihood of referring the eligible vignette patient (coefficient 0.47; SE 0.13; 95% CI 0.20-0.73; P<.001).

The intention to refer future eligible patients was the dependent variable for model 2 whose explanatory variables included random assignment of information received (reference group was shown own referral rate), the self-rated likelihood to refer the vignette patient, and all explanatory variables from model 1. The likelihood of referring the vignette patient was significantly associated with their intention to refer future patients (coefficient 0.62, SE 0.08, 95% CI 0.46 to 0.78; P<.001).

Table 1. Participant demographic characteristics and department.

	Arm A—own (n=32), n (%)	Arm B—own + peer (n=38), n (%)	Total (n=70), n (%)
Years of practice			
1-5	8 (25)	14 (37)	22 (31)
6-10	6 (19)	5 (13)	11 (16)
11-20	10 (31)	8 (21)	18 (26)
More than 20	8 (25)	7 (18)	15 (21)

Qualitative Results

After participants were asked to numerically score their knowledge of the digital RBPM program for hypertension management provided by UCSD Population Health, they were then asked to provide free text comments on their score. A total of 23 participants expressed high perceived knowledge of the program, scoring themselves 8-10 on the 10-point scale; 28 participants expressed moderate perceived knowledge (score 6-7) of the program; and 19 participants expressed low perceived knowledge (score <6) of the program. Of these, 13 participants exhibited low knowledge about the existence or basic function of the PHSO digital program, while 6 participants were aware of the program, but had low knowledge about patient eligibility criteria, which in turn meant they did not use it. Table 4 summarizes the findings.

After participants were asked to numerically score how likely they were to refer an eligible vignette patient with BP 150/95 mm Hg, they were asked to explain their reasons why. Primarily, it was clinical reasons that justified referral to the program, for example, “blood pressure is uncontrolled,” as well as the additional help provided by the program to physicians in monitoring patients of this type, for example, “Having additional oversight for this patient’s blood pressure would be beneficial especially when we as providers can only see the patient on an intermittent basis,” “[patient is] more likely to continue to engage if more people are touching base with him.” Others stated that the program is “not appropriate for all cases” and that the hypothetical patient’s trajectory also “depends on other factors.” Those who suggested they would not refer had hesitations about the program rather than clinical need; one participant said, “I forget about this resource”; while another said, “many older patients are not interested in the extra hassles and intimidated by technology.”

Physicians were randomized to be shown their referral rate to the program (Arm A) versus their own referral rate and the referral rate of their peers in the same clinic (Arm B) and asked to score the likelihood that they would refer patients to the program in the future. After giving their score, they were asked to explain the reason for their score. Nine participants (n=4 Arm A; n=5 Arm B) discussed how they already use the program and intend to continue doing so, for example, “I have been using the program more recently and have seen improvements in my hypertensive patients.” Six participants in Arm B and 2 participants in Arm A professed that their newfound understanding of the utility of the program would lead to greater referrals, for example, “Seeing this information prompts me to recognize that maybe I am not taking advantage of this resource as much as I thought.” However, some expressed hesitations about future referrals. Notably, 9 participants in Arm A and 4 participants in Arm B hesitated about further patient adoption of the program, worrying about technological aptitude: “I find most of my patients do not enroll in the program because they cannot manage the technology involved”; about insurance coverage: “I don’t know about insurance coverage for this service”; or simply refusing: “most patients referred decline.” Five participants from Arm A and 1 participant from Arm B had no intention to refer.

Table 4. Quantitative score of perceived knowledge of the digital program (0-10) alongside qualitative responses.

Knowledge of the digital RBPM[a] program and code, and quote
Very knowledgeable (8-10), n=23
"Used the program frequently"
"[I] Feel confident in how to access their services, how to view the home blood pressures, and how to communicate with the main nurses, pharmacists ... etc."
Somewhat knowledgeable (6-7), n=28
"Refer many patients, see some messages, but not truly aware on logistics and options of services provided"
Lacking knowledge of program features (<6), n=13
"I have no idea on how this program works and how the data collected help me directly manage my patients. Or whether the Population health will manage these patients for me."
Lacking knowledge of patient eligibility (<6), n=6
"Unclear which patients are eligible."

[a]RBPM: remote blood pressure monitoring.

To meet the requirements for MOC, participants were asked to reflect on the QI intervention, and how it would affect their future practice. They were asked about what they would change personally and clinically because of the intervention, as well as what their key learnings and takeaways were. Participants were excited by how the clinical data would improve their practice and patient gaps. Some simply appreciated having more, and more continuous, data: "I have gained valuable data about my patients from their home monitoring, and have been able to, and felt more comfortable to intervene with medical treatment when needed for blood pressure that is uncontrolled." Many highlighted how at-home monitoring clearly demonstrated the extent of overdiagnosis of hypertension stemming from white coat syndrome: "I also found that patients with anxiety and white coat hypertension were less likely to be overtreated with medications when referred to this program." Having contemporaneous data would lead to better clinical outcomes, many felt: "This blood pressure monitoring program and hypertension management program can lead to better cardiovascular outcomes and better overall health for patients because of the real-time monitoring."

A total of 29 (41%) providers expressed a determination to refer to PHSO more often as part of their clinical practice, acknowledging its value in comments, including the following: "I plan to utilize the PHSO HTN program more often. Also to use it when indicated. This improves patient's outcomes." Some went further, noting the availability of collaborative programs within UCSD Health that may improve clinical outcomes and reduce clinician workload: "Better understanding of health systems programs that can address complex cardiovascular care from the primary care perspective." A few noted that the program brought them confidence and assurance: "Participating in the program reassured me about the quality and accuracy of their reading."

Another theme emerging from the reflections was that providers were happy with how the patients were empowered to participate in their own care through the program. One said that patients "were excited when starting digital health monitoring," while another said, "I have learned the benefit of patient participation in collecting data to view where they are in their health." One went further, saying "patients can be more engaged in their health when we make access to decision-making easier." A patient education theme also emerged: "The digital health options have increased patient compliance, participation, and knowledge in the management of hypertension."

Finally, more physicians in Arm B (n=10) than in Arm A (n=6) expressed an increased desire and capacity to harness medical technology in the future, particularly in concert with their patients, due to the QI intervention. One provider suggested they underestimated the ability of their older people, nonnative speaking patient population to do this: "Maybe not underestimating PHSO ability to provide services to my elderly Mandarin-speaking population through the use of interpreters as many of them are still tech-savvy enough to use smartphones so could likely incorporate similar technology at home." By using technology, patients and providers could be in closer contact, but also better connected to the wider medical infrastructure for a more thorough, networked care experience: "It renewed a sense of institutional support for keeping our patients healthy. It also renewed my appreciation that there are teams of health care staff in our system who stand ready to assist us in our work and keep us focused." Finally, the program enabled physicians to practice state-of-the-art medicine: "I feel like the QI project has made my practice more up to date with current medical care trends."

Table 5 summarizes key facilitators and barriers to physician participation in the program. There are 4 key facilitators to ongoing physician participation in the program. First, getting an initial referral underway is important, as the benefits of the program become apparent quickly and diffuse many initial apprehensions. Second, having BP data at more regular intervals provides greater data clarity to inform clinical decision-making, and identifies instances of white coat hypertension. Third, physicians are encouraged to continue in the program by 2 improvements to patients; first, their clinical care, but also the education, empowerment, and agency they receive by participating in their care in collaboration with their doctor. Fourth, physicians can benefit from advances in medical

XSL•FO
RenderX

technology and are well supported by a team while doing so. Four key barriers to physician participation in the program also surfaced. First, PCPs express concerns about patients' ability to adhere to the program, like an inability to use the technology or reluctance to take BP measurements. Second, some PCPs view the program as reducing their control over managing their patient's hypertension, and possibly increasing their workload in the process rather than reducing it. Third, some physicians do not understand the program structure, thinking it costs patients or requires insurance. Fourth, physicians were unclear about patient eligibility to enroll in the program.

Table 5. Qualitative categories of facilitators and barriers to physician use of the digital RBPM[a] program.

Subtheme	Quote
Facilitators to PCP[b] participation in the program	
Getting PCPs started is vital, once they begin using the program they see improvements in patients and understand it better	"I discovered the benefits of home BP readings which directed to manage and control my patients' Hypertension. But, I was not sure that their readings were accurate or the quality of their devices since they were not calibrated. Participating in the program reassured me about the quality and accuracy of their reading."
Continuous clinical oversight improves PCP understanding of hypertension, reduces white coat and other clinical errors	"I also found that patients with anxiety and white coat hypertension were less likely to be overtreated with medications when referred to this program"
Observing 2-fold patient benefit, whereby patient care is improved but also patient experience and agency is heightened	"I have learned the benefit of patient participation in collecting data to view where they are in their health"
Program is a way to harness advancing medical technology and increase patient touchpoints with team-based support	"I'm learning about the power of harnessing remote digital technology to provide another layer of support to patients outside of the office. The more regular the medical contact with a poorly controlled medical problem the better."
Barriers to PCP participation in the program	
Concerns about patient capacity to adhere to the program	"Many older patients are not interested in the extra hassles and intimidated by technology"
Fear over losing control over how patient hypertension is managed	"I feel like it is taking away from my own work for helping patients with their HTN"
Misunderstanding of program funding structure	"I don't know about insurance coverage for this service"
Misunderstanding of eligibility criteria for the program	"I was not aware who qualifies for the program"

[a]RBPM: remote blood pressure monitoring.

[b]PCP: primary care physician.

Discussion

Principal Results

Quantitative analyses suggest knowledge of the program was significantly associated with physicians' likelihood to refer the eligible vignette patient, which itself was significantly associated with the intention to refer future patients. Those with high knowledge scores frequently explained how this knowledge came from frequent use and experience with the program, and those with low knowledge scores frequently expressed reservations about basic eligibility criteria and the clinical and practical utility of the program, which indicates lower use.

Similarly, those more inclined to refer the vignette patient tended to mention their experience receiving additional help referring prior patients with these clinical needs and were less likely to be concerned about whether their patients could use the technology—other studies indicate fears about patients using digital RBPM are often overestimated by physicians [9]. Some of those who were reluctant to refer the vignette patients expressed the need for more clinical context, which, in essence, is what the program offers with minimal additional clinical or administrative burden to PCPs. Additionally, as seen in existing literature [15], some providers are hesitant to refer as they feel it affects the clinician's ownership of the patient's care.

Despite some participants identifying barriers to referring patients, reflections from PCPs about the program were generally positive. Many referenced the improved clinical outcome it produced, and its capacity to provide patients with education and enhanced agency over their care as key reasons why they would use the program in the future. One important clinical insight, that supports other studies of digital monitoring for hypertension [25], is that the program helps clarify the incidence of white coat syndrome—one participant said "I also found that patients with anxiety and white coat hypertension were less likely to be overtreated with medications when referred to this program"—which wastes clinical resources, as well as physician's and patient's time [3]. One previous study discovered as many as 8% of their cohort had white coat syndrome [25] when enrolled in a digital RBPM program; our qualitative data gently supports this clinical justification for digital RBPM programs.

Criteria for hypertension can vary in different clinical contexts, and misalignment between being categorized as hypertensive in a PCP native data environment (>130/80 mm Hg) and being a candidate for the population health program (>140/90 mm

XSL•FO
RenderX

Hg) may have left some physicians questioning the appropriate time to refer. How to best prompt physicians to consider this resource for eligible patients remains a somewhat unanswered question. In addition to PCP awareness of clinical eligibility criteria for the program—which qualitative and quantitative data suggests is mixed—it is important for physicians to be aware of the program's payor-neutral status. Patients face no cost-sharing in this program. Some PCPs incorrectly believed that insurance status and financial limitations might preclude patient participation.

Furthermore, it is vital that health care organizations ensure that team-based services like these are perceived as supportive partners rather than adding to already-excessive administrative burden. In the future, it would be prudent to solicit physician input on determining the most appropriate channels for communication regarding patients comanaged by the PHSO digital health program and PCP. This applies to communicating eligibility, enrollment, and ongoing monitoring. Several physicians who used the program frequently noted that it not only supported and empowered patients, but also actively reduced physician burden, particularly with patients who had poor access to consistent health care for reasons of socioeconomics, geography, or age-related mobility issues. Simple BP follow-up appointments can easily clog a physician's already limited availability, especially if no-shows are frequent, while also placing demands on patients ill-suited to frequent clinic visits due to chronic disease burden. A collaborative emphasis that does not place responsibility solely on the PCP is most appropriate [9].

Some physicians reported concerns regarding patient receptivity to digital monitoring tools, whether it be older patients who are less technologically savvy, patients who are non-English speakers, or those with limited financial resources—highlighting the need to address these potential barriers more proactively to enhance the footprint of this program to those in need. There may be patients with negative attitudes about having others involved in their care, and perhaps that perception reflects PCP practice habits if physician autonomy in care management tends to be prioritized or viewed as superior to referring to other members of the health care team. Though one might intuit that earlier career physicians may be more receptive to team-based care initiatives such as this program as a new way of practice, our data did not show evidence of an effect in the likelihood to refer across years of practice groups. Furthermore, physician concerns regarding their autonomy in patient management did arise in qualitative findings, highlighting the need to emphasize the collaborative nature of such initiatives which recognizes the physician as an essential member of a patient's care team.

This study found no evidence of an effect of seeing own+peer's referral rates compared with seeing only their own referral rate. That said, it is unclear whether awareness of the clinical practices of one's peers might warrant an immediate impact on one's own practices but over time could be a factor of influence. As such, future studies might follow a cohort for a longer time, sharing peer referral data rates, to determine if the effect has a greater influence over time.

Limitations

Outreach approaches varied. FM physicians received a 10-minute presentation about the survey project and were given time to complete the survey, which had been sent prior to the meeting via an email invitation from the FM Clinical Services Chief. GIM, Geriatrics, and CC practice physicians did not receive a formal presentation nor allotted time to complete the survey, which may have contributed to the underrepresentation of these 2 practices.

Patient referrals were attributed to the patient's PCP in the EHR. Patients may not see their attributed PCP at every visit, so a colleague, Resident Physician, or Advanced Practice Provider may have made the referral. Thus, the referral rates as abstracted might not be entirely representative of any given physician's actual personal utilization of the program based upon the data, though we presume that this general foundation of comanaging patients in academic practices likely evens out such that it still is an adequate approximation of their referral patterns. Given our sample size is relatively small and collected at a single institution, this study may be underpowered and limited in its generalizability. Future studies might seek larger PCP populations across multiple institutions situated in diverse socioeconomic and geographic contexts with variable overall chronic disease burden. They might also investigate whether differences exist between FM, Internal Medicine, and other departments, or between academic and community settings, in the acceptance and utilization of digital health for chronic disease care. Finally, the program at the time of the study was limited to English-speaking patients only, limiting the potential patient pool eligible for the study.

Conclusions

This study indicates that PCP knowledge and understanding of digital health monitoring programs, in terms of clinical outcome, practical application, and the reduction of work burden, is crucial to increased use and thus widespread effectiveness of these programs. Contextualizing PCP referrals with their peers' referrals showed no evidence of an effect in furthering their intention to adopt the program. Since remote patient monitoring has an increasing volume of empirical support for improving clinical outcomes, we encourage more robust communication of the effectiveness of these programs, their ease of use, and the availability of support to PCPs to increase enrollment and improve population health.

Acknowledgments

We would like to acknowledge all the University of California San Diego (UCSD) faculty who contributed to our data by completing our survey regarding the remote digital health monitoring program. We appreciate the diligent and dedicated work of our UCSD Family Medicine research team (RG, CB, and AW) without whom the analysis, interpretation of data, and research

Abstract

Background: Torsades de pointes (TdP) is a rare yet potentially fatal cardiac arrhythmia that is often drug-induced. Drug-drug interactions (DDIs) are a major risk factor for TdP development, but the specific drug combinations that increase this risk have not been extensively studied.

Objective: This study aims to identify clinically significant, high-priority DDIs to provide a foundation to minimize the risk of TdP and effectively manage DDI risks in the future.

Methods: We used the following 4 frequency statistical models to detect DDI signals using the Food and Drug Administration Adverse Event Reporting System (FAERS) database: Ω shrinkage measure, combination risk ratio, chi-square statistic, and additive model. The adverse event of interest was TdP, and the drugs targeted were all registered and classified as "suspect," "interacting," or "concomitant drugs" in FAERS. The DDI signals were identified and evaluated using the Lexicomp and Drugs.com databases, supplemented with real-world data from the literature.

Results: As of September 2023, this study included 4313 TdP cases, with 721 drugs and 4230 drug combinations that were reported for at least 3 cases. The Ω shrinkage measure model demonstrated the most conservative signal detection, whereas the chi-square statistic model exhibited the closest similarity in signal detection tendency to the Ω shrinkage measure model. The κ value was 0.972 (95% CI 0.942-1.002), and the $P_{positive}$ and $P_{negative}$ values were 0.987 and 0.985, respectively. We detected 2158 combinations using the 4 frequency statistical models, of which 241 combinations were indexed by Drugs.com or Lexicomp and 105 were indexed by both. The most commonly interacting drugs were amiodarone, citalopram, quetiapine, ondansetron, ciprofloxacin, methadone, escitalopram, sotalol, and voriconazole. The most common combinations were citalopram and quetiapine, amiodarone and ciprofloxacin, amiodarone and escitalopram, amiodarone and fluoxetine, ciprofloxacin and sotalol, and amiodarone and citalopram. Although 38 DDIs were indexed by Drugs.com and Lexicomp, they were not detected by any of the 4 models.

XSL•FO
RenderX

Conclusions: Clinical evidence on DDIs is limited, and not all combinations of heart rate–corrected QT interval (QTc)–prolonging drugs result in TdP, even when involving high-risk drugs or those with known risk of TdP. This study provides a comprehensive real-world overview of drug-induced TdP, delimiting both clinically significant DDIs and negative DDIs, providing valuable insights into the safety profiles of various drugs, and informing the optimization of clinical practice.

KEYWORDS

torsades de pointes; FAERS database; drug-drug interactions; QTc-prolonging drugs; adverse drug events

Introduction

Torsades de pointes (TdP) is a rare but life-threatening cardiac arrhythmia characterized by a prolonged heart rate–corrected QT interval (QTc) on an electrocardiogram. TdP is often induced by QTc-prolonging drugs, which can further increase the risk when used in combination. According to the Arizona Center for Education and Research on Therapeutics, 268 drugs are known to be QTc-prolonging drugs, including antiarrhythmics, antibiotics, antipsychotics, antidepressants, and antineoplastic drugs. These drugs are classified into 3 categories: 68 drugs with a known risk of TdP, 148 drugs with a possible risk of TdP, and 52 drugs with a conditional risk of TdP [1]. Chien et al [2] conducted a large-scale, case-crossover study demonstrating that QT-prolonging drug use and related drug-drug interactions (DDIs), particularly “known risk” or “conditional risk” drugs, are significantly associated with QTc prolongation. This risk is further exacerbated by the concurrent administration of these drugs with other QT-prolonging agents or potent cytochrome P450 inhibitors. The resulting exponential increase in potential DDIs is considerable and warrants careful consideration when these medications are used concurrently. In clinical settings, DDI alerts are implemented to warn of potential QTc DDI risks. However, their unclear clinical relevance often leads to indiscriminate alerts, resulting in over 90% being ignored, limiting the effectiveness of QTc DDI alerts [3,4]. Wasserman et al [4] found an average of 3 unique QTc DDI alerts presented per patient admission (range 1-44), with an average of 6 overridden QTc DDI alerts (range 1-432), ultimately resulting in 29% of admissions experiencing a drug-induced QTc prolongation with a ≥60-point increase in QTc value from baseline or a post-QTc value of ≥500 ms, representing a significant increase in TdP risk. Although DDIs are recognized as a significant risk factor for TdP development, the specific drug combinations contributing to this risk remain poorly characterized.

In clinical practice, the assessment of DDI risks often relies on multiple information sources, such as Micromedex, UpToDate, Drugs.com, and Medscape.com. However, significant variability exists among these resources, as demonstrated by Shariff et al [5], who reported poor intersource reliability scores ($\kappa<0.20$, $P<.05$) [5]. This inconsistency complicates decision-making for health care professionals and underscores the importance of using real-world data to detect clinically significant DDIs. The challenge is particularly acute with older adults, patients with cancer, and critically ill patients with multiple comorbidities, who often receive complex drug regimens that extend beyond the 2-drug combinations typically considered in DDI reports [6-8].

Literature data serve as valuable real-world evidence, with numerous cases of drug-induced TdP documented. However, there is a notable paucity of evidence concerning DDIs in these reports. Krumpholz et al [9] conducted a comprehensive review of literature-reported cases of drug-induced TdP from 1980 to 2021, encompassing 424 papers of 634 case reports, which primarily documented suspected and concomitant drugs without adequately considering interacting drugs. This highlights the need for studies focusing on identifying clinically significant DDIs.

The Food and Drug Administration Adverse Event Reporting System (FAERS) database is a spontaneous reporting system that provides information about adverse events (AEs) in clinical settings and has emerged as a valuable resource for pharmacovigilance research. Although the database has limitations, including potential inaccuracies, underreporting, and missing data, it provides unique insights into postmarketing drug safety. In the FAERS database, 2 or more suspected, interacting, or concomitant drugs for each event can be given, which is particularly useful for identifying DDIs that result in severe or fatal AEs. However, significant uncertainty exists regarding the association between drugs and AEs in the given report, as these reports encompass all potential drugs and AEs for a patient. Recent methodological advances have enhanced the utility of FAERS for DDI detection, particularly through the application of multiple statistical models that can improve signal detection reliability [10,11]. This study aimed to integrate multiple data sources, including the FAERS database, DDI information resources, and relevant literature, to detect clinically significant DDIs associated with TdP risk. By using advanced analytical methods and cross-validating findings across multiple sources, we sought to provide more reliable and actionable insights for clinical decision-making.

Methods

Data Sources

A retrospective, disproportionality, pharmacovigilance study was conducted from the first quarter of 2004 to the second quarter of 2023 using the FAERS database to detect potential DDIs that increase the incidence of TdP in a large-scale population. In the FAERS database, each report is coded using the preferred terms (PTs) provided by the Medical Dictionary for Regulatory Activities (MedDRA), and each drug is assigned a code according to its association with AEs: suspect drugs, concomitant drugs, or interacting drugs. OpenVigil

XSL•FO
RenderX

2.1-MedDRA-v24 [12], an open tool for data mining and analysis of pharmacovigilance data using cleansed FDA AE reporting data, was used to detect DDIs.

Definition of AE

In this study, the targeted AE was TdP, which was extracted from FAERS using the PT of TdP (PT code: 10044066). In these cases, all drugs classified as suspected drugs, interacting drugs, and concomitant drugs were included in the process to investigate DDIs. For signal detection, we focused only on combinations of 2 drugs with 3 or more cases.

Suspect Drugs of TdP Cases

Single-drug TdP signals were assessed for disproportionality using the established pharmacovigilance index, the reporting odds ratio (ROR). ROR values were calculated as (a × d)/(b × c) and expressed as point estimates with a 95% CI. In our study, an event was considered significant when the ROR value was greater than 2 and the lower limit of the 95% CI of the ROR was greater than 1, and at least 3 cases were required to define a positive signal for the ROR.

DDI Signal Detection Statistical Models and Standards

Several statistical algorithms have been developed for exploring DDI signals, yet no de facto standard exists for DDI signal detection in spontaneous reporting systems [10,11]. Each method has inherent advantages and limitations. Among them, the Ω shrinkage measure model, proposed by Norén et al [13] and used by the World Health Organization Uppsala Monitoring Center, calculates an observed-to-expected ratio for disproportionality measurement of potential DDIs. This method demonstrates a conservative signal detection trend among frequentist-based approaches, effectively minimizing false positives by handling sparse data, adjusting for deviations in expected frequencies, and shrinking the extreme ratios toward the overall mean. It is particularly well-suited for monitoring rare AEs (eg, TdP) in noisy databases like FAERS but requires clinical validation to confirm associations between drug combinations and adverse reactions. The additive model, as described by Thakrar et al [14], estimates co-medication risks by evaluating target AE incidences across different exposure scenarios. Although highly sensitive for detecting potential drug synergies, it is prone to spurious associations due to noise and biases in spontaneous reporting systems. Similarly, the chi-square statistic model with Yates correction, proposed by Gosho et al [15], is widely used but vulnerable to false negatives or false positives when applied to sparse data, limiting its utility for rare events like TdP. The combination risk ratio model, proposed by Noguchi et al [16], offers a theoretical framework for assessing the joint risk of co-medicated drugs by assuming that the occurrence of AEs represents a combined risk of both drugs. This approach is valuable for exploring potential interactions but relies heavily on sufficient co-medication frequency, limiting its effectiveness with rare drug combinations.

To address these limitations, a multimethod cross-validation approach was used, integrating the Ω shrinkage measure model, additive model, chi-square statistic model, and the combination risk ratio model (calculation methods are detailed in Multimedia Appendix 1). This ensures that signals detected by multiple methods are less likely to be statistical artifacts. Ω shrinkage was prioritized as the baseline model due to its robustness at handling sparse data and its ability to minimize false positives. Additive models were further screened using Ω shrinkage to reduce spurious associations. For signal confirmation, all 4 statistical models were applied, with a positive signal defined as one consistently detected by all 4 methods. We constructed 2 contingency tables—a 4-by-2 table and a 2-by-2 table—to facilitate the analysis (detailed in Multimedia Appendix 1). Additionally, the specific criteria for signal detection applied to each model are detailed in Table 1.

Table 1. The signal detection criteria for each statistical model.

Statistical models	Criteria for positive signals
Ω shrinkage measure model	$\Omega_{025} > 0$, $n_{111} \geq 3$
Chi-square statistic model	$\chi > 2$, $n_{111} \geq 3$
Combination risk ratio model	$PRR^{a}_{drug\ D1 \cap drug\ D2} > 2$, $\chi^2_{drug\ D1 \cap drug\ D2} > 4$, $CRR^{b} > 2$, $n_{111} \geq 3$
Additive model	$P_{11} - P_{10} - P_{01} + P_{00} > 0$, $n_{111} \geq 3$

[a]PRR: proportional reporting ratio.

[b]CRR: combination risk ratio.

To ensure robustness and minimize false positives, positive DDI signals underwent external validation by cross-referencing with established DDI databases and a comprehensive literature review of relevant case reports to verify their clinical significance.

Evaluation of Commonality of Signals Detected

The commonality of the signals detected by each statistical model was evaluated using the Cohen kappa coefficient (κ), the proportionate agreement for positive rating ($P_{positive}$), and the proportionate agreement for negative rating ($P_{negative}$), as reported in a previous study (calculation methods are detailed in Multimedia Appendix 1). The κ provides a measure that adjusts the observed agreement for the chance agreement, which ranges from –1 to 1, and indicates the level of agreement between observed and expected values [16]. A κ value of 0 to 0.20 indicates slight agreement, 0.21 to 0.4 indicates fair agreement, 0.41 to 0.60 indicates moderate agreement, 0.61 to 0.80 indicates substantial agreement, 0.81 indicates upward excellent agreement, and the absolute agreement is 1 [17]. Conversely, κ<0 means that the observed agreement rate is less

XSL•FO
RenderX

than the chance agreement rate, which rarely occurs in practical research.

Signal Verification

As positive controls, we downloaded a list of 268 drugs with known (n=68), possible (n=148), and conditional (n=52) risks of TdP from CredibleMed, an online compendium of QTc drugs [1], and 217 drugs with the highest (n=32), moderate (n=70), and low (n=115) risks of interacting from UpToDate [18].

To ensure the accuracy and reliability of DDI results, the Lexicomp point-of-care database, known for its comprehensive scope, was used to validate DDI signals. Additionally, the open-access online drug interaction checker Drugs.com was used to cross-validate the DDI signals. The severity classifications of DDIs in the 2 drug databases are detailed in Multimedia Appendix 1 [18,19]. Subsequently, a search was conducted in the PubMed database for literature pertaining to drug-induced TdP, and an open-access database of literature-derived drug-related TdP cases, containing 624 TdP cases from 424 papers, was used to further evaluate the clinical relevance of the DDIs [9].

Sensitivity Analyses

Given that nonprofessional reporters may not have the expertise to accurately distinguish between AEs and the symptoms of the disease itself, this could potentially affect the interpretability of aggregated results, particularly in large-scale data sets like FAERS. To improve the clarity and reliability of the findings, we excluded data reported by nonprofessionals from the validated positive signal data, and conducted sensitivity analysis to assess robustness.

Ethical Considerations

This study uses the publicly accessible and anonymized FAERS database, which contains no personally identifiable information and does not involve human subject experimentation. As a result, it is exempt from review and approval by an institutional review board.

Results

Basic Information on TdP Cases

As of September 2023, a total of 4313 TdP cases from 11,439,756 AE cases were included in this study. Of the 4313 TdP cases, 2403 (55.7%) were female, and 1398 (32.4%) were male. The average age was 55.5 (range 0-97) years, and 1653 (38.3%) were older than 60 years. TdP is serious and fatal, with many of the reported cases leading to hospitalization (initial or prolonged; n=1310, 30.4%), life-threatening events (n=1705, 39.5%), or death (n=363, 8.4%). Notably, reports submitted by nonprofessionals, such as consumers and lawyers, accounted for only 290 (6.7%) of the total. This proportion is significantly lower than the 20% to 30% typically reported, likely due to the rarity and severity of TdP, which often requires hospitalization, thereby limiting the likelihood of reports from consumers. Geographically, 1784 (41.4%) of these 4313 cases originated from the United States (Table 2).

Figure 1 depicts a cocurrent network of AEs associated with TdP, providing a comprehensive overview of the patterns of TdP occurrence. The size of a node is proportional to the number of neighboring AEs, while the width of an edge is proportional to the number of unique AEs. Among the 4313 TdP cases analyzed, the most common presentations were electrocardiogram QT prolonged (n=1736), long QT syndrome (n=298), electrocardiogram QT-corrected interval prolonged (n=61), cardiac arrest (n=892), ventricular tachycardia (n=738), ventricular fibrillation (n=622), syncope (n=492), ventricular extrasystoles (n=224), loss of consciousness (n=214), cardiorespiratory arrest (n=205), atrial fibrillation (n=144), arrhythmia (n=140), ventricular arrhythmia (n=135), tachycardia (n=115), palpitations (n=114), and dizziness (n=109). The risk factors of hypokalemia, hypomagnesemia, bradycardia, electrolyte imbalance, decreased blood magnesium, and hypocalcemia were observed in 524, 235, 225, 65, 63, and 50 cases, respectively. The drug-related risk factors of drug interactions, overdose, drug abuse, intentional overdose, and toxicity to various agents were present for 513, 271, 168, 164, and 162 cases, respectively.

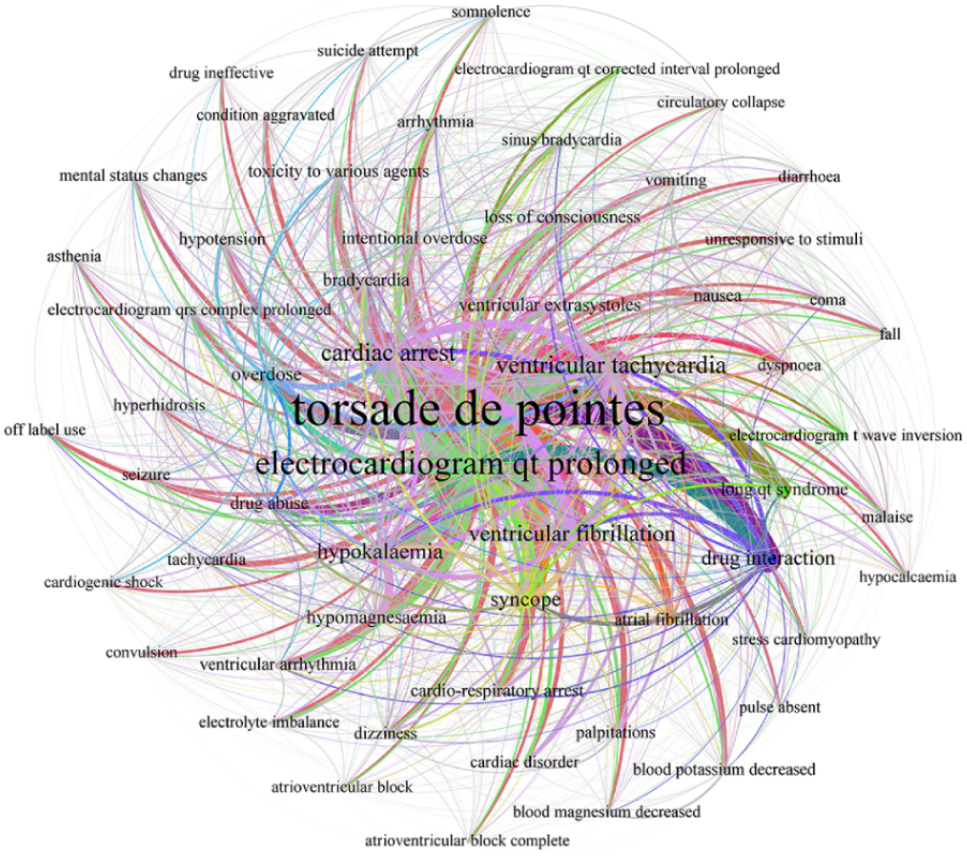

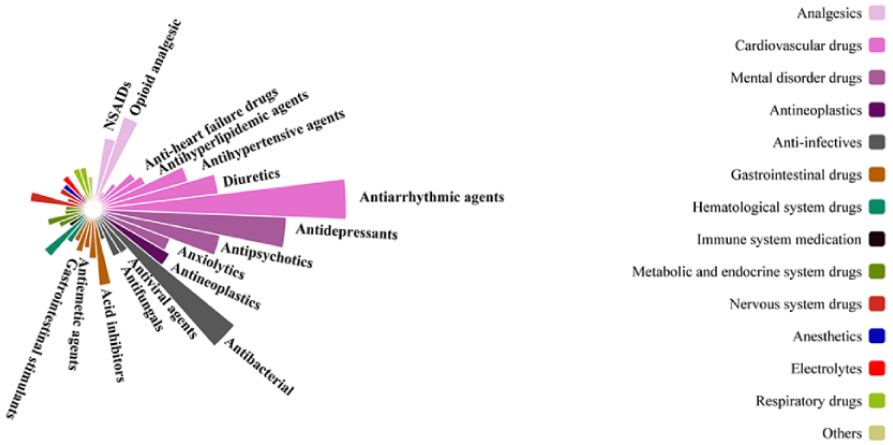

Figure 2. Distribution of torsades de pointes–related drug classes.

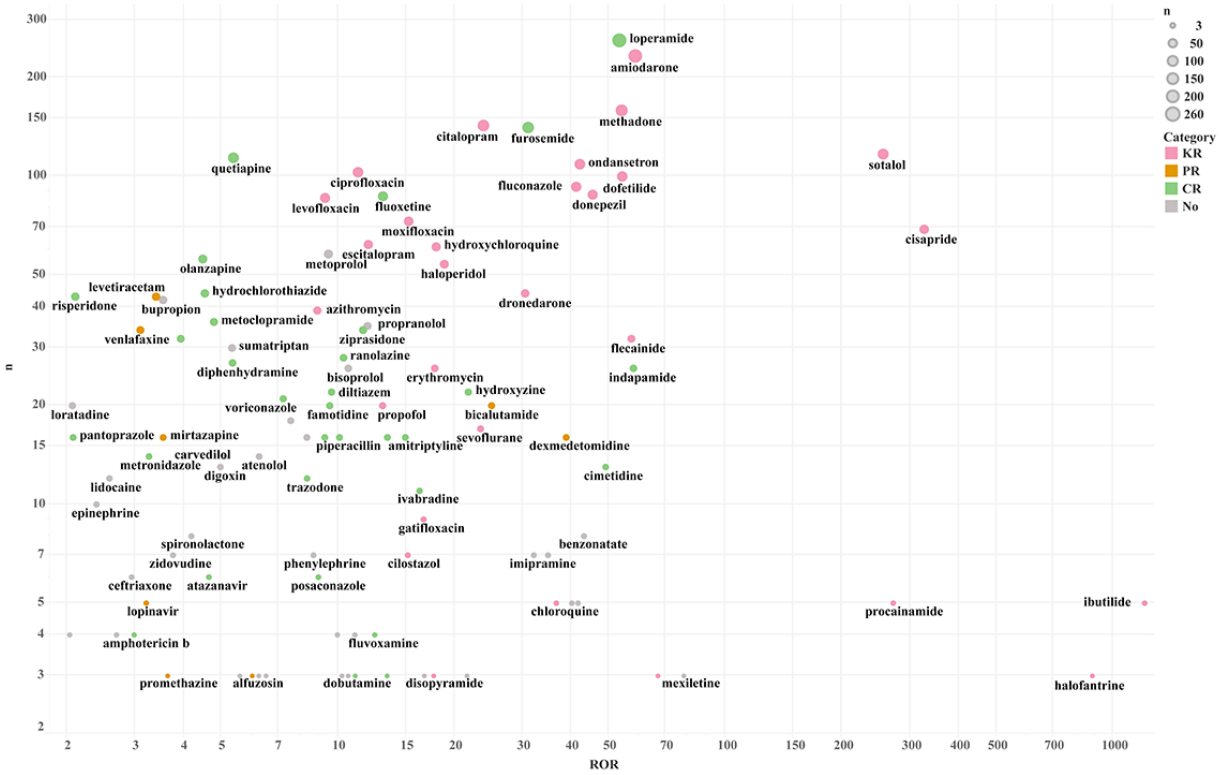


Suspect Drugs of TdP Cases

Of the 4313 analyzed TdP cases, 721 drugs, including 136 QT-prolonging drugs, were implicated in 3 or more cases. The most reported drugs were antiarrhythmics, antidepressants, antibacterials, antipsychotics, analgesics, antineoplastics, and others (Figure 2). Amiodarone had the most reports (n=524), followed by furosemide (n=448), methadone (n=312), loperamide (n=301), and citalopram (n=299). However, loperamide (n=260; ROR 53.19, 95% CI 46.87-60.36) was the most frequently reported primary suspect drug, followed by amiodarone (n=233; ROR 58.48, 95% CI 51.18-66.82), citalopram (n=143; ROR 23.72, 95% CI 20.06-28.04), methadone (n=159; ROR 53.91, 95% CI 45.95-63.26), furosemide (n=141; ROR 30.93, 95% CI 26.13-36.62), and sotalol (n=117; ROR 255.06, 95% CI 210.53-309.02). Ibutilide (n=5; ROR 1206.58, 95% CI 419.04-3474.16) had the strongest signal for TdP, followed by halofantrine (n=3; ROR 884.41, 95% CI 239.35-3267.99), cisapride (n=69; ROR 325.59, 95% CI 253.16-418.74), procainamide (n=5; ROR 270.86, 95% CI 107.87-680.12), and sotalol (n=117; ROR 255.06, 95% CI 210.53-309.02), and these drugs had a known TdP risk (Figure 3).

XSL•FO
RenderX

Figure 3. Scatterplot of the number of reports and reporting odds ratio (ROR) for torsades de pointes–related primary suspect drugs. CR: conditional risk; KR: known risk; PR: possible risk.

DDI Signals of Statistical Models

We evaluated the reports of TdP for concomitant use of 2 of the 721 drugs, totaling 8264 drug combinations, of which 4230 combinations were reported for at least 3 cases. The additive model detected the most signals with 3296 (77.9%) pairs, followed by the combination risk ratio model with 2574 (60.8%) pairs, the chi-square statistic model with 2243 (53%) pairs, and the Ω shrinkage measure model with 2236 (52.9%) pairs.

Commonality of DDI Signals Detected

Table 3 shows the κ coefficients and proportionate agreements for $P_{positive}$ and $P_{negative}$ among the 4 frequency statistical models. The chi-square statistics showed the greatest similarity to the Ω shrinkage measure, with κ, $P_{positive}$, and $P_{negative}$ values of 0.972 (95% CI 0.942-1.002), 0.987, and 0.985, respectively. In contrast, the κ, $P_{positive}$, and $P_{negative}$ values for the Ω shrinkage measure and additive models were 0.482 (95% CI 0.451-0.513), 0.808, and 0.638, respectively, with moderate similarity.

Table 3. The Cohen kappa coefficient (κ) and proportionate agreements for positive rating (Ppositive) and negative rating (Pnegative) among 4 frequency statistical models

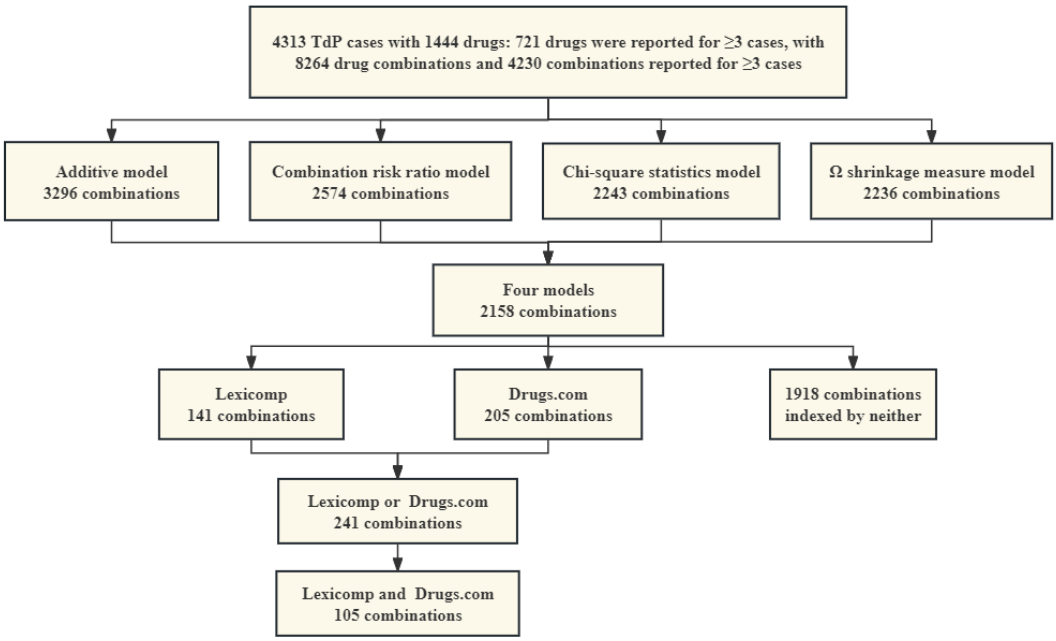
Models	$P_{positive}$	$P_{negative}$	κ (95% CI)
Ω shrinkage measure model vs chi-square statistic model	0.987	0.985	0.972 (0.942-1.002)
Ω shrinkage measure model vs combination risk ratio model	0.904	0.874	0.780 (0.749-0.810)
Ω shrinkage measure model vs additive model	0.808	0.638	0.482 (0.451-0.513)
Chi-square statistic model vs combination risk ratio model	0.910	0.881	0.793 (0.762-0.823)
Chi-square statistic model vs additive model	0.810	0.640	0.485 (0.454-0.516)
Combination risk ratio model vs additive model	0.877	0.721	0.612 (0.578-0.646)

DDI Signal Verification

All 4 statistical models detected 2158 combinations (96.2% of the Ω shrinkage measure model), with 141 combinations indexed by Lexicomp, 205 combinations indexed by Drugs.com, 241 combinations indexed by either, and 1918 combinations indexed by neither as of October 8, 2023. In addition, 105 combinations were indexed by both, with 52 combinations being present in 10 or more cases (Figures 4 and 5).

XSL•FO
RenderX

Figure 4. Process of drug-drug interaction signal monitoring and verification. TdP: torsades de pointes.



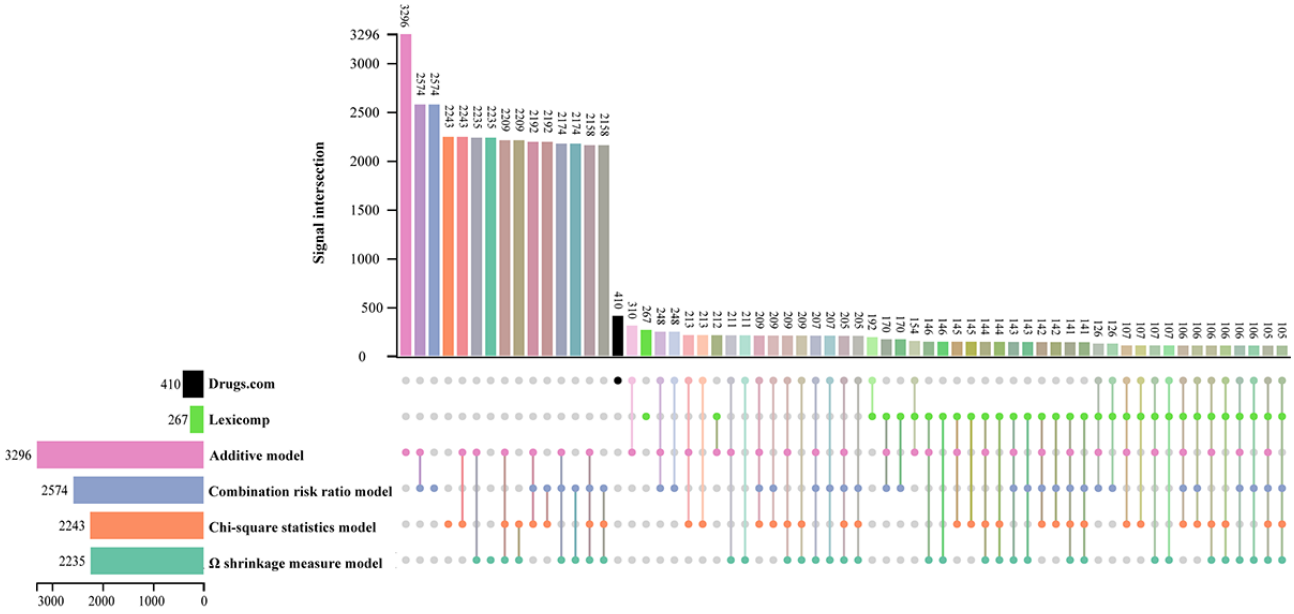


Figure 5. Number of drug-drug interaction signal intersections.

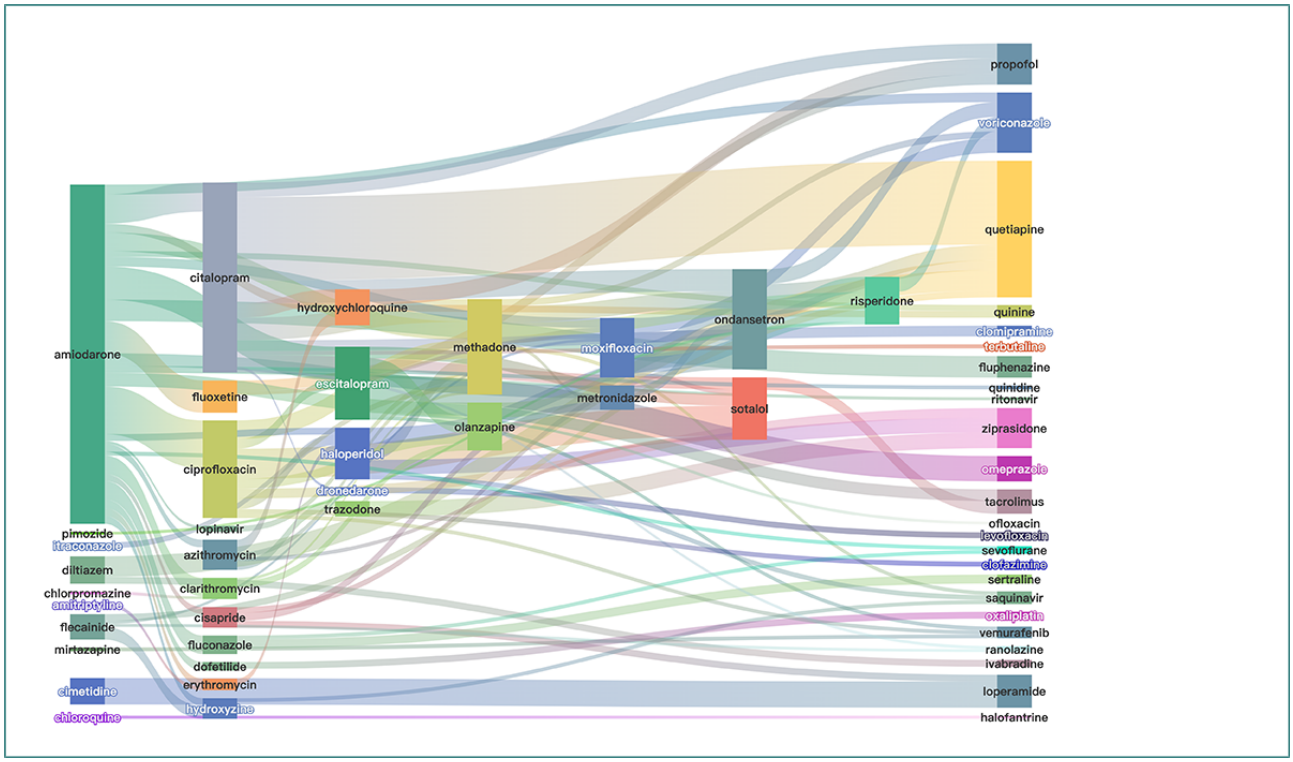
DDI Assessment

Of 2158 combinations, 409 individual drugs were involved. Categorization in CredibleMeds showed 35 “known risk,” 31 “possible risk,” and 45 “conditional risk” drugs. In Lexicomp, 12 were “high risk,” 29 were “moderate risk,” and 29 were “low risk.” The drug with the highest number of interactions was amiodarone, which interacted with 68 other drugs, followed by methadone (n=51), fluoxetine (n=46), bisoprolol (n=42), ciprofloxacin (n=41), citalopram (n=37), and lorazepam (n=37).

However, the drugs with the most reported interaction cases were amiodarone, citalopram, quetiapine, ondansetron, ciprofloxacin, methadone, escitalopram, sotalol, and voriconazole. The drug combinations are shown in Figures 6 and 7, with citalopram and quetiapine (n_{111}=86) having the highest number of cases, followed by amiodarone and ciprofloxacin (n_{111}=49), amiodarone and escitalopram (n_{111}=34), amiodarone and fluoxetine (n_{111}=33), ciprofloxacin and sotalol (n_{111}=31), and amiodarone and citalopram (n_{111}=30). The size of the nodes is proportional to the number of specific drugs with TdP, while the width of the extension branch is proportional to the number of specific combinations with TdP.

XSL•FO
RenderX

Figure 6. Drug-drug interactions (n=105) for torsades de pointes (detected by 4 models and indexed by Drugs.com and Lexicomp，n111≥3).



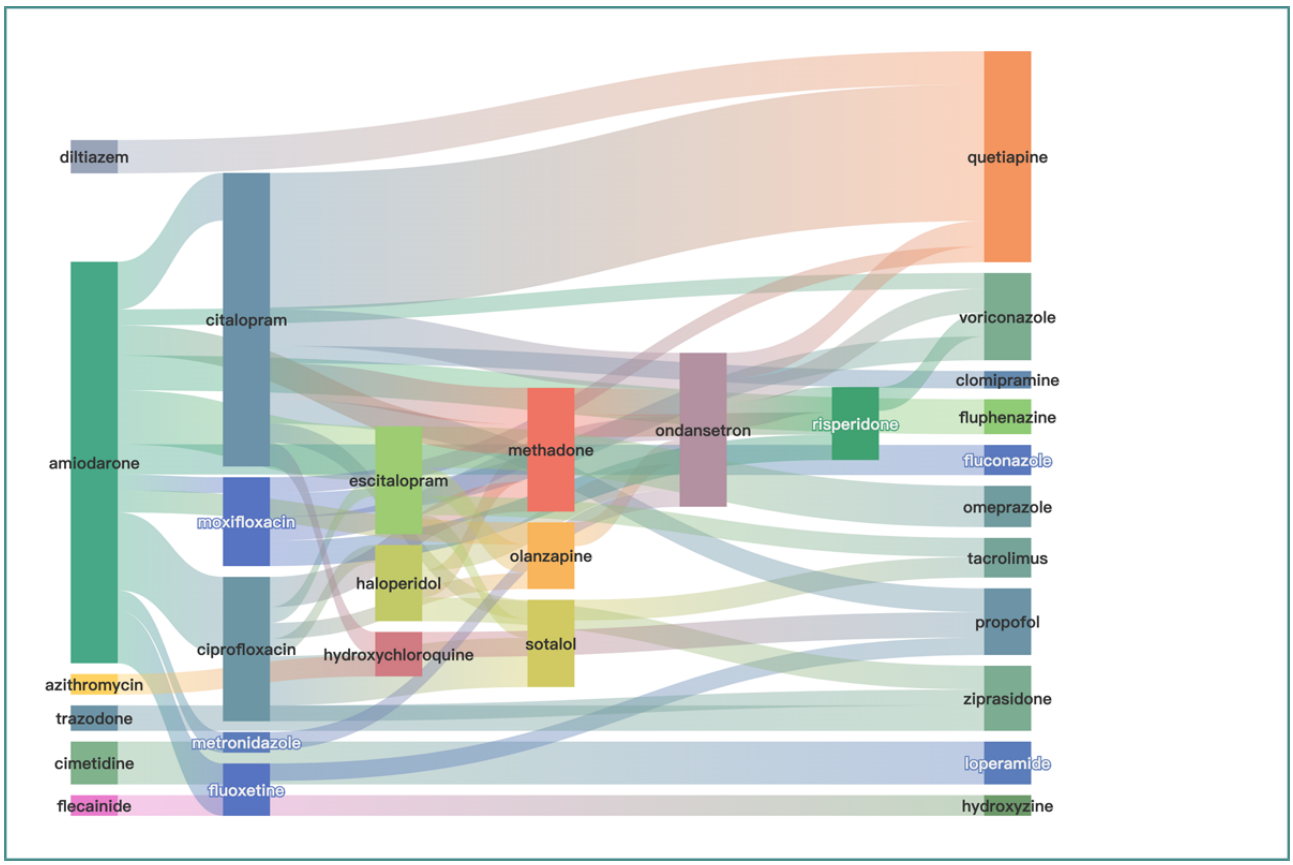


Figure 7. Drug-drug interactions (n=52) for torsades de pointes (detected by 4 models and indexed by Drugs.com and Lexicomp, n111≥10).

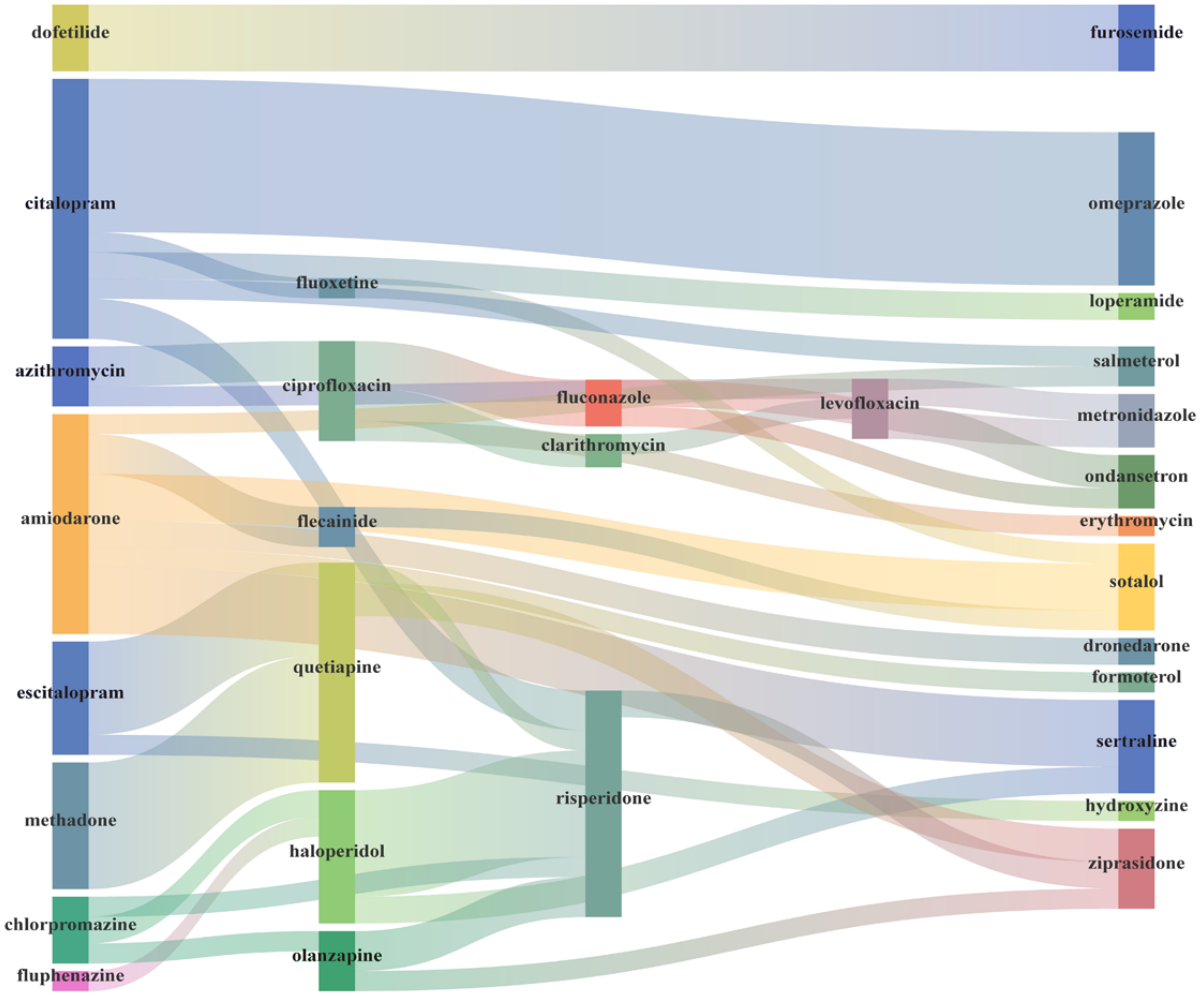

Multimedia Appendix 2 presents the characteristics of 105 drug combinations. Lexicomp classified 20 combinations as “X,” 25 as “D,” 42 as “C,” and 18 as “B.” In contrast, Drugs.com categorized 27 combinations as “Moderate risk” and 78 as “Major risk.” Additionally, 25 combinations were recorded in the literature-derived database of drug-related TdPs with enhanced clinical relevance.

Regrettably, 38 drug combinations indexed in both databases were not detected by any of the 4 models. These included 2 “X”

XSL•FO
RenderX

class (methadone and quetiapine, quetiapine and ziprasidone), 11 “D” class, 14 “C” class, and 9 “B” class drug combinations, with amiodarone and sotalol, chlorpromazine and haloperidol, and amiodarone and dronedarone being the high-risk QT-prolonging drug combinations (Multimedia Appendix 2; Figure 8).

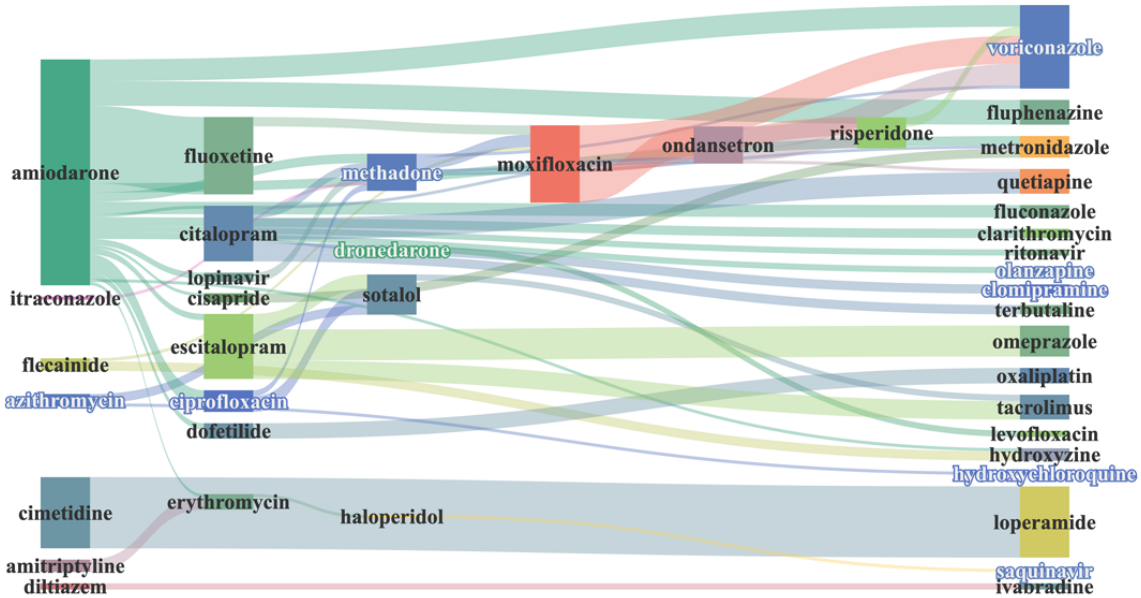

Figure 8. Drug-drug interactions (n=38) for torsades de pointes (indexed by Drugs.com and Lexicomp, n111≥3, but not detected by any of the 4 models).

Among the 4313 cases analyzed, 513 involved drug interaction events, with 984 interacting drugs reported for 460 cases. The most commonly interacting drugs were amiodarone, citalopram, fluoxetine, furosemide, escitalopram, ondansetron, omeprazole, moxifloxacin, and metoprolol. By matching the results of signal detection and validation of drug combinations, a total of 189 drug combinations were identified by the 4 models. Of these, 65 combinations were indexed by Lexicomp, 74 were indexed by Drugs.com, 84 were indexed by either, and 55 were indexed by both. Figure 9 illustrates the 55 DDIs classified as “interacting drugs” in FAERS that were detected by the 4 models and indexed by Drugs.com and Lexicomp. These include combinations like amiodarone and fluoxetine (n=25), loperamide and cimetidine (n=23), escitalopram and omeprazole (n=10), and moxifloxacin and ondansetron (n=10). Some combinations, although reported more frequently, were excluded from the analysis as they were either not detected by the model or not indexed in the database. For example, venlafaxine and quetiapine (n=17) and furosemide and metoprolol (n=17) were only detected by the additive model. Additionally, combinations like fluoxetine and fluphenazine (n=16) and fluconazole and ritonavir (n=13) were not indexed either Drugs.com or Lexicomp.

XSL•FO
RenderX

Figure 9. Drug-drug interactions (n=55) for torsades de pointes (drugs classified as "interacting drugs" in the Food and Drug Administration Adverse Event Reporting System, detected by the 4 models, and indexed by Drugs.com and Lexicomp).

Sensitivity Analyses

Despite the relatively low proportion of reports from nonprofessionals, we conducted an analysis of TdP cases reported by nonprofessionals, such as consumers and lawyers. We evaluated TdP by nonprofessionals for concomitant use of 2 of the drugs, totaling 1862 drug combinations, with 89 combinations reported for at least 3 cases. Among these, 49 combinations were detected by all 4 statistical models, and only 5 combinations were indexed by Lexicomp and Drugs.com when considering all data, including reports from nonprofessionals. Sensitivity analyses revealed that the inclusion of nonprofessional reports did not alter the final determination of the signal detection (Multimedia Appendix 2).

Discussion

Main Findings

This study presents the initial comparative safety evaluation of FAERS data aimed at assessing clinically significant DDIs triggering fatal TdP. Clinical evidence regarding DDIs remains limited, and not all combinations of QTc-prolonging drugs lead to TdP, even when high-risk drugs or those with established TdP risks are involved. This study offers a comprehensive real-world analysis of drug-induced TdP, identifying both clinically significant and nonsignificant DDIs. These findings contribute valuable insights into the safety profiles of various drugs, aiding in the optimization of clinical practice.

Matsuo and Yamaori [20] attempted to use the Japanese Adverse Drug Event Report database to identify and summarize potential DDIs associated with an increased risk of drug-induced long QT syndrome. However, their methodology relied on the ROR, which is typically used for assessing safety signals of individual drugs that may not be appropriate for detecting safety signals of DDIs, potentially leading to false positive signals. To address this limitation, 4 frequency statistical models—namely, the Ω shrinkage measure, combination risk ratio, chi-square statistic, and additive model—were used to detect DDI signals in our study, thereby greatly enhancing the validity and comprehensiveness of the identified signals. Furthermore, the verification of these signals was conducted using the Drugs.com, Lexicomp, and literature databases, thereby ensuring the credibility and reliability of the DDI data.

Consistent with previous studies, the Ω shrinkage measure model demonstrated the most conservative signal detection, while the chi-square statistic model exhibited the closest similarity in signal detection tendency to the Ω shrinkage measure model [16]. In contrast, the additive model detected considerably more signals [5] and had less similarity in signal detection tendency with the other models; therefore, care must be taken when interpreting the signals. For a specific positive signal result, the more models that detected it, the more reliable the result is. In this study, 2158 combinations were detected by the 4 frequency statistical models, of which 241 combinations were indexed by Drugs.com or Lexicomp and 105 were indexed by both. In addition, 171 combinations were indexed by only 1 of the databases, which was related to the poor consistency between the 2 databases [11] due to the various rating criteria and procedures and definitions of different levels of acceptable risk. Drugs.com validated more interactions than Lexicomp, which may be related to the fact that Drugs.com can recognize brand names. Despite using an open-access database of literature-derived, drug-related TdP cases containing 624 TdP cases from 424 papers to evaluate the clinical relevance of DDIs, only concomitant drugs were documented in all cases except for suspected drugs, with no recorded interacting drugs [9].

XSL•FO
RenderX

Unsurprisingly, limited clinical evidence on DDIs is available, owing to the inherent difficulty of judging when interactions lead to AEs. However, DDIs do exist, which highlights the value of detecting clinically significant DDIs based on real-world data.

In our study, a list containing all potential DDIs related to TdP from FAERS was provided. To the best of our knowledge, this is the most comprehensive list derived from a pharmacovigilance database so far. Consistent with the results of existing studies, antiarrhythmics, antidepressants, antipsychotics, antibacterials, analgesics, and antineoplastics drugs, such as amiodarone, citalopram, quetiapine, ondansetron, ciprofloxacin, methadone, escitalopram, sotalol, and voriconazole, were the most common interacting drugs causing TdP [20,21]. Additionally, diuretics were also common interacting drugs causing TdP, and the potential mechanism underlying this may be related to electrolyte disorder caused by diuretics. The most common combinations were citalopram and quetiapine, amiodarone and ciprofloxacin, amiodarone and escitalopram, amiodarone and fluoxetine, ciprofloxacin and sotalol, and amiodarone and citalopram, and previous studies have proven these DDIs are closely related to TdP [22-24]. Trazodone may lead to QTc prolongation and TdP, which is potentially fatal even without risk factors for QTc prolongation [25]. In addition, co-interaction with ziprasidone increases the risk of TdP. Therefore, we can use this report's findings to quickly understand the DDIs that commonly result in TdP in the real world. However, it is worth noting that a high reporting ratio does not always represent a high risk because, for different combinations, the frequency of drug use will vary greatly, which will directly affect the proportion of TdP reports.

The development of TdP in the context of DDIs is likely attributable to two key mechanisms: altered drug concentrations due to metabolic inhibition or induction and superimposed pharmacological effects on cardiac ion channels. For instance, co-administration of drugs that prolong the QT interval may synergistically increase the risk of TdP. Moreover, inhibition of the metabolism of a QT-prolonging drug by a co-administered agent could lead to elevated plasma concentrations, thereby exacerbating the risk. Amiodarone is the most widely interacting drug, with interactions with other 68 drugs, followed by methadone, fluoxetine, bisoprolol, ciprofloxacin, and citalopram [26-28], which interact with 51, 46, 42, 41, and 37 other drugs, respectively. Therefore, additional caution and increased electrocardiogram monitoring may be still warranted when these drugs are combined, especially for patients with risk factors such as increasing age, female sex, bradycardia, heart failure, history of ventricular arrhythmias, use of diuretics, hypothyroidism, hypokalemia, hypomagnesemia, and hypocalcemia.

In addition to offering a complete list of drugs, our study provides novel perspectives and opportunities for further exploration. As real-world negative reporting is missing, counterexamples that could serve as contradictory evidence may exist. Therefore, identifying negative DDI pairs shall enhance the confidence of health care professionals with a level of certainty on DDIs, which in turn will improve medical research and decision-making. It is widely accepted that co-administration of QTc-prolonging drugs, especially those with a known risk or high risk for TdP, heighten the risk of TdP. Our research identified 38 DDIs for QTc prolongation indexed by Drugs.com and Lexicomp but were not detected by any of the 4 models. This finding supports the notion that not all combinations of QTc-prolonging drugs result in TdP, even when involving high-risk drugs or those with a known risk of TdP. There is only a limited increase in QTc prolongation with concurrent use of QTc-prolonging drugs, and that magnitude of TdP risk depends on the specific drugs involved and patient risk factors. If clinical decision support systems generate alerts for QTc DDI whenever 2 QTc-prolonging drugs with a known risk of TdP are combined, irrespective of the clinical relevance of these interactions, a substantial number of false-positive alerts may be produced. The rising incidence of false-positive QTc DDI alerts can contribute to alert fatigue among physicians, potentially leading to the disregard of important warnings. Furthermore, these false-positive alerts may prompt unwarranted discontinuation or substitution of medications, thereby compromising the efficacy of clinical treatments. Consequently, identifying negative QTc DDIs is a rational approach to mitigating the challenge of alert fatigue. Nevertheless, caution must be exercised even when a signal is identified as negative, due to the inherent limitations of the FAERS database.

We acknowledge the inherent limitations of our study. First, our analysis primarily focused on the potential for TdP resulting from the concomitant use of 2 drugs. However, in patients with polypharmacy, there are documented cases of concurrent use of 3 or more suspect drugs. This raises the possibility that a third drug may act as a confounding factor in the relationship between coadministration and TdP risk, which was not accounted for in our analysis. Second, the use of a spontaneous reporting system inherently introduces various biases into the signal detection process, thus rendering the obtained signals as hypotheses rather than definitive conclusions. Moreover, the absence of a universally accepted gold standard for DDI signal detection further impacts the reliability of our findings. Although we devoted significant attention to the interpretation of results in the context of signal research for DDIs, validation efforts have been conducted using resources such as Lexicomp and Drugs.com. Unfortunately, there is a paucity of reliable information on DDIs, and the available data exhibit substantial variability across different drug information resources. Furthermore, there is a scarcity of robust clinical evidence on DDIs. Consequently, it is challenging to use "real" true data for signal verification. Third, although 2 databases were used for signal validation, there exists a risk of overlooking genuine DDIs due to inconsistencies between the databases; when considering only the DDIs present in both as true signals, some valid associations may have been excluded. Fourth, the failure to convert drug trade names to their generic counterparts prior to analysis may have resulted in an elevated number of DDI-positive signals. Nevertheless, this did not substantially affect the outcomes, as the analysis exclusively included DDIs validated by Lexicomp and Drugs.com using generic names. Fifth, we did not initially stratify the analysis based on the reporter population, as reports from nonprofessionals, such as lawyers and consumers, made up only 6.7% of the total. However, despite this small proportion, we could not completely

XSL•FO
RenderX

rule out the potential influence of these nonprofessional reports on the signal detection results due to their limited ability to differentiate between AE symptoms and underlying disease symptoms. Last, the FAERS database lacks sufficient clinical details to exclude comorbidities, such as heart-related diseases, as potential contributing factors to TdP cases. Future research should integrate more comprehensive clinical data or conduct prospective studies to better distinguish between medication-induced and disease-induced TdP, thereby enhancing the reliability of such analyses.

Conclusion

This study provides a preliminary overview of potential culprit DDIs, as well as negative DDIs, for TdP in real-world settings. These findings offer valuable insights for regulators, health care professionals, and stakeholders involved in DDI management. However, it is important to acknowledge the limitations inherent to our study stemming from the reliance on a pharmacovigilance database. It is crucial to recognize that DDI signals only indicate a statistical association between drug combinations and AEs and should not be mistaken for confirmed causal relationships. Further validation through well-designed clinical studies is necessary to establish a causal relationship. Although we validated signals using DDI resources and literature-based evidence, the available clinical evidence is limited and subject to significant inconsistencies. Therefore, in clinical practice, DDI signals should be considered as supplementary evidence rather than a substitute for the expertise of cardiologists and clinical pharmacists.

Although our study provides promising initial findings regarding the identification of high-priority DDIs for TdP, the scalability of these findings should be framed as hypotheses for future research. Specifically, the ability to generalize these results for clinical settings requires further investigation. Future studies should integrate clinical data from electronic health records or prospective trials to validate our findings and provide more actionable insights for clinicians.

Abstract

Background: Young gay, bisexual, and other men who have sex with men have been referred to as a “hard-to-reach” or “hidden” community in terms of recruiting for research studies. With widespread internet use among this group and young adults in general, web-based avenues represent an important approach for reaching and recruiting members of this community. However, little is known about how participants recruited from various web-based sources may differ from one another.

Objective: This study aimed to determine how young gay, bisexual, and other men who have sex with men recruited from various web-based sources differ from one another in terms of participant characteristics and study engagement.

Methods: Data were collected as part of a randomized controlled trial of Outsmart HPV, a web-based human papillomavirus (HPV) vaccination intervention for young gay, bisexual, and other men who have sex with men. From 2019 to 2021, we recruited young gay, bisexual, and other men who have sex with men in the United States who were aged 18-25 years and not vaccinated against HPV (n=1227) through various web-based avenues. We classified each participant as being recruited from either (1) social media (eg, Facebook, Instagram, Snapchat), (2) a dating app (eg, Grindr, Scruff), or (3) some other digital recruitment source (eg, existing research panel, university-based organization). Analyses compared participants from these 3 groups on demographic and health-related characteristics and metrics involving study engagement.

Results: Most demographic and health-related characteristics differed by web-based recruitment source, including race or ethnicity (P<.001), relationship status (P<.001), education level (P<.001), employment status (P<.001), sexual self-identity (P<.001), health insurance status (P<.001), disclosure of sexual orientation (P=.048), and connectedness to the LGBTQ (lesbian, gay, bisexual, transgender, queer) community (P<.001) The type of device used by participants during study enrollment also differed across groups, with smartphone use higher among participants recruited via dating apps (n=660, 96.6%) compared to those recruited via social media (n=318, 78.9%) or other digital sources (n=85, 60.3%; P<.001). Participants recruited via social media were more likely than those recruited via dating apps to complete follow-up surveys at 3 different timepoints (odds ratios 1.52-2.09, P=.001-.008). These participants also spent a longer amount of time viewing intervention content about HPV vaccination (3.14 minutes vs 2.67 minutes; P=.02).

XSL•FO
RenderX

Conclusions: We were able to recruit a large national sample of young gay, bisexual, and other men who have sex with men for a web-based HPV vaccination intervention via multiple methodologies. Participants differed on a range of demographic and health-related characteristics, as well as metrics related to study engagement, based on whether they were recruited from social media, a dating app, or some other digital recruitment source. Findings highlight key issues and considerations that can help researchers better plan and customize future web-based recruitment efforts of young gay, bisexual, and other men who have sex with men.

KEYWORDS

study recruitment; gay and bisexual men; human papillomavirus; vaccination promotion; digital intervention; social media; dating apps; recruitment; young adults; adolescents; gay; bisexual; men who have sex with men

Introduction

Human papillomavirus (HPV) is the most common sexually transmitted infection in the United States [1], with infections having the potential to cause multiple types of cancer (ie, anal, oropharyngeal, and penile cancers) and genital warts in men [2]. Gay, bisexual, and other men who have sex with men tend to have higher rates of HPV infection and HPV-related disease compared to other men [3-5]. Routine HPV vaccination is currently recommended for those aged 11-12 years in the United States, while also recommended for everyone through the age of 26 years who has not already been vaccinated [6]. However, a recent review paper suggests that fewer than 40% of young gay, bisexual, and other men who have sex with men who are age-eligible for HPV vaccination have received any doses of the vaccine series [5]. In response, HPV vaccination interventions for young gay, bisexual, and other men who have sex with men have recently been developed to improve knowledge and increase vaccination rates [7-10].

One issue central to these interventions is reaching and recruiting young gay, bisexual, and other men who have sex with men as study participants [11]. Gay, bisexual, and other men who have sex with men have previously been referred to as a "hard-to-reach" or "hidden" population for study recruitment [12,13], and traditional recruitment approaches for this community often included snowball sampling, use of "gatekeeper" organizations associated with the community, and venue-based recruitment at community events, health clinics, or other settings [11,14,15]. These traditional approaches faced recruitment challenges including potential participants not being comfortable identifying as gay, bisexual, and other men who have sex with men, lack of inclusive language in recruitment materials, and concerns about stigmatization associated with participation [11-13,15,16].

Web-based recruitment methods, including the use of social media and dating apps, present an alternative approach that has gained popularity for recruiting young gay, bisexual, and other men who have sex with men [17-21]. Social media use is ubiquitous among young adults in the United States, with nearly all reporting prior use [22]. Further, about 80% of young gay, bisexual, and other men who have sex with men report using a dating app on at least a monthly basis [23]. Past studies have shown that digital venues can successfully reach and recruit large numbers of participants, including young gay, bisexual, and other men who have sex with men, and that the content of study advertisements on these platforms can affect recruitment metrics [17,24-29]. Studies have also provided a great deal of information about the costs associated with web-based recruitment [24,28,29] and shown that participants recruited via web-based methodologies are demographically different from those recruited through more traditional approaches [13,30-33]. For example, gay, bisexual, and other men who have sex with men participants recruited via web-based methodologies may differ in terms of age, race or ethnicity, and socioeconomic status (eg, education level) compared to those recruited via more traditional approaches [13,30-32]. Furthermore, a few studies have shown that gay, bisexual, and other men who have sex with men participants tend to be more diverse when multiple recruitment sources are used (eg, using Facebook and Craigslist) [18,21].

Even with our current amount of knowledge about the digital recruitment of young gay, bisexual, and other men who have sex with men, important research gaps remain. One key area to examine is how participants recruited from various web-based sources (eg, social media vs dating apps) may differ from one another. This is true not only for demographic characteristics but also for participants' study experience (eg, retention, engagement with study content). The latter is particularly relevant to studies that include the delivery of interventions or involve longitudinal data collection. In this report, we address these research gaps by analyzing data from Outsmart HPV, an HPV vaccination intervention study that recruited young gay, bisexual, and other men who have sex with men through various web-based venues. Results will inform and help guide future web-based recruitment efforts of young gay, bisexual, and other men who have sex with men for research studies.

Methods

Participants

All data were collected as part of a randomized controlled trial (RCT) of Outsmart HPV. The methods of the RCT have been described previously [7] and are briefly summarized below. We recruited a convenience sample of young gay, bisexual, and other men who have sex with men via social media sites, dating

XSL•FO
RenderX

apps, and other web-based avenues. Advertisements on these digital platforms included a combination of images (eg, men in the targeted age range) and brief text about the study (eg, information about HPV, the study being web-based). Although we standardized advertisement content where possible, some content did differ across platforms due to varying advertisement requirements and options (eg, amount of text allowed, advertisement placement). For example, some of our advertisements through dating apps featured content that was sent directly to users' in-app inboxes over a 24-hour period, which was an approach that was not available across all platforms.

Interested individuals were linked via advertisements to a mobile-friendly project website to complete an eligibility screener. Eligibility criteria included self-identifying as (1) cisgender male; (2) aged 18-25 years; (3) either gay, bisexual, or queer; ever having oral or anal sex with another male; or being sexually attracted to other males; (4) living in the United States; (5) not having received any doses of HPV vaccine; and (5) not having previously participated in Outsmart HPV. Eligible individuals provided informed consent and created a project website account.

Participants next completed a baseline survey ("T1 survey") and were then immediately randomized using a 1:1:1 allocation scheme to 1 of 3 study groups. The 3 study groups included 2 groups that received intervention content and 1 control group [7]. Participants then viewed intervention content about HPV vaccination on the project website, with participants in both intervention groups viewing Outsmart HPV content about HPV vaccination and participants in the control group viewing standard information about HPV vaccination. After viewing the intervention content, participants completed a second survey ("T2 survey"). Additional follow-up surveys occurred 3 and 9 months later ("T3 survey" and "T4 survey," respectively). All study surveys were completed on the project website. A total of 1227 participants were randomized from October 2019 to June 2021.

Measures

The main independent variable for this report was the type of web-based recruitment source, with each participant categorized as being recruited from either: (1) social media (eg, Facebook, Instagram, Snapchat); (2) a dating app (eg, Grindr, Scruff); or (3) some other recruitment source (eg, existing research panel, university-based organization).

The T1 survey collected information on a range of demographic and health-related characteristics. This included participants' disclosure of their sexual orientation (3 items; α=.77; possible range 1-5) [34], concealment of their sexual orientation (3 items; α=.75; possible range 1-5) [34], connectedness to the LGBTQ (lesbian, gay, bisexual, transgender, queer) community (2 items; α=.72; possible range 1-4), and electronic health literacy (4 items; α=.83; possible range 1-5) [35]. Items were coded so that higher values indicate greater levels of a given construct. We examined the type of device that participants used during study enrollment, with each participant categorized as using either a smartphone, tablet device, or a personal computer (eg, desktop, laptop).

To examine study retention, we determined whether participants completed the T2, T3, and T4 surveys. For each survey separately, participants were categorized as having either completed the survey or not completed the survey. Among participants in the 2 intervention groups, we also examined additional metrics of study engagement by calculating the total amount of time (in minutes) spent viewing Outsmart HPV content about HPV vaccination and the total number of logins to the project website. Both of these metrics were winsorized so that the top 10% of values were set to equal the value corresponding to the 90th percentile.

Data Analysis

We first calculated descriptive statistics for all variables. We examined differences by recruitment source in participants' demographic and health-related characteristics and device type. To make these comparisons, we used the Pearson chi-square test for categorical dependent variables and 1-way ANOVA (analysis of variance) for continuous dependent variables. We made post hoc pairwise comparisons between the 3 web-based recruitment source groups and used the Bonferroni adjustment to account for multiple comparisons.

We then used regression models to examine differences by recruitment source in study retention and other study engagement metrics. Logistic regression models produced odds ratios (ORs) and 95% CIs for completion of the T2, T3, and T4 surveys. Linear regression models produced standardized β coefficients for the other study engagement metrics. The recruitment source of dating apps served as the referent group in regression models. These statistical tests were 2-tailed with a critical α value of .05. Data were analyzed using R (version 4.2.1; R Foundation for Statistical Computing), and Stata (version 15.0; StataCorp).

Ethical Considerations

The institutional review board at The Ohio State University approved this study (IRB 2019C0028), and the RCT is registered at ClinicalTrials.gov (NCT04032106). We based the reporting of results for this manuscript on the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines [36] since most of the included data were collected at baseline. Informed consent was obtained from all participants, and all data were deidentified. Participants could earn up to US $95 in gift cards for completing study surveys.

Results

Participant Characteristics

Overall, 52.8% (n=648) of participants indicated a minoritized racial or ethnic identity, 64.4% (n=790) were between 22 and 25 years of age, 69% (n=847) had at least some college education, and 66.4% (n=815) self-identified as gay. Most participants (n=974, 79.4%) had some form of health insurance, but more than half (n=666, 54.3%) had not had a preventive health visit in the prior year.

A total of 403 (32.8%) participants were recruited via social media, 683 (55.7%) participants via dating apps, and 141 (11.5%) participants via other recruitment sources. Most

XSL•FO
RenderX

demographic and health-related characteristics differed by recruitment source (Table 1). Generally, a higher proportion of participants recruited via dating apps reported a minoritized racial or ethnic identity, were single and having sex or casually dating, had less education, reported having sex with a male partner in the past, and had public or no health insurance. Conversely, a higher proportion of participants recruited via social media indicated not being currently employed full-time or part-time, self-identified as gay, and reported being HIV-negative. Participants recruited via social media also reported a higher level of connectedness to the LGBTQ community and a higher level of disclosure of their sexual orientation. Table 1 shows the results of all pairwise comparisons.

The type of device used by participants during study enrollment also differed by recruitment source (P<.001; Table 1). Smartphone use was higher among participants recruited via dating apps (n=660, 96.6%) compared to those recruited via social media (n=318, 78.9%) or other web-based sources (n=85, 60.3%). Conversely, personal computer use was higher among participants recruited via social media (n=81, 20.1%) or other web-based sources (n=55, 39%) compared to those recruited via dating apps (n=17, 2.5%).

[i]4-item scale; items had a 5-point response scale ranging from 1="strongly disagree" to 5="strongly agree."

Study Engagement

Participant retention overall was 90% for the T2 survey (n=1001), 70% for the T3 survey (n=858), and 69% for the T4 survey (n=842). Compared to participants recruited via dating apps, retention was higher among participants recruited via social media for the T2 survey (94% vs 87%; OR 2.09, 95% CI 1.32-3.30), the T3 survey (75% vs 66%; OR 1.52, 95% CI 1.15-2.00), and the T4 survey (75% vs 65%; OR 1.66, 95% CI 1.26-2.19; Figure 1). There were no statistically significant differences in retention for participants recruited via other web-based sources.

Among participants in the 2 intervention groups (n=815), the average amount of time spent viewing intervention content about HPV vaccination was 2.83 minutes. Participants recruited via social media spent a longer amount of time viewing this content compared to those recruited via dating apps (3.14 minutes vs 2.67 minutes; 95% CI 0.03-0.33; *P*=.02; Table 2). The average number of project website logins was 4.94, and there were no differences in the number of logins by recruitment source (*P*=.83 for social media, *P*=.54 for other web-based sources; Table 2).

Table 2. Study engagement of young gay, bisexual, and other men who have sex with men in the United States by recruitment source for a web-based human papillomavirus vaccination intervention (n=815)[a,b].

	Time spent on intervention content (minutes)		Number of project website log-ins	
	Mean (SD)	β (95% CI)	Mean (SD)	β (95% CI)
Dating app	2.67 (2.44)	Reference	4.98 (2.40)	Reference
Social media	3.14 (2.80)	0.18[b] (0.03-0.33)	4.94 (2.42)	–0.02 (–0.17 to 0.13)
Other web-based sources	2.74 (2.56)	0.02 (–0.20 to 0.25)	4.81 (2.17)	–0.07 (–0.29 to 0.15)

[a]Table reports data for the 815 participants in the 2 intervention groups. β represents standardized regression coefficients from linear regression models.
[b]Statistically significant at the α=.05 level.

Discussion

Principal Results

With digital methodologies becoming increasingly popular for recruiting young gay, bisexual, and other men who have sex with men for research studies, [17-21] it is important to examine if different web-based recruitment sources yield varying types of participants. The Outsmart HPV study provided an opportunity to address this research topic by recruiting a national sample of young gay, bisexual, and other men who have sex with men through multiple web-based sources, and there are 2 main findings. First, most of the demographic and health-related characteristics examined differed by recruitment sources. Participants recruited via social media tended to be less diverse (eg, race or ethnicity, sexual self-identity), of higher socioeconomic status (eg, education level, health insurance status), and have higher levels of outness (eg, disclosure of sexual orientation, connectedness to the LGBTQ community) compared to participants recruited via dating apps. This pattern differs from a past study that found participants recruited from a social media site (Facebook) were highly similar to those recruited from a dating app (Grindr) in terms of race or ethnicity [18]. Interestingly, the characteristics of participants recruited via social media in our study better align with the characteristics of other national samples of young gay, bisexual, and other men who have sex with men and the larger gay, bisexual, and other men who have sex with men community in the United States than participants recruited via dating apps in our study [37-40]. A potential explanation for this pattern is that users of dating apps tend to be more demographically diverse compared to the general population [41]. Interestingly, some characteristics (eg, socioeconomic status) of participants that were recruited via social media for our study were more comparable to gay, bisexual, and other men who have sex with men recruited through in-person venues in past research than via dating apps in our study [42].

Second, study engagement also differed by recruitment source. Participants who were recruited via dating apps tended to interact less with study content and were less likely to complete follow-up surveys compared to participants recruited via social media. This may be attributable to users of dating apps having an emphasis on immediate gratification [43] and impulsivity [44] as a justification for their app usage (and study enrollment), which in turn may affect their awareness of and interest in engaging with study content and completing study-related activities (eg, follow-up surveys). Related, given that dating app users are more impulsive than nonusers, [44] young gay, bisexual, and other men who have sex with men who use dating apps might experience an initial interest in joining a research study and earning an initial study incentive. However, interest in completing study-related activities at later timepoints may

XSL•FO
RenderX

not be as strong as their general preference for some level of anonymity [45] might dissuade them from wanting to continue discussing their health behaviors (eg, sexual history, vaccination status).

We think these 2 main findings can help researchers better plan and customize future digital recruitment efforts of young gay, bisexual, and other men who have sex with men by highlighting key issues and considerations. For example, researchers will now be able to better anticipate how the selection of web-based recruitment sources may affect the representativeness and diversity (and the potential balance between the two) of their study sample. Recruiting through social media may lead to a sample of participants that better reflect the larger young gay, bisexual, and other men who have sex with men population in the United States, but dating apps may be more effective in reaching more diverse young gay, bisexual, and other men who have sex with men, including those from communities that are often underrepresented in research studies [46]. Recruitment goals differ across studies in terms of representativeness and diversity, and our data on differences in demographic and health-related characteristics can help inform future efforts. Furthermore, studies involving interventions and/or longitudinal data collection should consider how various web-based recruitment sources can impact study retention and participants' engagement with study content. Some studies may want to maximize participant retention and engagement (ie, suggesting that recruitment primarily through social media may be appropriate), whereas other studies may be willing to have slightly lower study engagement metrics in exchange for being able to include additional recruitment sources, such as dating apps. Future studies that do include recruitment from dating apps may also want to consider prioritizing brief study-related activities and other strategies to promote engagement.

One final implication involves the types of devices that were used by participants in our study. Overall, a majority of participants used a smartphone to enroll in the study, including nearly all participants who were recruited via dating apps. This pattern is similar to national data showing that young adults use smartphones much more frequently than other device types [47,48]. Thus, it is important that future digital interventions and other research studies for young adults, including young gay, bisexual, and other men who have sex with men, ensure that study content and data collection instruments are optimized for use on smartphones. For example, to increase usability, it has been suggested that the interface of smartphone-based interventions have a minimal number of screens, limited manual data entry, limited pop-ups and notifications, and personal identification number-based entry (as compared to full passwords). The content of such interventions should be succinct with easy-to-read graphics [49]. Data collection instruments (eg, surveys) should have limited open-ended questions and different "pages" in the survey, rather than having participants scroll through one continuous page. Lastly, and perhaps most generally, mobile surveys should be pilot-tested prior to the start of data collection activities [50]. As smartphone usage continues to be a common approach for participants enrolling in and interacting with digital interventions, such recommendations can help optimize intervention delivery and data collection.

Limitations

Although we were able to compare different groupings of web-based recruitment sources, we were not able to examine potential differences between individual platforms (eg, Facebook vs Twitter vs Grindr) due to modest sample sizes for some of the platforms. These sample sizes also did not allow us to examine how differences between recruitment sources may have changed over time during the recruitment period for our study. Examining potential differences between individual platforms and potential temporal changes are important areas for future research. Our recruitment focused on the social media and dating apps that were among the most popular among young adults in the United States around the time of the start of our study [51,52]. It is likely that the use and popularity of various platforms will evolve over time, and future efforts should examine new and emerging platforms. We were not able to examine advanced metrics related to recruitment efficiency and cost due to a lack of available data. However, past studies have reported such information for various web-based platforms [17,27]. Study recruitment occurred both prior to and during the COVID-19 pandemic, and it is not known how the pandemic may have affected the interest of young gay, bisexual, and other men who have sex with men to enroll in a study focusing on vaccination (which would subsequently affect the characteristics of study participants). Fraudulent accounts with inaccurate self-reported data occur in digital studies, but we used several recommended strategies for detecting such accounts and minimizing this risk [53,54].

Conclusions

We were able to recruit a large national sample of young gay, bisexual, and other men who have sex with men for an HPV vaccination intervention via multiple web-based methodologies. Participants differed on a range of demographic and health-related characteristics based on whether they were recruited from social media, a dating app, or some other web-based recruitment source. Study retention and engagement with study content also differed by web-based recruitment source. These findings and patterns highlight key issues and potential tradeoffs that can help researchers better plan and customize future web-based recruitment efforts of young gay, bisexual, and other men who have sex with men.

Data Availability

The data for this study may be made available from the corresponding author on reasonable request.

Authors' Contributions

DJM, ALG, and PLR created the original concept and design of this manuscript, with DJM writing the initial draft and performing the initial analyses under the supervision of ALG and PLR. DJM, ALG, MLK, JAB, ABS, and PLR all contributed to the final analysis and interpretation of the data, with all authors also providing critical revision and feedback on the final drafts. All authors reviewed the final manuscript. All authors approve of the final version to be published and agree to be accountable for all aspects of the work.

Abstract

Background: Recruiting and retaining participants in pediatric research has always been challenging, particularly in healthy populations and remote areas, leading to selection bias and increased health disparities. In the digital age, medical research has been transformed by digital tools, offering new opportunities to enhance engagement in clinical research. However, public perspectives on digitalizing pediatric research and potential differences between urban and suburban areas remain unclear.

Objective: This study aimed to investigate public perspectives on digitalizing pediatric research and compare differences between urban and suburban areas to help diversify participants and address health disparities.

Methods: A cross-sectional web-based survey targeting caregivers of kindergarten children (aged 2-7 years) in Chongqing was conducted between June and December 2023. A total of 4231 valid questionnaires were analyzed, with 25.1% (n=1064) of the children residing in urban areas and 74.9% (n=3167) in suburban areas. Descriptive statistics and intergroup comparisons were used for data analysis.

Results: Approximately 59.8% (n=2531) of the caregivers had first impressions of pediatric research, with 36.9% (n=1561) being positive and 22.9% (n=970) being negative. A total of 38.3% (n=1621) of caregivers recognized the growing popularity of digital tools, and 36.7% (n=1552) supported their use in pediatric research, but only 25.2% (n=1068) favored online-only research methods. The main concerns regarding the use of software in pediatric research were privacy issues (n=3273, 77.4%) and potential addiction (n=2457, 58.1%). Public accounts of research institutions (n=3400, 80.4%) were the most favored for online recruitment. Telephones (1916/3076, 62.3%) and social media apps (1801/3076, 58.6%) were the most popular for regular contact. Intergroup comparisons revealed that suburban caregivers had more positive first impressions of pediatric research (38.6% vs 32%; *P*<.001; adjusted odds ratio [aOR] 1.27, 95% CI 1.09-1.47) and faced fewer participation barriers: "worry about being an experimental subject" (70.9% vs 76.6%; *P*<.001; aOR 0.79, 95% CI 0.67-0.93), "pose a risk to children's health" (58.6% vs

XSL•FO
RenderX

67.8%; *P*<.001; aOR 0.71, 95% CI 0.61-0.83), "do not have enough background information" (55.2% vs 61.6%; *P*<.001; aOR 0.78, 95% CI 0.67-0.89), and "worry about recommending other products" (48.2% vs 55%; *P*<.001; aOR 0.78, 95% CI 0.67-0.89). They also showed greater support for online-only research methods (26% vs 22.9%; *P*=.045; aOR 1.19, 95% CI 1.01-1.41) and greater openness to unofficial online recruitment sources (social media friends: 24.7% vs 18.9%; *P*<.001; aOR 1.33, 95% CI 1.11-1.59; moments on social media: 15.5% vs 11.1%; *P*<.001; aOR 1.35, 95% CI 1.09-1.67).

Conclusions: In the digital age, enhancing recruitment and retention in pediatric research can be achieved by integrating both official and unofficial social media strategies, implementing a hybrid online-offline follow-up approach, and addressing privacy concerns.

Introduction

Recruitment and retention in pediatric research have consistently posed challenges [1-3]. In the United States, pediatric randomized clinical trials are often discontinued or unpublished, with patient recruitment difficulties (37%) being the primary reason [4]. Our experiences further corroborate this trend. For instance, in a cross-sectional hospital-based survey, we recruited only 65.8% of the caregivers [5]. Similarly, in a longitudinal study on the growth of critically ill children after liver transplantation, follow-up was completed for only 68.6% of the children one year after the procedure [6]. Recruitment and retention challenges frequently prevent studies from achieving their preset objectives, resulting in inefficiency and wasted personnel and financial resources.

While traditional research has focused on children with evident illnesses, emerging concerns such as overweight, internet addiction, and emotional or behavioral issues [7-10] highlight the importance of studying seemingly healthy children [11-13]. However, recruiting and retaining healthy children for research is more challenging than for those with specific diseases, as shown by pediatric reference interval studies [14]. Additionally, children in remote areas are frequently underrepresented in research [15-17], leading to selection bias and exacerbating health disparities. In China, geographical location has been a primary longstanding contributor to child health inequity [18]. Therefore, researchers need to devise strategies to address these challenges to meet the increasing demands of pediatric research. In this context, obtaining participants' perspectives by seeking their opinions may provide more practical solutions.

Caregivers, typically parents, are key decision makers regarding younger children's participation in research [19]. Numerous studies have examined parental decision-making in enrolling children in pediatric research, primarily focusing on traditional research methods [20-27]. In the digital age, medical research has been significantly transformed by digital tools and the process of digitalization [28,29]. Digital medicine has created new opportunities to enhance engagement in clinical research, especially in healthy populations and remote areas, which improves health outcomes for participants [30-32]. This study investigated public perspectives on pediatric research in the digital age and examined potential differences between urban and suburban areas. The goal was to provide insights to advance the digitalization of pediatric research, which may diversify the pool of participants and address health disparities among children.

Methods

Study Design and Participants

This study was a cross-sectional, web-based questionnaire survey. The study targeted caregivers of kindergarten children in Chongqing, a municipality in southwestern China, with a total of 12.58 million households and 995,239 kindergarten children. Chongqing is divided into urban and suburban areas based on geographical location and development level, with 3.07 million (23.9%) households in urban areas and 9.79 million (76.1%) in suburban areas [33]. Kindergarten children are typically between 3 and 6 years old, with exceptions depending on individual circumstances [34]. The inclusion criteria for kindergarten children were (1) residency in Chongqing, (2) kindergarten attendance, (3) aged 2 to 7 years, and (4) voluntary completion of the questionnaire by the caregiver. The exclusion criteria were (1) failure to pass validation questions, (2) logical errors in responses, and (3) self-reported lack of seriousness in answering.

Ethical Considerations

This study was approved by the Ethics Committee of the Children's Hospital of Chongqing Medical University (Protocol #2023-236), with informed consent signatures waived. The collected data were anonymized, and no compensation was given.

Reporting Guidelines

The CHERRIES (Checklists for Reporting Results of Internet E-Surveys) and STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines were followed for reporting the results [35,36].

Research Outcomes and Measurements

The primary outcome of this study was public perspectives on pediatric research, with differences between urban and suburban areas as the secondary outcome. These perspectives were divided into 4 key categories: "Facilitators and Barriers to Participation," "Perspectives on Digital Medicine," "Perspectives on Recruitment," and "Perspectives on the Research Process." Each

XSL•FO
RenderX

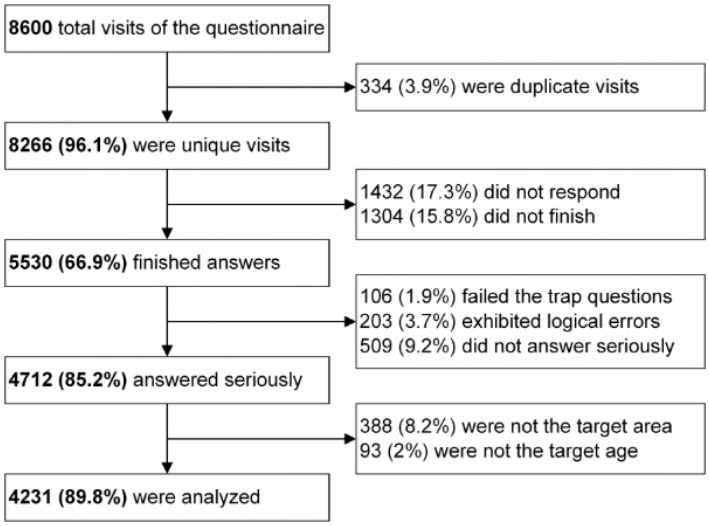
category comprised single-choice and multiple-choice questions designed to collect data. In the intergroup comparison, participants were classified as urban or suburban (exposure) based on their responses to a residential address question (Multimedia Appendix 1).

Development of the Questionnaire

The questionnaire was initially developed and refined based on the literature and clinical experience [20-27,37-39], then revised and culturally adapted by 7 pediatric doctors with diverse professional backgrounds (see Acknowledgments). The final version was converted to a web-based format using "Lediaocha," a web-based survey platform, with 50 mandatory questions spread across 4 pages. Of these, 11 questions focused on general characteristics, while the rest investigated perspectives on pediatric research, particularly digital medicine. To ensure data reliability, one question on caregivers' roles was repeated at the beginning and end of the questionnaire, along with a self-assessment query on response seriousness before submission. Participation was voluntary, anonymous, and accessible through WeChat (Tencent) on smartphones. Device IDs were recorded to prevent duplicate entries. When caregivers started answering, the system marked them as "in progress." Although it was technically feasible to save "in progress" answers automatically, ethical concerns led to a decision not to do so, as these were not final submissions. The process of developing questionnaires and the methodological considerations for web-based surveys followed our team's established practices [40].

Determination of the Sample Size

Due to the lack of a clear sample size calculation method for multioutcome survey studies, we used the estimation method from quality-of-life studies, which suggests 5-10 questionnaires per question [41]. Therefore, with 50 questions, a minimum of 500 questionnaires were required. To mitigate potential selection bias [42], the minimum sample size was doubled to 1000. Further calculations took into account the number of households in Chongqing, with questionnaires planned to be collected at a 1:3 ratio between urban and suburban areas. As a result, a total of 4000 questionnaires were needed, with at least 1000 from urban areas and 3000 from suburban areas. Given the possibility of a high invalid response rate (approximately 50%) in public surveys [43], at least 8000 households were estimated to be needed. This sample size represented 0.4% of the entire population of kindergarten children in Chongqing, placing the sampling ratio between the national population dynamics survey (0.1%) and the sample survey (1%). Finally, the actual proportions of recruited participants from urban and suburban areas were 25.1% and 74.9%, respectively, which is consistent with the planned sample distribution.



Survey Process

The survey was conducted between June and December 2023. Prior to the official launch, a pilot test with 50 participants was conducted to validate the survey process. A flexible survey was then conducted in urban and suburban areas over 20 days to accommodate different kindergarten schedules. The questionnaire was distributed to kindergartens and forwarded to caregivers, ensuring that recruitment focused on the target audience and minimized nontarget responses. Forwarding questionnaires by kindergarten teachers was not mandatory. Caregivers could view a short introduction and an anonymous, voluntary declaration of the study on the questionnaire homepage to avoid any sense of obligation. After the survey, researchers downloaded and saved the data from the cloud servers and then removed them from the cloud.

Data Processing

The collected questionnaires were assessed for adherence to the inclusion and exclusion criteria. Specifically, 8600 online visits were documented during the survey, with 8266 (96.1%) identified as unique after eliminating duplicates. Among the visitors, 6834 started the questionnaire (response rate of 82.7%), and 5530 completed it (completion rate of 66.9%). After unreliable and nontarget questionnaires were excluded, 4231 questionnaires were ultimately analyzed (inclusion rate of 76.5%), representing 0.43% of the entire population of kindergarten children (Figure 1).

Figure 1. The inclusion and exclusion process.

XSL•FO
RenderX

Statistical Analysis

Data analysis was performed using SPSS (version 25; IBM Corp). Qualitative data are presented as frequencies (percentages), while quantitative data are presented as medians (IQRs) after tests for normality. Intergroup comparisons were conducted using chi-square and Mann-Whitney tests. Multivariate logistic regression was used to adjust for potential confounders, including child age and sex, caregiver age, role, education level, and family size, when examining the relationship between region (independent variable) and public perspectives (outcome variables). Stepwise methods were not applied (Multimedia Appendix 2). The results of the logistic regression are presented as adjusted odds ratios (aORs) with 95% CIs. A *P* value less than .05 was considered statistically significant.

Results

General Characteristics

Table 1 presents the general characteristics of the children and caregivers. Among the children, 1064 (25.1%) resided in urban areas, while 3167 (74.9%) children were from suburban areas. Most children (n=3774, 89.2%) had never participated in pediatric research, while only 7.7% (n=326) and 5.4% (n=230) had taken part in offline and online research, respectively. Interestingly, suburban children had a greater proportion of online research participation than urban children (6% vs 3.9%; *P*=.008). Among the caregivers, 3547 (83.8%) were mothers, 2334 (55.2%) had an education level of senior high school or below, and 2297 (54.3%) lived in households with 4 or fewer members.

Table 1. General characteristics of the children and caregivers.

General characteristics	Overall	Urban	Suburban	*P* value
Age of the children (years), median (IQR)	4.8 (4.1-5.6)	4.6 (4.0-5.5)	4.9 (4.2-5.7)	<.001
Sex of the children, n (%)				.44
Male	2167 (51.2)	534 (50.2)	1633 (51.6)	
Female	2064 (48.8)	530 (49.8)	1534 (48.4)	
Ever participated in offline pediatric research, n (%)	326 (7.7)	72 (6.8)	254 (8)	.19
Ever participated in online pediatric research, n (%)	230 (5.4)	41 (3.9)	189 (6)	.008
Age of the caregivers (years), median (IQR)	33 (29-36)	33 (30-36)	32 (29-36)	.81
Role of the caregivers, n (%)				.005
Mother	3547 (83.8)	921 (86.6)	2626 (82.9)	
Father or others	684 (16.2)	143 (13.4)	541 (17.1)	
Education levels of the caregivers, n (%)				<.001
Senior high school or below	2334 (55.2)	455 (42.8)	1879 (59.3)	
College or above	1897 (44.8)	609 (57.2)	1288 (40.7)	
Number of people in the family, n (%)				<.001
2-4 people	2297 (54.3)	707 (66.4)	1590 (50.2)	
≥5 people	1934 (45.7)	357 (33.6)	1577 (49.8)	

Facilitators and Barriers to Participation

When questioned about their perspectives on research participation, 2531 (59.8%) caregivers expressed their first impressions, with 1561 (36.9%) caregivers inclined to participate and 970 (22.9%) caregivers inclined to decline. Suburban caregivers had more positive impressions than urban caregivers (38.6% vs 32%; *P*<.001; aOR 1.27, 95% CI 1.09-1.47). Additionally, caregivers with positive impressions reported higher rates of both offline (14.2% vs 2.9%; *P*<.001) and online (9.8% vs 2.7%; *P*<.001) research participation compared to those with negative impressions.

Table 2 presents the facilitators and barriers to participation, with most facilitators reporting rates lower than the barriers. The most significant facilitator was “be beneficial for children’s health” (n=3579, 84.6%), which was more common among urban caregivers (87.5% vs 83.6%; *P*<.001; aOR 1.45, 95% CI 1.17-1.79). Interestingly, although “be suggested by close people” was deemed less important (n=635, 15%), it had a higher rate among suburban caregivers (16.2% vs 11.5%; *P*<.001; aOR 1.47, 95% CI 1.18-1.79). On the other hand, the most significant barriers were “worry about being an experimental subject” (Guinea pig concerns: n=3060, 72.3%) and “pose a risk to children’s health” (n=2577, 60.9%). These barriers reflected a general apprehension about potential health risks. Furthermore, suburban caregivers had lower reporting rates for most barriers than urban caregivers, including “worry about being an experimental subject” (70.9% vs 76.6%; *P*<.001; aOR 0.79, 95% CI 0.67-0.93), “pose a risk to children’s health” (58.6% vs 67.8%; *P*<.001; aOR 0.71, 95% CI 0.61-0.83), “do not have enough background information” (55.2% vs 61.6%; *P*<.001; aOR 0.78, 95% CI 0.67-0.89), and “worry about recommending other products” (48.2% vs 55%; *P*<.001; aOR 0.78, 95% CI 0.67-0.89).

Table 2. Facilitators and barriers to pediatric research participation.

Questions about facilitators and barriers	Overall, n (%)	Urban, n (%)	Suburban, n (%)	*P* value
Facilitators				
Be beneficial for children's health	3579 (84.6)	931 (87.5)	2648 (83.6)	<.001[a]
Trust the hospital and researchers	1454 (34.4)	371 (34.9)	1083 (34.2)	.69
Acknowledge the importance of research	1409 (33.3)	358 (33.6)	1051 (33.2)	.78
Increase contact with doctors	1189 (28.1)	295 (27.7)	894 (28.1)	.75
Have small burden on the participants	1139 (26.9)	323 (30.4)	816 (25.8)	.003[a]
Be driven by altruism	1044 (24.7)	261 (24.5)	783 (24.7)	.90
Be suggested by close people	635 (15)	122 (11.5)	513 (16.2)	<.001[a]
Have economic subsidies	390 (9.2)	100 (9.4)	290 (9.2)	.81
Barriers				
Worry about being an experimental subject	3060 (72.3)	815 (76.6)	2245 (70.9)	<.001[a]
Pose a risk to children's health	2577 (60.9)	721 (67.8)	1856 (58.6)	<.001[a]
Do not have enough background information	2404 (56.8)	655 (61.6)	1749 (55.2)	<.001[a]
Worry about personal privacy	2153 (50.9)	574 (53.9)	1579 (49.9)	.02
Worry about recommending other products	2112 (49.9)	585 (55)	1527 (48.2)	<.001[a]
Refuse procedures like venipuncture	1721 (40.7)	468 (44)	1253 (39.6)	.01
Cause disagreements among family members	1106 (26.1)	294 (27.6)	812 (25.6)	.20
Affect the purchase of medical insurance	803 (19)	201 (18.9)	602 (19)	.93

[a]Confirmed by multivariate logistic regression that adjusted general characteristics (Multimedia Appendix 2).

Perspectives on Digital Medicine

When questioned about digital medicine (Table 3), 36.4% (n=1542) of caregivers reported following online health-related accounts, while 38.4% (n=1626) had used online information for health-related decisions. Additionally, 38.3% (n=1621) and 36.7% (n=1552) of caregivers recognized the increasing popularity of digital tools in future health care practices and supported their integration into pediatric research. Nearly half of caregivers (n=2073, 49%) were willing to collect data daily using digital tools, and 61.7% (n=2610) supported the use of gamification in pediatric research. However, only 25.2% (n=1068) of caregivers supported online-only research methods, with slightly more support from suburban caregivers (26% vs 22.9%; *P*=.045; aOR 1.19, 95% CI 1.01-1.41). When asked about concerns regarding smartphone data collection software, privacy was the main issue (n=3273, 77.4%), followed by concerns about potential software addiction (n=2457, 58.1%). Multivariate logistic regression revealed privacy concerns as the barrier to supporting digital tools in pediatric research (aOR 0.61, 95% CI 0.52-0.71).

XSL•FO

Table 3. Perspectives on digital medicine.

Questions about digital medicine	Overall, n (%)	Urban, n (%)	Suburban, n (%)	*P* value
Have followed online health-related accounts	1542 (36.4)	410 (38.5)	1132 (35.7)	.10
Can use online information to make health-related decisions	1626 (38.4)	327 (30.7)	1299 (41)	<.001[a]
Knowing that digital tools will become popular in future health care practices	1621 (38.3)	411 (38.6)	1210 (38.2)	.81
Support digital tools in pediatric research	1552 (36.7)	372 (35)	1180 (37.3)	.18
Support gamification of pediatric research	2610 (61.7)	680 (63.9)	1930 (60.9)	.09
Support online-only research methods	1068 (25.2)	244 (22.9)	824 (26)	.045[a]
Be willing to use digital tools daily to collect data	2073 (49)	484 (45.5)	1589 (50.2)	.008
Concerns about using smartphone software in research				
Personal privacy issues	3273 (77.4)	855 (80.4)	2418 (76.3)	.007[a]
Possible addiction of the tools	2457 (58.1)	606 (57)	1851 (58.4)	.39
Transparency of data	2159 (51)	564 (53)	1595 (50.4)	.14
Health impacts of the tools (such as radiation)	1830 (43.3)	439 (41.3)	1391 (43.9)	.13
Possible expenses	1465 (34.6)	367 (34.5)	1098 (34.7)	.92
Ease of use	1279 (30.1)	320 (30.1)	959 (30.3)	.90

[a]Confirmed by multivariate logistic regression that adjusted general characteristics (Multimedia Appendix 2).

Perspectives on Recruitment

Regarding recruitment (Table 4), 39.4% (n=1666) and 39.5% (n=1670) of caregivers expressed interest in reviewing recruitment information presented offline and online, respectively. Only 930 (22%) caregivers reported they would check both online and offline recruitment information. Notably, a greater proportion of suburban caregivers preferred checking offline recruitment information (41.2% vs 34%; *P*<.001; aOR 1.28, 95% CI 1.11-1.49). Additionally, 42.9% (n=1813) of caregivers expressed doubts about the reliability of online recruitment, while 58.1% (n=2457) doubted that research participation through online recruitment would lead to different treatments compared to offline methods.

When questioned about preferences, caregivers indicated that doctors with senior titles (n=2157, 51%) and specific researchers (n=2053, 48.5%) were the preferred recruiters, together accounting for 70.8% (n=2996) of caregivers. Research institution public accounts (n=3400, 80.4%) were the most favored source of online recruitment, with higher preferences among urban caregivers (85.9% vs 78.5%; *P*<.001; aOR 1.62, 95% CI 1.33-1.97). Although social media friends (n=984, 23.3%) and moments (n=608, 14.4%) were less popular sources for online recruitment, they were more frequently reported by suburban caregivers (friends: 24.7% vs 18.9%; *P*<.001; aOR 1.33, 95% CI 1.11-1.59; moments: 15.5% vs 11.1%; *P*<.001; aOR 1.35, 95% CI 1.09-1.67). Finally, the majority of caregivers (n=2963, 70%) preferred cartoon-style recruitment advertisements.

Perspectives on the Research Process

When questioned about the research process (Table 5), 1445 (34.2%) caregivers reported that they knew they could withdraw from the study, and 79.8% (n=1153) of them would consult with the research team before doing so. Regarding follow-up, 3076 (72.7%) caregivers reported that regular contact was necessary. Telephones (n=1916, 62.3%) were the preferred method, followed by social media apps (n=1801, 58.6%). Social media apps were more common among urban participants (64.7% vs 56.4%; *P*<.001; aOR 1.39, 95% CI 1.17-1.65). For research feedback, 4017 (94.9%) caregivers expressed willingness to receive it, with social media apps (n=2624, 65.3%) being the preferred method, followed by email (n=2535, 63.1%). Additionally, we questioned at the beginning and end of the questionnaire whether caregivers were willing to provide phone numbers in anonymous surveys; a total of 3065 (72.4%) caregivers expressed willingness in offline surveys, a rate significantly higher than that in online surveys (72.4% vs 43.4%; *P*<.001).

Discussion

Principal Findings

This study investigated public perspectives on the digitalization of pediatric research, comparing views between urban and suburban areas. The findings indicate that the current support for digital approaches in pediatric research is suboptimal but still offers valuable strategies for using digital methods to reduce urban-suburban health disparities in children. This study is relatively rare in the literature and explores innovative ways to enhance participation and equity through digital approaches. Previous studies have emphasized the importance of understanding the barriers and facilitators that parents face when considering their children's participation in research [20-27]. As much of the research has already begun digitalization [28-32], it is beneficial to periodically pause and gather insights from participants by considering their perspectives.

Perspectives on Pediatric Research

A previous study on neonatal clinical trials revealed that one-quarter of parents made immediate enrollment decisions [27]. Our research found that 59.8% (n=2531) of caregivers formed initial impressions of pediatric research, with 36.9% (n=1561) expressing positive inclinations and 22.9% (n=970) expressing negative inclinations. These findings emphasize the importance of recruitment strategies during initial contact. Further analysis identified health benefits as the main facilitators and risks as the primary barriers, which aligns with previous studies from other regions [20]. This suggests the results could be applicable beyond Chongqing. The lower reporting rates of facilitators than barriers may explain challenges in pediatric research. Preferences in recruitment leaned toward doctors with senior titles and specific researchers as recruiters, emphasizing the influence of authority on caregivers' decision-making. Additionally, previous research has shown that cartoon images influence children's decision-making [44]. This study found that 70% (n=2963) of caregivers also preferred cartoon-style recruitment materials, possibly because they convey a sense of care for children, which resonates well with caregivers [45].

Perspectives on Digital Medicine

Public perspectives on digital medicine revealed suboptimal acceptance among caregivers. Approximately one-third of caregivers acknowledged the increasing popularity of digital tools and supported their application in pediatric research. This was reflected in a lower willingness to provide phone numbers in online surveys than in offline surveys. The transition from traditional to remote trials, particularly during the COVID-19 pandemic, has been successful [30,46], though some unsatisfactory outcomes have been reported [47,48]. Our results showed that public accounts from research institutions were the most preferred source of online recruitment, aligning with offline sources that emphasize authority. Given that 42.9% (n=1813) and 58.1% (n=2457) of caregivers doubted the reliability and consistency of online recruitment, establishing a credible public account by research institutions could enhance recruitment success on social media, a novel strategy compared to previous studies [49]. On the other hand, the most commonly mentioned methods for regular contact were telephone and social media apps. This may explain the effectiveness of the hybrid follow-up model, which encourages using both phone calls and social media [50]. However, only 25.2% (n=1068) of caregivers supported online-only research methods, highlighting the importance of face-to-face interactions. This raises important questions about the effectiveness of a fully remote model in postpandemic pediatric research. When questioned about gamification in research, 61.7% (n=2610) of caregivers were in favor. Studies on gamified medicine have shown positive outcomes [51,52], but concerns about potential risks remain [53,54]. In this study, 58.1% (n=2457) of caregivers expressed concerns about addiction. Additionally, 77.4% (n=3273) of

XSL•FO
RenderX

caregivers expressed concerns about personal privacy when using smartphone software for research, which served as a barrier to supporting digital tools in pediatric research. Another advantage of digitalizing pediatric research is the availability of personalized real-time feedback, with 94.9% (n=4017) of participants willing to receive it. This meets caregivers' needs and serves as a strategy to increase motivation [55].

Differences Between Urban and Suburban Areas

When comparing urban and suburban areas, demographic differences were not adjusted using methods like propensity score matching, as these differences were inherent to the population. Instead, multivariate logistic regression was used to validate the results. Interestingly, suburban caregivers expressed greater interest in pediatric research and fewer barriers and concerns. These findings contradict common knowledge [15,16,56] but align with a previous study on congenital heart disease [57]. Another recent study also showed that rural caregivers had lower concerns about data privacy and security [58]. A possible explanation for suburban caregivers' higher enthusiasm is that the suburban areas in this study may not accurately represent resource-poor regions. These caregivers demonstrate sufficient health awareness and capabilities, making them value participation in pediatric research. This is evident in their willingness to access offline recruitment information, use digital tools for data collection, and support online-only research methods. Since suburban areas usually have more kindergarten children than urban areas (eg, Chongqing [33]), they represent a valuable potential pool of potential research participants. Further analysis revealed that suburban caregivers more frequently mentioned suggestions from close people. Similarly, suburban caregivers more often cited social media friends and moments as sources of online recruitment information. While these results raise concerns about caregivers' ability to assess the quality of online health information [59], they also highlight the potential for incorporating informal channels in recruitment strategies for suburban participants [60].

Strengths and Limitations

This study has several strengths. First, this study examined perspectives on digital medicine, which is distinct from conventional pediatric research topics [16,20-27] and provides essential data for the digital age. Second, this study included a more diverse sample from the general public, offering a broader representation compared to studies focused on specific illnesses. Third, the sample size was larger than that in previous studies, likely providing a more population-based overview. Finally, we performed a comparative analysis between urban and suburban areas, contributing to the understanding and mitigation of health inequalities among children in different geographical locations.

Despite these strengths, the limitations require careful consideration. First, this study was conducted in Chongqing, China. It is important to consider this when generalizing the findings to other regions. Therefore, further studies across different regions or countries are recommended to expand these findings. Second, although comparisons were made between urban and suburban areas, conditions in rural areas remain unknown and require further investigation. Third, perspectives were assessed using a structured questionnaire but lacked qualitative interview data. Additionally, despite cultural adaptations and a preliminary survey, individuals may still interpret certain questions differently based on their personal experiences. Finally, although smartphones are a prominent tool in digital health, the study's focus on them may introduce bias. However, less common digital tools may not be widely known to the general public, making it difficult to survey participants effectively about unfamiliar technologies.

Conclusions

In the digital age, approximately one-third of caregivers support pediatric research and endorse the use of digital tools in such studies. Caregivers in suburban areas show greater enthusiasm for research and digital medicine. Integrating official and unofficial social media recruitment strategies, implementing a hybrid online-offline follow-up approach, and addressing privacy concerns could help researchers increase participant recruitment and retention rates.

Acknowledgments

YH was affiliated with the Children's Hospital of Chongqing Medical University at the time of the study and is currently affiliated with Beijing Children's Hospital. The authors would like to thank Drs Shuyao Zhu, Keran Ling, Lin Chen, Zehao Li, Wei Zhang, Liyu Chen, and Yuxin Lv for their contributions to revising and culturally adapting the questionnaire. Special thanks are also extended to the kindergartens, teachers, and caregivers for their cooperation in distributing and responding to the questionnaire. This study was supported by the Major Program of the National Clinical Research Center for Child Health and Disorders in Children's Hospital of Chongqing Medical University (NCRCCHD-2023-MP-01) and the Program for Youth Innovation in Future Medicine, Chongqing Medical University, "Clinical Innovation Team for Standardized Management of Food Allergy in Children" (2022-26-W0120). The funder had no role in the preparation, review, or approval of the manuscript or the decision to submit it for publication. No generative artificial intelligence was used to generate the manuscript content.

Data Availability

The datasets generated during or analyzed during this study are available from the corresponding author upon reasonable request.

Abstract

Background: With increasing adoption of remote clinical trials in digital mental health, identifying cost-effective and time-efficient recruitment methodologies is crucial for the success of such trials. Evidence on whether web-based recruitment methods are more effective than traditional methods such as newspapers, media, or flyers is inconsistent. Here we present insights from our experience recruiting tertiary education students for a digital mental health artificial intelligence–driven adaptive trial—Vibe Up.

Objective: We evaluated the effectiveness of recruitment via Facebook and Instagram compared to traditional methods for a treatment trial and compared different recruitment methods' retention rates. With recruitment coinciding with COVID-19 lockdowns across Australia, we also compared the cost-effectiveness of social media recruitment during and after lockdowns.

Methods: Recruitment was completed for 2 pilot trials and 6 minitrials from June 2021 to May 2022. To recruit participants, paid social media advertising on Facebook and Instagram was used, alongside mailing lists of university networks and student organizations or services, media releases, announcements during classes and events, study posters or flyers on university campuses, and health professional networks. Recruitment data, including engagement metrics collected by Meta (Facebook and Instagram), advertising costs, and Qualtrics data on recruitment methods and survey completion rates, were analyzed using RStudio with R (version 3.6.3; R Foundation for Statistical Computing).

Results: In total, 1314 eligible participants (aged 22.79, SD 4.71 years; 1079, 82.1% female) were recruited to 2 pilot trials and 6 minitrials. The vast majority were recruited via Facebook and Instagram advertising (n=1203; 92%). Pairwise comparisons revealed that the lead institution's website was more effective in recruiting eligible participants than Facebook (z=3.47; P=.003) and Instagram (z=4.23; P<.001). No differences were found between recruitment methods in retaining participants at baseline, at midpoint, and at study completion. Wilcoxon tests found significant differences between lockdown (pilot 1 and pilot 2) and postlockdown (minitrials 1-6) on costs incurred per link click (lockdown: median Aus $0.35 [US $0.22], IQR Aus $0.27-$0.47 [US $0.17-$0.29]; postlockdown: median Aus $1.00 [US $0.62], IQR Aus $0.70-$1.47 [US $0.44-$0.92]; W=9087; P<.001) and the amount spent per hour to reach the target sample size (lockdown: median Aus $4.75 [US $2.95], IQR Aus $1.94-6.34 [US $1.22-$3.97]; postlockdown: median Aus $13.29 [US $8.26], IQR Aus $4.70-25.31 [US $2.95-$15.87]; W=16044; P<.001).

Conclusions: Social media advertising via Facebook and Instagram was the most successful strategy for recruiting distressed tertiary students into this artificial intelligence–driven adaptive trial, providing evidence for the use of this recruitment method for this type of trial in digital mental health research. No recruitment method stood out in terms of participant retention. Perhaps

XSL•FO

a reflection of the added distress experienced by young people, social media recruitment during the COVID-19 lockdown period was more cost-effective.

Introduction

Background

Advances in digital clinical trial infrastructure have made fully remote clinical trials more commonplace, particularly in the field of digital mental health. In such trials, participants are screened, assessed, treated, and followed up entirely via remote digital methods. Pivotal to the scientific validity of these trials is the timely and adequate recruitment of target participants who meet a set of prespecified eligibility criteria. Due to the paucity of research into best practice methods for efficiently recruiting trial samples, in this paper, we present insights from our experiences recruiting young participants for a digital mental health trial that used an artificial intelligence (AI)–driven adaptive trial design. This type of trial design has the potential to minimize time, costs, and the sample size needed to achieve sufficient statistical power [1]. Additionally, this method facilitates the optimization of treatment plans, which can enhance adherence and lower attrition [2]. However, compared to traditional randomized controlled trials (RCTs), AI-adaptive trials face an increased risk of insufficient and untimely enrollment due to the need for frequent, short-spanned recruitment drives (eg, monthly recruitment drives over a year). Hence, identifying recruitment methodologies that are both cost-effective and time-efficient is crucial for the success of such trials.

What recruitment methods are currently used and how do they compare with each other? A review by Lane et al [3] on online recruitment methods for web-based and mHealth studies found that successful recruitment of participants into a trial varied widely depending on the population, budget, intervention, costs, and study design. Of the studies included in their review, less than half (42%) found Facebook advertisements to be an effective method of recruitment and a quarter found Google advertisements to be the most effective method [3]. Only 1 study reported better outcomes using traditional methods of recruitment (eg, print advertisements and flyers) [3]. Overall, there was no consistent evidence on whether web-based recruitment methods were more effective than traditional methods such as newspapers, media, or flyers [3]. Similar mixed findings were echoed by a systematic review of recruitment strategies in mental health clinical trials [4], and a scoping review that examined the role of social media in clinical trials recruitment [5].

Specific to online recruitment methods, there is also contradictory evidence regarding the most cost-effective platform. Morgan et al [6] used a range of internet-based methods to recruit for the Mood Memos depression prevention study, including Facebook, emails, search engine advertisements, and forum posts, and reported that advertising on Google was more cost-effective than Facebook advertising (Aus $12 [US $7.46] per recruited participant vs Aus $19.89 [US $12.37] per recruited participant) in signing up participants. Similarly, recruitment costs for a large RCT of web-based smoking interventions were highest for Facebook (US $40.51) per randomized participant, compared to Google (US $34.71), traditional sources such as press releases, newspaper, radio, and television interviews (US $20.30), and using an online survey panel company (US $13.95) [7]. In contrast, Facebook advertising was found to be more cost-effective for recruiting a large sample of general community participants for suicide prevention research (Aus $2.81 [US $1.75] per completed survey) [8]. Similarly, Batterham [9] reported that advertising on a Facebook page that featured links to a survey on suicidal ideation was more effective in yielding completions (Aus $1.51 [US $0.94] per completion), compared to advertisements linked to an external website (Aus $9.82 [US $6.11] per completion). Both were more cost-effective than postal surveys, which averaged Aus $19.10 [US $11.88] per completion [9]. In a review of 176 studies that used social media for mental health research recruitment, Facebook was found to be the most preferred platform, at a median cost of US $19.47 per final recruited study participant [10]. The authors also found that in 2 out of 3 studies included in the review, social media recruitment performed as well as or better than traditional methods in the number and cost of final enrolled participants [10].

Differences in effectiveness between recruitment methods can often be difficult to interpret. In their systematic review, Liu et al [4] found that it was difficult to assess the overall effectiveness of any particular recruitment strategy as some strategies that worked well for a particular population may not work as well for others. For example, the greater costs of Facebook advertising for the Mood Memos study relative to the other studies described may be due to study requirements to target adults with subthreshold depression symptoms as opposed to recruiting a nonclinical sample. In terms of recruitment of young participants, evidence suggests that online advertisements are effective at appealing to this particular demographic. For example, Ford et al [11] examined paid advertising on Instagram, Snapchat, and Facebook to recruit youths (aged 13-20 years) for 2 cross-sectional surveys. They concluded that these platforms appear to be a modern and cost-effective approach to reaching youths with surveys on sensitive health topics [11]. Similar findings were obtained from

XSL•FO
RenderX

an Australian health survey study that assessed the feasibility of recruiting young females using targeted advertising on Facebook [12]. In another study, Lee et al [8] found that male participants were more difficult to recruit compared to female participants but were able to use targeted, gender-specific advertisements (different language and imagery compared to gender-neutral advertisements) on Facebook to recruit more males. This ability to target different subgroups and easily make changes to targeting strategies are significant benefits of Facebook recruitment. The impact of different targeting strategies can be monitored (eg, costs per click), and further tweaks can be made to determine the best way to reach the target population. In addition, marketing collaterals such as images, headlines, and copy can be changed in order to find the most effective study advertisement [7].

Overall, these studies suggest that online advertising via platforms such as Facebook and Instagram is promising for the effective recruitment of young adults for mHealth survey studies. However, evidence supporting using these recruitment strategies for treatment studies is scarcer. A recent Danish study demonstrated the feasibility of using Facebook and Instagram to recruit young Danes (aged 15-25 years) for an RCT to evaluate a national online youth mental health promotion service [13]. A study that assessed the effectiveness of social media (Facebook), targeted mailing, and in-person recruitment of young adults for diabetes self-management clinical trials found that leveraging a variety of recruitment strategies produced a more representative sample of young adults [14]. To our knowledge, no single study has investigated the effectiveness of various recruitment methods to enlist distressed young adults in digital intervention studies.

The Vibe Up Trial

Vibe Up is an AI-driven adaptive trial, in which a series of "mini" trials are performed instead of 1 large trial. AI methods are used to update an underlying model of the interventions' effectiveness and alter the proportion of participants allocated to each intervention in the next minitrial. Under this scheme, progressively fewer participants are allocated to less effective interventions in later minitrials, with the aim of identifying the most effective intervention as quickly as possible. This trial delivered brief interventions, including mindfulness (a set of five 3-5 minute instructor-guided audio meditations), physical activity (an evidence-based 7-minute high-intensity circuit training protocol, or self-selected daily physical activity), sleep hygiene (a program of 4 infographic-based information modules), and ecological momentary assessment (blended protocol consisting of signal contingent and event-contingent), to ease psychological distress in Australian tertiary education students [15]. A mobile app, Vibe Up, was purpose-built for these trials, allowing eligible students to participate in a "minitrial" by downloading the app from the App Store or Google Play. To ensure that data was captured as intended and to detect fraudulent activities, data verification was carried out by the data manager after the completion of each minitrial. Recruitment for Vibe Up coincided with COVID-19 lockdowns in Australia. This provided us with the opportunity to assess the cost-effectiveness of social media recruitment during a pandemic compared to its aftermath. Research has shown significant increases in distress among young people as a result of the COVID-19 pandemic [16-18]. Transition to online learning for students and restrictions on routine daily activities affected the well-being of young people [19-21]. With access to in-person mental health support no longer possible, we examined whether the cost-effectiveness of recruitment differed between the lockdown and the postlockdown period.

Aims

This study evaluated recruitment data of an AI-driven adaptive digital mental health trial aimed at reducing psychological distress in Australian tertiary education students [15]. This study aims to (1) evaluate the effectiveness of recruitment via Facebook and Instagram compared to traditional methods for a treatment study, (2) compare the cost-effectiveness of online recruitment during and after COVID-19 lockdown, and (3) compare retention rates of different recruitment methods used in this study.

Methods

Study Design

This study evaluated recruitment data collected from the Vibe Up study [15]. Data included engagement metrics collected by Meta (Facebook and Instagram), advertising costs, and Qualtrics data [22] on recruitment methods and rates of survey completion. To recruit participants, paid social media advertising on Facebook and Instagram was used, alongside mailing lists of university networks and student organizations or services, media releases, announcements during classes and events, study posters or flyers on university campuses, and our health professionals' network. Recruitment for 2 pilot trials and 6 minitrials occurred between June 2021 and May 2022.

Participants

Participants were Australian tertiary education students. No restrictions were placed on the state or territory of origin. In order to participate in the study, participants must (1) be aged 18 years or older; (2) be currently enrolled as a student at an Australian university, technical and further education, or other higher education institution; (3) be currently residing in Australia and planning to be a resident throughout the study period; (4) be an advanced, fluent, or native English speaker; (5) own an eligible personal smartphone (iPhone 6S or Android 5 or later) with active mobile number and internet access; and (6) score 20 or more on the Kessler Psychological Distress Scale, 10-item version [23].

Participants are excluded if they (1) score 21 or more on the Suicide Ideation Attributes Scale [24]; (2) report a current active diagnosis of psychosis or bipolar disorder; (3) have already participated in a "minitrial" in the study; (4) indicate major disruptions or events in the next 2 months which may make it difficult to take part in the study; (5) indicate plans to travel outside of Australia in the next 2 months; and (6) indicate that they would be unable to safely undertake a physical activity intervention if allocated to receive this treatment.

XSL•FO
RenderX

Procedure

Recruitment was conducted by the research team in collaboration with the lead institution's in-house marketing and communications department. A social media targeting strategy was developed (Table 1). Clicking on the Meta advertisements (Facebook and Instagram) took potential participants to a landing page, hosted on the lead research institution's website, which contained study information and a direct link to the screening survey that was administered on the Qualtrics XM survey platform [22]. The recruitment window for each Vibe Up trial remained open for up to 7 days only; however, to not risk losing any potential participants between recruitment drives, the survey link was replaced by an expression of interest form on the website to capture the name, email address, and education institution of interested students. These students were contacted at the beginning of the following recruitment drive. Two pilot trials were carried out before recruitment began for 6 minitrials.

Table 1. Profile of individuals targeted on social media.

Category	Detail
Location	Australia
Age (years)	18-40
Sex	Male or female
Education	At university (undergraduate) or at university (postgraduate)
Interests	Science, artificial intelligence, mindfulness, computer science, *DSM-5*[a], mental health foundation, Headspace, Beyond Blue or Lifeline (crisis support service), and international students

[a]DSM-5: Diagnostic and Statistical Manual of Mental Disorders (Fifth Edition).

Active recruitment was conducted via paid advertising on Facebook and Instagram. Traditional methods for recruiting students such as mailing lists, study flyers or posters, class or event announcements, and posts on the Black Dog Institute website and university media were also used. Meta's "dynamic creative" function was used to upload a variety of images, copies, and headlines. Meta delivered a combination of these elements until it determined the top-performing combination and the combination that delivered on the objective at the cheapest cost.

We trialed different advertising objectives, using Meta's (Facebook and Instagram) preset choices. For example, the use of link clicks allowed Meta to deliver study advertisements to people most likely to click on them, with the aim of obtaining the cheapest cost per click. We then unsuccessfully trialed a "landing page view objective" which focused on getting people to not just click on the advertisement, but to load and engage with the content on the page. To improve performance, for minitrials 5 and 6, the Meta pixel was used to set up an "initiate checkout" conversion on the "GET STARTED" button which appeared at the bottom of the recruitment website and took participants to the Qualtrics screening survey. In this instance, Meta optimized study advertisements toward people most likely to take this action.

Measures

Metrics used to measure recruitment in this study were derived from Facebook analytics data and Qualtrics survey data. For ease of comparison, metrics were largely based on previous research in this area [8,9] and are included in Table 2.

XSL•FO
RenderX

Table 2. Study measures and definitions.

Variable name	Definition
Amount spent on advertising per trial (Aus $)	Facebook and Instagram advertising costs per trial in Australian dollars.
Impressions	Number of times study advertisements were viewed.
Reach	Number of people that viewed study advertisements.
Link clicks	Number of times that links to study advertisements were clicked on.
Unique link clicks	Number of people that clicked on study advertisement links, regardless of how many times they clicked on a link.
Click through rate	The percentage of people who viewed and then clicked on the study advertisement. This was calculated by dividing the total number of clicks by the total number of impressions multiplied by 100. Click-through rates measure how successful the study advertisements are in capturing people's attention.
Number of students screened	Number of people who completed screening.
Number of eligible students	Number of people who were eligible to take part in the study.
Number of students who downloaded the study app	Number of people who downloaded the study app from Google Play or the App Store.
Number of students who completed a trial	Number of people who completed the 3 phases of the study (baseline, midpoint, and post).
Costs per screened	Costs per person who completed the screening questionnaires in Australian dollars.
Costs per eligible	Costs per person who was eligible to participate in the study in Australian dollars.
Costs per downloaded	Costs per person who downloaded the study app from Google Play or the App Store in Australian dollars.
Costs per completed	Costs per person who completed all three phases of the study in Australian dollars.

Statistical Analysis

Analyses were performed in RStudio with R (version 3.6.3; R Foundation for Statistical Computing). Descriptive analyses were conducted using Facebook and Instagram analytics data to assess how study advertisements performed and using Qualtrics survey data to determine rates of screened, eligible, and completed participants. A general linear model with pairwise post hoc estimates was used to compare the effectiveness of different methods in recruiting and retaining participants. For each recruitment pathway (Facebook and Instagram advertisement or post, other, and website of lead institution), Fischer exact tests were conducted to determine if gender, student status (domestic or international), and student level (undergraduate or postgraduate) of participants changed significantly as a result of dropout across different stages of the trial. To test for differences in age, Kruskal-Wallis tests were performed. For the purpose of comparing cost-effectiveness between COVID-19 lockdown and post–COVID-19 lockdown, pilot 1 and pilot 2 were classified in the former category and minitrials 1-6 fell into the latter. Inferential statistics were performed using Wilcoxon tests.

Ethical Considerations

Ethical approval was sought and obtained from the University of New South Wales Sydney Human Research Ethics Committee (HC200466). The trial sponsor is the University of New South Wales Sydney. The trial is registered with the Australian New Zealand Clinical Trials Registry (Pilot trials: ACTRN12621001092886; Mini-trials 1-6: ACTRN12621001223820). Informed consent was obtained from each trial participant, and the collected data were stored in a deidentified format. Each participant received Aus $30 [US $18.65] in gift cards.

Results

Demographics

In total, 1314 participants were recruited for 2 pilot trials and 6 minitrials. Participants had a mean age of 22.79 (SD 4.71) years, predominately female (n=1079, 82.1%), domestic (n=1226, 93.3%), and undergraduate students (n=1045, 79.5%). Participants were recruited from 72 tertiary education institutions from across Australia (for the top 10 institutions; Table S1 in Multimedia Appendix 1).

Breakdown by Recruitment Methods

For the 2 pilot trials and 6 minitrials, 3638 students attempted the screening survey. The majority of students who screened for the trials were recruited via social media advertising or posts via Facebook (n=1690, 47%) and Instagram (n=922, 25%). Of the 1314 students (36%) eligible to participate in the study, the vast majority were recruited via social media advertising or posts (n=1203, 92%). Of the 1058 students (81% of those eligible) who provided baseline data, similar proportions were recruited via social media advertising or posts. Of the 982 students (75% of those eligible) who provided midpoint data, recruitment via social media remained the most fruitful (n=889, 91%). Of the 862 students (66% of those eligible) who completed a trial, 90 percent of students were recruited via social media advertising or posts. In terms of participant retention, see Table 3 for a detailed breakdown by recruitment method.

Table 3. Breakdown of participants by recruitment pathway and trial retention.[a]

Recruitment pathway	Number of students retained in the trial				
	Attempted screening (N=3638), n	Screened eligible (n=1314), n (%)	Completed baseline (n=1058), n (%)	Completed midpoint (n=982), n (%)	Completed a trial (n=862), n (%)
Facebook advertisement or post	1690	810 (47.9)	644 (38.1)	597 (35.3)	518 (30.7)
Instagram advertisement or post	922	393 (42.6)	316 (34.3)	292 (31.7)	257 (27.9)
Other	107	61 (57)	55 (51.4)	52 (48.6)	49 (45.8)
Website of lead institution	72	50 (69.4)	43 (59.7)	41 (56.9)	38 (52.7)
Survey not completed	847	—[b]	—	—	—

[a]Other included class or event, email, health professional, poster or flyer, press or media. Retention percentages were calculated based on the number of participants who attempted screening.

[b]Not applicable.

Pairwise comparisons revealed that the lead institution's website was more effective in recruiting eligible participants compared to Facebook (z=3.47; P=.003) and Instagram (z=4.23; P<.001). No statistically significant difference was found between website recruitment and other methods (eg, email, poster or flyer) in recruiting eligible participants. No statistically significant differences were found between recruitment methods in retaining participants at baseline, at mid-point, and at study completion (Tables S2-S9 in Multimedia Appendix 1). To assess possible sample selection effects by recruitment pathway, characteristics of participants who dropped out at each trial stage were examined. No statistically significant age, sex, and student level (undergraduate vs postgraduate) differences were found for recruitment by Facebook, Instagram, others, and the website of the lead institution (Tables S10-S13 in Multimedia Appendix 1). For recruitment by Facebook, statistically significant differences were found for student status (domestic vs international; P=.001; Table S10 in Multimedia Appendix 1). No such differences were found for Instagram, others, and the website of the lead institution (Tables S11-S13 in Multimedia Appendix 1).

Facebook and Instagram Recruitment

Across the 2 pilot trials and 6 minitrials, Aus $7571.72 (US $4707.72) was spent on social media recruitment via Facebook and Instagram advertising, at an average of Aus $946.47 (US $588.47; SE Aus $160.99 [US $100.10]) per trial. A total of 1,119,661 impressions were counted, at an average of 139,958 (SE 27,927) impressions per trial. The performance of study advertisements was measured by the number of clicks generated that led potential participants from the social media platform to the Vibe Up recruitment page. See Figures S1 and S2 in Multimedia Appendix 2 for the top-performing Vibe Up advertisements. During the recruitment drives, 825,635 people were reached, at an average of 103,204 people (SE 17,569) per trial. 8138 clicks were registered on the study website (mean 1017, SE 71), with 7858 being unique link clicks (mean 982, SE 68). The overall click-through rate was 0.73. See Table 4 for the detailed breakdown of participant engagement by trial, during and post–COVID-19 lockdown.

Table 4. Breakdown of trial costs and engagement metrics.

Trial (stage)	Amount spent (Aus $[a])	Impressions, n	Reach, n	Clicks, n	Unique clicks, n	Click-through rate
Pilot 1(lockdown)	445.98	82,266	65,654	1227	1155	1.49
Pilot 2 (lockdown)	254.11	39,709	31,592	699	669	1.76
Trial 1 (postlockdown)	850.00	91,322	71,994	1142	1112	1.25
Trial 2 (postlockdown)	999.70	237,201	150,766	1197	1156	0.50
Trial 3 (postlockdown)	1100.00	247,540	175,161	1203	1168	0.49
Trial 4 (postlockdown)	1750.80	207,799	146,423	967	937	0.47
Trial 5 (postlockdown)	1095.12	99,285	81,652	850	824	0.86
Trial 6 (postlockdown)	1076.01	114,539	102,393	853	837	0.74
Total	7571.72	1,119,661	825,635	8138	7858	0.73

[a]Aus $1=US $0.62.

XSL•FO
RenderX

Cost-Effectiveness of Trial Recruitment

On average, it costs Aus $2.28 (US $1.42; SE Aus $0.49 [US $0.30]) per screened participant, Aus $6.59 (US $4.10; SE Aus $1.39 [US $0.86]) per eligible participant, Aus $7.78 (US $4.84; SE Aus $1.64 [US $1.02]) per participant who downloaded the study mobile app, and Aus $10.01 (US $6.22; SE Aus $2.20 [US $1.37]) per completion. See Table S16 in Multimedia Appendix 1 for the breakdown of costs by trial.

Impacts of COVID-19 Lockdowns

Wilcoxon tests were carried out to compare costs incurred per link click between COVID-19 lockdown (pilot 1 and pilot 2), and post–COVID-19 lockdown (minitrials 1-6). Significant differences were found in the cost per click (lockdown: median Aus $0.35 [US $0.22], IQR Aus $0.27-$0.47 [US $0.17-$0.29]; postlockdown: median Aus $1.00 [US $0.62], IQR Aus $0.70-$1.47 [US $0.44-$0.92]; W=9087; P<.001; Table S14 in Multimedia Appendix 1). As recruitment drives occurred in short bursts (3-7 days as opposed to weeks or months for other recruitment campaigns), we compared lockdown and postlockdown costs using hourly spending on Facebook and Instagram advertising. Differences between lockdown and postlockdown on the amount spent per hour to reach the target sample size were also statistically significant (lockdown: median Aus $4.75 [US $2.95], IQR Aus $1.94-$6.34 [US $1.22-$3.97]; postlockdown: median Aus $13.29 [US $8.26], IQR Aus $4.70-$25.31 [US $2.95-$15.87]; W=16044; P<.001; Table S15 in Multimedia Appendix 1).

Discussion

Principal Findings

With the increasing adoption of remote clinical trials in digital mental health research, and the uptake of the AI-driven adaptive trial methodology, strategies to optimize timely recruitment of suitable participants warrant investigation. Advancements in the way online social media platforms can be manipulated to reach target audiences faster and cheaper provided further impetus for this study. The effectiveness of participant recruitment via Facebook and Instagram was compared with traditional methods such as mailing lists and study flyers or posters. Results suggest that Facebook and Instagram are effective in recruiting young adults for remote digital mental health trials. Social media advertising outperformed more traditional methods in the total number of eligible participants recruited. However, we also found that compared to Facebook and Instagram, recruitment via the lead institution's website was more effective in yielding eligible participants from those who completed screening. It may be the case that participants recruited while browsing the institution's website (a mental health research institute) were actively seeking information to manage mental health concerns, and thus more likely to be eligible for the study than someone shown the study advertisement via social media because they fit the target age group. In addition, although not statistically significant, the completion rate was higher for participants recruited via the website. This could be explained by the familiarity, trust, and support of the mental health research carried out by the lead institution and suggests that this recruitment pathway can be effective for trial enrollment and importantly, trial completion. Given that the vast majority of eligible participants were recruited via social media advertising (92%) compared to website recruitment (4%), if funds are available, it would still make sense to include social media in the recruitment strategy to recruit young people for digital mental health trials. In terms of participant retention from study baseline to completion, there was no stand-out recruitment method. Similar to the number of eligible participants, the sheer volume of completers recruited via social media (90%) compared to traditional methods, provides a rationale for including this method in participant recruitment strategies. We did not find evidence of a sample selection effect due to the recruitment methods used. However, similar trials in the future should identify strategies to attract more international students. For example, targeted social media advertising for this student group and liaising with student leaders to disseminate trial information to club or society members.

In terms of cost-effectiveness, this study provided further evidence to support the benefits of using social media to recruit young adults for mental health research participation. Our results (Aus $7.78 [US $4.84] per participant app download and Aus $10.01 [US $6.22] per trial completion) compared favorably with the Mood Memos Study (Aus $19.89 [US $12.37] per recruited participant) [6], a health survey study targeting young females (US $20 per compliant participant) [12], a health intervention study of 334 young Australian adults (Aus $105.77 [US $65.76] per recruited participant) [25], diabetes self-management clinical trial for young adults (US $334 per enrolled participant) [14], and a review that calculated estimated median recruitment costs for RCTs in mental health research (US $42.82) [10]. Even though costs per completion for our trial were higher than studies conducted by Lee et al [8] (Aus $2.81 [US $1.75] per completion), Ash et al [26] (Aus $6.07 [US $3.77] per completion) [26], and Batterham [9] (Aus $1.51 [US $0.94] per completion), additional costs are explained by the nature of research activities involved; one-off survey completions, as opposed to completing a 29-day trial involving brief mental health interventions in Vibe Up. In comparison to an RCT that recruited 560 Danes aged 15-25 years to evaluate an online youth mental health promotion service [13], US $4.20 per baseline survey completion reported for this trial was almost identical to costs per eligible participant for Vibe Up (Aus $6.59 [US $4.10]).

More than 1.1 million impressions were counted during our recruitment drives, reaching 825,635 people. These are numbers difficult to achieve in a short period of time using flyers or posters, class announcements, and mailing lists. The ability to track the number of clicks on the study website (n=8138), and determine if clicks were by different individuals (7858 unique clicks), in addition to the ability to alter targeting setup (eg, tailoring advertisements to male students), makes social media recruitment via Facebook and Instagram an attractive proposition for researchers looking to recruit a large sample within a limited period of time. Further, click-through rates provided valuable insights into how engaging the study advertisements are to the target audience, allowing fine-tuning of recruitment materials during recruitment drives to maximize participant sign-up.

XSL•FO
RenderX

According to WordStream [27], a good click-through rate for Facebook advertising averages approximately 0.90%. This study achieved an overall click-through rate of 0.73%, with the highest rates achieved during the COVID-19 lockdown (pilot 1: 1.49 and pilot 2: 1.76). It is important to acknowledge that the success in recruiting young people for our trial also leveraged the well-established and trusted brand of the lead institution in the mental health space in Australia.

A spike in costs for minitrial 4 warranted our attention. Up until then, a "link click" objective was used wherein Facebook and Instagram directed the study advertisements toward individuals most likely to click on them. A change to the "landing page view" objective for trial 4, where individuals more likely to load the page content were targeted, resulted in higher costs. It was a tactic that did not pay off as Facebook and Instagram needed time and more money to relearn the change in objective. For subsequent trials, a conversion pixel on the "GET STARTED" button was implemented, targeting people most likely to participate. This was a cost-saving strategy, homing in on people more likely to take action. Although the ability to change strategies demonstrated advancements in social media recruitment to reach specific target samples, it does come with additional financial costs that researchers should be aware of. In addition, fraudulent participants have increasingly infiltrated research recruitment via social media, especially trials offering monetary reimbursement. The current study implemented several safeguards including the use of time-based one-time password for app downloads and manual checking of participant details before inclusion in the study.

The first 2 recruitment drives coinciding with the COVID-19 lockdowns provided us with the unique opportunity to assess whether social media recruitment was more cost-effective during the lockdown period compared to postlockdown. Comparisons between the 2 periods found that fewer funds were needed during lockdown to trigger interest from prospective participants and result in sign-ups. The COVID lockdown may have facilitated recruitment, with students taking the opportunity to learn new, evidence-based coping strategies for psychological distress offered by the trial. The planned recruitment period of 2 weeks was reduced to 7 days, with almost 300 participants recruited for the first pilot trial. Adjustments were made for pilot 2 (7-day recruitment period); however, intake was closed after 3 days with sign-ups exceeding the target of 120-150 participants. COVID-19 lockdown was the most cost-effective recruitment period, with fewer funds required per screened participant, per eligible participant, per app download, and per completed participant. The psychological impact of the lockdown may have prompted students to seek ways to improve their mental well-being. Even though recruitment periods for subsequent trials (postlockdown) remained consistent (3-5 days), more funds were expended to reach the target sample size. Costs per completed participant increased to between Aus $8 (US $4.97) and Aus $21 (US $13.06; compared to under Aus $3 [US $1.87] for the pilot trials). These opportunistic findings suggest that recruitment of young people may yield better results during their "downtime," for example, during semester breaks or festive seasons, when they have the capacity to contribute to research. In addition, recruitment materials need to include information on benefits to participants (for example, providing an opportunity to learn evidence-based coping strategies), and screening needs to exclude those unable to commit for the entire study (for example, asking participants to indicate major disruptions or events in the next 2 months which may make it difficult to take part in the study) to help boost retention rates.

Limitations

First, we were unable to accurately assign a monetary value to the traditional recruitment methods used for our trials (eg, poster or flyer and classroom announcements) so no direct comparisons were made on cost-effectiveness with social media recruitment. As a result, we are unable to comment on whether one recruitment method is more cost-effective than another in this study. Instead, the costs of social media recruitment were compared with previously published data to help determine if this method should be pursued in future mental health AI-driven adaptive trials. Secondly, we struggled to correct the sex imbalance within our sample. This is consistent with the recruitment literature [28,29]. Even though more funds were allocated to the recruitment of male participants from main trial 4 onwards, we were unable to correct the skew. For future studies, user testing of tailored advertisements for male participants should be considered before the start of recruitment campaigns. Next, given that our participants were recruited from all over Australia, it was difficult to isolate which participants were in lockdown, as lockdown periods varied across the country. We have categorized our trials based on dates published online by the Australian government [30]. Finally, the young people referred to in our study are all tertiary education students. Their characteristics and inclination to participate in research may differ from others in this group (eg, in full-time employment). Hence, our findings may not be generalizable to all young people in Australia but are likely to reflect those currently attending an Australian tertiary education institution.

Conclusions

Social media advertising on Facebook and Instagram is a productive method to recruit young people for AI-driven adaptive digital mental health intervention trials. Given that repeated recruitment drives are necessary for this trial methodology (in our case, once every month for 2 pilot trials and 6 minitrials), we found social media to be more effective in reaching potential participants all over Australia than traditional recruitment methods such as mailing lists and flyers or posters. In addition, advertising costs from this study compared favorably with other large-scale traditional trials, providing evidence that social media advertising can be effective for participant recruitment in future AI-driven adaptive trials. Perhaps a reflection of the added distress experienced by young people, online advertising costs were low during COVID-19 lockdowns and increased post lockdown. Based on our experience, we encourage other researchers interested in running AI-driven adaptive trials to consider the use of social media advertising to recruit participants.

Abstract

Background: Results on parental burden during the COVID-19 pandemic are predominantly available from nonrepresentative samples. Although sample selection can significantly influence results, the effects of sampling strategies have been largely underexplored.

Objective: This study aimed to investigate how sampling strategy may impact study results. Specifically, we aimed to (1) investigate if outcomes on parental health and child maltreatment during the COVID-19 pandemic from a convenience sample differ from those of a specific representative sample and (2) investigate reasons for differences in the results.

Methods: In 2020, we simultaneously conducted 2 studies: (1) a web-based survey using a convenience sample of 4967 parents of underage children, primarily recruited via social media, and (2) a study using a quota sample representative of the German adult population with underage children (N=1024), recruited through a combination of telephone interviews and computer-assisted web interviews. In both studies, the same questionnaire was used. To evaluate the impact of sampling, we compared the results on outcomes (parental stress, subjective health, parental mental health, general stress, pandemic-related stress, and the occurrence of child maltreatment) between the 2 samples. To explain differences in the results between the 2 studies, we controlled for sociodemographic data, parent-related risk factors, and COVID-19–related experiences.

Results: Compared to parents from the quota sample, parents from the convenience sample reported significantly more parental stress (η^2=0.024); decreased subjective health (η^2=0.016); more anxiety and depression symptoms (η^2=0.055); more general stress (η^2=0.044); more occurrences of verbal emotional abuse (VEA; ϕ=0.12), witnessing domestic violence (WDV; ϕ=0.13), nonverbal emotional abuse (NEA; ϕ=0.03), physical abuse (ϕ=0.10), and emotional neglect (ϕ=0.06); and an increase of child maltreatment (VEA: exp(B)=2.95; WDV: exp(B)=3.19; NEA: exp(B)=1.65). Sociodemographic data, parent-related risk factors, and COVID-19–related experiences explained the differences in parental stress (remaining difference between samples after controlling for covariates: η^2=0.002) and subjective health (remaining difference between samples after controlling for covariates: η^2=0.004) and partially explained differences in parental mental health (remaining: η^2=0.016), general stress (remaining: η^2=0.014),

XSL•FO
RenderX

and child maltreatment (remaining: VEA: exp(B)=2.05 and WDV: exp(B)=2.02) between the 2 samples. The covariates could not explain the difference in NEA (exp(B)=1.70). We discuss further factors that may explain the unexplained differences.

Conclusions: Results of studies can be heavily impacted by the sampling strategy. Scientists are advised to collect relevant explaining variables (covariates) that are possibly related to sample selection and the outcome under investigation. This approach enables us to identify the individuals to whom the results apply and to combine findings from different studies. Furthermore, if data on the distribution of these explanatory variables in the population are available, it becomes possible to adjust for sample selection bias.

Introduction

Background

The COVID-19 pandemic and the resulting consequences (eg, restrictions, such as school and daycare closings, social distancing, and stay-at-home orders) posed various challenges, especially for families. Parents felt stressed [1-4] and were especially burdened during the COVID-19 pandemic [1,5,6]. Studies showed worsening or significant impairments of parental mental health (depression, anxiety, and stress) [2,6-16], a significant increase in parental stress [3,14,17-20], and an increase in the occurrence of child maltreatment during the COVID-19 pandemic [17,21,22].

The existing trend toward convenience sampling in psychological research [23-25] increased during the COVID-19 pandemic [26]. As is the case for most studies on mental burden and well-being of families during the COVID-19 pandemic, findings on parental outcomes are primarily generated through web-based studies with convenience sampling (eg, [4,7,10,13-17,19,22,27,28]). In a web-based study, convenience sampling is often conducted by recruiting participants through easily accessible methods, such as social media posts, previous study participants, or email lists. Consequently, they are often not representative of the population of interest. Only a few studies evaluating the impact of the COVID-19 pandemic on families recruited a representative sample (eg, [1-3,11]). Therefore, many studies are not representative of the general population or the specific population of interest. In other words, in web-based convenience samples, the general population is often not adequately represented. Differences in sample characteristics may not be a problem, if the sample characteristics that differ are irrelevant for the outcome one wants to assess. However, if the samples differ in variables that are relevant for the outcomes (eg, single parents are less likely to take part in a web-based convenience study on parental burden because they may not have the time; at the same time, single parents will more likely be affected by COVID-19 restrictions), the results will be biased and cannot be generalized to the overall population.

Studies have shown substantial differences in sociodemographic composition from web-based convenience samples in comparison with representative samples [29-32]. In their systematic literature review on recruitment via Facebook for health-related studies, Whitaker et al [33] found that some studies showed an overrepresentation of White, female, younger individuals with higher education and higher income. The overrepresentation of these sample characteristics in web-based convenience samples on parenting and family research is also known [34-39]. In various web-based convenience samples assessing the impact of the COVID-19 pandemic on parents, participants are more likely to be female [4,9,14-17,19,22,27,40-45], in a relationship [4,15,19,22,40,41,43], and have higher education [4,14,16,17,27,41-43,45-47]. Differences in sociodemographic variables (eg, sex, child age, parental age, and socioeconomic status) compared to the general population further influence the outcomes, as some of these factors are associated with poorer parental outcomes and greater family burden during the pandemic [8,11,16,40-42,48-60]. Thus, these study results may not necessarily generalize to the overall population during the COVID-19 pandemic [26,61-66].

The generalizability of results from nonprobability studies with web-based convenience samples was already discussed before the COVID-19 pandemic [29,31,67-69]. In their literature review, Cornesse et al [31] concluded that the generalizability of probability sample surveys (eg, representative samples) is higher than that of nonprobability sample surveys (eg, web-based convenience samples). Similar results were found by other researchers [25,30,32,70-76]. Even before the COVID-19 pandemic, studies assessing mental health indicated that individuals with higher burden were more likely to choose to participate in web-based convenience sample studies, resulting in discrepancies in burden scores compared to representative samples [25,77,78]. This selection effect is also evident in studies assessing the impact of the COVID-19 pandemic, resulting in an overestimation and underestimation of specific outcomes [65,79].

Studies on the generalizability of web-based convenience sampling in parenting and family research are scarce. One Australian study found that mothers surveyed on the web via Facebook, compared to a population-representative sample, showed sociodemographic differences (eg, overrepresentation of younger individuals, those in a relationship, with higher education, and who spoke only English at home) as well as poorer mental health and self-rated health [39]. Similarly, Bennetts et al [80] reported higher psychological distress in

XSL•FO
RenderX

their parent sample recruited through Facebook compared to a representative sample.

Objective

To the best of our knowledge, no published studies have investigated the generalizability of results from web-based convenience samples on parental outcomes during the COVID-19 pandemic, leaving the potential biasing effect unknown. The following research questions were addressed: (1) Are results from a convenience sample during the COVID-19 pandemic comparable to results from a specific representative sample regarding parental outcomes (ie, parental stress, parental health, and the occurrence of child maltreatment)? and (2) To what extent can we explain differences in outcomes between the studies by sample characteristics?

Methods

Study Design

This study is based on the project "Parenting in Pandemic Times." The target population of the project was parents with underage children in the household in Germany (national) with sufficient German language skills. Data presented in this paper refer to 2 separate studies conducted simultaneously. First, a quota sample was collected by the market research company INFO Marktforschungsinstitut between August 3 and August 11, 2020. Computer-assisted telephone interviews (CATIs; n=402) were combined with a computer-assisted web interview (CAWI; n=622) to provide data that are as representative as possible. The CAWI allowed respondents to complete the questionnaire on the web at home on a computer, tablet, cell phone, or other smart device. A dual-frame design was used for the CATI sample to reach respondents via landline and cell phone. Participants in the CAWI sample were recruited from an active web-based access panel of the market research institute. They received incentives for their participation. In the first step, specific representativity was assured by recruiting participants based on quota obtained from the latest microcensus data regarding parental sex, parental age, number of children, federal state, school educational level (with vs without A-level), and income. In the second step, to adjust for the remaining disproportion in these variables due to unit nonresponse, INFO Marktforschungsinstitut additionally used poststratification weighting. While educational level was assessed in 4 categories, representativeness (eg, quota and weighting) was only ensured for the dichotomous variable of having an A-level (high education) versus not having an A-level. For the dichotomous variable on education, specific representativity could be assured. The weighting took place retrospectively to the actual quota sampling. (For more information, refer to the study by Calvano et al [2]; in this study, weighting only slightly altered the strata-variable distribution in the specific representative study. Calvano et al [2] determined that using unweighted as compared to weighted data does not alter the findings or conclusions.) Second, a convenience sample was collected between August 2 and September 16, 2020. The recruitment of this sample (N=4967) took place through requests and emails via an web link through social media (eg, Facebook groups, Instagram, and Twitter; 2561/4967, 51.56%; refer to Multimedia Appendix 1, picture 1), friends and family (769/4967, 15.48%), internet (658/4967, 13.25%), schools (551/4967, 11.09%), daycare facilities (263/4967, 5.29%), work (84/4967, 1.69%), clubs (65/4967, 1.31%), clinics for child and adolescent psychiatry (34/4967, 0.68%), child and adolescent therapists and pediatricians (18/4967, 0.36%), newspapers (32/4967, 0.64%), and child protection outpatient clinics (16/4967, 0.32%). As the research team was based in Berlin, Germany, recruitment primarily took place in Berlin through schools, daycare facilities, child and adolescent therapists and physicians, clubs, and newspapers. Social media requests were placed in groups with German-speaking parents. A total of 42.5% (2111/4967) of the convenience sample came from Berlin. Participants in the convenience sample were able to take part in a raffle for vouchers and iPads at the end of the survey. In both samples, few data were excluded due to an unrealistic short completion time (convenience: 53/5020, 1.06%; specific representative: 66/1090, 6.06%). Noteworthily, the surveys were identical in content, that is, all measures and instructions applied were identical.

Ethical Considerations

Data collection, analysis, evaluation, and reporting were conducted in accordance with the current ethical guidelines and data protection laws. All data are anonymized. The Ethics Committee of Charité – Universitätsmedizin Berlin (EA2/128/20; July 27, 2020) approved the study. Participants received information on the purpose of the research, the scope and duration of the diagnostic measures, possible risks and benefits, the voluntary nature of participation, and all aspects of data protection. For participation in the study, participants agreed to an informed consent declaration. Participants were provided with contact details for support services. Participants in the convenience sample could take part in a prize raffle for cash vouchers. Participants in CAWI received incentives from the market research company.

Measures

We distinguished between explaining variables (sociodemographic data, parent-related risk factors, and pandemic-related experience) and parental outcomes (parental stress, subjective health, parental mental health, general stress, and child maltreatment).

Explaining Variables

Sociodemographic Data

Data on parental sex and age, parental status (biological parent, stepparent, and other), nationality, number of children in the household, children's age and sex, marital status, federal state, parental school and professional education, and parental current employment status were assessed. We calculated the Winkler Index [81] with reference data from the German population to classify the socioeconomic status as low, medium, or high.

Parent-Related Risk Factors

The alcohol abuse module of the Patient Health Questionnaire, German version [82,83] was applied to assess parents' risk of alcohol abuse during the COVID-19 pandemic. Furthermore, the study assessed parents' experiences of sexual or physical

XSL•FO
RenderX

violence in adulthood, their own history of childhood sexual or physical abuse, and the presence of mental disorders. In addition, parents were asked to report the presence of a severe or chronic physical condition and if they belonged to the risk group for COVID-19.

Pandemic-Related Experience

To measure pandemic-related experiences and stress related to COVID-19, the Pandemic Stress Scale (Winter, S, Corona Belastungsskala. Charité - Universitätsklinikum Berlin, Klinik für Psychiatrie, Psychosomatik und Psychotherapie des Kindes- und Jugendalter, Sektion Traumafolgen und Kinderschutz, unpublished data, January 2020) was developed. Questions were answered with respect to household members, the family, or the parents themselves. At first, COVID-19–related personal experiences were assessed, that is, contact with persons with a COVID-19 infection, hospital admission, or death. Afterward, the month or months with the subjectively highest burden (January 2020 to August 2020) were assessed.

Parental Outcomes

Parental Stress

To assess negative and positive perceptions of parenthood, the Parental Stress Scale [84] was implemented for (1) the time with the subjectively highest burden (total sample [convenience and specific representative sample combined]: Cronbach α=0.88) and (2) before the COVID-19 pandemic, that is, January 2020 in retrospect (total sample: Cronbach α=0.86). Parents rated their perception on the 18 items on a 5-point frequency scale. Higher scores expressed higher parental stress.

Subjective Health

To measure parents' perception of their own health (1) at the time of the highest burden and (2) retrospectively in January 2020, a well-established single-item measure [85] with a 10-point scale was implemented. Higher scores indicated better self-rated health.

Parent Mental Health

To assess depression and anxiety symptoms, the Patient Health Questionnaire 4 [86] was applied (total sample: generalized anxiety, Cronbach α=0.70; depression, Cronbach α=0.68; and total score, Cronbach α=0.78). Higher scores on the 4-point scale indicated poorer mental health.

Pandemic-Related Stress

The Pandemic Stress Scale (Winter, S, Corona Belastungsskala. Charité - Universitätsklinikum Berlin, Klinik für Psychiatrie, Psychosomatik und Psychotherapie des Kindes- und Jugendalter, Sektion Traumafolgen und Kinderschutz, unpublished, January 2020) consists of 14 items about specific restrictions (eg, daycare closings and social distancing), which parents rated regarding their subjective burden on a 5-point scale (ranging from not at all burdening to very burdening). The answering format also included a "not applicable" option. The Pandemic Stress Scale refers to the time point with the subjectively highest burden during the COVID-19 pandemic so far, from the beginning to August 2020. The scale had good internal consistency (total sample: Cronbach α=0.85). Higher scores expressed a higher subjective burden.

General Stress

To measure general parental stress at the time of the subjectively highest burden, we implemented the stress module of the Patient Health Questionnaire, German version [83] (total sample: Cronbach α=0.71). It consists of 10 items with several psychosocial stressors on a 3-point scale, and higher scores indicated higher general stress.

Child Maltreatment

Parents provided information about child maltreatment regarding the children in their household. The Pediatric Maltreatment and Abuse Chronology of Exposure interview [87-89] was adjusted to collect data on household dysfunction, child neglect, and abuse. First, parents were asked if the children ever faced severe stressful life experiences (eg, abuse, violence, and neglect). Afterward, 10 items on distinct subtypes of child maltreatment experiences were asked: 5 items on different types of child abuse (nonverbal emotional abuse [NEA], verbal emotional abuse [VEA], physical abuse, witnessing domestic violence [WDV], and sexual abuse), 3 items on different types of neglect (supervisory neglect, physical neglect, and emotional neglect), and 2 items on different types of household dysfunction (problems regarding mental illness or alcohol or substance use in the household). Only the first item explicitly referred to severe levels of maltreatment; the other items on subtypes mirrored comparatively lower severity levels in our surveys (according to the maltreatment classification system [90,91]). First, a dichotomous yes or no item was presented for each subtype asking parents if the children ever experienced a specific subtype of child maltreatment. If the answer was yes, a follow-up question was posed, asking about the change in frequency since the beginning of the COVID-19 pandemic, with response options on a 5-point scale ranging from "significantly more often" to "significantly less often." For more details about the measure, refer to the study by Calvano et al [2]. To simplify the presentation of the results, we dichotomized the responses on child maltreatment during the COVID-19 pandemic into increase (increase or significant increase) versus no increase (staying the same, decrease, or significant decrease). To provide meaningful results, we decided not to further compare subtypes with case numbers smaller <30.

Data Analysis

For investigating the research questions, we aimed to answer the following: To what extent do the 2 studies differ with respect to the parental outcomes and specific sample characteristics? How well can we predict sample membership by these sample characteristics? How well can we explain differences in parental outcomes between the 2 samples by sample characteristics?

Investigating Differences in Explaining Variables Between Samples

We calculated effect sizes describing the differences in explaining variables/covariates (sociodemographic data, parent-related risk factors, and COVID-19–related experiences) between the 2 studies. The significance of differences between the samples was investigated using 2-tailed *t* tests or Welch tests for interval-scaled variables (eg, age, rooms in the household, parental mental health, and parental stress) and

XSL•FO
RenderX

chi-square tests for nominal and ordinal variables (eg, sex, federal state, nationality, garden, belonging to a risk group for COVID-19, and school education). For metric variables, we report Cohen *d*, and for nominal and ordinal-scaled variables, we report the phi coefficient.

After examining differences between studies for each individual variable, the next step was to consider all covariates simultaneously. As such, we used logistic regression to predict sample membership (0=specific representative sample and 1=convenience sample) by the covariates, that is, sociodemographic data, parent-related risk factors, and COVID-19–related experience. Due to estimation requirements, we only reported on the prediction of study membership for categories of categorical outcomes with an absolute frequency >30.

Investigating Differences in Parental Outcomes Between Samples

We calculated effect sizes describing the differences in outcomes between the 2 studies, using ANOVA. We report partial η^2 for effect size. Chi-square tests were used for nominal and ordinal outcomes, with the phi coefficient reported for effect size.

Explaining Differences in Parental Outcomes Between Samples

We conducted analyses of covariance (ANCOVAs) using sample type and all covariates as predictors for the respective outcome variable. We then compared the adjusted effect estimates for sample type from the ANCOVA with the unadjusted effect estimates from an ANOVA that did not include any covariates. When in the ANCOVA the equality of error variances assumption was violated, we calculated parameter estimates with robust standard errors for the ANCOVAs. We could not find any considerable differences in the results, and therefore, we decided to present the results of the common and well-known standard methods. The size of the adjusted difference in outcomes between types of samples (adjusted effect estimate) indicates how much the covariates describe the difference in study results between the 2 samples. If effect estimates of the type of sample on the outcome variable decrease or even disappear after controlling for covariates, the considered covariates explain partly (in case of just decrease) or fully (in case of disappearance) the differences between samples for the respective outcome. Herein, we compared the effect sizes (η^2) of the sample indicator using ANOVA, with the covariate-adjusted effect sizes (η^2) of the sample indicator from the ANCOVA.

For an increase in child maltreatment (0=no increase and 1=increase), binary logistic regressions for predicting each subtype of child maltreatment from study type (and covariates) were used. Odds (exp(B)) of the type of sample adjusted for all covariates were compared to unadjusted odds (exp(B)) with study type being the only predictor. If the odds of sample type influencing the outcome variable decrease or approach 1 after controlling for covariates, it indicates that the covariates partially (if the odds decrease) or fully (if the odds approach 1) explain the differences between the samples for the respective outcome. Due to estimation requirements, we only reported on covariate-adjusted outcome differences between studies for categories of categorical outcomes with an absolute frequency >30. All analyses were performed using SPSS (version 29; IBM Corp).

Results

In the following, the results of the convenience sample are compared with the results of the specific representative sample. Note that results are hardly impacted by the weighting [2].

Investigating Differences in Sample Characteristics

We evaluated differences in sociodemographic data, parent-related risk factors, and COVID-19–related experiences.

Sociodemographic Data

Tables 1 and 2 depict the comparison of sociodemographic characteristics of the 2 samples (convenience vs specific representative). In the convenience sample, 4967 people, primarily women (n=4349, 87.56%), participated with a mean age of 39.11 (SD 6.25; range 20-70) years. The average number of children in the household was 1.82 (SD 0.78; range 1-11). These children were on average aged 6.46 (SD 4.25; range 0-17) years. In 42.5% (2111/4967) of the convenience sample, the families lived in Berlin. The distribution of the participants among the federal states and a comparison between the samples is shown in Table S1 in Multimedia Appendix 1. In most cases, participants worked either part time (2051/4967, 41.29%) or full time (1778/4967, 35.8%). Most participants were highly educated with a high school education (4305/4967, 86.67%) or a university degree (3390/4967, 68.25%), and they had a high socioeconomic status (3165/4967, 63.72%).

The specific representative sample comprised 1024 participants (n=534, 52.14% women) with a mean age of 40.89 (SD 8.17; range 18-73) years. On average, 1.69 (SD 0.77; range 1-6) children aged <18 years lived in the household. The mean age of the children was 8.92 (SD 4.92; range 0-17) years. In total, 4.3% (44/1024) of the participants lived in Berlin. In 55.66% (570/1024) of the cases, the parent worked full time, and in 27.64% (283/1024) of the cases, they worked part time. Most participants had a middle school education (480/1024, 46.88%), had completed an apprenticeship (586/1024, 57.23%), and had a middle socioeconomic status (585/1024, 57.13%).

Previous contact with social and family services	1197 (24.1)	249 (24.3)	χ^2_1=0.2	.88	ϕ=–.01

[a]Weighted data.

[b]Not applicable.

The 2 samples differed substantially in relevant characteristics. The convenience sample had a significantly higher number of women, the children were younger, participants were more frequently from a city-state (ie, Berlin), and had a higher school and professional education than the specific representative sample (all differences with medium effect sizes). Compared to the specific representative sample, in the convenience sample, we observed small differences in the following variables: participants were significantly younger, had more children aged <18 years in the household, had a higher socioeconomic status, were of another nationality than German, were more frequently biological parents and in a relationship, had fewer rooms in the household, and had less frequently a garden. Samples were comparable regarding being a single parent, child sex, current employment status, having a balcony, children living in 2 households (eg, in case of separated parents), and having others in the household or previous contact with social family services.

Parent-Related Risk Factors

Table 3 shows parent-related risk factors. Significantly fewer parents from the convenience sample reported belonging to the risk group for severe COVID-19. A significantly higher share of parents from the convenience sample reported a current or previous mental disorder and a history of own child abuse or neglect. Furthermore, a significantly higher share of parents from the convenience sample reported March and April 2020 as the most stressful months. In contrast, a significantly higher share of parents from the specific representative sample reported that "all months were equally stressful" and "no month was especially stressful." The effect-sizes were small.

Table 3. Parent-related risk factors: descriptive data and comparison between the samples.

	Convenience sample 2020 (N=4967), n (%)	Specific representative sample 2020[a] (N=1024), n (%)	Comparison		
			χ^2 (*df*)	*P* value	ϕ
Parental risk of alcohol abuse[b]	317 (6.38)	56 (5.47)	1.2 (1)	.27	0.01
Parental mental disorder	864 (17.39)	107 (10.45)	30.2 (1)	<.001	0.07
Chronic severe health condition	604 (12.16)	146 (14.26)	3.4 (1)	.07	–.02
Parental history of child abuse or neglect	1562 (31.45)	238 (23.24)	27.0 (1)	<.001	0.07

COVID-19–Related Experiences

Table 4 shows the COVID-19–related experiences. In both samples, nearly a quarter of the participants reported reduced working hours (convenience sample: 1197/4967, 24.1% and specific representative sample: 277/1024, 27.05%), and one-fifth of the participants reported a significant financial loss due to COVID-19 (convenience sample: 1111/4967, 22.37% and specific representative sample: 221/1024, 21.58%). In addition, April 2020 (convenience sample: 3508/4967, 70.62% and specific representative sample: 487/1024, 47.56%) and May 2020 (convenience sample: 2975/4967, 59.89% and specific representative sample:430/1024, 42%) were the most stressful months until August 2020 in both samples.

Table 4. COVID-19–related experiences: descriptive data and comparison.

No month was especially stressful	381 (7.67)	186 (18.16)	109.1 (1)	<.001	–0.14

[a]Weighted data.

All 34 covariates were simultaneously considered in a binomial logistic regression for the prediction of sample membership (0=specific representative sample and 1=convenience sample). Explained variance in outcomes by the predictors was large (Nagelkerke R^2=0.56) and statistically significant from 0 (χ^2_{36}=2411.4; *P*<.001). The overall accuracy percentage in classification was 89.6%, with a sensitivity of 96.3% and a specificity of 57.2%. The 5 most important predictors for convenience sample membership were as follows: living in a federal state in Germany (Berlin, Bremen, or Hamburg; odds ratio [OR] 14.75, 95% CI 10.93-19.91), parental sex female (OR 11.13, 95% CI 8.89-13.94), parental mental disorder (OR 2.18, 95% CI 1.63-2.92), being a biological parent (OR 2.05, 95% CI 1.11-3.79), and higher education (professional education [university]: OR 2.02, 95% CI 1.33-3.08 and school education [high school]: OR 2.01, 95% CI 0.77-5.23). All model coefficients and odds ratios can be found in Table S2 in Multimedia Appendix 1.

Investigating Differences in Parental Outcomes Between Samples

Differences in parental outcomes between the convenience sample and the specific representative sample are displayed in Table 5 for parental outcomes and Tables 6 and 7 for child maltreatment outcomes.

[m]Covariates with a significant partial regression coefficient: Previous contact with social and family services, significant financial loss, and parental mental disorder.

Parental Stress

In January 2020, parents from the convenience sample reported significant but negligibly more parental stress (η^2=0.003). However, at the time of the highest burden, parents from the convenience sample reported significantly higher parental stress than parents from the specific representative sample, with a small effect (η^2=0.024).

Subjective Health

In January 2020, there was no significant difference (η^2<0.001) between parents of the 2 samples regarding subjective health (η^2<0.001). Again, at the time of the highest burden, parents from the convenience sample reported significantly poorer subjective health, with a small effect (η^2=0.016).

Mental Health and General Stress

Parents in the convenience sample reported higher overall anxiety and depression symptoms (Patient Health Questionnaire-4) than parents in the specific representative sample at times of the highest burden, with a medium effect size (η^2=0.055). The same pattern applied to general stress, with a medium effect (η^2=0.044).

Pandemic-Related Stress

Samples did not differ in their overall pandemic-related stress (η^2<0.001).

Child Maltreatment

In both samples, the lifetime occurrence of WDV (convenience sample: 2488/4966, 50.2% and specific representative sample: 332/1024, 32.42%) and VEA (convenience sample: 2423 4965, 48.82% and specific representative sample: 3321023, 32.4%) were the most frequent subtypes (Table 6). In the convenience sample, a higher share of parents reported the lifetime occurrence of VEA (ϕ=0.12), WDV (ϕ=0.13), NEA (ϕ=0.03), physical abuse (ϕ=0.10), and emotional neglect (ϕ=0.06). No differences were found for severe stressful living conditions, NEA, or supervisory neglect. The odds of a child experiencing an increase in one of the following subtypes of child maltreatment were higher in the convenience sample: for VEA (convenience sample: 1585/4966, 31.91% and specific representative sample: 140/1024, 13.7%), it was 2.95 times higher; for WDV (convenience sample: 1236/4961, 24.91% and specific representative sample: 97/1024, 9.47%), it was 3.19 times higher; and for NEA (convenience sample: 356/4966, 7.17% and specific representative sample: 45/1024, 4.39%), it was 1.65 times higher during the COVID-19 pandemic (Table 7). The odds (0.87) of an increase in the frequency of emotional

XSL•FO
RenderX

neglect were not significantly different between the samples (convenience sample: 284/4967, 5.72% and specific representative sample: 66/1024, 6.45%).

Explaining Differences in Parental Outcomes Between the 2 Samples

To explain differences in parental outcomes, we calculated ANCOVAs with sociodemographic data, parent-related risk factors, and COVID-19–related experiences as covariates. Only significant covariates are listed in Tables 5 and 7.

Parental Stress

At the time of the highest burden, the difference in parental stress between the samples remained significant but was negligible in size (η^2=0.002) after controlling for sociodemographic data, parent-related risk factors, and COVID-19–related experiences. The covariates explained 92% of the difference in the outcome between the studies. The difference in parental stress between the samples in January was still not significant, and the effect size was negligible (η^2<0.001). As there were no differences between samples, the covariates cannot explain any of them. It must be noted that the covariates also do not induce any relevant differences.

Subjective Health

The difference between the samples at the time of the highest burden was significant but negligible in size (η^2=0.004) after controlling for sociodemographic data, parent-related risk factors, and COVID-19–related experiences. The covariates explained 75% (at the time of the highest burden) of the difference in outcome between the samples. The difference between the samples in January regarding subjective health was still not significant, and the effect size was negligible (η^2<0.001). As there were no differences between samples, the covariates cannot explain any of them. It must be noted that the covariates also do not induce any relevant differences.

Mental Health and General Stress

The difference between the samples regarding mental health was small (η^2=0.016) but significant after controlling for sociodemographic data, parent-related risk factors, and COVID-19–related experiences. The covariates explained 71% of the difference in the outcome between the samples. The same pattern applied to general stress (η^2=0.014). In total, 68% of the difference in the outcome between the samples was explained by the covariates.

Pandemic-Related Stress

The difference between the samples regarding pandemic-related stress was significant, and the effect size slightly grew but was still negligible (η^2=0.001) after controlling for sociodemographic data, parent-related risk factors, and COVID-19–related experiences. As there are no differences between studies, the covariates cannot explain any of them.

Child Maltreatment

There are large and significant differences in child maltreatment between the 2 samples in all subcategories except emotional neglect. The odds of experiencing VEA, WDV, and NEA were between 1.65 and 3.19 times higher in the convenience sample as compared to the specific representative sample. The difference in VEA and WDV between the samples could partly be explained by the covariates. After controlling for sociodemographic data, parent-related risk factors, and COVID-19–related experiences, the odds ratio of a child experiencing an increase in VEA and WDV in the convenience sample compared to the specific representative sample were 2.05 (as compared to 2.95 before adjustment) and 2.02 (as compared to 3.19 before adjustment), respectively. The differences in NEA between the samples could not be explained by the covariates. As there were no differences in emotional neglect between samples, there were no effect differences to be explained by the covariates. It must be noted that the covariates also do not induce any relevant differences.

Discussion

Principal Findings

So far, research has paid little attention to the representativeness of samples. However, this is crucial for drawing valid inferences on the population of interest. This is especially important in areas in which far-reaching decisions are made based on results of a study. This is specifically prevalent in studies on psychological consequences of the COVID-19 pandemic, which made immediate decisions necessary. In this paper, we showed that sampling strategy can have a great impact on the results of a study. We relied on data investigating parental outcomes in the COVID-19 pandemic of 2 web-based studies that differ in their sampling scheme, one being a typical convenience sample (N=4967) and the other a typical specific representative sample drawn by a survey institute (N=1024).

Our first aim was to investigate the impact of sampling strategy on the results. For this, we examined differences in results between the 2 samples. Our second aim was to investigate reasons for these differences. For this, we assessed (1) to what extent the studies differ in sample characteristics and to what extent the sample characteristics may explain group membership and (2) to what extent differences in parental outcomes between the 2 samples can be explained by sample characteristics (sociodemographic data, parent-related risk factors, and COVID-19–related experiences).

Discussion of Results

Differences in Sample Characteristics

We found that the convenience sample differed from the specific representative sample in sociodemographic composition, parent-related risk factors, and COVID-19–related experiences. Sociodemographic data, parent-related risk factors, and COVID-19–related experiences predicted sample membership well. Thus, this study identified a set of variables that partly explain differences in study results and explain differences in the sample selection.

As expected, the sociodemographic composition of the 2 study samples (convenience and specific representative sample) differed in several ways (eg, overrepresentation of the female

XSL•FO
RenderX

sex, younger parental and child age, a higher number of children, higher socioeconomic status, and higher education level in the convenience sample). The differences in the sociodemographic composition of the convenience sample were in line with previous findings [29-32,34-39]. Whitaker et al [33] also reported an overrepresentation of White, female individuals, and younger individuals with higher income and educational status compared to the general population in some studies in their literature review on Facebook recruitment. The overrepresentation of women in convenience samples is likely to be especially pronounced in studies related to mental and physical health [33,69] as well as parenting and family [35,38,80,92-94]. In various convenience samples evaluating parenthood during the COVID-19 pandemic, mothers constituted the majority [4,9,14-17,19,22,27,40-42,44,45]. However, the effects of this overrepresentation have not yet been empirically examined. Furthermore, in many of these convenience samples, most participants reported higher education [4,14,16,17,27,41,42,45-47]. One reason could be that women [95,96], younger people with younger children, and people with higher educational qualifications may more readily participate in web-based research and are thus more likely to be reached for study purposes [80,95,97]. Individuals with high educational attainment may be more familiar and more interested in research. In addition, the use of personal emails and invitations for recruitment may have resulted in a participant pool primarily from academic circles. The overrepresentation of women, along with younger parents and those with more children, could also be attributed to thematic self-selection. This group of parents, who were particularly stressed during the pandemic [4,14,59], may have been more motivated to share their experiences of hardship [30]. In summary, the sample composition of our convenience sample is comparable to many other samples recruited during the COVID-19 pandemic.

Differences in Parental Outcomes

Results on parental outcomes during the COVID-19 pandemic differed notably between the 2 samples. Overall, parents from the convenience sample were more burdened during the COVID-19 pandemic than parents from the specific representative sample. Compared with parents from the specific representative sample, parents from the convenience sample reported significantly more parental stress at the time of the highest burden, less subjective health, more anxiety and depression symptoms overall (Patient Health Questionnaire-4), more general stress, more often the occurrence of child maltreatment (VEA, WDV, physical abuse, NEA, and emotional neglect), and an increase of child maltreatment during the COVID-19 pandemic (VEA, WDV, and NEA). These results corroborate the claim that sampling has considerable impact on the results [31].

Our results are in line with findings from previous studies. Studies show that people with higher burdens are more likely to participate in web-based surveys than those with lower burdens [25,39,77,78]. The reasons may be a higher motivation to share one's burden and a thematic awareness of the topic due to one's own burden [30]. A higher amount of mental health burden in web-based studies with convenience sampling compared to representative sampling has also been observed in other studies with samples of parents [39,80] before the COVID-19 pandemic. Lawson et al [98] showed that the recruitment of web-based convenience samples influenced the prevalence of child abuse. Joyal-Desmarais et al [79] also found differences between samples in >70% of their variables when comparing their web-recruited convenience samples with representative surveys regarding preventive behaviors.

Explaining Differences in Parental Outcomes Between Studies

Differences in parental outcomes between the 2 samples could (partially) be explained by differences in sociodemographic data, parent-related risk factors, and COVID-19–related experiences between the samples. Consequently, at least for this study, we seem to have identified relevant confounders for the difference in effects between the 2 samples.

On the basis of our results, it is initially not possible to say which covariates are explicitly responsible for the differences. However, we can identify covariates that differed between the 2 samples: parental sex and age, children's age, federal state (ie, city-state), school and professional education, number of children in the household, socioeconomic status, nationality, relationship status, biological parents, rooms and garden in the household, risk group of severe COVID-19, current or previous mental disorder, and history of own child abuse or neglect. Other studies identified sociodemographic variables as correlates for poorer mental health outcome (eg, female sex, younger parental and children age, parental psychological or physical health conditions before the COVID-19 pandemic, and lower financial background and income or financial stress) [8,11,16,40-42,48-60]. Furthermore, sociodemographic variables were also related to higher parental stress (eg, more children in the household, younger age of the children, and being a single parent) [4,14,17,20,41,46,59], and the occurrence of child maltreatment and parent-child conflicts (eg, younger parental and children age, job and financial loss, living in an urban area, and having low income or financial concerns) [1,2,43,46,47,59,98-100] for parents during the COVID-19 pandemic. Our convenience sample showed a higher presence of individuals with sociodemographic risks (such as more female individuals, younger age, and more and younger children), potentially contributing to greater disparities in parental outcomes due to an overrepresentation of these identified risk factors. Thus, these sociodemographic risk factors may explain differences in parental outcomes.

Strengths

Investigation of the Impact of Sampling

So far, research has largely overlooked the impact of sampling on the informativeness of the results. With this paper, we present one of the few studies that highlight and evaluate the impact of sampling on the results of studies in clinical psychology.

Availability of 2 Studies With the Same Measurements

We were able to use 2 samples in which not only the same outcome measures but also the same explaining variables were measured in exactly the same way. This is a rather rare case, but it was essential for answering the research question. This

XSL•FO
RenderX

also allowed us to identify variables explaining these differences. These factors could be assessed in future research on parental outcomes during pandemics to (1) understand which population groups a study provides information for and (2) for understanding differences in study results. Note that while we compared 2 typical sampling approaches—a convenience sample and a specific representative sample, as commonly used by survey institutes—this comparison provided insights into how these approaches lead to different results. However, this type of design and analysis is not limited to these specific sampling methods. The results of any sampling approaches, including 2 different convenience samples, can be compared in this way. The key is that the same variables are assessed in both studies.

Explaining Differences in Results

We not only investigated the differences in results between studies due to different sampling approaches but also aimed to understand why studies yield different results. The collection of a comprehensive set of explaining variables in both studies allowed us to explain most of the differences in study results. This is remarkable, as usually this is often not the case (eg, [31]). In many studies, only a few sociodemographic variables are available that are similarly assessed in the different studies. These usually cannot explain differences in results very well [101]. With sociodemographic data, parent-related risk factors, and COVID-19–related experiences, we had powerful explanatory variables for the differences in study results. If, as in many other studies, we had only limited sociodemographic data, we likely would have explained much less of the differences in the results.

Strategy for Investigating Differences in Results Across Studies

Our paper also presents a strategy for investigating reasons for differences in results across different studies. This strategy can also be applied to compare different sampling strategies in other fields. Thus, researchers may at the same time conduct studies with different types of sampling strategies. This may also be 2 different convenience samples. Relevant explaining variables need to be collected in the same way in both studies to analyze to what extent these can explain differences in outcomes between the 2 studies.

Limitations and Outlook

Limitations of the Comparison of the Studies

Our aim was to investigate the impact of the sampling strategy on the study results on parental outcomes. While we could make use of the rare case of having 2 studies with different sampling strategy that were almost identical in their design and setup, not all design aspects were identical. First, while participants in the convenience sample were interviewed via web surveys (CAWI), parents in the specific representative sample were interviewed either via CAWI or CATIs. This could have led to differences in response behavior, especially with regard to sensitive topics (eg, adverse childhood experiences and parental mental disorder) due to social desirability. Second, the 2 studies partly differed with respect to the incentives they received. Parents in the convenience sample and parents in the specific representative study that were interviewed via CAWI may have been particularly motivated by the prospect of incentives (money, vouchers, and Ipad). In contrast, parents in the specific representative study that were interviewed via telephone did not receive any incentives. This could have also influenced response behavior, leading to differences in study results. In summary, in addition to differences in the sample composition, there are further explanations for differences in the results between the samples, such as different modes of data collection in the representative sample (CATI and CAWI) versus the convenience sample (only CAWI) and different motivations of participants (no incentives for participants in CATI in the quota sample vs incentives for participants in CAWI and the convenience sample). These were not controlled for and must be considered in the final evaluation of the study results. While we could explain a large part of the differences in results between the 2 studies, some unexplained differences remained. These may be due to unobserved explanatory variables, other factors that could account for both sample differences and variations in parental outcomes, or differences in the study designs.

From our study, we cannot necessarily conclude that the specific representative sample results in more valid conclusions on the underlying population than the convenience sample. If selection bias is stronger on relevant variables not controlled for in the specific representative sample as compared to the convenience sample, bias could even be larger in the specific representative study. What we surely can conclude is that the sampling strategy does have a large impact on the study results. For the specific representative study, we can rule out that sample selection due to strata variables biases the results in this study.

Limitations of Single Studies

While both studies were conducted rigorously with the aim of accurately inferring parental outcomes in the population, each study has its own limitations. First, while the 2 studies aimed at drawing inferences on parents with underaged children in Germany, due to practical reasons, they had to restrict the sample to German-speaking parents, which excludes a part of the population [102]. Second, although anonymity was assured by different measures, we cannot rule out that participants answered in a socially desirable way, refraining from reporting, for example, child maltreatment. Though we tried to reduce this, it needs to be kept in mind when interpreting the results. All data were collected and evaluated anonymously. The researchers did not have the contact details of the participants available at any time. This was also explained to the participants in the informed consent form. Overall, our lifetime prevalence rates of child maltreatment are in line with the prevalence rates found in the literature [103]. Third, neither of the 2 samples is globally representative of the general population and is, thus, limited in generalizing to the overall population. While specific representativeness for some variables can be assured for the specific representative study, selection bias may still exist for all other variables. Note that in this specific setting, it would have been possible to weight the convenience sample using census data, thereby achieving representativeness for this sample as well. As compared to the quota sample, specific representativity in the convenience sample would be solely achieved by poststratification. As our aim was to investigate

XSL•FO
RenderX

the impact of sampling on study results, we did not consider this here.

Even if their results cannot necessarily be generalized to the underlying population, both the specific representative as well as the convenience samples may provide valuable insights if the sample is well described with respect to variables relevant to the construct under investigation. Adding up information from many studies (that may all be convenience samples) does help to build theory and to describe for which type of persons the theory has been tested for. For this, it is important that relevant person characteristics of the sample are comprehensively described. These should go beyond just some demographic variables and should consider the variables that are relevant to the phenomena of interest. Further, if we know the distribution of these variables in the population, we can infer population-level results from a convenience sample (eg, by weighting the observations in the convenience sample). This approach is similar to how election results are predicted [104].

Generalizability of Our Results

As with any research study, it is not possible to generalize findings from a single investigation to all other studies. Therefore, the results presented in this paper may not necessarily apply to other studies in clinical psychology or those focused on parental outcomes. As in other research, our study provides another piece on the topic that together with other studies adds up to a broader picture. We presume that the results of our study also hold for studies that use similar outcomes to those of our study and recruitment or sampling strategies that do not differ massively from ours. The results of this study may not necessarily be the same for other research topics (specifically other outcomes) and other sample selection mechanisms. In a different study, the selection mechanism of participants in the sample may be different, which leads to different results and possibly also different explaining variables that explain the differences. Different research questions within a study lead to different outcome measures. These are most likely impacted by different explaining variables (covariates). While it is not possible to generalize the findings of this study to other studies, this study shows (1) that sampling strategy can have a large impact on the results and (2) how one can investigate reasons for differences in the results. Relevant covariates that explain differences in study results will most probably be those that are strongly related to the outcomes (researchers usually have a good theory about that from the literature in their field) as well as are relevant for participating in a study (research on this is usually a bit scarce, but pilot studies may help). Assessing these variables as covariates is a promising strategy as it leaves less room for unexplained variation in the outcome [101]. Note that this is not tied to having a quota (ie, a specific representative) sample; it can be done with any 2 studies. The requirement is that the same covariates are assessed in both studies. Future studies may want to incorporate this into their study planning.

Conclusions

To allow readers to judge the representativity of a study, detailed information on sampling and recruitment as well as on generalizability should be provided (eg, constraints on generality [105]).

Our results show that the results of studies differ depending on the sampling strategy. We were able to investigate this. Scientists need to be aware of the fact that from a single study, one cannot directly generalize to the population of interest. Full (global) representative studies are the gold standard in research. However, these are often not feasible for various reasons. Therefore, scientists should collect as many relevant explaining variables (covariates) as possible to describe the sample selection. Such variables are usually those that may have an impact on the results. Collecting these variables makes it possible to understand for which subgroups in the population conclusions can be drawn. As our study shows, if the same explaining variables are assessed in different studies, it is also possible to explain differences in the study results by differences in the group characteristics.

Even if researchers just perform a single study with a specific sampling strategy, we recommend collecting data on potentially explaining variables. This (1) allows to judge for which part of the population the results hold and (2) may allow future studies that assess the same explaining variables to explain differences in their results. If researchers even have information on the distribution of these variables in the general population, they may adjust for sampling bias using sampling weights [31] (eg, [12,13,106]). The choice of explanatory variables is crucial for this.

If possible, scientists may want to consider assessing explaining variables and covariates that are (1) relevant to the outcome under consideration and (2) possibly related to the selection into the study. These will help to identify which piece of the puzzle is actually added to the overall theory by this study. It also helps to integrate results over multiple studies in the future. If they have information on the distribution of these variables in the target population, they may even draw a quota sample or weight their convenience sample to assure specific representativeness. In most cases, it will not be possible to assess all relevant explaining variables. However, considering some relevant explanatory variables can already enhance the robustness of the results.

Acknowledgments

This study was funded by a grant by the Berlin University Alliance to SMW and BR. The funding source Berlin University Alliance had no role in the study design, data collection, analysis, or interpretation of data; the writing of the article; or decision to submit the article for publication.

Data Availability

The datasets generated and analyzed during this study are available from the corresponding author upon reasonable request.

Authors' Contributions

BR and SMW conceived and designed the study. CC, SMW, BR, and LE contributed to the compilation of measures. LE and CC compiled the literature review. LE and SP analyzed the data. LE wrote the first draft of the paper. All authors critically reviewed the manuscript and contributed to data interpretation and discussion. All authors approved the final manuscript for submission.

Conflicts of Interest

BR and SMW have received funding from the Berlin University Alliance for the study. All other authors declare no other conflicts of interest.

Multimedia Appendix 1

The flyer on the recruitment of the convenience sample, a table about the sample composition regarding the Federal State of Germany of the web-based convenience sample and the representative sample, and a detailed table about the logistic regression analysis to predict sample membership through our sociodemographic data, parent-related risk factors, and COVID-19–related experiences.

Abstract

Background: Social behavioral research studies have increasingly shifted to remote recruitment and enrollment procedures. This shifting landscape necessitates evolving best practices to help mitigate the negative impacts of deceptive attempts (eg, fake profiles and bots) at enrolling in behavioral research.

Objective: This study aimed to develop and implement robust deception detection procedures during the enrollment period of a remotely conducted randomized controlled trial.

Methods: A 32-group (2×2×2×2×2) factorial design study was conducted from November 2021 to September 2022 to identify mobile health (mHealth) survey design features associated with the highest completion rates of smartphone-based ecological momentary assessments (n=485). Participants were required to be at least 18 years old, live in the United States, and own an Android smartphone that was compatible with the Insight app that was used in the study. Recruitment was conducted remotely through Facebook advertisements, a 5-minute REDCap (Research Electronic Data Capture) prescreener, and a screening and enrollment phone call. The research team created and implemented a 12-step checklist (eg, address verification and texting a copy of picture identification) to identify and prevent potentially deceptive attempts to enroll in the study. Descriptive statistics were calculated to understand the prevalence of various types of deceptive attempts at study enrollment.

Results: Facebook advertisements resulted in 5236 initiations of the REDCap prescreener. A digital deception detection procedure was implemented for those who were deemed pre-eligible (n=1928). This procedure resulted in 26% (501/1928) of prescreeners being flagged as potentially deceptive. Completing multiple prescreeners (301/501, 60.1%) and providing invalid addresses (156/501, 31.1%) were the most common reasons prescreeners were flagged. An additional 1% (18/1928) of prescreeners were flagged as potentially deceptive during the subsequent study screening and enrollment phone call. Reasons for exclusion at the screening and enrollment phone call level included having an invalid phone type (6/18, 33.3%), completing multiple prescreeners (6/18, 33.3%), and providing an invalid address (5/18, 27.7%). This resulted in 1409 individuals being eligible after all deception checks were completed. Postenrollment social security number checks revealed that 3 (0.6%) fully enrolled participants out of 485 provided erroneous social security numbers during the screening process.

Conclusions: Implementation of a deception detection procedure in a remotely conducted randomized controlled trial resulted in a substantial proportion of cases being flagged as potentially engaging in deceptive attempts at study enrollment. The results of the deception detection procedures in this study confirmed the need for vigilance in conducting remote behavioral research in

XSL•FO
RenderX

order to maintain data integrity. Implementing systematic deception detection procedures may support study administration, data quality, and participant safety in remotely conducted behavioral research.

Trial Registration: ClinicalTrials.gov NCT05194228; https://clinicaltrials.gov/study/NCT05194228

Introduction

A paradigm shift in methodologies used to conduct randomized controlled trials (RCT) focused on human behavior and behavior change is underway [1]. Specifically, remotely conducted behavioral trials, trials that do not require in-person visits, are increasingly commonplace. This was true before the onset of the COVID-19 pandemic, and this trend has accelerated in recent years due to technological advancements and shifting social norms [2].

By reducing barriers to participation in RCTs (eg, transportation limitations and inability to take off work), remotely conducted trials may have greater generalizability than traditional in-person RCTs and may extend health promotion programs to those who might otherwise lack access to them. Furthermore, the widespread use of smartphones, now owned by 90% of adults in the United States, presents an unprecedented opportunity to provide personally tailored health-promoting content to vast numbers of people [1,3].

There are potential disadvantages to conducting behavioral trials remotely via smartphones. First, obtaining appropriately representative samples to study digitally mediated behavior interventions can be challenging [4,5]. While this issue is not unique to remotely delivered interventions, participation requires a willingness and ability to operate various technologies that may systematically affect inclusion, potentially leaving remotely conducted research prone to limitations imposed by the "digital divide" [6]. For example, lower ownership of smartphones among older adults, Americans with lower incomes, and people who reside in rural environments can limit equitable inclusion of these groups if these realities are not carefully addressed [7].

Second, remotely conducted behavioral trials may be prone to participant deception [8]. Several types of deception among research participants in clinical trials have been identified [8]. Concealment has been defined as the act of failing to disclose relevant information to facilitate study admittance (eg, a potential participant not sharing that they have an exclusionary comorbidity) [8]. *Fabrication* refers to the duplicitous invention on the part of a potential participant to support their inclusion in a research trial (eg, erroneously claiming to be diagnosed with a health-related condition) [8]. *Collusion* is a coordinated sharing of information among potential research participants to gain study admittance [8]. Deception on the part of research participants can lead to considerable waste of study resources, compromised integrity of data resulting from a study, and threats to participant safety [8]. Indeed, severe symptoms and death have been attributed, in part, to deception on the part of research participants [9,10].

Financial gain appears to be a primary reason people engage in deceptive practices to enroll in research studies [11,12]. Participants are commonly paid to participate in research studies to reimburse for out-of-pocket expenses associated with study participation (eg, smartphone data usage), to compensate for time and effort associated with study participation, and to incentivize participation [13]. The prevailing consensus is that paying individuals to participate in research is ethical if it does not undermine informed consent [13]. Qualitative research studies have highlighted the critical role that monetary payment plays in increasing willingness to participate in RCTs [14,15]. However, higher levels of compensation can increase the likelihood of deceptive practices to gain admittance into research studies [15].

Financial incentives may motivate people to serially engage in clinical trials. Devine et al [11] recruited "experienced research participants" (ie, individuals who had participated in more than one study in the past year). Research participants (N=100) reported participating in an average of 12 studies within the previous year (range 2-100 studies), with reported lifetime earnings from research participation to be US $9809 on average (range US $50-US $175,000). A total of 75% of participants in this study reported engaging in concealment to avoid study exclusion, and 25% reported engaging in fabrication to facilitate study inclusion. Qualitative data from this study also characterized instances of collusion, including a description of how "research kingpins" have been known to trade information with individuals to facilitate their admittance into research studies [11]. The researchers suggested that "professional subjects" may be substantially overrepresented in clinical research [11].

Technologies that can greatly extend the reach of remotely conducted behavioral research may leave this type of research especially prone to deception from research participants. The enhanced accessibility of digitally mediated behavioral interventions may disproportionately attract individuals who aim to "game the system" [7]. For example, digital screening processes may be exploited by individuals who repeatedly restart the screening process to change their information to satisfy eligibility requirements [7]. There are reports of individuals accessing ClinicalTrials.gov and other clinical trial repositories to identify study inclusion and exclusion criteria to support deceptive enrollment into RCTs [11]. Remotely conducted behavioral research trials may be especially attractive to experienced study participants (1) because they are often low

XSL•FO
RenderX

risk—this appears to be an especially salient consideration among people who participate in many research studies annually [11], and (2) because considerable remuneration is often used as a strategy to reduce the high rates of attrition that can afflict digitally mediated studies [16].

Although it may be impossible to entirely eliminate this threat, there is a growing catalog of techniques for preventing and minimizing the ill effects of deception from research participants in digitally mediated behavioral interventions. Devine et al [11] suggested that limiting the face validity of items used to screen out participants and concealing specific reasons for nonadmittance may reduce deception. Dahne et al [7] created a visual database to aid members of their research team in the identification of potential participants who may have entered numerous screening records. Abroms et al [17] and Bricker et al [18] used techniques such as a CAPTCHA (Completely Automated Public Turing test to tell Computers and Humans Apart) to validate potential participants as human (ie, not automated programs [bots]), to evaluate screening IP addresses (eg, removing all duplicated IP addresses or those not of US origin), and to review system usage data (ie, taking less than 90 seconds to complete a screening survey or taking less 10 minutes to complete the baseline survey). For flagged cases, members of these research teams contacted individuals to further evaluate the authenticity of attempts at study enrollment. Resnik and McCann [19] have recommended that any evidence of potentially deceptive activity should result in the exclusion of the prospective participant from the study enrollment.

Verifying information provided by participants via photo identification, objective measures, and social security numbers (SSNs) may reduce deceptive attempts at study enrollment [8,11,19]. Smartphone-mediated screening processes may facilitate submitting photographs of identification cards. Smoking status can be tested biochemically using devices that can be remotely delivered [8,11,19]. Advising participants that their self-report responses will subsequently be verified may dissuade deception. Incentivizing the provision of accurate information may further support data integrity (eg, providing a "bonus" for providing information that is not discrepant with subsequent objective measures) [19].

This study details techniques that we implemented to minimize the effects of deception from individuals who attempted to enroll in the Exemplar study, a remotely delivered, nationwide RCT. We conclude by providing recommendations for future remotely conducted behavioral interventions.

Methods

Study Overview

The Exemplar study used a 2×2×2×2×2 factorial design to determine smartphone survey factors related to high daily survey completion rates. Eligible participants were randomly assigned and completed a baseline survey, 28 days of brief daily ecological momentary assessments (EMAs), and a final survey. The entire study was conducted remotely via REDCap (Research Electronic Data Capture; Vanderbilt University) and the Insight platform [20]. The Insight platform allows researchers to rapidly create, develop, and implement EMA studies [21]. This study was registered with ClinicalTrials.gov (NCT05194228). Details concerning the study design, participants, and outcomes are presented elsewhere [20].

Recruitment Strategy

The target population for this study was adults (ie, 18 years or older) living in the United States who had an active Android smartphone. Participants were recruited via Facebook advertisements from November 2021 to September 2022. The advertisements were targeted to individuals aged at least 18 years old who possessed an Android smartphone. Examples of Facebook advertisements included:

> *We're looking for Android users to complete brief daily surveys on their smartphones. Qualified participants will be compensated up to $152 over 4 weeks. NO in person visits required." and "Have an Android smartphone? See if you're eligible to participate in a 4-week research study. Qualified participants will be compensated up to $152 for their time. NO in person visits required.*

Clicking on a Facebook advertisement initiated an encrypted REDCap prescreener survey that was used to determine initial eligibility for the study. Individuals were not shown their eligibility results until after all prescreener items were complete. Ineligible individuals were informed that they were not eligible for the study, but the specific reason(s) were not provided. If a participant was potentially eligible based on the REDCap prescreener, they selected times for a screening and enrollment call. Study staff texted eligible participants, thanking them for completing the prescreener and confirming the date and time for their screening and enrollment call.

Enrollment and Participant Flow

During the screening and enrollment call, individuals were asked additional screening questions; verified that their smartphone was compatible with the Insight mobile health (mHealth) platform [21]; completed a reading comprehension test, Rapid Estimate of Adult Literacy in Medicine – Short Form [22]; and completed the informed consent process. Individuals were also required to text a picture of their photo ID with a US address. Once fully enrolled, participants downloaded the Insight smartphone app onto their personal Android smartphones. They received instructions on how to use the smartphone app to complete the baseline survey, daily EMAs for 28 days, and the final survey. After the baseline survey was completed, participants were mailed a reloadable Greenphire Mastercard. Baseline compensation (ie, US $10) was loaded onto the Greenphire card after the participant confirmed that they received the card by texting study staff the last 4 digits of their card. The rationale for requiring participants to text the last 4 digits of their card was to confirm when they received their card. Funds were loaded onto participant cards after they verified receipt of the card to ensure payment was received (eg, to overcome the possibility of cards being lost in the mail). Compensation for completing EMAs (ie, up to US $56 for those randomly assigned to complete two daily EMAs, up to US $112 for those randomly assigned to complete four daily EMAs) and

XSL•FO
RenderX

the final survey (US $30) was loaded onto the Greenphire card at the completion of the study.

Measures

REDCap Prescreener

All individuals who clicked a Facebook advertisement were taken to an encrypted REDCap screening survey hosted by the University of Oklahoma Health Sciences Center (OUHSC). Individuals completed demographic questions (eg, age, race, address, and phone number) and questions about their smartphones (eg, phone ownership and type of phone). Individuals who met the study inclusion criteria were asked to select a primary and secondary time for the screening and enrollment phone call. Deception detection steps, along with associated considerations and decisions, for the REDCap prescreener can be seen in Table 1. These steps address the deception detection review that occurs once an individual is determined to be eligible at the REDCap prescreener level. REDCap tracking allowed for easy reporting and periodic checks of the data to determine if there were any prescreener patterns that could indicate new types of attempts at deceptive enrollment. This was initially how it was determined to add reCAPTCHA and the identity statement (Table 1, step 6).

Table 1. Steps taken to detect potential deception in REDCap[a] prescreeners that were completed by individuals that viewed study advertisements.

Deception detection step for the REDCap prescreener	Considerations and decisions
1. Incomplete prescreeners	Incomplete prescreeners were not reviewed.
2. Duplicative prescreeners	Previous prescreeners with identical information, individuals currently or previously enrolled in the study, and previously ineligible individuals were not scheduled for a screening and enrollment call.
3. Home and mailing address	Validated by Google and Google Maps; invalid addresses and business addresses not linked to an individual's residence were not scheduled for a screening and enrollment call.
4. Phone number	Phone number provider search was conducted to determine use of bandwidth phones (ie, a phone not connected to a cellular provider); participants were scheduled for a screening and enrollment call but not excluded; this step was collected for future consideration of exclusion.
5. Email address	Verified by Google search as an exploratory approach to deception detection; participants were scheduled for a screening and enrollment call but not excluded.
6. reCAPTCHA[b] and identity statement	8.5 weeks into the study, reCAPTCHA was added to prevent bots from autofilling the prescreener; 9.5 weeks into the study, an identity statement was added, "Due to a large number of spam accounts, we will verify your identity prior to enrolling you in the study."
7. Periodic data checking	Data were periodically reviewed to determine potential patterns of deception. Cases that passed the deception deterrence checklist but were flagged as suspicious were scheduled for a screening and enrollment phone call.
8. Conservative decision-making	In cases where there was any doubt about whether a prescreener contained deceptive information, the screening and enrollment call was scheduled. This conservative approach allowed for the reduction in deceptive enrollments while ensuring that eligible individuals could participate in the study.

[a]REDCap: Research Electronic Data Capture.

[b]CAPTCHA: Completely Automated Public Turing test to tell Computers and Humans Apart.

Screening and Enrollment Phone Call

During this phone call, individuals reviewed and electronically signed the informed consent through the REDCap link, completed a reading comprehension test [22], provided their SSN, and uploaded a copy of their photo identification. All pictures of identification were deleted after identity verification to reduce potential breaches in confidentiality. Eligible individuals provided a minimum 14-hour window of waking hours for each day of the week (EMAs could only be prompted during waking hours). Table 2 shows the deception detection steps for the screening and enrollment phone call.

XSL•FO
RenderX

Table 2. Steps taken to detect potential deception during the study enrollment phone calls.

Deception detection step for the screening and enrollment phone call	Considerations and decisions
9. Informed consent	• If the signed name differed from the REDCap[a] prescreener, study staff asked the individual to confirm the name that was signed. If the name did not match, the screening and enrollment call was terminated, and the screener was marked as "deceptive." • Shortened names (eg, Chris instead of Christopher) were not considered to be deceptive. • Married versus maiden names were confirmed by uploading a picture of a piece of stamped mail with the correct name and matching mailing address. If a matching piece of stamped mail could not be provided, the screening and enrollment call was terminated, and the individual was not invited to enroll in the study.
10. Photo identification	• The name and address on the individual's photo identification had to match information provided during the REDCap prescreener. If the address did not match, individuals were required to send a picture of a piece of stamped mail that was sent to them at their address. If no other information could be provided to verify their address, the screening and enrollment call was ended, and the individual was not allowed to enroll in the study.
11. Social security number	• SSN[b] was required to pay research participants at our institution and was needed for tax reporting purposes. If an individual declined to provide their SSN, the screening and enrollment call was ended, and the individual was marked as "Opt to not participate" in REDCap
12. Greenphire Mastercards	• Physical Greenphire Mastercards, rather than virtual gift cards, were used to compensate participants for completing study surveys. Greenphire cards were only mailed to the verified mailing address for each participant after they completed the baseline survey in the Insight app.

[a]REDCap: Research Electronic Data Capture.

[b]SSN: social security number.

Baseline Survey, EMAs, and Final Survey

Participants used the Insight app to complete the baseline, daily EMAs (2-4 per day), and follow-up surveys. These surveys asked about affect, health, and health behaviors.

Compensation

Once a participant received their Greenphire card in the mail, they were instructed to contact study staff to confirm the card had been received. Study staff then sent the participant a link to sign that they had received their card. This was an additional step to ensure that participants lived at the address they provided in their prescreener and that they interacted with study staff for an additional time. Individuals who did not confirm their card did not receive any study payments.

Statistical Methods

Descriptive statistics were used to describe the sample and highlight deception detection outcomes. All analyses were conducted using SPSS (IBM Corp, version 29).

Ethical Considerations

The University of Oklahoma Health Sciences Institutional Review Board approved this study (IRB#13684). All participants in this study signed an informed consent via REDCap before engaging in any research study activities. The informed consent provided language that the study is optional and participants could withdraw at any time. All study datasets were deidentified before analyses were conducted. Participants could be compensated up to US $152 depending on the group they were randomized into for the study. Since this paper focused on the steps leading up to the start of the study, no further compensation details are provided, but they can be found in the primary outcomes paper [20].

Results

From November 29, 2021, to September 27, 2022, Facebook advertisements yielded 5236 clicks and openings of the REDCap screener. Of those screeners, 3308 were ineligible (eg, 1158 blank prescreeners), and 1928 REDCap prescreeners indicated initial eligibility for the study. Of the 1928 eligible screeners, 195 (15.3%) out of 1928 were duplicates of previously eligible individuals, and 206 (10.7%) out of 1928 were marked as potentially deceptive (Table 3). All screening outcomes are presented in Table 3. Ultimately, 1409 individuals remained eligible after deception detection steps 1-8 were implemented. The deception detection checklist required, on average, approximately 1-4 minutes to complete for each eligible REDCap prescreener.

On January 27, 2022, reCAPTCHA was added to prevent bots from autocompleting the REDCap prescreener in rapid succession. On February 2, 2022, an identity statement was added in the REDCap prescreener so individuals were aware their identity would be verified before enrollment. A total of 3 (1.5%) inaccurate SSNs were detected out of 202 participants who earned over US $100, the OUHSC minimum reporting requirement for participant compensation. The SSNs of the 283 participants who earned less than US $100 were not checked. During the screening and enrollment call, 65 (3.4%) out of 1928 pre-eligible individuals declined to provide their SSN and opted to not participate in the study.

XSL•FO
RenderX

A total of 1928 nonduplicate, complete REDCap screeners were examined using our deception detection and abatement procedure. The majority of deceptive attempts at enrolling into the study were detected at the REDCap screener level (501/1928, 26%) and a minority of deceptive attempts at study enrollment were detected during the screening and enrollment call (18/1928, 1%; see Table 3). Table 4 displays reported characteristics of deceptive attempts at enrollment at the REDCap screener level, screening and enrollment call level, and those that fully enrolled in the study. After all deception checks were complete, 1409 individuals remained eligible to enroll in the study. Ultimately, 924 individuals did not enroll due to various reasons (ie, unable to contact, canceled screening and enrollment call, or ineligible phone) and 485 individuals were randomly assigned into the study. Participants completed 83.8% (28,948/34,552) of all EMAs, and 96.6% (397/411) completed the follow-up assessment. Additional details are provided elsewhere [20].

Male	212 (42.3)	10 (55.6)	115 (23.7)

Discussion

Principal Findings

This study used a systematic deception detection procedure to attempt to preserve study resources, data integrity, and participant safety in a remotely delivered behavioral study. Given the relatively large scale of our digitally mediated recruitment methods, the low risk involved in study participation, considerable financial compensation, and robust practices for ultimately verifying participants' identity, this study provided unique insight into how deceptive practices may be occurring in large, remotely delivered behavioral studies, as well as how to mitigate their impact. The digitally mediated deception check implemented at the REDCap prescreener level (steps 1-8) resulted in 26% (501/1928) of the eligible sample being excluded. Only 1% (18/1928) of the eligible sample was excluded during the subsequent screening and enrollment call. The systematic deception detection steps detailed in this paper support data integrity and may minimize the risk of deceptive enrollments.

Within the digitally mediated REDCap prescreener steps, duplicate screeners and address checks provided the most benefit to the deception detection process in terms of the number of potentially deceptive instances identified. Study staff sorted and compared the data and metadata associated with various submissions. The practices employed at this step were similar to those that have been used elsewhere [7]. Some of the submissions removed during the REDCap prescreener level appeared to have been initiated by automated programs (ie, "bots"). This led to the decision to implement a reCAPTCHA checkpoint before allowing potentially eligible individuals to proceed with the prescreener survey. This practice has been successfully used in other remotely conducted research studies [17,18].

In contrast to other studies, we did not exclude individuals on the basis of their IP address. The university institutional review board did not allow us to save and track IP addresses. Further, while IP addresses can provide information useful for determining if an individual is submitting multiple prescreeners from the same device, location-based decision rules may limit enrollments unnecessarily. For example, many companies, academic institutions, and individuals use roaming IP addresses. This can entail a limited number of IP addresses being associated with one large organization or IP addresses that regularly change for a given user. The use of roaming IP addresses can increase security and preserve privacy. Thus, while IP address information may be an important part of identifying potentially deceptive practices, caution should be used to avoid unnecessarily prohibitive practices.

While individuals were not excluded from this study if they had a bandwidth or voice over internet provider (VoIP) phone number, we observed the limited abilities of such devices to interact with the study app. Bandwidth and VoIP phone numbers can be used to mask true phone numbers or to create an internet-based phone number without a physical phone. Bandwidth and VoIP phone numbers are generally not considered "smartphones" and are typically not able to download phone apps. In this study, people with bandwidth phone numbers were allowed to proceed to the enrollment phone call, but we have since decided to exclude them from our studies due to incompatibility. Researchers should carefully consider how they will handle problematic smartphone types and phone number-masking services in mHealth studies, as they are increasingly commonplace and have a bearing on app compatibility and how surveys and notifications are received.

Few attempts at deceptive enrollment were detected at the screening and enrollment call level. This may provide evidence in support of the steps we took to prevent deceptive enrollments

XSL•FO
RenderX

at the REDCap prescreener level. During the REDCap prescreener, individuals were informed that identification would be verified before enrollment; the mode of verification, however, was not disclosed. Requiring photo identification and ensuring addresses entered into the prescreener assessment matched the photo identification allowed for a relatively quick and easy way to verify an individual's identity. To remain compliant with institutional policy, individuals were also required to provide their SSN during the screening and enrollment call. While SSNs could not be checked in real time, we ultimately observed that of the 202 of participants who provided this information and had their SSNs checked, 98.5% (n=199) provided accurate information. Systematically checking SSNs before full study enrollment would likely reduce deceptive enrollments into research studies but would come with costs (eg, staff time and effort, some qualified individuals may refuse to share their SSN).

Some of the deception detection methods that were used in this study were previously employed in other studies [7]. However, some deception detection strategies were novel to this study (eg, requiring photo identification in a remotely conducted trial and conducting phone number checks). Study results demonstrated that using multiple deception abatement strategies can mitigate deceptive enrollments in remotely conducted clinical trials. Future studies should implement similar strategies and further innovate to reduce deceptive attempts at enrollment into clinical trials.

Limitations

The true sensitivity and specificity of our deception detection and abatement processes are unknown. It is possible that some individuals may have successfully used deception to enroll in the study, and it is possible that some individuals were unnecessarily excluded. In order to deceptively enroll in the study, individuals would have had to fake their identification, mailing address, phone number, and SSN. Following recommended practices to preserve data integrity [19], we conservatively disqualified individuals who had been flagged as potentially engaging in deceptive practices. It is possible, however, that some qualified individuals were excluded from participating in the study.

Future Directions

One of the goals of this work is to inform the development of more sophisticated, digital solutions to deception detection and abatement. Using automation rather than manual deception detection may increase accuracy and reduce staff burden. Further, sensors (eg, GPS) could be integrated into deception detection procedures to verify home addresses and participant locations. Future studies should calculate study costs and potential cost savings of implementing deception detection and abatement procedures.

Conclusions

We implemented a systematic deception detection procedure to reduce the likelihood of deceptive enrollments into a nationwide RCT. To maintain data integrity and participant safety, we recommend engaging in robust identification practices with study participants in a live enrollment call. Before this phase, personnel and financial resources can be preserved by implementing systematic, digitally mediated processes to flag cases of potential deception. Technologies and study operating procedures centered on analyzing incoming screening survey data and their associated metadata can help to efficiently screen out instances of likely deception. More research is needed to improve upon and automate these processes, and researchers must remain vigilant to the advent of new threats. While deception detection procedures are primarily aimed at reducing the likelihood of enrolling individuals who do not actually meet the study inclusion criteria, they can also positively impact staff time, motivation, job satisfaction, and the study budget.

Acknowledgments

Programming and technical support were provided through the mobile health shared resource of the Stephenson Cancer Center via an NCI Cancer Center Support Grant (P30CA225520). Data analysis and manuscript preparation were additionally supported through R00DA046564 and the Oklahoma Tobacco Settlement Endowment Trust grant R22-02.

Abstract

Background: Despite rapid technological advancement and a considerably aging US population, there remains a gap in the literature pertaining to online-based recruitment strategies for older adults.

Objective: This study aimed to describe the lessons learned from the authors' experience of recruiting a sample for PLAN (Preparing successful aging through dementia Literacy education And Navigation), an ongoing, community-based randomized controlled trial designed to promote the transition of community-dwelling Korean American older adults with probable dementia and their caregivers into the health care system. The authors also present online-based recruitment strategies focused on older adults reported in relevant published studies to compare with their experiences.

Methods: Data sources included PLAN recruitment tracking files, study team meeting minutes, and interviews with community consultants. We also conducted a scoping review of published studies, searching PubMed in July 2021, and updated our search in September 2023. Eligibility criteria included (1) focus on older adults aged more than 65 years, (2) sample recruited from a community setting, and (3) inclusion and description of online-based recruitment strategies. Exclusion criteria (1) did not focus on adults older than 65 years in a community setting, (2) did not include or describe online-based recruitment strategies, or (3) used online-based methods but not for the purpose of recruitment. The review followed the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews). Information was extracted using a data charting table and synthesized by conducting a thematic analysis.

Results: In total, 8 articles were included in the scoping review and primarily addressed health promotion and recruitment strategy evaluation. When compared with PLAN data sources, five key themes emerged as relevant to the online-based recruitment of community-dwelling older adults: (1) unfamiliarity with technology—limited digital literacy, (2) differences in internet access and use across older age groups, (3) providing technological support to promote recruitment, (4) successful and unsuccessful recruitment using social media, and (5) other diverse online-based methods of recruitment. In particular, direct quotes from multiple sources for the PLAN trial revealed technological challenges that were common among immigrant older adults as the study team used various online-based recruitment activities.

Conclusions: The literature was limited in the discussion of online-based recruitment among older participants. Data sources revealed the digital divide and limited digital literacy, particularly among non–English-speaking immigrant older adults and their caregivers. The usefulness of online-based recruitment of older adults is uncertain due, in large part, to limited sociodemographic diversity noted in the samples recruited in the included studies. Future research should explore the role of race and ethnicity and

XSL•FO
RenderX

other characteristics, such as socioeconomic status, sex, education, access to technology, and digital literacy, in relation to online-based recruitment for adequate representation of diverse older adults in research.

Trial Registration: ClinicalTrials.gov NCT03909347; https://clinicaltrials.gov/study/NCT03909347

KEYWORDS

older adults; online; online recruitment; community-dwelling; strategies; America; Americans; technology adoption; digital technologies; COVID-19; pandemic; digital health; dementia; caregivers; healthcare system; community health workers; consultants; mobile phone

Introduction

The US population is rapidly aging and expected to experience continued significant growth. According to the US Census Bureau, the population aged 65 years and more surged by 38% from 40.3 million in 2010 to 55.8 million in 2020, compared with a 7% increase in the total population [1]. More than 1 in 5 (22%) Americans will be aged 65 years and more by 2040, reaching 80.8 million in total [2]. The increasing proportion of older adults in the United States distinctly positions this group as a priority study population.

While American adults have seen overall gains in technology adoption and increased dependence on digital technologies, especially during the COVID-19 pandemic, the digital divide—the unequal access to digital technology and the internet—persists among older adults aged 65 years and older. For example, internet usage in 2021 was nearly ubiquitous among adults aged 18-64 years (18-29 years: 99%; 30-49 years: 98%; and 50-64 years: 96%) meanwhile internet usage trailed among older adults aged 65 years and older (75%) [3]. Nevertheless, the older adults' group has also reported a steady increase in internet use over time, up from 14% in 2001, to 46% in 2011, to 75% in 2021 [3].

The COVID-19 pandemic presented unprecedented challenges to study teams with respect to the recruitment of study participants in community-based clinical trials. Globally, COVID-19–related restrictions were implemented including nationwide lockdowns and social distancing, and study teams had to quickly adjust study protocols to operate in an online-based environment. Engaging online with potential participants for recruitment activities (ie, identification, eligibility verification, informed consent, and enrollment) may be particularly challenging when the study population is older adults due to limited digital literacy [4]. Furthermore, limited digital access is also more common among older adults [5].

Despite rapid technological advancement and a considerably aging US population, there remains a gap in the literature pertaining to online-based recruitment strategies for older adults. Extant reviews related to online-based recruitment strategies included the examination of health research recruitment via Facebook (Meta) among adolescents [6], adults [7], and participants of all ages [8,9], as well as the examination of diverse digital tools for recruitment and retention of participants in randomized controlled trials (RCTs) [10], web-based mobile health studies [11], and recruitment performance of web-based respondent-driven sampling [12]. To our knowledge, a review specific to online-based recruitment methods among older adults has not been conducted.

PLAN (Preparing successful aging through dementia Literacy education And Navigation) is an ongoing, community-based RCT designed to promote the transition of community-dwelling Korean American older adults with probable dementia and their caregivers into the health care system for adequate diagnostic follow-up and care. The original protocol was designed to include community-based in-person outreach as the main recruitment approach. The start of PLAN recruitment coincided with the national lockdown and in-person activity restrictions resulting from the COVID-19 pandemic. Consequently, our study team had to devise online-based strategies to recruit study participants. The purpose of this paper is to describe our lessons learned from the experience of recruiting a sample comprised non–English-speaking older individuals who are cognitively impaired along with their caregivers for the PLAN trial. We also present our findings from a scoping review examining online-based recruitment strategies focused on older adults to compare with our experiences.

Methods

Description of the PLAN Trial

The PLAN trial uses an RCT design (ClinicalTrials.gov NCT03909347). Details of the study design and methods are described elsewhere [13]. Briefly, the study intervention consists of 1-hour dementia literacy education followed by monthly phone counseling for 6 months, all delivered by trained community health workers (CHWs). The study is dyad-based and the inclusion criteria for Korean American older adults are (1) self-identified as first-generation Korean American in the New York-New Jersey or Greater Washington Metropolitan Areas, (2) aged more than 65 years, (3) has probable dementia (1+ on clinical dementia rating), (4) has a caregiver who lives in the same household or has at least weekly interaction, and (5) able to consent or has a proxy available for consent. The study inclusion criteria for caregivers are (1) older than 18 years, (2) able to read and speak Korean, (3) living in the same household with the Korean American older adult or has at least weekly interactions, and (4) written consent to participate in the study and permission granted to the study team to audit medical records for linkage to health care. Eligible dyads (ie, Korean American older adult scoring clinical dementia rating 1+ and caregiver) are asked to fill out the study questionnaire at baseline, 3 months, and 6 months.

XSL•FO
RenderX

The trial was launched in late February 2021, when the COVID-19 pandemic was rampant and in-person recruitment activities were not allowed. Therefore, potential participants were recruited through ethnic mass media advertisements such as newspapers, television, and radio. The study team also began to use other online-based recruitment methods including the web pages of the participating community centers and local ethnic commercial websites as well as digital social platforms including Facebook, Instagram (Meta), Twitter (rebranded to X), YouTube (Google), and KakaoTalk (Kakao Corporation), a mobile messaging app popular among Koreans. The study team continues to use such online-based recruitment strategies to date.

Sources of Data and Study Selection

Data sources used to identify online-based recruitment strategies and challenges for the PLAN trial included study recruitment tracking files and study team meeting minutes from the period of February to August 2021 when PLAN recruitment activities were solely online-based due to restrictions resulting from the COVID-19 pandemic. Additional data sources included interviews that took place in August 2021 immediately following the recruitment restriction period; interviewees included PLAN CHWs and community site coordinators as well as community consultants. We compared key lessons learned from the PLAN trial with a scoping review of published studies using digital technology to recruit community-dwelling older adults.

Our review followed the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) checklist (Multimedia Appendix 1) [14]. The review protocol is not registered. In consultation with a health science librarian, we formulated a comprehensive search strategy comprising variations of the following search terms: “digital technology,” “recruitment,” “strategies,” and “older adults.” Additional restrictions applied included peer-reviewed literature published in English and with full-text availability. The detailed search strategy is presented in Multimedia Appendix 2. Our initial literature search involved the electronic database PubMed and was conducted on July 13, 2021, and updated on September 20, 2023.

The initial search yielded 505 nonduplicative records including titles and abstracts. Furthermore, 2 reviewers (among DM, J-YY, CP, and AJ) were assigned to screen each title and abstract independently for inclusion eligibility, and disagreements were resolved through consensus. Records were reviewed based on 3 eligibility criteria, that were (1) focus on older adults aged more than 65 years, (2) sample recruited from a community setting, and (3) inclusion and description of online-based recruitment strategies. Records were excluded if they (1) did not focus on older adults aged more than 65 years in a community setting, (2) did not include or describe online-based recruitment strategies, or (3) used online-based methods but not for the purpose of recruitment. After titles and abstracts were screened, a total of 103 full-text records were assessed for eligibility by 1 reviewer (DM) and a second reviewer (J-YY, CP, or AJ) reviewed every tenth record. In total, 6 studies met the eligibility criteria from the initial search. Using the same strategy, the second search yielded 91 additional titles and abstracts, with no duplicate records found. In addition, 2 reviewers (among DM, J-YY, and AJ) independently screened each title and abstract and 12 records entered the full-text review. One reviewer (DM) assessed each full-text record and a second reviewer (J-YY) reviewed every fourth record. With 2 records meeting the eligibility criteria in the updated search, a total of 8 records were included in this review. Articles were screened using Covidence (Veritas Health Innovation Ltd), a systematic review management platform.

Data Extraction

Using a data charting table in Microsoft Excel, we systematically extracted the following information from each of the articles included in our review: first author’s last name, study design, study goal, country, sample characteristics (including sample size, key inclusion criteria, participant age cut-off or range, percentage of female participants, and percentage of White participants), recruitment methods along with associated yield rates, challenges related to technology and older adults, lessons learned, and identified themes.

Data Analysis

We used a variety of methods to analyze relevant data from the PLAN trial and 8 relevant studies. Specifically, we used descriptive statistics, including frequencies and percentages, to calculate recruitment yield rates by different recruitment sources for the PLAN trial. For text-based data derived from the PLAN study team’s meeting minutes, stakeholder interviews, and recruitment-related information extracted from the 8 studies, we conducted a thematic analysis [15] to identify common themes related to recruiting older adults using online-based methods. To do this, the data were systematically coded to identify themes, which were then examined to identify those that were most common and relevant. The coding process informed the timing of interview completion, as we assessed data saturation by noting when no new themes emerged from the analysis.

Methodological rigor was ensured through the following approaches. First, for interview data collected in Korean from PLAN CHWs, community site coordinators, and Korean American community consultants, only the final results—themes, subthemes, and selected quotes—were translated and presented in English. This strategy minimized methodological challenges associated with repeated translations. Second, trustworthiness was established through several measures: (1) credibility was maximized by leveraging the bilingual research team’s extensive experience with the Korean American population and involving community consultants who are trusted members of the Korean American community; (2) dependability was enhanced through the use of multiple data sources and methods, ensuring triangulation of findings; (3) transferability was achieved by including verbatim transcripts and relevant quotes, enabling readers to assess the applicability of the study findings beyond the current context; and (4) confirmability was strengthened by revisiting the data through collaborative review by the initial coders and coauthors [16].

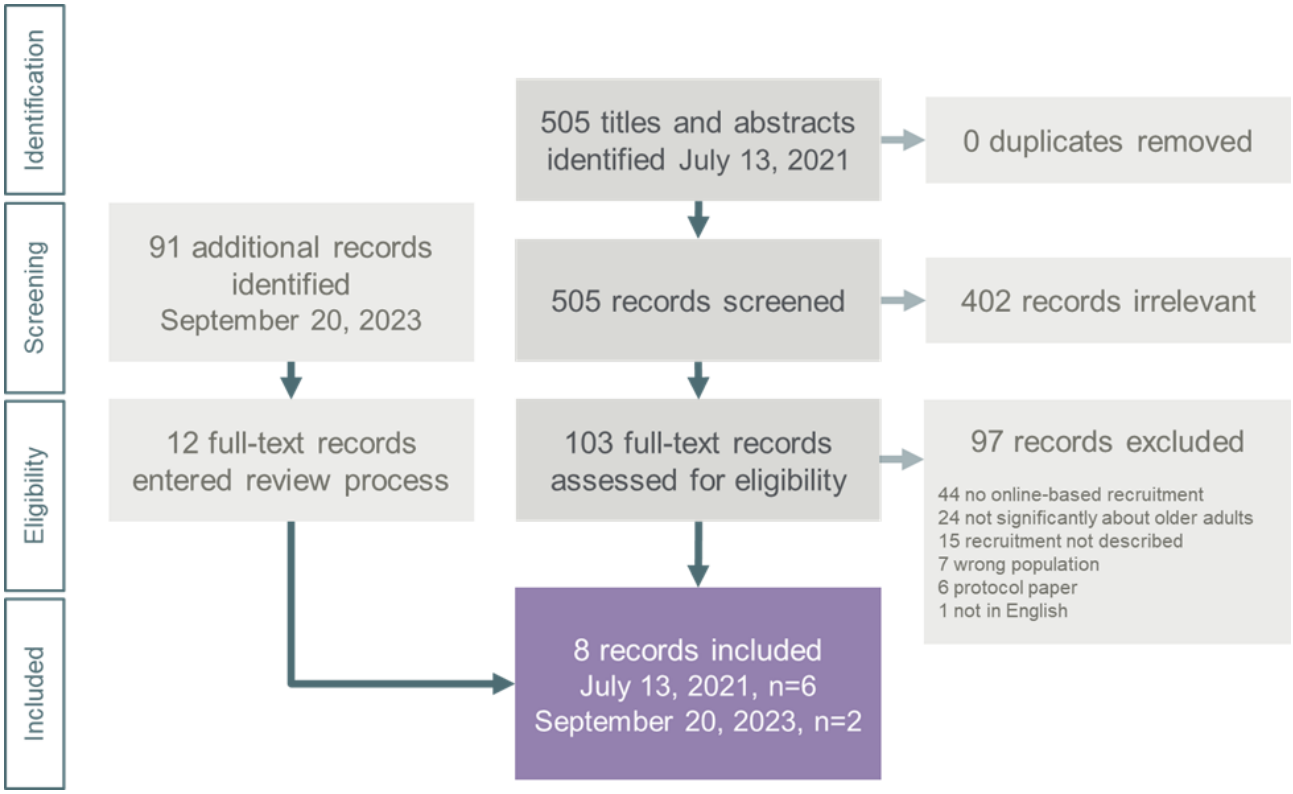
Ethical Considerations



The Johns Hopkins Medicine Institutional Review Board reviewed and approved procedures of the human subjects research component of this study (IRB00242241). Written consent was not deemed as required by the institutional review board. Study staff members assured anonymity and confidentiality of participant information and responses and participants were not compensated for their participation. For the scoping review, ethics approval was not required as published articles were used.

Results

Overview

The initial and updated searches yielded 505 and 91 nonduplicative records, respectively, including titles and abstracts. Of these, 103 and 12 records from the initial and updated searches met the inclusion criteria for full-text review. A combined total of 8 records (6 from initial search and 2 from updated search) were included in this review (Figure 1).

Figure 1. PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews) flow diagram.

Characteristics of PLAN and Other Relevant Studies

Table 1 details key characteristics of the PLAN trial [13] and 8 relevant published studies [17-24] that used online-based strategies to recruit community-dwelling older adults. The scope of the relevant studies addressed health promotion and recruitment strategy evaluation. Of the 8 relevant studies, there were 3 observational studies [17,18,23], 2 secondary analyses [19,20], 2 RCTs [21,24], and 1 feasibility study [22]; 3 studies were conducted in the United States [18-20], while 2 studies were based in Australia [17,21], 2 studies based in Sweden [23,24], and 1 study based in Israel [22]. The 3 US-based studies involved English-speaking older adults with varying characteristics including 171 former caregivers of individuals with dementia (155/171, 91% White and 156/171, 91% female) [19]; 45 healthy older adults (90% White and 29/45, 64% female) [18]; and 795 adults, comprising 176 (22%) high-risk (having ischemic heart disease or congestive heart failure) older adults, 521 (66%) healthy older adults, and 98 (12%) healthy young adults (759/795 96% White and 504/795, 63% female) [20]. All 8 studies involved participants with normal cognition.

Miller et al [21]	RCT; to describe the recruitment strategies used and the success of each approach in recruiting older adults with type 2 diabetes into a 6-month community-based exercise and nutritional supplementation RCT	Australia; 198 adults aged 50-75 years with type 2 diabetes; 50-59 years (39%), 60-69 years (53%), older than 70 years (11%); 35% (n=70) female; race and ethnicity breakdown not specified	Contribution[e,f]: Facebook advertising (0%, 0%) and website advertising (8%, 10%)	Contribution[e,f]: Targeted mail-outs (41%, 39%); state-wide newspapers (28%, 27%); local newspapers (15%, 14%); physician referrals (2%, 5%); word of mouth (3%, 3%); flyers and community presentations (1%, 2%); radio advertising (1%, 0%); and not specified (0%, 0%)
Pettersson et al [24]	RCT; to describe recruitment strategies, reach, and participant characteristics for a digital fall-prevention intervention	Sweden; 1628 Swedish older adults aged more than 70 years who previously experienced a fall or decline in balance in the past year; 79% (n=1292) female	Contribution[f]: Social media including Facebook pages, paid Facebook advertisements, and Instagram (76%—breakdowns per platform not specified)	Contribution[f]: Newspaper advertisements (7%); family and friends (6%); senior citizen organizations (6%); articles in newspapers or radio (2%); other (2%); and not specified (1%)
Schwartz et al [22]	Feasibility study; to promote physical activity among older adults through live, online group training sessions over 8 weeks among older adults	Israel; 31 Israeli older adults aged 68-76 years medically approved to participate in moderate physical activity by a physician; 65% (n=20) female	Contribution[e,f]: Posts in Facebook groups (100%, 100%)	—[g]

[a]PLAN: Preparing successful aging through dementia Literacy education And Navigation.

[b]RCT: randomized controlled trial.

[c]CHW: community health worker.

[d]Referral sources from February 2021 to August 2021 (restrictions for in-person activities due to the COVID-19 pandemic).

[e]Contribution defined as the percentage of all potential participant expressions of interest resulting from a particular recruitment method.

[f]Contribution defined as the percentage of all participant enrollments resulting from a particular recruitment method.

[g]Not applicable.

Table 1 also summarizes key recruitment methods used in each study along with yield rates, indicated as contributions, by source. Notably, 2 types of yield rates were found across PLAN and the 8 studies, that were (1) the percentage of all potential participant expressions of interest resulting from a particular recruitment method [13,17,18,20-22], and (2) the percentage of all participant enrollments resulting from a particular recruitment method [17,19,21-24]. Online-based recruitment methods for the PLAN trial included YouTube and social media platforms such as Facebook, Instagram, Twitter (rebranded as X), and KakaoTalk, of which only KakaoTalk served as a referral source for potential participants (3/461, 1%). Community-based online strategies were more successful to draw interest; e-newsletters and websites by Korean community organizations (26/261, 6% to 28/461, 6%), local eHealth fair events and seminars (11/461, 2%), and dementia caregiver online support groups (5/461, 1%). Though not online-based, ethnic newspaper advertising was most successful to draw interest (194/461, 42%), followed by word of mouth (90/461, 20%). For the 8 relevant studies, the most widely used (all but 1 study by Corey et al [19]) online-based recruitment method was the social media platform Facebook, with varying yield rates from 0% to 100%, used in various forms such as Facebook pages [17,19,23,24], Facebook advertising [17,18,21,24], and Facebook groups [22]. Additional online-based recruitment strategies included other internet (Google AdWords campaigns, study websites, links on other websites) [17,23], listserve broadcast emails [20,24], and advertising on other and related websites [17-19,21,24] with varying yield rates from 0% to 15%.

Recruitment of Older Adults Using Online-Based Strategies

We identified several key themes and lessons learned relevant to the recruitment of community-dwelling older adults (Table 2). These included unfamiliarity with technology, differences in internet access and use across older age groups, providing technological support to promote recruitment, successful and unsuccessful recruitment using social media, and other diverse online-based methods of recruitment.

XSL•FO
RenderX

Table 2. Key themes for online-based recruitment of older adults.

Theme	Lessons learned
Unfamiliarity with technology—limited digital literacy	• Some participants struggle to understand basic concepts such as an "app" or smartphone versus 2G phone (PLAN[a]) • Korean American older adults may reject the use of new technology, such as Zoom, because they are not used to nor familiar with it (PLAN)
Differences in internet access and use across older age groups	• Online-based recruitment strategies are useful across age groups (young, middle-aged, young-old, and older-old), but provide greater access to young and middle-aged adults than older adults [19] • Older-old (75 years and older) participants recruited only through caregiving- and dementia-related websites and none through Facebook [19]
Providing technological support to promote recruitment	• Triaging participant technological capability through study intake call (PLAN) • Zoom downloading assistance and tutorial through 1:1 precall with CHW[b] (PLAN) • Providing technological support through 1:1 15-minute online-based introductory session with study team member [22]

Successful and unsuccessful recruitment using social media	• Social media yielded no results (Facebook, Instagram, Twitter, and YouTube), with the exception of KakaoTalk (1%; PLAN)
	• Facebook was primary social media platform used across studies and presented mixed results (PLAN) [17-19,21-23]
	  • Successful: Facebook groups (100%) [22], Facebook advertising (73%) [18], and Facebook page (31%) [19]
	  • Unsuccessful: Facebook advertising (0%) [21], Facebook unpaid page and paid advertising (2%) [17], and Facebook page (11%) [23]

Using other diverse online-based methods of recruitment	• Community center e-newsletters, ethnic community websites, e-health fair events or seminar, dementia caregiver online support groups with modest success (PLAN) • Emails more successful with younger individuals; physician-signed letters more successful with older adults [20] • Survey invitation to participate and survey link posted on websites of organizations related to caregivers and dementia less successful than Facebook pages; professional referrals most successful [19]

[a]PLAN: Preparing successful aging through dementia Literacy education And Navigation.

[a]CHW: community health worker.

Unfamiliarity With Technology—Limited Digital Literacy

Unfamiliarity with technology and limited technological proficiency can be a barrier to online-based recruitment for older adults. In the PLAN trial, we saw this among Korean American older adult participants who had varying levels of familiarity and experiences with technology like Zoom (Zoom Communications). Our CHWs reported that some Korean American older adults, when asked if they had a smartphone, could not distinguish between a smartphone and a 2G phone. Similarly, many older adults had difficulty finding the Google Play or the Apple Store to download an app such as Zoom or were unfamiliar with the word "app" or "Zoom." One CHW shared her experience about the level of ability to use technology of PLAN study participants:

> *When I sent a Zoom link to a participant, in most cases, I had to send the link via text message because most KA older adults use phones [as opposed to computers]. Also, for most of them who received the Zoom invitation via text message, it was their first time using Zoom. Only those who use computers were able to communicate via email.*

Community consultants shared a broad spectrum of responses to online-based study participation and affirmed that differences in technology use and familiarity have influenced the decisions of Korean American older adults to participate. A community consultant shared:

> *There are people who want to try new things, and there are people who absolutely reject things that they are not used to. Most older adults [I have encountered] are like that; not limited to Zoom, but because they don't want to do anything that they are not familiar with.*

However, others had previous experience and familiarity with Zoom through personal tasks such as attending telehealth medical visits and church meetings. Such older adults expressed positivity toward participating in PLAN via Zoom, as noted by another community consultant:

> *I did [Zoom] with my doctor about two weeks ago. If Zoom is the only way [to get a doctor's appointment], we would do it...*

Differences in Internet Access and Use Across Older Age Groups

Online-based recruitment may present different challenges and opportunities for older adults across different age groups. While rates of internet use and experiences of different age cohorts of older adults often go unacknowledged in the literature, Corey

XSL•FO
RenderX

et al [19] used a 4-step internet-based approach for the recruitment of previous caregivers of people with dementia to participate in an online-based survey. The approach included the steps, such as (1) creation of study Facebook page, study invitation, and survey link posted to Facebook page; (2) study invitation and survey link posted to caregiver- and dementia-related websites; (3) study invitation and survey link posted to Facebook pages of relevant groups; and (4) study invitation and survey link email to principal investigator's professional contacts [19]. Rates of referral through online-based sources were found to be comparable between the older-old subsample (46.7%) and the young-old subsample (47%), suggesting that internet accessibility and use between young-old and older-old adults is similar [19]. Nevertheless, diverse use of several online-based recruitment strategies was least successful in the recruitment of older-old (aged 75 years and older), with this age cohort only being recruited directly from caregiving- and dementia-related websites and none through Facebook [19].

Providing Technological Support to Promote Recruitment

When the PLAN study team conducted solely online-based research activities, from February through August 2021, early implementation revealed limited use of Zoom and varying levels of familiarity with technology among Korean older adults. One of the most common problems encountered by participants was the downloading process of Zoom. Community feedback supported the utility of technological assistance including that of a community consultant:

> *I don't know how to use [Zoom], but I can do it if someone explains it to me side by side. But I don't know how to go in and navigate through Zoom.*

Responding to community feedback, we integrated an additional component to the PLAN intake call to triage interested potential participants with respect to technological capacity by posing questions related to device (eg, laptop, desktop, or smartphone), WiFi access, previous Zoom experience, and availability of someone to assist with Zoom set up. Based on their responses, individuals were categorized as either green to indicate technological self-sufficiency, or yellow, red, or black to signify lower levels of technological capacity; individuals of the latter groups were scheduled for a 1:1 precall with a CHW for Zoom downloading assistance and a tutorial before the cognitive screening. Similarly, Schwartz et al [22] scheduled online-based introductory sessions through Zoom with each interested potential participant to promote recruitment and provide technological assistance. The 15-minute 1:1 sessions included a Zoom tutorial as well as a brief overview of the study goals and required equipment for participation.

Successful and Unsuccessful Recruitment Using Social Media

All but 2 studies included in the review used social media as one of several recruitment strategies. Among the studies that leveraged social media, Facebook was the primary platform with a mix of targeted, paid advertisements, and unpaid postings [17-19,21-23]. Overall, the success of social media as a recruitment tool for older adults was mixed. For example, in an exercise and nutrition RCT for diabetes control, Miller et al [21] used paid Facebook advertisements with targeted key words based on age and location to capture attention of potential participants. Despite 16,600 clicks, among the 1157 total expressions of interest across recruitment types, only 5 came from social media; among those expressions of interest, no study participants were deemed eligible [21]. Similarly, in a study on diabetes prevention, Bracken et al [17] used both paid Facebook advertisements as well as unpaid Facebook posts. Facebook recruitment yielded a small proportion of expressions of interest as well as participant enrollment (2% and 2%, respectively), slightly more than other internet (combination of Google AdWords campaigns, study website, and links on other websites; 1% and 2%, respectively); radio advertising accounted for the largest proportion of both expressions of interest in addition to participant enrollment (42% and 40%, respectively) in the trial [17]. In a digital fall prevention intervention, Bajraktari et al [23] used the Facebook page of a local municipality, which yielded relatively low enrollment of 11% (19/173) compared with a 47% (81/173) yield from brochures mailed to households with at least 1 community-dwelling person aged 70 years or older as identified by a register provided by the local municipality. Similarly, social media was not an effective means of recruitment for the PLAN trial; relative to other methods, only 1% (3/461) of those screened for the PLAN trial were recruited via Facebook, Instagram, Twitter, YouTube, or Kakao Channel (a feature of a popular messaging app among Koreans—KakaoTalk).

A few studies successfully used social media to identify and enroll older adult participants. For example, using Facebook groups as the primary means of recruitment, 1 study surpassed their goal of 30 participants for an online-based physical activity intervention (using Zoom) for older adults in Israel [22]. In addition, in a study leveraging only social media channels that were unpaid, 24% (12/51) of the study sample aged 65-75 years were recruited via Facebook, although 0% (N=0) among those aged 75 years or older [19]. Recruitment through Facebook (unpaid) consisted of a dedicated page, created and managed by the PI, and posts to Facebook pages of other stakeholder groups [19]. There were no other indications of what other applications or websites were used other than postings on Facebook pages. Another study focused specifically on the effectiveness of social media recruitment to an Alzheimer treatment clinical trial via Facebook, as the study was failing to achieve the recruitment targets from its first phase of traditional recruitment methods (eg, billboards, newspaper advertising, word of mouth, personal referrals, and direct mail) [18]. Compared with the 11-week period of traditional recruitment methods that resulted in 178 inquiries and 6 enrolled subjects, the 8-week period with Facebook advertising resulted in 691 inquiries and 39 enrolled subjects. In the study by Cowie and Gurney [18], older men had a slightly higher engagement rate with the Facebook ads compared with women. However, women were found to have a higher engagement rate with their ad appealing to altruism (the recruitment campaigns targeted "typical" recruits by highlighting financial incentives for participation and "altruistic" recruits by highlighting the need for help) [18].

XSL•FO
RenderX

Using Other Diverse Online-Based Methods of Recruitment

There were other, nonsocial media online-based methods used for the recruitment of older adults with varying ranges of success. In the PLAN trial, other online-based methods used included community center e-newsletters, pop-up advertisements on websites for community sites, and e-health fair events and seminars organized by the trial's 2 partnering community sites, and dementia caregiver online support groups. These diverse online-based methods yielded 16% (73/461) of potential participants referred to the study. Nonetheless, such methods were ineffective relative to traditional ethnic newspaper recruitment through which we identified 42% (194/461) of potential participants. Dill et al [20] used emails to recruit adults aged 20-40 years and older adults aged more than 60 years to compare immune responses with an inactive influenza vaccine between the groups and found that emails were more effective among younger individuals (57/94, 61%) compared with older individuals (25/645, 4%) [20]. Finally, 1 sample of former dementia caregivers was divided into 3 age groups (young and middle-aged: 18-64 years; young-old: 65-74 years; older-old 75+ years) to examine variation in internet-based recruitment and retention [19]. Corey et al [19] used websites of relevant caregiver and dementia organizations (Family Caregiver Alliance and Alzheimer's Association) and found that older-old adults were most frequently directed to the study survey through such relevant websites (3/15, 20% and 4/15, 27%, respectively) compared with the young and middle-aged and young-old groups.

Discussion

Principal Results

Knowledge about online-based recruitment strategies among older adults is limited. This study set out to describe lessons learned from a community-based dementia literacy education intervention in cognitively impaired non–English-speaking older adults and their caregivers, as well as to compare such experiences with what is presented in the literature with respect to recruitment strategies that are online-based and older adult–focused. We learned that the most widely used online-based recruitment method across studies was the social media platform Facebook, with yield rates spanning 0% to 100% [13,17,19,21,22]. Despite an ongoing increase of internet use among older adults [3], recruiting older adults using other online-based methods such as internet (Google AdWords campaigns, study websites, and links on other websites), listserve broadcast emails, and advertising on other and related websites resulted in little to modest success with yield rates ranging from 1% to 15% [17-22].

The digital divide—one of the most significant social determinants of health [25]—was a theme that was particularly relevant to Korean American older adults and their caregivers in the PLAN trial [13]. Through direct recruitment encounters with potential study participants, the CHWs in the trial noted a 2G phone (aka, a "flip phone") as a barrier to working toward online-based eligibility screening. A recent report by the Pew Research Center [26] revealed that in 2021, 97% of Americans owned a cellphone of some kind; 85% owned a smartphone. According to the report, smartphone ownership varied by age (from 96% for those aged 18-29 years to 61% for people aged more than 65 years) and level of education (from 75% for people with high school or less to 93% for those with college education). The rate of smartphone ownership was similar across White, Black, and Hispanic Americans. With the advent of a digital era, smartphone ownership often equates to connectivity to the world and access to the internet [27]. While it is unclear how many immigrant older adults use smartphones, our finding suggests the importance of addressing the issue of limited access to adequate digital devices in this vulnerable group.

Limited digital literacy was also a main barrier frequently reported in our and other studies included in the review [13,22]. Digital literacy is defined as "the ability to use information and communication technologies to find, evaluate, create, and communicate information, requiring both cognitive and technical skills." In the PLAN trial, our CHWs recognized the challenges associated with limited digital literacy among Korean American older adults who often lacked a basic understanding of key technologies to enable them to follow through instructions for Zoom-based recruitment procedures. In particular, our observation of many Korean American older adults rejecting to learn "new things" (such as Zoom) is similar to the finding reported in a study involving community-dwelling adults [28]. In the study, participants were asked to perform a short task on a tablet involving a brief search with the same number of steps using either a familiar or a less familiar app. The authors found that older participants who used unfamiliar technology felt older after using the technology. Given these findings, trials using online-based recruitment should consider technological support for older adults as part of the recruitment process. Indeed, technological support through diverse methods (eg, triaging potential participants based on technological capabilities or 1:1 precall for assistance) was used to promote recruitment in our and other studies [13,22]. In addition, in a recently published experimental study involving individuals aged 55 and older, a series of in-person workshops incorporating hands-on training activities using the participants' select mobile device, tablet, or smartphone (eg, touch and manual dexterity for mobile use, varying forms of communication such as text, image, voice, video, engaging tasks such as sharing of pictures, video, or other info, and other autonomous activities such as messaging for e-learning) resulted in significant improvement in digital literacy at 1-month follow-up [29]. Taken together, these results highlight some of the promising avenues to promote inclusiveness among older adults. In addition, future study teams may refer to a number of national and state-based resources that have been established to address digital literacy [30-33].

The usefulness of internet-based recruitment methods varied significantly among different age cohorts of older adults. Nevertheless, diverse use of several internet-based recruitment strategies was least successful in the recruitment of older-old (aged 75 years and older), with this age cohort only being recruited directly from caregiving- and dementia-related websites, which suggests the need for supplementary recruitment strategies for this age demographic rather than relying solely on internet-based methods [19]. Also, none of the recruited

XSL•FO
RenderX

older-old participants were directed to the survey from Facebook, which suggests purposeful internet use among this age demographic and that social media use in this age group may not be sufficient for the use of social media–based recruitment methods, suggesting that response bias may be a significant consideration when using the internet in studies including older adults [19].

There was limited sociodemographic diversity in older adult participants recruited through internet-based strategies [17-22]. For example, we found that participant demographics, especially sample composition in terms of race or ethnicity, were not always reported; when reported, it was mainly White samples than non-White samples [18-20]. Furthermore, older participants included in the studies using internet-based recruitment had a high level of education and middle-upper class socioeconomic background [22]. More research is needed to explore the possible relationship between race or ethnicity, education, socioeconomic status, and ability to access and use online-based resources. There is also a demonstrated need to address the feasibility of online-based recruitment and research among older adults from lower socioeconomic backgrounds [19,22].

Success with social media as a recruitment tool for older adults varied. Social media is internet-based digital technology that allows the sharing of information and ideas and includes platforms such as Facebook, YouTube, X (previously called Twitter), Instagram, or WhatsApp. Given its wide reach and efficiency, researchers often find social media as an attractive tool for recruitment. Nonetheless, a recent integrative review [34] of 96 studies on social media use for research participant recruitment revealed that with the exception of 1, all other studies included in the review exclusively involved younger populations (eg, teens, young adults, or middle-aged participants); none specifically targeted older individuals with limited English proficiency. One of the studies included in the current review was a diabetes prevention trial and used Facebook for recruitment [17]. Yet, it only focused on older men and the authors were unable to determine whether lack of engagement via online-based strategies was due to the content of the advertisements and posts or sex-related differences with respect to the social media habits of men over the age of 50 [17]. Given the small number of relevant studies using social media to recruit older adults, more research is necessary to understand the effects of age and sex in relation to the utility of social media platforms for recruitment.

Limitations

Our study has several limitations that warrant consideration. First, due to the timing of our exclusively online-based recruitment (early phase of COVID-19 pandemic), most potential participants who approached the study team had access to the internet. Naturally, we did not find any theme addressing the gap in internet access, although it is important to acknowledge that nationally, the rate of internet access among older adults aged 65 years and older is 75% [3]. The role of social media in our study is also noteworthy. For the most part, earlier articles using social media platforms for recruitment often lacked detailed information compared with more recent articles, providing gaps in reported online-based recruitment methodology and outcome. Furthermore, the articles in our review lacked ethnically diverse samples, and most studies were predominantly female, White, and with higher education, presenting a limitation in terms of generalizability of our findings (eg, 1 study used a Facebook algorithm to target individuals in higher income brackets [18]). Our review included articles published in English only and resulted in a total of 8 studies. The inclusion criteria around language restriction may have limited both the diversity and total number of articles, potentially influencing the level of comprehensiveness of our findings. In addition, due to the time-sensitive nature of our study, we used 1 primary database and selected PubMed given its widespread use and comprehensive coverage. This decision was made to maximize our search results within the constraints of limited time and resources. However, we note this as a limitation as relying solely on PubMed may have excluded relevant studies from other databases. Finally, we acknowledge the possibility of recalling bias. To minimize this, we used data sources that were based on written documentation (ie, recruitment tracking files and study team meeting minutes); in addition, interviews with CHWs, community site coordinators, and community consultants were conducted in August 2021, immediately following the 6-month period from February to August 2021 when PLAN recruitment activities were solely online-based due to restrictions resulting from the COVID-19 pandemic.

Conclusions

Recruiting older adults using online-based strategies had varying success with most studies included in the review reporting more challenges than successes. As our nation continues to age, it is also becoming increasingly diverse [35]. Limited internet access and digital devices were noted as some of the main reasons for unsuccessful recruitment in the published studies of older adults included in our review; the same issue was also observed in our ongoing trial. The persistence of an age-based digital divide in the post–COVID-19 pandemic warrants both careful planning of recruitment activities to ensure technological support during the pre-enrollment period and the analysis of relevant recruitment outcomes as part of the study design. Such endeavors may promote better representation of those in research who are particularly vulnerable to the digital divide such as the older old, the less educated, and non–English-speaking ethnic minorities.

Acknowledgments

The authors would like to acknowledge Ja'Lynn Gray for her contribution to an early version of this work. This study was supported by the National Institute on Aging (R01AG062649).

Abstract

Background: Gastrointestinal endoscopy represents a useful tool for the diagnosis and treatment of gastrointestinal diseases. Video platforms for spreading endoscopy-related knowledge may help patients understand the pros and cons of endoscopy on the premise of ensuring accuracy. However, videos with misinformation may lead to adverse consequences.

Objective: This study aims to evaluate the quality of gastrointestinal endoscopy-related videos on YouTube and to assess whether large language models (LLMs) can help patients obtain information from videos more efficiently.

Methods: We collected information from YouTube videos about 3 commonly used gastrointestinal endoscopes (gastroscopy, colonoscopy, and capsule endoscopy) and assessed their quality (rated by the modified DISCERN Tool, mDISCERN), reliability (rated by the *Journal of the American Medical Association*), and recommendation (rated by the Global Quality Score). We tasked LLM with summarizing the video content and assessed it from 3 perspectives: accuracy, completeness, and readability.

Results: A total of 167 videos were included. According to the indicated scoring, the quality, reliability, and recommendation of the 3 gastrointestinal endoscopy-related videos on YouTube were overall unsatisfactory, and the quality of the videos released by patients was particularly poor. Capsule endoscopy yielded a significantly lower Global Quality Score than did gastroscopy and colonoscopy. LLM-based summaries yielded accuracy scores of 4 (IQR 4-5), completeness scores of 4 (IQR 4-5), and readability scores of 2 (IQR 1-2).

Conclusions: The quality of gastrointestinal endoscope-related videos currently on YouTube is poor. Moreover, additional regulatory and improvement strategies are needed in the future. LLM may be helpful in generalizing video-related information, but there is still room for improvement in its ability.

(J Med Internet Res 2025;27:e58855) doi:10.2196/58855

Introduction

Gastrointestinal endoscopy is a medical procedure performed by the insertion of an endoscope into the digestive tract through the oral and anal routes. It allows direct visualization of the inner lining of the esophagus, stomach, and intestines and enables the treatment of various conditions, such as ulcers, polyps, and tumors [1]. In recent years, the incidence and

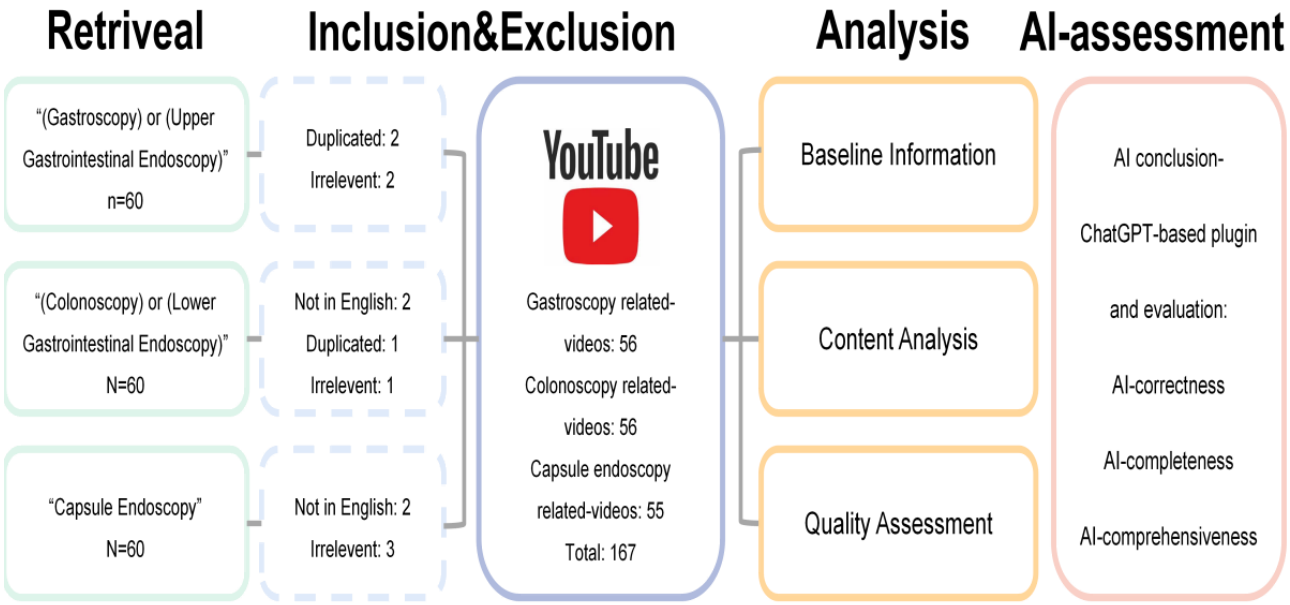
XSL•FO
RenderX

gradual rejuvenation of gastrointestinal diseases have increased [2]. As a significant screening and diagnostic tool for gastrointestinal diseases, gastrointestinal endoscopy is increasing in importance. Gastroscopy and colonoscopy screening have significantly increased the rate of early diagnosis of gastrointestinal cancers, reduced mortality, and improved disease prognosis [3,4]. However, previous studies have shown that 38.1% of people refuse to undergo gastroscopy because they do not sufficiently recognize the knowledge related to this examination [5]. More seriously, some patients are delayed in the diagnosis and treatment of their disease because of misinformation about gastroscopy [6]. Capsule endoscopy is another important gastrointestinal examination technique that has emerged over the past few years. It has the advantages of being painless, noninvasive, and relatively less demanding to operate [7]. However, due to insufficient knowledge of the indications, contraindications, and effects of capsule endoscopy [8], it is difficult for patients to independently make a choice that is appropriate for their condition. Therefore, providing medical education to patients about the indications, contraindications, and key points of preoperative preparation for various gastrointestinal endoscopic techniques can help them receive appropriate treatment in a timely manner and may improve the outcome of their disease.

In recent years, the increasing popularity of mobile electronic devices and the development of internet applications have led to a rising utilization of social media in the medical field [9,10]. Social media platforms that disseminate health information web-based have been proven to enhance the efficiency of doctors' consultations and improve the experience of patients [11-13]. Due to the convenience of accessing information, an increasing number of patients are turning to social media platforms as a source of health-related information [11]. In the field of gastroenterology, social media-based telemedicine is actively involved in patient health care for patients and in doctors' decision-making [12]. It has been reported that communication through social media improves the quality of bowel preparation for patients undergoing colonoscopy [13]. Notably, the advent of large language models, such as ChatGPT (OpenAI), has facilitated faster access to endoscopic information [14]. Interestingly, a video content summarization tool built on the foundation of big language models offers a new option for individuals who are unable or unwilling to watch an entire video [15].

YouTube has emerged as a paramount platform for disseminating web-based content, boasting an impressive global user base of 256 million [16]. Moreover, the amount of medical content on this platform has increased significantly in recent years [17]. Used appropriately, platforms such as YouTube can prompt behavioral change in viewers, enhancing their health [18]. However, YouTube also allows the distribution of unverified and nonprofessional content [19], leading to an increase in low-quality videos, which are created by nonspecialist users with little to no medical training [6]. This compromises the overall quality of medical content on YouTube, providing potentially misleading health information to unsuspecting viewers. Therefore, additional efforts from health care professionals are needed to correct patients' misconceptions from the abovementioned misinformation during their treatments, reducing the efficiency of health care services and potentially escalating doctor-patient conflicts [20,21]. Currently, a substantial number of gastrointestinal endoscopy-related videos have emerged on YouTube. However, there is a lack of research evaluating the quality of these videos.

The aim of the present study was to examine the quality, reliability, and recommendability of videos related to gastroscopy, colonoscopy, and capsule endoscopy available on YouTube. Additionally, we also sought to assess the practicality of a large language model (LLM)–based video content summarization tool for summarizing health-related video content [15].



Methods

Search Strategy and Selection Approach for the Included Videos

All the videos included in the analysis were obtained from the web-based YouTube platform. The keywords used were "(gastroscopy) or (upper gastrointestinal endoscopy)," "(colonoscopy) or (lower gastrointestinal endoscopy)," and "capsule endoscopy." To minimize the impact of the personalized recommendation algorithm on the inclusion of videos, we registered 3 separate brand-new accounts to retrieve the 3 different endoscopies. No filter settings were used during the retrieval process to faithfully simulate the usage scenarios of patients or other regular users. The search process for videos of the 3 gastrointestinal endoscopies was completed between September 28, 2023, and September 30, 2023. Duplicate videos, non-English videos, and videos that were not relevant to the search topic were excluded. Based on the experience from previous studies and the browsing habits of video platform users, namely, they mostly prioritize top search results over extensive browsing on video platforms [22-27], we selected videos that appeared within the top 5 pages of the YouTube interface, which is a total of 60 results for each endoscope for subsequent analysis. The specific retrieval and filtering process is shown in Figure 1.

Evaluating Methodologies of the Videos

The reliability and content quality of the videos were evaluated using the Modified DISCERN (mDISCERN), the *Journal of the American Medical Association* (*JAMA*) score, and the Global Quality Scoring (GQS) scale. Before this assessment, the participating physicians familiarized themselves with the endoscopy guidelines and official descriptions of the 3 scales, enabling them to assess the accuracy and completeness of the video content while adhering to the guidelines. The mDISCERN scale was initially devised by Charnock et al [28] for evaluating written health information and was employed to examine video content quality [29]. The scale's modified version contains a 5-question questionnaire (Table S1 in the Multimedia Appendix), providing 1 point for each affirmative response for a maximum of 5 points. Videos scoring 3 or more on the mDISCERN scale were deemed high-quality health information providers [29]. The *JAMA* Rating Scale (Table S2 in the Multimedia Appendix) was used to assess health-related video information reliability [30]. It includes 4 assessment criteria: authorship, attribution, disclosure, and timeliness, with each carrying a 1-point score of up to a total of 4. Higher *JAMA* scores suggest better reliability of health information [30]. The GQS (Table S3 in the Multimedia Appendix) uses a 1-5 scale across 5 criteria, with greater GQS indicating a more highly recommended video [31]. Additionally, the artificial intelligence (AI)–summarized content was evaluated in terms of accuracy, reliability, and readability (Table S4 in the Multimedia Appendix), with accuracy-related elements divided into 6 dimensions from 1 to 6 and completeness and readability divided into 3 dimensions from 1 to 3.

Data Collection and Evaluation of Video Reliability and Content Quality

Essential video information was gathered for subsequent analysis, including video length, release date, number of days since release, play count, likes, steps, comments, uploader's follower count, uploader's identity, and the Video Power Index (VPI). We divided the uploaders into 4 groups based on their status: doctors or hospitals, medical media, other health organizations (including medical associations, medical examination centers, equipment companies, etc), and patients. The VPI, used to measure video popularity, was computed with the formula VPI=([number of likes]/[number of likes+number of dislikes])×100)×([number of views/days after upload]/100) [32]. Additionally, the ratios of (number of likes+number of steps)/plays and number of comments/plays were calculated to evaluate viewer interaction levels. The LLM processes the raw text extracted from video content, including both text and subtitles, and subsequently synthesizes a summary and general insights. To avoid sequence bias, the video order was randomized. All videos included in the analysis and the content synthesized by LLM were assessed by 2 senior gastroenterologists (YL and YF). For scoring items prompting disagreement, a third senior physician (WP) made the final decision.

Statistical Analysis

The nonnormal distribution of the entire data set was initially confirmed using the Shapiro-Wilk test. The median, interquartile range, mean, and variance were calculated for the continuous variables and the frequency of the categorical variables. For continuous variables that deviated from a normal distribution, the Wilcoxon-Mann-Whitney test and the Kruskal-Wallis test were used for between-group differences. All the data analyses were carried out with IBM SPSS Statistics for Mac (version 27; IBM Corp) via a 2-sided test approach. A *P* value of less than 0.05 was considered to indicate statistical significance. Moreover, for comparisons among multiple subgroups, Bonferroni corrections were applied to the *P* values. Finally, data visualization was performed using R software (R Core Team, the R Foundation).

Results

Video Features

A total of 167 relevant videos were included in the analysis; 56 were gastroscopy-related videos, 56 were colonoscopy-related videos, and 55 were capsule endoscopy-related videos. We divided the uploaders into 4 groups based on their status: doctors or hospitals, medical media, other health organizations (including medical associations, medical examination centers, equipment companies, etc), and patients (Figure 2A). Most of the videos were uploaded via platforms with medically related backgrounds, including medical media (n=52, 31.3%), other health organizations (n=49, 29.5%), and doctors or hospitals (n=39, 23.5%; Figure 2A). Colonoscopy-related videos were relatively longer, with a median of 288 (IQR 159-477) seconds, followed by gastroscopy-related videos (median 251, IQR 115-530) and capsule endoscopy-related videos (median 213, IQR 110-487). Capsule endoscopy-related videos were significantly less popular (median VPI 4.45, IQR 1.75-15.59) than gastroscopy-related (median VPI 32.47, IQR 7.77-88.20) and colonoscopy-related (median VPI 31.52, IQR 9.69-129.52) videos were. The trend in the number of views was also similar to that for the VPI; gastroscopy-related videos and colonoscopy-related videos both had significantly more plays than did capsule endoscopy-related videos, while there was no significant difference between the former two (Table 1).

Figure 2. The characteristics and quality of gastrointestinal-related videos on YouTube. (A) Proportion of the 4 groups of the uploaders. (B) Radar charts showing the percentage of each kind of content categorization among videos of different types of endoscopes. (C) mDISCERN score, (D) JAMA score, (E) GQS score of videos of different types of endoscopes. * denotes *P*<.05, and ** denotes *P*<.01 using the Kruskal-Wallis test. GQS: Global Quality Score; JAMA: Journal of the American Medical Association.

[a]VPI: Video Power Index.

[b]Significantly different from capsule endoscopy-related videos; $P<.05$ using the Kruskal-Wallis test.

Video Content

Based on the guidelines and the videos included in the analysis, we categorized the content of the 3 types of endoscopy videos. We assessed the comprehensiveness of the included videos' content from the following five perspectives: (1) process: this refers to the process by which a patient undergoes gastrointestinal endoscopy; (2) principle: this refers to the principles of construction and operation of gastrointestinal endoscopes; (3) advantages and benefits: this refers to the roles of gastrointestinal endoscopy techniques, indications, and roles in relation to other investigations; (4) matters that need attention: this means that the patient needs to be aware of the following things before, during, and after the gastrointestinal endoscopic examination; and (5) complications and side effects: possible complications and adverse effects of endoscopic techniques in the digestive system. As shown by the radar chart (Figure 2B), among the 3 types of videos, the content coverage of gastroscopy-related videos was broadest, and the coverage of colonoscopy-related videos and capsule endoscopy-related videos was approximate; both of these videos were narrower than that of gastroscopy-related videos. Of the 167 endoscopy-associated videos analyzed, a substantial majority encompassed depictions of the process and enumerated potential advantages or benefits, accounting for 87 (52.1%) and 66 (39.5%) videos, respectively. In stark contrast, only 15 (9.0%) videos addressed possible complications and adverse reactions associated with gastrointestinal endoscopy.

Information Quality and Reliability

We evaluated the quality and reliability of the videos across different endoscope types and within groups of the same endoscope type (Table 2). On average, colonoscopy-related videos had an mDISCERN of 3.29 (SD 0.94), which was slightly greater than that of both gastroscopy (2.88, SD 0.99) and capsule endoscopy (2.93, SD 1.05), albeit not significantly (Figure 2C). In contrast, capsule endoscopy-related videos significantly underperformed, with a GQS of 1.88 (SD 0.83) when compared to gastroscopy (2.96, SD 0.97; $P=.03$) and colonoscopy (3.13, SD 0.79; $P<.01$; Figure 2D). However, the *JAMA* scores across all 3 endoscopy types remained similar (Figure 2E).

XSL•FO
RenderX

Category	mDISCERN		*JAMA*		GQS	
	Median (IQR)	Mean (SD)	Median (IQR)	Mean (SD)	Median (IQR)	Mean (SD)
Gastroscopy	3 (2-4)	2.88 (0.99)	2 (2-3)	2.29 (0.78)	3 (2-4)	2.96 (0.97)
Colonoscopy	4 (3-4)	3.29 (0.94)	2 (2-3)	2.29 (0.79)	3 (3-4)	3.13 (0.79)
Capsule endoscopy	3 (2-4)	2.93 (1.05)	2 (2-2)	2.07 (0.50)	2 (2-3)	2.53 (0.88)

[a]JAMA: Journal of the American Medical Association.

[b]GQS: Global Quality Scoring.

In terms of the different sources of the video uploaders (Table 3), we observed that the GQS scores of patient-provided gastroscopy-related videos were significantly lower than those of doctors or hospitals (1.88, SD 0.83 vs 3.05, SD 0.85; *P*=.04), medical media (1.88, SD 0.83 vs 3.27, SD 1.10; *P*<.01), and other professional organizations (1.88, SD 0.83 vs 3.45, SD 0.52; *P*=.02; Figure 3C). Consistent with the GQS results, the mDISCERN score (1.50, SD 0.53) and the *JAMA* score (1.13, SD 0.35) were also lower for patient-provided gastroscopy-related videos than for the other 3 videos (Figures 3A and B). Similarly, when analyzing colonoscopy-related videos, we found that the scores of patient-provided videos were lower than those of the other 3 videos in all 3 categories (Figures 3D-F). Interestingly, while patient-provided capsule endoscopy-related videos were scored lower in quality than videos provided by medical media (mDISCERN: 1.71, SD 0.76 vs 3.18, SD 0.64; *P*<.05) and other professional organizations (mDISCERN: 1.71, SD 0.76 vs 3.10, SD 1.25; *P*<.05), there was no significant difference in quality between patient-provided videos and videos provided by doctors or hospitals according to all the mDISCERN scores, *JAMA* scores and GQS scores (Figures 3G-I).

Table 3. mDISCERN, JAMA[a], and GQS[b] scores of videos from 4 groups of the uploaders.

(A) mDISCERN score, (B) JAMA score, and (C) GQS score of videos about gastroscopy from different identities of the uploaders. (D) mDISCERN score, (E) JAMA score, and (F) GQS score of videos about colonoscopy from different identities of the uploaders. (G) mDISCERN score, (H) JAMA score, and (I) GQS score of videos about capsule endoscopy from different identities of the uploaders. * denotes $P<.05$, and ** denotes $P<.01$ using the Kruskal-Wallis test. GQS: Global Quality Score; JAMA: Journal of the American Medical Association.

Conclusion and Evaluation

To assess the utility of the LLM-based video content summarization tool for summarizing health videos related to gastrointestinal endoscopy, we imported the 167 videos and collected the content summarized by the video content summarization tool. The summarized content was then evaluated in terms of accuracy, completeness, and readability (Figures 4A-C). LLM-based summaries yielded accuracy scores of 4 (4-5), completeness scores of 2 (1-2), and readability scores of 2 (1-2). None of the 3 scores were significantly different among the 3 gastrointestinal endoscopies.

Discussion

Major Findings

In this study, we reviewed the relevant videos about gastroscopy, colonoscopy, and capsule endoscopy posted on YouTube before October 2023. First, we collected basic information such as the number of plays, posting time, number of likes, number of dislikes, and VPI of these videos and categorized and summarized the video content in 5 aspects. Second, we evaluated the quality, reliability, and degree to which the related videos were recommended. Finally, we explored the value of the LLM-based video summarization tool for health-related videos.

Previous research has indicated that mDISCERN scores and GQS scores less than 3 often indicate lower quality and lower levels of recommendation [19]. In our study, the average mDISCERN score was 2.88 for gastroscopy-related videos and 2.93 for capsule endoscopy-related videos. Only 38.9% (67/167) of the videos were assigned an mDISCERN score higher than 3, and for GQS scores, the proportion of videos with a score higher than 3 was even lower. Moreover, only 23.4% (39/167) of the videos were assigned a value above 3 when considering both criteria. Therefore, the overall quality and recommendability of these videos were insufficient. A surprising conclusion is that even professionally produced videos are not always suitable for viewer recommendations. This phenomenon may be attributed to 3 potential reasons: first, a small number of videos were too specialized and not applicable to patients; second, some videos were broad and lacked in-depth information; and third, certain videos were outdated, had lower production quality, and offered a poor viewing experience. In the present study, the mean *JAMA* score for both gastroscopy- and colonoscopy-related videos was 2.29, while for capsule endoscopy-related videos, it was only 2.07. These results suggest that the reliability of gastrointestinal endoscopy videos currently available on YouTube is also questionable. Specifically, we discovered that the majority of video producers did not include references or additional sources of information. Furthermore, some physicians featured in the videos were hesitant to disclose their affiliation unless they were promoting a specific institution. These results are similar to those of previous studies in that some funded physician users did not explicitly disclose conflicts of interest in their YouTube videos [33]. This lack of transparency compromises the videos' reliability and adds to viewer distress. Fortunately, although many videos lacked sufficient information, we did not find any videos that provided clearly incorrect information. When assessing content, our radar chart analysis revealed that only a small number of videos mentioned the potential complications and side effects of endoscopy in the digestive system.

A previous study revealed that the quality of health-related videos varies among authors with different backgrounds [34]. Specifically, in the context of gastrointestinal endoscopy videos, except for the *JAMA* scores of the capsule endoscopy group, videos created by individuals with a medical specialty background demonstrated higher levels of quality and reliability than those produced by nonmedical users. While there was no significant discrepancy in the *JAMA* scores for capsule endoscopy between medical professionals and patients, videos created by professionals still scored higher on average. This outcome can be attributed to 2 potential reasons. First, professionals possess greater familiarity with clinical guidelines and the latest research findings, whereas nonprofessionals are more inclined to share personal experiences and lessons learned. Second, medical professionals are skilled at presenting relevant information coherently and in an organized manner, while videos produced by laypeople tend to be more relaxed and casual, which, to some extent, affects patient quality [35].

Video Education Is an Important Part of Patient Education

Health education plays a pivotal role in patient care [36]. Providing high-quality health education to patients not only enhances patient-physician collaboration and facilitates smoother treatment processes but also contributes to a partial reduction in complications and alleviates the health care burden on society [37]. A previous study demonstrated that physician-led telephone education improved patient preparation prior to gastrointestinal endoscopy, thus enhancing the detection of lesions in the digestive system [38].

With the increasing popularity of short video sharing platforms, increasingly more health-related short videos are becoming known to the public [39]. Compared to traditional text-based information, videos are more interesting and intuitive [40].

XSL•FO
RenderX

High-quality videos play a crucial role in enhancing patients' understanding of the disease and increasing the likelihood of their acceptance of treatment plans [41]. Additionally, they effectively alleviate patient anxiety and enhance satisfaction levels [42]. Therefore, the role of video platforms will become increasingly important in patient education.

The Use of AI in Health-Related Information Dissemination Is Debatable

AI has played a significant role in identifying fake health-related information, as evidenced by studies on the detection of COVID-19 misinformation through machine learning algorithms [43,44]. However, there is a lack of research on AI applications for content summarization and information extraction in health-related videos. The video summarization tool used in this study is based on the LLM model, which summarizes video content using the text and subtitles present within the video [15]. This subtitle-based AI video content summarization tool not only offers a quick summary of the video content but also strives to maintain consistency with the original video. Nonetheless, this approach has several limitations. Upon comparing the text generated by the LLM-based video summarization tool with the actual video content, we observed instances where the tool missed key points and overly emphasized minor details. Moreover, providing a summary solely based on subtitles means that the LLM tool does not truly "watch" the video or refine its content, potentially leading to the omission of valuable information provided by the video creators beyond the subtitles, thereby reducing the comprehensiveness of the summary. The computer graphics and live-action scenes provided in videos allow viewers to create visual impressions, a dimension that the LLM tool lacks in the summarization process. Significantly, the present study indicates that for videos that lack subtitles and rely solely on image presentations, the LLM summarization tool tends to rely on the video title, resulting in discrepancies in accuracy and completeness when compared to the actual video content. Therefore, while summarizing health-related videos using existing LLM-based video summarization tools can enhance viewers' information absorption efficiency to some degree, the nature of this approach suggests that it cannot truly serve as a substitute for the experience of watching a video, which enables viewers to form a more intuitive understanding of diseases and treatment techniques.

Limitations and Future Directions

This study has several limitations. First, only English videos posted on the YouTube platform were analyzed, making it challenging to directly generalize the findings to other platforms or videos in different languages. Second, the video content summarization plugin used in this study was developed based on ChatGPT (version 3.5), and a plugin based on ChatGPT (version 4.0) may yield improved performance.

Many current gastrointestinal endoscopy videos lack details on equipment makers and resolutions. Though not crucial for patient preparation, such information can help viewers better understand the equipment used during procedures. We suggest future videos include this data consistently. We recognize the absence of mandatory policies governing health education videos [40]. As video-sharing platforms continue to gain popularity, it becomes crucial to implement a certain level of censorship and regulation for videos disseminated on the internet. Government agencies and video-sharing platforms should establish a body composed of health care professionals dedicated to screening and monitoring health-related videos uploaded web-based and promptly identifying and flagging videos containing controversial information. Given the intricacy of medical content, we recommend that individuals with professional backgrounds in health care exercise caution when using specialized vocabulary when producing videos and strike a balance between popularity and the scientific nature of educational videos. This approach ensures that a broader audience can comprehend the information presented in the videos. Additionally, labeling the sources of arguments and information in the video will enhance its reliability and further improve viewers' acceptance of the content.

Conclusions

This study evaluated the information quality of videos discussing gastroscopy, colonoscopy, and capsule endoscopy on the YouTube platform. Overall, the videos exhibited an average relatively low quality. Notably, videos created by professionals had a higher level of reliability and quality than did those produced by nonprofessionals. We look forward to the availability of a greater number of high-quality gastroenterology-related videos in the future, as they greatly contribute to providing patients with valuable health-related information. Additionally, we urge the government to swiftly implement policies that curtail the dissemination of low-quality health-related videos.

Abstract

Background: Online health platforms are currently experiencing significant growth. Patients can conveniently seek medical consulting services on such platforms. Against the backdrop of the thriving development of digital health care, the patterns of physician-patient communication are undergoing profound changes. It is imperative to focus on physician discourse strategies during online physician-patient interactions, which will improve the efficiency of physician-patient communication and achieve better management of the physician-patient relationship.

Objective: This study aims to explore the influencing mechanism between physician discourse strategies and patient consultation behavior on online health platforms. Additionally, we explore the crucial mediating role of online physician-patient trust and the moderating role of shared decision-making in the online physician-patient communication process.

Methods: We used a mixed research approach to explore the influencing mechanism. Data on physician basic attributes and physician-patient communication text records were collected from the Chunyu Doctor website using a web spider. The study obtained a total of 8628 interaction texts from January 2022 to July 2023. Physician discourse strategies (capacity-oriented strategy, quality-oriented strategy, and goodwill-oriented strategy), online physician-patient trust, and shared decision-making were captured through text mining and a random forest model. First, we employed text mining to extract the speech acts, modal resources, and special linguistic resources of each record. Then, using a well-trained random forest model, we captured the specific discourse strategy of each interaction text based on the learned features and patterns. The study generated 863 groups of physician samples with 17 data fields. The hypotheses were tested using an "ordinary least squares" model, and a stability test was conducted by replacing the dependent variable.

Results: The capacity-oriented strategy, goodwill-oriented strategy, and quality-oriented strategy had significant effects on patient consultation behavior (β=.151, *P*=.007; β=.154, *P*<.001; and β=.17, *P*<.001, respectively). It should be noted that the anticipated strong effect of the capacity-oriented strategy on patient consultation behavior was not observed. Instead, the effects of the quality-oriented strategy and goodwill-oriented strategy were more prominent. Physician notification adequacy from shared decision-making moderated the effect between the goodwill-oriented strategy and patient consultation behavior (β=.172; *P*<.001). Additionally, patient expression adequacy from shared decision-making moderated the effect between the capacity-oriented strategy and patient consultation behavior (β=.124; *P*<.001), and between the goodwill-oriented strategy and patient consultation behavior (β=.104; *P*=.003). Online physician-patient trust played a significant mediating role between physician discourse strategies and patient consultation behavior.

XSL•FO
RenderX

Conclusions: The study findings suggest significant implications for stimulating patient consultation behavior on online health platforms by providing guidance on effective discourse strategies for physicians, thus constructing a trustworthy physician image, improving the physician-patient relationship, and increasing platform traffic.

KEYWORDS

online health consultation; physician discourse strategies; online physician-patient trust; shared decision-making; patient consultation behavior

Introduction

Background

Digital health service resources in China have experienced accelerated expansion, with over 26.7 million people receiving online medical services in 2022 [1]. Notably, online health platforms, such as "Haodf" [2], "Chunyu Doctor" [3], and "JD Health" [4], in China have emerged to offer online medical services, such as health condition assessment and treatment planning. Patients primarily use online health platforms to communicate with suitable physicians about their health conditions. This behavior is commonly called "patient consultation behavior."

Compared with offline consultation, the emergence of online health platforms has helped foster a 2-way, interactive, and democratic environment for both physicians and patients [5], but new problems have emerged. The patient consultation behavior during the online physician-patient communication process is invisible, and patients often exhibit higher levels of anxiety and eagerness to receive valuable health suggestions [6]. Moreover, it is impossible to ensure a constant online presence for both physicians and patients. These aspects may result in the quality of online consultation services for patients being compromised on the platform.

Ancient Greek scholar Hippocrates, the father of Western medicine, said, "There are two elements in the world effective of curing disease: medicine and language." In other words, the language used by physicians plays a crucial role in enhancing the treatment effectiveness and ensuring patients' well-being. At the beginning of online health consultation, patients select the physician who can fulfill their health care demands in terms of their disease, health condition, and preferred communication style. The physician's title and history of peer-patient consultation are important references for potential patients to make consulting decisions. The texts entered by physicians in the chat box often encompass the diagnosis of patients' conditions, their concerns and empathy, and the recommended treatment plans. It is crucial for physicians to communicate with patients smoothly and trustworthily by optimizing their discourse strategies, which is beneficial for stimulating patient consultation behavior. Research on physician discourse strategies in online medical consultation can provide insights into the relationship management between physicians and patients [7]. Some scholars analyzed the construction of the physician image from the perspective of language application by using qualitative research methods. It has been proven that physicians can help patients comprehend their health conditions by using reasonable, logical, and well-intended language, enabling shared decision-making and fostering rapport between both parties [8-10]. However, few studies have specifically explored the impact mechanism of physician discourse strategies on patient consultation behavior from the perspective of pragmatics, with the use of quantitative analysis.

Unlike the interaction process on other platforms, online health platforms require attentive and thorough services at every stage. Maintaining a strong and trustworthy relationship between physicians and patients greatly benefits the health management quality of patients. The "virtualized," "fragmented," and "casual" communication nature during online health consultation can exacerbate tensions in the physician-patient relationship [11]. These platforms and physicians face the critical stage of establishing trust. Thus, it becomes essential to consider patient consultation behavior from the perspective of trust. In addition, shared decision-making is a personalized diagnosis and communication method that was introduced by Veatch [12] in 1972. Veatch argued that shared decision-making would greatly impact the quality of physician-patient communication and medical care. Physician-patient shared decision-making is considered crucial for strengthening trust, improving communication, and enhancing the effectiveness of medical diagnosis [13]. Consequently, shared decision-making could be a significant factor affecting the relationship between discourse strategies and patients' online consultation behavior.

Our research aims to contribute to the existing literature on patient consultation behavior by addressing 2 research objectives. First, we aim to investigate the correlation between physician discourse strategies and patient consultation behavior. Second, we seek to determine the significance of online physician-patient trust and shared decision-making in relation to the interplay between physician discourse strategies and patient consultation behavior. Based on these research objectives, we propose the following three research questions:

1. What is the relationship between physician discourse strategies and patient consultation behavior?
2. How do physician discourse strategies influence patient consultation behavior by influencing the construction of online physician-patient trust?
3. What role does shared decision-making play between physician discourse strategies and patient consultation behavior?

XSL•FO

Research Model and Hypotheses

Physician Discourse Strategies and Patient Consultation Behavior

In 1984, Frankel [14] defined physician-patient communication as the "process of exchanging information between a doctor and a patient, which is influenced by various psychological factors and their interactions." Multiple studies have focused on the direct effects of communication style on communication outcomes [15]. We also identified that physicians often use linguistic and discursive tools to convey medical suggestions and express empathy, which can profoundly influence patients' decision-making during consultations. We refer to these communication strategies as "physician discourse strategies."

The SOR (stimulus, organism, and response) model was proposed by Mehrabian and Russell [16] in 1974. This psychological theory explains that environmental factors act as stimuli (S) that first influence an individual's psychological state (O), which in turn affects their behavioral responses (R) [17,18]. In the context of online health platforms, patients encounter a wealth of external information (eg, titles, service volume, prices, etc) before and during interactions, which can stimulate their engagements, including patient consultation behavior [5,18-20]. Aligning with the SOR theory, we examined the discourse strategy employed by physicians as external stimuli received by patients, exploring their potential impact on patient consultation behavior.

Among the essential elements of these texts, language shapes not only the content of the message (ie, what is said?) but also the style (ie, how is it said?) [21]. Most studies addressed how physicians' communication skills during consultation interactions (eg, response speed [22], interaction depth [23], and interaction rounds [24]) can shape patients' perceptions and influence their behavioral outcomes. Unskillful responses to patients' inquiries can not only place extra burden on physicians but also discourage patients from seeking consultation services online [21]. Additionally, scholars found that a physician with high-quality content responses [25-27], proper emotional expressions [26], the right response time [22,25], and in-depth interactions [25,28], can support a patient's willingness to consult on online health platforms. These findings indicate that the appropriate use of discourse strategies is crucial and necessary, especially in the online interaction environment. However, these studies about physician discourse strategies are still in their infancy. Existing research has primarily focused on the superficial characteristics during physician-patient communication, neglecting the complexity of the discourse strategies employed and the foundational structures that inform them. In the study by Wu et al [27], discourse strategies were constructed according to the response time, detailed style, and emotional comfort, with the aim of investigating their effects on patient consultation satisfaction. We have incorporated insights from this study into our own research, but we delve deeper into the application of linguistic resources within physician discourse strategies. Based on the SOR theory and existing research, our research first focuses on the impact of physician discourse strategies on patient consultation behavior. We propose the following hypothesis: different types of physician discourse strategies have varying positive effects on patient consultation behavior (H1).

Trust is crucial for effective physician-patient communication, and online health platforms must prioritize building patients' trust, which helps potential patients transition from curious observers to customers who are willing to use the platform for health consultation [29]. The trust theory proposed by Mayer et al [30] in 1995 identifies trust in 3 main dimensions: capability, quality, and goodwill. In line with the trust theory by Mayer et al [30], we categorized discourse strategies into the following: capacity-oriented strategy, quality-oriented strategy, and goodwill-oriented strategy.

The capacity-oriented strategy indicates that physicians highlight their professional skills and experiences, and show personal authority in the communication process [31]. Demonstrating such professional competencies can foster patient consultation behavior [32]. The goodwill-oriented strategy reflects that physicians are patient-centered, fulfill the needs of patients, patiently guide patients to overcome their negative emotions, and comfort their fragile hearts during communication. Empathetic communication that is easily understood by the patient can help manage expectations, ensure follow-up and treatment adherence, and improve the perception of the entire health care experience [33,34]. Such strategies may be conducive to fostering a willingness among patients to use the platform for health consultations. The quality-oriented strategy emphasizes that physicians focus on their professional code and show sincerity, honesty, and reliability in the communication process. By conveying such a communication style, physicians can foster a sense of professional quality in their interactions, thereby increasing patient trust and willingness to engage [35,36].

In combination with H1, we propose the following hypotheses: the capacity-oriented strategy enhances patient consultation behavior (H1a); the goodwill-oriented strategy enhances patient consultation behavior (H1b); and the quality-oriented strategy enhances patient consultation behavior (H1c).

Physician-Patient Trust

Trust is a complex dynamic that exists among individuals, organizations, and events, involving uncertainties and expectations regarding the future actions of one party by another [37,38]. Most physicians and patients communicate and interact by sending texts or audio in the chat box. Moreover, given the constraints of the online environment and the offline working hours of physicians, it is impossible to ensure a constant online presence for both physicians and patients. Patients need to share their health conditions with physicians, even those involving some private information. The establishment of trust may determine whether the patient consults and honestly shares necessary information with the doctor [39]. Thus, trust could be even more critical in the online health care environment due to individuals' higher levels of information sensitivity and the existence of uncertainty and a lack of regulation [11].

Online trust is generated on an internet platform, where the trustor possesses attributes that benefit the trustee [40]. Online trust (eg, trust in websites, online news, and social networking

XSL•FO
RenderX

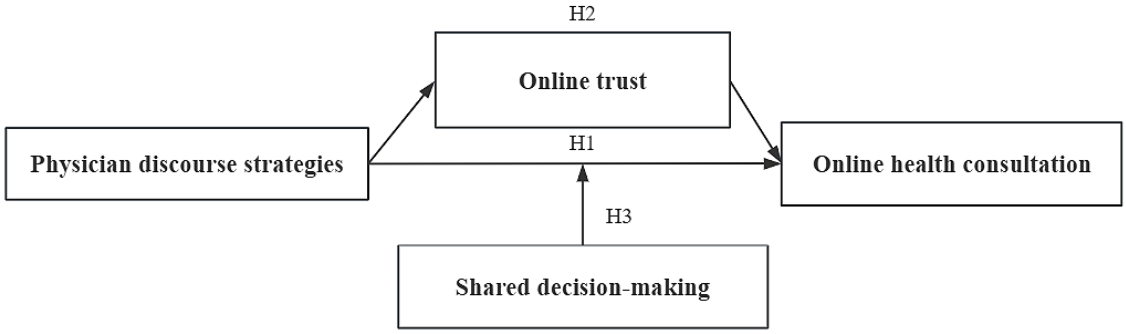
site providers) has been studied extensively [41-44]. Notably, some studies have revealed that online trust strongly influences online purchase behavior [45]. In the health care sector, the influencing factors of trust are commonly studied in online health platforms, but there is less discussion on the influence of online trust on patient behavior. The establishment of trust between physicians and patients on online health platforms is often influenced by the physician's title, gender, and reputation [46-48]. A physician's service quality, empathy expression, average word count, and cumulative number of sessions, and the physician-patient session ratio significantly impact physician-patient trust [49,50]. Patient self-disclosure of personal information during consultations leads to increased satisfaction and trust [51,52]. The attributes, quantity, length, sentiment orientation, and composition of negative feedback in physician-patient interactions similarly influence the formation of trust between physicians and patients.

Therefore, in line with the SOR model, we conducted supplementary research on the mediating role of online physician-patient trust in the interaction between physician discourse strategies and patient consultation behavior. Hence, we propose the following hypotheses regarding the mediating role of online trust: online physician-patient trust mediates between physician discourse strategies and patient consultation behavior (H2); online physician-patient trust mediates between the capacity-oriented strategy and patient consultation behavior (H2a); online physician-patient trust mediates between the goodwill-oriented strategy and patient consultation behavior (H2b); and online physician-patient trust mediates between the quality-oriented strategy and patient consultation behavior (H2c).

Shared Decision-Making

The concept of shared decision-making was initially introduced by Veatch [12] in 1972 in the article "A Model for Medical Ethics in a Revolutionary Era." Later, in 1997, Charles et al [53] further elaborated on the meaning of shared decision-making and proposed the following four crucial elements that it should encompass: (1) the participation of 2 parties; (2) the exchange of information between both parties; (3) the achievement of consensus on the treatment plan; and (4) the implementation of specific actions by both parties. Since then, shared decision-making has gained significant attention in the medical field, primarily due to the increasing emphasis on patients' right to access information and their demand for satisfactory medical care [53]. Shared decision-making promotes the transformation of the patient's role from a passive recipient of medical care to an active participant and supervisor, fully embracing the concept of "patient centeredness."

Shared decision-making is a common topic in physician-patient communication and relationship management, which has been widely accepted and applied in the medical field. Some studies have proven the significance of shared decision-making in the quality and process of physician-patient communication by using qualitative methods [54,55]. Veatch [12] argued that shared decision-making would greatly impact the quality of physician-patient communication and medical care. Both patients and physicians tend to overestimate the potential benefits of interventions, and shared decision-making has been proven to be useful in influencing expectations and beliefs [56,57]. Some scholars also developed shared decision-making assessment scales [58-60] and explored the factors influencing participation in shared decision-making to gain better behavioral outcomes [61,62].



Shared decision-making could be a significant factor affecting the relationship between discourse strategies and patient online consultation behavior. However, the research issue of how shared decision-making affects the shaping process of patient behavior has not been solved, especially in the online health care environment. Under the shared decision-making philosophy, 2-way communication helps to prevent the distortion or loss of information that can result from 1-way communication, ensuring that decisions are more aligned with the best interests of the patient. Through shared decision-making, patients can gain a more comprehensive understanding of their condition and treatment options, thereby enhancing their adherence to the prescribed treatment regimen [58] and encouraging high-quality communication and patient well-being. Shared decision-making may indirectly moderate the impact of physician discourse strategies on patient consultation behavior by enhancing patient engagement, regulating physician discourse strategies, and improving medical communication.

In this study, our research objective was to clarify how shared decision-making moderates the influence of physician discourse strategies on patient consultation behavior in online health platforms, and thus, the following hypotheses are proposed: shared decision-making moderates the effect of physician discourse strategies on patient consultation behavior (H3); shared decision-making moderates the effect of the capacity-oriented strategy on patient consultation behavior (H3a); shared decision-making moderates the effect of the goodwill-oriented strategy on patient consultation behavior (H3b); and shared decision-making moderates the effect of the quality-oriented strategy on patient consultation behavior (H3c).

Figure 1 shows our research model. The research explores the relationship between physician discourse strategies and patient consultation behavior on online health platforms (H1 and H1a-H1c), the possible mediating role of online physician-patient trust (H2 and H2a-H2c), and the moderating role of shared decision-making (H3 and H3a-H3c) in the above process.

Methods

Data Collection

Registered physicians on the Chunyu Doctor website are the research subjects of this paper. Chunyu Doctor, a platform with over 660,000 physicians from governmental hospitals, offers medical services to over 140,000,000 patients.

Our research explores the relationship between physician discourse strategies and patient consultation behavior while also contemplating the influences of online physician-patient trust and shared decision-making. We collected data in 2 main categories. The first category involved the basic attributes of physicians, such as gender and title. The second category involved the texts extracted from online physician-patient communication records. These anonymized patient consultation records are publicly accessible and serve as typical cases for our research [63]. We used a web spider to crawl and collect physician-patient interaction data from the "Positive Q&A" module on the Chunyu Doctor website from January 2022 to July 2023. These interaction data include information, such as consultation time, topic summary, and specific consultation text records. In total, we collected the basic attribute data of 863 physicians and 10 communication text records displayed by each doctor (8628 groups of physician-patient communication texts in total). These data cover a wide range of medical specialties, including 15 first-level departments and 43 second-level departments, with 201 groups of data per second-level department. Taking the pediatrics department as an example, we collected the attribute data of 40 physicians in the neonatology and pediatrics departments and 400 interactive text records. These texts were very complete, recording the whole physician-patient communication process.

Ethical Considerations

This study has been reviewed and approved by the Institutional Review Board of the School of Economics and Management, Beihang University (BE-202306082). All research procedures comply with the ethical guidelines and standards set by the Institutional Review Board. The data employed in this study were deidentified interaction texts from patients, ensuring that all personal information had been anonymized in accordance with ethical guidelines. Some private data, such as the patient's name, private disease data, and image examination records, were hidden.

Variable Measurements

The main variables examined in this study were discourse strategies, patient consultation behavior, online physician-patient trust, and shared decision-making. The description and measurement of each variable are presented in Table 1.

For the measurement of these variables, we employed text mining to analyze the physician-patient interaction texts that were scraped and applied random forest to predict the specific discourse strategy used by physicians. The data processing for all variables is illustrated in Figure 2, which will be elaborated upon in detail below. Given that the focus of this research is the physician, the data must be matched and integrated individually according to the physician ID. The integration method (summation or averaging) was employed to depict different variables regarding the performance of each physician. Ultimately, a total of 8628 data groups were integrated on a one-to-one correspondence basis with physicians, resulting in a sample dataset of 863 physicians. Each dataset included 17 data fields.

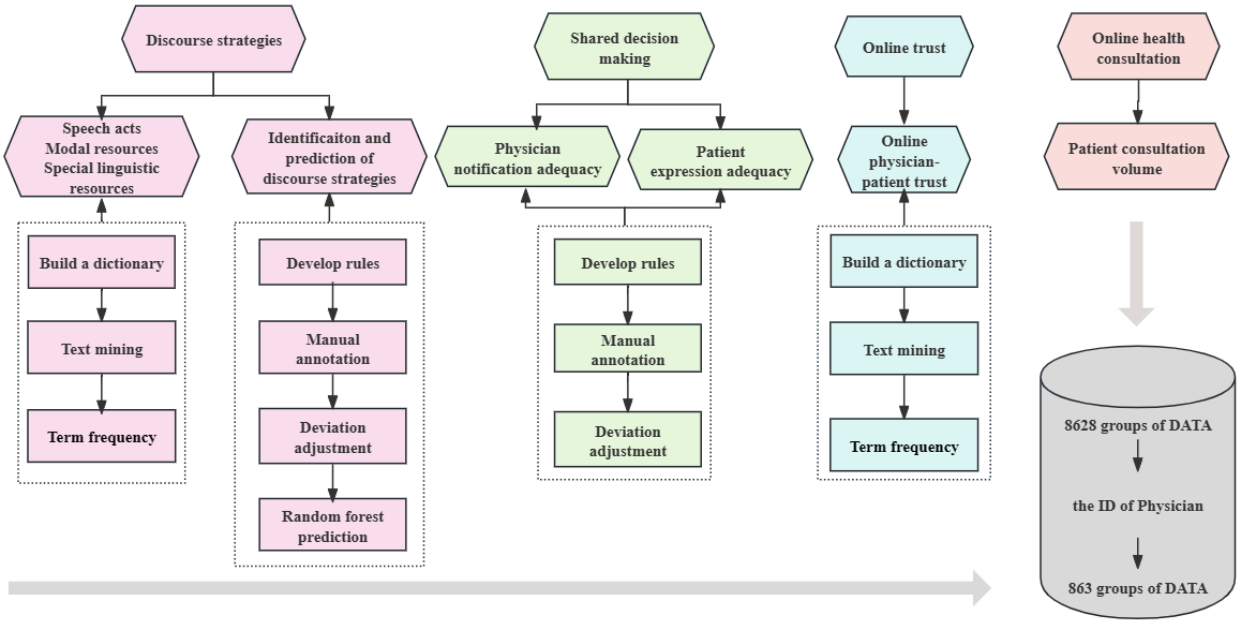
Table 1. Variables and their measurements.

Variables and dimensions	Measurements
Dependent variables	
Patient consultation behavior	
Patient consultation volume	It represents the number of physicians (*i*) offering online consultation service in (*t*) time.
Patient satisfaction	It represents patients rating their physicians based on their consultations.
Independent variables	
Gender	
Male	1
Female	2
Title	
Resident physician	1
Attending physician	2
Associate chief physician	3
Chief physician	4
Department	
First-level department	It is divided into 15 first-level departments, including obstetrics, pediatrics, internal medicine, surgery, etc.
Analyzing variables	
Discourse strategies	
Capacity-oriented strategy[a]	 Physician (*i*) highlights professional skills and experiences, and shows personal authority in (*t*) time.
Goodwill-oriented strategy[b]	 Physician (*i*) is patient-centered, fulfills the needs of patients, patiently guides patients to overcome their negative emotions, and comforts their fragile hearts in the communication process in (*t*) time.
Quality-oriented strategy[c]	 Physician (*i*) emphasizes that physicians focus on their professional code and show sincerity, honesty, and reliability in (*t*) time.
Shared decision-making	
Physician notification adequacy	Physicians should be fully informed about alternative treatment options, including their advantages and disadvantages. Take the value of 1 if physicians exhibit the above characteristics; otherwise, take the value of 0.
Patient expression adequacy	Patients should openly communicate their views, concerns, values, and preferences to the physician. Take the value of 1 if patients exhibit the above characteristics; otherwise, take the value of 0.
Trust	
Online physician-patient trust	The term frequency of words, such as “trustworthy,” “enthusiastic,” “conscientious,” and “effective,” is used to indicate the patient’s recognition of the treatment plan provided by the physician.



[a]The abbreviations for the equation are as follows: COS: capability-oriented strategy; ASA: assertive speech acts; ISA: indicative speech acts; AMR: affirmative modal resources; MT: medical terminology.

[b]The abbreviations for the equation are as follows: GOS: goodwill-oriented strategy; ESA: expressive speech acts; FD: first-person deixis; H: honorifics; E: emojis.

[c]The abbreviations for the equation are as follows: QOS: quality-oriented strategy; RSA: refusal speech acts; CSA: committed speech acts; VMR: vague modal resources; IS: interrogative sentences.

XSL•FO
RenderX

Figure 2. Data processing.

Discourse Strategies

We classified discourse strategies into 3 categories: capacity-oriented strategy, quality-oriented strategy, and goodwill-oriented strategy, which were derived from the trust theory by Mayer et al [30]. To describe discourse strategies by the linguistic characteristics of speech acts, modal resources, and special linguistic resources, we have provided details in Table 2.

In describing discourse strategies, Searle and Vanderveken [64] proposed the speech act theory and categorized speech acts into 5 types based on grammatical indicators, including assertive speech acts, indicative speech acts, refusal speech acts, expressive speech acts, and committed speech acts [64,65]. The use of modal resources can also impact physician-patient communication quality [26]. First-person deixis, emojis, honorifics, and other special linguistic resources often appear in the consultation texts. The inclusion of first-person deixis facilitates the psychological convergence between physicians and patients, effectively shortening the psychological distance between the 2 parties [66]. Additionally, the appropriate use of medical terminology demonstrates the physician's professional proficiency, fostering trust among patients [67,68]. Therefore, this paper proposes that discourse strategies used by physicians are communication strategies that appear during physician-patient interactions, regulating the way physicians exchange information and convey their emotions through the use of speech acts, modal resources, and special linguistic resources.

We calculated term frequencies corresponding to the variables according to dictionaries, which were divided into 2 categories. The first involved summarizing frequently occurring words in the physician-patient interaction texts and using the Chinese word segmentation dictionary to establish the speech act dictionary, modal resource dictionary, and special linguistic resources dictionary. The second was used to calculate the term frequency of medical terminology. We used a Chinese medical vocabulary dictionary with approximately 18,000 words, covering various dimensions, such as symptoms, drugs, medical tests, and diseases.

We then identified the discourse strategies of each text. To achieve this, we used a combination of artificial labeling and random forest for discourse strategy identification. Initially, we formulated the mathematical and semantic features of these discourse strategies. Subsequently, we analyzed the mean value of the data fields grouped by physician ID. To ensure robustness, we enlisted the help of 5 experts, either working in the medical field or studying medical-related majors. They grouped all interaction texts according to first-level departments and randomly selected 100 groups of texts for strategy identification. Each of the 5 experts independently labeled the sampled data for the 15 groups of first-level departments. To gauge the consistency of strategy identification, the identification results were cross-checked against 5 copies of each text, and the identification rules were revised accordingly. The iterative process was repeated until the labeling differences were negligible. Overall, the final average consistency for each first-level department approached over 95%.

XSL•FO
RenderX

Table 2. Linguistic characteristics index system.

Linguistic characteristics and index	Description
Speech acts	
Assertive speech acts	Physicians judge the patient's condition, medication, diagnosis plan, etc.
Indicative speech acts	Physicians indicate the patient to do something.
Refusal speech acts	Physicians express denial and disapproval of something.
Committed speech acts	Physicians promise to do something.
Expressive speech acts	Physicians express empathy and reassurance for the patient's condition, experience, etc.
Modal resources	
Affirmative modal resources	Physicians use words with a strongly positive attitude.
Vague modal resources	Physicians use words with an ambiguous attitude.
Special linguistic resources	
Interrogative sentences	Term frequency of the words used by physicians to express a questioning tone.
First-person deixis	Term frequency of first-person indicative words used by physicians such as "I" and "we."
Honorifics	Term frequency of the words used by physicians to express respect for patients.
Emojis	Frequency of emojis used by physicians.
Medical terminology	Term frequency of specialized words used by physicians such as disease, medication, symptoms, and diagnosis.

Finally, a random forest algorithm was used to predict the remaining unlabeled samples. Overall, 20% of the data items with discourse strategy labels were used as test sets and 80% were used as learning sets. The algorithm had good classification performance and met the classification requirements, with a test accuracy of 85.1% and *F*-score of 0.915. The data items with blank discourse strategies were predicted and filled. Using the well-trained random forest model, we predicted the unlabeled samples in the 8628 interaction texts. The model automatically filled in the corresponding discourse strategy labels for each unlabeled interaction text based on the learned features and patterns. This process not only improved the efficiency of data annotation but also provided a more comprehensive data foundation for subsequent analysis.

Additionally, we have presented examples of physician-patient interaction texts that exemplify each of the 3 main discourse strategies to enhance readers' comprehension of their specific meanings in Multimedia Appendix 1.

Online Physician-Patient Trust

We established an online trust expression word dictionary and calculated the level of online trust between physicians and patients by analyzing the frequency of relevant expression words in patient texts. Words, such as "trustworthy," "enthusiastic," "conscientious," and "effective" were used to indicate the patient's recognition of the treatment plan provided by the physician.

Patient Consultation Behavior

Most of the research on patient consultation often uses patient conversion rates, service volume, and patient satisfaction as feedback [25,69,70]. To measure patient consultation behavior, we used physician consultation volume on the Chunyu Doctor website, which is part of the basic physician attribute data.

Shared Decision-Making

The concept of shared decision-making highlights 2 important aspects. First, physicians should be fully informed about alternative treatment options, including their advantages and disadvantages. Second, patients should openly communicate their views, concerns, values, and preferences to physicians. Therefore, 2 primary indicators of shared decision-making were designed to encompass the above meanings: physician notification adequacy and patient expression adequacy.

The measurement of shared decision-making was mainly conducted through the formulation of label rule development, manual labeling, and bias adjustment. Initially, we proposed the key labeling rules of shared decision-making based on a literature search, medical knowledge, and text comprehension. Subsequently, the texts were organized and grouped within each first-level department. Five experts, either working in the medical field or studying medical-related majors, were selected to assess the 2 indicators of shared decision-making for each text in each department.

Modeling and Statistical Analysis

Ordinary Least Squares Model

Before testing the main effects, moderating effects, and mediating effects, we conducted a general descriptive analysis to describe the basic attributes of physicians and the textual information on physician-patient interactions. Subsequently, a bivariate correlation model was used to test the correlations between patient consultation behavior and other variables.

We then proceeded with the test of main effects, which primarily explored the influence of discourse strategies (capacity-oriented strategy, quality-oriented strategy, and goodwill-oriented strategy) on patient consultation behavior. Additionally, we conducted the test of moderating effects, which explored the influence of shared decision-making on patient consultation

XSL•FO
RenderX

behavior, and the test of mediating effects, which examined the mediating role of online physician-patient trust between discourse strategies and patient consultation behavior. The empirical models pertaining to these tests were as follows:

Main effects model: $Patient\ consultation\ behavior_i = \beta_0 + \beta_1 COS_i + \beta_2 GOS_i + \beta_3 QOS_i + \beta_4 Control + \varepsilon$

Mediating effects model: $Ln\ Patient\ consultation\ behavior_i = \alpha_0 + Ln\ Discourse\ stategies_i$; $Ln\ w = \beta_0 + \beta_1 Ln\ Discourse\ stategies_i + \varepsilon$; $Ln\ tPatient\ consultation\ behavior_i = \beta_0 + \beta_1 Ln\ Discourse\ stategies_i + \beta_2 Ln\ Online\ physician\text{-}patient\ trust_i + \varepsilon$

Moderating effects model: $Patient\ consultation\ behavior_i = \beta_0 + \beta_1 COS_i + \beta_2 GOS_i + \beta_3 QOS + \beta_4 COS_i \times SDM_i + \beta_5 GOS_i \times SDM_i + \beta_6 QOS_i \times SDM_i + \beta_7 Control + \varepsilon$

Control variables include the gender, title, and department of the physician. ε represents the error term. Previous research has shown that physician gender can impact patient interactions, communication styles, and potentially patient satisfaction [46,71,72]. The title of a physician can influence patient perceptions and expectations [72]. Patients may respond differently based on the physician's level of experience or expertise, which could affect their consultation behavior. In addition, physicians from different departments may have varying approaches to communication and may encounter different patient demographics or types of consultations [73].

Next, we analyzed the data using the ordinary least squares regression model to test for main effects, moderating effects, and mediating effects. Stata (StataCorp) was used for the analysis, and all variables were standardized in the regression.

Results

Descriptive Statistics

Our dataset encompassed 863 physicians providing online health consultation services to 77,248 patients. The online health consultations specifically pertain to 15 first-level departments, including internal medicine, surgery, obstetrics, pediatrics, oncology, and prevention and treatment. Among the 863 physicians, there were 637 male physicians and 226 female physicians from 15 departments. The plastic and cosmetic department had the fewest physicians (n=18), while the surgery department had the most physicians (n=197). Attending physicians had the highest count (n=411), while chief physicians had the lowest count (n=83). The 863 physicians had an average of 7847.81 total patient consultations and a mean patient satisfaction rate of 98.53%. Among the 3 types of discourse strategies, the largest number of physicians (n=347) employed the capacity-oriented strategy. Moreover, 411 physicians on the online health platform were primary care physicians. The descriptive statistics are shown in Table 3.

Oncology department	59 (6.8)

Pearson Correlation Analysis and Collinearity Testing

As shown in Table 4, patient consultation volume had the highest positive correlation with the goodwill-oriented strategy (r=0.261; P=.008). Patient consultation satisfaction showed positive correlations with the capacity-oriented strategy (r=0.282; P=.008), quality-oriented strategy (r=0.271; P=.003), goodwill-oriented strategy (r=0.122; P=.005), and physician notification adequacy (r=0.187; P=.003).

When there is a high correlation between 2 independent variables, the existence of one variable may cause the regression coefficient of the other variable to rise sharply. Collinearity becomes a problem in regression analysis, but this does not mean that this variable has no predictive effect on the dependent variable. Because the correlation coefficient between the quality-oriented strategy and capacity-oriented strategy was high (more than 0.7), there might have been a multiple collinearity issue. Thus, this study used variance inflation factor (VIF) testing to examine the collinearity between the 2 variables.

In the regression model, the VIF can measure the severity of multicollinearity. It is generally believed that if the VIF value is greater than 10, there is a multicollinearity problem (strictly greater than 5) [74]. We conducted collinearity analysis on physician discourse strategies, the capacity-oriented strategy, the quality-oriented strategy, the goodwill-oriented strategy, physician notification adequacy, patient expression adequacy, online physician-patient trust, and patient consultation satisfaction, and found that the VIF values of these variables were 1.398, 4.768, 4.803, 1.667, 1.245, 1.510, 1.096, and 2.083, respectively. All VIF values of the variables were lower than 5, indicating that there was no serious collinearity issue among the independent variables in this study.

Hypothesis Testing

Our research focused on the Chunyu Doctor platform, a leading online health market in China with a significant number of physician and patient registrations. We investigated the impact

XSL•FO
RenderX

of physician discourse strategies on patient consultation behavior in this online health platform. To validate our research models, we first examined the relationship between physician discourse strategies (capacity-oriented strategy, quality-oriented strategy, and goodwill-oriented strategy) and patient consultation behavior. Then, we introduced moderating variables, namely physician notification adequacy and patient expression adequacy, into the model. This allowed us to test our main effects hypotheses (H1, H1a-H1c) as well as the moderating effect of shared decision-making between physician discourse strategies and patient consultation behavior (H3, H3a-H3c). The regression results are summarized in Table 5.

The capacity-oriented strategy, goodwill-oriented strategy, and quality-oriented strategy had significant effects on patient consultation behavior (β=.151, *P*=.003; β=.154, *P*<.001; and β=.170, *P*<.001, respectively). It should be noted that the anticipated strong effect of the capacity-oriented strategy on patient consultation behavior was not observed. Instead, the effects of the quality-oriented strategy and goodwill-oriented strategy were more prominent.

We then conducted a test on the moderating effects. The interaction term between the capability-oriented strategy and physician notification adequacy did not show significance (β=.062; *P*=.62), while the interaction term between the capability-oriented strategy and patient expression adequacy showed significance (β=.124; *P*<.001). This suggests that there is a significant difference in the effect of the capability-oriented strategy on patient consultation behavior at different levels of the moderating variable (patient expression adequacy).

Similarly, the interaction term between the goodwill-oriented strategy and physician notification adequacy was significant (β=.172; *P*<.001), indicating that the effect of the goodwill-oriented strategy on patient consultation behavior varies significantly at different levels of the moderating variable (physician notification adequacy).

In addition, the interaction term between the goodwill-oriented strategy and patient expression adequacy showed significance (β=.104; *P*=.003), suggesting that the effect of the goodwill-oriented strategy on patient consultation behavior differs significantly at different levels of the moderating variable (patient expression adequacy).

The interaction term between the quality-oriented strategy and physician notification adequacy did not show significance (β=.013; *P*=.23). Similarly, the interaction term between the quality-oriented strategy and patient expression adequacy did not show significance (β=.033; *P*=.42). This implies that the effect of the quality-oriented strategy on patient consultation remains consistent at different levels of the moderating variable.

Figure 5. Moderating role of patient expression adequacy with the goodwill-oriented strategy.

Next, our study examined the mediating role of online physician-patient trust using the nonparametric percentile bootstrap method to test the mediating effects, as shown in Table 6. Physician discourse strategies significantly affected patient consultation behavior (β=.292; *P*<.001). The capacity-oriented strategy significantly affected patient consultation behavior (β=0.260; *P*<.001). The quality-oriented strategy significantly affected patient consultation behavior (β=.223; *P*<.001). The goodwill-oriented strategy significantly affected patient consultation behavior (β=.075; *P*<.001). It involved repeating the sampling 2000 times and estimating 95% CIs. If the CI does not include zero, it indicates a significant mediating effect [75]. In our analysis, online physician-patient trust (95% CI 0.724-0.743) was found to mediate the relationship between physician discourse strategies and patient consultation behavior, with a mediation effect value of 0.348. The mediating effect of online physician-patient trust on the relationship between the capacity-oriented strategy and patient consultation behavior showed a value of 0.031. Additionally, the mediating effect of online physician-patient trust on the relationship between the quality-oriented strategy and patient consultation behavior showed a value of 0.042. Moreover, the mediating effect of online physician-patient trust on the relationship between the goodwill-oriented strategy and patient consultation behavior showed a value of 0.095. Likewise, the goodness-of-fit of the mediating effect model between online physician-patient trust in the 3 dimensions of physician discourse strategies and patient consultation behavior reached the standard (χ^2/df <5; comparative fit index [CFI] >0.9; Tucker-Lewis index [TLI] >0.9; root mean square error of approximation [RMSEA] <0.08; standardized root mean square residual [SRMR] <0.5).

Robustness Testing

This section primarily aims to validate the stability of the derived model and establish the validity of the research conclusions. In this study, patient consultation volume was considered as a variable representing patient consultation behavior. However, patients on online health platforms can rate the physicians they interact with. Thus, patient consultation satisfaction is considered as an alternative variable for patient consultation behavior [25,69,70], which replaced patient consultation volume and was included in the regression analysis model. The robustness testing results are presented in Table 7, reconfirming the earlier findings and indicating the relatively stable nature of this study's results.

The capacity-oriented strategy, goodwill-oriented strategy, and quality-oriented strategy had significant effects on patient consultation behavior (β=.169, *P*=.002; β=.274, *P*<.001; and β=.357, *P*<.001, respectively). Physician notification adequacy from shared decision-making moderated the effect between the goodwill-oriented strategy and patient consultation behavior (β=.153; *P*<.001). Patient expression adequacy from shared decision-making moderated the effect between the capacity-oriented strategy and patient consultation behavior (β=.121; *P*<.001) and between the goodwill-oriented strategy and patient consultation behavior (β=.106; *P*=.03).

Furthermore, we employed the nonparametric percentile bootstrap method to test the significance of the mediating effects. The results are shown in Table 8. This involved repeating the sampling 2000 times and estimating 95% CIs. If the CI does not include zero, it indicates a significant mediating effect. In our analysis, online physician-patient trust (95% CI 0.002-0.061) was found to mediate the relationship between physician discourse strategies and patient consultation behavior, with a mediation effect value of 0.014. The mediating effect of online physician-patient trust on the relationship between the capacity-oriented strategy and patient consultation behavior showed a value of 0.034. Additionally, the mediating effect of online physician-patient trust on the relationship between the quality-oriented strategy and patient consultation behavior showed a value of 0.038. Moreover, the mediating effect of online physician-patient trust on the relationship between the goodwill-oriented strategy and patient consultation behavior showed a value of 0.077. Likewise, the goodness-of-fit of the mediating effect model between online physician-patient trust in the 3 dimensions of physician discourse strategies and patient consultation behavior reached the standard (χ^2/df <5; CFI >0.9; TLI >0.9; RMSEA <0.08; SRMR <0.5).

Discussion

Principal Findings

The study confirmed that the 3 primary discourse strategies (capacity-oriented strategy, quality-oriented strategy, and goodwill-oriented strategy) used by physicians have positive impacts on patient consultation behavior. It should be noted that the anticipated strong effect of the capacity-oriented strategy on patient consultation behavior was not observed. Instead, the effects of the quality-oriented strategy and goodwill-oriented strategy were more prominent. Physician notification adequacy from shared decision-making moderated the effect between the goodwill-oriented strategy and patient consultation behavior. Patient expression adequacy from shared decision-making moderated the effect between the capacity-oriented strategy and patient consultation behavior, and between the goodwill-oriented strategy and patient consultation behavior. Online physician-patient trust played significant mediating roles between physician discourse strategies and patient consultation behavior.

Theoretical Implications

This study addresses the gap in research on the influence of physician discourse strategies on patient consultation behavior, providing a new perspective and theoretical basis for the study of the antecedents of patient consultation behavior, especially in the online health environment. Previous studies on patient consultation behavior have mainly focused on influencing factors, such as text amount, response time, negative emotions, empathy, and information disclosure exhibited in physician texts [25,26,69,74]. Few studies have focused on the influence of discourse strategies on patient consultation behavior. Furthermore, this research extends the SOR theory, speech act theory, and trust theory by Mayer et al [30] to the study of patient behavior on online health platforms. Linguistic characteristics of physician texts are used to depict discourse strategies, including speech act features, modal resource features, and special linguistic resource features.

Moreover, the dimensions of research on the characterization of physician discourse strategies have been expanded. The study identified the significant value of managing physician discourse strategies in stimulating patient consultation behavior. Our findings demonstrate that physicians on the platform are required to have comprehensive expressions, in-depth knowledge of the patient's health condition, and accountability to the patient. This is more important than simply showing professional competence to enhance both the quantity and quality of consulting services. The results are counterintuitive, revealing that a quality-oriented strategy has a greater positive impact on patient consultation behavior compared to a goodwill-oriented strategy and capacity-oriented strategy, which have weaker effects. The findings suggest that physician discourse strategies that minimize the use of strong words, focus on comprehensive questioning about the patient's condition, and take responsibility for the patient's well-being are crucial for stimulating potential patients to seek the first consultation and reconsultations. Additionally, the use of emojis, first-person deixis, and honorifics can help physicians build rapport with patients and encourage them to seek consultations. On the other hand, patients do not prefer physicians who solely demonstrate professional competence, create a greater power distance between themselves and their patients, and adopt an assertive approach in their interactions.

Building on the generalized model of online trust proposed by Shankar et al [40] in 2002 and the SOR model [17,18], this study investigated the mediating role of online physician-patient trust between physician discourse strategies and patient consultation behavior. The concept of "online trust" in e-commerce platforms has been extended to online health platforms [44]. Our findings indicate that online physician-patient trust has a mediating effect on the relationship between physician discourse strategies and patient consultation behavior, offering guidance for the platform to strategically position its future competitiveness, particularly in the construction of the physician's image.

We divided shared decision-making into 2 dimensions based on its fundamental concept: physician notification adequacy and patient expression adequacy. Importantly, our study is the first to incorporate physician-patient shared decision-making as a moderating variable in the research of patient consultation behavior. Shared decision-making, which has gained attention in the medical field in recent years, lacks quantitative empirical research in medical practice [61,62]. Our findings revealed that physician notification adequacy only moderated the effect of the goodwill-oriented strategy on patient consultation behavior. It did not play a moderating role in the relationship between the capacity-oriented strategy and patient consultation behavior, as well as the quality-oriented strategy and patient consultation behavior. Patient expression adequacy had moderate effects on the capacity-oriented strategy and goodwill-oriented strategy in relation to patient consultation behavior, but it failed to moderate the relationship between the quality-oriented strategy and patient consultation behavior. It suggests that, when using the capacity-oriented strategy, allowing patients to express their doubts regarding their condition and treatment plan strongly impacts patient consultation behavior. This finding highlights the importance of communication barriers between physicians and patients. Under the capacity-oriented strategy, physicians pay little attention to whether patients can comprehend medical principles or professional considerations and instead adhere to the attitude of "just listen to me." Consequently, the participation and experiences of patients are compromised. For physician-patient communication to be smooth, patients must express their doubts and accurately understand the information conveyed by the physician. Under the goodwill-oriented strategy, there are fewer communication barriers between physicians and patients, creating more opportunities for the shared decision-making dimension to have a positive impact on patient consultation behavior. Conversely, under the quality-oriented strategy, the physician's expression has already provided a greater space for information exchange between the 2 parties. For example, using words, such as "better" and "suggest," and employing interrogative sentences can induce patients to provide a detailed description of their health condition. As a result, the role of shared decision-making may

XSL•FO
RenderX

be partially played by the quality-oriented strategy, and thus, it does not have a notable impact on patient consultation behavior.

Managerial Implications

In terms of contributions to platform management, our results offer guidance for the platform to strategically position its future competitiveness, particularly in terms of physician image construction. This includes the use of physician discourse strategies and shared decision-making, both of which can help increase patient consultation volume. It should be noted that the term "patients" refers to not only current patients but also potential patients, and the term "physicians" also includes artificial intelligence (AI) medical chatbots [76]. If physicians respond to patients in a more appealing and effective way, the online health consultation experiences of patients will be more enjoyable and comfortable. To meet patients' preferences for physician discourse strategies, communication training for physicians or future training of AI medical chatbots can be used to assist in physician-patient interactions, with the corpus in large language models designed accordingly. In addition, the platform should enhance the supervision and evaluation of the quality of physician-patient communication, develop scientifically formulated standards and norms for physicians to respond to patients, and improve physicians' communication skills and abilities [28,32].

Limitations

Regarding the classification of physician discourse strategies, it is important to note that different theories may lead to different categorizations. In this study, our focus was on how physician discourse strategies enhance patient consultation behavior by strengthening online trust between physicians and patients. The categorization of our discourse strategies is rooted in the trust theory. If future research is based on other theoretical frameworks, the understanding of physician discourse strategies will naturally be different.

To identify physician discourse strategies, our study adopted a combination of manual annotation and the random forest algorithm. This means that the "capacity-oriented strategy," "quality-oriented strategy," and "goodwill-oriented strategy" are determined by human judgments based on identification rules. While we designed a bias adjustment mechanism and calculated the level of bias among different judges, it is important to acknowledge that current prevalent large language models, such as the Bidirectional Encoder Representations from Transformers (BERT) algorithm and Generative Pre-trained Transformers (GPT) algorithm, may have a better understanding of semantics and higher efficiency than the manual annotation approach.

In this study, due to regulations regarding patient personal privacy on online health platforms, there were limitations in collecting data and samples. Moreover, there may have been endogenous issues like missing variables and 2-way causality, although we made some effort to solve these issues. In the future, we will conduct thorough research on these issues.

Abstract

Background: Readability is important to consider when developing informed consent communications for prospective research participants, but not the most important consideration. Other factors to consider relate to learning preferences and literacy needs of people recruited to participate in research, as these factors can influence understanding of consent communications. To promote understanding among prospective participants, researchers should take a human-centered approach to develop consent communications.

Objective: This study aims to explore how factors related to readability, topic, and participant demographic characteristics play into preferences for digital health research consent material. These factors are important to consider as not attending to some details that matter to a specific subgroup of prospective participants may systematically exclude people from research.

Methods: People eligible to participate in a digital health study were recruited to review 31 paragraph length sections of a consent form, referred to as "text snippets," for an existing institutional review board–approved digital health study. Participants (N=79) were surveyed and asked to choose between 2 variations of the text snippets, either indicating a preference for the institutional review board–approved original or a version that was modified to improve readability.

Results: A slim majority of participants provided feedback about the snippets (n=44; 55%). Our qualitative analysis of the feedback found that participants preferred shorter snippets, in general, but the snippets also elicited new questions not addressed by the original consent material. This observation is supported by our quantitative analysis, which found that when the character length of the original was longer, participants were less likely to prefer the original (P<.001) and more likely to prefer the modified text by a factor of 1.20 times (P=.04), and particularly for snippets explaining study risks (P=.03). Our analysis also found significant differences in participant demographic characteristics. For example, older participants tended to prefer the original more than younger participants, by a factor of 1.95 times (P=.004). The results present illustrative examples of how factors related to sex, age, physical activity, and ethnicity all play into preference for consent communication.

Conclusions: The findings point toward new ways of evaluating informed consent communication: (1) for responsiveness to specific prospective participant populations, and (2) effectiveness at eliciting informed questions from people considering participation. We discuss how creating partnerships with prospective participants to prototype informed consent materials, specifically study procedures and risks, can be a way to identify those details before launching a study. Furthermore, future research should go beyond "readability" to explore alternate measures of evaluating consent materials, such as the likelihood that the consent material and communication procedures will elicit "informed questions" for the research team.

Introduction

Background

The process of obtaining and providing informed consent to participate in research is a cornerstone of research ethics. The content of the consent form and its readability has been a topic of concern in health research and is well documented in academic literature [1-3]. Several peer-reviewed studies have focused on improving the ability of prospective research participants to comprehend these documents [4-6]. Specific to promoting the readability of consent materials, institutional review boards (IRBs) in the United States suggest the consent form be written at a sixth- to eighth-grade reading level. Aiming for the sixth- to eighth-grade reading level is a practical guideline with the goal of providing comprehensive information that is, ideally, accessible to most prospective participants. Researchers and IRBs try to follow the reading level guidelines and create consent communications that are clear, concise, and accessible to those who may consider participation. Consent forms that use plain language strategies, including shorter sentences and fewer syllables, appear to improve participant comprehension [7,8]. Consent forms that are not accessible compromise the goal of being informed and undermine the ethical principle of respect for persons [9,10].

Digital health research introduces new complexities to the process of communicating study information to prospective participants. Digital health research can involve data collection strategies and intervention delivery using tools like mobile apps, wearable sensors, social media platforms, and ecological momentary assessment. There is also growing attention on the use of health data repositories, including electronic health records, for training machine learning and other forms of artificial intelligence. These technologies support health research in many ways. For example, health data including sleep, heart rate, and step count can be collected passively in real time. Surveys assessing caloric intake, physical activity, and mental health can be deployed at scheduled or random times using an ecological momentary assessment app, reducing the need for recording data in a journal or relying on self-report [11] and personalized algorithms may be used to test strategies to motivate increased physical activities [12].

There are benefits associated with the use of digital health tools and strategies in health research, but there are also new risks associated with the volumes of granular health data produced and the potential inferences emerging from combining various data types. These risks involve data management protocols and privacy limitations that are important to convey to those considering research participation [10]. Moreover, many of the technologies used in digital health research are commercial products that may have data management processes and privacy protections that put a prospective participant at increased risk of harm. As with any health research, including clinical trials, some specialized knowledge may be needed to understand the study purpose and approach to data collection and management. It is also unlikely that people will have the time to obtain the foundational knowledge needed to facilitate truly informed consent. These tensions create additional challenges for digital health research. While a patient recruited to participate in a study may be somewhat knowledgeable about their specific health condition, they may not understand how the technologies used in digital health research gather, process, and store their data [10]. In fall 2023, the National Institutes of Health (NIH) posted a request for information specific to how informed consent may be improved for digital health research, which included sample language and points to consider [13]. This initiative by the NIH to assist the digital health research community in communicating complex digital health study information is consistent with the goals of our study reported in this paper.

This survey-based study was conducted to identify ways of improving consent communications in digital health research. Specifically, the study investigated the following research question exploring the relationship between the content of consent communications and prospective participant background characteristics on preferences for more and less information in consent material.

Research Question

How do factors related to the content of consent material (eg, readability, length, and lexical diversity) and background characteristics associated with prospective participants (eg, sex, age, physical activity, and tracking physical activity) play into preferences for more and less information in an informed consent process?

This research received support from an NIH bioethics supplement to a parent study called “Your Move.” The “Your Move” study sought to test if a personalized digital health intervention that included several features including a smartwatch, a personalized adaptation algorithm called a controller, and a web-based self-experimentation tool, could help individuals improve their physical activity relative to providing digital health support that is not personalized and represents current deployed wellness program offerings. One challenge, when designing this study, was how to convey to prospective participants that a personalized algorithm would be used to nudge behavior change toward increased physical activity. This paper presents recommendations about how researchers can address these types of concerns, by making practical improvements to informed consent materials and procedures.

Methods

Participant Recruitment

Our study recruited participants who met the eligibility criteria to participate in the “Your Move” digital health study. Potential participants were recruited through a variety of sources, such

XSL•FO
RenderX

as digital research portals (eg, ResearchMatch and Craigslist), via word of mouth through community partnerships with local university and public-school employee networks, as well as through digital advertisements.

Participant eligibility was the same as for the parent digital health study with the following inclusion and exclusion criteria.

Inclusion Criteria

Inclusion criteria were as follows: ability to read English; age of 25 years or older at enrollment; being physically inactive, which in the context of the study means less than 150 minutes (about 2.5 hours) of exercise per week; and the ability to access the internet through a smartphone, computer, or internet-connected device.

Exclusion Criteria

Exclusion criteria were as follows: participants develop a physical or mental health issue that prohibits compliance with the study's protocol, participants become pregnant, and participants do not follow the instructions given to them by the research team.

Ethical Considerations

This study was registered with the University of California San Diego IRB (#201720) and determined to be exempt as defined by the Common Rule (45 CFR 46.104(d)(2)). The consent process involved emailing prospective participants a summary of the study's purpose and procedures, and a link to an interest survey. The digital interest survey included the full text of the consent communication describing study involvement on the first page, with a response item to indicate willingness to participate. Those who did not agree to participate automatically exited the survey. All participants were recruited during June 2022. The study team exported the collected data on a regular basis and stored it in a secure folder with limited access under the University of California San Diego Health Microsoft OneDrive environment. Storage conforms to the Health Insurance Portability and Accountability Act requirements. Completed surveys were manually deidentified by removing names and email addresses. After deidentifying the survey data, the list of participants was randomized by assigning everyone a random number in Excel. This list was shared via University of California San Diego Health Outlook email, utilizing encryption technology. Participants received a US $20 value Amazon.com gift card via email after confirming completion of the survey.

Survey-Based Study Procedures

The survey-based study included three parts to elicit: (1) perspectives on information provided using standard consent processes, in general, (2) ratings to evaluate the clarity and comprehensiveness of specific snippets of consent information, and (3) demographic and background characteristics to consider the participant's eligibility to participate and interest in the digital health technology study (eg, level of physical activity). Part 2 of the study involved reviewing 16 pairs of consent communication "snippets," which were small sections of the consent form text. The snippets differed in terms of their assessed readability, specifically, each pair included a snippet of text from the IRB-approved consent form (hereafter the "original") as well as a version of the original that had been improved for readability (hereafter the "modified").

To create the modified variation of the original consent materials, three members of the research team independently used a free web-based readability analysis software, Readability Calculator, to rewrite the original text, while using the software to monitor how their edits played into specific measures, including the character length, Flesch Kincaid Reading Ease, and lexical density. All researchers then compared their modified text to each original snippet, and associated readability measures, to agree on a final version of the modified text that was the "most readable" based on the readability software (Multimedia Appendix 1). An illustration of a snippet before and after modification is evident in snippet 7 (Textbox 1), which describes the procedure for assessing participant heart rate with moderate to difficult walking conditions.

Textbox 1. Snippet 7 example of the original and modified versions of the consent material presented to participants.

Original text from the study consent form

- "You will complete a treadmill walking test, while wearing a heart monitor on your chest, so that the research team can record your heart rate and blood pressure. The treadmill test will last approximately 5-10 minutes. The treadmill will start at a slow pace and gradually increase in speed and steepness, as though you are gradually walking faster up a hill. If you want to stop the test for any reason—such as if you feel lightheaded, dizzy, or breathless—a member of the research team will be there with you to help."
- Flesch Kincaid Grading level of 10.52.

Modified version of the consent material

- "You will be asked to walk on a treadmill for 5-10 minutes, or as long as you can, while wearing a monitor on your chest to record your heart rate and blood pressure. A member of the research team will be there to help."
- Flesch Kincaid Grading level of 8.92.

To confirm that the modified versions were, in fact, more readable than the original text based on standard measures, Table 1 presents descriptive statistics comparing the original and modified snippets, which indicates significant differences in terms of reading ease and character length. However, lexical diversity was not significantly different, which may be due to challenges in finding synonyms for technical and scientific terminology.

XSL•FO
RenderX

Table 1. Descriptive statistics related to text analysis variables.

	Mean (SD)	Maximum	ANOVA comparison between original and modified, *F* test (*df*)
Original			
Flesch Reading Ease	49.70 (9.31)	64.59	—[a]
Character length	310.53 (151.81)	766.00	—
Lexical diversity	47.65 (5.77)	57.81	—
Modified			
Flesch Reading Ease	55.69 (13.81)	77.41	4.13 (1, 62)[b]
Character length	173.37 (91.57)	480.00	19.51 (1, 62)[c]
Lexical diversity	49.62 (10.21)	80.00	0.89 (1, 62)

[a]No comparison.

[b]$P<.01$.

[c]$P<.001$.

During part 2 of the survey protocol, participants were instructed to compare the original and modified versions of 16 of 31 total snippets, which included 1 comparison that was evaluated by all participants (ie, "Item #01 Purpose: What is this study about?"). Specifically, participants were presented with the original text and asked the following questions.

- How relevant is the content to you (not at all, somewhat, very)?
- How clear is the content to you (not at all, somewhat, very)?

Then participants were presented with the original and modified texts, in a randomized order. Randomization was used to account for any potential ordering effect, which may influence the degree to which participants engage with the materials. For each snippet pair, participants were instructed the following.

"The following are 2 variations on the consent language. Please indicate the variation that you prefer," using the options: (1) prefer version 1; (2) prefer version 2; (3) both versions 1 and 2 look good; and (4) both need improvement.

While options 1 and 2 directly contrast the modified and original options, options 3 and 4 allow for the possibility that the participant did not perceive enough of a difference between the 2 options. For consistency, throughout the paper we refer to preferences for either the original, modified, or both versions (option 3) as "good," and both versions needing improvement (option 4) as "need." From a methodological perspective, including options 3 and 4 also reduces the likelihood of guessing, which otherwise would add noise to the analysis. After comparing the original and modified snippets, participants were asked "What changes would you recommend to the text above?" to capture additional information about their perceptions of the content.

The snippets were labeled as either about the study purpose, procedures, risks, or benefits. All participants (N=79) reviewed a single snippet about the digital health technology study purpose. While all participants reviewed a total of 15 additional snippets, when they initiated the survey, they were randomly assigned to either read a set of snippets that included more risk items (called "survey A") or more procedural items (called "survey B"). The random assignment resulted in 41 (52%) participants receiving survey A and 38 (48%) participants receiving survey B. We found no significant difference in the distribution of participant preferences for the original and modified versions of the snippets ($\chi^2_6=5.9$; $P=.42$; Table 1). This indicates that the responses can be evaluated together in a series of logistic regression analyses. During the logistic regression analysis process, we considered including a variable to capture the effects associated with the survey A and survey B groups, but we found that including this variable did not significantly improve model performance and explainability.

Mixed Methods Data Analysis

To investigate factors that increase the likelihood of participants preferring the original or modified versions of the consent snippets, a series of logistic regressions were fit to evaluate each preference independently: that is, prefer original, prefer modified, both are good, and both need improvement. A logistic regression is used to evaluate the log odds of a condition being true or false, where model A presents the log odds of preferring the original ("true") over all other options ("false").

To investigate how factors related to the content (eg, readability, length, lexical diversity) and background characteristics associated with prospective participants (eg, sex, age, physical activity, and tracking physical activity) play into preferences for the original or modified versions, we applied the survey data and reading analysis tools to construct a series of independent measures for the logistic regression analysis. Each model was fit by beginning with a beyond optimal set of the independent predictors, and then measures of overall "goodness of fit," including a chi-square test of the model with and without predictors, were used in conjunction with tests to evaluate the effect of each predictor on the model, such as the Wald test, to select predictors for each final model. This iterative process helped to identify potential confounding factors in the analysis. As an example, initially, our team considered a broader range of readability measures (eg, Gunning Fog Index, Flesch Kincaid Grade level, Automated Readability Index); however, we found

XSL•FO
RenderX

that many of the measures were highly correlated. To address this, we selected readability measures that reflect a range of important considerations in writing and that are not well correlated (Table 2).

Table 2. Correlations between text analysis variables.

	Original			Modified		
	Flesch Reading Ease	Character length	Lexical diversity	Flesch Reading Ease	Character length	Lexical diversity
Original						
Flesch Reading Ease	1.00	–0.21	–0.12	0.20	0.06	0.09
Character Length	–0.21	1.00	0.08	–0.12	0.54	–0.05
Lexical Diversity	–0.12	0.08	1.00	–0.20	0.08	0.69
Modified						
Flesch Reading Ease	0.20	–0.12	–0.20	1.00	–0.31	–0.14
Character length	0.06	0.54	0.08	–0.31	1.00	–0.09
Lexical diversity	0.09	–0.05	0.69	–0.14	–0.09	1.00

In the findings, the logistic regressions table presents the estimate and standard error for each predictor in each model. To improve the interpretation of the models, the inline description of the analysis in the Results presents odds ratios (ORs), which are the predictor estimates exponentiated. The raw estimates are on a logit scale, which is from negative infinity to positive infinity, but when exponentiated the predictor OR reflects the effect of the predictor on the probability of the dependent measure occurring. For example, in model A the effect of sex male on the preference for the original snippet is –0.68, which when exponentiated as OR is 0.50. As the OR of 0.50 is less than 1, the interpretation is that participants who identify as male are 0.50 times less likely than female participants to prefer the original snippet. As another example, the estimate for sex male in model C is 1.35, which when exponentiated translates to an OR of 3.84, implying that male participants are 3.84 times more likely to feel that both snippets are good enough than female participants. For measures of readability, the interpretation reflects a one standard deviation change in the predictor, for example, in model A an increase in the modified snippet character length by one standard deviation (estimate=–0.39) contributed to a decrease in the likelihood that participants preferred the original snippet by a factor of 0.67 times.

Results

Review of Participant Demographics

In total 79 of 118 (67%) initiating the survey completed the study. Just more than half of the participants identified as female (n=41, 52%), most were under the age of 40 years (n=51, 64%), and 16 participants identified as Hispanic or Latino (20%). The participants reported a range of self-assessed physical activity. The number of people rating themselves as “more active than average” (n=31, 39%) was roughly equivalent to those rating themselves “less active than average” (n=32, 40%). A third of participants also indicated that they track their physical activity, which is important to note as the study context involves a digital health technology intended to promote an active lifestyle (Table 3).

No	54 (69)

The majority preferred the original to the modified version improved for readability, then both are good enough. In just 6 comparisons, participants preferred the modified version, which was improved for readability, to the original IRB-approved text (Table 4). To investigate why participants may have preferred the modified version to the original and vice versa, we first reviewed feedback from participants. Of the 79 participants, 44 (55%) provided feedback related to the snippets, and those who provided feedback provided a fair amount (mean 6.5, SD 5.24 responses per participant).

Table 4. Preferences by snippet and consent form topic[a].

Preferences for the consent form snippets	Original, %	Modified. %	Good, %	Need, %
Benefits	36.90	26.19	32.74	4.17
Procedures	35.29	23.11	33.61	7.98
Purpose	34.15	27.44	29.88	8.54
Risks	33.72	26.05	31.16	9.07

[a]Percentages are based on the total number of snippets reviewed per topic. Specifically, the "benefits" section included 4 snippets, "procedures" included 12, "purpose" included 3, and "risks" included 11. Overall, participants tended to prefer the original version of the snippets; however, our qualitative analysis of the feedback and quantitative analysis of preferences by subgroup indicate that there are many additional factors to consider when developing a consent communication.

In snippet comparisons where participants preferred the modified version, participants shared 55 responses (31 unique participants). Most responses indicate that they preferred the modified version because it was shorter and less confusing than the original version, "[original] has too much text about eligibility. I prefer [modified] because it was more concise: If you are eligible..." [Participant 57] and "[original] too many numbers thrown at me-way way too wordy" [Participant 16]. However, participants also requested additional details that were not included in either version. Specifically, the 55 responses included 19 follow-up questions for the researchers, such as "Is it a licensed health care professional conducting the exam?" [Participant 28], "Maybe clarify how points are earned using an example" [Participant 26], and "[...] do I have to take time off work?" [Participant 25]. While participants appreciate brevity, the consent snippets elicited a range of follow-up questions for the research team.

For the most part, participants preferred the original version (in 14 comparisons) and shared a total of 140 responses (made by 40 unique participants) about their preferences. In these cases, many participants felt that the modified text was too short and "[...] leaves too many questions" [Participant 25]; though

XSL•FO
RenderX

participants also made specific suggestions about how to trim the original version, “I think everything after measuring your blood sugar level is not necessary” [Participant 06] and “too much jargon” [Participant 47]. In some instances, the modified text was missing key details, “[modified] does not state that the treadmill will start at a slow pace and gradually increase speed. That is an important detail missing from [the] text” [Participant 23]. In general, participants preferred a trimmed-down version of the original, rather than the modified version.

The desire for more information was especially strong in response to snippets about study procedures and risks. While participants tended to prefer the original version to the modified version, they also identified many missing details, such as, whether they would be disqualified if stopping during a physical fitness examination involving a treadmill. However, participants did not raise any questions about the time commitment, retracting consent, removal from the study, costs associated with participation, and contact information for the research team. For a research team, knowing when to add and remove details from a consent document can be challenging, if they have yet to share drafts with prospective participants.

In 11 of the comparisons, participants indicated that they had no preference between the original and modified, that is, both are good. Participants shared 94 responses about these snippet comparisons (31 unique participants). In these cases, participants felt that both the original and modified versions had value that could be combined, “[modified] is more clear, but does not include the daily survey requirements listed in [original]” [Participant 40] and “[modified] needs to be more specific on what it means to have mental health issues, [but the original] has a clear understanding” [Participant 43].

Several participants suggested ways to rewrite the snippets to promote specific values in the communication, “combine them to remain positive: Our staff will show you how to wear the Fitbit so that it is comfortable. Our staff will show you how to wear it, help you adjust if needed, and provide an (optional) tutorial” [Participant 17]. However, 1 participant was just not sure what to suggest, “This just sounds awkward to me. I don't know how to improve. Maybe even deleting it completely” [Participant 6]. While each version of the consent material could be improved, in most comparisons, participants preferred the original version or felt that the modified and original could be combined.

Risks and Readability, but Inconclusive

To explore how factors related to the consent communication content play into participant preferences for the original or modified versions, we conducted a logistic regression analysis of each preference category: that is, prefer original, prefer modified, prefer both, prefer neither. Presented in Table 5, our analysis evaluated how various factors related to content (eg, total character count including spaces and punctuation, reading level), as well as participant background characteristics (eg, sex and physical activity), may play into consent communication preferences.

XSL•FO
RenderX

Table 5. Logistic regressions to evaluate how aspects of the study and participant backgrounds relate to preferences. Note that all 79 participants responded to snippet 1, then 41 participants responded to 14 items, and 38 participants responded to 15 other items (a total of 15 items for all participants)=1223 responses.

[a]Goodness-of-fit χ^2_{18}=142.0; *P*<.001.

[b]Goodness-of-fit χ^2_{18}=88.9; *P*<.001.

[c]Goodness-of-fit χ^2_{18}=340.9; *P*<.001.

[d]Goodness-of-fit χ^2_{18}=101.2; *P*<.001.

[e]No significant effect.

A primary observation is that character count (scaled) significantly affects a participant's preference for the original version of the consent material. Specifically, for every SD increase in the character length for the modified version, there is a corresponding decrease in the likelihood that participants prefer the original version, by a factor of 0.67 times (*P*<.001), and a corresponding increase in the likelihood that they prefer the modified version, by a factor of 1.20 times (*P*=.04). This directly responds to participant feedback that they tended to prefer the readability of the modified versions, though appreciate when additional details are provided. Other readability factors,

XSL•FO
RenderX

including lexical diversity and Reading Ease, did not significantly affect participant preferences in our analysis.

Our analysis also found that the consent section (eg, purpose, procedures, risks, and benefits) played into participant preferences. Specifically, participants were slightly more likely to choose the modified version when presented with information about study risks, by a factor of 1.8 times (P=.03), and less likely to select that "both versions 1 and 2 look good," by a factor of 0.57 times (P=.04). An initial takeaway is that participants tended to prefer risk communications that are more readable. As the results are marginally significant, future research should investigate the specific study risk topics that prospective participants would like described in more and less detail, rather than simply comparing differences between risks and benefits, as is the case in our analysis.

Sex, Age, Physical Activity, and Tracking Physical Activity

Readability in consent communication, particularly character count, is an important consideration; however, our analysis highlights other factors related to the participants, specifically their demographic and background characteristics, that play into their consent communication preferences. Participants who identified as male were significantly more likely to indicate that "both versions 1 and 2 look good," than participants identifying as female, by a factor of 3.84 (P<.001). This observation is useful to note, as female participants may have had stronger opinions about consent communication. Specifically, female participants were significantly more likely to choose between the original and modified versions, by a factor of 1.96 times (P<.001) and 1.60 times (P=.003). Future studies investigating consent communication content should carefully consider how sex identity may factor into preferences.

Additionally, our analysis found differences by age group. While participants in our study, grouped between the ages of 20-29 and 30-39 years were not statistically different in their preferences for consent communication, participants aged 40 years and older wanted different considerations. Specifically, participants aged 40-49 years tended to prefer the original version more than younger participants, by a factor of 1.95 times (P=.004) and were significantly less likely to state that both versions look good, by a factor of 0.22 times (P<.001). While our study recruited relatively few participants in the age ranges of 50-59 years (n=7, 8%) and 60 years and older (n=4, 5%), they tended to not prefer the modified, rather feeling that both versions needed improvement, in comparison to younger participants. As the specific digital health study used as a context for our research involved physical exercise and cardiovascular risks, prospective participants who are older in age may have preferred the original version of the consent materials because it included more detail. Future research should explore this trend further by recruiting older adult participants.

Study participants were asked about their level of physical activity, as people with already high or already low levels of activity may value different levels of detail about the study. By comparison to people who rate their physical activity as average, our analysis found that participants who perceive their activity as lower-than-average were less likely to prefer the modified version, by a factor of 0.46 times (P<.001), whereas participants with higher-than-average physical activity were less likely to prefer the original versions, by a factor of 0.48 times (P<.001). Our interpretation is that these differences in what participants do not prefer points toward general feelings that both versions were missing details that are relevant to the 60% of study participants (n=48) who rated their physical activity as higher or lower than average; however, these groups may need different levels of study detail.

Participants were also asked about their physical activity and tracking behaviors, as the digital health study context would involve wearing a smartwatch fitness tracking device. Our analysis found that participants who already track their own physical activity were less likely to prefer the modified version than participants who do not track their physical activity, by a factor of 0.40 times (P<.001). By comparison, participants who do not track their physical activity preferred the modified version, by a factor of 2.49 times (P<.001). While recommendations about how to communicate study details tend toward providing as much detail as possible, in our study the participants tended to prefer a pared-down version.

Finally, participants identifying as Hispanic or Latino felt that both versions of the consent communication need improvement, by a factor of 2.40 (P<.001). This is likely due to an oversight in our study design, as both versions of the content were presented in English, and participants were not offered a translated version. Despite this oversight in the study design, the strong signal in our analysis should be taken as a reminder to pay attention to the language needs of participants. In general, preferences related to the option "both need improvement," deserve further consideration as our analysis found a significant effect in the intercept term for model D, which points to additional unexplained variation in the model.

Discussion

Principal Results

Researchers have an ethical obligation to provide information about the technologies used in digital health research, including related risks, benefits, and risk mitigation strategies. This information exchange within the context of health research currently occurs via the informed consent process. Standard recommendations for designing a consent communication encourage researchers to provide considerable details about all aspects of a study, which can yield a consent communication that is lengthy and dense.

Our study investigated the research question: How do factors related to the content of consent material (eg, readability, length, and lexical diversity) and background characteristics associated with prospective participants (eg, sex, age, physical activity, tracking physical activity) play into preferences for more and less information in an informed consent process? While in the aggregate participants in our study preferred the original IRB-approved consent language, our qualitative and quantitative analyses demonstrate that participants often missed information that seemed to matter to specific prospective participant subgroups for the study. Our analysis also found that the snippets

XSL•FO
RenderX

elicited many informed questions about the hypothetical research, underscoring the importance of partnering with prospective participants to plan and finalize study materials.

Partnering with prospective participants to identify how to improve the research informed consent process has led to understanding the study information they most need and want. For instance, Koh et al [5] found that research participants were underinformed and prioritized information about risks or discomforts and study procedures. Similarly, McCarty et al [14] found that the 2 concepts research participants struggled with understanding were the experimental aspects of the study and who was responsible for paying for research-related injuries.

In general, our analysis found that participants prefer brevity but need details that correspond with their background and experiences related to the study. For example, participants who were older preferred the more detailed original version of the consent, whereas participants who identified as being younger than 40 years of age preferred the modified version. These differences may relate to the perception of physical risks associated with study procedures. However, lower-risk study procedures, such as tracking your physical activity with a smartwatch, may not need as much detail, as participants who do not currently track their activity tended to prefer the modified version of the consent. These and other findings point toward different information to offer for each subgroup in the study population, by sex, race, and ethnicity, as well as physical health, and technology adoption.

Prospective participants could help to identify these gaps. A slim majority of participants shared feedback about the consent material (n=44, 55%). While participants by and large preferred the original, many saw value in the way that the content was communicated through the modified consent material and suggested that the two could be combined. Partnering with prospective participants in research could create opportunities for researchers to identify these gaps early in the study design process, by sharing ideas and asking prospective participants for feedback [10]. As participants in our study reflected on ways to improve the snippets, they shared feedback that included questions related to study procedures, expectations, and risks.

The informed consent process is a starting point for people to cultivate a trusting relationship with researchers. Regardless of whether they choose to participate in a study, trust is likely cultivated when people feel as though they can have the opportunity to fully grasp study materials and raise questions with the research team. As algorithmic decision-making plays an increasingly central role in digital health studies, cultivating trust among all the people involved in research becomes ever more important as, without trust and shared understanding, research quality will be compromised. Researchers should consider actively partnering with study participants so that together they can work through any interesting outcomes and misalignments that may emerge through the algorithmic decision-making in a study.

Recommended Practices for Working With Prospective Partners to Develop Trustworthy Consenting Processes

Many of the questions raised by participants focused on details not included in the original consent materials. By listening to prospective participants, research teams could identify barriers to participation that could be mitigated prior to recruitment [10]. While speculative, we contend that this could pay off in the long run-in terms of improved recruitment and retention based on increased confidence in the research team and understanding of what participants are committing to. In this way, the text snippets taken from the consent form offered a foundation for prospective participants to raise informed questions about the study, thereby enabling them to participate as guides of the research.

Researchers can take a few simple steps to incorporate participants as partners in guiding the study and the consenting process. Researchers can present prospective participants with a sample of the study consent materials to identify the unique needs and considerations of specific subgroups within the sample population. Our findings demonstrate that demographic background, susceptibility to possible risks, and study interest all play into a participant's need for more and less detail about a study. Similar findings have been reported in previous studies, which found that ethnicity, level of education, age, and gender were factors impacting participants' comprehension of informed consent information for genetics research, while factors like substance dependency were significantly more likely to increase the level of consent participants accepted [5,15,16].

By taking a 2-step approach to consent material development, digital health researchers can potentially identify these considerations and incorporate them to refine the study materials.

- Step 1: Broadly sample prospective participants for their perspective on snippets of the draft consent materials. At this stage, a sample of the prospective participants is presented with specific sections of the consent materials to comment on to elicit feedback on the language and any questions about the study details. Like our study design, the results should help to shed light on any differences based on demographic, interest-based, and other participant characteristics. Differences may include preferences for level of detail and methods of communication.
- Step 2: Adapt the consent materials for prospective participants. By surveying a sample of prospective participants about their preferences and questions about the consent materials, researchers will learn about any gaps and questions that need to be resolved in general, and for specific participant subgroups (eg, older adults, early technology adopters). This information can be adapted and integrated into broader consent processes for a study.

Our analysis shows how prospective participants in a study are not a monolith but reflect a diverse collection of subgroups that require specific considerations when supporting their learning about a study. Specifically, sex, age, level of physical activity, and ethnicity all played into preferences for more detail in the consent material. Researchers and IRBs should strive to identify and promote these considerations with research sponsors, to

XSL•FO
RenderX

encourage the research funding necessary so that all participants may feel informed through research consent processes. The findings point toward new ways of supporting prospective participants through their process of making an informed decision about whether to participate in a research study. While these recommendations encourage more work on the part of researchers, we contend that the benefits have the real potential to outweigh the added time in the form of improving trustworthiness between researchers and participants. This has the likelihood of producing several benefits overall including improved recruitment, retention, and, likely most critically, the quality of science being conducted as prospective partners can help researchers to understand implicit assumptions of risks, questions, and opportunities that they may not have otherwise been aware of.

Limitations

There are several limitations associated with this study. First, the research involved just 1 digital health study context, which was a low-risk smartwatch intervention to boost physical activity over a 1-year period. Future research should vary the study context to explore how higher risk and more complex study procedures, data management protocols, and digital health systems might play into prospective participant preferences for consent material. In particular, the use of artificial intelligence in health research is still novel and the implications are not fully understood. Researchers should explore best practices for communicating the details of a study involving such novel technologies.

Second, the study involved a survey-based approach to investigate participant perspectives on 31 text-based comparisons related to different aspects of the consent material. In some cases, the points of comparison were more similar than different, in other cases the opposite was true. In some cases, participants clearly agreed that more details were necessary on specific topics. Future research should explore various ways of communicating in more detail on specific topics, such as study risk. Rather than applying a survey-based approach, future research should aim to understand how people process this information by applying approaches like a cognitive interview, in which participants are asked to talk through their thought processes as they review the material. Rather than present 2 points of comparison, researchers should evaluate a wider range of options that include text and non-text-based methods of communicating consent materials [10]. Finally, readability is an important consideration when developing materials, but as demonstrated in this study the measures of readability selected for the analysis did not meaningfully impact prospective participant preferences related to the consent material. There may be other measures of the consent content that would provide meaningful ways of identifying content that is readable, useful, accessible, considerate, and so on. Our own analysis highlights how consent content can elicit informed questions, which may be a future measure of consent communication effectiveness.

Conclusions

Readability has been a primary metric for evaluating the effectiveness of consent communication materials; yet, our study demonstrates that there are other considerations for researchers to weigh. Our analysis highlights that people prefer short and simple text descriptions of study details, but also want answers to questions that relate to their personal circumstances. This finding is based on the breadth of personal questions elicited through the study as well as quantitative analyses demonstrating that factors related to participant sex, age, level of physical activity, and ethnicity all played into preferences for more detail in the consent material. The paper presents a 2-step approach that researchers can take to investigate how such factors may play into consent communication design for a digital health research study. Future research should explore ways to incorporate people and communities into the development of consent communication, to promote understanding and partnership in science.

Conflicts of Interest

None declared.

Abstract

Background: The integration of artificial intelligence (AI) into health care has become a crucial element in the digital transformation of health systems worldwide. Despite the potential benefits across diverse medical domains, a significant barrier to the successful adoption of AI systems in health care applications remains the prevailing low user trust in these technologies. Crucially, this challenge is exacerbated by the lack of consensus among experts from different disciplines on the definition of trust in AI within the health care sector.

XSL•FO
RenderX

Objective: We aimed to provide the first consensus-based analysis of trust in AI in health care based on an interdisciplinary panel of experts from different domains. Our findings can be used to address the problem of defining trust in AI in health care applications, fostering the discussion of concrete real-world health care scenarios in which humans interact with AI systems explicitly.

Methods: We used a combination of framework analysis and a 3-step consensus process involving 18 international experts from the fields of computer science, medicine, philosophy of technology, ethics, and social sciences. Our process consisted of a synchronous phase during an expert workshop where we discussed the notion of trust in AI in health care applications, defined an initial framework of important elements of trust to guide our analysis, and agreed on 5 case studies. This was followed by a 2-step iterative, asynchronous process in which the authors further developed, discussed, and refined notions of trust with respect to these specific cases.

Results: Our consensus process identified key contextual factors of trust, namely, an AI system's environment, the actors involved, and framing factors, and analyzed causes and effects of trust in AI in health care. Our findings revealed that certain factors were applicable across all discussed cases yet also pointed to the need for a fine-grained, multidisciplinary analysis bridging human-centered and technology-centered approaches. While regulatory boundaries and technological design features are critical to successful AI implementation in health care, ultimately, communication and positive lived experiences with AI systems will be at the forefront of user trust. Our expert consensus allowed us to formulate concrete recommendations for future research on trust in AI in health care applications.

Conclusions: This paper advocates for a more refined and nuanced conceptual understanding of trust in the context of AI in health care. By synthesizing insights into commonalities and differences among specific case studies, this paper establishes a foundational basis for future debates and discussions on trusting AI in health care.

KEYWORDS

expert consensus; trust; artificial intelligence; clinical decision support; assistive technologies; public health surveillance; framework analysis

Introduction

Background

The integration of artificial intelligence (AI) systems into health care is one of the most widely anticipated transformations of health systems worldwide [1]. AI promises improved diagnostics [2,3], optimized treatment strategies [4], and early identification of at-risk patients [5]. Prominent examples also include AI for assistive technologies offered to patients directly [6,7] and for informing public health decision-making beyond the individual [8]. More recently, large language model–based applications promise to revolutionize health care, with applications spanning from clinical research and processes to physician-patient relations [9]. Despite this range of potentially beneficial applications, the broader adoption of AI systems in health care has been struggling due to many inhibiting factors. Problems arise at the level of development, with data bottlenecks impeding the training of machine learning models or a lack of user-centered and value-sensitive design procedures affecting AI acceptability [10,11], and stretch to the level of practical implementation of AI systems [12-14]. Questionable improvements in real-life health care settings [15], a lack of regulatory frameworks [16], and unresolved questions of reimbursement [17] further complicate adoption of AI in health care.

In this paper, we focus on a central inhibitor of successful AI adoption in health care, namely, the low levels of user trust in AI systems [18]. Understanding and fostering trust in AI remains challenging, not only practically but also conceptually. Interpersonal trust constitutes a complex and contested construct in philosophy and social sciences [19-24]. Moreover, accounts diverge on what constitutes being worthy of trust, namely, on the definition of *trustworthiness* [19,20]. Unsurprisingly, there is also no consensus across disciplines such as computer science, philosophy of technology, and social sciences on the definition of trust in AI and the capabilities that a trustworthy AI should maintain [25,26]. As a recent publication assembling existing empirical literature on trust in AI and clinical decision support put it, "Different groups [of researchers], whilst seemingly agreeing in principle that 'trust' and 'trustworthiness' are important, can in fact be referring to very different concepts and talking past one another" [27].

The combination of fragmented conceptual research, practical concerns, and implementation difficulties inhibits fostering warranted trust in AI (ie, trust caused by the trustworthiness of the AI) [25,28], which will be increasingly crucial for delivering health care [29]. As recent empirical work using path analysis has highlighted, trust in AI-based technologies seems to have a significant effect on users' intention to use such systems [30]. However, to build trust in—possibly trustworthy—AI systems in health care applications, we first need a conceptual understanding of trust in AI within the health care sector. This goal requires considering the diverse perspectives, expectations, and limitations that various research disciplines bring to the table in the context of human-AI interactions. Without conceptual clarity, attempts to foster the multifaceted concept of trust in AI—whatever it may *precisely* mean—run the risk of being inefficient or even detrimental, leaving users, including data scientists, physicians, and patients, vulnerable to placing trust in systems that may not warrant it or refraining from it in

XSL•FO
RenderX

situations in which grounds for trusting actually exist, an occurrence of what we might call "unwarranted distrust" [31,32].

Objectives

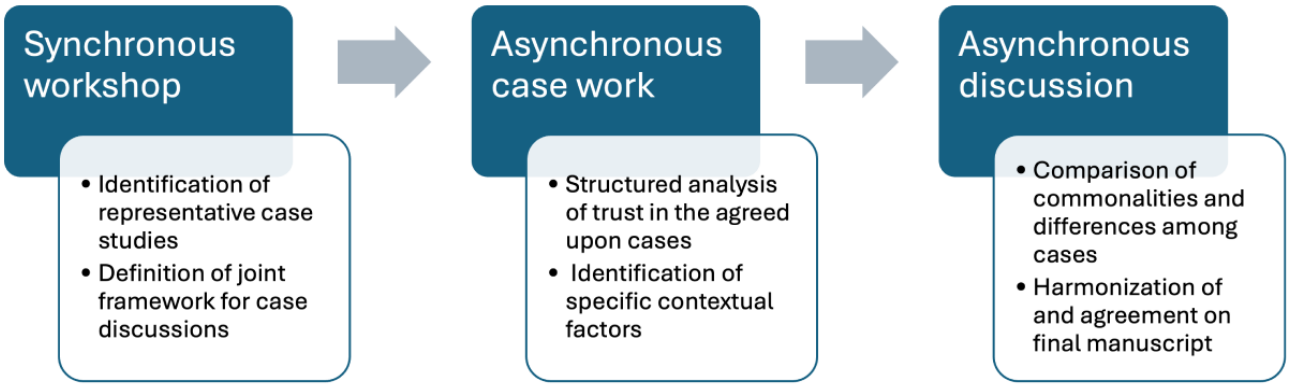
Bringing together international and multidisciplinary perspectives on the topic of trust in AI, this paper aims to provide common ground for defining trust in AI in health care as a reference point for future debates. To this end, we developed the first consensus statement on trust in AI in health care based on input from international experts on the topic drawing on iterative synchronous and asynchronous discussions of realistic case studies. Our results highlight the need for a more refined and nuanced understanding of trust in the context of AI in health care if the concept is to guide AI design and adoption processes and inform national and international governance.

Methods

Overview

Consensus statements from meetings of experts working on a particular topic constitute a common scientific approach across the fields of medicine [33,34] and ethics [35,36]. While they can take many different forms [37], their shared goal is to identify agreement among people working in a field and assemble multiple perspectives with peer-informed legitimacy [38]. The reporting of our findings follows the Accurate Consensus Reporting Document guidelines [37] and considered applicable elements of guidelines for reporting qualitative research [39,40].

Recruitment



Recruitment for the consensus process took place as part of a 3-day workshop held at the École Polytechnique Fédérale de Lausanne in September 2022 in Lausanne, Switzerland. Authors GS, FG, AT, A Facchini, and MI, who organized the workshop, invited some participants directly based on their contribution to the field and to accommodate different types of expertise and backgrounds. They selected further participants from submissions to a call for abstracts for the workshop. Unanimous agreement concerning participants was achieved among conference organizers GS, FG, AT, A Facchini, and MI.

Consensus Process

Overview

The consensus process comprised 3 sequential steps involving both synchronous (step 1) and asynchronous (steps 2 and 3) activities. We describe them in the following sections. Figure 1 shows the steps of the consensus process and provides an overview of the intended outputs of each step.

Figure 1. The 3-step consensus process and envisioned results.

Synchronous Phase: Selection of Case Studies and Framework

We conducted a workshop involving an international group of researchers from various disciplines. To arrive at a consensus regarding trust in AI in health care, we discussed the topic from complementary angles in a series of group activities that iteratively involved talks on specific aspects of trust, moderated group discussions, plenary sessions, and interactive panels. The moderated group discussions were spread over 3 days. They covered the topics of (1) conceptualizing trust in the context of human-AI interactions, (2) conceptualizing trust in AI in the context of health care specifically, (3) requirements for trustworthy AI in health care, and (4) recommendations for implementing requirements for trustworthy AI in health care. To achieve consensus on the case studies, all participants reviewed them. Only case studies assessed as representative yet distinct from other cases by all participants were promoted to the next step.

To guide our analysis, we made use of a conceptual framework. The framework was proposed by FG, critically discussed, and agreed upon by all authors. A conceptual framework represents a phenomenon in the form of a network with interlinked themes that describe how the phenomenon works [41]. Conceptual framework analysis provides an established qualitative method to guide the identification and organization of key aspects and relationships in contexts that draw on multidisciplinary bodies of knowledge [41]. We used framework analysis to provide structure and coherence of discussions for the asynchronous steps, systematically evaluating various dimensions of trust in AI in health care.

Asynchronous Step: Developing Case Studies on Trust in AI in Health Care

To understand how trust unfolds in the context of the agreed upon 5 cases, in the second step, smaller groups of authors expanded on the individual cases agreed upon in step 1. All contributors involved in the writing are listed as authors.

XSL•FO
RenderX

Participants in this step were asked to explicate trust-relevant factors of the cases in accordance with the agreed upon conceptual framework. Responsibilities for coordinating the writing of individual case studies were distributed among the authors, with 1 person taking responsibility for leading each case study. KJ led the consensus for the first case study, JH led the consensus for the second case study, YSJA led the consensus for the third case study, GS led the consensus for the fourth case study, and JW led the consensus for the fifth case study. The results were compiled and shared by GS, FG, and MI.

Asynchronous Step: Comparison and Discussion of Case Studies

Having combined the individual case studies, we compared and discussed relevant aspects to synthesize our findings. We discussed our findings critically in light of existing literature and asked participants again to provide written feedback on the synthesized findings. This process was coordinated by GS, who wrote a first draft of the manuscript, which was then refined by FG, A Facchini, A Ferrario, and MI. All authors provided their feedback on the manuscript, which was incorporated and harmonized by GS and shared with all authors for approval.

Ethical Considerations

In accordance with the existing regulatory framework in Switzerland, such as the Human Research Act and the local rules at the École Polytechnique Fédérale de Lausanne as hosting institution, no ethics approval was required for this collaborative research project involving only consenting experts in the field.

Results

Overview

The results of our study unveil the complexities of understanding trust in AI within the health care domain. Our findings represent consensus among international experts guided by conceptual framework analysis. The following sections provide the characteristics of the involved experts and report the findings from the individual synchronous and asynchronous steps of our consensus process.

Recruitment

The characteristics of the 18 participants in the consensus process are described in Table 1.

Table 1. Participant characteristics—multiple entries possible for location and background (N=18).

Characteristics	Participants, n (%)

Consensus on Trust and Trustworthiness

Synchronous Phase: Selection of Case Studies and Framework

A total of 5 case studies emerged from the synchronous group discussion and were identified as paradigmatic examples of the various applications of AI in health care, namely, diagnosis, clinical risk assessment, public health surveillance, assistive technologies, and health care resource allocation. The involved experts agreed that these cases may not provide an exhaustive sample of all potential AI applications in health care yet allow for a meaningful representation and comparison of trust in AI across largely different health care settings.

To guide the asynchronous analysis of the individual cases, all involved experts identified and defined key components of a conceptual framework for trust in AI in health care. We developed this framework with the backdrop of existing conceptual work on trust in data use in health care, preliminary discussions of the shortcomings of present conceptual work describing what trust in AI is, and existing guidance on conceptual framework development for research and scale development in medicine [29,31,42-49].

XSL•FO
RenderX

Following existing conceptualizations of trust in the context of data use in health care [47], themes were grouped into two main areas: (1) the context of trust and (2) causes and effects of trusting. We considered trust as a context-specific, relational construct between 2 actors that is shaped by the environment in which it develops over time [50]. Therefore, our framework implemented the context specificity of trust by considering (1) the environment within which an AI system is deployed (ie, the health care application in which the AI operates), (2) the actors involved in the specific trust relationship, and (3) the factors that frame the trusting relationship. Here, framing factors influence "the process by which people develop a particular conceptualization of an issue or reorient their thinking about an issue" [51]. Examples of framing factors are historical context, cultural aspects, norms and values, fears, public sentiment, overarching belief systems, and religious beliefs. In addition to context, our framework includes factors that support or inhibit trust as well as the effects of trusting AI systems. Causally important themes for trusting relationships typically relate to factors that make AI trustworthy or untrustworthy in the eyes of those placing trust. Examples are the reliability and accuracy of the AI and, arguably, the level of interpretability of its outcomes [28,52]. In summary, our framework comprised 5 themes: environment, actors, frames, causes, and effects (Textbox 1).

Textbox 1. Conceptual framework for warranted trust in artificial intelligence (AI) in health care.

Context of trust in AI in health care

- Environment: What is the setting for which the AI system is intended?
- Actors: Who are the involved actors in the trust relationship?
- Frame: What frames trust in relation to AI?

Cause and effect of trust in AI in health care

- Cause: What makes AI trustworthy?
- Effect: What is the effect of trust in relation to AI?

Asynchronous Step: Developing Case Studies on Trust in AI in Health Care

Drawing on our framework and previous research, smaller groups of authors examined particular aspects of AI used for diagnostic purposes, clinical risk assessment, public health surveillance, assistive technologies, and health care resource allocation. The results of the individual groups led by KJ, JH, YSJA, GS, and JW, respectively, are reported in the following sections.

Diagnostic AI in the Clinic

Machine learning and, more specifically, deep learning have proven to be particularly suitable for computer vision, especially image processing and pattern recognition. Important preconditions to apply these techniques in medicine, such as suitable infrastructure or availability and storage of digital images, are also being increasingly met, at least in high-income countries. This may explain why most current and proposed AI systems in medicine are used to aid image-based diagnostics in fields such as radiology, ophthalmology, and pathology [53-55]. As a large part of the workload of, for instance, radiologists is to interpret medical images [56], diagnostic AI systems could increase this capacity; support or take over the tasks; and, thereby, change the organization of image-driven diagnostics [57].

Some studies have indicated that, under specific circumstances, AI systems achieve accuracy that is at least equal to that of expert radiologists and pathologists or even outperform them when detecting, classifying, and segmenting tumors in ultrasonography, x-ray imaging, magnetic resonance imaging scans, and digitized microscopy slides [58,59]. These findings have raised massive enthusiasm and fueled the motivation to develop and use algorithms in image-driven diagnostics. As a particular example, we will focus on a recently approved AI system for the diagnostic analysis of chest x-rays [60].

The system aids diagnosis by analyzing chest x-rays, the most frequent radiological examination worldwide. It does so by classifying the scans in nonpathological and potentially pathological cases. For the first group, the program provides a fully automated report, removing the necessity for any further follow-up on the image by radiologists. The scans of the second group are forwarded to trained physicians for further radiological analysis. A test of the software on approximately 10,000 chest x-rays from Finland showed a very high sensitivity (99.8%) with a low specificity (36.4%), yielding a very low probability of missing any critical findings [61].

However, the use of diagnostic AI is associated with technological obstacles as well as epistemic and ethical challenges [62]. Although the potential of self-supervised learning to generate expertlike annotations has been demonstrated, an insufficient number of expertly annotated diverse images is currently often a limiting factor in training AI models on a technical level [63]. Large datasets, for instance, in pathology, can also pose problems if downsampling leads to crucial information being lost, demanding different kinds of representation [64]. Beyond such technical difficulties, there are also more fundamental obstacles, including the fact that diagnostic tasks are not usually choices between 2 distinct outcomes [65]. Another concern is the frequent lack of explainability of medical AI, which limits physicians' ability to recheck the AI's output [66]. It has been argued that this raises particular challenges as decisions based on black-box AI systems are potentially not fully interpretable for the human physician. Moreover, when offering explanations, it is essential

XSL•FO
RenderX

to consider the epistemic requirements of users (eg, radiologists and patients). Explanations that lack a clear connection to clinical knowledge despite being technically accurate fall short in delivering the desired support for clinical practice. Similarly, patients who wish to understand the basis of their diagnosis may find explanations that diverge from their own illness experiences unsatisfactorily [67,68]. That said, there is empirical evidence that a lack of explainability is not necessarily perceived as a problem by physicians if a diagnostic system has been properly validated and other detailed information about the AI system is available [69,70].

The case discussed here takes place in a clinical environment of image-driven diagnostics. It directly involves medical professionals and the AI system, whereas patients do not interact with the system itself; in addition, the developing company and regulatory bodies are indirectly involved. Framing factors are discourses about job security in radiology and the danger of physicians being replaced by AI [71]. Trust leads to acceptance of the system by physicians, potentially at the cost of deskilling, and is arguably fostered by the accuracy of the diagnostic program in question [72].

Predictive AI for Clinical Risk Assessment

AI algorithms can be used to predict individual patient trajectories. Examples include the prediction of COVID-19 severity [73], the prediction of delirium [74], prognostic models of respiratory diseases [75], or systems predicting future lung cancer risk [76]. In addition, predictive models are crucial for determining individualized treatment plans, often particularly relevant in oncology [77]. The difference from the diagnostic use case is that the prognostic case concerns the future (ie, informs decision-making under situations characterized by an inherently larger uncertainty). The prognostic prediction informs choices of action, treatments offered, support, and resource allocation and, therefore, can, in turn, influence the very outcome that has been predicted [78].

As a specific case study, let us consider the prediction of circulatory failure in intensive care units (ICUs) [5]. In ICUs, a great number of machines monitor the state of patients and need to be observed constantly as patient conditions may worsen rapidly. The existing technologies for life support and vital sign monitoring provide information and alerts that clinicians need to oversee. However, the high rates of alerts, including false positives, may cause alert fatigue for practicing clinicians, impairing optimal care. In this context, systems that predict severe deterioration more accurately can obviate alert fatigue and potentially lead to better patient outcomes. The system reported in the study by Hyland et al [5] integrates information from multiple organ function–monitoring systems to alert clinicians to potential circulatory failure 8 hours in advance. Note that the information available to the system is necessarily incomplete, and it is impossible to predict future circulatory failure with 100% accuracy using any algorithm. However, the system in question successfully predicted 90% of cases of circulatory failure in the test set and 82% of them >2 hours before the event [5], so it would likely prove useful in a clinical setting.

The system described here can only be deployed in the environment of hospitals or clinics. Physicians, nurses, and potentially caregivers may interact directly with the AI system, and the social circle of a patient could also potentially receive information derived by the AI system, whereas the patients admitted to an ICU will likely not interact with the system itself. Critical contextual factors are the system's use in stressful situations with the risk of severe consequences, sometimes under time pressure, and the need to synthesize a multitude of complex information. Trust in such a situation can be built by overall improved outcomes in settings where the algorithm is used, ideally by investigating it through a randomized controlled trial. In addition, there should be reasons to believe that the AI system is not biased or will not lead to harmful consequences for any subgroups of the population and that it produces reliable individual decisions that are robust to design choices [79,80] or randomness [79,81] in the AI pipelines. Trust built on these premises will promote AI's acceptance and use. However, as with other medical interventions aiming to change the future, such as screening programs [82,83], trust could also lead to worse outcomes if the system does not actually deserve it (ie, if it is not *trustworthy*).

AI for Public Health Surveillance

Public health surveillance involves the identification of signs of population-level health anomalies and potential disease outbreaks from a heterogeneous collection of data sources [8]. With its intrinsically data-driven nature, public health surveillance has increasingly become a domain for AI applications as AI provides a range of novel methods for data collection and data analysis in large and varied samples [8]. A comprehensive survey of the literature showed that the COVID-19 pandemic highlighted the potential of AI systems in improving surveillance of infectious disease outbreaks [84].

Consider the example of EPIWATCH among the numerous AI-based surveillance systems that provide early signs of disease outbreaks [85]. Developed at the University of New South Wales in Australia, EPIWATCH is an open access web-based tool that offers an interactive dashboard with a sortable, searchable, and filterable global map based on 30 days of data [85]. The tool has been successfully used to model and identify patterns of disease outbreaks, providing crucial information on risk factors and geographic distribution.

For instance, using publicly available data, EPIWATCH has been used to trace global Zika virus outbreaks, tracing transmission modes, affected countries, and complications such as microcephaly [86]. Similarly, a different group of authors used EPIWATCH to model the global epidemiology of hepatitis A, identifying the United States and Europe as major centers of outbreaks, and provided quantitative global data on the most common risk factors, which seem to be homelessness and foodborne outbreaks [87]. Such data can be helpful to inform policy making at both a global and local level.

Let us summarize the contextual factors of this case. Contrary to the previous examples, AI systems for public health are deployed in nonclinical settings. This web-based example is potentially accessible by anyone with a computer or mobile phone with an internet connection interested in data analysis to

XSL•FO
RenderX

predict disease outbreaks. Therefore, relevant actors include the developers as well as a broad spectrum of potential users, ranging from public health practitioners and policy makers to the public. Important framing factors for trust are the severity of the modeled disease as well as the stage of the epidemic or pandemic, impacting the relevance and acceptability of the tool. As the COVID-19 pandemic has demonstrated, antiscience sentiments and conspiracy theories contribute to how public health tools are viewed. Finally, usability aspects further influence whether information will be taken up by practitioners. Trust in the application will likely lead to increased uptake among decision makers. The trustworthiness of the platform developers and endorsement by authorities, such as public health experts and policy makers, will further determine whether the wider public will trust the model's output.

AI for Assistive Neurotechnology

In comparison to the examples discussed previously, a quite different trust relationship can be found in the case of assistive neurotechnologies based on brain-computer interfaces (BCIs). BCIs can, for instance, be used for neurorehabilitation, restoring lost function, or augmenting and enhancing existing cognitive or motor abilities [7]. AI, especially data-driven machine learning with deep neural networks, plays a crucial role in their development and use as these methods enable and facilitate the modeling and decoding of complex neural signals as well as the adaptation to individual users [88]. To delineate differences in the trust relationship between AI-based neurotechnology and other medical AI, we focus on a specific example: a BCI-guided robotic hand orthosis for rehabilitative purposes.

Orthoses are external wearable devices that can be "used to compensate for impairments of the structure and function of the neuromuscular and skeletal systems" [89]. In line with numerous existing research projects at the level of preclinical prototypes [90], let us consider a specific BCI-based robotic orthosis that allows patients with stroke to restore some volitional control of hand-grasping movements. To do so, the system records electrical activity of the dominant motor cortex noninvasively through an electroencephalography cap and extracts features from the measured signals using machine learning–based classifiers to extract patient-specific neural markers of intended hand movements, which are then translated into mechanical movements of the robotic hand orthosis.

There are several aspects of such personalized AI-based assistive neurotechnologies for neurorehabilitation that set them apart from medical AI used for diagnosis, prediction, or public health surveillance. One crucial difference that stands out is that the AI in question is *embodied* in the sense that the AI used for decoding neural signals and for translating them to mechanical movement is inextricably linked to a physical object—namely, the hand orthosis. This implies that physical design aspects play a crucial role on whether trust is expedited to the device [91].

However, there are further differences that impact the trust relationship involving actors, the environment, and framing. First, assistive rehabilitative neurotechnology is designed for patients with impairment of cognitive or motor functions who need to engage with the technology. These patients are also the main trusters of this technology, not health care professionals or public health experts. Second, suppose the neurotechnology also helps patients in their everyday life. In that case, it should not only work under highly constrained and controlled laboratory or clinical conditions but also in a patient's home. This implies additional demands for the devices' ease of use and their security in a more open environment, which would be crucial for the trust of bystanders in these devices. Third, due to the BCIs' physicality, trust in assistive neurotechnology may also be framed differently, invoking widely known images from science fiction [92]. Fourth, users may be concerned that decoding their brain activity could be used not only to control the robotic orthosis but also to infer other types of information that would not be available using other sensing technologies, thus raising potential threats to their privacy. Therefore, addressing potential fears of patients and designing AI that assures human control (in the sense of "human in the loop") at any moment adds to the complexities of building trust in such embodied AI.

To summarize, the assistive AI system discussed here is embedded in an environment of clinical neurorehabilitation. Its trusters are primarily patients and rehabilitation experts who trust in the developing engineers and the pertinent regulatory bodies. In the context of embodied AI, many specific framing factors influence its perception, especially from science fiction literature and cinema. It is also shaped by public attitudes and policies on related technologies such as robotics. To build trust in this environment and prove the accuracy of the AI, a lack of conflicts of interest on the part of the developers; sufficient understanding of the underlying technology by its users and rehabilitation experts; and independent, long-term technical support seem key. Successful trust building will result in wider acceptance and adherence by users, as well as potential inclusion of the technology in public health programs, facilitated regulatory compliance, and improved insurance reimbursement. Taken together, these elements can facilitate access and increase the technology's affordability by expanding the number of its users.

AI for Health Care Resource Allocation

A 2019 study in *Science* revealed that software provided by the health service company Optum, and which was being used to manage the care of >200 million patients at hospital centers across the United States, was significantly—even if unintentionally—biased against Black patients [93]. The machine learning algorithm aimed to predict the future health care needs of patients and direct extra medical care toward the most vulnerable. However, it was shown to systematically underestimate the needs of Black patients. It did this because it used health care costs as a proxy for need in its risk score despite health care costs not being a neutral and reliable proxy for health needs in this context. This led it to assign consistently lower risk scores to Black patients compared to White patients who were equivalently sick. This was despite the model being "race blind" in the sense that race was not specified in the input data [94].

When considering how this case study relates to trust in and trustworthiness of AI in health care, it is important to note that this is not a case of AI being introduced into a dyadic

XSL•FO
RenderX

physician-patient relationship but, rather, of its integration into the operations of complex health systems involving many actors and institutions. Therefore, philosophical accounts of trust that focus on the properties of individuals—these accounts traditionally comprise reliability *plus* some appropriate motivational state on the part of the trustee toward the truster, for example, goodwill [95]—are insufficient to capture the conditions necessary for trustworthy AI in these contexts.

Accounts of institutional trustworthiness are more useful here. They often emphasize features such as transparency as well as competence and reliability [96]. Accounts of trustworthiness that do not necessarily require a phenomenological state such as goodwill may also be useful. For example, the trust responsiveness account by McGeer and Pettit [97] emphasizes the importance of an agent—or, in our case, institutions—responding appropriately to the reasons for doing what they are being relied upon to do. Alternatively, one might provide a deflationary account that either equates trustworthiness with reliability [48] or rejects trust as an appropriate attitude altogether [98].

What does it mean to meet these conditions in this and similar cases of integrating machine learning into resource allocation decisions across an entire hospital or health system? Trust responsiveness demands that systems such as the one provided by Optum be introduced to promote health and well-being and improve patient outcomes and not to meet other goals such as cutting costs to maximize profits for insurance companies and health systems. Using a system such as Optum may not necessarily require internal algorithmic transparency, which is often the focus of work considering the ethics of machine learning algorithms in health care [99], yet may be difficult to translate into a genuine understanding of the AI system by clinicians or patients. However, there needs to be openness regarding design decisions and value choices involved in the algorithm's construction and implementation [100]. Demonstrating these may require engaging in ethical and algorithmic impact assessments during the design process [101,102], welcoming algorithmic auditing after implementation [49], and abiding by regulatory frameworks throughout the product life cycle [103]. Ideally, transparency for AI systems for resource allocation would highlight both global explanations [104], given that the goal of the algorithm is to distribute resources across a population [105], and local explanations for individual decisions as the biased program impacts individual care. Both are potentially useful for promoting fairness [104].

In addition, it is crucial to consider contextual factors impacting such trust relationships. The program was developed by a for-profit health service provider in the US health care system and used to determine resource allocation. Key actors were the health service company itself, which provided the algorithm; the health systems; clinicians interacting with the algorithm's recommendations; patients having their care influenced by the algorithm's recommendations; and, finally, regulatory bodies and (internal and external) algorithmic auditors. Important framing factors include media reporting on algorithms and their impact and, on a conceptual level, theories of institutional trust. Such trust, though unwarranted here, would result in the model's acceptance and use. It is supported by an AI's reliability and competence as well as by the transparency of the developers concerning design choices and the values reflected in them.

Asynchronous Step: Comparison and Discussion of Case Studies

As the 5 cases highlight, medical AI is a multifaceted concept encompassing a diverse group of systems, environments, actors, and framing factors. Talking about trust in medical AI in general can only be a first approximation to the phenomenon. However, some general elements of trust were accepted by all experts. First, they agreed that trust provides a way to deal with complex situations in the face of uncertainty [106,107] and is established in anticipation of a beneficial outcome. Therefore, in a rather minimal fashion, and in line with existing literature, an agreed upon definition of trust in AI in health care focuses on giving discretionary power to an AI system with respect to a specific health care–related task [29,108]. At the same time, it was agreed that situations of trust were characterized by risks, rendering the trusting agent vulnerable to betrayal of trust [21]. To minimize such risks, potentially of life and death in health care, experts agreed that we need to only promote warranted trust in medical AI (ie, trust that is justified, plausible, and well grounded [19,28,49]). In the literature as well as in regulatory contexts, AI systems that warrant such trust have been described as trustworthy [49,109,110]. Therefore, in the eyes of the experts, a complete assessment of trust in AI includes epistemological and practical considerations of trust as much as examining the trustworthiness of the AI in question (ie, the functionalities of an AI system that morally and practically vindicate a relationship of trust [111]).

The involved experts agreed on many practical shortfalls of current AI in health care potentially impacting its trustworthiness. These include the lack of explainability of many AI algorithms [28,66,112]; the difficulties of benchmarking model performance [113]; or the longtail of exceptional situations that will be difficult to anticipate at the development stage, from nonstandard data inputs to the system's deployment in a health care system for which it was not originally trained [114]. In the eyes of the experts, anticipatory difficulty also relates to risks of AI perpetuating, hiding, or reinforcing statistical and social biases as well as other data problems [115,116]. Finally, it was stressed that many medical AI tools so far lack proper engagement with stakeholders in their development, which is crucial for ensuring that they adequately address a real clinical problem and identifying their relevant ethical implications [117].

When looking at the individual case studies, commonalities and differences among them arose at micro and macro levels. Table 2 provides an overview of the contextual factors of each case study.

XSL•FO
RenderX

Table 2. Contextual factors for the 5 case studies.

	Environment	Actors	Framing factors	Causes of trust	Effects of trust
Diagnostic AI[a] (chest x-rays)	Image-driven diagnostics (radiology)	Medical professionals and AI system; patients to a limited extent	Discourse regarding job security and potential AI replacement	Accuracy, design transparency, and human competencies and virtues	Acceptance of systems by physicians, potentially at the cost of deskilling
Predictive AI (ICU[b] setting)	Clinical setting of an ICU	Physicians, nurses, and AI system; patients to a limited extent; and potentially caregivers and family members	Stressful situations potentially with a need to act under time pressure, risk of severe consequences, the need to synthesize too much information, and alert fatigue	Accuracy, transparency, and explainability; fairness; exclusion of harm; and rigorous testing (eg, in the form of an RCT[c])	Acceptance and use of the system, potentially at the risk of erroneous clinical decisions following misleading predictions
Public health AI (disease outbreak model)	Nonclinical setting—publicly accessible web-based tool for the analysis of heterogeneous data	Developers, public health practitioners, policy makers, and the public	Stage and severity of disease outbreak; usability aspects (eg, intuitive interface or data visualization); and, potentially, antiscience sentiments and conspiracy theories with regard to the disease and health service providers	Historical accuracy and endorsement by authorities	Acceptance and use of the system by public decision makers (public health experts and policy makers)
Assistive AI (neurorehabilitation)	Clinical neurorehabilitation; elective use of different technologies for different activities, potentially every day	Patients and their caregivers and social circle, potentially including employers, engineers, and regulators	Clinical setting, science fiction literature and cinema, and public attitudes and policies on related technologies	Accuracy, privacy, lack of conflicts of interest, independence, long-term technical support, and user understanding of the underlying technology	Technology acceptance by users, health care professionals, and health care providers; potentially facilitated reimbursement and increased affordability and accessibility
Resource-allocating AI (predicting costs and needs)	Health service providers and health care system	The developing company providing the algorithm, the health system implementing it, the clinicians interacting with it, the patients having their care influenced by the algorithm, and regulatory bodies and algorithmic auditors	Media reporting on algorithms and their impact and theories of institutional trust	Reliability, accuracy, transparency, design, and model-centric explanations	Acceptance and use in health care systems

[a]AI: artificial intelligence.

[b]ICU: intensive care unit.

[c]RCT: randomized controlled trial.

Most commonalities among the different cases can be found with regard to their causes and effects, some of which arise from the very structure of trust. A common effect of trust was found in it leading to wider acceptance of the technology in question. Such acceptance implies an increased uptake by its intended end users, resulting in a larger role in health care systems, facilitating access, and potentially increasing the systems' affordability. In line with the literature, common aspects with regard to trust-supporting features included both aspects intrinsic to the system, such as transparency and explicability, and extrinsic factors, such as proper external validation and assessment of potential biases [25,29].

Across the discussed cases, some forms of transparency were identified as supportive of establishing trust. Such transparency included openness by the developers about their measures of a well-working system, enabling an alignment with the goals and values of patients and clinicians. Promoting transparency was also assessed as a good way of promoting trust among clinicians using the systems. For instance, there is some empirical evidence that being transparent about the functioning of a triage system makes clinicians more likely to trust it [118]. The extent to which this is possible depends on the exact nature of the system, with clear differences among algorithms that are interpretable by design [119], algorithms that can be explained in terms of their exact functioning on the level of predictors and their weights, and algorithms whose decision process cannot be interpreted causally.

Informational openness was also recognized as central to promoting a system's external trustworthiness (eg, if a system's reliability and performance metrics are publicly available). From the discussed cases, it also emerged that rendering information accessible to all relevant auditing bodies is crucial for mechanisms of accountability and, in doing so, for creating the necessary epistemic basis for trust at an individual level as much as among the public, who can have confidence that the AI systems have been subject to meaningful scrutiny. In this sense,

XSL•FO
RenderX

transparency was deemed to support trust among affected communities and stakeholders by providing the means to evaluate claims made about these systems with regard to bias and discrimination. AI systems reproducing inequalities and exacerbating injustices may, in turn, erode public trust not only in the AI-based tools themselves but also in stakeholders involved in building, deploying, and using such systems. Addressing and testing for such biases was deemed particularly relevant considering that "personal and collective experiences with discrimination or degradation-along lines of race, class, gender, or other personal characteristics especially create reasons for suspicion if not outright distrust" [99]. However, as the experts agreed, such testing needs to go beyond the sole measure of excluding apparently discriminatory information. Deep learning models may predict a patient's race from medical images such as chest and hand x-rays and mammograms [100] or identify patient self-reported race from redacted clinical notes [101] despite human experts being unable to do the same. Therefore, as indicated by the resource allocation case study, discrimination can occur even when models are apparently *race blind* through implicit proxy features, as is well understood and documented in algorithmic fairness research [120]. Moreover, discrimination through differential impact across subpopulations might occur precisely because models are insufficiently sensitive to inequitable distribution of social determinants of health along ethnic or racial lines [121].

Beyond these common themes, our cases highlight important contextual differences among trust in different kinds of medical AI. In particular, these relate to (1) framing factors, (2) previous knowledge of the targeted trusters demanding different levels of explicability and transparency, and (3) the different risk-benefit trade-offs in different environments. Sometimes, the risks in medicine are grave for individual patients, such as in an ICU setting. However, in the resource allocation setting, the risk-benefit trade-offs concern both individual-level consequences of allocating or denying a resource to an individual and group- or population-wide benefits or harms due to better or worse resource use.

Discussion

Principal Findings

Using conceptual framework analysis, our study provides the first consensus-based publication investigating trust in AI in the domain of health care. Commonalities and differences emerged from the examination of our case studies, particularly with respect to causes and effects of user trust. Across all cases, trust was found to enhance acceptance and adoption of AI technologies, and some factors such as a system's accuracy were similarly deemed to be crucial for the trustworthiness of all discussed systems. Developers' openness about a system's internal workings, assumptions, and value judgments underlining the technical choices were also considered crucial across the case studies. Such transparency fosters alignment with the goals and values of health care professionals and patients; supports accountability mechanisms; and may help address biases and discrimination, which is essential for building trust among affected communities and stakeholders. However, our analysis also highlights contextual differences among trust in various forms of AI in health care. These differences relate to a multitude of case-specific aspects, such as framing factors, previous knowledge of the trusters, and risk-benefit trade-offs in different environments, necessitating tailored approaches to establish trust and trustworthiness. This finding has implications for anyone aiming to foster trust in AI within the health care domain, from developers and health care professionals using AI systems to public health experts and regulators—trust-building measures should distinguish among different types of AI systems considering not only implied risk levels and legal responsibilities in case of errors but also the factors outlined in our conceptual framework: context, actors, discourse, and the mechanisms of trust building.

Implications

Our findings have implications for developers, patients and health care professionals, and regulators aiming to increase trust in medical AI systems. The developing companies should communicate openly about the algorithmic design and training of their AI systems and tailor their level of transparency to the communicative needs of their respective audiences [122]. Such needs will be very different depending on whether the AI is used by patients directly (assistive AI case), trained physicians (diagnostic and predictive AI cases), health economists and policy makers (resource allocation AI case), or potentially the interested public (public health AI case). Individual AI end users need to be educated on the technology's limitations and carefully consider who bears the risk and responsibility of involving the AI—especially if it is not themselves.

At a regulatory level, distinguishing among different kinds of AI systems in medicine seems also crucial, regulating them according to the level of implied risk as currently proposed by the European Union AI Act—or possibly at a finer-grained level specific for health care [123]. Regulation is also needed to clarify who bears legal responsibility in the case of specific errors. While there is a clear responsibility by developers to avoid systematic errors as much as possible, for the foreseeable future, it will not be possible to design an AI system without any errors. Therefore, some responsibility also falls on health care providers who use the systems as part of their workflows to use them appropriately and with the right level of human oversight. This requires strengthening both the technical capabilities of health care practitioners to evaluate AI systems and the responsibilities placed on the developers of systems to openly document where a system may be expected to generate errors. Given the limits of both, proper certification of AI systems is furthermore crucial, allowing for trust in an overseeing institution to be extended to the system itself [124].

A final important point is that there should be a focus on institutions implementing these tools in a trustworthy manner, not on increasing trust. There are several reasons for this. First, trust could be increased through marketing and presentational gimmicks targeted at patients and clinicians, which would do nothing to increase trustworthiness [105]. Second, trust may be hard to achieve given prevailing and justified distrust in health service providers such as Optum and private health systems and marginalized communities' distrust in health care systems due

XSL•FO
RenderX

to historic or entrenched disparities in outcomes or experiences of care [125]. In contrast, this may be less of a problem where there are higher levels of trust in health institutions that might implement AI systems [106]. Finally, the size and complexity of health systems complicate questions of where, why, and in whom the individual patient should place trust within these systems [87]. This creates challenges in assessing how far the design and implementation of an algorithmic system for resource allocation impacted the attitudes of trust in affected patients.

Limitations

While our findings aim to provide a starting point for fruitful further work on AI in health care, there are several limitations to our consensus process and its results. Of these limitations, 3 are related to the selection of experts for our consensus process. First, owing to the recruitment of participants working on trust in AI in health care, our work is biased toward a position that considers trust a useful and meaningful concept in the context of AI in the first place. While this position is supported by a substantive part of the literature [28,31,49,52], it should be noted that there are also outspoken critics of using the notion of trust with respect to AI in the first place [98,126,127]. Second, given the location of our workshop, our recruitment focused largely on experts from Europe, with only a small addition of participants from North America and Oceania. While this may reflect the central role that trust and trustworthiness have taken in regulatory debates across the European Union, it limits the generalizability of our findings to other contexts. A recent systematic review of empirical research on trust in AI also revealed a lack of diversity in the discussion surrounding this topic [26]. This review underscored the need for a broader range of perspectives to more comprehensively understand and address the complexities of trust in AI systems [26]. Third, to address the lack of agreement on trust in AI in health care among experts, our work focused on expert agreement, leaving out some other relevant stakeholders. As the backgrounds of our participants highlight, some stakeholders were actively involved, from developers to practicing clinicians, but others were not included, such as patients, nurses, or hospital administrators. Further work is needed to address this gap.

There were 2 additional limitations more conceptual in nature, and we thank an anonymous reviewer for flagging these. First, our framework does not distinguish between trust *before* and trust *during* use of an AI-based system, yet causal and framing factors of trust may evolve with the experience of using a technology over time. In fact, all our case studies focus more on the initial adoption of a technology and less on trust evolving during its use, reflecting the current early-stage integration of AI systems into health care. That being said, we do hold that our framework can adequately reflect the relevant factors of trust in different AI systems in health care—even if they may change over time. Second, our work did not focus on the phenomenon of distrust despite its undebatable influence on user acceptance and its irreconcilability with trust. We consciously omitted distrust as it is often considered to not be a mere absence of trust but a more complex, richer phenomenon [19,23,95]. Therefore, we believe that a consensus on distrust deserves a paper of its own. However, it should be noted that distrust toward a specific technology, or potentially against AI in general, can of course play a crucial role in inhibiting trust building at a causal level.

Finally, when considering wider conceptual work on trust and the focus on warranted trust in this paper, we need to acknowledge a body of literature that understands trust to be motivated by emotions rather than calculated decisions [128]. The conceptual thinking in this paper leans more toward a cognitive approach to trust building. Thereby, the effect of affective states on trust might be somehow undervalued. However, these affective states can play an important role in trusting and accepting AI in medicine, although their contribution to trusting AI can vary greatly across different instances of human-AI interactions [129]. Therefore, it will be necessary to extend the conceptual thinking beyond cognitive approaches to encompass traits of affective trust.

In summary, our findings suggest that achieving trustworthy AI systems in health care requires a multifaceted approach bridging human-centered and technology-centered approaches. While regulatory precision and boundaries help provide the legal basis needed to develop trustworthy AI, and while technological design features are critical to successful AI development, communication and positive lived experiences with AI systems are at the forefront of user trust. From a user perspective, especially for those who are not AI aficionados, trustworthy technological features and legal compliance should be a sure thing, whereas communication and positive experiences point beyond the technical sphere of AI.

Conclusions

This paper examines 5 diverse AI systems in health care, revealing the complex landscape of trust in this field. These cases highlight how AI in health care is influenced by various environments, actors, and framing factors. While discussing trust in medical AI in a broad sense may serve as an initial overview, the specific nuances uncovered in these 5 cases demand a more detailed understanding to characterize trusting AI in health care.

Ultimately, however, focus should shift toward ensuring that institutions implement these tools in a *trustworthy* manner rather than merely aiming to indefinitely increase *trust*—only warranted trust is needed for valuable AI implementation. This approach recognizes the complexity of trust dynamics, the risk of superficial increase in trust without a substantial enhancement of trustworthiness, and the importance of trustworthiness in health care institutions. Despite all domain-specific variations, addressing these challenges and embracing transparency and accountability by design can help build a foundation of trust that will underpin the successful integration of AI into health care for the benefit of patients, physicians, and society at large.

Acknowledgments

This paper was produced within the framework of the workshop titled “To trust or not to trust: When should AI be allowed to make decisions?” funded by the Swiss National Science Foundation (SNSF) under grant IZSEZ0_213480 (applicant: MI; coapplicants: A Facchini and FG) and with local support from the École Polytechnique Fédérale de Lausanne. At the time of the workshop, A Ferrario was affiliated with the Mobiliar Lab for Analytics at Federal Institute of Technology Zürich and gratefully acknowledges their support. FG acknowledges the support of the Digital Society Initiative, University of Zurich. Unrelated and outside of the work leading to this paper, FG acknowledges funding from Novartis International AG, Sanitas Krankenversicherung (Stiftung), the Swiss Academy of Engineering Sciences, and the World Health Organization. RC acknowledges the support of the Digitalization Initiative of the Zurich Higher Education Institutions fellowship program of Zurich University of Applied Sciences digital. KJ acknowledges funding from the Wilhelmina Onderzoeksfonds (grant wkz22040701). ER’s research is supported by a Medical Sciences Graduate School Studentship, issued by the Nuffield Department of Population Health, and the Baillie Gifford-Institute for Ethics in AI Scholarship, both associated with the University of Oxford. PT acknowledges funding from Warsaw University of Technology within the Excellence Initiative – Research University program (grant 1820/97/Z01/2023). A Facchini and AT acknowledge funding from the University of Applied Sciences and Arts of Southern Switzerland Best4EthicalAI research program. MI and GS also acknowledge funding from the ERA-NET NEURON network and the SNSF under grant 32NE30_199436 (HybridMinds). GS acknowledges generous support from Fondation Brocher, Hermance, to finish a first full draft during a research residence. The work reported in this paper was funded by the SNSF (grant 32NE30_199436).

Data Availability

The datasets generated during and/or analyzed during this study are available from the corresponding author on reasonable request. The asynchronous consensus-building process was tracked in repeatedly updated documents.

Authors' Contributions

GS, FG, AT, A Facchini, and MI conceived and planned the workshop and the consensus process. All authors provided input on the choice of case studies and the framework. GS coordinated the consensus process and compiled the individual authors’ contributions for a first full draft of the manuscript. GS, AT, A Facchini, and MI drafted a first introduction, and GS, FG, AT, YSJA, JH, KJ, BK, EP, PT, JW, and A Facchini contributed text to the Methods section. KJ led the consensus for the first case study, JH led the consensus for the second case study, YSJA led the consensus for the third case study, GS led the consensus for the fourth case study, and JW led the consensus for the fifth case study. The discussion was jointly developed by GS, FG, AT, A Facchini, and MI. A Ferrario further contributed substantially to the development of the manuscript by providing extensive critical feedback during the review phase. All authors provided repeated critical feedback and read and approved the final manuscript.

Abstract

Background: The publication of patient photographs in scientific journals continues to pose challenges regarding privacy and confidentiality, despite existing ethical guidelines. Recent studies indicate that key stakeholders—including health care professionals and patients—lack sufficient awareness of the ethical considerations surrounding patient photographs, particularly in the context of digital scientific publishing.

Objective: This qualitative study aims to explore how different stakeholders—patients, medical students, and doctors—understand the challenges of patient privacy and confidentiality in scientific publications. Additionally, it sought to identify key areas for future research, particularly in the context of online, open-access articles.

Methods: We conducted 4 online focus groups due to COVID-19 restrictions: 1 with patients, 2 with final-year medical students, and 1 with head and neck physicians and dentists who regularly handle patient photographs. Participants were invited via email, and those who accepted took part in discussions lasting approximately 1 hour. All interviews were recorded and transcribed for analysis. All 4 focus groups were asked the same set of questions, covering the following topics: (1) consent for publishing patient photographs, (2) information on guidelines and standards for consent to publish patient photographs, (3) the importance of informed consent for various purposes, (4) methods for deidentifying patient photographs, and (5) the use of patient photographs in online, open-access publishing.

Results: Three key themes emerged from the focus group discussions: (1) no definitive resources or practical recommendations available, (2) online publishing of patient images makes them more open to misuse, and (3) anonymization techniques have limitations. All stakeholder groups expressed a lack of knowledge about online publishing in general and concerns about the fate of patient photographs in the digital environment after publication. They emphasized the need for increased awareness among all relevant stakeholders and more stringent procedures for obtaining informed patient consent before publishing photographs. While they recognized the usefulness of image anonymization techniques in protecting patient identity, they were also aware that current methods remain insufficient to ensure complete anonymity.

Conclusions: This qualitative study highlights that publishing patient photographs in open-access scientific journals is an important, serious, and largely unexplored issue, with all stakeholders still uncertain about the best ways to protect patient privacy. Clinicians, publishers, and journal editors should not only implement best practices to ensure fully informed patient consent for publishing identifiable photographs but also develop technical and governance safeguards. Future quantitative studies are needed

to identify the most effective ways to enhance stakeholders' knowledge, policies, and procedures, ultimately guiding the development of practical recommendations for the ethical publication of patient photographs in scientific journals.

(J Med Internet Res 2025;27:e59970) doi:10.2196/59970

KEYWORDS

patient photographs; patient privacy, confidentiality; data protection; ethical publishing; informed consent; open access; scientific journals; focus group.

Introduction

Patient photographs are an essential tool in medical education and are routinely used in daily communication between health professionals to illustrate various clinical problems, procedures, treatment outcomes, and follow-ups. They are ubiquitous on social media platforms, websites, and in scientific journals; however, it is not always clear whether patient privacy is adequately protected in these outlets. As patient photographs are part of confidential medical documentation, their use must adhere to standards consistent with best ethical practices.

According to best practices outlined by the International Committee for Medical Journal Editors (ICMJE), it is recommended to avoid identifying patients in photographs whenever possible and to prioritize patient privacy [1]. The challenge lies in defining the boundary between nonidentifiable and identifiable photographs, particularly in the case of facial images. Traditionally, photographs of body parts or radiographs have been considered nonidentifiable and, therefore, do not require written patient consent. However, when such images are tagged with patient information in an article, they can become identifiable [2]. Additionally, artificial intelligence (AI)–based computer programs have demonstrated the ability to identify individuals from various types of patient photographs previously considered nonidentifiable [3].

Studies suggest that patients generally have a high acceptance of the use of their photographs for various purposes [4-6]. However, these studies also highlight the risk of privacy invasion through the disclosure of an individual's identity. Several studies have shown that patients prefer the use of nonidentifiable photographs [4,6,7]. Additionally, patients are more likely to approve the use of their photographs for follow-up and education rather than for publications, social media, websites, or television broadcasts [8-10].

Although existing ethical standards for protecting patient privacy in the use of photographs are governed by various professional guidelines and legal regulations [1,11-13], a standardized practice has yet to be established. In a recent scoping review, we identified a wide range of disclosure practices for identifiable patient photographs and a lack of awareness of these practices and associated risks among both patients and health professionals [14].

The ethical publication of patient images is particularly relevant in the era of open-access journals and digital publishing [15,16]. For example, some Creative Commons licenses allow anyone to access and reuse parts or entire published scientific articles for any purpose, including commercial use, provided the source and authors are acknowledged [17]. Our previous study found that patients have a high level of trust in their doctors, often believing that verbal consent is sufficient or that permission is not even necessary to publish photographs of their bodies [18]. However, it remains unclear whether both patients and doctors fully understand the potential consequences of publishing identifiable patient photographs in open-access publications.

We conducted a focus group study with patients, students, and doctors—key stakeholders in scientific publishing—to further explore their views on publishing patient photographs in scientific journals, particularly in the context of open-access publishing.

Methods

Study Design

This qualitative study was conducted and reported following the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist for qualitative research (available in Multimedia Appendix 1) [19]. We conducted 4 focus groups using semistructured interviews with different stakeholder groups.

Participants and Recruitment Procedure

Participants in this study included patients, students, and doctors from the University of Split School of Medicine (USSM) and the University Hospital of Split. We used purposive sampling to ensure the representation of different stakeholders across various roles in the research and publishing process:

Patients from the Department of Dentistry, University Hospital of Split, who had experience with diagnostic or therapeutic procedures related to the head and neck area, including participation in research studies.

Doctors with expertise in head and neck conditions from the Departments of Neurology, Dermatology, Maxillofacial Surgery, and Otorhinolaryngology at the University Hospital of Split, Split, Croatia.

Students in the final years of medical school at the USSM. We conducted 2 focus groups with medical students—1 with students from Croatia enrolled in the Croatian-language medical program and another with international students attending the English-language medical program. This distinction was made to capture perspectives from students with experiences in different health care settings (Croatia vs other countries, primarily within the European Union).

We contacted potential participants via email, inviting them to take part in a focus group discussion on research and publication ethics. In total, 30 individuals were invited to participate, and the groups were formed using a purposive sampling method.

XSL•FO
RenderX

Each focus group was designed to achieve a balance in age and gender.

The focus group with non-Croatian students was conducted in English, while the other groups were held in Croatian.

Focus Group Setting and Data Collection

Focus groups were conducted and recorded at the USSM during April and May 2020. The USSM is located in Split, the second-largest city in Croatia, with a metropolitan area population of approximately 350,000.

The focus group interviews were conducted online by 2 lead researchers: 1 female (MR) and 1 male (IB). As a result of COVID-19 restrictions on in-person meetings, we held virtual focus groups using the Zoom platform (Zoom Video Communications, Inc.).

The focus group questions were prepared in advance, and all 4 groups were asked the same set of questions, as outlined in the study protocol (Multimedia Appendix 2). Participants were asked about (1) their opinion on study findings showing that patients trust their doctors to publish identifiable photographs responsibly [18]; (2) sources of information on guidance and standards for obtaining valid informed consent; (3) different purposes for using patient clinical photographs; (4) anonymization of photographs; (5) consequences of publishing identifiable photographs in scientific journals; and (6) open-access publishing and licensing in relation to patient privacy protection.

Each focus group session lasted approximately 1 hour. The discussions were recorded using an audio-recording device and transcribed into a document file by one of the researchers (DŠ). The transcripts were then coded, and the codes were entered into a spreadsheet (Microsoft Excel).

Research Team and Data Analysis

Most participants were familiar with the research team before the study began. The interviewer (MR), who served as the lead investigator, is a certified dental medicine doctor and an Assistant Professor at the USSM. Data analysis involved coding the transcripts, categorizing the initial codes, and identifying themes and patterns. Participant identities were anonymized by 1 of the investigators (DŠ). Each participant was assigned a code based on their focus group and a consecutive number as follows: F1, patients; F2, doctors; F3, medical students in the Croatian-language program; and F4, medical students in the English-language program, with individual participants numbered from P1 to P28.

Two researchers (MR and DŠ) conducted the initial coding of themes based on participants' comments. Preliminary themes were identified during the analysis based on the focus group questions and were iteratively refined using a constant comparative approach [20], allowing for both the refinement of existing themes and the identification of new ones. During the initial coding, 1 researcher (DŠ) defined a large number of codes (>20), which were then reviewed and refined by 2 researchers (MR and AM) to reach a final consensus. Each code was assigned to a single theme category. Data saturation was reached after 3 focus groups, as the analysis of the third group did not yield any new themes. After deriving the themes, summaries of the identified themes were sent to participants for validation. Participants' statements were translated from Croatian into English by 1 author (DŠ), checked for accuracy by another (MR), and finally reviewed by a professional translator. A selection of participant quotations is presented to illustrate the theme categories.

Ethical Considerations

Ethics approval was obtained from the Ethics Committee of the USSM (Class: 003-08/20-03/0005, Reg. No.: 2181-198-04-20-0048) under the project funded by the Croatian Research Foundation, Professionalism in Health: Decision Making in Practice and Research (principal investigator: AM).

Before the focus group interviews, all participants were provided with an information letter and an informed consent form. This documentation outlined the study's purpose, funding, recruitment process, methodology, potential risks or adverse effects, beneficiaries of the research findings, communication of results, data collection, analysis, and protection of personal information. It also informed participants of their right to withdraw from the study at any time and their opportunity to review and, if relevant, comment on interview transcripts and quotations. All participants signed the consent form after reviewing the study information. No compensation was provided for participation.

At the beginning of each focus group, participants were reminded about the confidentiality of any information shared during the discussion and were asked to avoid using identifying characteristics when describing their experiences. They were also informed that only the lead investigator, who conducted all focus groups, would have access to identifying data and that all data would be anonymized for analysis and publication.

Results

Overview

Thirty individuals were initially contacted and agreed to participate; however, 2 later withdrew due to online connectivity issues, resulting in a final total of 28 participants in the focus groups. There was a good balance of gender, age, and education level among participants in each focus group (Table 1), except for a wider age range among the patient group.

Three main topics emerged from the focus group discussions: (1) no definitive resources or practical recommendations available, (2) online publishing of patient images makes them more open to misuse, and (3) anonymization techniques have limitations.

Table 1. Characteristics of the participants in focus groups on publishing identifiable patient photographs

Characteristics	Patients (n=8)	Doctors (n=8)	Students of medical studies in Croatian (n=7)	Students of medical studies in English (n=5)
Gender (female/male), n	4/3	3/5	4/3	2/3
Age (years), median (range)	40.5 (24-61)	37.5 (28-48)	24 (24-25)	25 (24-25)
Country of origin	Croatia	Croatia	Croatia	Croatia (n=1), Germany (n=3), and United States (n=1)
Place of recruitment	Department of Dental Medicine, University Hospital of Split	Departments of Dentistry (n=4), Maxillofacial Surgery (n=1), Neurology (n=1), Dermatology (n=1), and Otorhinolaryngology (n=1) at the University Hospital of Split	University of Split School of Medicine	University of Split School of Medicine
Education level	Master's degree (n=7), PhD degree (n=1)	MD degree (n=2), MD/PhD degree (n=6)	Final (6th) year of the study	Final (6th) year of the study

No Definitive Resources or Practical Recommendations Available

The first theme highlighted the lack of clear best-practice recommendations for obtaining informed consent for the use of patient photographs in online journals. Participants expressed that universal guidelines, applicable to all cases and types of patient photographs, would be ideal. However, they also acknowledged the complexity and variability of different types of patient photographs and the contexts in which they are used, noting that not all images pose the same level of risk to patient privacy.

When asked about the resources they would turn to for best practices, participants expressed considerable uncertainty and gave varied responses. Some felt there should be someone they could consult but were unsure who that would be, while others suggested referring to journal-specific guidelines or seeking advice from their local ethics committee:

> *There should be a body that answers such questions. I am not sure which one it is or if it even exists. But there should definitely be someone to turn to.* [F3/P23, student]
>
> *Maybe on the site of one of the journals in which I want to submit my paper to. I think most of them have some kind of criteria for publishing patients' data, so I would start there.* [F4/P24, student]
>
> *I would definitely check with the journal, check with somebody who had more experience, maybe Google and see what are like general guidelines.* [F4/P27, student]
>
> *...first, there are some instructions from the journal, the ethical commission and the ethical protocol. That is second, and after that, if we had to go further, I don't know, we didn't have the opportunity to have some kind of education about it.* [F2/P16, doctor]

Other participants suggested consulting colleagues or someone within their institution who might have the necessary knowledge, but again, no definitive source was identified.

> *I would also check in with more senior authors, there is someone else on the paper I am working with, maybe my supervisor or anyone who maybe has more experience. They would probably point me to some guidelines but I would also contact someone that I can talk to.* [F4/P26, student]
>
> *Well, we can informally consult with the ethics committee of Clinical Hospital Centre Split, I guess they know, they don't have to give us anything officially, but we can just ask them as colleagues.* [F3/P21, student]
>
> *I guess they should appoint someone to deal with it.* [F3/P22, student]

The uncertainty and variability in responses indicated a general lack of awareness about reliable resources for publishing patient photographs in online journals. Building on this, participants emphasized the need for a clear and comprehensive set of recommendations and best practices to address this issue:

> *Well, maybe there should be some universal form that needs to be filled out and then it's the same for everyone, so that we know, that we can't make a mistake.* [F3/P17, student]
>
> *I think we should have a uniform attitude for any purpose of the image.* [F2/P11, doctor]
>
> *...you never know in the beginning what study might end up in a textbook so I think there should be one form of consent in the beginning of the study and once this is signed it should be OK either to publish into only the study or into the textbook.* [F4/P28, student]

Regarding the idea of definitive or universal best-practice recommendations, participants acknowledged that while desirable, creating such guidelines would be challenging due to the variability in patient photographs and the specific body parts that need to be shown in scientific publications. They provided examples, emphasizing that not all body parts carry the same level of sensitivity when publicly disclosed, potentially placing patients in more vulnerable positions to varying degrees.

XSL•FO
RenderX

> *Because most people don't even care if it's a picture of a tooth, nobody can connect him to it so he doesn't care, on the other hand, when you send him a picture of your face, he is not indifferent.* [F3/P18, student]
>
> *A photo of the face is one thing, and a photo of the genitals is another. Let's say these are two different categories within which a face could be seen according to some criteria.* [F1/P6, patient]

The complexity of the issue was further highlighted by participants who suggested that decisions should be based on the potential audience size for the photograph.

> *wherever that image is shown to a larger number of people, the greater the need for protection and the more detailed the consent should be.* [F1/P6, patient]
>
> *I think it's actually about the number of people who will be seeing the image.* [F1/P4, patient]

Overall, participants' responses suggested a lack of certainty and knowledge on how to obtain patient consent for publicly displayed photographs. One participant explicitly voiced this concern, stating, "I think it is something all of us need to get educated more on" [F4/P26]. This lack of awareness was further compounded by the absence of a universal or easily accessible resource to guide them, as well as the inherent complexity of the issue. Additionally, some doctors in the study believed they were not obligated to seek patient consent for using photographs, arguing that, as health care professionals, they were the most qualified to make such decisions.

> As long as photographs are used in good and positive purposes, there is no need to obtain the consent for education, showing students, publication in journal. Of course, it implies that it will not be any type of abuse. It is mandatory to protect dignity and identity as far as possible. [F2/P14, doctor]

Online Publishing of Patient Images Makes Them More Open to Misuse

Participants viewed the online publication of patient images as a complex issue, where patient privacy and photographs could be vulnerable to unregulated or illegal use. A key concern was the lack of control over how and where these images might be used. Additionally, participants highlighted that patients often lack sufficient knowledge to make fully informed decisions about digital publishing, including how images can be reused or the implications of different copyright licenses. Some proposed solutions included clarifying who is responsible for preventing misuse and finding ways to empower patients in their decision-making. Finally, participants—especially students—emphasized the crucial role of the doctor-patient relationship in ensuring proper informed consent and maintaining ethical integrity.

Despite existing copyright regulations, including requirements to credit the original material (eg, even under the most open Creative Commons license, CC BY 4.0), participants felt that patients and their images remained vulnerable to misuse.

> *People copy them [patient images] and take them for themselves and put them in their presentations when they need them for lectures and seminars.* [F3/P21, student]
>
> *So it makes a little difference to me because it refers to my private life, my private medical case or problem. So if such a picture is misused, I think it's a little worse than the one on the profile picture, which someone can cut out and put on something else.* [F1/P4, patient]
>
> *most of us have social networks and understand that a profile picture can be used for any purpose. Same thing [with pictures in journals].* [F1/P1, patient]

This potential for misuse was seen as higher in open-access journals:

> *Patients are losing their privacy in any case so even if you still say OK, we want to preserve the rights, technically you still end up doing it. The authors are giving up a part of their rights. They are also losing a part of protection of the patient.* [F4/P26, student]
>
> *In my opinion, it should be limited how the images of these scientific papers can be used, whether they are open-access or not. I mean, the man didn't sign to be on some advertisement one day, he signed to be in a scientific magazine, so in my opinion it should be arranged a little, what can be done with that open-access.* [F3/P18, student]
>
> *I think the main difference is whether the journal is published online or not, is it open-access or not. I think that is a huge issue...If this photo is something that someone can find on the internet easily or it is a physical copy of the journal. This really changes their issue.* [F4/P26, student]

Some participants held a contrasting opinion, stating that they saw no distinction between open-access and closed-access publications, as most articles could still be illegally accessed through pirate websites.

> *Theoretically, we can find every locked paper on Sci-Hub and take those pictures, so as XX said, you signed that it can be used anywhere.* [F3/P18, student]

Participants noted that most patients were unaware of the implications of having their images published in an online article, including the meaning and impact of Creative Commons licenses. By contrast, some participants believed that patients might not be concerned with the details of how their images are used.

> *I don't think many people think about this.* [F4/P26, student]
>
> *Patients are not aware of the availability of their images.* [F2/P9, doctor]
>
> *I think it doesn't matter what kind of license it is. I think it means nothing to the patient.* [F2/P11, doctor]
>
> *Patients are generally happy when they realize they have ended up in a scientific journal because it means that their case was really special. And then they brag, I am in a book, I am there, they showed my image at the congress.* [F2/P13, doctor]

XSL•FO
RenderX

Building on the idea that patients may be unaware of potential risks, some participants expressed the view that the responsibility lies with the manuscript author, physician, or the individual obtaining informed consent for image use. Some potential solutions to the risks of image misuse that were suggested were "warn the patient" [F3/P18, student], "to explain as much as possible to people because not everyone has the same amount of knowledge about the Internet" [F1/P4, patient], "communication with the patient, check everything" [F4/P26, student], and "check what the licences are that the journal has and maybe choose those that have a more strict criteria on further usage on the photos" [F4/P24, student].

Others said that the responsibility lies with the party that is culpable for the unauthorized use of the image, and suggested "arrange that it is punishable by law if someone's image is published on an advertisement without permission" [F3/P22, student] and "it should somehow be regulated by law" [F3/P21, student].

A third proposed solution was to enhance patient autonomy by giving them greater control over how their images are used. For example, a participant suggested allowing patients to specify where their images could or could not be shared: "I [could] literally mark where I want and where I don't want [the image to be shared]" [F1/P4, student]. Another offered that one could "allow a certain deadline for withdrawing the image if the patient changes his mind within a week" [F1/P4, student], and a third participant suggested that "In the informed consent, put in a special box for publication for commercial purposes, that it can be published in open-access" [F3/P19, student].

Anonymization Techniques Have Limitations

Building on the previous theme of patient images in online journals being vulnerable to misuse, a related concern emerged regarding anonymization techniques for photographs where the face is fully or partially visible. Participants expressed mixed opinions on whether a patient's face could or should be protected using methods such as a black bar over the eyes. While some viewed these techniques as somewhat helpful, the overall sentiment was that they offer only limited protection and may not fully safeguard patient identities.

Some participants, particularly those from the patient stakeholder group, agreed that a patient's identity should be protected as much as possible. As a result, they viewed anonymization techniques as a positive tool with the potential to at least partially achieve this goal:

> *I would put, I would use that anonymization system. Then I would feel less as if I was exposing the person.* [F3/P19, student]

> *I would be more inclined to mask the eyes, but with that tape, not with those two black dots. So, some kind of wide black band, such an option, but I would not show the patient completely.* [F2/P9, doctor]

> *I agree that I would feel more comfortable if I had black stripe over my face and I actually think [that], even though is not complete anonymization of the person, I feel like it is more abstract.* [F4/P27, student]

> *[With the black bar over the eyes] I am still not anonymous but at least I wouldn't feel totally exposed like not 100-percent exposed but 80% and that 20% of non-exposure would give me some kind of comfort.* [F4/P25, student]

Building on the idea that anonymization is not highly effective in protecting patient identity, some participants viewed these techniques as potentially diminishing the clinical value of the image, thereby undermining the purpose of including the photograph in the first place:

> *I am the first one who doesn't even want to look at the image when I see an image with those things on patient's eyes in books. It's like I can't see anything.* [F3/P18, student]

> *It's a much better display without that anonymization, which doesn't really have a function. And the patient, if he has already agreed, I don't think it matters at all what the topic is because he was informed about the topic of the paper and about everything that is in the picture that he decided that it was OK for him. I don't think there is any reason to cover his eyes.* [F3/P21, student]

> *I would rather publish it without it because it is somehow simpler...and is a better presentation of the case.* [F3/P23, student]

Additionally, not all cases were perceived the same in terms of anonymization techniques. Some participants distinguished between different patients in photographs or the conditions displayed:

> *But again, it depends on what we want to show. If you're trying to show, I don't know, the result of forehead wrinkle correction, then you have to show the eyes as well so that it can be better displayed all together. If we do anything aesthetically, if he already agreed, I would show everything.* [F3/P18, student]

> *It is some degree of anonymisation, not complete but still I would not want my face to be, you know, especially in some disease or something. (...) It depends on the condition.* [F4/P26, student]

Overall, participants' accounts indicated uncertainty and ambivalence regarding the use of anonymization techniques. Few concrete suggestions were identified; instead, we observed a plurality of personal opinions and preferences on the subject. However, one participant suggested a possible way to reconcile the tension between clinical utility and patient protection: "to reveal only the part of the face that is important for it" [F1/P2, patient].

Discussion

Principal Findings

In this study, 3 main topics emerged from the focus group discussions, highlighting the need to improve existing guidelines and enhance stakeholders' knowledge regarding the use of patient photographs in digital academic journals. While all participants recognized the challenges of maintaining patient

XSL•FO
RenderX

privacy and confidentiality when using patient photographs, they were not fully aware of the potential consequences of publishing such images online, particularly in open-access formats. They viewed anonymization techniques as useful for protecting identity but also acknowledged their limitations in ensuring complete anonymity.

To the best of our knowledge, this is the first study to explore the knowledge and opinions of relevant stakeholders through focus group interviews to better understand the emerging issue of accessible identifiable patient photographs in the digital scientific environment. Previous studies were mostly cross sectional and relied on questionnaires with preset answers, which limited deeper insights into the problem [14]. This methodological approach offers a new perspective on the publication process of patient photographs in scientific journals. Our previous cross-sectional study, which examined opinions on obtaining consent for publishing patient photographs in academic journals, found that patients were generally lenient toward consenting to the publication of their facial photographs [18]. However, in this study, after focus group discussions that provided deeper insights into digital publishing and open-access formats, patients expressed a more rigorous stance on informed consent for the publication of their photographs compared with our earlier findings. They demonstrated a heightened awareness of the potential consequences of publishing their photographs in digital scientific journals and emphasized the need for full disclosure before providing written consent. This shift in perspective may, at least in part, be attributed to the higher education levels of the patients in this study. Furthermore, despite recognizing the limitations of fully anonymizing facial photographs by concealing the eyes, patients still considered it a useful method for providing at least some level of protection. Similarly, a study by Oh et al [21], which examined dermatology patients' views on the clinical and nonclinical use of their photographs, found that patients were particularly concerned about privacy protection in nonclinical contexts, such as scientific publication.

When comparing the different stakeholder groups among the participants, we found that students were more aware of potential issues and had greater knowledge about sharing and publishing information online than patients and doctors. This was not unexpected, given their younger age and greater familiarity with digital technology. Recent studies on e-professionalism among medical and dental students and trainees have shown that they frequently use social media to communicate, learn, and share experiences, often by sharing information and patient data [22-24], which could include articles in open-access journals containing patient photographs. Discrepancies between students' self-reported behaviors and their actual practices in social media activities have been noted, highlighting the need for clearer guidelines on ethical behavior in the digital environment [22]. Similarly, students in our study reported a lack of practical knowledge on how to ethically publish identifiable patient photographs in scientific journals, indicating that the future generation of doctors is aware of this issue. They also emphasized the need for clear and practical ethical guidelines on digital publishing in medicine and expressed openness to learning how to effectively protect their patients' privacy in the digital environment.

In contrast to students and patients, medical and dental doctors predominantly believed that patients were unlikely to find or understand academic publications or the publication process in medicine. They considered themselves better positioned to make decisions on behalf of patients regarding the publication of their photographs. However, the doctors themselves demonstrated limited knowledge of available resources on ethical best practices in digital publishing. Although doctors are regarded as key stakeholders in this process [25], some believed that obtaining patient consent for using clinical photographs was not mandatory, and they were uncertain about how to address issues related to the misuse of such images. This raises concerns that doctors may not be adequately equipped to inform patients about the publication of their photographs in online journals or to obtain valid informed consent. The importance of obtaining such consent varies across countries [26,27], suggesting that cultural differences may influence ethical requirements for publishing patient photographs. Previous studies indicate that existing ethical guidelines are not uniformly implemented, highlighting the need for revision and improvement [14-16]. Additionally, publication requirements in scientific journals may sometimes be stricter than local ethical policies, potentially complicating the publication process. Furthermore, online publishing is evolving more rapidly than practical ethical guidelines are being reviewed, updated, and implemented, creating an ongoing challenge that requires continuous scrutiny and engagement. Particularly relevant is the increasing use of AI and deep learning methods in handling patient photographs. Several studies have already demonstrated the successful application of AI in detecting dental caries from patient photographs [28]. At the same time, concerns have been raised about the risks AI poses to patient privacy, as its use on photographs constitutes a form of secondary data usage that may not be adequately covered by existing privacy and patient protection guidelines [29]. A key risk associated with AI tools in dental imaging is the potential for patient reidentification or the inclusion of unprotected patient data in training data sets without proper consent. However, not all implications of AI are negative. An AI tool has been developed to generate a "digital mask" to enhance patient anonymity [30], demonstrating AI's potential to help address some of the privacy and consent challenges associated with patient photographs.

Patient involvement in decision-making regarding diagnostic and treatment procedures is becoming increasingly important [27]. Qualitative studies exploring patients' perspectives on the use of medical images—both for understanding recommended clinical procedures and for nonclinical purposes—have shown that most patients prefer to be involved in such decisions [21,31-33]. Although these studies had different research focuses, their findings align with those of our study, in which patients emphasized the importance of being fully informed before consenting to the publication of their photographs. In our study, participants also expressed concerns about the potential misuse of patient photographs, even when published under most open Creative Commons licenses. This highlights the importance of providing comprehensive information about

XSL•FO
RenderX

all possible consequences. When developing practical guidelines for protecting patients with identifiable photographs in online scientific publishing, it would be advisable to identify key scenarios that require separate, targeted guidelines—considering factors such as the body part exposed and the applicable anonymization techniques. Similar to their involvement in medical treatment and research, patients should also be included as key stakeholders in the development of new guidelines on the ethical publication of their photographs in online scientific journals [34].

A limitation of this study is that the patient focus group included participants with a university degree, whereas survey studies investigating opinions on identifying photographs primarily included participants with a high school education [14]. The educational level can influence individuals' opinions and knowledge about obtaining consent for the publication of identifying photographs in scientific journals. However, our study also highlights that even highly educated individuals, as well as young people—who are generally expected to be more proficient in using online information sources—still have limited awareness and understanding of the consequences of open-access publishing of identifying photographs. We also did not ask participants for their opinions on publishing identifiable photographs of children, which is a significant ethical issue, particularly in cases of rare and complex clinical conditions where sharing valuable information is crucial [35]. Additionally, the focus group interviews were conducted online rather than in person. However, this did not impact the quality of the discussion, as we used reliable technology that ensured high-quality audio transcripts, and participants were already accustomed to this format due to the COVID-19 pandemic [36]. Finally, while the study was conducted at a single medical school in a country, its findings can likely be generalized to many countries with publicly funded health care systems and to most countries in Europe, particularly in Central, Eastern, and Southeastern Europe [37].

Conclusions

All stakeholders in our study—patients, doctors, and students as future doctors—lacked sufficient knowledge about best practices for the ethical publication of patient photographs in scientific journals, particularly when published in open-access formats. They also expressed considerable uncertainty about how to navigate such situations in practice. Even doctors at the university hospital were unfamiliar with the implications of open-access publication under open-access licenses, which suggests that they may be unable to adequately inform patients during the consent process to obtain valid consent for research. Based on these findings, it is crucial to enhance the education of health care professionals on the evolving digital landscape of publishing, different models of patient-doctor relationships, and ethical practices for protecting patient-sensitive data such as photographs—not only at the graduate education level but also throughout their professional careers.

Health care professionals should be equipped to adequately protect patients by discussing potential privacy violations when their photographs are published in open-access journals. Institutional review boards and research ethics committees should ensure that researchers address this critical ethical issue at the protocol stage of their studies. Publishers and journal editors should not only implement best practices to ensure fully informed patient consent for publishing identifiable photographs but also develop technical and governance safeguards. The increasing use of AI in handling patient photographs warrants special attention, as it introduces new and potentially unforeseen risks to patient privacy. However, AI tools also have the potential to enhance privacy protections and should be further explored for their utility in this context. This study may serve as a foundation for future interventional studies and expert panel surveys aimed at finding an appropriate balance between protecting patient privacy and facilitating the dissemination of new medical knowledge.

Acknowledgments

We thank our patients and colleagues who accepted our invitation to participate in the focus group discussions. This study is funded by the grant of Croatian Research Foundation "Professionalism in Health: Decision Making in Practice and Research" (principal investigator: AM [grant IP-2014-09-7672]).

Data Availability

To preserve participants' privacy and confidentiality, only anonymized transcripts of the focus groups are available from the authors on reasonable request.

Authors' Contributions

MR contributed to study planning and organization, recruitment of participants, conducting the interviews, data analysis, interpretation of the results, and writing the manuscript. DŠ contributed to recording and transcribing interviews, data analysis, interpretation of the results, and writing the manuscript. IB contributed to study planning, conducting the interviews, interpretation of the results, and writing the manuscript. MFŽ contributed to data analysis, interpretation of the results, and writing the manuscript. AT contributed to data analysis, interpretation of the results, and writing the manuscript. AM contributed to study planning, data analysis, interpretation of the results, writing the manuscript, and supervised all phases of the study.

Abstract

Background: The COVID-19 pandemic, declared in March 2020, profoundly affected global health, societal, and economic frameworks. Vaccination became a crucial tactic in combating the virus. Simultaneously, the pandemic likely underscored the internet's role as a vital resource for seeking health information. The proliferation of misinformation on social media was observed, potentially influencing vaccination decisions and timing.

Objective: This study aimed to explore the relationship between COVID-19 vaccination rates, including the timing of vaccination, and reliance on internet-based information sources in Japan.

Methods: Using a cross-sectional study design using a subset of panel data, this nationwide survey was conducted in 7 waves. A total of 10,000 participants were randomly selected through an internet survey firm, narrowing down to 8724 after applying inclusion and exclusion criteria. The primary outcome was the COVID-19 vaccination date, divided into vaccinated versus unvaccinated and early versus late vaccination groups. The main exposure variable was the use of internet-based information sources. Control variables included gender, family structure, education level, employment status, household income, eligibility for priority COVID-19 vaccination due to pre-existing medical conditions, and a health literacy scale score. Two regression analyses using generalized estimating equations accounted for prefecture-specific correlations, focusing on vaccination status and timing. In addition, chi-square tests assessed the relationship between each information source and vaccination rates.

Results: Representing a cross-section of the Japanese population, the regression analysis found a significant association between internet information seeking and higher vaccination rates (adjusted odds ratio [aOR] 1.42 for those younger than 65 years; aOR 1.66 for those aged 65 years and older). However, no significant link was found regarding vaccination timing. Chi-square tests showed positive associations with vaccination for television, government web pages, and web news, whereas blogs and some social networking sites were negatively correlated.

Conclusions: Internet-based information seeking is positively linked to COVID-19 vaccination rates in Japan, underscoring the significant influence of online information on public health decisions. Nonetheless, certain online information sources, including blogs and some social networks, negatively affected vaccination rates, warranting caution in their use and recognition. The study highlights the critical role of credible online sources in public health communication and the challenge of combating
